Tree-based topics distinguish polysemous words. In Figure 5, the upper sub-tree comes from the Politics topic (“president”, “people”, “clinton”, “myers”, “money”, etc.) where “pounds” is more likely to be reached in the sense of British currency. In the Health topic (Table 3), “pounds” is more associated with weights (lower tree).

5 Conclusions and Future Work

Combining topic models and vector space models is an emerging area. We introduce a method that is simpler and more flexible than previous work (Hu and Tsujii, 2016), and although we extract prior knowledge from word vectors, our model is not restricted to this and can use *any* word association scores. Our model yields more coherent topics and maintains extrinsic performance, and in addition it is less computationally costly.[7]

Model	Tree	Path	20NG	Amazon
BOW	–	–	86.64	86.73
BOW+VEC	–	–	86.59	**87.30**
LDA	–	–	86.67	86.99
LCTM	–	–	86.52	86.83
tLDA	W2V-2LV	N	86.75	87.07
		Y	86.73	87.13
	W2V-HAC	–	86.79	87.19
	W2V-HAC-LD	N	86.73	87.02
		Y	86.94	86.88
tLDA	G2-2LV	N	86.82	87.15
		Y	**86.96**	87.05
	G2-HAC	–	86.63	87.11
	G2-HAC-LD	N	86.73	87.07
		Y	86.91	86.94

Table 4: Accuracies of topical classification on 20NewsGroups and sentiment analysis on Amazon reviews. Although not significantly improving the performance, tLDA topics at least do not hurt.

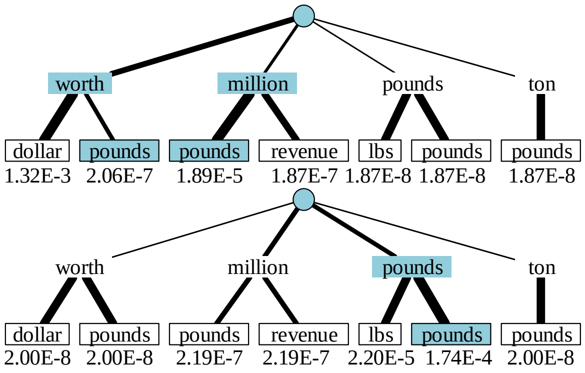

Figure 5: Sub-trees for “pounds” in two topics, from 20NewsGroups corpus using two-level tree prior from word2vec. “Pounds” is more associated with British currency in Politics (upper), while closer to weight in Health (lower). High probability *paths* are shaded; high probability *edges* have thicker lines.

We plan to merge tree prior construction and the topic modeling into a unified framework (Teh et al., 2007; Görür and Teh, 2009; Hu et al., 2013). This will allow tree priors to change along with the topics they produce instead of using a static one constructed *a priori*.

[7] tLDA Java implementation converges in twelve hours; LCTM needs sixty hours (2.8GHz Intel Xeon and 110G RAM).

Finding Patterns in Noisy Crowds: Regression-based Annotation Aggregation for Crowdsourced Data

Natalie Parde and **Rodney D. Nielsen**
Department of Computer Science and Engineering
University of North Texas
{natalie.parde,rodney.nielsen}@unt.edu

Abstract

Crowdsourcing offers a convenient means of obtaining labeled data quickly and inexpensively. However, crowdsourced labels are often noisier than expert-annotated data, making it difficult to aggregate them meaningfully. We present an aggregation approach that learns a regression model from crowdsourced annotations to predict aggregated labels for instances that have no expert adjudications. The predicted labels achieve a correlation of 0.594 with expert labels on our data, outperforming the best alternative aggregation method by 11.9%. Our approach also outperforms the alternatives on third-party datasets.

1 Introduction

Publicly-available labeled datasets are scarce for many NLP tasks, and crowdsourcing services such as Amazon Mechanical Turk[1] (AMT) offer researchers a quick, inexpensive means of labeling their data. However, workers employed by these services are typically unfamiliar with the annotation tasks, and they may have little motivation to perform high-quality work due to factors such as low pay and anonymity. To further complicate matters, some workers may produce spam or malicious responses. Thus, it is not uncommon for workers to correlate poorly with one another.

Researchers using crowdsourcing services commonly aggregate the labels they receive via simple strategies such as using the majority or average label. These methods are best suited for simple, straightforward tasks; with noisier data such as that which may be obtained for more difficult or subjective tasks, these strategies may produce skewed labels that misrepresent the instance. Thus, it is desirable to devise more effective aggregation strategies that consider factors such as label distribution and worker quality, while still avoiding manual adjudication of all instances.

In this work, our contributions are as follows: (1) we develop a regression-based method for automatically aggregating crowdsourced annotations of varying quality, with poor agreement and minimal expert-adjudicated data, that addresses multiple potential flaws or biases in non-expert human annotation. To do so, we (2) crowdsource annotations for a difficult NLP task, metaphor novelty scoring, and (3) describe a process by which we automatically detect untrustworthy workers. We then (4) introduce a feature set that captures label distribution and trustworthiness, and extract the features from our crowdsourced annotations. Finally, (5) we train a regression model that predicts aggregated labels for unseen instances and compare the predictions to expert annotations, finding that our method outperforms the best alternative approach. We evaluate our approach both on our data and on existing crowdsourcing datasets. All datasets and source code are available for the research community to improve on our results.[2]

2 Related Work

Several methods have been proposed to identify low-quality workers in crowdsourced data. Jagabathula et al. (2016) filtered adversarial workers in binary labeling tasks by identifying those with outlier labeling patterns, and Lin et al. (2014) identified when additional labels for binary tasks should be crowdsourced to optimize classifier accuracy. Unlike these approaches, our filtering algorithm is suitable for multi-class annotation tasks.

Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

Various methods have also been explored as intelligent modes of label aggregation. Most (Snow et al., 2008; Raykar et al., 2010; Karger et al., 2011; Liu et al., 2012; Hovy et al., 2013; Felt et al., 2014; Huang et al., 2015) have built upon the probabilistic item-response model first proposed by Dawid and Skene (1979), which simultaneously estimates annotator quality and aggregated labels using an expectation-maximization algorithm. MACE (Hovy et al., 2013) is a popular implementation inspired by this that aggregates labels as a function of the annotation and a learned binary variable indicating whether the annotator is a spammer. We posit that although annotator quality is an important factor in predicting accurate aggregations, the interplay between it and other factors is more nuanced. Thus, rather than adapting the item-response method, our learning approach incorporates features that address multiple potential flaws or biases in crowdsourced annotations.

Some researchers have also used data-aware approaches to predict aggregations (Raykar et al., 2010; Felt et al., 2014, 2015, 2016). We do not use the data itself in this work, to avoid skewing labels in a way that makes it trivial to learn classifiers based on the same data. To the best of our knowledge, our work is the first to frame label aggregation as a regression task, with features based solely on workers and their labels, that learns entirely from a small amount of expert-adjudicated crowdsourced annotations.

3 Methods

3.1 Data Collection

We evaluated our approach on our new metaphor novelty dataset, as well as on third-party datasets. To build our dataset, we crowdsourced annotations for 3112 potentially metaphoric word pairs, and randomly divided the instances into training (1036), validation (1038), and test (1038) subsets. We developed features and selected our regression algorithm using the training and validation sets only; the test set was withheld until the evaluation.

3.1.1 Annotation Task

Instances were comprised of pairs of words from 1840 sentences in the VU Amsterdam Metaphor Corpus (VUAMC) (Steen et al., 2010). The VUAMC consists of documents for which individual words are labeled as metaphors. The novelty of those metaphors varies widely, from highly conventional to quite novel. Each sentence for which we collected annotations contained a content word (noun, verb, adjective, or adverb) labeled as being metaphoric, and one or more other content words or personal pronouns that were syntactically related to the metaphoric word. Word pairs containing a metaphoric word and a syntactically-related content word or personal pronoun were considered instances. AMT workers ("Turkers") were asked to score each instance on a discrete scale from non-metaphoric (0) to highly novel metaphor (3). Some examples are shown in Table 1.[3]

Example	**Score**
Alice looked up, and there stood the Queen in front of them, with her arms folded, *frowning* like a **thunderstorm**.	Novel Metaphor (3)
'Once,' said the Mock Turtle at last, with a **deep** *sigh*, 'I was a real Turtle.'	Conventional Metaphor (1)
A large rose-tree **stood** near the *entrance* of the garden: the roses growing on it were white, but there were three gardeners at it, busily painting them red.	Non-Metaphor (0)

Table 1: Sample word pairs provided to Turkers.

Instances were grouped into Human Intelligence Tasks (HITs) containing all instances associated with 10 sentences each. Five worker assignments were requested per HIT, and Turkers were paid $0.20 per HIT. Overall, 237 Turkers annotated 942 assignments, with an average correlation of 0.269 per HIT (the poor agreement suggests this is a very difficult annotation task). An expert adjudicated all 3112 instances; those labels were considered the gold standard.

3.1.2 Data Filtering

Spam and malicious workers were identified during data collection using a filtering algorithm that compared annotations with those completed by "potentially good annotators" (PGA). Alg. 1 describes this process. Letting H_i be a set of HITs collected, A_i be the set of annotators who annotated H_i, and A=$\cup(A_1, \ldots, A_j)$ be the set of all annotators, the algorithm computes three sets of annotators: good annotators (GA), spammers or malicious annotators (Bad Robots, or BR), and annotators of currently unknown quality UQA.

$\text{R}(a_j, a_k)$ computes the correlation coefficient between two annotators a_j and a_k, where a_k is a potentially good annotator whose annotations overlap with a_j's, and $\text{AVG\_R}(a_j)$ computes the average correlation between a_j and all a_k. HITs

[3] Sentences are from Lewis Carroll's *Alice in Wonderland*.

Algorithm 1 Worker Filtering for Annotation Set i

```
  $PGA \leftarrow A \setminus BR$
  **repeat**
      **for** $a_j$ in $A$ **do**
          $A^j \leftarrow \{a \in PGA\}$ who annotated $\geq 1$ unfiltered
                  HIT in common with $a_j$
          **for** $a_k$ in $A^j$ **do**
              $r_{j,k} \leftarrow \mathrm{R}(a_j, a_k)$
          $r_j \leftarrow \mathrm{AVG\_R}(a_j)$
      $B^- \leftarrow \{a_j \in A | r_j < 0.0\}$
      $B^0 \leftarrow \{a_j \in A | r_j == 0.0$ or $r_j == \infty\}$[4]
      $B^+ \leftarrow \{a_j \in A\}$, of size $|B^-|$, with the lowest $r_j >$
  0.0
      $B^{<.1} \leftarrow \{a_j \in A | r_j < 0.1\}$
      $PGA = A - (B^- + B^0 + B^+ + B^{<.1})$
  **until** convergence or iterations = max
  $GA \leftarrow \{a_j \in A | r_j > 0.35\}$
  $BR \leftarrow B^- + B^0 + \mathrm{BOTTOM}(\mathrm{ROUND}(\frac{2}{3}|B^-|), B^+)$
```

completed under a minimum time threshold were also filtered. Following algorithm completion, filtered HITs and unpaid HITs from members of BR were rejected, and annotators in BR were disqualified from accepting future HITs. 116 total assignments were rejected by the filtering algorithm. Annotators in UQA (UQA=A−GA−BR) who had completed $\geq$ 2 HITs and had an $r_j < 0.1$ were also disqualified. All other HITs were accepted.

3.2 Features

We designed features to capture the distribution and trustworthiness of crowdsourced labels for each instance. The features are described in Table 2. Annotations are designed to provide the regression algorithm with label distributions based on label value and worker trustworthiness. Avg. R features are intended to further clarify worker quality, and Avg. R (Good) is meant to provide a more selective view of the same characteristic. Avg., Weighted Avg., and Weighted Avg. (Good) allow the regressor to consider three different versions of a popular aggregation strategy, and finally, HIT R supplies the algorithm with an estimate of agreement on the current instance to consider when making its prediction.

Feature	Description
Annotations	From highest to lowest label, the five annotations for the instance.[5]
Avg. R	For each annotator, in order of label value, his/her avg. correlation with other workers across all instances he/she annotated.[5]
Avg. R (Good)	Avg. R in which each annotator is compared only to annotators with r_j>0.35. If the annotator has no overlapping annotations with those, Avg. R is repeated.
Avg.	Average of the five Annotations.
Weighted Avg.	Let l_i be the i^{th} Annotation, and r_i be its annotator's Avg. R. Then, Weighted Avg. $= \frac{\sum_{i=1}^{5}(l_i \times r_i)}{\sum_{i=1}^{5} r_i}$.
Weighted Avg. (Good)	Similar to Weighted Avg., with weights (r_i) taken from Avg. R. (Good) instead of Avg. R.
HIT R	The average weighted correlation among annotators for the HIT containing the instance. Letting $w_{i,j}$ be the weight for a pair of annotators equal to $\frac{r_i + r_j}{2}$, where r_i and r_j are the Avg. R associated with annotators a_i and a_j, $r_{i,j}$ be the correlation between annotators a_i and a_j for the HIT, and P contain all annotator pairs (a_i, a_j) for the HIT, HIT R $= \frac{\sum_{p \in P} r_{i,j} \times w_{i,j}}{\sum_{p \in P} w_{i,j}}$

Table 2: Features used.

	Affect (Emo.)	Affect (Val.)	WebRel	Ours
Instances	600	100	2439	3112
Annotators	38	38	722	237
Annotators / Instance	10	10	5	5
Label Range	0-100	-100-100	0-2	0-3

Table 3: Dataset Details

3.3 Regression Algorithm

The approach utilizes a random subspace regressor, which was selected based on its performance on the training and validation data relative to a large variety of other regression algorithms. Random subspace is similar in nature to bagging and random forests, using multiple decision trees constructed from subsets of features selected randomly without replacement to make its predictions (Ho, 1998). We used the implementation from the Weka library (Frank et al., 2016), with Weka's REPTree classifier as the base decision tree model.

4 Evaluation

4.1 Other Datasets

In addition to evaluating our approach on our data, we evaluate it on three existing crowdsourcing datasets that differ in terms of their size, noise level, and number of annotators. Details about each dataset are shown in Table 3, with additional information below. Each third-party dataset was randomly divided into 66% training and 34% test.

[4] Turkers who assigned the same label to every instance, or whose assignments had already been filtered for some other reason (e.g., violating the minimum time threshold).

[5] We also include a second copy of these features ordered by the annotators' average r values.

Affect (Emotion and Valence). Affect (Emotion) and Affect (Valence) were created for Snow et al.'s (2008) work, and contain emotion (*anger*, *fear*, *disgust*, *joy*, *sadness*, and *surprise*) and valence ratings for 100 headlines from the SemEval affective text annotation task (Strapparava and Mihalcea, 2007) test set. Annotations indicate the degree of emotion in an emotion-headline pair (Affect (Emotion)) and the overall positive or negative valence of a headline (Affect (Valence)). Snow et al. report an average correlation among annotators of 0.669 (emotion) and 0.844 (valence).

WebRel. WebRel was originally created for the TREC 2010 Relevance Feedback Track (Buckley et al., 2010), and its annotations indicate the relevance of web documents retrieved for queries. The full dataset contains crowdsourced annotations for 20,232 topic-document pairs; 3277 of those pairs additionally have gold-standard labels. The number of annotations collected per instance varied. We used the subset of instances with gold standard labels and at least five annotations, and reconstructed their HIT groupings based on the workers that annotated each instance (we assumed all instances annotated by the exact same set of workers were originally from the same HIT). Average correlation per HIT was 0.102 (quite noisy).

4.2 Experimental Setup

We compare our approach to a number of alternative methods, detailed with justifications in Table 4. The alternatives are popular aggregation techniques that address different potential flaws in non-expert annotation. We train our approach on the training (and validation, for our dataset) data, and test on the test set. Since MACE (used for *Item-Response*) learns from and outputs predictions for the same data, we provide it with the entire dataset (training, validation if available, and test), but report its results for the test instances only. We provide input to MACE in an n-dimensional sparse matrix (1 row per instance and 1 column per each of n distinct annotators in the dataset, with filled values only for the annotators who provided annotations for that instance), since the approach requires knowledge of which annotator provided each annotation to function properly.[6]

Approach	Description
Majority Vote	The most frequent label given by annotators for the instance. Ties were broken by taking the highest of the tied labels—assumes the most popular opinion should be trusted.
Highest	The highest label for the instance—assumes those who see a metaphor should be trusted.
Item-Response	The prediction expected from an item-response model. We use MACE (Hovy et al., 2013) to generate predictions since it is a well-documented item-response approach that is publicly available online.
Mode Average	The real-valued average of the mode(s) of the instance's labels (if only one mode, this feature is that mode)—assumes popular opinions should be trusted, and equally popular opinions are equally trustworthy.
Average	The average of all five labels—assumes each annotator's opinion is equally valid.
Rule-Based	Assigns a value of 0 if 4+ annotators labeled the instance as such; otherwise, takes the avg. non-zero label—assumes annotators frequently miss tricky or subtle instances.

Table 4: Alternative Approaches.

We also evaluate the performance of different feature subsets on our data. *All–Averages* contains all features except for AVG., WEIGHTED AVG., and WEIGHTED AVG. (GOOD). Each other subset contains all features except for the respective feature type noted from Table 2. The correlation coefficient (r) and root mean squared error (RMSE) were recorded for each test condition since our estimator produced continuous-valued scores. Since *Mode Average*, *Average*, and *Rule-Based* result in continuous values and *Majority Vote*, *Highest*, and *Item-Response* result in discrete values, we present two versions of our results; in one, predictions were rounded to the nearest integer (forcing a 0, 1, 2, or 3) and in the other, they were left as-is. For the discrete approaches on our data, we also report accuracy.

4.3 Results

The results are presented in Tables 5, 6, and 7. Table 5 compares our method with each alternative approach on our data, and Table 6 compares our method with the alternatives on each third-party dataset. Table 7 shows the results of the feature ablation. On our dataset, our approach outperformed all other approaches, with r = 0.594 with the gold standard and RMSE (0-3) = 0.605. This represented correlation improvements of 18.6%, 11.9%, and 69.2% relative to the continuous alternative approaches (*Mode Average*, *Average*, and *Rule-Based*, respectively). The

[6] Note: Item-response approaches are better-suited to scenarios in which fewer workers annotate more instances each, but our results would also improve under such circumstances where a worker's trustworthiness, as measured by average r value, is more reliable.

Method	*r*	**RMSE**	**Acc.**
Majority Vote	0.443	1.011	0.536
Highest	0.295	1.701	0.183
Item-Response	0.362	1.083	0.483

	Ours (R)	**0.412**	**0.8**
	Mode Average	0.350	0.9
	Average	0.372	0.8
	Rule-Based	0.282	0.9
	Ours (C)	**0.523**	**0.7**

Table 6: Comparison on third-party datasets.

rounded predictions also outperformed all discrete alternatives (*Majority Vote*, *Highest* and *Item-Response*) with relative correlation improvements of 10.6%, 66.1%, and 35.4%, respectively. All approaches had strong positive statistically significant (p<<0.0001) correlations and the improvement of our results over the alternatives was statistically significant (p<<0.0001).

On WebRel and Affect (Valence), our approach outperformed all other approaches for both the discrete and continuous conditions. On Affect (Emotion), our approach outperformed all alternatives for the discrete condition and had a lower RMSE than all other approaches for the continuous condition (relative reductions in error to Rule-Based, Average, and Mode Average were 37.4%, 0.6%, and 24.2%, respectively), but the predictions from Average correlated better with the gold standard than did those of our approach.

	Rounded		**Continuous**	
Feature Set	*r*	**RMSE**	*r*	**RMSE**
All	0.490	**0.690**	**0.594**	**0.605**
All−Annotations	0.440	0.716	0.557	0.627
All−Avg. R	0.480	0.701	0.581	0.611
All−Avg. R (G.)	**0.494**	0.692	0.582	0.611
All−Averages	0.465	0.703	**0.594**	0.607
All−HIT R	0.486	0.693	0.587	0.608

Table 7: Feature subset performance comparison.

Interestingly, Table 7 shows that the discrete version of our approach performed slightly better when the features indicating annotators' correlations with good annotators were removed; this was not the case for the continuous-labeled version. The raw annotations themselves were the most valuable features for both cases. Their removal led to a correlation reduction of 10.2% (rounded) and 6.2% (continuous) relative to using all features.

The results suggest that our approach is a suitable means of automatically aggregating noisy crowdsourced labels, and that reasonable results can be obtained even when training on only a small amount of expert-adjudicated instances. Further, the performance of the alternative approaches suggests that typical aggregation techniques may be less suitable for tasks with many workers who completed relatively few annotations.

5 Conclusion

In this work, we present a regression-based aggregation method that addresses multiple potential flaws or biases in non-expert human annotation. We show that the predictions from our approach correlate at r=0.594 with expert adjudications for a noisy, difficult task, outperforming the best alternative approach by 11.9% on our data and by up to 63.7% on third-party crowdsourcing datasets. This improvement shows that a learning approach can overcome some of the challenges faced by simple label aggregation techniques for these types of tasks. Our data and source code is publicly available for further research by others.

Abstract

Crowdsourcing has proven to be an effective method for generating labeled data for a range of NLP tasks. However, multiple recent attempts of using crowdsourcing to generate gold-labeled training data for semantic role labeling (SRL) reported only modest results, indicating that SRL is perhaps too difficult a task to be effectively crowdsourced. In this paper, we postulate that while producing SRL annotation does require expert involvement in general, a large subset of SRL labeling tasks is in fact appropriate for the crowd. We present a novel workflow in which we employ a classifier to identify difficult annotation tasks and route each task either to experts or crowd workers according to their difficulties. Our experimental evaluation shows that the proposed approach reduces the workload for experts by over two-thirds, and thus significantly reduces the cost of producing SRL annotation at little loss in quality.

1 Introduction

Semantic role labeling (SRL) is the task of labeling the predicate-argument structures of sentences with semantic *frames* and their *roles* (Baker et al., 1998; Palmer et al., 2005). It has been found useful for a wide variety of NLP tasks such as question-answering (Shen and Lapata, 2007), information extraction (Fader et al., 2011) and machine translation (Lo et al., 2013). A major bottleneck impeding the wide adoption of SRL is the need for large amounts of labeled training data to capture broad-coverage semantics. Such data requires trained experts and is highly costly to produce (Hovy et al., 2006).

Crowdsourcing SRL *Crowdsourcing* has shown its effectiveness to generate labeled data for a range of NLP tasks (Snow et al., 2008; Hong and Baker, 2011; Franklin et al., 2011). A core advantage of crowdsourcing is that it allows the annotation workload to be scaled out among large numbers of inexpensive *crowd workers*. Not surprisingly, a number of recent SRL works have also attempted to leverage crowdsourcing to generate labeled training data for SRL and investigated a variety of ways of formulating crowdsourcing tasks (Fossati et al., 2013; Pavlick et al., 2015; Akbik et al., 2016). All have found that crowd feedback generally suffers from low inter-annotator agreement scores and often produces incorrect labels. These results seem to indicate that, regardless of the design of the task, SRL is simply too difficult to be effectively crowdsourced.

Proposed Approach We observe that there are significant differences in difficulties among SRL annotation tasks, depending on factors such as the complexity of a specific sentence or the difficulty of a specific semantic role. We therefore postulate that a subset of annotation tasks is in fact suitable for crowd workers, while others require expert involvement. We also postulate that it is possible to use a classifier to *predict* whether a specific task is easy enough for crowd workers.

Based on these intuitions, we propose CROWD-IN-THE-LOOP, a hybrid annotation approach that involves both crowd workers and experts: All annotation tasks are passed through a decision function (referred to as TASKROUTER) that classifies them as either *crowd-appropriate* or *expert-required*, and sent to crowd or expert annotators accordingly. Refer to Figure 1 for an illustration of this workflow.

Figure 1: Overview of proposed CROWD-IN-THE-LOOP approach for curating SRL annotations.

We conduct an experimental evaluation that shows (1) that we are able to design a classifier that can distinguish between crowd-appropriate and expert-required tasks at very high accuracy (96%), and (2) that our proposed workflow allows us to pass over two-thirds of the annotation workload to crowd workers, thereby significantly reducing the need for costly expert involvement.

Contributions In detail, our contributions are:

- We propose CROWD-IN-THE-LOOP, a novel approach for creating annotated SRL data with both crowd workers and experts. It reduces overall labeling costs by leveraging the crowd whenever possible, and maintains annotation quality by involving experts whenever necessary.
- We propose TASKROUTER, an *annotation task decision function* (or *classifier*), that classifies each annotation task into one of two categories: *expert-required* or *crowd-appropriate*. We carefully define the classification task, discuss features and evaluate different classification models.
- We conduct a detailed experimental evaluation of the proposed workflow against several baselines including standard crowdsourcing and other hybrid annotation approaches. We analyze the strengths and weaknesses of each approach and illustrate how expert involvement is required to address errors made by crowd workers.

Outline This paper is organized as follows: We first conduct a baseline study of crowdsourcing SRL annotation, and analyze the difficulties of relying solely on crowd workers (Section 2). Based on this analysis, we define the classification problem for CROWD-IN-THE-LOOP, discuss the design of our classifier, and evaluate its accuracy (Section 3). We then employ this classifier in the proposed CROWD-IN-THE-LOOP approach and comparatively evaluate it against a number of crowdsourcing and hybrid workflows (Section 4). We discuss related work (Section 5) and conclude the study in Section 6.

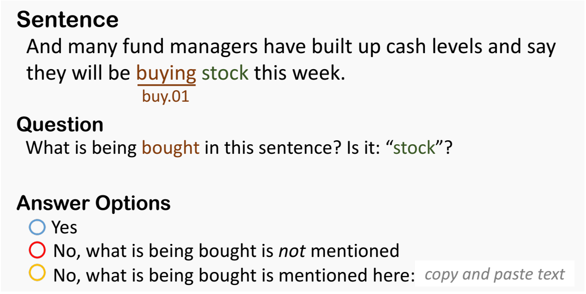
2 Crowdsourcing SRL

We first conduct a baseline study of crowdsourcing SRL. We illustrate how we design and create annotation tasks, how we gather and interpret crowd feedback, and analyze the results of the study to determine the applicability of crowdsourcing for producing SRL annotation.

SRL formalism. In this study, and throughout the paper, we use the PROPBANK formalism of SRL (Palmer et al., 2005), which defines verb-specific frames (BUY.01, BUY.02), frame-specific core roles (**A0** to **A5**), and frame-independent non-core roles (for temporal, location and other contexts).

2.1 Annotation Task Design

To design the annotation task, we replicate a setup proposed in previous work (Akbik et al., 2016) in which crowd workers are employed to *curate* the output of a statistical SRL system. This setup generates annotation tasks as following:



Sentence

And many fund managers have built up cash levels and say they will be buying stock this week.
buy.01

Question

What is being bought in this sentence? Is it: "stock"?

Answer Options

○ Yes
○ No, what is being bought is *not* mentioned
○ No, what is being bought is mentioned here: copy and paste text

Figure 2: Example annotation task, consisting of a *sentence* with predicted role labels, a human readable *question* regarding to one label, and a set of answer *options*. By answering, crowd workers curate a prediction made by the SRL.

Step 1. We use a statistical SRL system to predict SRL labels for a set of sentences (see Figure 1). While state-of-the-art SRL will predict many correct labels, some predicted labels will be incorrect, and some labels will be missing. Annotation tasks are therefore designed to detect and correct precision and recall errors.

Step 2. We generate two types of annotation tasks for the study, namely ConfirmPrediction and AddMissing tasks: (1) The first, ConfirmPrediction tasks, ask users to confirm, reject or correct each predicted frame or role. This type of task addresses *precision* issues in the SRL. We present to workers a human-readable question-answer pair (He et al., 2015) for each predicted label, an example of which is illustrated in Figure 2. (2) The second, AddMissing tasks, address potentially missing annotation, i.e. *recall* issues in the SRL. We generate a question without a suggested answer and ask workers to either confirm that this role does not appear in the sentence, or supply the correct span. We identify potentially missing annotation using PropBank frame definitions; any unseen core role in a sentence is considered potentially missing.

We use a manually created mapping of frame-roles to questions to generate these tasks. See Table 1 for a mapping of the roles of the buy.01 frame to questions.

Step 3. Each question is presented to crowd workers together with the sentence and a set of answer options. Example annotation tasks are illustrated in Figures 2 and 3. A task thus is defined as follows:

Definition 1 Annotation Task*: A task consists of a sentence, a human readable question regarding a predicted label, and a set of answer options.*

We collect worker responses to these tasks. If the majority of crowd workers agrees on a correction, we remove or correct incorrectly predicted labels for ConfirmPrediction tasks and add new labels for AddMissing tasks.

Frame: buy.01 (*purchase*)		
Role	Description	Question
A0	buyer	Who is buying something?
A1	thing bought	What is being bought?
A2	seller	From whom is something bought?
A3	price paid	What is the price paid?
A4	benefactive	For whom is something bought?

Table 1: Examples of mapping between semantic labels and question phrases of frame buy.01. The description column lists the textual role descriptions from PropBank frame files.

Agreement	#Tasks	#Correct	#Incorrect	Precision
all 5 agree on answer	1,801	1,679	122	**0.93**
4 out of 5 agree	436	376	60	0.86
3 out of 5 agree	278	187	91	0.67
no majority answer	34	0	34	0.0
total	2,549	2,242	307	0.88

Table 2: Tasks in our crowdsourcing study by ratio of how many workers agreed on an answer. If all five workers agree, the majority answer is correct in 93% of cases. If fewer workers agree, the precision of the majority answer decreases.

2.2 Crowdsourcing Study

We conduct a crowdsourcing study consisting of 2,549 annotation tasks, generated by running a state-of-the-art SRL system (Akbik and Li, 2016) over 250 randomly selected gold-labeled sentences from the English training dataset in the CoNLL-2009 shared task (Hajič et al., 2009). We generated tasks using our question mappings from the predicted labels. This setup allows us to compare crowd feedback to gold labels and determine how often the crowd provides incorrect answers.

Human Annotators For *crowd annotators*, we employ five native speakers of English from Upwork[1], selected using the following procedure: We required workers to complete a short tutorial[2], followed by 20 annotation tasks, which we evaluated against the gold data. We used the results to select the best-scoring 5 of 7 applicants. We then asked them to complete the remaining labeling tasks. The study was conducted in a span of three weeks. Crowd workers were paid a fixed sum for the completion of the study, which resulted in a cost of 2 cents per worker per task. In total, workers estimated an average of 9 hours to complete the full task.

2.3 Analysis

We gather crowd feedback and compare the majority answer for each task with the gold label. Refer to Table 2 for an overview of results. We make several observations:

The more workers agree, the better the answer. Generally, we note that majority answers tend to be more often correct if more workers agree. Specifically, as Table 2 shows, all 5 annota-

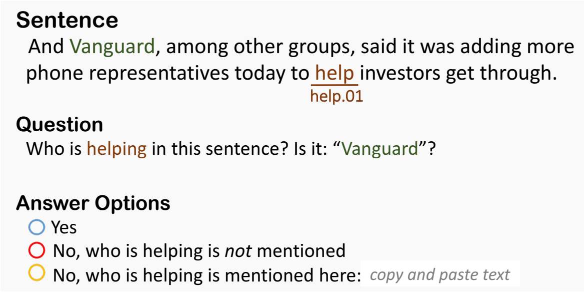
Type		Frame	A0	A1	A2	A3	A4	LOC	TMP
CONFIRM-PREDICTION	Expert-required	**134 (38%)**	280 (32%)	382 (32%)	73 (33%)	**6 (43%)**	**8 (50%)**	36 (35%)	120 (36%)
	Crowd-appropriate	222 (62%)	608 (68%)	797 (68%)	146 (67%)	8 (57%)	8 (50%)	67 (65%)	211 (64%)
ADD-MISSING	Expert-required	0	82 (31%)	54 (33%)	**240 (37%)**	99 (34%)	**72 (38%)**	0	0
	Crowd-appropriate	0	186 (69%)	111 (67%)	405 (63%)	190 (66%)	120 (62%)	0	0

Table 3: Breakdown of annotation tasks by question types and semantic labels, and proportion of expert-required tasks (formally defined in Section 3). Percentages in each cell add up to 100%. On average, 34% of tasks are expert required. Task types that lie above this average are highlighted bold. For instance, 38% of all frame confirmation questions are expert-required, indicating that this question type is of above-average difficulty.

tors agreed in 1,801 out of all 2,549 tasks (71%). Of these tasks, the majority answer was correct in 1,679 cases, and incorrect in 122, yielding a precision of 93% for tasks in full agreement. If only 4 out of 5 agree (i.e. one annotator provided a different answer), the precision drops to 86%. If only three annotators agree on an answer, the precision is even lower, at 67%. Furthermore, we note 34 cases in which there was no majority answer (no agreement by at least 3 workers). We therefore see a direct correlation between agreement scores and the validity of majority answers.

Even if all workers agree, errors are made. We also note that all 5 crowd workers sometimes unanimously agree an *incorrect annotation*, in a total of 122 cases. To illustrate such a case, consider the example in Figure 3: In our study, all 5 workers incorrectly selected **yes** as answer. However, (perhaps somewhat counterintuitively to non-experts) under the PropBank paradigm it is the "phone representative" that provide explicit help in this sentence, not "Vanguard."

Characteristics of difficult annotation tasks. As illustrated in Table 3, we break down annotation tasks by question types and semantic labels to gain a better understanding of which tasks are difficult for the crowd. The first row in the table lists results for CONFIRMPREDICTION tasks. We note that some tasks of this type require above-average expert involvement, such as confirmation questions that pertain to the frame label or higher numbered roles (A3 and A4). The second row lists results for ADDMISSING tasks. Here, we note that again higher order roles tend to be above average expert-required[3]. However, while the breakdown in Table 3 indicates some general trends for the difficulty of annotation tasks, the question type itself does not suffice to determine whether an individual instance requires expert involvement or not.



Sentence
And Vanguard, among other groups, said it was adding more phone representatives today to help investors get through.
help.01

Question
Who is helping in this sentence? Is it: "Vanguard"?

Answer Options
○ Yes
○ No, who is helping is *not* mentioned
○ No, who is helping is mentioned here: *copy and paste text*

Figure 3: Example of an annotation task where crowd workers unanimously provided an incorrect answer in our study (see 2.3). This task is classified as *expert-required.*

Summary. Our crowdsourcing study supports the initial hypothesis that a portion of SRL tasks is in fact appropriate for crowd workers, but also shows that identifying such tasks is not straightforward since neither crowd agreement scores nor the annotation task type is sufficient indicators of difficult tasks. We investigate this problem further in the next section.

3 TASKROUTER: Annotation Task Classification

Our study shows that some annotation tasks are appropriate for crowd workers, while others are not. In this section, we define a classification problem in which we wish to classify each task into one of the two following classes:

Definition 2 Crowd-appropriate*: A task for which: (1) All crowd workers agree on the answer. (2) The agreed-upon answer is correct.*

Definition 3 Expert-required*: A task that is not crowd-appropriate.*

According to these definitions, our crowdsourcing study found that the task in Figure 2 is *crowd-appropriate*, i.e. easy enough for the crowd to provide correct and consistent answers, while the task in Figure 3 is considered *expert-required*.

[3] Note that there are no ADDMISSING questions for frames since our SRL predicts a label for each verb in a sentence. Also there are no missing optional arguments since we ask missing argument questions only for core roles.

3.1 Features

To solve the task classification problem, we note two groups of distinct features (see Table 4):

Task-level features $\mathbf{X}^g$ capture the general difficulty of a labeling task, as defined by a frame or role type. The intuition here is that certain frames/roles are inherently difficult for non-experts, and that annotation tasks related to such frames/roles should be handled by experts. In the BUY.01 frame for instance, *buyer* (**A0**) is a simple crowd-appropriate semantic concept, while *benefactive* (**A4**) generally produces lower agreement scores. Task-level features therefore include the frame and role labels themselves, as well as the complexity of each question, measured in features such as the question word (*what*, *how*, *when* etc.), its length measured in number of tokens, and all tokens, lemmas and POS-tags in the question.

Sentence-level features $\mathbf{X}^l$ capture complexity associated with the specific *task instance*. The intuition is that some sentences are more complex and more difficult to understand than others. In such sentences, even roles with generally crowd-appropriate definitions might be incorrectly answered by non-experts. We capture the complexity of a sentence with features such as its length (number of tokens in sentence), the numbers of frames, roles, verbs, and nouns in the sentence, as well as all tokens, lemmas and POS-tags.

3.2 Classification Model

In addition to task- and sentence-level features, we present a classifier that also models the interplay between multiple annotation tasks generated from the same sentence. The intuition here is that there is an interdependence between labeling decisions in the same sentence. For instance, the presence of a difficult role may alter the interpretation of a sentence and make other labeling decisions more complicated. We thus propose a fuzzy classification model with two layers (Ishibuchi et al., 1995) of SVM classifiers (Wang et al., 2016), which introduces the context of the task using fuzzy indicators to model the interplay between the two groups of features.

Type	Features
Task-level features	Frame label; role label; question type; length of question in # tokens; Wh-word; tokens, lemmas, POS tags of all words in question.
Sentence-level features	# of questions for sentence, # of question types for sentence; # of verbs, # of nouns, # of frames, # of roles in sentence; length of sentence in # tokens; tokens, lemmas and POS tags of all words in sentence; head word and dependency relation to head word.

Table 4: Features for annotation task classification.

Specifically, we train a *local-layer SVM classifier* $\mathcal{L}^l$ using the sentence-level features $\mathbf{X}^l$ (computed from sentences). We also train a *global-layer SVM classifier* $\mathcal{L}^g$ using the task-level features $\mathbf{X}^g$ (computed from tasks). We refer to the predictions of the local and global classifiers as *fuzzy indicators* and we incorporate them as additional features to the fuzzy two-layer SVM classifier $\mathcal{L}^f$ as follows. Given task a_i among all tasks a_1 to a_n for a sentence s, the first layer of the fuzzy classifier, consists of applying the local-layer classifier using the sentence-level features of s. The second layer of the fuzzy classifier consists in applying the global-layer classifier n times, each time using task-level features for task $a_j, 1 \leq j \leq n$, resulting in $n+1$ values: one *local-layer indicator*, and n *global-layer indicators*. Our final fuzzy classifier model uses the $n+1$ local and global indicators as features, in addition to the sentence- and task-level features of a_i.

Note that the classification of task a_i considers features from other tasks a_j from the same sentence, but more efficiently than placing all task-level features of all tasks into a single feature vector. Formally, the objective function of the fuzzy two-layer SVM classification model $\mathcal{L}^f$ is:

$$\max_{\alpha} \mathbf{1}^T \boldsymbol{\alpha} - \frac{1}{2} \boldsymbol{\alpha}^T \mathbf{Y} \mathbf{K}(\mathbf{X}^{f^T} \mathbf{X}^f) \mathbf{Y} \boldsymbol{\alpha} \qquad (1)$$
$$s.t. \quad \boldsymbol{y}^T \boldsymbol{\alpha} = 0, 0 \leq \boldsymbol{\alpha} \leq C\mathbf{1}.$$

where $\mathbf{K}(\mathbf{X}^{f^T} \mathbf{X}^f)$ is the fuzzy two-layer RBF kernel function, $\mathbf{X}^f = [\mathbf{X}^{gT}, \mathbf{X}^{l^T}, \mathbf{Y_1}^{gT}, \cdots, \mathbf{Y}_j{}^{gT}, \cdots, \mathbf{Y}_n{}^{gT}, \mathbf{Y}^{l^T}]$ is the fuzzy two-layer feature matrix, n is the number of annotation tasks generated from a sentence, $\mathbf{Y}_j{}^g$ represents the j-th fuzzy indicator generated by the j-th global classifier $\mathcal{L}^g{}_j$, $\mathbf{Y}^l$ is the fuzzy indicator generated by the local classifier $\mathcal{L}^l$, $\mathbf{Y}$ is the label matrix, $\mathbf{1}$ is a vector of all ones and C is a positive trade-off parameter.

3.3 Evaluation

To evaluate the accuracy of TASKROUTER we use the standard measure of *accuracy* for binary classifiers. As Table 5 shows, we evaluate four setups

Approach	Accuracy
SVM$_{task}$: Task features only	0.91
SVM$_{sentence}$: Sentence features only	0.87
SVM$_{task+sentence}$: All features	0.94
TaskRouter: Fuzzy two-layer	**0.96***

Table 5: Performance of classifiers trained with five-fold cross validation on training set. The improvements of TaskRouter over other classifiers are significant at the * 0.05 level, paired t-test.

in which we train an SVM with (1) task-level features, (2) sentence-level features, (3) all features, and (4) our proposed fuzzy two-layer classifier.

Data. We use the dataset created in our crowdsourcing study (see Section 2.2), which consists of 2,549 annotation tasks labeled as either *expert-required* or *crowd-appropriate* according to our definitions and the results of the study. We leverage five-fold cross validation to train the classifiers over a training split (80%).

Results. The cross validation results are listed in Table 5. Our proposed classifier outperforms all baselines and reaches a classification accuracy of **0.96**. Interestingly, we also note that task-level features are significantly more important than sentence-level features, as the setup SVM$_{task}$ outperforms SVM$_{sentence}$ by 6 accuracy points. Furthermore, our proposed approach outperforms SVM$_{task+sentence}$, indicating a positive impact of modeling the global interplay of annotation tasks.

These experiments confirm our initial postulation that it is possible to train a high quality classifier to detect expert-required tasks. We refer to the best performing setup as TaskRouter.

4 Crowd-in-the-Loop Study

Having created TaskRouter, we now execute our proposed crowd-in-the-loop workflow and comparatively evaluate it against a number of crowdsourcing and hybrid approaches. We wish to determine (1) to what degree does having the crowd in the loop reduce the workload of experts? (2) How does the quality of the produced annotated data compare to purely crowdsourced or expert annotations?

4.1 Approaches

We evaluate the following approaches:

1. Baseline without curation The first is a simple baseline in which we use the output of SRL as-is, i.e. with no additional curation either by the crowd or experts. We list this method to show the quality of the starting point for the curation workload.

2. Crowd (Crowdsourcing) The second baseline is a standard crowdsourcing approach as described in Section 2, i.e. without experts. We send all annotation tasks (100%) to the crowd and gather crowd feedback to correct labels in three different settings. We correct all labels based on majority vote, i.e., if at least 3 (Crowd$_{min3}$), 4 (Crowd$_{min4}$) or all 5 (Crowd$_{all5}$) out of 5 annotators agree on an answer.

3. Hybrid (Crowdsourcing + Expert curation) In this setting, we replicate the approach proposed by (Akbik et al., 2016): After first executing crowdsourcing (i.e. sending 100% of the tasks to the crowd), we identify all tasks in which crowd workers provided conflicting answers. These tasks are sent to experts for additional curation (expert answers are used for curation instead of the crowd response). We use three definitions of what constitutes a conflicting answer: (1) We consider all answers in which at least a majority (3 out of 5) agreed as crowd-appropriate and send the rest (2.2%) to experts. We refer to this setup as Hybrid$_{min3}$. (2) Only tasks where 4 out of 5 agreed are crowd-appropriate, the remaining 9.9% go to experts (Hybrid$_{min4}$). (3) Any task in which there is no unanimous agreement (27.3%) is deemed expert-required (Hybrid$_{all5}$).

4. Crowd-in-the-Loop This setup is *the proposed approach* in which we use TaskRouter trained over a holdout training set to split annotation tasks into crowd and expert groups. In our experiments, TaskRouter determines the following partitions: 66.4% of tasks to the crowd, the remaining 33.6% to experts. To give an indication of the lower bound of the approach given these partitions, we list results for two settings: (1) Crowd-in-the-Loop$_{Random}$, a lower bound setting in which we randomly split into these partitions. (2) Crowd-in-the-Loop$_{TaskRouter}$, the proposed setting in which we use TaskRouter to perform this split.

Refer to Table 6 for an overview of these experiments. The workload columns indicate what percentage of tasks is sent to crowd and experts.

4.2 Experimental Setup

Data We use the dataset created in the crowdsourcing study in Section 2, consisting of 2,549 annotation tasks labeled either as expert-required

Approach	Annotation Quality			Workload		Correctness	
	P	R	F1	crowd	expert	crowd-only	hybrid
Baseline without curation	0.86	0.83	0.85	0%	0%	-	-
Crowd$_{min3}$	0.92	0.88	0.90	100.0%	0%	0.84	0.84
Crowd$_{min4}$	0.89	0.85	0.87	100.0%	0%	0.84	0.84
Crowd$_{all5}$	0.87	0.84	0.85	100.0%	0%	0.84	0.84
Hybrid$_{min3}$	0.90	0.86	0.88	100.0%	2.2%	0.84	0.84
Hybrid$_{min4}$	0.91	0.87	0.89	100.0%	9.9%	0.84	0.86
Hybrid$_{all5}$	0.93	0.89	0.91	100.0%	27.3%	0.84	0.88
Crowd-in-the-Loop$_{Random}$	0.92	0.88	0.90	**66.4%**	**33.6%**	0.83	0.89
Crowd-in-the-Loop$_{TaskRouter}$	**0.96***	**0.92***	**0.94***	**66.4%**	**33.6%**	**0.92***	**0.95***

Table 6: Comparative evaluation of different approaches for generating gold-standard SRL annotation. The improvements of Crowd-in-the-Loop$_{TaskRouter}$ over other approaches are significant at the * 0.05 level, paired t-test.

or crowd-appropriate [4]. As shown in Section 3.3, we use 80% of the dataset to train TaskRouter under cross validation, and conduct the comparative evaluation using the remaining 20%.

Human annotators & curation We simulate an *expert annotator* using the CoNLL-2009 gold SRL labels and reuse the crowd answers from the study for *crowd annotators*. For each setting, we gather crowd and expert answers to the annotation tasks, and interpret the answers to curate the SRL labels that were produced by the statistical SRL system. After curation, we evaluate the resulting labeled sentences against gold-labeled data to determine the annotation quality in terms of precision, recall and F$_1$-score.

Evaluation Metrics Next to the quality of resulting annotations, we are interested to evaluate how effectively we integrate the crowd. We measure this in two metrics. (1) One is the percentage of tasks that go to the crowd and to experts respectively. Note that in the Hybrid setup, some tasks go to both crowd workers and experts, so that the percentages can add up to over a hundred percent. This information is illustrated in column Workload in Table 6. (2) The second is the overall validity of crowd feedback, referred to as *correctness*, measured as the ratio of correct answers among all answers retrieved from the crowd. We provide two values for correctness in Table 6, under column Correctness: The first is the correctness only over crowd feedback. Note that this value is the same for all Crowd and Hybrid setups since in these approaches 100% of annotation tasks are passed to the crowd. The second named *hybrid* is the overall correctness of the resolved answers with both expert and crowd feedback.

4.3 Experimental Results

The results of our experiments are summarized in Table 6. We make the following observations:

Crowd-in-the-Loop significantly increases annotation quality. Our evaluation shows that crowd-in-the-loop produces SRL annotation with significantly higher quality compared to crowdsourcing or hybrid scenarios. With a resulting F$_1$-score of 0.94, it outperforms the best performing crowdsourcing setup (0.90) by 4 points. More importantly, our proposed approach also outperforms other hybrid approaches that partially leverage experts. It outperforms the best hybrid approach (0.91) by 3 points, indicating that TaskRouter is better to select expert-required tasks than a method with only crowd agreement.

Significantly less expert involvement required. In our experiments, more than two-thirds of all tasks were determined to be crowd-appropriate by TaskRouter. This considerably reduces the need for expert involvement compared to expert labeling, while still maintaining relatively high annotation quality. In particular, our approach compares favorably to other hybrid setups in which a similar partition of tasks is completed by experts. Since TaskRouter is more capable to choose expert-required tasks than previous approaches, we achieve higher overall quality at similar levels of expert involvement.

Crowd workers more effective. As the correctness column in Table 6 shows, the selection of tasks by TaskRouter is more appropriate for the crowd in general. Their average correctness increases to 0.92, compared to 0.84 if the crowd completes 100% of the tasks.

[4] We will release the dataset soon.

4.4 Discussion and Outlook

The proposed approach far outperforms crowdsourcing and hybrid approaches in terms of annotation quality. In particular, even at similar levels of expert involvement, it outperforms the HYBRID$_{all5}$ approach. However, we also note that with an F$_1$-score of 0.94, our approach does not yet reach the quality of gold annotated data.

Insights for further improving quality. To further improve the quality of generated SRL training data, future work may (1) investigate additional features (Wang et al., 2015) and classification models to improve the TASKROUTER to better distinguish between crowd-appropriate and expert-required tasks, and (2) experiment with other SRL crowdsourcing designs to make more tasks crowd-appropriate. Nevertheless, we suspect that a small decrease in quality cannot be fully avoided if large amounts of non-experts are involved in a labeling task such as SRL. Given such involvement of non-experts, we believe that our proposed approach is a compelling way for increasing crowdsourcing quality while keeping expert costs relatively low.

Flexible trade-off of costs vs quality. Another avenue for research is to experiment with classifier parameters that allow us to more flexibly control the trade-off between how many experts we wish to involve and what annotation quality we desire (e.g., active learning (Wang et al., 2017)). This may be helpful to scenarios in which costs are fixed, or where one aims to compute the costs for generating annotated data of specific quality.

Use for SRL domain adaptation. One intended avenue for study is to apply our approach to generate training data for a specific textual domain for which little or no SRL training data currently exists. We believe that due to its relatively lower costs, our approach may be an ideal candidate for practical domain adaptation of SRL.

Applicability to other NLP crowdsourcing tasks. Finally, while in this paper we focused on the task of generating labeled training data for SRL, we believe that our proposed approach may be applicable to other NLP tasks that have only reported moderate results to-date. To study this applicability, one would first need to conduct a similar study as in Section 2 to identify crowd-appropriate and expert-required tasks and attempt the training of a classifier.

5 Related Work

Crowdsourcing SRL Annotation Different approaches have been adapted to formulate SRL tasks for non-expert crowd workers (Hong and Baker, 2011). Typical tasks include selecting answers from a set of candidates (Fossati et al., 2013), marking text passages that contain specific semantic roles (Feizabadi and Padó, 2014), and constructing question-answer pairs (He et al., 2015, 2016). However, a particular challenge is that SRL annotation tasks are often complex and crowdsourcing inevitably leads to low-quality annotations (Pavlick et al., 2015).

Instead of attempting to design a better annotation task, our proposed approach addresses this problem by accepting that a certain portion of annotation tasks is too difficult for the crowd. We create a classifier to identify such tasks and involve experts whenever necessary.

Routing Tasks Recent approaches have been developed to address the task routing problem in crowdsourcing (Bragg et al., 2014; Bozzon et al., 2013; Hassan and Curry, 2013). As workers vary in skill and tasks vary in difficulty, prior recommended approaches often consider the match between the task content and workers' profiles. However, these approaches are difficult to apply to the particular context of SRL annotation since we only distinguish between either experts familiar with PropBank, or non-expert crowd workers.

Rather than routing tasks to the most appropriate workers, our proposed approach determines which SRL tasks are appropriate for crowdsourcing, and sends the remaining ones to experts.

Human-in-the-loop Methods Our method is similar in the spirit of human-in-the-loop learning (Fung et al., 1992; Li et al., 2016). Human-in-the-loop learning generally aims to leverage humans to complete easy commonsense tasks, such as the recognition of objects in images (Patterson et al., 2013). Recent work also proposed human-in-the-loop parsing (He et al., 2016) to include human feedback into parsing. However, unlike these approaches, we aim to combine both experts and non-experts to address the difficulty of some SRL annotation tasks, while leveraging the crowd for the majority of tasks.

6 Conclusion

In this paper, we proposed CROWD-IN-THE-LOOP an approach for creating high-quality annotated data for SRL that leverages both crowd and expert workers. We conducted a crowdsourcing study and analyzed its results to design a classifier to distinguish between crowd-appropriate and expert-required tasks. Our experimental evaluation showed that our proposed approach significantly outperforms baseline crowdsourcing and hybrid approaches, and successfully limits the need for expert involvement while achieving high annotation quality.

Abstract

Transfer and multi-task learning have traditionally focused on either a single source-target pair or very few, similar tasks. Ideally, the linguistic levels of morphology, syntax and semantics would benefit each other by being trained in a single model. We introduce a joint many-task model together with a strategy for successively growing its depth to solve increasingly complex tasks. Higher layers include shortcut connections to lower-level task predictions to reflect linguistic hierarchies. We use a simple regularization term to allow for optimizing all model weights to improve one task's loss without exhibiting catastrophic interference of the other tasks. Our single end-to-end model obtains state-of-the-art or competitive results on five different tasks from tagging, parsing, relatedness, and entailment tasks.

1 Introduction

The potential for leveraging multiple levels of representation has been demonstrated in various ways in the field of Natural Language Processing (NLP). For example, Part-Of-Speech (POS) tags are used for syntactic parsers. The parsers are used to improve higher-level tasks, such as natural language inference (Chen et al., 2016) and machine translation (Eriguchi et al., 2016). These systems are often pipelines and not trained end-to-end.

Deep NLP models have yet shown benefits from predicting many increasingly complex tasks each at a successively deeper layer. Existing models often ignore linguistic hierarchies by predicting different tasks either entirely separately or at the same depth (Collobert et al., 2011).

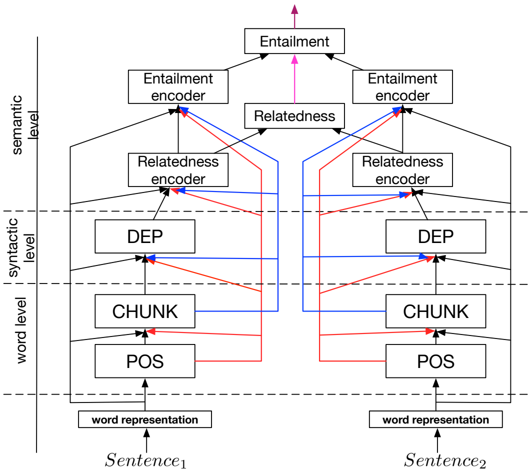

Figure 1: Overview of the joint many-task model predicting different linguistic outputs at successively deeper layers.

We introduce a Joint Many-Task (JMT) model, outlined in Figure 1, which predicts increasingly complex NLP tasks at successively deeper layers. Unlike traditional pipeline systems, our single JMT model can be trained end-to-end for POS tagging, chunking, dependency parsing, semantic relatedness, and textual entailment, by considering linguistic hierarchies. We propose an adaptive training and regularization strategy to grow this model in its depth. With the help of this strategy we avoid catastrophic interference between the tasks. Our model is motivated by Søgaard and Goldberg (2016) who showed that predicting two different tasks is more accurate when performed in different layers than in the same layer (Collobert et al., 2011). Experimental results show that our single model achieves competitive results for all of the five different tasks, demonstrating that us-

ing linguistic hierarchies is more important than handling different tasks in the same layer.

2 The Joint Many-Task Model

This section describes the inference procedure of our model, beginning at the lowest level and working our way to higher layers and more complex tasks; our model handles the five different tasks in the order of POS tagging, chunking, dependency parsing, semantic relatedness, and textual entailment, by considering linguistic hierarchies. The POS tags are used for chunking, and the chunking tags are used for dependency parsing (Attardi and DellOrletta, 2008). Tai et al. (2015) have shown that dependencies improve the relatedness task. The relatedness and entailment tasks are closely related to each other. If the semantic relatedness between two sentences is very low, they are unlikely to entail each other. Based on this observation, we make use of the information from the relatedness task for improving the entailment task.

2.1 Word Representations

For each word w_t in the input sentence s of length L, we use two types of embeddings.

Word embeddings: We use Skip-gram (Mikolov et al., 2013) to train word embeddings.

Character embeddings: Character n-gram embeddings are trained by the same Skip-gram objective. We construct the character n-gram vocabulary in the training data and assign an embedding for each entry. The final character embedding is the average of the *unique* character n-gram embeddings of w_t. For example, the character n-grams ($n = 1, 2, 3$) of the word "Cat" are {C, a, t, #B#C, Ca, at, t#E#, #B#Ca, Cat, at#E#}, where "#B#" and "#E#" represent the beginning and the end of each word, respectively. Using the character embeddings efficiently provides morphological features. Each word is subsequently represented as x_t, the concatenation of its corresponding word and character embeddings shared across the tasks.[1]

2.2 Word-Level Task: POS Tagging

The first layer of the model is a bi-directional LSTM (Graves and Schmidhuber, 2005; Hochreiter and Schmidhuber, 1997) whose hidden states are used to predict POS tags. We use the following Long Short-Term Memory (LSTM) units for the forward direction:

$$\begin{aligned} i_t &= \sigma\left(W_i g_t + b_i\right), \; f_t = \sigma\left(W_f g_t + b_f\right), \\ u_t &= \tanh\left(W_u g_t + b_u\right), \\ c_t &= i_t \odot u_t + f_t \odot c_{t-1}, \qquad (1) \\ o_t &= \sigma\left(W_o g_t + b_o\right), \; h_t = o_t \odot \tanh\left(c_t\right), \end{aligned}$$

where we define the input g_t as $g_t = [\overrightarrow{h}_{t-1}; x_t]$, i.e. the concatenation of the previous hidden state and the word representation of w_t. The backward pass is expanded in the same way, but a different set of weights are used.

For predicting the POS tag of w_t, we use the concatenation of the forward and backward states in a one-layer bi-LSTM layer corresponding to the t-th word: $h_t = [\overrightarrow{h}_t; \overleftarrow{h}_t]$. Then each h_t $(1 \le t \le L)$ is fed into a standard softmax classifier with a single ReLU layer which outputs the probability vector $y^{(1)}$ for each of the POS tags.

2.3 Word-Level Task: Chunking

Chunking is also a word-level classification task which assigns a chunking tag (B-NP, I-VP, etc.) for each word. The tag specifies the region of major phrases (e.g., noun phrases) in the sentence.

Chunking is performed in the second bi-LSTM layer on top of the POS layer. When stacking the bi-LSTM layers, we use Eq. (1) with input $g_t^{(2)} = [h_{t-1}^{(2)}; h_t^{(1)}; x_t; y_t^{(pos)}]$, where $h_t^{(1)}$ is the hidden state of the first (POS) layer. We define the weighted label embedding $y_t^{(pos)}$ as follows:

$$y_t^{(pos)} = \sum_{j=1}^{C} p(y_t^{(1)} = j | h_t^{(1)}) \ell(j), \qquad (2)$$

where C is the number of the POS tags, $p(y_t^{(1)} = j | h_t^{(1)})$ is the probability value that the j-th POS tag is assigned to w_t, and $\ell(j)$ is the corresponding label embedding. The probability values are predicted by the POS layer, and thus no gold POS tags are needed. This output embedding is similar to the K-best POS tag feature which has been shown to be effective in syntactic tasks (Andor et al., 2016; Alberti et al., 2015). For predicting the chunking tags, we employ the same strategy as POS tagging by using the concatenated bi-directional hidden states $h_t^{(2)} = [\overrightarrow{h}_t^{(2)}; \overleftarrow{h}_t^{(2)}]$ in the chunking layer. We also use a single ReLU hidden layer before the softmax classifier.

[1] Bojanowski et al. (2017) previously proposed to train the character n-gram embeddings by the Skip-gram objective.

2.4 Syntactic Task: Dependency Parsing

Dependency parsing identifies syntactic relations (such as an adjective modifying a noun) between word pairs in a sentence. We use the third bi-LSTM layer to classify relations between all pairs of words. The input vector for the LSTM includes hidden states, word representations, and the label embeddings for the two previous tasks: $g_t^{(3)} = [h_{t-1}^{(3)}; h_t^{(2)}; x_t; (y_t^{(pos)} + y_t^{(chk)})]$, where we computed the chunking vector in a similar fashion as the POS vector in Eq. (2).

We predict the parent node (*head*) for each word. Then a dependency label is predicted for each child-parent pair. This approach is related to Dozat and Manning (2017) and Zhang et al. (2017), where the main difference is that our model works on a multi-task framework. To predict the parent node of w_t, we define a matching function between w_t and the candidates of the parent node as $m\left(t, j\right) = h_t^{(3)} \cdot (W_d h_j^{(3)})$, where W_d is a parameter matrix. For the root, we define $h_{L+1}^{(3)} = r$ as a parameterized vector. To compute the probability that w_j (or the root node) is the parent of w_t, the scores are normalized:

$$p(j|h_t^{(3)}) = \frac{\exp\left(m\left(t, j\right)\right)}{\sum_{k=1, k\neq t}^{L+1} \exp\left(m\left(t, k\right)\right)}. \quad (3)$$

The dependency labels are predicted using $[h_t^{(3)}; h_j^{(3)}]$ as input to a $\mathrm{softmax}$ classifier with a single ReLU layer. We greedily select the parent node and the dependency label for each word. When the parsing result is not a well-formed tree, we apply the first-order Eisner's algorithm (Eisner, 1996) to obtain a well-formed tree from it.

2.5 Semantic Task: Semantic relatedness

The next two tasks model the semantic relationships between two input sentences. The first task measures the semantic relatedness between two sentences. The output is a real-valued relatedness score for the input sentence pair. The second task is textual entailment, which requires one to determine whether a premise sentence entails a hypothesis sentence. There are typically three classes: entailment, contradiction, and neutral. We use the fourth and fifth bi-LSTM layer for the relatedness and entailment task, respectively.

Now it is required to obtain the sentence-level representation rather than the word-level representation $h_t^{(4)}$ used in the first three tasks. We compute the sentence-level representation $h_{\mathbf{s}}^{(4)}$ as the element-wise maximum values across all of the word-level representations in the fourth layer:

$$h_{\mathbf{s}}^{(4)} = \max\left(h_1^{(4)}, h_2^{(4)}, \ldots, h_L^{(4)}\right). \quad (4)$$

This max-pooling technique has proven effective in text classification tasks (Lai et al., 2015).

To model the semantic relatedness between s and s', we follow Tai et al. (2015). The feature vector for representing the semantic relatedness is computed as follows:

$$d_1(s, s') = \left[\left|h_{\mathbf{s}}^{(4)} - h_{\mathbf{s}'}^{(4)}\right|; h_{\mathbf{s}}^{(4)} \odot h_{\mathbf{s}'}^{(4)}\right], \quad (5)$$

where $\left|h_{\mathbf{s}}^{(4)} - h_{\mathbf{s}'}^{(4)}\right|$ is the absolute values of the element-wise subtraction, and $h_{\mathbf{s}}^{(4)} \odot h_{\mathbf{s}'}^{(4)}$ is the element-wise multiplication. Then $d_1(s, s')$ is fed into a $\mathrm{softmax}$ classifier with a single Maxout hidden layer (Goodfellow et al., 2013) to output a relatedness score (from 1 to 5 in our case).

2.6 Semantic Task: Textual entailment

For entailment classification, we also use the max-pooling technique as in the semantic relatedness task. To classify the premise-hypothesis pair (s, s') into one of the three classes, we compute the feature vector $d_2(s, s')$ as in Eq. (5) except that we do not use the absolute values of the element-wise subtraction, because we need to identify which is the premise (or hypothesis). Then $d_2(s, s')$ is fed into a $\mathrm{softmax}$ classifier.

To use the output from the relatedness layer directly, we use the label embeddings for the relatedness task. More concretely, we compute the class label embeddings for the semantic relatedness task similar to Eq. (2). The final feature vectors that are concatenated and fed into the entailment classifier are the weighted relatedness label embedding and the feature vector $d_2(s, s')$. We use three Maxout hidden layers before the classifier.

3 Training the JMT Model

The model is trained jointly over all datasets. During each epoch, the optimization iterates over each full training dataset in the same order as the corresponding tasks described in the modeling section.

3.1 Pre-Training Word Representations

We pre-train word embeddings using the Skip-gram model with negative sampling (Mikolov et al., 2013). We also pre-train the character n-gram embeddings using Skip-gram.[2] The only difference is that each input word embedding is replaced with its corresponding average character n-gram embedding described in Section 2.1. These embeddings are fine-tuned during the model training. We denote the embedding parameters as θ_e.

3.2 Training the POS Layer

Let $\theta_{\text{POS}} = (W_{\text{POS}}, b_{\text{POS}}, \theta_e)$ denote the set of model parameters associated with the POS layer, where W_{POS} is the set of the weight matrices in the first bi-LSTM and the classifier, and b_{POS} is the set of the bias vectors. The objective function to optimize θ_{POS} is defined as follows:

$$J_1(\theta_{\text{POS}}) = -\sum_s \sum_t \log p(y_t^{(1)} = \alpha | h_t^{(1)}) + \lambda \|W_{\text{POS}}\|^2 + \delta \|\theta_e - \theta'_e\|^2, \tag{6}$$

where $p(y_t^{(1)} = \alpha_{w_t} | h_t^{(1)})$ is the probability value that the correct label α is assigned to w_t in the sentence s, $\lambda \|W_{\text{POS}}\|^2$ is the L2-norm regularization term, and λ is a hyperparameter.

We call the second regularization term $\delta \|\theta_e - \theta'_e\|^2$ a *successive* regularization term. The successive regularization is based on the idea that we do not want the model to forget the information learned for the other tasks. In the case of POS tagging, the regularization is applied to θ_e, and θ'_e is the embedding parameter after training the final task in the top-most layer at the previous training epoch. δ is a hyperparameter.

3.3 Training the Chunking Layer

The objective function is defined as follows:

$$J_2(\theta_{\text{chk}}) = -\sum_s \sum_t \log p(y_t^{(2)} = \alpha | h_t^{(2)}) + \lambda \|W_{\text{chk}}\|^2 + \delta \|\theta_{\text{POS}} - \theta'_{\text{POS}}\|^2, \tag{7}$$

which is similar to that of POS tagging, and θ_{chk} is $(W_{\text{chk}}, b_{\text{chk}}, E_{\text{POS}}, \theta_e)$, where W_{chk} and b_{chk} are the weight and bias parameters including those in θ_{POS}, and E_{POS} is the set of the POS label embeddings. θ'_{POS} is the one after training the POS layer at the current training epoch.

3.4 Training the Dependency Layer

The objective function is defined as follows:

$$J_3(\theta_{\text{dep}}) = -\sum_s \sum_t \log p(\alpha | h_t^{(3)}) p(\beta | h_t^{(3)}, h_\alpha^{(3)}) + \lambda (\|W_{\text{dep}}\|^2 + \|W_d\|^2) + \delta \|\theta_{\text{chk}} - \theta'_{\text{chk}}\|^2, \tag{8}$$

where $p(\alpha | h_t^{(3)})$ is the probability value assigned to the correct parent node α for w_t, and $p(\beta | h_t^{(3)}, h_\alpha^{(3)})$ is the probability value assigned to the correct dependency label β for the child-parent pair (w_t, α). θ_{dep} is defined as $(W_{\text{dep}}, b_{\text{dep}}, W_d, r, E_{\text{POS}}, E_{\text{chk}}, \theta_e)$, where W_{dep} and b_{dep} are the weight and bias parameters including those in θ_{chk}, and E_{chk} is the set of the chunking label embeddings.

3.5 Training the Relatedness Layer

Following Tai et al. (2015), the objective function is defined as follows:

$$J_4(\theta_{\text{rel}}) = \sum_{(s,s')} \text{KL}\left(\hat{p}(s, s') \middle\| p(h_s^{(4)}, h_{s'}^{(4)})\right) + \lambda \|W_{\text{rel}}\|^2 + \delta \|\theta_{\text{dep}} - \theta'_{\text{dep}}\|^2, \tag{9}$$

where $\hat{p}(s, s')$ is the gold distribution over the defined relatedness scores, $p(h_s^{(4)}, h_{s'}^{(4)})$ is the predicted distribution given the the sentence representations, and $\text{KL}\left(\hat{p}(s, s') \middle\| p(h_s^{(4)}, h_{s'}^{(4)})\right)$ is the KL-divergence between the two distributions. θ_{rel} is defined as $(W_{\text{rel}}, b_{\text{rel}}, E_{\text{POS}}, E_{\text{chk}}, \theta_e)$.

3.6 Training the Entailment Layer

The objective function is defined as follows:

$$J_5(\theta_{\text{ent}}) = -\sum_{(s,s')} \log p(y_{(s,s')}^{(5)} = \alpha | h_s^{(5)}, h_{s'}^{(5)}) + \lambda \|W_{\text{ent}}\|^2 + \delta \|\theta_{\text{rel}} - \theta'_{\text{rel}}\|^2, \tag{10}$$

where $p(y_{(s,s')}^{(5)} = \alpha | h_s^{(5)}, h_{s'}^{(5)})$ is the probability value that the correct label α is assigned to the premise-hypothesis pair (s, s'). θ_{ent} is defined as $(W_{\text{ent}}, b_{\text{ent}}, E_{\text{POS}}, E_{\text{chk}}, E_{\text{rel}}, \theta_e)$, where E_{rel} is the set of the relatedness label embeddings.

4 Related Work

Many deep learning approaches have proven to be effective in a variety of NLP tasks and are becoming more and more complex. They are typically

[2] The training code and the pre-trained embeddings are available at https://github.com/hassyGo/charNgram2vec.

designed to handle single tasks, or some of them are designed as general-purpose models (Kumar et al., 2016; Sutskever et al., 2014) but applied to different tasks independently.

For handling multiple NLP tasks, multi-task learning models with deep neural networks have been proposed (Collobert et al., 2011; Luong et al., 2016), and more recently Søgaard and Goldberg (2016) have suggested that using different layers for different tasks is more effective than using the same layer in jointly learning closely-related tasks, such as POS tagging and chunking. However, the number of tasks was limited or they have very similar task settings like word-level tagging, and it was not clear how lower-level tasks could be also improved by combining higher-level tasks.

More related to our work, Godwin et al. (2016) also followed Søgaard and Goldberg (2016) to jointly learn POS tagging, chunking, and language modeling, and Zhang and Weiss (2016) have shown that it is effective to jointly learn POS tagging and dependency parsing by sharing internal representations. In the field of relation extraction, Miwa and Bansal (2016) proposed a joint learning model for entity detection and relation extraction. All of them suggest the importance of multi-task learning, and we investigate the potential of handling different types of NLP tasks rather than closely-related ones in a single hierarchical deep model.

In the field of computer vision, some transfer and multi-task learning approaches have also been proposed (Li and Hoiem, 2016; Misra et al., 2016). For example, Misra et al. (2016) proposed a multi-task learning model to handle different tasks. However, they assume that each data sample has annotations for the different tasks, and do not explicitly consider task hierarchies.

Recently, Rusu et al. (2016) have proposed a progressive neural network model to handle multiple reinforcement learning tasks, such as Atari games. Like our JMT model, their model is also successively trained according to different tasks using different layers called columns in their paper. In their model, once the first task is completed, the model parameters for the first task are fixed, and then the second task is handled with new model parameters. Therefore, accuracy of the previously trained tasks is never improved. In NLP tasks, multi-task learning has the potential to improve not only higher-level tasks, but also lower-level tasks. Rather than fixing the pre-trained model parameters, our successive regularization allows our model to continuously train the lower-level tasks without significant accuracy drops.

5 Experimental Settings

5.1 Datasets

POS tagging: To train the POS tagging layer, we used the Wall Street Journal (WSJ) portion of Penn Treebank, and followed the standard split for the training (Section 0-18), development (Section 19-21), and test (Section 22-24) sets. The evaluation metric is the word-level accuracy.

Chunking: For chunking, we also used the WSJ corpus, and followed the standard split for the training (Section 15-18) and test (Section 20) sets as in the CoNLL 2000 shared task. We used Section 19 as the development set and employed the IOBES tagging scheme. The evaluation metric is the F1 score defined in the shared task.

Dependency parsing: We also used the WSJ corpus for dependency parsing, and followed the standard split for the training (Section 2-21), development (Section 22), and test (Section 23) sets. We obtained Stanford style dependencies using the version 3.3.0 of the Stanford converter. The evaluation metrics are the Unlabeled Attachment Score (UAS) and the Labeled Attachment Score (LAS), and punctuations are excluded for the evaluation.

Semantic relatedness: For the semantic relatedness task, we used the SICK dataset (Marelli et al., 2014), and followed the standard split for the training, development, and test sets. The evaluation metric is the Mean Squared Error (MSE) between the gold and predicted scores.

Textual entailment: For textual entailment, we also used the SICK dataset and exactly the same data split as the semantic relatedness dataset. The evaluation metric is the accuracy.

5.2 Training Details

We set the dimensionality of the embeddings and the hidden states in the bi-LSTMs to 100. At each training epoch, we trained our model in the order of POS tagging, chunking, dependency parsing, semantic relatedness, and textual entailment. We used mini-batch stochastic gradient decent and empirically found it effective to use a gradient clipping method with growing clipping values for the different tasks; concretely, we employed the simple function: $\min(3.0, depth)$, where $depth$ is the number of bi-LSTM layers involved in each task, and 3.0 is the maximum value. We applied our successive regularization to our model, along with L2-norm regularization and dropout (Srivastava et al., 2014). More details are summarized in the supplemental material.

6 Results and Discussion

Table 1 shows our results on the test sets of the five tasks.[3] The column "Single" shows the results of handling each task separately using single-layer bi-LSTMs, and the column "JMT$_{\text{all}}$" shows the results of our JMT model. The single task settings only use the annotations of their own tasks. For example, when handling dependency parsing as a single task, the POS and chunking tags are *not* used. We can see that all results of the five tasks are improved in our JMT model, which shows that our JMT model can handle the five different tasks in a single model. Our JMT model allows us to access arbitrary information learned from the different tasks. If we want to use the model just as a POS tagger, we can use only first bi-LSTM layer.

Table 1 also shows the results of five subsets of the different tasks. For example, in the case of "JMT$_{\text{ABC}}$", only the first three layers of the bi-LSTMs are used to handle the three tasks. In the case of "JMT$_{\text{DE}}$", only the top two layers are used as a two-layer bi-LSTM by omitting all information from the first three layers. The results of the closely-related tasks ("AB", "ABC", and "DE") show that our JMT model improves both of the high-level and low-level tasks. The results of "JMT$_{\text{CD}}$" and "JMT$_{\text{CE}}$" show that the parsing task can be improved by the semantic tasks.

It should be noted that in our analysis on the greedy parsing results of the "JMT$_{\text{ABC}}$" setting, we have found that more than 95% are well-formed dependency trees on the development set. In the 1,700 sentences of the development data, 11 results have multiple root notes, 11 results have no root nodes, and 61 results have cycles. These 83 parsing results are converted into well-formed trees by Eisner's algorithm, and the accuracy does not significantly change (UAS: 94.52%→94.53%, LAS: 92.61%→92.62%).

6.1 Comparison with Published Results

POS tagging Table 2 shows the results of POS tagging, and our JMT model achieves the score close to the state-of-the-art results. The best result to date has been achieved by Ling et al. (2015), which uses character-based LSTMs. Incorporating the character-based encoders into our JMT model would be an interesting direction, but we have shown that the simple pre-trained character n-gram embeddings lead to the promising result.

Chunking Table 3 shows the results of chunking, and our JMT model achieves the state-of-the-art result. Søgaard and Goldberg (2016) proposed to jointly learn POS tagging and chunking in different layers, but they only showed improvement for chunking. By contrast, our results show that the low-level tasks are also improved.

Dependency parsing Table 4 shows the results of dependency parsing by using only the WSJ corpus in terms of the dependency annotations.[4] It is notable that our simple greedy dependency parser outperforms the model in Andor et al. (2016) which is based on beam search with global information. The result suggests that the bi-LSTMs efficiently capture global information necessary for dependency parsing. Moreover, our single task result already achieves high accuracy without the POS and chunking information. The best result to date has been achieved by the model propsoed in Dozat and Manning (2017), which uses higher dimensional representations than ours and proposes a more sophisticated attention mechanism called *biaffine attention*. It should be promising to incorporate their attention mechanism into our parsing component.

Semantic relatedness Table 5 shows the results of the semantic relatedness task, and our JMT model achieves the state-of-the-art result. The result of "JMT$_{\text{DE}}$" is already better than the previous state-of-the-art results. Both of Zhou et al. (2016) and Tai et al. (2015) explicitly used syntactic trees, and Zhou et al. (2016) relied on attention mechanisms. However, our method uses the simple max-pooling strategy, which suggests that it is worth

[3] In chunking evaluation, we only show the results of "Single" and "JMT$_{\text{AB}}$" because the sentences for chunking evaluation overlap the training data for dependency parsing.

[4] Choe and Charniak (2016) employed a tri-training method to expand the training data with 400,000 trees in addition to the WSJ data, and they reported 95.9 UAS and 94.1 LAS by converting their constituency trees into dependency trees. Kuncoro et al. (2017) also reported high accuracy (95.8 UAS and 94.6 LAS) by using a converter.

investigating such simple methods before developing complex methods for simple tasks. Currently, our JMT model does not explicitly use the learned dependency structures, and thus the explicit use of the output from the dependency layer should be an interesting direction of future work.

Textual entailment Table 6 shows the results of textual entailment, and our JMT model achieves the state-of-the-art result. The previous state-of-the-art result in Yin et al. (2016) relied on attention mechanisms and dataset-specific data pre-processing and features. Again, our simple max-pooling strategy achieves the state-of-the-art result boosted by the joint training. These results show the importance of jointly handling related tasks.

6.2 Analysis on the Model Architectures

We investigate the effectiveness of our model in detail. All of the results shown in this section are the development set results.

Shortcut connections Our JMT model feeds the word representations into all of the bi-LSTM layers, which is called the shortcut connection. Table 7 shows the results of "JMT$_{\mathrm{all}}$" with and without the shortcut connections. The results without the shortcut connections are shown in the column of "w/o SC". These results clearly show that the importance of the shortcut connections, and in particular, the semantic tasks in the higher layers strongly rely on the shortcut connections. That is, simply stacking the LSTM layers is not sufficient to handle a variety of NLP tasks in a single model. In the supplementary material, it is qualitatively shown how the shortcut connections work in our model.

Output label embeddings Table 7 also shows the results without using the output labels of the POS, chunking, and relatedness layers, in the column of "w/o LE". These results show that the explicit use of the output information from the classifiers of the lower layers is important in our JMT

model. The results in the column of “w/o SC&LE” are the ones without both of the shortcut connections and the label embeddings.

Different layers for different tasks Table 8 shows the results of our “JMT$_{\text{ABC}}$” setting and that of not using the shortcut connections and the label embeddings (“w/o SC&LE”) as in Table 7. In addition, in the column of “All-3”, we show the results of using the highest (i.e., the third) layer for all of the three tasks without any shortcut connections and label embeddings, and thus the two settings “w/o SC&LE” and “All-3” require exactly the same number of the model parameters. The “All-3” setting is similar to the multi-task model of Collobert et al. (2011) in that task-specific output layers are used but most of the model parameters are shared. The results show that using the same layers for the three different tasks hampers the effectiveness of our JMT model, and the design of the model is much more important than the number of the model parameters.

Successive regularization In Table 9, the column of “w/o SR” shows the results of omitting the successive regularization terms described in Section 3. We can see that the accuracy of chunking is improved by the successive regularization, while other results are not affected so much. The chunking dataset used here is relatively small compared with other low-level tasks, POS tagging and dependency parsing. Thus, these results suggest that the successive regularization is effective when dataset sizes are imbalanced.

Vertical connections We investigated our JMT results without using the vertical connections in the five-layer bi-LSTMs. More concretely, when constructing the input vectors g_t, we do not use the bi-LSTM hidden states of the previous layers. Table 9 also shows the JMT$_{\text{all}}$ results with and without the vertical connections. As shown in the column of “w/o VC”, we observed the competitive results. Therefore, in the target tasks used in our model, sharing the word representations and the output label embeddings is more effective than just stacking the bi-LSTM layers.

Dependency LAS	91.37	90.44

Table 12: Effects of the character embeddings.

Order of training Our JMT model iterates the training process in the order described in Section 3. Our hypothesis is that it is important to start from the lower-level tasks and gradually move to the higher-level tasks. Table 10 shows the results of training our model by randomly shuffling the order of the tasks for each epoch in the column of “Random”. We see that the scores of the semantic tasks drop by the random strategy. In our preliminary experiments, we have found that constructing the mini-batch samples from different tasks also hampers the effectiveness of our model, which also supports our hypothesis.

Depth The single task settings shown in Table 1 are obtained by using single layer bi-LSTMs, but in our JMT model, the higher-level tasks use successively deeper layers. To investigate the gap between the different number of the layers for each task, we also show the results of using multi-layer bi-LSTMs for the single task settings, in the column of “Single+” in Table 11. More concretely, we use the same number of the layers with our JMT model; for example, three layers are used for dependency parsing, and five layers are used for textual entailment. As shown in these results, deeper layers do not always lead to better results, and the joint learning is more important than making the models complex only for single tasks.

Character n-gram embeddings Finally, Table 12 shows the results for the three single tasks with and without the pre-trained character n-gram embeddings. The column of "W&C" corresponds to using both of the word and character n-gram embeddings, and that of "Only W" corresponds to using only the word embeddings. These results clearly show that jointly using the pre-trained word and character n-gram embeddings is helpful in improving the results. The pre-training of the character n-gram embeddings is also effective; for example, without the pre-training, the POS accuracy drops from 97.52% to 97.38% and the chunking accuracy drops from 95.65% to 95.14%.

6.3 Discussion

Training strategies In our JMT model, it is not obvious when to stop the training while trying to maximize the scores of all the five tasks. We focused on maximizing the accuracy of dependency parsing on the development data in our experiments. However, the sizes of the training data are different across the different tasks; for example, the semantic tasks include only 4,500 sentence pairs, and the dependency parsing dataset includes 39,832 sentences with word-level annotations. Thus, in general, dependency parsing requires more training epochs than the semantic tasks, but currently, our model trains all of the tasks for the same training epochs. The same strategy for decreasing the learning rate is also shared across all the different tasks, although our growing gradient clipping method described in Section 5.2 helps improve the results. Indeed, we observed that better scores of the semantic tasks can be achieved before the accuracy of dependency parsing reaches the best score. Developing a method for achieving the best scores for all of the tasks at the same time is important future work.

More tasks Our JMT model has the potential of handling more tasks than the five tasks used in our experiments; examples include entity detection and relation extraction as in Miwa and Bansal (2016) as well as language modeling (Godwin et al., 2016). It is also a promising direction to train each task for multiple domains by focusing on domain adaptation (Søgaard and Goldberg, 2016). In particular, incorporating language modeling tasks provides an opportunity to use large text data. Such large text data was used in our experiments to pre-train the word and character n-gram embeddings. However, it would be preferable to efficiently use it for improving the entire model.

Task-oriented learning of low-level tasks Each task in our JMT model is supervised by its corresponding dataset. However, it would be possible to learn low-level tasks by optimizing high-level tasks, because the model parameters of the low-level tasks can be directly modified by learning the high-level tasks. One example has already been presented in Hashimoto and Tsuruoka (2017), where our JMT model is extended to learning task-oriented latent graph structures of sentences by training our dependency parsing component according to a neural machine translation objective.

7 Conclusion

We presented a joint many-task model to handle multiple NLP tasks with growing depth in a single end-to-end model. Our model is successively trained by considering linguistic hierarchies, directly feeding word representations into all layers, explicitly using low-level predictions, and applying successive regularization. In experiments on five NLP tasks, our single model achieves the state-of-the-art or competitive results on chunking, dependency parsing, semantic relatedness, and textual entailment.

Abstract

Cross-lingual natural language processing hinges on the premise that there exists invariance across languages. At the word level, researchers have identified such invariance in the word embedding semantic spaces of different languages. However, in order to connect the separate spaces, cross-lingual supervision encoded in parallel data is typically required. In this paper, we attempt to establish the cross-lingual connection without relying on any cross-lingual supervision. By viewing word embedding spaces as distributions, we propose to minimize their earth mover's distance, a measure of divergence between distributions. We demonstrate the success on the unsupervised bilingual lexicon induction task. In addition, we reveal an interesting finding that the earth mover's distance shows potential as a measure of language difference.

1 Introduction

Despite tremendous variation and diversity, languages are believed to share something in common. Indeed, this belief forms the underlying basis of computational approaches to cross-lingual transfer (Täckström et al., 2013, *inter alia*), otherwise it would be inconceivable for the transfer to successfully generalize.

Linguistic universals manifest themselves at various levels of linguistic units. At the word level, there is evidence that different languages represent concepts with similar structure (Youn et al., 2016). Interestingly, as computational models of word semantics, monolingual word embeddings also exhibit isomorphism across languages (Mikolov et al., 2013a). This finding opens up the possibility to use a simple transformation, e.g. a linear map, to connect separately trained word embeddings cross-lingually. Learning such a transformation typically calls for cross-lingual supervision from parallel data (Faruqui and Dyer, 2014; Lu et al., 2015; Dinu et al., 2015; Lazaridou et al., 2015; Smith et al., 2017).

In this paper, we ask the question: Can we uncover the transformation without any cross-lingual supervision? At first sight, this task appears formidable, as it would imply that a bilingual semantic space can be constructed by using monolingual corpora only. On the other hand, the existence of structural isomorphism across monolingual embedding spaces points to the feasibility of this task: The transformation exists right there only to be discovered by the right tool.

We propose such a tool to answer the above question in the affirmative. The key insight is to view embedding spaces as distributions, and the desired transformation should make the two distributions close. This naturally calls for a measure of distribution closeness, for which we introduce the earth mover's distance. Therefore, our task can be formulated as the minimization of the earth mover's distance between the transformed source embedding distribution and the target one with respect to the transformation. Importantly, the minimization is performed at the distribution level, and hence no word-level supervision is required.

We demonstrate that the earth mover's distance minimization successfully uncovers the transformation for cross-lingual connection, as evidenced by experiments on the bilingual lexicon induction task. In fact, as an *unsupervised* approach, its performance turns out to be highly competitive with *supervised* methods. Moreover, as an interesting byproduct, the earth mover's distance provides a distance measure that may quantify a facet of language difference.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1934–1945
Copenhagen, Denmark, September 7–11, 2017.

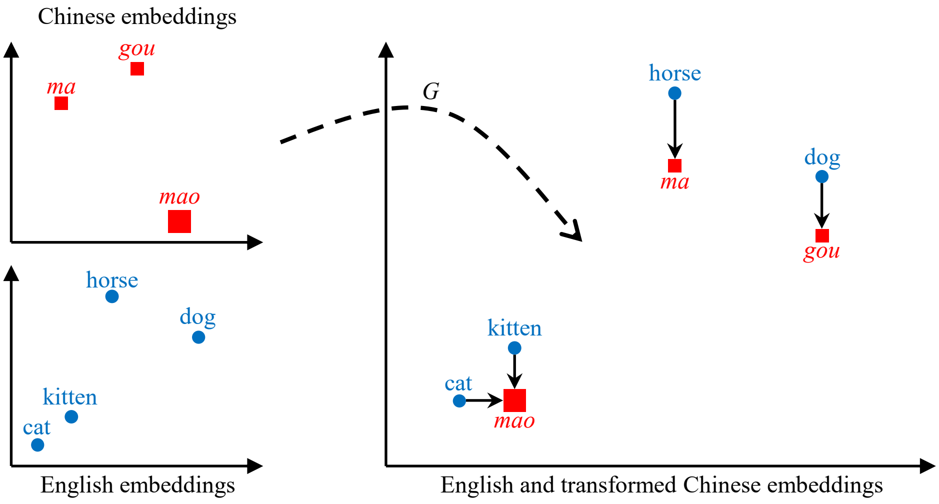

Figure 1: An illustration of our earth mover's distance minimization formulation. The subplots on the left schematically visualize Chinese and English embeddings. Due to isomorphism, there exists a simple transformation G that aligns the two embedding spaces well, as shown on the right. We expect to find the transformation G by minimizing the earth mover's distance without the need for cross-lingual word-level supervision, because the earth mover's distance holistically measures the closeness between two sets of weighted points. It computes the minimal cost of transporting one set of points to the other, whose weights are indicated by the sizes of squares and dots. We show the transport scheme in the right subplot with arrows, which can be interpreted as word translations.

2 Background

2.1 Aligning Isomorphic Embeddings

As discovered by previous work (Mikolov et al., 2013a), monolingual word embeddings exhibit isomorphism across languages, i.e., they appear similar in structure. However, as they are trained independently, the specific "orientation" of each embedding space is arbitrary, as illustrated in the left part of Figure 1. In order to connect the separate embedding spaces, we can try to transform the source embeddings so that they align well with target ones. Naturally, we need a measure for the quality of the alignment to guide our search for the transformation.

As we aim to eliminate the need for cross-lingual supervision from word translation pairs, the measure cannot be defined at the word level as in previous work (Mikolov et al., 2013a). Rather, it should quantify the difference between the entire distributions of embeddings. With this in mind, we find the earth mover's distance to be a suitable choice (Zhang et al., 2016b). Its workings are illustrated in the right part of Figure 1. We can think of target embeddings as piles of earth, and transformed source embeddings as holes to be filled. Then the earth mover's distance computes the minimal cost of moving the earth to fill the holes. Clearly, if the two sets of embeddings align well, the earth mover's distance will be small. Therefore, we can try to find the transformation that minimizes the earth mover's distance.

Another desirable feature of the earth mover's distance is that the computed transport scheme can be readily interpreted as translations. Moreover, this interpretation naturally handles multiple alternative translations. For example, the Chinese word "*mao*" can be translated to "cat" or "kitten", as shown in Figure 1.

2.2 The Form of the Transformation

The approximate isomorphism across embedding spaces inspires researchers to use a simple form of transformation. For example, Mikolov et al. (2013a) chose to use a linear transformation, i.e. the transformation G parametrized by a matrix. Later, proposals for using an orthogonal transformation are supported empirically (Xing et al., 2015; Zhang et al., 2016c; Artetxe et al., 2016) and theoretically (Smith et al., 2017). Indeed, an orthogonal transformation has desirable properties in this setting. If G is an orthogonal matrix that transforms the source embeddings into the target space, then its transpose (also its inverse) $G^\top$

performs transformation in the reverse direction. In that case, any word embedding a can be recovered by transforming back and forth because $G^{\top}Ga = a$. Moreover, computing the cosine similarity between a source embedding a and a target embedding b will be independent of the semantic space in which the similarity is measured, because $b^{\top}Ga / \|Ga\| \|b\| = a^{\top}G^{\top}b / \|a\| \left\|G^{\top}b\right\|$. Therefore we are inclined to use an orthogonal transformation for our task.

2.3 The Earth Mover's Distance

The earth mover's distance (EMD) is a powerful tool widely used in computer vision and natural language processing (Rubner et al., 1998; Kusner et al., 2015; Huang et al., 2016; Zhang et al., 2016b,a). Mathematically speaking, the EMD defines a distance between probability distributions. In the discrete case, a probability distribution can be represented by a sum of Dirac delta functions. For a pair of discrete distributions $\mathbb{P}_1 = \sum_i u_i \delta_{x_i}$ and $\mathbb{P}_2 = \sum_j v_j \delta_{y_j}$, the EMD is defined as

$$\mathrm{EMD}\left(\mathbb{P}_1, \mathbb{P}_2\right) = \min_{T \in \mathcal{U}(u,v)} \sum_i \sum_j T_{ij} c\left(x_i, y_j\right), \quad (1)$$

where $c\left(x_i, y_j\right)$ gives the ground distance between x_i and y_j, and $\mathcal{U}\left(u, v\right)$ is known as the transport polytope, defined as

$$\left\{ T | T_{ij} \geq 0, \sum_j T_{ij} = u_i, \sum_i T_{ij} = v_j, \forall i, j \right\}. \quad (2)$$

After solving the minimization program (1), the transport matrix T stores information of the transport scheme: A non-zero T_{ij} indicates the amount of probability mass transported from y_j to x_i. For our task, this can be interpreted as evidence for word translation (Zhang et al., 2016b), as indicated by arrows in the right part of Figure 1.

The EMD is closely related to the Wasserstein distance in mathematics, defined as

$$\mathrm{W}\left(\mathbb{P}_1, \mathbb{P}_2\right) = \inf_{\gamma \in \Gamma(\mathbb{P}_1, \mathbb{P}_2)} \mathbb{E}_{(x,y)\sim\gamma}\left[c\left(x, y\right)\right], \quad (3)$$

where $\Gamma\left(\mathbb{P}_1, \mathbb{P}_2\right)$ denotes the set of all joint distributions $\gamma\left(x, y\right)$ with marginals $\mathbb{P}_1$ and $\mathbb{P}_2$ on the first and second factors respectively. As we can see, the Wasserstein distance generalizes the EMD to allow continuous distributions. In our context, we will use both terms interchangeably.

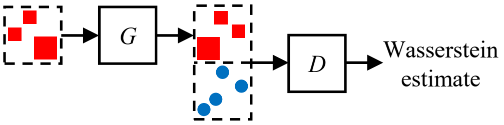

Figure 2: The Wasserstein GAN for unsupervised bilingual lexicon induction. The generator G transforms the source word embeddings into the target space. The critic D takes both sets of embeddings and tries to estimate their Wasserstein distance, and this information will be passed to the generator G during training to guide it towards minimizing the Wasserstein estimate.

3 Approaches

In our task, we are interested in a pair of distributions of word embeddings, one for the source language and the other for the target language. A source word embedding w_s^{S} is a d-dimensional column vector that represents the s-th source word in the V^{S}-sized source language vocabulary. Its distribution is characterized by a positive vector of frequencies f^{S} satisfying $\sum_{s=1}^{V^{\mathrm{S}}} f_s^{\mathrm{S}} = 1$, i.e. $P\left(w_s^{\mathrm{S}}\right) = f_s^{\mathrm{S}}$. Notations are similar for the target side. We assume the embeddings are normalized to have unit L_2 norm, which makes no difference to the result as we use cosine to measure semantic similarity.

Under this setting, we develop two approaches to our EMD minimization idea, called WGAN (Section 3.1) and EMDOT (Section 3.2) respectively.

3.1 Wasserstein GAN (WGAN)

Generative adversarial nets (GANs) are originally proposed to generate natural images (Goodfellow et al., 2014). They can generate sharp images if trained well, but they are notoriously difficult to train. Therefore, a lot of research efforts have been dedicated to the investigation into stabler training (Radford et al., 2015; Salimans et al., 2016; Nowozin et al., 2016; Metz et al., 2016; Poole et al., 2016; Arjovsky and Bottou, 2017), and the recently proposed Wasserstein GAN (Arjovsky et al., 2017) is a promising technique along this line of research.

While the original GAN is formulated as an adversarial game (hence its name), the Wasserstein GAN can be directly understood as minimizing the Wasserstein distance (3). Figure 2 illustrates the concept in the context of our unsupervised bilingual lexicon induction task. The generator G takes source word embeddings and transforms them, with the goal that the transformed source distribution $\mathbb{P}^{G(\mathrm{S})}$ and the target distribution $\mathbb{P}^{\mathrm{T}}$ should be close as measured by the Wasserstein distance. The critic D takes both transformed source word embeddings and target word embeddings and attempts to accurately estimate their Wasserstein distance, which will guide the generator during training. The overall objective is

$$\min_{G \in \mathbb{R}^{d \times d}} \mathrm{W}\left(\mathbb{P}^{G(\mathrm{S})}, \mathbb{P}^{\mathrm{T}}\right), \tag{4}$$

where $\mathbb{P}^{G(\mathrm{S})} = \sum_{s=1}^{V^{\mathrm{S}}} f_s^{\mathrm{S}} \delta_{G w_s^{\mathrm{S}}}$ and $\mathbb{P}^{\mathrm{T}} = \sum_{t=1}^{V^{\mathrm{T}}} f_t^{\mathrm{T}} \delta_{w_t^{\mathrm{T}}}$ are the distributions of transformed source word embeddings and target word embeddings. Here we do not impose the orthogonal constraint on G to facilitate the use of a gradient-based optimizer. With the ground distance c being Euclidean distance L_2, the Kantorovich-Rubinstein duality (Villani, 2009) gives

$$\begin{aligned} & \mathrm{W}\left(\mathbb{P}^{G(\mathrm{S})}, \mathbb{P}^{\mathrm{T}}\right) \\ = & \frac{1}{K} \sup_{\|f\|_L \leq K} \mathbb{E}_{y \sim \mathbb{P}^{\mathrm{T}}}\left[f(y)\right] - \mathbb{E}_{y \sim \mathbb{P}^{G(\mathrm{S})}}\left[f(y)\right], \end{aligned} \tag{5}$$

where the supremum is over all K-Lipschitz functions f. As neural networks are universal function approximators (Hornik, 1991), we can attempt to approximate f with a neural network, called the critic D, with weight clipping to ensure the function family is K-Lipschitz. Therefore the objective of the critic is

$$\max_{D} \mathbb{E}_{y \sim \mathbb{P}^{\mathrm{T}}}\left[f_D(y)\right] - \mathbb{E}_{x \sim \mathbb{P}^{\mathrm{S}}}\left[f_D(Gx)\right]. \tag{6}$$

Conceptually, the critic D assigns scores f_D to real target embeddings and fake ones generated by the generator G. When the objective (6) is trained until optimality, the difference of the scores will approximate the Wasserstein distance up to a multiplicative constant. The generator G then aims to minimize the approximate distance, which leads to

$$\min_{G \in \mathbb{R}^{d \times d}} -\mathbb{E}_{x \sim \mathbb{P}^{\mathrm{S}}}\left[f_D(Gx)\right]. \tag{7}$$

3.2 EMD Minimization Under Orthogonal Transformation (EMDOT)

Alternative to minimizing the Wasserstein distance by duality, the primal program with the orthogonal constraint can be formalized as

$$\min_{G \in \mathcal{O}(d)} \mathrm{EMD}\left(\mathbb{P}^{G(\mathrm{S})}, \mathbb{P}^{\mathrm{T}}\right), \tag{8}$$

where $\mathcal{O}(d)$ is the orthogonal group in dimension d. The exact solution to this minimization program is NP-hard (Ding and Xu, 2016). Fortunately, an alternating minimization procedure is guaranteed to converge to a local minimum (Cohen and Guibas, 1999). Starting from an initial matrix $G^{(0)}$, we alternate between the following subprograms repeatedly:

$$T^{(k)} = \operatorname*{arg\,min}_{T \in \mathcal{U}(f^{\mathrm{S}}, f^{\mathrm{T}})} \sum_{s=1}^{V^{\mathrm{S}}} \sum_{t=1}^{V^{\mathrm{T}}} T_{st} c\left(G^{(k)} w_s^{\mathrm{S}}, w_t^{\mathrm{T}}\right), \tag{9}$$

$$G^{(k+1)} = \operatorname*{arg\,min}_{G \in \mathcal{O}(d)} \sum_{s=1}^{V^{\mathrm{S}}} \sum_{t=1}^{V^{\mathrm{T}}} T_{st}^{(k)} c\left(G w_s^{\mathrm{S}}, w_t^{\mathrm{T}}\right). \tag{10}$$

The minimization in (9) is the EMD program (1), with existing solvers available. For better scalability, we choose an approximate solver (Cuturi, 2013).

The minimization in (10) aims to find the transformation $G^{(k+1)}$ with cross-lingual connection provided in $T^{(k)}$. This is exactly the supervised scenario, and previous works typically resort to gradient-based solvers (Mikolov et al., 2013a). But they can be cumbersome especially as we impose the orthogonal constraint on G. Fortunately, if we choose the ground distance c to be the squared Euclidean distance L_2^2, the program (10) is an extension of the orthogonal Procrustes problem (Schönemann, 1966), which admits a closed-form solution:

$$G^{(k+1)} = UV^{\top}, \tag{11}$$

where U and V are obtained from a singular value decomposition (SVD):

$$\sum_{s=1}^{V^{\mathrm{S}}} \sum_{t=1}^{V^{\mathrm{T}}} T_{st}^{(k)} w_t^{\mathrm{T}} w_s^{\mathrm{S}\top} = USV^{\top}. \tag{12}$$

Note that the SVD is efficient because it is performed on a $d \times d$ matrix, which is typically low-dimensional. Choosing $c = L_2^2$ is also motivated by its equivalence to the cosine dissimilarity, as proved in Appendix A.

3.3 Discussion

Starting from the idea of earth mover's distance minimization, we have developed two approaches towards the goal. They employ different optimization techniques, which in turn lead to different practical choices. For example, we choose $c = L_2^2$ for the EMDOT approach to obtain a closed-form solution to the subprogram (10), otherwise we would have to use gradient-based solvers. In contrast, the WGAN approach calls for $c = L_2$ because the Kantorovich-Rubinstein duality takes a simple form only in this case.

The EMDOT approach is attractive for several reasons: It is consistent for training and testing (the equivalence between the ground distance $c = L_2^2$ and cosine dissimilarity), compatible with the orthogonal constraint, mathematically sound (without much assumption and approximation), guaranteed to converge, almost hyperparameter free, and fast in speed (the alternating subprograms have either effective approximate solvers or closed-form solutions). However, it suffers from a serious limitation: The alternating minimization procedure only converges to local minima, and they often turn out to be rather poor in practice.

Although the WGAN approach employs a stochastic-gradient-based optimizer (RMSProp) and does not guarantee global optima either, it works reasonably well in practice. It seems better at exploring the parameter space and finally landing in a neighborhood of a good optimum. Like other success stories of using stochastic-gradient-based optimizers to train neural networks, theoretical understanding of the behavior remains elusive.

We can enjoy the best of both worlds by incorporating the merits of both approaches: First the WGAN approach locates a good neighborhood of the parameter space, and then, starting from a reasonable initialization, the EMDOT approach efficiently explores the neighborhood to achieve enhanced performance.

4 Experiments

We first investigate the learning behavior of our WGAN approach, and then present experiments on the bilingual lexicon induction task, followed by a showcase of the earth mover's distance as a language distance measure. Details of the data sets and hyperparameters are described in Appendices B and C.

4.1 Learning Behavior of WGAN

We analyze the learning behavior of WGAN by looking at a typical training trajectory on Chinese-English. During training, we save 100 models, translate based on the nearest neighbor, and record their accuracy as the bilingual lexicon induction performance indicator at these training checkpoints. In theory, the critic objective (6) provides an estimate of the Wasserstein distance up to a multiplicative constant, and a smaller Wasserstein distance should mean the transformed source embedding space and the target embedding space align better, which should in turn result in a better bilingual lexicon. This is validated in Figure 3 by the correlation between Wasserstein estimate and accuracy. Therefore, the Wasserstein estimate can serve as an indicator for the bilingual lexicon induction performance, and we can save the model with the lowest value during training as the final model.

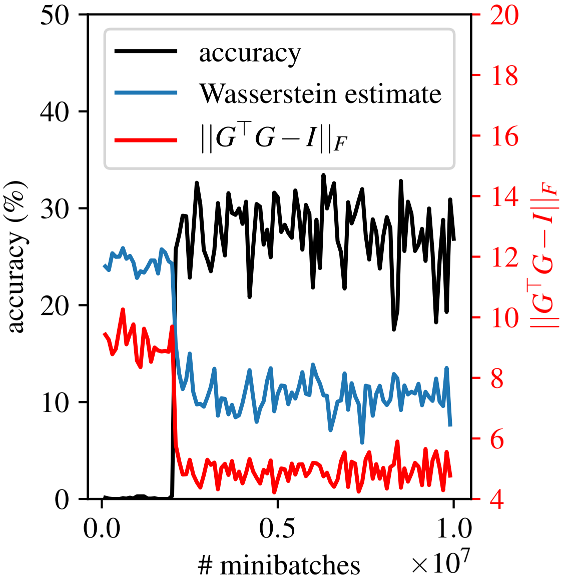

Figure 3: A typical training trajectory of WGAN. The three curves all correlate well. The Wasserstein estimate is rescaled because its magnitude is irrelevant.

In Figure 3, we also plot the value of $\left\|G^\top G - I\right\|_F$, which indicates the degree of orthogonality of the transformation matrix G. Interestingly, this also correlates nicely with the other curves, even though our WGAN formulation does not encourage G towards orthogonality. This finding confirms that a good transformation matrix is indeed close to orthogonality, and empirically justifies the orthogonal constraint for the EMDOT formulation.

Finally, we observe that the curves in Figure 3 are not very smooth. This means that although WGAN does well in exploring the parameter space and locating a reasonable transforma-

The supervised methods TM and IA require seeds to train, and are listed for reference. Our EMDOT approach is initialized with the transformation found by WGAN, and consistently improves on it, reaching competitive performance with supervised methods.

tion matrix, it cannot stably refine the transformation. Fortunately, this is where EMDOT thrives, and hence combining them enjoys the benefits of both approaches.

4.2 Bilingual Lexicon Induction Performance

We test the quality of the cross-lingual transformation by evaluating on the bilingual lexicon induction task for five language pairs: Chinese-English, Spanish-English, Italian-English, Japanese-Chinese, and Turkish-English.

As the EMD automatically handles multiple alternative translations, we follow (Zhang et al., 2016b,a) to use F_1 score as the preferred evaluation metric.

Baselines

Our formulation is based on the isomorphism found across monolingual word embeddings. This idea has led to previous supervised methods:

- Translation matrix (TM) (Mikolov et al., 2013a): the pioneer of this type of methods, using linear transformation. We use a publicly available implementation.[1]
- Isometric alignment (IA) (Zhang et al., 2016c): an extension of TM by augmenting its learning objective with the isometric (orthogonal) constraint. Although Zhang et al. (2016c) had subsequent steps for their POS tagging task, it could be used for bilingual lexicon induction as well.

Although they need seed word translation pairs to train and thus not directly comparable to our system, we nonetheless report their results using {50, 100, 200, 500} seeds for a ballpark range of expected performance on this task, and skip the set of 500 seeds when testing all systems. We ensure the same input embeddings for these methods and ours. Their seeds are obtained through Google Translate (details in Appendix B.2). We apply the EMD as a postprocessing step (Zhang et al., 2016b) to allow them to handle multiple alternative translations. This is also done for our WGAN approach, as it does not produce the transport scheme to interpret as translation due to its duality formulation.

Results

Table 1 shows the F_1 scores on the five language pairs. As we can see, WGAN successfully finds a transformation that produces reasonable word translations. On top of that, EMDOT considerably improves the performance, which indicates that EMDOT refines the transformation found by WGAN.

Similar behavior across language pairs proves the generality of our approaches, as they build on embeddings learned from monolingual corpora without language-specific engineering. The quality of the embeddings, thus, will have an important effect on the performance, which may explain the lower scores on Turkish-English, as this low-resource setting may lack sufficient data to produce reliable embeddings. Higher noise levels in the preprocessing and ground truth for this lan-

guage pair (cf. the supplemental material), as well as the morphological richness of Turkish, may also be contributing factors to the relatively low scores.

Concerning the supervised methods TM and IA, they attain better performance with more supervision from seeds, as expected. For TM in particular, hundreds of seeds are needed for generalization, in line with the finding in (Vulić and Korhonen, 2016). Below that threshold, its performance drops dramatically, and this is when IA fares better with the orthogonal constraint. This indicates the importance of orthogonality when the seeds are few, or even zero as faced by our system. As the number of seeds increases, the performance of the supervised methods converges to a level comparable to our system.

4.3 The EMD as Language Distance

As our system minimizes the earth mover's distance between embeddings of two languages, we show here the final EMD can indicate the degree of difference between languages, serving as a proxy for language distance. Table 2 lists the EMD for the five language pairs considered in this paper, as well as their typology dissimilarity and geographical distance. The typology dissimilarity is computed from features in the WALS database (Dryer and Haspelmath, 2013). It is defined as one minus relative Hamming similarity, which is in turn defined as the number of agreeing features divided by the number of total features available for the language pair (Albu, 2006; Cysouw, 2013b). As a rough approximation, the geographical distance is measured by the distance between the capital cities of the countries where the considered languages are spoken (Eger et al., 2016).

The typology dissimilarity reflects genealogical influence on the divergence between languages, while the geographical distance indicates the effect of language contact. Both play important roles in shaping the languages we perceive today, and they also correlate with each other (Cysouw, 2013a). As we analyze Table 2, we find the EMD may be explained by both factors. Spanish-English and Italian-English are close both genealogically and geographically, and their EMD values are the lowest. English, Chinese, and Japanese belong to different language families, but the geographical proximity of the latter two enables intensive language contact, especially for the vocabularies, causing relatively smaller EMD. Finally, Turkish and English are distant in both aspects, and the EMD between them is large. Note that, however, the large EMD may also be caused by the relatively poor quality of monolingual embeddings due to low resource, and this should be a caveat of using the EMD to measure language distance.

5 Related Work

5.1 Bilingual Lexicon Induction

Bilingual lexicon induction is a long-standing research task in cross-lingual natural language processing. Traditional methods build statistical models for monolingual word co-occurrence, and combine cross-lingual supervision to solve the task. As word alignment for parallel sentences can produce fairly good bilingual lexica (Och and Ney, 2003), these methods focus on non-parallel data with a seed lexicon as cross-lingual supervision (Rapp, 1999; Gaussier et al., 2004).

An exception that does not rely on cross-lingual supervision is the decipherment approach (Dou and Knight, 2012, 2013; Dou et al., 2015). It views the source language as a cipher for the target language, and solves a statistical model that attempts to decipher the source language.

Following the popularity of monolingual word embeddings, cross-lingual word representation learning has also attracted significant attention in recent years. Building bilingual lexica from the learned cross-lingual embeddings is often considered an evaluative tool. Most methods rely on supervision encoded in parallel data, at the document level (Vulić and Moens, 2015), the sentence level (Zou et al., 2013; Chandar A P et al., 2014; Hermann and Blunsom, 2014; Kočiský et al., 2014; Gouws et al., 2015; Luong et al., 2015; Coulmance et al., 2015; Oshikiri et al., 2016), or the word level (i.e. in the form of seed lexicon) (Gouws and Søgaard, 2015; Wick et al., 2016; Duong et al., 2016; Shi et al., 2015; Mikolov et al., 2013a; Faruqui and Dyer, 2014; Lu et al., 2015; Dinu et al., 2015; Lazaridou et al., 2015; Ammar et al., 2016; Zhang et al., 2016a, 2017; Smith et al., 2017).

There is a recent work that aims to remove the need for cross-lingual supervision (Cao et al., 2016). Similar to ours, the underlying idea is to match cross-lingually at the level of distribution rather than word. However, the distributions considered in that work are the hidden states of neural embedding models during the course of training. They are assumed to be Gaussian, so that the matching of distributions reduces to matching their means and variances, but this assumption is hard to justify and interpret. In contrast, our proposal does not make any assumption on the distributions, and directly matches the transformed source embedding distribution with the target distribution by minimizing their earth mover's distance.

Another attempt to learn cross-lingual embedding transformation without supervision is (Barone, 2016). Architectures of generative adversarial nets and adversarial autoencoders (Makhzani et al., 2015) are experimented, but the reported results are not positive. We tried the publicly available code on our data and obtained negative results as well. This outcome is likely caused by the training difficulty pointed out by (Arjovsky and Bottou, 2017), as traditional GAN training minimizes Jensen-Shannon divergence between distributions, which can provide pathological gradient to the generator and hamper its learning. The use of Wasserstein GAN addresses this problem and allows our simple architecture to be trained successfully.

5.2 Language Distance

Quantifying language difference is an open question with on-going efforts that put forward better measures based on manually compiled data (Albu, 2006; Hammarström and O'Connor, 2013). Researchers in computational linguistics also try to contribute corpus-based approaches to this question. Parallel data is typically exploited, and ideas range from information-theoretic (Juola, 1998), statistical (Mayer and Cysouw, 2012), to graph-based (Eger et al., 2016; Asgari and Mofrad, 2016). To our knowledge, the earth mover's distance is proposed for language distance for the first time, with the distinctive feature of relying on non-parallel data only.

5.3 The Earth Mover's Distance

First introduced into computer vision (Rubner et al., 1998), the earth mover's distance also finds application in natural language processing (Kusner et al., 2015; Huang et al., 2016), including bilingual lexicon induction (Zhang et al., 2016b,a). Zhang et al. (2016b) build upon bilingual word embeddings and apply the EMD program as a postprocessing step to automatically produce multiple alternative translations. Later, Zhang et al. (2016a) introduce the EMD into the training objective of bilingual word embeddings as a regularizer. These previous works rely on cross-lingual supervision, and do not approach the task from the view of embedding transformation, while our work formulates the task as EMD minimization to allow zero supervision.

Apart from the usage as a regularizer (Zhang et al., 2016a), the EMD can also play other roles in optimization programs designed for various applications (Cuturi and Doucet, 2014; Frogner et al., 2015; Montavon et al., 2016).

6 Conclusion and Future Work

In this work, we attack the problem of finding cross-lingual transformation between monolingual word embeddings in a purely unsupervised setting. We introduce earth mover's distance minimization to tackle this task by exploiting its distribution-level matching to sidestep the requirement for word-level cross-lingual supervision. Even though zero supervision poses a clear challenge, our system attains competitive performance with supervised methods for bilingual lexicon induction. In addition, the earth mover's distance provides a natural measure that may prove helpful for quantifying language difference.

We have implemented the earth mover's distance minimization framework from two paths, and their combination has worked well, but both can be potentially improved by recent advances in optimization techniques (Gulrajani et al., 2017; Ding and Xu, 2016). Future work should also evaluate the earth mover's distance between more languages to assess its quality as language distance.

A Proof

The following proof shows that using squared Euclidean distance as the ground distance ($c = L_2^2$) is equivalent to using cosine dissimilarity when minimizing Equation (10).

$$\begin{aligned}
&\min_{G \in \mathcal{O}(d)} \sum_{s=1}^{V^{\mathrm{S}}} \sum_{t=1}^{V^{\mathrm{T}}} T_{st}^{(k)} \left\| G w_s^{\mathrm{S}} - w_t^{\mathrm{T}} \right\|^2 \\
=& \min_{G \in \mathcal{O}(d)} \sum_{s=1}^{V^{\mathrm{S}}} \sum_{t=1}^{V^{\mathrm{T}}} T_{st}^{(k)} \\
&\left(\left\| w_s^{\mathrm{S}} \right\|^2 + \left\| w_t^{\mathrm{T}} \right\|^2 - 2 w_t^{\mathrm{T}\top} G w_s^{\mathrm{S}} \right) \qquad (13) \\
=& \min_{G \in \mathcal{O}(d)} -2 \sum_{s=1}^{V^{\mathrm{S}}} \sum_{t=1}^{V^{\mathrm{T}}} T_{st}^{(k)} \cos\left(G w_s^{\mathrm{S}}, w_t^{\mathrm{T}} \right) \\
&+ \mathrm{const} \\
=& \min_{G \in \mathcal{O}(d)} - \sum_{s=1}^{V^{\mathrm{S}}} \sum_{t=1}^{V^{\mathrm{T}}} T_{st}^{(k)} \cos\left(G w_s^{\mathrm{S}}, w_t^{\mathrm{T}} \right).
\end{aligned}$$

B Data Preparation

B.1 Non-Parallel Corpora for Training Embeddings

The data for training monolingual word embeddings comes from Wikipedia comparable corpora.[2] Following (Vulić and Moens, 2013), we retain only nouns with at least 1,000 occurrences except for Turkish-English, whose frequency cutoff threshold is 100, as the amount of data is relatively small in this low-resource setting. For the Chinese side, we first use OpenCC[3] to normalize characters to be simplified, and then perform Chinese word segmentation and POS tagging with THULAC.[4] The preprocessing of the English side involves tokenization, POS tagging, lemmatization, and lowercasing, which we carry out with the NLTK toolkit[5] for the Chinese-English pair. For Spanish-English and Italian-English, we choose to use TreeTagger[6] for preprocessing, as in (Vulić and Moens, 2013). For the Japanese corpus, we use MeCab[7] for word segmentation and POS tagging. For Turkish, we utilize the preprocessing tools (tokenization and POS tagging) provided in LORELEI Language Packs (Strassel and Tracey, 2016), and its English side is preprocessed by NLTK. The statistics of the preprocessed corpora is given in Table 3.

		# tokens	vocabulary size
zh-en	zh	21m	3,349
	en	53m	5,154
es-en	es	61m	4,774
	en	95m	6,637
it-en	it	73m	8,490
	en	93m	6,597
ja-zh	ja	38m	6,043
	zh	16m	2,814
tr-en	tr	6m	7,482
	en	28m	13,220

Table 3: Statistics of the non-parallel corpora for training monolingual word embeddings. Language codes: zh = Chinese, en = English, es = Spanish, it = Italian, ja = Japanese, tr = Turkish.

B.2 Seed Word Translation Pairs

The seed word translation pairs for the translation matrix (`TM`) and isometric alignment (`IA`) approaches are obtained as follows. First, we ask Google Translate[8] to translate the source language vocabulary. Then the target translations are queried again and translated back to the source language, and those that do not match the original source words are discarded. This helps to ensure the translation quality. Finally, the translations are discarded if they fall out of our target language vocabulary.

B.3 Ground Truth

As the ground truth bilingual lexicon for evaluation, we use Chinese-English Translation Lexicon Version 3.0 (LDC2002L27) for the Chinese-English pair. For Spanish-English and Italian-English, we access Open Multilingual WordNet[9] through NLTK. For Japanese-Chinese, we use an in-house lexicon. For Turkish-English, we build a set of ground truth translation pairs in the same

way as how we obtain seed word translation pairs from Google Translate, described above.

C Hyperparameters

C.1 WGAN

We parametrize the critic D as a feed-forward neural network with one hidden layer of 500 neurons. The generator G is initialized with a random orthogonal matrix. The expectations in critic and generator objectives (6)(7) are approximated by minibatches of 1024 samples. We train for 10^7 minibatches. Most other hyperparameters follow from (Arjovsky et al., 2017) except the learning rates, for which larger values of 0.05 and 0.0005 are used for the generator and the critic respectively for faster convergence.

C.2 EMDOT

The approximate EMD solver (Cuturi, 2013) gives fairly accurate approximation with orders of magnitude speedup. However, it makes the transport matrix T no longer sparse. This is problematic, as we rely on interpreting a non-zero T_{st} as evidence to translate the s-th source word to the t-th target word (Zhang et al., 2016b). We therefore retain the largest pV^{S} elements of T, where p encodes our belief of the expected number of translations a source word can have. We set $p = 1.3$.

The alternating minimization procedure converges very fast. We run 10 iterations.

C.3 Monolingual Word Embeddings

As input monolingual word embeddings to the tested systems, we train the CBOW model (Mikolov et al., 2013b) with default hyperparameters in `word2vec`[10]. The embedding dimension d is 50.

Unfolding and Shrinking Neural Machine Translation Ensembles

Felix Stahlberg and **Bill Byrne**
{fs439,wjb31}@cam.ac.uk
Department of Engineering
University of Cambridge, UK

Abstract

Ensembling is a well-known technique in neural machine translation (NMT) to improve system performance. Instead of a single neural net, multiple neural nets with the same topology are trained separately, and the decoder generates predictions by averaging over the individual models. Ensembling often improves the quality of the generated translations drastically. However, it is not suitable for production systems because it is cumbersome and slow. This work aims to reduce the runtime to be on par with a single system without compromising the translation quality. First, we show that the ensemble can be unfolded into a single large neural network which imitates the output of the ensemble system. We show that unfolding can already improve the runtime in practice since more work can be done on the GPU. We proceed by describing a set of techniques to shrink the unfolded network by reducing the dimensionality of layers. On Japanese-English we report that the resulting network has the size and decoding speed of a single NMT network but performs on the level of a 3-ensemble system.

1 Introduction

The top systems in recent machine translation evaluation campaigns on various language pairs use ensembles of a number of NMT systems (Bojar et al., 2016; Sennrich et al., 2016a; Chung et al., 2016; Neubig, 2016; Wu et al., 2016; Cromieres et al., 2016; Durrani et al., 2017). Ensembling (Dietterich, 2000; Hansen and Salamon, 1990) of neural networks is a simple yet very effective technique to improve the accuracy of NMT. The decoder makes use of K NMT networks which are either trained independently (Sutskever et al., 2014; Chung et al., 2016; Neubig, 2016; Wu et al., 2016) or share some amount of training iterations (Sennrich et al., 2016b,a; Cromieres et al., 2016; Durrani et al., 2017). The ensemble decoder computes predictions from each of the individual models which are then combined using the arithmetic average (Sutskever et al., 2014) or the geometric average (Cromieres et al., 2016).

Ensembling consistently outperforms single NMT by a large margin. However, the decoding speed is significantly worse since the decoder needs to apply K NMT models rather than only one. Therefore, a recent line of research transfers the idea of *knowledge distillation* (Bucilu et al., 2006; Hinton et al., 2014) to NMT and trains a smaller network (the student) by minimizing the cross-entropy to the output of the ensemble system (the teacher) (Kim and Rush, 2016; Freitag et al., 2017). This paper presents an alternative to knowledge distillation as we aim to speed up decoding to be comparable to single NMT while retaining the boost in translation accuracy from the ensemble. In a first step, we describe how to construct a single large neural network which imitates the output of an ensemble of multiple networks with the same topology. We will refer to this process as *unfolding*. GPU-based decoding with the unfolded network is often much faster than ensemble decoding since more work can be done on the GPU. In a second step, we explore methods to reduce the size of the unfolded network. This idea is justified by the fact that ensembled neural networks are often over-parameterized and have a large degree of redundancy (LeCun et al., 1989; Hassibi et al., 1993; Srinivas and Babu, 2015). Shrinking the unfolded network leads to a smaller model which consumes less space on the disk and in the memory; a crucial factor on mobile devices. More importantly, the

(c) Unfolded network.

Figure 1: Unfolding mimics the output of the ensemble of two single layer feedforward networks.

decoding speed on all platforms benefits greatly from the reduced number of neurons. We find that the dimensionality of linear embedding layers in the NMT network can be reduced heavily by low-rank matrix approximation based on singular value decomposition (SVD). This suggest that high dimensional embedding layers may be needed for training, but do not play an important role for decoding. The NMT network, however, also consists of complex layers like gated recurrent units (Cho et al., 2014, GRUs) and attention (Bahdanau et al., 2015). Therefore, we introduce a novel algorithm based on linear combinations of neurons which can be applied either during training (*data-bound*) or directly on the weight matrices without using training data (*data-free*). We report that with a mix of the presented shrinking methods we are able to reduce the size of the unfolded network to the size of the single NMT network while keeping the boost in BLEU score from the ensemble. Depending on the aggressiveness of shrinking, we report either a gain of 2.2 BLEU at the same decoding speed, or a 3.4× CPU decoding speed up with only a minor drop in BLEU compared to the original single NMT system. Furthermore, it is often much easier to stage a single NMT system than an ensemble in a commercial MT workflow, and it is crucial to be able to optimize quality at specific speed and memory constraints. Unfolding and shrinking address these problems directly.

2 Unfolding K Networks into a Single Large Neural Network

The first concept of our approach is called *unfolding*. Unfolding is an alternative to ensembling of multiple neural networks with the same topology. Rather than averaging their predictions, unfolding constructs a single large neural net out of the individual models which has the same number of input and output neurons but larger inner layers. Our main motivation for unfolding is to obtain a single network with ensemble level performance which can be shrunk with the techniques in Sec. 3.

Suppose we ensemble two single layer feedforward neural nets as shown in Fig. 1. Normally, ensembling is implemented by performing an isolated forward pass through the first network (Fig. 1(a)), another isolated forward pass through the second network (Fig. 1(b)), and averaging the activities in the output layers of both networks. This can be simulated by merging both networks into a single large network as shown in Fig. 1(c). The first neurons in the hidden layer of the combined network correspond to the hidden layer in the first single network, and the others to the hidden layer of the second network. A single pass through the combined network yields the same output as the ensemble if the output layer is linear (up to a factor 2). The weight matrices in the unfolded network can be constructed by stacking the corresponding weight matrices (either horizontally or vertically) in network 1 and 2. This kind of aggregation of multiple networks with the same topology is not only possible for single-layer feedforward architectures but also for complex networks consisting of multiple GRU layers and attention.

For a formal description of unfolding we address layers with indices $d = 0, 1, \ldots, D$. The special layer 0 has a single neuron for modelling bias vectors. Layer 1 holds the input neurons and layer D is the output layer. We denote the size of a layer in the individual models as $s(d)$. When combining K networks, the layer size $s'(d)$ in the unfolded network is increased by factor K if d is an inner layer, and equal to $s(d)$ if d is the in-

$$W'(d_1,d_2) = \begin{cases} \begin{pmatrix} W_1(d_1,d_2) & 0 & \cdots & 0 \\ 0 & W_2(d_1,d_2) & \vdots & \vdots \\ \vdots & \cdots & \ddots & 0 \\ 0 & \cdots & & W_K(d_1,d_2) \end{pmatrix} & \text{if } d_1 \in \text{InnerLayers and } d_2 \in \text{InnerLayers} \\ \frac{1}{K}\begin{pmatrix} W_1(d_1,d_2) \\ \vdots \\ W_K(d_1,d_2) \end{pmatrix} & \text{if } d_1 \in \text{InnerLayers and } d_2 \notin \text{InnerLayers} \\ \begin{pmatrix} W_1(d_1,d_2) & \cdots & W_K(d_1,d_2) \end{pmatrix} & \text{if } d_1 \notin \text{InnerLayers and } d_2 \in \text{InnerLayers} \end{cases}$$

Figure 2: General formula for unfolding weight matrices. The set InnerLayers $:= [2, D-1]$ includes all layers except the input, output, and bias layer.

put or output layer. We denote the weight matrix between two layers $d_1, d_2 \in [0, D]$ in the k-th individual model ($k \in [1, K]$) as $W_k(d_1, d_2) \in \mathbb{R}^{s(d_1)\times s(d_2)}$, and the corresponding weight matrix in the unfolded network as $W'(d_1, d_2) \in \mathbb{R}^{s'(d_1)\times s'(d_2)}$. We explicitly allow d_1 and d_2 to be non-consecutive or reversed to be able to model recurrent networks. We use the zero-matrix if layers d_1 and d_2 are not connected. The construction of the unfolded weight matrix $W'(d_1, d_2)$ from the individual matrices $W_k(d_1, d_2)$ depends on whether the connected layers are inner layers or not. The complete formula is listed in Fig. 2.

Unfolded NMT networks approximate but do not exactly match the output of the ensemble due to two reasons. First, the unfolded network synchronizes the attentions of the individual models. Each decoding step in the unfolded network computes a single attention weight vector. In contrast, ensemble decoding would compute one attention weight vector for each of the K input models. A second difference is that the ensemble decoder first applies the softmax at the output layer, and then averages the prediction probabilities. The unfolded network averages the neuron activities (i.e. the logits) first, and then applies the softmax function. Interestingly, as shown in Sec. 4, these differences do not have any impact on the BLEU score but yield potential speed advantages of unfolding since the computationally expensive softmax layer is only applied once.

3 Shrinking the Unfolded Network

After constructing the weight matrices of the unfolded network we reduce the size of it by iteratively shrinking layer sizes. In this section we denote the incoming weight matrix of the layer to shrink as $U \in \mathbb{R}^{m_{in}\times m}$ and the outgoing weight matrix as $V \in \mathbb{R}^{m\times m_{out}}$. Our procedure is inspired by the method of Srinivas and Babu (2015). They propose a criterion for removing neurons in inner layers of the network based on two intuitions. First, similarly to Hebb's learning rule, they detect redundancy by the principle *neurons which fire together, wire together*. If the incoming weight vectors $U_{:,i}$ and $U_{:,j}$ are exactly the same for two neurons i and j, we can remove the neuron j and add its outgoing connections to neuron i ($V_{i,:} \leftarrow V_{i,:} + V_{j,:}$) without changing the output.[1] This holds since the activity in neuron j will always be equal to the activity in neuron i. In practice, Srinivas and Babu use a distance measure based on the difference of the incoming weight vectors to search for similar neurons as exact matches are very rare.

The second intuition of the criterion used by Srinivas and Babu (2015) is that neurons with small outgoing weights contribute very little overall. Therefore, they search for a pair of neurons $i, j \in [1, m]$ according the following term and remove the j-th neuron.[2]

$$\arg\min_{i,j\in[1,m]} ||U_{:,i} - U_{:,j}||_2^2 ||V_{j,:}||_2^2 \tag{1}$$

Neuron j is selected for removal if (1) there is another neuron i which has a very similar set of incoming weights and if (2) j has a small outgoing weight vector. Their criterion is *data-free* since

[1] We denote the i-th row vector of a matrix A with $A_{i,:}$ and the i-th column vector as $A_{:,i}$.

[2] Note that the criterion in Eq. 1 generalizes the criterion of Srinivas and Babu (2015) to multiple outgoing weights. Also note that Srinivas and Babu (2015) propose some heuristic improvements to this criterion. However, these heuristics did not work well in our NMT experiments.

it does not require any training data. For further details we refer to Srinivas and Babu (2015).

3.1 Data-Free Neuron Removal

Srinivas and Babu (2015) propose to add the outgoing weights of j to the weights of a similar neuron i to compensate for the removal of j. However, we have found that this approach does not work well on NMT networks. We propose instead to compensate for the removal of a neuron by a linear combination of the remaining neurons in the layer. Data-free shrinking assumes for the sake of deriving the update rule that the neuron activation function is linear. We now ask the following question: How can we compensate as well as possible for the loss of neuron j such that the impact on the output of the whole network is minimized? Data-free shrinking represents the incoming weight vector of neuron j ($U_{:,j}$) as linear combination of the incoming weight vectors of the other neurons. The linear factors can be found by satisfying the following linear system:

$$U_{:,\neg j}\lambda = U_{:,j} \tag{2}$$

where $U_{:,\neg j}$ is matrix U without the j-th column. In practice, we use the method of ordinary least squares to find λ because the system may be overdetermined. The idea is that if we mix the outputs of all neurons in the layer by the λ-weights, we get the output of the j-th neuron. The row vector $V_{j,:}$ contains the contributions of the j-th neuron to each of the neurons in the next layer. Rather than using these connections, we approximate their effect by adding some weight to the outgoing connections of the other neurons. How much weight depends on λ and the outgoing weights $V_{j,:}$. The factor $D_{k,l}$ which we need to add to the outgoing connection of the k-th neuron to compensate for the loss of the j-th neuron on the l-th neuron in the next layer is:

$$D_{k,l} = \lambda_k V_{j,l} \tag{3}$$

Therefore, the update rule for V is:

$$V \leftarrow V + D \tag{4}$$

In the remainder we will refer to this method as *data-free* shrinking. Note that we recover the update rule of Srinivas and Babu (2015) by setting λ to the i-th unit vector. Also note that the error introduced by our shrinking method is due to the fact that we ignore the non-linearity, and that the solution for λ may not be exact. The method is error-free on linear layers as long as the residuals of the least-squares analysis in Eq. 2 are zero.

GRU layers The terminology of *neurons* needs some further elaboration for GRU layers which rather consist of update and reset gates and states (Cho et al., 2014). On GRU layers, we treat the states as neurons, i.e. the j-th neuron refers to the j-th entry in the GRU state vector. Input connections to the gates are included in the incoming weight matrix U for estimating λ in Eq. 2. Removing neuron j in a GRU layer means deleting the j-th entry in the states and both gate vectors.

3.2 Data-Bound Neuron Removal

Although we find our data-free approach to be a substantial improvement over the methods of Srinivas and Babu (2015) on NMT networks, it still leads to a non-negligible decline in BLEU score when applied to recurrent GRU layers. Our data-free method uses the incoming weights to identify similar neurons, i.e. neurons expected to have similar activities. This works well enough for simple layers, but the interdependencies between the states and the gates inside gated layers like GRUs or LSTMs are complex enough that redundancies cannot be found simply by looking for similar weights. In the spirit of Babaeizadeh et al. (2016), our *data-bound* version records neuron activities during training to estimate λ. We compensate for the removal of the j-th neuron by using a linear combination of the output of remaining neurons with similar activity patterns. In each layer, we prune 40 neurons each 450 training iterations until the target layer size is reached. Let A be the matrix which holds the records of neuron activities in the layer since the last removal. For example, for the decoder GRU layer, a batch size of 80, and target sentence lengths of 20, A has $20 \cdot 80 \cdot 450 = 720K$ rows and m (the number of neurons in the layer) columns.[3] Similarly to Eq. 2 we find interpolation weights λ using the method of least squares on the following linear system.

$$A_{:,\neg j}\lambda = A_{:,j} \tag{5}$$

The update rule for the outgoing weight matrix is the same as for our data-free method (Eq. 4).

[3] In practice, we use a random sample of 50K rows rather than the full matrix to keep the complexity of the least-squares analysis under control.

The key difference between data-free and data-bound shrinking is the way λ is estimated. Data-free shrinking uses the similarities between incoming weights, and data-bound shrinking uses neuron activities recorded during training. Once we select a neuron to remove, we estimate λ, compensate for the removal, and proceed with the shrunk network. Both methods are prior to any decoding and result in shrunk parameter files which are then loaded to the decoder. Both methods remove neurons rather than single weights.

The data-bound algorithm runs gradient-based optimization on the unfolded network. We use the AdaGrad (Duchi et al., 2011) step rule, a small learning rate of 0.0001, and aggressive step clipping at 0.05 to avoid destroying useful weights which were learned in the individual networks prior to the construction of the unfolded network.

Our data-bound algorithm uses a data-bound version of the neuron selection criterion in Eq. 1 which operates on the activity matrix A. We search for the pair $i, j \in [1, m]$ according the following term and remove neuron j.

$$\arg\min_{i,j\in[1,m]} ||A_{:,i} - A_{:,j}||_2^2 ||A_{:,j}||_2^2 \tag{6}$$

3.3 Shrinking Embedding Layers with SVD

The standard attention-based NMT network architecture (Bahdanau et al., 2015) includes three linear layers: the embedding layer in the encoder, and the output and feedback embedding layers in the decoder. We have found that linear layers are particularly easy to shrink using low-rank matrix approximation. As before we denote the incoming weight matrix as $U \in \mathbb{R}^{m_{in}\times m}$ and the outgoing weight matrix as $V \in \mathbb{R}^{m\times m_{out}}$. Since the layer is linear, we could directly connect the previous layer with the next layer using the product of both weight matrices $X = U \cdot V$. However, X may be very large. Therefore, we approximate X as a product of two low rank matrices $Y \in \mathbb{R}^{m_{in}\times m'}$ and $Z \in \mathbb{R}^{m'\times m_{out}}$ ($X \approx YZ$) where $m' \ll m$ is the desired layer size. A very common way to find such a matrix factorization is using truncated singular value decomposition (SVD). The layer is eventually shrunk by replacing U with Y and V with Z.

4 Results

The individual NMT systems we use as source for constructing the unfolded networks are trained using AdaDelta (Zeiler, 2012) on the Blocks/Theano implementation (van Merriënboer et al., 2015; Bastien et al., 2012) of the standard attention-based NMT model (Bahdanau et al., 2015) with: 1000 dimensional GRU layers (Cho et al., 2014) in both the decoder and bidrectional encoder; a single maxout output layer (Goodfellow et al., 2013); and 620 dimensional embedding layers. We follow Sennrich et al. (2016b) and use subword units based on byte pair encoding rather than words as modelling units. Our SGNMT decoder (Stahlberg et al., 2017)[4] with a beam size of 12 is used in all experiments. Our primary corpus is the Japanese-English (Ja-En) ASPEC data set (Nakazawa et al., 2016). We select a subset of 500K sentence pairs to train our models as suggested by Neubig et al. (2015). We report cased BLEU scores calculated with Moses' `multi-bleu.pl` to be strictly comparable to the evaluation done in the Workshop of Asian Translation (WAT). We also apply our method to the WMT data set for English-German (En-De), using the *news-test2014* as a development set, and keeping *news-test2015* and *news-test2016* as test sets. En-De BLEU scores are computed using `mteval-v13a.pl` as in the WMT evaluation. We set the vocabulary sizes to 30K for Ja-En and 50K for En-De. We also report the *size factor* for each model which is the total number of model parameters (sum of all weight matrix sizes) divided by the number of parameters in the original NMT network (86M for Ja-En and 120M for En-De). We choose a widely used, simple ensembling method (prediction averaging) as our baseline. We feel that the prevalence of this method makes it a reasonable baseline for our experiments.

Shrinking the Unfolded Network First, we investigate which shrinking methods are effective for which layers. Tab. 1 summarizes our results on a 2-unfold network for Ja-En, i.e. two separate NMT networks are combined in a single large network as described in Sec. 2. The layers in the combined network are shrunk to the size of the original networks using the methods discussed in Sec. 3.

Shrinking the linear embedding layers with SVD (Sec. 3.3) is very effective. The unfolded model with shrunk embedding layers performs at the same level as the ensemble (compare rows (b) and (c)). In our initial experiments, we applied the method of Srinivas and Babu (2015) to

Table 1: Shrinking layers of the unfolded network on Ja-En to their original size.

shrink the other layers, but their approach performed very poorly on this kind of network: the BLEU score dropped down to 15.5 on the development set when shrinking all layers except the decoder maxout and embedding layers, and to 9.9 BLEU when applying their method only to embedding layers.[5] Row (e) in Tab. 1 shows that our data-free algorithm from Sec. 3.1 is better suited for shrinking the GRU and attention layers, leading to a drop of only 1 BLEU point compared to the ensemble (b) (i.e. 0.8 BLEU better than the single system (a)). However, using the data-bound version of our shrinking algorithm (Sec. 3.2) for the GRU layers performs best.[6] The shrunk model yields about the same BLEU score as the ensemble on the test set (25.2 in (b) and 25.3 in (f)). Shrinking the maxout layer remains more of a challenge (rows (g) and (h)), but the number of parameters in this layer is small. Therefore, shrinking all layers except the maxout layer leads to almost the same number of parameters (factor 1.05 in row (f)) as the original NMT network (a), and thus to a similar storage size, memory consumption, and decoding speed, but with a 1.8 BLEU gain. Based on these results we fix the shrinking method used for each layer for all remaining experiments as follows: We shrink linear embedding layers with our SVD-based method, GRU layers with our data-bound method, the attention layer with our data-free method, and do not shrink the maxout layer.

Our data-bound algorithm from Sec. 3.2 has two mechanisms to compensate for the removal of a neuron. First, we use a linear combination of the remaining neurons to update the outgoing weight matrix by imitating its activations (Eq. 4). Second, stochastic gradient descent (SGD) fine-tunes all weights during this process. Tab. 2 demonstrates that both mechanisms are crucial for minimizing the effect of shrinking on the BLEU score.

	Compensation Method		**BLEU**	
	Linear Combination	**SGD**	**dev**	**test**
(a)			16.3	18.0
(b)	✓		22.1	24.3
(c)		✓	21.7	24.4
(d)	✓	✓	22.4	25.3

Table 2: Compensating for neuron removal in the data-bound algorithm. Row (d) corresponds to row (f) in Tab. 1.

Decoding Speed Our testing environment is an Ubuntu 16.04 with Linux 4.4.0 kernel, 32 GB RAM, an Intel® Core i7-6700 CPU at 3.40 GHz and an Nvidia GeForce GTX Titan X GPU. CPU decoding uses a single thread. We used the first 500 sentences of the Ja-En WAT development set for the time measurements.

Our results in Tab. 3 show that decoding with ensembles (rows (b) and (e)) is slow: combining the predictions of the individual models on the CPU is computationally expensive, and ensemble decoding requires K passes through the softmax layer which is also computationally expensive. Unfolding the ensemble into a single network and shrinking the embedding and attention layers improves the runtimes on the GPU significantly without noticeable impact on BLEU (rows (c) and (f)). This can be attributed to the fact that unfolding can reduce the communication overhead between CPU and GPU. Comparing rows (d) and (g) with row (a) reveals that shrinking the unfolded networks even further speeds up CPU and GPU decoding almost to the level of single system decoding. However, more aggressive shrinking yields a BLEU score of 25.3 when combining three systems (row (g)) – 1.8 BLEU better than the single system, but 0.6 BLEU worse than the 3-

[5] Results with the original method of Srinivas and Babu (2015) are not included in Tab. 1.

[6] If we apply different methods to different layers of the same network, we first apply SVD-based shrinking, then the data-free method, and finally the data-bound method.

ensemble. Therefore, we will investigate the impact of shrinking on the different layers in the next sections more thoroughly.

Degrees of Redundancy in Different Layers We applied our shrinking methods to isolated layers in the 2-Unfold network of Tab. 1 (f). Fig. 3 plots the BLEU score when isolated layers are shrunk even below their size in the original NMT network. The attention layer is very robust against shrinking and can be reduced to 100 neurons (10% of the original size) without impacting the BLEU score. The embedding layers can be reduced to 60% but are sensitive to more aggressive pruning. Shrinking the GRU layers affects the BLEU score the most but still outperforms the single system when the GRU layers are shrunk to 30%.

Adjusting the Target Sizes of Layers Based on our previous experiments we revise our approach to shrink the 3-Unfold system in Tab. 3. Instead of shrinking all layers except the maxout layer to the same degree, we adjust the aggressiveness of shrinking for each layer. We suggest three different setups (*Normal*, *Small*, and *Tiny*) with the layer sizes specified in Tab. 4. *3-Unfold-Normal* has the same number of parameters as the original NMT networks (size factor: 1.0), *3-Unfold-Small* is only half their size (size factor: 0.5), and *3-Unfold-Tiny* reduces the size by two thirds (size factor: 0.33). When comparing rows (a) and (c) in Tab. 5 we observe that *3-Unfold-Normal* yields a gain of 2.2 BLEU with respect to the original single system and a slight improvement in decoding speed at the same time.[7] Networks with the size factor 1.0 like *3-Unfold-Normal* are very likely to yield about the same decoding speed as the *Single* network regardless of the decoder implementation, machine learning framework, and hardware. Therefore, we think that similar results are possible on other platforms as well.

	System	Words/Min.		BLEU	
		CPU	GPU	dev	test

(d)	3-Unfold-Small	946.1	3572.0	21.7	23.9
(e)	3-Unfold-Tiny	1102.5	3483.7	20.6	23.2

Table 5: Our best models on Ja-En.

CPU decoding speed directly benefits even more from smaller setups – *3-Unfold-Tiny* is only 0.3 BLEU worse than *Single* but decoding on a single CPU is 3.4 times faster (row (a) vs. row (e) in Tab. 5). This is of great practical use: batch decoding with only two CPU threads surpasses production speed which is often set to 2000 words per minute (Beck et al., 2016). Our initial experiments in Tab. 6 suggest that the *Normal* setup is applicable to En-De as well, with substantial improve-

[7] To validate that the gains come from ensembling and unfolding and not from the layer sizes in *3-Unfold-Normal* we trained a network from scratch with the same dimensions. This network performed similarly to our *Single* system.

5 Related Work

The idea of pruning neural networks to improve the compactness of the models dates back more than 25 years (LeCun et al., 1989). The literature is therefore vast (Augasta and Kathirvalavakumar, 2013). One line of research aims to remove unimportant network connections. The connections can be selected for deletion based on the second-derivative of the training error with respect to the weight (LeCun et al., 1989; Hassibi et al., 1993), or by a threshold criterion on its magnitude (Han et al., 2015). See et al. (2016) confirmed a high degree of weight redundancy in NMT networks.

In this work we are interested in removing neurons rather than single connections since we strive to shrink the unfolded network such that it resembles the layout of an individual model. We argued in Sec. 4 that removing neurons rather than connections does not only improve the model size but also the memory footprint and decoding speed. As explained in Sec. 3.1, our data-free method is an extension of the approach by Srinivas and Babu (2015); our extension performs significantly better on NMT networks. Our data-bound method (Sec. 3.2) is inspired by Babaeizadeh et al. (2016) as we combine neurons with similar activities during training, but we use linear combinations of multiple neurons to compensate for the loss of a neuron rather than merging pairs of neurons.

Using low rank matrices for neural network compression, particularly approximations via SVD, has been studied widely in the literature (Denil et al., 2013; Denton et al., 2014; Xue et al., 2013; Prabhavalkar et al., 2016; Lu et al., 2016). These approaches often use low rank matrices to approximate a full rank weight matrix in the original network. In contrast, we shrink an entire linear layer by applying SVD on the product of the incoming and outgoing weight matrices (Sec. 3.3).

In this paper we mimicked the output of the high performing but cumbersome ensemble by constructing a large unfolded network, and shrank this network afterwards. Another approach, known as *knowledge distillation*, uses the large model (the teacher) to generate soft training labels for the smaller student network (Bucilu et al., 2006; Hinton et al., 2014). The student network is trained by minimizing the cross-entropy to the teacher. This idea has been applied to sequence modelling tasks such as machine translation and speech recognition (Wong and Gales, 2016; Kim and Rush, 2016; Freitag et al., 2017). Our approach can be computationally more efficient as the training set does not have to be decoded by the large teacher network.

Junczys-Dowmunt et al. (2016a; 2016b) reported gains from averaging the weight matrices of multiple checkpoints of the same training run. However, our attempts to replicate their approach were not successful. Averaging might work well when the behaviour of corresponding units is similar across networks, but that cannot be guaranteed when networks are trained independently.

6 Conclusion

We have described a generic method for improving the decoding speed and BLEU score of single system NMT. Our approach involves unfolding an ensemble of multiple systems into a single large neural network and shrinking this network by removing redundant neurons. Our best results on Japanese-English either yield a gain of 2.2 BLEU compared to the original single NMT network at about the same decoding speed, or a $3.4\times$ CPU decoding speed up with only a minor drop in BLEU.

The current formulation of unfolding works for networks of the same topology as the concatenation of layers is only possible for analogous layers in different networks. Unfolding and shrinking diverse networks could be possible, for example by applying the technique only to the input and output layers or by some other scheme of finding associations between units in different models, but we leave this investigation to future work as models in NMT ensembles in current research usually have the same topology (Bojar et al., 2016; Sennrich et al., 2016a; Chung et al., 2016; Neubig, 2016; Wu et al., 2016; Durrani et al., 2017).

Appendix: Probabilistic Interpretation of Data-Free and Data-Bound Shrinking

Data-free and data-bound shrinking can be interpreted as setting the expected difference between network outputs before and after a removal operation to zero under different assumptions.

For simplicity, we focus our probabilistic treatment of shrinking on single layer feedforward networks. Such a network maps an input $\mathbf{x} \in \mathbb{R}^{m_{in}}$ to an output $\mathbf{y} \in \mathbb{R}^{m_{out}}$. The l-th output y_l is computed according the following equation

$$y_l = \sum_{k \in [1,m]} \sigma(\mathbf{x}\mathbf{u}_k^T) V_{k,l} \tag{7}$$

where $\mathbf{u}_k \in \mathbb{R}^{m_{in}}$ is the incoming weight vector of the k-th hidden neuron (denoted as $U_{:,k}$ in the main paper) and $V \in \mathbb{R}^{m \times m_{out}}$ the outgoing weight matrix of the m-dimensional hidden layer. We now remove the j-th neuron in the hidden layer and modify the outgoing weights to compensate for the removal:

$$y'_l = \sum_{k \in [1,m] \backslash \{j\}} \sigma(\mathbf{x}\mathbf{u}_k^T) V'_{k,l} \tag{8}$$

where y'_l is the output after the removal operation and $V' \in \mathbb{R}^{m \times m_{out}}$ are the modified outgoing weights. Our goal is to choose V' such that the expected error introduced by removing neuron j is zero:

$$\mathbb{E}_{\mathbf{x}}(y_l - y'_l) = 0 \tag{9}$$

Data-free shrinking Data-free shrinking makes two assumptions to satisfy Eq. 9. First, we assume that the incoming weight vector $\mathbf{u}_j$ can be represented as linear combination of the other weight vectors.

$$\mathbf{u}_j = \sum_{k \in [1,m] \backslash \{j\}} \lambda_k \mathbf{u}_k \tag{10}$$

Second, it assumes that the neuron activation function $\sigma(\cdot)$ is linear. Starting with Eqs. 7 and 8 we can write $\mathbb{E}_{\mathbf{x}}(y_l - y'_l)$ as

$$\begin{aligned}
&\mathbb{E}_{\mathbf{x}}\Big(\sigma(\mathbf{x}\mathbf{u}_j^T)V_{j,l} + \underbrace{\sum_{k \in [1,m] \backslash \{j\}} \sigma(\mathbf{x}\mathbf{u}_k^T)(V_{k,l} - V'_{k,l})\Big)}_{:=R} \\
\overset{\text{Eq. 10}}{=} \quad & \mathbb{E}_{\mathbf{x}}\Big(\sigma(\mathbf{x}(\sum_{k \in [1,m] \backslash \{j\}} \lambda_k \mathbf{u}_k)^T)V_{j,l} + R\Big) \\
\overset{\sigma(\cdot)\text{ lin.}}{=} \quad & \mathbb{E}_{\mathbf{x}}\Big(\sum_{k \in [1,m] \backslash \{j\}} \sigma(\mathbf{x}\mathbf{u}_k^T)\lambda_k V_{j,l} + R\Big) \\
= \quad & \sum_{k \in [1,m] \backslash \{j\}} \mathbb{E}_{\mathbf{x}}\Big(\sigma(\mathbf{x}\mathbf{u}_k^T)\Big)(V_{k,l} - V'_{k,l} + \lambda_k V_{j,l})
\end{aligned}$$

We set this term to zero (and thus satisfy Eq. 9) by setting each component of the sum to zero.

$$\forall k \in [1,m] \setminus \{j\} : V'_{k,l} = V_{k,l} + \lambda_k V_{j,l} \tag{11}$$

This condition is directly implemented by the update rule in our shrinking algorithm (Eq. 3 and 4).

Data-bound shrinking Data-bound shrinking does not require linearity in $\sigma(\cdot)$. It rather assumes that the expected value of the neuron activity j is a linear combination of the expected values of the other activities:

$$\mathbb{E}_{\mathbf{x}}(\sigma(\mathbf{x}\mathbf{u}_j^T)) = \sum_{k \in [1,m] \backslash \{j\}} \lambda_k \mathbb{E}_{\mathbf{x}}(\sigma(\mathbf{x}\mathbf{u}_k^T)) \tag{12}$$

$\mathbb{E}_{\mathbf{x}}(\cdot)$ is estimated using importance sampling:

$$\hat{\mathbb{E}}_{\mathbf{x}}(\sigma(\mathbf{x}\mathbf{u}_k^T); \mathcal{X}) = \frac{1}{|\mathcal{X}|} \sum_{\mathbf{x}' \in \mathcal{X}} \sigma(\mathbf{x}'\mathbf{u}_k^T) \tag{13}$$

In practice, the samples in $\mathcal{X}$ are collected in the activity matrix A from Sec. 3.2. We can satisfy Eq. 9 by using the λ-values from Eq. 12, so that $\mathbb{E}_{\mathbf{x}}(y_l - y'_l)$ becomes

$$\begin{aligned}
\overset{\text{Eqs. 7,8}}{=} \quad & \mathbb{E}_{\mathbf{x}}\Big(\sigma(\mathbf{x}\mathbf{u}_j^T)V_{j,l} \\
& + \sum_{k \in [1,m] \backslash \{j\}} \sigma(\mathbf{x}\mathbf{u}_k^T)(V_{k,l} - V'_{k,l})\Big) \\
= \quad & \mathbb{E}_{\mathbf{x}}(\sigma(\mathbf{x}\mathbf{u}_j^T)V_{j,l}) \\
& + \sum_{k \in [1,m] \backslash \{j\}} \mathbb{E}_{\mathbf{x}}(\sigma(\mathbf{x}\mathbf{u}_k^T))(V_{k,l} - V'_{k,l}) \\
\overset{\text{Eq. 12}}{=} \quad & \sum_{k \in [1,m] \backslash \{j\}} \mathbb{E}_{\mathbf{x}}(\sigma(\mathbf{x}\mathbf{u}_k^T))(V_{k,l} - V'_{k,l} + \lambda_k V_{j,l})
\end{aligned}$$

Again, we set this to zero using Eq. 11.

Abstract

We present a simple and effective approach to incorporating syntactic structure into neural attention-based encoder-decoder models for machine translation. We rely on graph-convolutional networks (GCNs), a recent class of neural networks developed for modeling graph-structured data. Our GCNs use predicted syntactic dependency trees of source sentences to produce representations of words (i.e. hidden states of the encoder) that are sensitive to their syntactic neighborhoods. GCNs take word representations as input and produce word representations as output, so they can easily be incorporated as layers into standard encoders (e.g., on top of bidirectional RNNs or convolutional neural networks). We evaluate their effectiveness with English-German and English-Czech translation experiments for different types of encoders and observe substantial improvements over their syntax-agnostic versions in all the considered setups.

1 Introduction

Neural machine translation (NMT) is one of success stories of deep learning in natural language processing, with recent NMT systems outperforming traditional phrase-based approaches on many language pairs (Sennrich et al., 2016a). State-of-the-art NMT systems rely on sequential encoder-decoders (Sutskever et al., 2014; Bahdanau et al., 2015) and lack any explicit modeling of syntax or any hierarchical structure of language. One potential reason for why we have not seen much benefit from using syntactic information in NMT is the lack of simple and effective methods for incorporating structured information in neural encoders, including RNNs. Despite some successes, techniques explored so far either incorporate syntactic information in NMT models in a relatively indirect way (e.g., multi-task learning (Luong et al., 2015a; Nadejde et al., 2017; Eriguchi et al., 2017; Hashimoto and Tsuruoka, 2017)) or may be too restrictive in modeling the interface between syntax and the translation task (e.g., learning representations of linguistic phrases (Eriguchi et al., 2016)). Our goal is to provide the encoder with access to rich syntactic information but let it decide which aspects of syntax are beneficial for MT, without placing rigid constraints on the interaction between syntax and the translation task. This goal is in line with claims that rigid syntactic constraints typically hurt MT (Zollmann and Venugopal, 2006; Smith and Eisner, 2006; Chiang, 2010), and, though these claims have been made in the context of traditional MT systems, we believe they are no less valid for NMT.

Attention-based NMT systems (Bahdanau et al., 2015; Luong et al., 2015b) represent source sentence words as latent-feature vectors in the encoder and use these vectors when generating a translation. Our goal is to automatically incorporate information about syntactic neighborhoods of source words into these feature vectors, and, thus, potentially improve quality of the translation output. Since vectors correspond to words, it is natural for us to use dependency syntax. Dependency trees (see Figure 1) represent syntactic relations between words: for example, *monkey* is a subject of the predicate *eats*, and *banana* is its object.

In order to produce syntax-aware feature representations of words, we exploit graph-convolutional networks (GCNs) (Duvenaud et al., 2015; Defferrard et al., 2016; Kearnes et al., 2016; Kipf and Welling, 2016). GCNs can be regarded as computing a latent-feature representation of a node (i.e. a real-valued vector) based on its k-

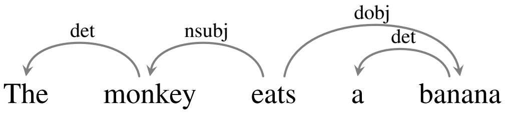

Figure 1: A dependency tree for the example sentence: "*The monkey eats a banana.*"

th order neighborhood (i.e. nodes at most k hops aways from the node) (Gilmer et al., 2017). They are generally simple and computationally inexpensive. We use Syntactic GCNs, a version of GCN operating on top of syntactic dependency trees, recently shown effective in the context of semantic role labeling (Marcheggiani and Titov, 2017).

Since syntactic GCNs produce representations at word level, it is straightforward to use them as encoders within the attention-based encoder-decoder framework. As NMT systems are trained end-to-end, GCNs end up capturing syntactic properties specifically relevant to the translation task. Though GCNs can take word embeddings as input, we will see that they are more effective when used as layers on top of recurrent neural network (RNN) or convolutional neural network (CNN) encoders (Gehring et al., 2016), enriching their states with syntactic information. A comparison to RNNs is the most challenging test for GCNs, as it has been shown that RNNs (e.g., LSTMs) are able to capture certain syntactic phenomena (e.g., subject-verb agreement) reasonably well on their own, without explicit treebank supervision (Linzen et al., 2016; Shi et al., 2016). Nevertheless, GCNs appear beneficial even in this challenging set-up: we obtain +1.2 and +0.7 BLEU point improvements from using syntactic GCNs on top of bidirectional RNNs for English-German and English-Czech, respectively.

In principle, GCNs are flexible enough to incorporate any linguistic structure as long as they can be represented as graphs (e.g., dependency-based semantic-role labeling representations (Surdeanu et al., 2008), AMR semantic graphs (Banarescu et al., 2012) and co-reference chains). For example, unlike recursive neural networks (Socher et al., 2013), GCNs do not require the graphs to be trees. However, in this work we solely focus on dependency syntax and leave more general investigation for future work.

Our main contributions can be summarized as follows:

- we introduce a method for incorporating structure into NMT using syntactic GCNs;
- we show that GCNs can be used along with RNN and CNN encoders;
- we show that incorporating structure is beneficial for machine translation on English-Czech and English-German.

2 Background

Notation. We use $\mathbf{x}$ for vectors, $\mathbf{x}_{1:t}$ for a sequence of t vectors, and X for matrices. The i-th *value* of vector $\mathbf{x}$ is denoted by x_i. We use $\circ$ for vector concatenation.

2.1 Neural Machine Translation

In NMT (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Cho et al., 2014b), given example translation pairs from a parallel corpus, a neural network is trained to directly estimate the conditional distribution $p(y_{1:T_y}|x_{1:T_x})$ of translating a source sentence $x_{1:T_x}$ (a sequence of T_x words) into a target sentence $y_{1:T_y}$. NMT models typically consist of an encoder, a decoder and some method for conditioning the decoder on the encoder, for example, an attention mechanism. We will now briefly describe the components that we use in this paper.

2.1.1 Encoders

An encoder is a function that takes as input the source sentence and produces a representation encoding its semantic content. We describe recurrent, convolutional and bag-of-words encoders.

Recurrent. Recurrent neural networks (RNNs) (Elman, 1990) model sequential data. They receive one input vector at each time step and update their hidden state to summarize all inputs up to that point. Given an input sequence $\mathbf{x}_{1:T_x} = \mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_{T_x}$ of word embeddings an RNN is defined recursively as follows:

$$\mathrm{RNN}(\mathbf{x}_{1:t}) = f(\mathbf{x}_t, \mathrm{RNN}(\mathbf{x}_{1:t-1}))$$

where f is a nonlinear function such as an LSTM (Hochreiter and Schmidhuber, 1997) or a GRU (Cho et al., 2014b). We will use the function RNN as an abstract mapping from an input sequence $\mathbf{x}_{1:T}$ to final hidden state $\mathrm{RNN}(\mathbf{x}_{1:T_x})$, regardless of the used nonlinearity. To not only summarize the past of a word, but also its future, a bidirectional RNN (Schuster and Paliwal, 1997; Irsoy and

Cardie, 2014) is often used. A bidirectional RNN reads the input sentence in two directions and then concatenates the states for each time step:

$$\text{BiRNN}(\mathbf{x}_{1:T_x}, t) = \text{RNN}_F(\mathbf{x}_{1:t}) \circ \text{RNN}_B(\mathbf{x}_{T_x:t})$$

where RNN_F and RNN_B are the forward and backward RNNs, respectively. For further details we refer to the encoder of Bahdanau et al. (2015).

Convolutional. Convolutional Neural Networks (CNNs) apply a fixed-size window over the input sequence to capture the local context of each word (Gehring et al., 2016). One advantage of this approach over RNNs is that it allows for fast parallel computation, while sacrificing non-local context. To remedy the loss of context, multiple CNN layers can be stacked. Formally, given an input sequence $\mathbf{x}_{1:T_x}$, we define a CNN as follows:

$$\text{CNN}(\mathbf{x}_{1:T_x}, t) = f(\mathbf{x}_{t-\lfloor w/2 \rfloor}, .., \mathbf{x}_t, .., \mathbf{x}_{t+\lfloor w/2 \rfloor})$$

where f is a nonlinear function, typically a linear transformation followed by ReLU, and w is the size of the window.

Bag-of-Words. In a bag-of-words (BoW) encoder every word is simply represented by its word embedding. To give the decoder some sense of word position, position embeddings (PE) may be added. There are different strategies for defining position embeddings, and in this paper we choose to learn a vector for each absolute word position up to a certain maximum length. We then represent the t-th word in a sequence as follows:

$$\text{BoW}(\mathbf{x}_{1:T_x}, t) = \mathbf{x}_t + \mathbf{p}_t$$

where $\mathbf{x}_t$ is the word embedding and $\mathbf{p}_t$ is the t-th position embedding.

2.1.2 Decoder

A decoder produces the target sentence conditioned on the representation of the source sentence induced by the encoder. In Bahdanau et al. (2015) the decoder is implemented as an RNN conditioned on an additional input $\mathbf{c}_i$, the context vector, which is dynamically computed at each time step using an attention mechanism.

The probability of a target word y_i is now a function of the decoder RNN state, the previous target word embedding, and the context vector. The model is trained end-to-end for maximum log likelihood of the next target word given its context.

2.2 Graph Convolutional Networks

We will now describe the Graph Convolutional Networks (GCNs) of Kipf and Welling (2016). For a comprehensive overview of alternative GCN architectures see Gilmer et al. (2017).

A GCN is a multilayer neural network that operates directly on a graph, encoding information about the neighborhood of a node as a real-valued vector. In each GCN layer, information flows along edges of the graph; in other words, each node receives messages from all its immediate neighbors. When multiple GCN layers are stacked, information about larger neighborhoods gets integrated. For example, in the second layer, a node will receive information from its immediate neighbors, but this information already includes information from their respective neighbors. By choosing the number of GCN layers, we regulate the distance the information travels: with k layers a node receives information from neighbors at most k hops away.

Formally, consider an undirected graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, where $\mathcal{V}$ is a set of n nodes, and $\mathcal{E}$ is a set of edges. Every node is assumed to be connected to itself, i.e. $\forall v \in \mathcal{V} : (v, v) \in \mathcal{E}$. Now, let $X \in \mathbb{R}^{d \times n}$ be a matrix containing all n nodes with their features, where d is the dimensionality of the feature vectors. In our case, X will contain word embeddings, but in general it can contain any kind of features. For a 1-layer GCN, the new node representations are computed as follows:

$$\mathbf{h}_v = \rho\left(\sum_{u \in \mathcal{N}(v)} W\mathbf{x}_u + \mathbf{b}\right)$$

where $W \in \mathbb{R}^{d \times d}$ is a weight matrix and $\mathbf{b} \in \mathbb{R}^d$ a bias vector.[1] ρ is an activation function, e.g. a ReLU. $\mathcal{N}(v)$ is the set of neighbors of v, which we assume here to always include v itself. As stated before, to allow information to flow over multiple hops, we need to stack GCN layers. The recursive computation is as follows:

$$\mathbf{h}_v^{(j+1)} = \rho\left(\sum_{u \in \mathcal{N}(v)} W^{(j)}\mathbf{h}_u^{(j)} + \mathbf{b}^{(j)}\right)$$

where j indexes the layer, and $\mathbf{h}_v^{(0)} = \mathbf{x}_v$.

[1] We dropped the normalization factor used by Kipf and Welling (2016), as it is not used in syntactic GCNs of Marcheggiani and Titov (2017).

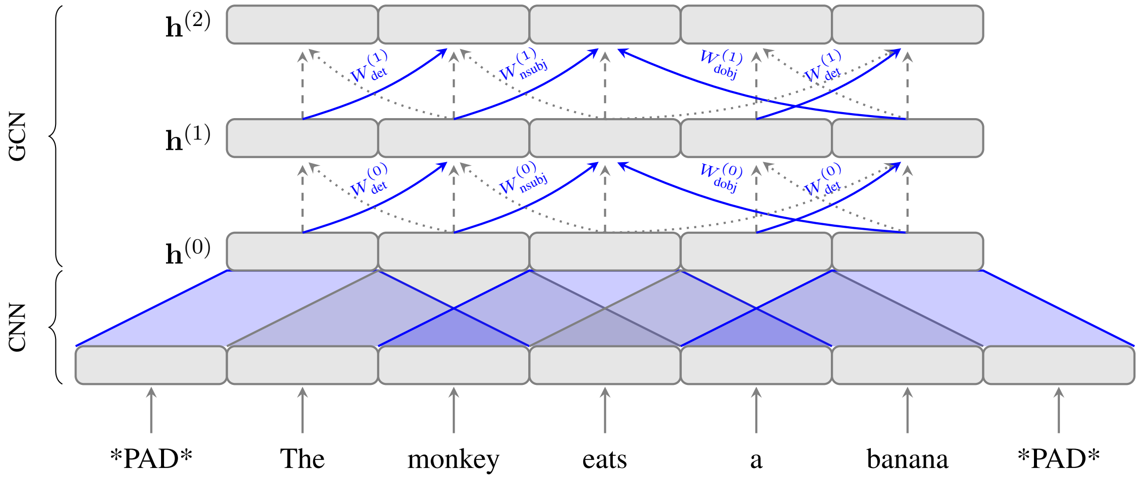

Figure 2: A 2-layer syntactic GCN on top of a convolutional encoder. Loop connections are depicted with dashed edges, syntactic ones with solid (dependents to heads) and dotted (heads to dependents) edges. Gates and some labels are omitted for clarity.

2.3 Syntactic GCNs

Marcheggiani and Titov (2017) generalize GCNs to operate on directed and labeled graphs.[2] This makes it possible to use linguistic structures such as dependency trees, where directionality and edge labels play an important role. They also integrate edge-wise gates which let the model regulate contributions of individual dependency edges. We will briefly describe these modifications.

Directionality. In order to deal with directionality of edges, separate weight matrices are used for incoming and outgoing edges. We follow the convention that in dependency trees heads point to their dependents, and thus *outgoing* edges are used for head-to-dependent connections, and *incoming* edges are used for dependent-to-head connections. Modifying the recursive computation for directionality, we arrive at:

$$\mathbf{h}_v^{(j+1)} = \rho\left(\sum_{u\in\mathcal{N}(v)} W^{(j)}_{\text{dir}(u,v)}\,\mathbf{h}_u^{(j)} + \mathbf{b}^{(j)}_{\text{dir}(u,v)}\right)$$

where $\text{dir}(u, v)$ selects the weight matrix associated with the directionality of the edge connecting u and v (i.e. W_{IN} for u-to-v, W_{OUT} for v-to-u, and W_{LOOP} for v-to-v). Note that self loops are modeled separately,

so there are now three times as many parameters as in a non-directional GCN.

Labels. Making the GCN sensitive to labels is straightforward given the above modifications for directionality. Instead of using separate matrices for each direction, separate matrices are now defined for each direction and label combination:

$$\mathbf{h}_v^{(j+1)} = \rho\left(\sum_{u\in\mathcal{N}(v)} W^{(j)}_{\text{lab}(u,v)}\,\mathbf{h}_u^{(j)} + \mathbf{b}^{(j)}_{\text{lab}(u,v)}\right)$$

where we incorporate the directionality of an edge directly in its label.

Importantly, to prevent over-parametrization, only bias terms are made label-specific, in other words: $W_{\text{lab}(u,v)} = W_{\text{dir}(u,v)}$. The resulting syntactic GCN is illustrated in Figure 2 (shown on top of a CNN, as we will explain in the subsequent section).

Edge-wise gating. Syntactic GCNs also include gates, which can down-weight the contribution of individual edges. They also allow the model to deal with noisy predicted structure, i.e. to ignore potentially erroneous syntactic edges. For each edge, a scalar gate is calculated as follows:

$$g^{(j)}_{u,v} = \sigma\left(\mathbf{h}_u^{(j)} \cdot \hat{\mathbf{w}}^{(j)}_{\text{dir}(u,v)} + \hat{b}^{(j)}_{\text{lab}(u,v)}\right)$$

where σ is the logistic sigmoid function, and $\hat{\mathbf{w}}^{(j)}_{\text{dir}(u,v)} \in \mathbb{R}^d$ and $\hat{b}^{(j)}_{\text{lab}(u,v)} \in \mathbb{R}$ are learned parameters for the gate. The computation becomes:

$$\mathbf{h}_v^{(j+1)}{=}\rho\Big(\sum_{u\in\mathcal{N}(v)} g^{(j)}_{u,v}\big(W^{(j)}_{\text{dir}(u,v)}\,\mathbf{h}_u^{(j)} + \mathbf{b}^{(j)}_{\text{lab}(u,v)}\big)\Big)$$

[2] For an alternative approach to integrating labels and directions, see applications of GCNs to statistical relation learning (Schlichtkrull et al., 2017).

3 Graph Convolutional Encoders

In this work we focus on exploiting structural information on the source side, i.e. in the encoder. We hypothesize that using an encoder that incorporates syntax will lead to more informative representations of words, and that these representations, when used as context vectors by the decoder, will lead to an improvement in translation quality. Consequently, in all our models, we use the decoder of Bahdanau et al. (2015) and keep this part of the model constant. As is now common practice, we do not use a maxout layer in the decoder, but apart from this we do not deviate from the original definition. In all models we make use of GRUs (Cho et al., 2014b) as our RNN units.

Our models vary in the encoder part, where we exploit the power of GCNs to induce syntactically-aware representations. We now define a series of encoders of increasing complexity.

BoW + GCN. In our first and simplest model, we propose a bag-of-words encoder (with position embeddings, see §2.1.1), with a GCN on top. In other words, inputs $\mathbf{h}^{(0)}$ are a sum of embeddings of a word and its position in a sentence. Since the original BoW encoder captures the linear ordering information only in a very crude way (through the position embeddings), the structural information provided by GCN should be highly beneficial.

Convolutional + GCN. In our second model, we use convolutional neural networks to learn word representations. CNNs are fast, but by definition only use a limited window of context. Instead of the approach used by Gehring et al. (2016) (i.e. stacking mulitple CNN layers on top of each other), we use a GCN to enrich the one-layer CNN representations. Figure 2 shows this model. Note that, while the figure shows a CNN with a window size of 3, we will use a larger window size of 5 in our experiments. We expect this model to perform better than BoW + GCN, because of the additional local context captured by the CNN.

BiRNN + GCN. In our third and most powerful model, we employ bidirectional recurrent neural networks. In this model, we start by encoding the source sentence using a BiRNN (i.e. BiGRU), and use the resulting hidden states as input to a GCN. Instead of relying on linear order only, the GCN will allow the encoder to 'teleport' over parts of the input sentence, along dependency edges, connecting words that otherwise might be far apart. The model might not only benefit from this teleporting capability however; also the nature of the relations between words (i.e. dependency relation types) may be useful, and the GCN exploits this information (see §2.3 for details).

This is the most challenging setup for GCNs, as RNNs have been shown capable of capturing at least some degree of syntactic information without explicit supervision (Linzen et al., 2016), and hence they should be hard to improve on by incorporating treebank syntax.

Marcheggiani and Titov (2017) did not observe improvements from using multiple GCN layers in semantic role labeling. However, we do expect that propagating information from further in the tree should be beneficial in principle. We hypothesize that the first layer is the most influential one, capturing most of the syntactic context, and that additional layers only modestly modify the representations. To ease optimization, we add a residual connection (He et al., 2016) between the GCN layers, when using more than one layer.

4 Experiments

Experiments are performed using the Neural Monkey toolkit[3] (Helcl and Libovický, 2017), which implements the model of Bahdanau et al. (2015) in TensorFlow. We use the Adam optimizer (Kingma and Ba, 2015) with a learning rate of 0.001 (0.0002 for CNN models).[4] The batch size is set to 80. Between layers we apply dropout with a probability of 0.2, and in experiments with GCNs[5] we use the same value for edge dropout. We train for 45 epochs, evaluating the BLEU performance of the model every epoch on the validation set. For testing, we select the model with the highest validation BLEU. L2 regularization is used with a value of 10^{-8}. All the model selection (incl. hyperparameter selections) was performed on the validation set. In all experiments we obtain translations using a greedy decoder, i.e. we select the output token with the highest probability at each time step.

We will describe an artificial experiment in §4.1 and MT experiments in §4.2.

[3] https://github.com/ufal/neuralmonkey

[4] Like Gehring et al. (2016) we note that Adam is too aggressive for CNN models, hence we use a lower learning rate.

[5] GCN code at https://github.com/bastings/neuralmonkey

4.1 Reordering artificial sequences

Our goal here is to provide an intuition for the capabilities of GCNs. We define a reordering task where randomly permuted sequences need to be put back into the original order. We encode the original order using edges, and test if GCNs can successfully exploit them. Note that this task is not meant to provide a fair comparison to RNNs. The input (besides the edges) simply does not carry any information about the original ordering, so RNNs cannot possibly solve this task.

Data. From a vocabulary of 26 types, we generate random sequences of 3-10 tokens. We then randomly permute them, pointing every token to its original predecessor with a label sampled from a set of 5 labels. Additionally, we point every token to an *arbitrary* position in the sequence with a label from a distinct set of 5 'fake' labels. We sample 25000 training and 1000 validation sequences.

Model. We use the BiRNN + GCN model, i.e. a bidirectional GRU with a 1-layer GCN on top. We use 32, 64 and 128 units for embeddings, GRU units and GCN layers, respectively.

Results. After 6 epochs of training, the model learns to put permuted sequences back into order, reaching a validation BLEU of 99.2. Figure 3 shows that the mean values of the bias terms of gates (i.e. $\hat{b}$) for real and fake edges are far apart, suggesting that the GCN learns to distinguish them. Interestingly, this illustrates why edge-wise gating is beneficial. A gate-less model would not understand which of the two outgoing arcs is fake and which is genuine, because only biases b would then be label-dependent. Consequently, it would only do a mediocre job in reordering. Although using label-specific matrices W would also help, this would not scale to the real scenario (see §2.3).

4.2 Machine Translation

Data. For our experiments we use the En-De and En-Cs News Commentary v11 data from the WMT16 translation task.[6] For En-De we also train on the full WMT16 data set. As our validation set and test set we use `newstest2015` and `newstest2016`, respectively.

Pre-processing. The English sides of the corpora are tokenized and parsed into dependency trees by SyntaxNet,[7] using the pre-trained Parsey McParseface model.[8] The Czech and German sides are tokenized using the Moses tokenizer.[9] Sentence pairs where either side is longer than 50 words are filtered out after tokenization.

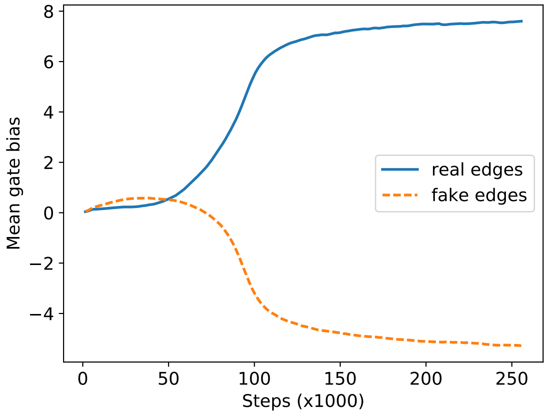

Figure 3: Mean values of gate bias terms for real (useful) labels and for fake (non useful) labels suggest the GCN learns to distinguish them.

Vocabularies. For the English sides, we construct vocabularies from all words except those with a training set frequency smaller than three. For Czech and German, to deal with rare words and phenomena such as inflection and compounding, we learn byte-pair encodings (BPE) as described by Sennrich et al. (2016b). Given the size of our data set, and following Wu et al. (2016), we use 8000 BPE merges to obtain robust frequencies for our subword units (16000 merges for full data experiment). Data set statistics are summarized in Table 1 and vocabulary sizes in Table 2.

	Train	Val.	Test
English-German	226822	2169	2999
English-German (full)	4500966	2169	2999
English-Czech	181112	2656	2999

Table 1: The number of sentences in our data sets.

Hyperparameters. We use 256 units for word embeddings, 512 units for GRUs (800 for En-De full data set experiment), and 512 units for convolutional layers (or equivalently, 512 'channels'). The dimensionality of the GCN layers is equiva-

[8] The used dependency parses can be reproduced by using the `syntaxnet/demo.sh` shell script.

[9] https://github.com/moses-smt/mosesdecoder

	Source	Target
English-German	37824	8099 (BPE)
English-German (full)	50000	16000 (BPE)
English-Czech	33786	8116 (BPE)

Table 2: Vocabulary sizes.

lent to the dimensionality of their input. We report results for 2-layer GCNs, as we find them most effective (see ablation studies below).

Baselines. We provide three baselines, each with a different encoder: a bag-of-words encoder, a convolutional encoder with window size $w = 5$, and a BiRNN. See §2.1.1 for details.

Evaluation. We report (cased) BLEU results (Papineni et al., 2002) using `multi-bleu`, as well as Kendall τ reordering scores.[10]

4.2.1 Results

English-German. Table 3 shows test results on English-German. Unsurprisingly, the bag-of-words baseline performs the worst. We expected the BoW+GCN model to make easy gains over this baseline, which is indeed what happens. The CNN baseline reaches a higher BLEU_4 score than the BoW models, but interestingly its BLEU_1 score is lower than the BoW+GCN model. The CNN+GCN model improves over the CNN baseline by +1.9 and +1.1 for BLEU_1 and BLEU_4, respectively. The BiRNN, the strongest baseline, reaches a BLEU_4 of 14.9. Interestingly, GCNs still manage to improve the result by +2.3 BLEU_1 and +1.2 BLEU_4 points. Finally, we observe a big jump in BLEU_4 by using the full data set and beam search (beam 12). The BiRNN now reaches 23.3, while adding a GCN achieves a score of 23.9.

	Kendall	BLEU_1	BLEU_4
BoW	0.3352	40.6	9.5
+ GCN	0.3520	44.9	12.2
CNN	0.3601	42.8	12.6
+ GCN	0.3777	44.7	13.7
BiRNN	0.3984	45.2	14.9
+ GCN	0.4089	47.5	16.1
BiRNN (full)	0.5440	53.0	23.3
+ GCN	0.5555	54.6	23.9

Table 3: Test results for English-German.

English-Czech. Table 4 shows test results on English-Czech. While it is difficult to obtain high absolute BLEU scores on this dataset, we can still see similar relative improvements. Again the BoW baseline scores worst, with the BoW+GCN easily beating that result. The CNN baseline scores BLEU_4 of 8.1, but the CNN+GCN improves on that, this time by +1.0 and +0.6 for BLEU_1 and BLEU_4, respectively. Interestingly, BLEU_1 scores for the BoW+GCN and CNN+GCN models are higher than both baselines so far. Finally, the BiRNN baseline scores a BLEU_4 of 8.9, but it is again beaten by the BiRNN+GCN model with +1.9 BLEU_1 and +0.7 BLEU_4.

	Kendall	BLEU_1	BLEU_4
BoW	0.2498	32.9	6.0
+ GCN	0.2561	35.4	7.5
CNN	0.2756	35.1	8.1
+ GCN	0.2850	36.1	8.7
BiRNN	0.2961	36.9	8.9
+ GCN	0.3046	38.8	9.6

Table 4: Test results for English-Czech.

Effect of GCN layers. How many GCN layers do we need? Every layer gives us an extra hop in the graph and expands the syntactic neighborhood of a word. Table 5 shows validation BLEU performance as a function of the number of GCN layers. For English-German, using a 1-layer GCN improves BLEU-1, but surprisingly has little effect on BLEU_4. Adding an additional layer gives improvements on both BLEU_1 and BLEU_4 of +1.3 and +0.73, respectively. For English-Czech, performance increases with each added GCN layer.

	En-De		En-Cs	
	BLEU_1	BLEU_4	BLEU_1	BLEU_4
BiRNN	44.2	14.1	37.8	8.9
+ GCN (1L)	45.0	14.1	38.3	9.6
+ GCN (2L)	46.3	14.8	39.6	9.9

Table 5: Validation BLEU for English-German and English-Czech for 1- and 2-layer GCNs.

[10] See Stanojević and Simaan (2015). TER (Snover et al., 2006) and BEER (Stanojević and Sima'an, 2014) metrics, even though omitted due to space considerations, are consistent with the reported results.

Effect of sentence length. We hypothesize that GCNs should be more beneficial for longer sentences: these are likely to contain long-distance syntactic dependencies which may not be adequately captured by RNNs but directly encoded in GCNs. To test this, we partition the validation data into five buckets and calculate BLEU for each of them. Figure 4 shows that GCN-based models outperform their respective baselines rather uniformly across all buckets. This is a surprising result. One explanation may be that syntactic parses are noisier for longer sentences, and this prevents us from obtaining extra improvements with GCNs.

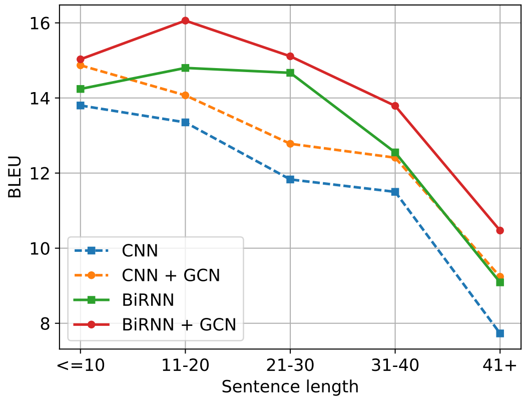

Figure 4: Validation BLEU per sentence length.

Discussion. Results suggest that the syntax-aware representations provided by GCNs consistently lead to improved translation performance as measured by BLEU$_4$ (as well as TER and BEER). Consistent gains in terms of Kendall tau and BLEU$_1$ indicate that improvements correlate with better word order and lexical/BPE selection, two phenomena that depend crucially on syntax.

5 Related Work

We review various accounts to syntax in NMT as well as other convolutional encoders.

Syntactic features and/or constraints. Sennrich and Haddow (2016) embed features such as POS-tags, lemmas and dependency labels and feed these into the network along with word embeddings. Eriguchi et al. (2016) parse English sentences with an HPSG parser and use a Tree-LSTM to encode the internal nodes of the tree. In the decoder, word and node representations compete under the same attention mechanism. Stahlberg et al. (2016) use a pruned lattice from a hierarchical phrase-based model (hiero) to constrain NMT. Hiero trees are not syntactically-aware, but instead constrained by symmetrized word alignments. Aharoni and Goldberg (2017) propose neural string-to-tree by predicting linearized parse trees.

Multi-task Learning. Sharing NMT parameters with a syntactic parser is a popular approach to obtaining syntactically-aware representations. Luong et al. (2015a) predict linearized constituency parses as an additional task. Eriguchi et al. (2017) multi-task with a target-side RNNG parser (Dyer et al., 2016) and improve on various language pairs with English on the target side. Nadejde et al. (2017) multi-task with CCG tagging, and also integrate syntax on the target side by predicting a sequence of words interleaved with CCG supertags.

Latent structure. Hashimoto and Tsuruoka (2017) add a syntax-inspired encoder on top of a BiLSTM layer. They encode source words as a learned average of potential parents emulating a relaxed dependency tree. While their model is trained purely on translation data, they also experiment with pre-training the encoder using treebank annotation and report modest improvements on English-Japanese. Yogatama et al. (2016) introduce a model for language understanding and generation that composes words into sentences by inducing unlabeled binary bracketing trees.

Convolutional encoders. Gehring et al. (2016) show that CNNs can be competitive to BiRNNs when used as encoders. To increase the receptive field of a word's context they stack multiple CNN layers. Kalchbrenner et al. (2016) use convolution in both the encoder and the decoder; they make use of dilation to increase the receptive field. In contrast to both approaches, we use a GCN informed by dependency structure to increase it. Finally, Cho et al. (2014a) propose a recursive convolutional neural network which builds a tree out of the word leaf nodes, but which ends up compressing the source sentence in a single vector.

6 Conclusions

We have presented a simple and effective approach to integrating syntax into neural machine translation models and have shown consistent BLEU$_4$ improvements for two challenging language pairs: English-German and English-Czech. Since GCNs are capable of encoding any kind of graph-based structure, in future work we would like to go beyond syntax, by using semantic annotations such as SRL and AMR, and co-reference chains.

Abstract

Recent research in neural machine translation has largely focused on two aspects; neural network architectures and end-to-end learning algorithms. The problem of decoding, however, has received relatively little attention from the research community. In this paper, we solely focus on the problem of decoding given a trained neural machine translation model. Instead of trying to build a new decoding algorithm for any specific decoding objective, we propose the idea of *trainable decoding algorithm* in which we train a decoding algorithm to find a translation that maximizes an arbitrary decoding objective. More specifically, we design an actor that observes and manipulates the hidden state of the neural machine translation decoder and propose to train it using a variant of deterministic policy gradient. We extensively evaluate the proposed algorithm using four language pairs and two decoding objectives, and show that we can indeed train a trainable greedy decoder that generates a better translation (in terms of a target decoding objective) with minimal computational overhead.

1 Introduction

Neural machine translation has recently become a method of choice in machine translation research. Besides its success in traditional settings of machine translation, that is one-to-one translation between two languages, (Sennrich et al., 2016; Chung et al., 2016), neural machine translation has ventured into more sophisticated settings of machine translation. For instance, neural machine translation has successfully proven itself to be capable of handling subword-level representation of sentences (Lee et al., 2016; Luong and Manning, 2016; Sennrich et al., 2015; Costa-Jussa and Fonollosa, 2016; Ling et al., 2015). Furthermore, several research groups have shown its potential in seamlessly handling multiple languages (Dong et al., 2015; Luong et al., 2015a; Firat et al., 2016a,b; Lee et al., 2016; Ha et al., 2016; Viégas et al., 2016).

A typical scenario of neural machine translation starts with training a model to maximize its log-likelihood. That is, we often train a model to maximize the conditional probability of a reference translation given a source sentence over a large parallel corpus. Once the model is trained in this way, it defines the conditional distribution over all possible translations given a source sentence, and the task of translation becomes equivalent to finding a translation to which the model assigns the highest conditional probability. Since it is computationally intractable to do so exactly, it is a usual practice to resort to approximate search/decoding algorithms such as greedy decoding or beam search. In this scenario, we have identified two points where improvements could be made. They are (1) training (including the selection of a model architecture) and (2) decoding.

Much of the research on neural machine translation has focused solely on the former, that is, on improving the model architecture. Neural machine translation started with with a simple encoder-decoder architecture in which a source sentence is encoded into a single, fixed-size vector (Cho et al., 2014; Sutskever et al., 2014; Kalchbrenner and Blunsom, 2013). It soon evolved with the attention mechanism (Bahdanau et al., 2014). A few variants of the attention mechanism, or its regularization, have been proposed recently to improve both the translation quality as well as the computational efficiency (Luong et al., 2015b; Cohn et al., 2016; Tu et al., 2016b). More recently, convolutional net-

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1968–1978
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

works have been adopted either as a replacement of or a complement to a recurrent network in order to efficiently utilize parallel computing (Kalchbrenner et al., 2016; Lee et al., 2016; Gehring et al., 2016).

On the aspect of decoding, only a few research groups have tackled this problem by incorporating a target decoding algorithm into training. Wiseman and Rush (2016) and Shen et al. (2015) proposed a learning algorithm tailored for beam search. Ranzato et al. (2015) and (Bahdanau et al., 2016) suggested to use a reinforcement learning algorithm by viewing a neural machine translation model as a policy function. Investigation on decoding alone has, however, been limited. Cho (2016) showed the limitation of greedy decoding by simply injecting unstructured noise into the hidden state of the neural machine translation system. Tu et al. (2016a) similarly showed that the exactness of beam search does not correlate well with actual translation quality, and proposed to augment the learning cost function with reconstruction to alleviate this problem. Li et al. (2016) proposed a modification to the existing beam search algorithm to improve its exploration of the translation space.

In this paper, we tackle the problem of decoding in neural machine translation by introducing a concept of *trainable greedy decoding*. Instead of manually designing a new decoding algorithm suitable for neural machine translation, we propose to learn a decoding algorithm with an arbitrary decoding objective. More specifically, we introduce a neural-network-based decoding algorithm that works on an already-trained neural machine translation system by observing and manipulating its hidden state. We treat such a neural network as an agent with a deterministic, continuous action and train it with a variant of the deterministic policy gradient algorithm (Silver et al., 2014).

We extensively evaluate the proposed trainable greedy decoding on four language pairs (En-Cs, En-De, En-Ru and En-Fi; in both directions) with two different decoding objectives; sentence-level BLEU and negative perplexity. By training such trainable greedy decoding using deterministic policy gradient with the proposed critic-aware actor learning, we observe that we can improve decoding performance with minimal computational overhead. Furthermore, the trained actors are found to improve beam search as well, suggesting a future research direction in extending the proposed idea of trainable decoding for more sophisticated underlying decoding algorithms.

2 Background

2.1 Neural Machine Translation

Neural machine translation is a special case of conditional recurrent language modeling, where the source and target are natural language sentences. Let us use $X = \{x_1, \ldots, x_{T_s}\}$ and $Y = \{y_1, \ldots, y_T\}$ to denote source and target sentences, respectively. Neural machine translation then models the target sentence given the source sentence as: $p(Y|X) = \prod_{t=1}^{T} p(y_t|y_{<t}, X)$. Each term on the r.h.s. of the equation above is modelled as a composite of two parametric functions:

$$p(y_t|y_{<t}, X) \propto \exp\left(g\left(y_t, z_t; \theta_g\right)\right),$$

where $z_t = f(z_{t-1}, y_{t-1}, e_t(X; \theta_e); \theta_f)$. g is a read-out function that transforms the hidden state z_t into the distribution over all possible symbols, and f is a recurrent function that compresses all the previous target words $y_{<t}$ and the time-dependent representation $e_t(X; \theta_e)$ of the source sentence X. This time-dependent representation e_t is often implemented as a recurrent network encoder of the source sentence coupled with an attention mechanism (Bahdanau et al., 2014).

Maximum Likelihood Learning We train a neural machine translation model, or equivalently estimate the parameters θ_g, θ_f and θ_e, by maximizing the log-probability of a reference translation $\hat{Y} = \{\hat{y}_1, ..., \hat{y}_T\}$ given a source sentence. That is, we maximize the log-likelihood function:

$$J^{\mathrm{ML}}(\theta_g, \theta_f, \theta_e) = \frac{1}{N} \sum_{n=1}^{N} \sum_{t=1}^{T_n} \log p_\theta(\hat{y}_t^n | \hat{y}_{<t}^n, X^n),$$

given a training set consisting of N source-target sentence pairs. It is important to note that this maximum likelihood learning does not take into account how a trained model would be used. Rather, it is only concerned with learning a distribution over all possible translations.

2.2 Decoding

Once the model is trained, either by maximum likelihood learning or by any other recently proposed algorithms (Wiseman and Rush, 2016; Shen et al., 2015; Bahdanau et al., 2016; Ranzato et al., 2015), we can let the model translate a given sentence by finding a translation that maximizes

$$\hat{Y} = \arg\max_{Y} \log p_\theta(Y|X),$$

where $\theta = (\theta_g, \theta_f, \theta_e)$. This is, however, computationally intractable, and it is a usual practice to resort to approximate decoding algorithms.

Greedy Decoding One such approximate decoding algorithm is greedy decoding. In greedy decoding, we follow the conditional dependency path and pick the symbol with the highest conditional probability so far at each node. This is equivalent to picking the best symbol one at a time from left to right in conditional language modelling. A decoded translation of greedy decoding is $\hat{Y} = (\hat{y}_1, \dots, \hat{y}_T)$, where

$$\hat{y}_t = \arg\max_{y \in V} \log p_\theta(y|\hat{y}_{<t}, X). \quad (1)$$

Despite its preferable computational complexity $O(|V| \times T)$, greedy decoding has been over time found to be undesirably sub-optimal.

Beam Search Beam search keeps $K > 1$ hypotheses, unlike greedy decoding which keeps only a single hypothesis during decoding. At each time step t, beam search picks K hypotheses with the highest scores ($\prod_{t'=1}^{t} p(y_t|y_{<t}, X)$). When all the hypotheses terminate (outputting the end-of-the-sentence symbol), it returns the hypothesis with the highest log-probability. Despite its superior performance compared to greedy decoding, the computational complexity grows linearly w.r.t. the size of beam K, which makes it less preferable especially in the production environment.

3 Trainable Greedy Decoding

3.1 Many Decoding Objectives

Although we have described decoding in neural machine translation as a maximum-a-posteriori estimation in $\log p(Y|X)$, this is not necessarily the only nor the desirable decoding objective.

First, each potential scenario in which neural machine translation is used calls for a unique decoding objective. In simultaneous translation/interpretation, which has recently been studied in the context of neural machine translation (Gu et al., 2016), the decoding objective is formulated as a trade-off between the translation quality and delay. On the other hand, when a machine translation system is used as a part of a larger information extraction system, it is more important to correctly translate named entities and events than to translate syntactic function words. The decoding objective in this case must account for how the translation is used in subsequent modules in a larger system.

Second, the conditional probability assigned by a trained neural machine translation model does not necessarily reflect our perception of translation quality. Although Cho (2016) provided empirical evidence of high correlation between the log-probability and BLEU, a *de facto* standard metric in machine translation, there have also been reports on large mismatch between the log-probability and BLEU. For instance, Tu et al. (2016a) showed that beam search with a very large beam, which is supposed to find translations with better log-probabilities, suffers from pathological translations of very short length, resulting in low translation quality. This calls for a way to design or *learn* a decoding algorithm with an objective that is more directly correlated to translation quality.

In short, there is a significant need for designing multiple decoding algorithms for neural machine translation, regardless of how it was trained. It is however non-trivial to manually design a new decoding algorithm with an arbitrary objective. This is especially true with neural machine translation, as the underlying structure of the decoding/search process – the high-dimensional hidden state of a recurrent network – is accessible but not interpretable. Instead, in the remainder of this section, we propose our approach of *trainable greedy decoding*.

3.2 Trainable Greedy Decoding

We start from the noisy, parallel approximate decoding (NPAD) algorithm proposed in (Cho, 2016). The main idea behind NPAD algorithm is that a better translation with a higher log-probability may be found by injecting unstructured noise in the transition function of a recurrent network. That is,

$$z_t = f(z_{t-1} + \epsilon_t, y_{t-1}, e_t(X; \theta_e); \theta_f),$$

where $\epsilon_t \sim \mathcal{N}(0, (\sigma_0/t)^2)$. NPAD avoids potential degradation of translation quality by running such a noisy greedy decoding process multiple times in parallel. An important lesson of NPAD algorithm is that there exists a decoding strategy with the asymptotically same computational complexity that results in a better translation quality, and that such a better translation can be found by manipulating the hidden state of the recurrent network.

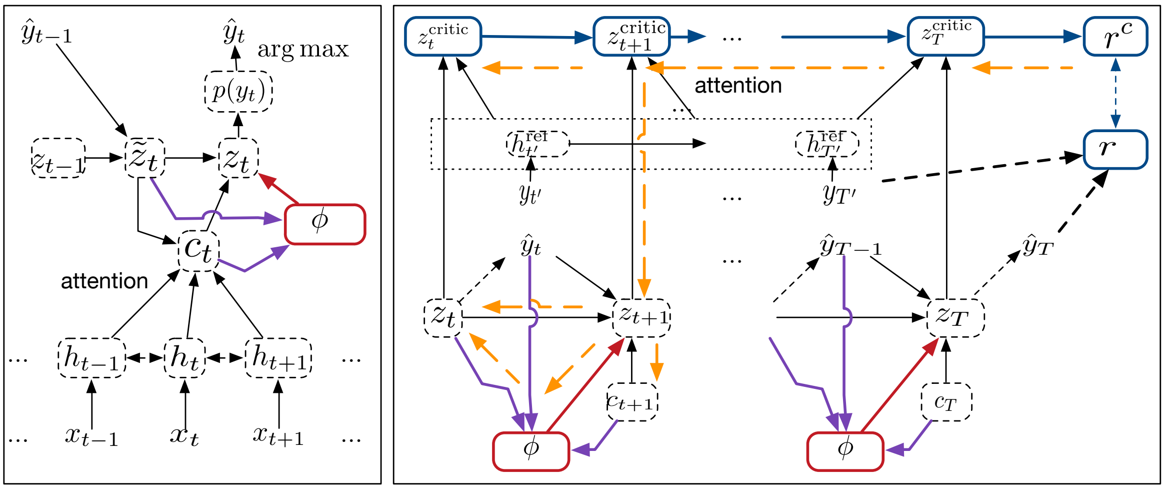

Figure 1: Graphical illustrations of the trainable greedy decoding. The left panel shows a single step of the actor interacting with the underlying neural translation model, and The right panel the interaction among the underlying neural translation system (dashed-border boxes), actor (red-border boxes), and critic (blue-border boxes). The solid arrows indicate the forward pass, and the dashed yellow arrows the actor's backward pass. The dotted-border box shows the use of a reference translation.

In this work, we propose to significantly extend NPAD by replacing the unstructured noise ϵ_t with a parametric function approximator, or an agent, π_ϕ. This agent takes as input the previous hidden state z_{t-1}, previously decoded word $\hat{y}_{t-1}$ and the time-dependent context vector $e_t(X; \theta_e)$ and outputs a real-valued vectorial action $a_t \in \mathbb{R}^{\dim(z_t)}$. Such an agent is trained such that greedy decoding with the agent finds a translation that maximizes any predefined, arbitrary decoding objective, while the underlying neural machine translation model is pretrained and fixed. Once the agent is trained, we generate a translation given a source sentence by greedy decoding however augmented with this agent. We call this decoding strategy *trainable greedy decoding*.

Related Work: Soothsayer prediction function Independently from and concurrently with our work here, Li et al. (2017) proposed, just two weeks earlier, to train a neural network that predicts an arbitrary decoding objective given a source sentence and a partial hypothesis, or a prefix of translation, and to use it as an auxiliary score in beam search. For training such a network, referred to as a Q network in their paper, they generate each training example by either running beam search or using a ground-truth translation (when appropriate) for each source sentence. This approach allows one to use an arbitrary decoding objective, but it still relies heavily on the log-probability of the underlying neural translation system in actual decoding. We expect a combination of these and our approaches may further improve decoding for neural machine translation in the future.

3.3 Learning and Challenges

While all the parameters—θ_g, θ_f and θ_e— of the underlying neural translation model are fixed, we only update the parameters ϕ of the agent π. This ensures the generality of the pretrained translation model, and allows us to train multiple trainable greedy decoding agents with different decoding objectives, maximizing the utility of a single trained translation model.

Let us denote by R our arbitrary decoding objective as a function that scores a translation generated from trainable greedy decoding. Then, our learning objective for trainable greedy decoding is

$$J^{\mathrm{A}}(\phi) = \mathbb{E}_{X \sim D}^{\hat{Y} = G_\pi(X)} \left[R(\hat{Y}) \right],$$

where we used $G_\pi(X)$ as a shorthand for trainable greedy decoding with an agent π.

There are two major challenges in learning an agent with such an objective. First, the decoding objective R may not be differentiable with respect to the agent. Especially because our goal is to accommodate an arbitrary decoding objective, this becomes a problem. For instance, BLEU, a standard quality metric in machine translation, is a piecewise linear function with zero derivatives almost everywhere. Second, the agent here is a real-valued, deterministic policy with a very high-dimensional action space (1000s of dimensions), which is well known to be difficult. In order to alleviate these difficulties, we propose to use a variant of the deterministic policy gradient algorithm (Silver et al., 2014; Lillicrap et al., 2015).

4 Deterministic Policy Gradient with Critic-Aware Actor Learning

4.1 Deterministic Policy Gradient for Trainable Greedy Decoding

It is highly unlikely for us to have access to the gradient of an arbitrary decoding objective R with respect to the agent π, or its parameters ϕ. Furthermore, we cannot estimate it stochastically because our policy π is defined to be deterministic without a predefined nor learned distribution over the action. Instead, following (Silver et al., 2014; Lillicrap et al., 2015), we use a parametric, differentiable approximator, called a critic R^c, for the non-differentiable objective R. We train the critic by minimizing

$$J^{\mathrm{C}}(\psi) = \mathbb{E}_{X \sim D}^{\hat{Y}=G_\pi(X)} \left[R^c_\psi(z_{1:T}) - R(\hat{Y}) \right]^2 .$$

The critic observes the state-action sequence of the agent π via the modified hidden states $(z_1, \ldots, z_T)$ of the recurrent network, and predicts the associated decoding objective. By minimizing the mean squared error above, we effectively encourage the critic to approximate the non-differentiable objective as closely as possible in the vicinity of the state-action sequence visited by the agent.

We implement the critic R^c as a recurrent network, similarly to the underlying neural machine translation system. This implies that we can compute the derivative of the predicted decoding objective with respect to the input, that is, the state-action sequence $z_{1:T}$, which allows us to update the actor π, or equivalently its parameters ϕ, to maximize the predicted decoding objective. Effectively we avoid the issue of non-differentiability of the original decoding objective by working with its proxy.

With the critic, the learning objective of the actor is now to maximize not the original decoding objective R but its proxy R^{C} such that

$$\hat{J}^{\mathrm{A}}(\phi) = \mathbb{E}_{X \sim D}^{\hat{Y}=G_\pi(X)} \left[R^{\mathrm{C}}(\hat{Y}) \right] .$$

Algorithm 1 Trainable Greedy Decoding

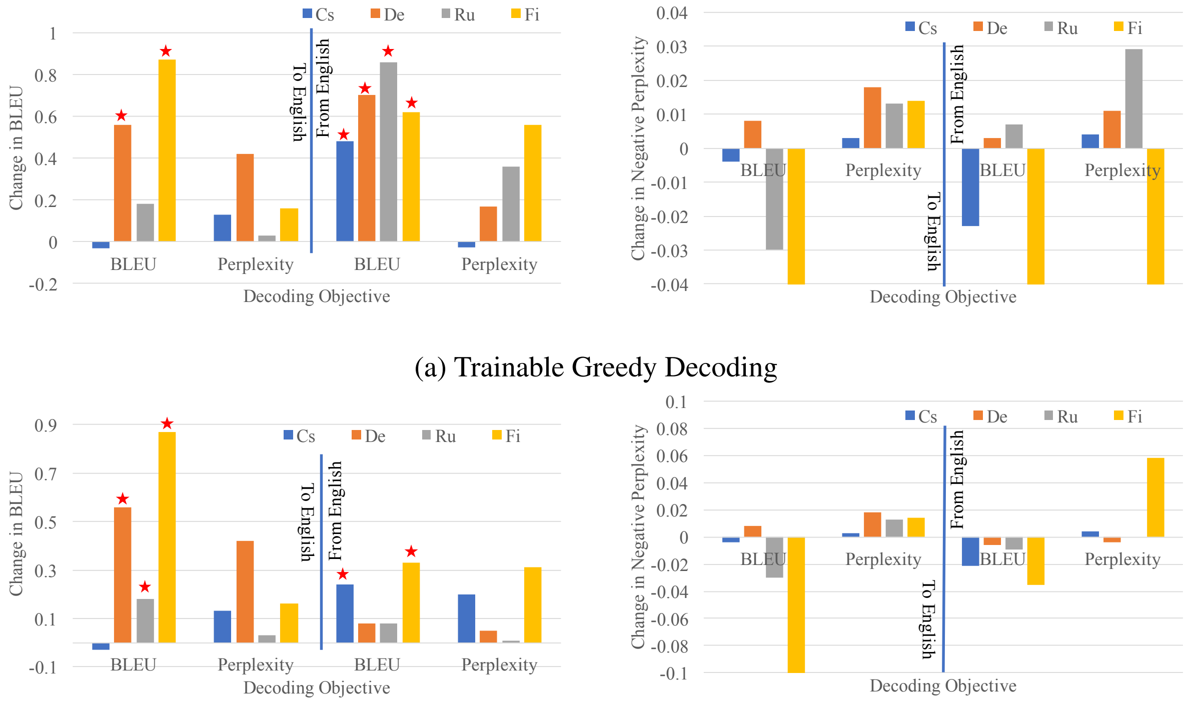
```
Require: NMT $\theta$, actor $\phi$, critic $\psi$, $N_c$, $N_a$, $S_c$, $S_a$, $\tau$
Train $\theta$ using MLE on training set $D$;
Initialize $\phi$ and $\psi$;
Shuffle $D$ twice into $D_\phi$ and $D_\psi$
while stopping criterion is not met do
    for $t = 1 : N_c$ do
        Draw a translation pair: $(X, Y) \sim D_\psi$;
        $r, r^c = $ DECODE$(S_c, X, Y, 1)$
        Update $\psi$ using $\nabla_\psi \sum_k (r^c_k - r_k)^2 / (S_c + 1)$
    for $t = 1 : N_a$ do
        Draw a translation pair: $(X, Y) \sim D_\phi$;
        $r, r^c = $ DECODE$(S_a, X, Y, 0)$
        Compute $w_k = \exp\left(-(r^c_k - r_k)^2 / \tau\right)$
        Compute $\tilde{w}_k = w_k / \sum_k w_k$
        Update $\phi$ using $-\sum_k (\tilde{w}_k \cdot \nabla_\phi r^c_k)$

Function: DECODE$(S, X, Y, c)$
$Y_s = \{\}, Z_s = \{\}, r = \{\}, r^c = \{\}$;
for $k = 1 : S$ do
    Sample noise $\epsilon \sim \mathcal{N}(0, \sigma^2)$ for each action;
    Greedy decoding $\hat{Y}^k = G_{\theta,\phi}(X)$ with $\epsilon$;
    Collect hidden states $z^k_{1:T}$ given $X$, $\hat{Y}$, $\theta$, $\phi$
    $Y_s \leftarrow Y_s \cup \{Y^k\}$
    $Z_s \leftarrow Z_s \cup \{z^k_{1:T}\}$
if $c = 1$ then
    Collect hidden states $z_{1:T}$ given $X$, $Y$, $\theta$
    $Y_s \leftarrow Y_s \cup \{Y\}$
    $Z_s \leftarrow Z_s \cup \{z_{1:T}\}$
for $\hat{Y}, Z \in Y_s, Z_s$ do
    Compute the critic output $r^c \leftarrow R^c_\psi(Z, \hat{Y})$
    Compute true reward $r \leftarrow R(Y, \hat{Y})$
return $r, r^c$
```

Unlike the original objective, this objective function is fully differentiable with respect to the agent π. We thus use a usual stochastic gradient descent algorithm to train the agent, while simultaneously training the critic. We do so by alternating between training the actor and critic. Note that we maximize the return of a full episode rather than the Q value, unlike usual approaches in reinforcement learning.

4.2 Critic-Aware Actor Learning

Challenges The most apparent challenge for training such a deterministic actor with a large action space is that most of action configurations will lead to zero return. It is also not trivial to devise an efficient exploration strategy with a deterministic actor with real-valued actions. This issue has however turned out to be less of a problem than in a usual reinforcement learning setting, as the state and action spaces are well structured thanks to pretraining by maximum likelihood learning. As observed by Cho (2016), any reasonable perturbation to the hidden state of the recurrent network generates a reasonable translation which would re-



(a) Trainable Greedy Decoding

(b) Beam Search + Trainable Greedy Decoding

Figure 2: The plots draw the improvements by the trainable greedy decoding on the test set. The x-axes correspond to the objectives used to train trainable greedy decoding, and the y-axes to the changes in the achieved objectives (BLEU for the figures on the left, and negative perplexity on the right.) The top row (a) shows the cases when the trainable greedy decoder is used on its own, and the bottom row (b) when it is used together with beam search. When training and evaluation are both done with BLEU, we test the statistical significance (Koehn, 2004), and we mark significant cases with red stars ($p < 0.05$.) The underlying neural machine translation models achieved the BLEU scores of 14.49/16.20 for En-Cs, 18.90/21.20 for Cs-En, 18.97/21.33 for En-De, 21.63/24.46 for De-En, 16.97/19.68 for En-Ru, 21.06/23.34 for Ru-En, 7.53/8.82 for En-Fi and 9.79/11.03 for Fi-En (greedy/beam).

ceive again a reasonable return.

Although this property of dense reward makes the problem of trainable greedy decoding more manageable, we have observed other issues during our preliminary experiment with the vanilla deterministic policy gradient. In order to avoid these issues that caused instability, we propose the following modifications to the vanilla algorithm.

Critic-Aware Actor Learning A major goal of the critic is not to estimate the return of a given episode, but to estimate the gradient of the return evaluated given an episode. In order to do so, the critic must be trained, or presented, with state-action sequences $z_{1:T'}$ similar though not identical to the state-action sequence generated by the current actor π. This is achieved, in our case, by injecting unstructured noise to the action at each time step, similar to (Heess et al., 2015):

$$\tilde{a}_t = \phi(z_t, a_{t-1}) + \sigma \cdot \epsilon, \tag{2}$$

where ϵ is a zero-mean, unit-variance normal variable. This noise injection procedure is mainly used when training the critic.

We have however observed that the quality of the reward and its gradient estimate of the critic is very noisy even when the critic was trained with this kind of noisy actor. This imperfection of the critic often led to the instability in training the actor in our preliminary experiments. In order to avoid this, we describe here a technique which we refer to as *critic-aware actor gradient estimation*.

Instead of using the point estimate $\frac{\partial R^c}{\partial \phi}$ of the gradient of the predicted objective with respect to the actor's parameters ϕ, we propose to use the expected gradient of the predicted objective with respect to the critic-aware distribution Q. That is,

$$\mathbb{E}_Q\left[\frac{\partial R^c_\psi}{\partial \phi}\right], \tag{3}$$

where we define the critic-aware distribution Q as

$$Q(\epsilon) \propto \exp(\underbrace{-(R^c_\psi - R)^2/\tau}_{\text{Critic-awareness}}) \exp(\underbrace{-\frac{\epsilon^2}{2\sigma^2}}_{\text{Locality}}). \tag{4}$$

This expectation allows us to incorporate the noisy, non-uniform nature of the critic's approximation of the objective by up-weighting the gradient computed at a point with a higher critic quality and down-weighting the gradient computed at a point with a lower critic quality. The first term in Q reflects this, while the second term ensures that our estimation is based on a small region around the state-action sequence generated by the current, noise-free actor π.

Since it is intractable to compute Eq. (3) exactly, we resort to importance sampling with the proposed distribution equal to the second term in Eq. (4). Then, our gradient estimate for the actor becomes the sum of the gradients from multiple realizations of the noisy actor in Eq. (2), where each gradient is weighted by the quality of the critic $\exp(-(R^c_\phi - R)^2/\tau)$. τ is a hyperparameter that controls the smoothness of the weights. We observed in our preliminary experiment that the use of this critic-aware actor learning significantly stabilizes general learning of both the actor and critic.

Reference Translations for Training the Critic In our setting of neural machine translation, we have access to a reference translation for each source sentence X, unlike in a usual setting of reinforcement learning. By force-feeding the reference translation into the underlying neural machine translation system (rather than feeding the decoded symbols), we can generate the reference state-action sequence. This sequence is much less correlated with those sequences generated by the actor, and facilitates computing a better estimate of the gradient w.r.t. the critic.

In Alg. 1, we present the complete algorithm. To make the description less cluttered, we only show the version of minibatch size = 1 which can be naturally extended. We also illustrate the proposed trainable greedy decoding and the proposed learning strategy in Fig. 1.

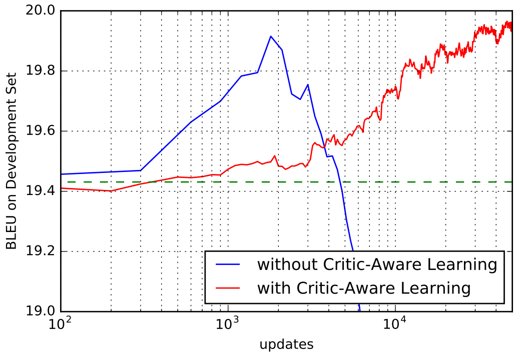


Figure 3: Comparison of greedy BLEU scores whether using the critic-aware exploration or not on Ru-En Dataset. The green line means the BLEU score achieved by greedy decoding from the underlying NMT model.

5 Experimental Settings

We empirically evaluate the proposed trainable greedy decoding on four language pairs – En-De, En-Ru, En-Cs and En-Fi – using a standard attention-based neural machine translation system (Bahdanau et al., 2014). We train underlying neural translation systems using the parallel corpora made available from WMT'15.[1] The same set of corpora are used for trainable greedy decoding as well. All the corpora are tokenized and segmented into subword symbols using byte-pair encoding (BPE) (Sennrich et al., 2015). We use sentences of length up to 50 subword symbols for MLE training and 200 symbols for trainable decoding. For validation and testing, we use newstest-2013 and newstest-2015, respectively.

5.1 Model Architectures and Learning

Underlying NMT Model For each language pair, we implement an attention-based neural machine translation model whose encoder and decoder recurrent networks have 1,028 gated recurrent units (GRU, Cho et al., 2014) each. Source and target symbols are projected into 512-dimensional embedding vectors. We trained each model for approximately 1.5 weeks using Adadelta (Zeiler, 2012).

Actor π We use a feedforward network with a single hidden layer as the actor. The input is a 2,056-dimensional vector which is the concatenation of the decoder hidden state and the time-dependent context vector from the attention mech-

anism, and it outputs a 1,028-dimensional action vector for the decoder. We use 32 units for the hidden layer with $\tanh$ activations.

Critic R^c The critic is implemented as a variant of an attention-based neural machine translation model that takes a reference translation as a source sentence and a state-action sequence from the actor as a target sentence. Both the size of GRU units and embedding vectors are the same with the underlying model. Unlike a usual neural machine translation system, the critic does not language-model the target sentence but simply outputs a scalar value to predict the true return. When we predict a bounded return, such as sentence BLEU, we use a sigmoid activation at the output. For other unbounded return like perplexity, we use a linear activation.

Learning We train the actor and critic simultaneously by alternating between updating the actor and critic. As the quality of the critic's approximation of the decoding objective has direct influence on the actor's learning, we make ten updates to the critic before each time we update the actor once. We use RMSProp (Tieleman and Hinton, 2012) with the initial learning rates of 2×10^{-6} and 2×10^{-4}, respectively, for the actor and critic.

We monitor the progress of learning by measuring the decoding objective on the validation set. After training, we pick the actor that results in the best decoding objective on the validation set, and test it on the test set.

Decoding Objectives For each neural machine translation model, pretrained using maximum likelihood criterion, we train two trainable greedy decoding actors. One actor is trained to maximize BLEU (or its smoothed version for sentence-level scoring (Lin and Och, 2004)) as its decoding objective, and the other to minimize perplexity (or equivalently the negative log-probability normalized by the length.)

We have chosen the first two decoding objectives for two purposes. First, we demonstrate that it is possible to build multiple trainable decoders with a single underlying model trained using maximum likelihood learning. Second, the comparison between these two objectives provides a glimpse into the relationship between BLEU (the most widely used automatic metric for evaluating translation systems) and log-likelihood (the most widely used learning criterion for neural machine translation).

Evaluation We test the trainable greedy decoder with both greedy decoding and beam search. Although our decoder is always trained with greedy decoding, beam search in practice can be used together with the actor of the trainable greedy decoder. Beam search is expected to work better especially when our training of the trainable greedy decoder is unlikely to be optimal. In both cases, we report both the perplexity and BLEU.

5.2 Results and Analysis

We present the improvements of BLEU and perplexity (or its negation) in Fig. 2 for all the language pair-directions. It is clear from these plots that the best result is achieved when the trainable greedy decoder was trained to maximize the target decoding objective. When the decoder was trained to maximize sentence-level BLEU, we see the improvement in BLEU but often the degradation in the perplexity (see the left plots in Fig. 2.) On the other hand, when the actor was trained to minimize the perplexity, we only see the improvement in perplexity (see the right plots in Fig. 2.) This confirms our earlier claim that it is necessary and desirable to tune for the target decoding objective regardless of what the underlying translation system was trained for, and strongly supports the proposed idea of trainable decoding.

The improvement from using the proposed trainable greedy decoding is smaller when used together with beam search, as seen in Fig. 2 (b). However, we still observe statistically significant improvement in terms of BLEU (marked with red stars.) This suggests a future direction in which we extend the proposed trainable greedy decoding to directly incorporate beam search into its training procedure to further improve the translation quality.

It is worthwhile to note that we achieved all of these improvements with negligible computational overhead. This is due to the fact that our actor is a very small, shallow neural network, and that the more complicated critic is thrown away after training. We suspect the effectiveness of such a small actor is due to the well-structured hidden state space of the underlying neural machine translation model which was trained with a large amount of parallel corpus. We believe this favourable computational complexity makes the proposed method suitable for production-grade neural machine translation (Wu et al., 2016; Crego et al., 2016).

Importance of Critic-Aware Actor Learning In Fig. 3, we show sample learning curves with and without the proposed critic-aware actor learning. Both curves were from the models trained under the same condition. Despite a slower start in the early stage of learning, we see that the critic-aware actor learning has greatly stabilized the learning progress. We emphasize that we would not have been able to train all these 16 actors without the proposed critic-aware actor learning.

Examples In Fig. 4, we present three examples from Ru-En. We defined the influence as the KL divergence between the conditional distributions without the trainable greedy decoding and with the trainable greedy decoding, assuming the fixed previous hidden state and target symbol. We colored a target word with magenta, when the influence of the trainable greedy decoding is large (> 0.001). Manual inspection of these examples as well as others has revealed that the trainable greedy decoder focuses on fixing prepositions and removing any unnecessary symbol generation. More in-depth analysis is however left as future work.

6 Conclusion

We proposed trainable greedy decoding as a way to learn a decoding algorithm for neural machine translation with an arbitrary decoding objective. The proposed trainable greedy decoder observes and manipulates the hidden state of a trained neural translation system, and is trained by a novel variant of deterministic policy gradient, called critic-aware actor learning. Our extensive experiments on eight language pair-directions and two objectives confirmed its validity and usefulness. The proposed trainable greedy decoding is a generic idea that can be applied to any recurrent language modeling, and we anticipate future research both on the fundamentals of the trainable decoding as well as on the applications to more diverse tasks such as image caption generating and dialogue modeling.

Abstract

Satirical news is considered to be entertainment, but it is potentially deceptive and harmful. Despite the embedded genre in the article, not everyone can recognize the satirical cues and therefore believe the news as true news. We observe that satirical cues are often reflected in certain paragraphs rather than the whole document. Existing works only consider document-level features to detect the satire, which could be limited. We consider paragraph-level linguistic features to unveil the satire by incorporating neural network and attention mechanism. We investigate the difference between paragraph-level features and document-level features, and analyze them on a large satirical news dataset. The evaluation shows that the proposed model detects satirical news effectively and reveals what features are important at which level.

1 Introduction

> *"When information is cheap, attention becomes expensive."* — James Gleick

Satirical news is considered to be entertainment. However, it is not easy to recognize the satire if the satirical cues are too subtle to be unmasked and the reader lacks the contextual or cultural background. The example illustrated in Table 1 is a piece of satirical news with subtle satirical cues.

Assuming readers interpret satirical news as true news, there is not much difference between satirical news and fake news in terms of the consequence, which may hurt the credibility of the media and the trust in the society. In fact, it is reported in *the Guardian* that people may believe satirical news and spread them to the public regardless of the ridiculous content[1]. It is also concluded that fake news is similar to satirical news via a thorough comparison among true news, fake news, and satirical news (Horne and Adali, 2017). This paper focuses on *satirical news detection* to ensure the trustworthiness of online news and prevent the spreading of potential misleading information.

> "Kids these days are done with stories where things happen," said CBC consultant and world's oldest child psychologist Obadiah Sugarman. "We'll finally be giving them the stiff Victorian morality that I assume is in vogue. Not to mention, doing a period piece is a great way to make sure white people are adequately represented on television."
> ...

Table 1: A paragraph of satirical news

Some works tackling fake news and misleading information favor to discover the truth (Xiao et al., 2016; Wan et al., 2016) through knowledge base (Dong et al., 2015) and truthfulness estimation (Ge et al., 2013). These approaches may not be feasible for satirical news because there is no ground-truth in the stories. Another track of works analyze social network activities (Zhao et al., 2015) to evaluate the spreading information (Gupta et al., 2012; Castillo et al., 2011). This could be ineffective for both fake news and satirical news because once they are distributed on the social network, the damage has been done. Finally, works evaluating culture difference (Pérez-Rosas and Mihalcea, 2014), psycholinguistic features (Ott et al., 2011), and writing styles (Feng et al., 2012) for deception detection are suitable for satirical news detection. These works consider features at document level, while we observe that satirical cues are usually located in certain para-

Copenhagen, Denmark, September 7–11, 2017.

graphs rather than the whole document. This indicates that many document level features may be superfluous and less effective.

To understand how paragraph-level features and document-level features are varied towards detection decision when only document level labels are available, we propose a 4-level neural network in a character-word-paragraph-document hierarchy and utilize attention mechanism (Bahdanau et al., 2014) to reveal their relative difference. We apply psycholinguistic features, writing stylistic features, structural features, and readability features to understand satire. The paragraph-level features are embedded into attention mechanism for selecting highly attended paragraphs, and the document-level features are incorporated for the final classification. This is the first work that unveils satirical cues between paragraph-level and document-level through neural networks to our knowledge.

We make the following contributions in our paper:

- We propose a 4-level hierarchical network for satirical news detection. The model detects satirical news effectively and incorporates attention mechanism to reveal paragraph-level satirical cues.

- We show that paragraph-level features are more important than document-level features in terms of the psycholinguistic feature, writing stylistic feature, and structural feature, while the readability feature is more important at the document level.

- We collect satirical news (16,000+) and true news (160,000+) from various sources and conduct extensive experiments on this corpus[2].

2 Related Work

We categorize related works into four categories: content-based detection for news genre, truth verification and truthfulness evaluation, deception detection, and identification of highly attended component using attention mechanism.

Content-based detection for news genre.Content-based methods are considerably effective to prevent satirical news from being recognized as true news and spreading through social media. Burfoot and Baldwin (2009) introduce headline features, profanity, and slang to embody satirical news. They consider absurdity as the major device in satirical news and model this feature by comparing entity combination in a given document with Google query results. Rubin et al. (2016) also consider absurdity but model it through unexpected new name entities. They introduce additional features including humor, grammar, negative affect, and punctuation to empower the detection. Besides satirical news, Chen et al. (2015) aim to detect click-baits, whose content exaggerates fact. Potthast et al. (2017) report a writing style analysis of hyperpartisan news. Barbieri et al. (2015) focus on multilingual tweets that advertise satirical news.

It is noteworthy that satirical news used for evaluation in above works are of limited quantity (around 200 articles). Diverse examples of satire may not be included as discussed by Rubin et al. (2016). This issue inspires us to collect more than 16,000 satirical news for our experiment.

Truth discovery and truthfulness evaluation. Although truth extraction from inconsistent sources (Ge et al., 2013; Wan et al., 2016; Li et al., 2016) and from conflicting sources (Yin et al., 2008; Li et al., 2014b), truth inference through knowledge base (Dong et al., 2015), and discovering evolving truth (Li et al., 2015) could help identify fact and detect fake news, they cannot favor much for satirical news as the story is entirely made up and the ground-truth is hardly found. Analyzing user activities (Farajtabar et al., 2017) and interactions (Castillo et al., 2011; Mukherjee and Weikum, 2015) to evaluate the credibility may not be appropriate for satirical news as it cannot prevent the spreading. Therefore, we utilize content-based features, including psycholinguistic features, writing stylistic features, structural features, and readability features, to address satirical news detection.

Deception detection. We believe satirical news and opinion spam share similar characteristics of writing fictitious and deceptive content, which can be identified via a psycholinguistic consideration (Mihalcea and Strapparava, 2009; Ott et al., 2011). Beyond that, both syntactic stylometry (Feng et al., 2012) and behavioral features (Mukherjee et al., 2013b) are effective for detecting deceptive reviews, while stylistic features are practical to deal with obfuscating and imitat-

[2] Please contact the first author to obtain the data

ing writings (Afroz et al., 2012). However, deceptive content varies among paragraphs in the same document, and so does satire. We focus on devising and evaluating paragraph-level features to reveal the satire in this work. We compare them with features at the document level, so we are able to tell what features are important at which level.

Identification of highly attended component using attention mechanism. Attention mechanism is widely applied in machine translation (Bahdanau et al., 2014), language inference (Rocktäschel et al., 2015), and question answering (Chen et al., 2016a). In addition, Yang et al. (2016b) propose hierarchical attention network to understand both attended words and sentences for sentiment classification. Chen et al. (2016b) enhance the attention with the support of user preference and product information to comprehend how user and product affect sentiment ratings. Due to the capability of attention mechanism, we employ the same strategy to show attended component for satirical news. Different from above works, we further evaluate linguistic features of highly attended paragraphs to analyze characteristics of satirical news, which has not been explored to our knowledge.

3 The Proposed Model

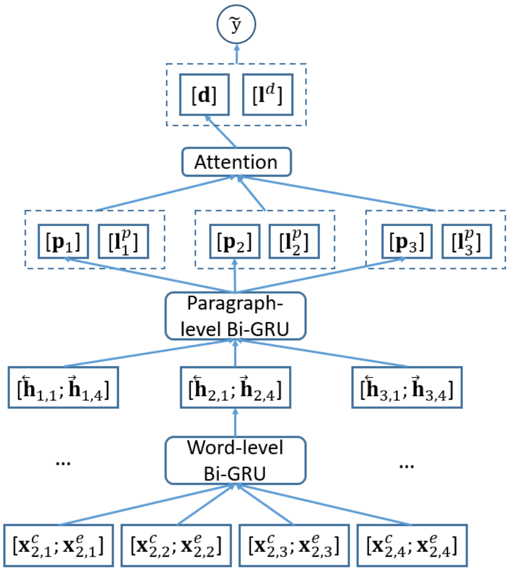
We first present our 4-level hierarchical neural network and explain how linguistic features can be embedded in the network to reveal the difference between paragraph level and document level. Then we describe the linguistic features.

3.1 The 4-Level Hierarchical Model

We build the model in a hierarchy of character-word-paragraph-document. The general overview of the model can be viewed in Figure 1 and the notations are listed in Table 2.

	Meaning
Superscript	Lowercase for notation purpose; $\top$ means matrix transpose.
Subscript	For index purpose.
Parameter	$\mathbf{W}$,$\mathbf{U}$,$\mathbf{w}^c$,$\mathbf{v}^a$: learnable weights; b: learnable bias.
Representation	$\mathbf{c}$: character; $\mathbf{x}$: word; $\mathbf{p}$: paragraph; $\mathbf{d}$: document; $\tilde{y}$: prediction $\mathbf{l}$: linguistic vector; y: label; $\mathbf{r}$: reset gate; $\mathbf{z}$: update gate; $\mathbf{h}$: hidden state for GRU; $\mathbf{u}$: hidden state for attention.

Table 2: Notations and meanings



$\tilde{y}$
$[\mathbf{d}]$
$[\mathbf{l}^d]$
Attention
$[\mathbf{p}_1]$
$[\mathbf{l}^p_1]$
$[\mathbf{p}_2]$
$[\mathbf{l}^p_2]$
$[\mathbf{p}_3]$
$[\mathbf{l}^p_3]$
Paragraph-level Bi-GRU
$[\overleftarrow{\mathbf{h}}_{1,1}; \overrightarrow{\mathbf{h}}_{1,4}]$
$[\overleftarrow{\mathbf{h}}_{2,1}; \overrightarrow{\mathbf{h}}_{2,4}]$
$[\overleftarrow{\mathbf{h}}_{3,1}; \overrightarrow{\mathbf{h}}_{3,4}]$
...
Word-level Bi-GRU
...
$[\mathbf{x}^c_{2,1}; \mathbf{x}^e_{2,1}]$
$[\mathbf{x}^c_{2,2}; \mathbf{x}^e_{2,2}]$
$[\mathbf{x}^c_{2,3}; \mathbf{x}^e_{2,3}]$
$[\mathbf{x}^c_{2,4}; \mathbf{x}^e_{2,4}]$

Figure 1: The overview of the proposed model. The document has 3 paragraphs and each paragraph contains 4 words. We omit character-level convolution neural network but leave $\mathbf{x}^c$ to symbolize the representation learned from it.

3.1.1 Character-Level Encoder

We use convolutional neural networks (CNN) to encode word representation from characters. CNN is effective in extracting morphological information and name entities (Ma and Hovy, 2016), both of which are common in news. Each word is presented as a sequence of n characters and each character is embedded into a low-dimension vector. The sequence of characters $\mathbf{c}$ is brought to the network. A convolution operation with a filter $\mathbf{w}^c$ is applied and moved along the sequence. Max pooling is performed to select the most important feature generated by the previous operation. The word representation $\mathbf{x}^c \in \mathbb{R}^f$ is generated with f filters.

3.1.2 Word-Level Encoder

Assume a sequence of words of paragraph i arrives at time t. The current word representation $\mathbf{x}_{i,t}$ concatenates $\mathbf{x}^c_{i,t}$ from character level with pretrained word embedding $\mathbf{x}^e_{i,t}$, as $\mathbf{x}_{i,t} = [\mathbf{x}^c_{i,t}; \mathbf{x}^e_{i,t}]$. Examples are given in Figure 1. We implement Gated Recurrent Unit (GRU) (Cho et al., 2014) rather than LSTM (Hochreiter and Schmidhuber, 1997) to encode the sequence because GRU has fewer parameters. The GRU adopts reset gate $\mathbf{r}_{i,t}$ and update gate $\mathbf{z}_{i,t}$ to control the information flow between the input $\mathbf{x}_{i,t}$ and the candidate state $\tilde{\mathbf{h}}_{i,t}$. The output hidden state $\mathbf{h}_{i,t}$ is computed by manipulating previous state $\mathbf{h}_{i,t-1}$ and the candidate state $\tilde{\mathbf{h}}_{i,t}$ regarding to $\mathbf{z}_{i,t}$ as in Equation 4, where $\odot$ denotes element-wise multiplication.

$$\mathbf{z}_{i,t} = \sigma(\mathbf{W}^z\mathbf{x}_{i,t} + \mathbf{U}^z\mathbf{h}_{i,t-1} + b^z) \tag{1}$$

$$\mathbf{r}_{i,t} = \sigma(\mathbf{W}^r\mathbf{x}_{i,t} + \mathbf{U}^r\mathbf{h}_{i,t-1} + b^r) \tag{2}$$

$$\tilde{\mathbf{h}}_{i,t} = \tanh(\mathbf{W}^h\mathbf{x}_{i,t} + \mathbf{r}_{i,t} \odot (\mathbf{U}^h\mathbf{h}_{i,t-1} + b^h)) \tag{3}$$

$$\mathbf{h}_{i,t} = (1 - \mathbf{z}_{i,t}) \odot \mathbf{h}_{i,t-1} + \mathbf{z}_{i,t} \odot \tilde{\mathbf{h}}_{i,t} \tag{4}$$

To learn a better representation from the past and the future, we use bidirectional-GRU (Bi-GRU) to read the sequence of words with forward $\overrightarrow{\text{GRU}}$ from $\mathbf{x}_{i,1}$ to $\mathbf{x}_{i,t}$, and backward $\overleftarrow{\text{GRU}}$ from $\mathbf{x}_{i,t}$ to $\mathbf{x}_{i,1}$. The final output of Bi-GRU concatenates the last state of $\overrightarrow{\text{GRU}}$ and $\overleftarrow{\text{GRU}}$, as $[\overrightarrow{\mathbf{h}}_{i,t}; \overleftarrow{\mathbf{h}}_{i,1}]$, to represent the ith paragraph.

3.1.3 Paragraph-Level Attention

We observe that not all paragraphs have satire and some of them are functional to make the article complete, so we incorporate attention mechanism to reveal which paragraphs contribute to decision making. Assuming a sequence of paragraph representations have been constructed from lower levels, another Bi-GRU is used to encode these representations to a series of new states $\mathbf{p}_{1:t}$, so the sequential orders are considered.

To decide how paragraphs should be attended, we calculate satirical degree α_i of paragraph i. We first convey $\mathbf{p}_i$ into hidden states $\mathbf{u}_i$ as in Equation 5. Then we product $\mathbf{u}_i$ with a learnable satire-aware vector $\mathbf{v}^a$ and feed the result into softmax function as in Equation 6. The final document representation $\mathbf{d}$ is computed as a weighted sum of α_i and $\mathbf{p}_i$.

$$\mathbf{u}_i = \tanh(\mathbf{W}^a\mathbf{p}_i + b^a) \tag{5}$$

$$\alpha_i = \frac{\exp(\mathbf{u}_i^\top\mathbf{v}^a)}{\sum_{j=0}^{t}\exp(\mathbf{u}_j^\top\mathbf{v}^a))} \tag{6}$$

$$\mathbf{d} = \sum_{i=0}^{t}\alpha_i\mathbf{p}_i \tag{7}$$

Linguistic features are leveraged to support attending satire paragraph. Besides $\mathbf{p}_i$, we represent paragraph i based on our linguistic feature set and transform it into a high-level feature vector $\mathbf{l}_i^p$ via multilayer perceptron (MLP). So $\mathbf{u}_i$ in Equation 5 is updated to:

$$\mathbf{u}_i = \tanh(\mathbf{W}^a\mathbf{p}_i + \mathbf{U}^a\mathbf{l}_i^p + b^a) \tag{8}$$

3.1.4 Document-Level Classification

Similar to the paragraph level, we represent document j based on our linguistic feature set and transform it into a high-level feature vector $\mathbf{l}_j^d$ via MLP. We concatenate $\mathbf{d}_j$ and $\mathbf{l}_j^d$ together for classification. Suppose $y_j \in (0, 1)$ is the label of the document j, the prediction $\tilde{y}_j$ and the loss function $\mathcal{L}$ over N documents are:

$$\tilde{y}_j = \text{sigmoid}(\mathbf{W}^d\mathbf{d}_j + \mathbf{U}^d\mathbf{l}_j^d + b^d) \tag{9}$$

$$\mathcal{L} = -\frac{1}{N}\sum_{j}^{N} y_j \log \tilde{y}_j + (1 - y_j)\log(1 - \tilde{y}_j) \tag{10}$$

3.2 Linguistic Features

Linguistic features have been successfully applied to expose differences between deceptive and genuine content, so we subsume most of the features in previous works. The idea of explaining fictitious content is extended here to reveal how satirical news differs from true news. We divide our linguistic features into four families and compute them separately for paragraph and document.

Psycholinguistic Features: Psychological differences are useful for our problem, because professional journalists tend to express opinion conservatively to avoid unnecessary arguments. On the contrary, satirical news includes aggressive language for the entertainment purpose. We additionally observe true news favors clarity and accuracy while satirical news is related to emotional cognition. To capture the above observations, we employ Linguistic Inquiry and Word Count (LIWC) (Pennebaker et al., 2007) as our psycholinguistic dictionary. Each category of LIWC is one independent feature and valued by its frequency[3].

Writing Stylistic Features: The relative distribution of part-of-speech (POS) tags reflects informative vs. imaginative writing, which contributes to detecting deceptions (Li et al., 2014a; Mukherjee et al., 2013a). We argue that the stories covered by satirical news are based on imagination. In addition, POS tags are hints of the underlying

[3] Total counts divided by total words.

	#Train	#Validation	#Test	#Para	#Sent	#Words	# Capitals	#Punc	#Digits
True	101,268	33,756	33,756	20±7.8	32±24	734±301	118±58	28±26	93±49
Satire	9,538	3,103	3,608	12±4.4	25±12	587±246	87±44	11±13	86±43

Table 3: The split and the description (mean and standard deviation) of the dataset. Para denotes paragraphs, sent denotes sentences, and punc denotes punctuations.

humor (Reyes et al., 2012), which is common in satirical news. So we utilize POS tags (Toutanova et al., 2003) to apprehend satire. Each tag is regarded as one independent feature and valued by its frequency.

Readability Features: We consider readability of genuine news would differ from satirical news because the former is written by professional journalists and tend to be clearer and more accurate, while satirical news packs numerous clauses to enrich the made-up story as introduced by Rubin et al. (2016). Different from their work, we use readability metrics, including Flesch Reading Ease (Kincaid et al., 1975), Gunning Fog Index (Gunning, 1952), Automated Readability Index (Senter and Smith, 1967), ColemanLiau Index (Coleman and Liau, 1975), and syllable count per word, as features.

Structural Features: To further reflect the structure of news articles, we examine the following features: word count, log word count, number of punctuations, number of digits, number of capital letters, and number of sentences.

4 Experiment and Evaluation

We report satirical news detection results and show high weighted word features. Then, we provide a thorough analysis between paragraph-level and document-level features. Finally, we visualize an example of satirical news article to demonstrate the effectiveness of our work.

4.1 Dataset

The satirical news is collected from 14 websites that explicitly declare they are offering satire, so the correct label can be guaranteed. We also notice websites that mix true news, fake news, and satirical news. We exclude these websites in this work because it requires experts to annotate the news articles.

We maintain each satire source in only one of the train/validation/test sets[4] as the cross-domain setting in (Li et al., 2014a). Otherwise, the problem may become writing pattern recognition or news site classification. We also combined different sources together[5] as a similar setting of leveraging multiple domains (Yang et al., 2016a). The true news is collected from major news outlets[6] and Google News using FLORIN (Liu et al., 2015). The satirical news in the corpus is significantly less than true news, reflecting an impressionistic view of the reality. We omit headline, creation time, and author information so this work concentrates on the satire in the article body. We realize the corpus may contain different degree of satire. Without the annotation, we only consider binary classification in this work and leave the degree estimation for the future. The split and the description of the dataset can be found in Table 3.

4.2 Implementation Detail

For SVM, we use the sklearn implementation[7]. We find that using linear kernel and setting "class_weight" to "balanced" mostly boost the result. We search soft-margin penalty "C" and find high results occur in range $[10^{-1}, 10^{-4}]$. We use the validation set to tune the model so selecting hyper-parameters is consistent with neural network based model.

For neural network based models, we use the Theano package (Bastien et al., 2012) for implementation. The lengths of words, paragraphs, and documents are fixed at 24, 128, and 16 with necessary padding or truncating. Stochastic Gradient Descent is used with initial learning rate of 0.3 and decay rate of 0.9. The training is early stopped if the F1 drops 5 times continuously. Word embeddings are initialized with 100-dimension Glove embeddings (Pennington et al., 2014). Character embeddings are randomly initialized with 30 dimensions. Specifically for the proposed model, the following hyper-parameters are estimated based on the validation set and used

[4] Train: Onion, the Spoof. Test: SatireWorld, Beaverton, Ossurworld. Validation: DailyCurrent, DailyReport, EnduringVision, Gomerblog, NationalReport, SatireTribune, SatireWire, Syruptrap, and UnconfirmedSource.

[5] The combination is chosen to ensure enough training examples and balanced validation/test sets.

Table 4: Satirical news detection results.

in the final test set. The dropout is applied with probability of 0.5. The size of the hidden states is set at 60. We use 30 filters with window size of 3 for convolution.

4.3 Performance of Satirical News Detection

We report accuracy, precision, recall, and F1 on the validation set and the test set. All metrics take satirical news as the positive class. Both paragraph-level and document-level linguistic features are scaled to have zero mean and unit variance, respectively. The compared methods include:

SVM word n-grams: Unigram and bigrams of the words as the baseline. We report 1,2-grams because it performs better than other n-grams.

SVM word n-grams + LF: 1,2-word grams plus linguistic features. We omit comparison with similar work (Ott et al., 2011) as their features are subsumed in ours.

SVM word + char n-grams: 1,2-word grams plus bigrams and trigrams of the characters.

SVM word + char n-grams + LF: All the proposed features are considered.

SVM Rubin et al. (2016): Unigram and bigrams tf-idf with satirical features as proposed in (Rubin et al., 2016). We compare with (Rubin et al., 2016) rather than (Burfoot and Baldwin, 2009) as the former claims a better result.

SVM Rubin et al. (2016) + char tf-idf + LF: Include all possible features.

Bi-GRU: Bi-GRU for document classification. The document representation is the average of the hidden state at every time-step.

SVM Doc2Vec: Unsupervised method learning distributed representation for documents (Le and Mikolov, 2014). The implementation is based on Gensim (Řehůřek and Sojka, 2010).

HAN: Hierarchical Attention Network (Yang et al., 2016b) for document classification with both word-level and sentence-level attention.

4LHN: 4-Level Hierarchical Network without any linguistic features.

4LHNP: 4-Level Hierarchical Network with Paragraph-level linguistic features.

4LHND: 4-Level Hierarchical Network with Document-level linguistic features.

4LHNPD: 4-Level Hierarchical Network with both Paragraph-level and Document-level linguistic features.

In Table 4, the performances on the test set are generally better than on the validation set due to the cross-domain setting. We also explored word-level attention (Yang et al., 2016b), but it performed 2% worse than 4LHN. The result of Doc2Vec is limited. We suspect the reason could be the high imbalanced dataset, as an unsupervised learning method for document representation heavily relies on the distribution of the document.

4.4 Word Level Analysis

True		Satire	
:	day	"	stated
video	said the	sources	press
but the	twitter	continued	reporter
in statement	told the	added	resident
com	pictured	washington dc	said that

Table 5: High weighted word-level features

We report high weighted word-grams in Table 5 based on the SVM model as incorporating word-level attention in our neural hierarchy model reduces the detection performance. According

Psycholinguistic Feature					Writing Stylistic Feature					Readability Feature				
Name	S.m	S.std	T.m	T.std	Name	S.m	S.std	T.m	T.std	Name	S.m	S.std	T.m	T.std
Human.P	.011	.021	.009	.023	**JJ.P**	.061	.045	.058	.046	**FRE.D**	58.4	12.2	56.0	10.1
Past.P	.034	.035	.040	.042	**PRP.P**	.054	.047	.044	.047	**CLI.D**	9.08	1.66	9.48	1.61
Self.P	.017	.032	.010	.027	**RB.P**	.051	.048	.045	.054	**FOG.D**	13.71	3.25	14.00	2.89
Funct.D	.453	.045	.437	.049	**VBN.P**	.021	.026	.024	.031	Structural Feature				
Social.P	.097	.067	.091	.073	**NN.D**	.273	.038	.300	.043	**Punc.P**	7.69	5.35	4.69	3.83
Leisure.P	.017	.027	.018	.032	**VBZ.P**	.019	.026	.021	.029	**Cap.P**	7.44	6.08	5.75	4.8
Hear.P	.011	.019	.012	.021	**CC.P**	.023	.024	.024	.026	**Digit.P**	0.97	2.40	1.39	3.00
Bio.P	.026	.035	.023	.036	**CD.P**	.013	.027	.024	.043	**LogWc.P**	3.69	0.71	3.39	0.53

Table 6: Comparing feature values within each category. P stands for paragraph level. D stands for document level. S stands for satirical news. T stands for true news. m stands for mean and std stands for standard deviation. FRE: Flesch Reading Ease, the lower the harder. CLI: ColemanLiau Index. FOG: Gunning Fog Index. Punc: punctuation. Cap: Capital letters. LogWc: Log Word count

to Table 5, we conclude satirical news mimics true news by using news related words, such as "stated" and "reporter". However, these words may be over used so they can be detected. True news may use other evidence to support the credibility, which explains "twitter", "com", "video", and "pictured". High weight of " : " indicates that true news uses colon to list items for clarity. High weight of " " " indicates that satirical news involves more conversation, which is consistent with our observation. The final interesting note is satirical news favors "washington dc". We suspect that satirical news mostly covers politic topics, or satire writers do not spend efforts on changing locations.

4.5 Analysis of Weighted Linguistic Features

We use 4LHNPD to compare paragraph-level and document-level features, as 4LHNPD leverages the two-level features into the same framework and yields the best result.

Because all linguistic features are leveraged into MLP with non-linear functions, it is hard to check which feature indicates satire. Alternatively, we define the importance of linguistic features by summing the absolute value of the weights if directly connected to the feature. For example, the importance I of feature k is given by $\mathrm{I}_k = \frac{1}{M}\sum_{m=0}^{M}|\mathbf{w}_{k,m}|$, where $\mathbf{w} \in \mathbb{R}^{K\times M}$ is the directly connected weight, K is the number of features, and M is the dimension of the output. This metric gives a general idea about how much does a feature contribute to the decision making.

We first report the scaled importance of the four linguistic feature sets by averaging the importance of individual linguistic features. Then we report individual important features within each set.

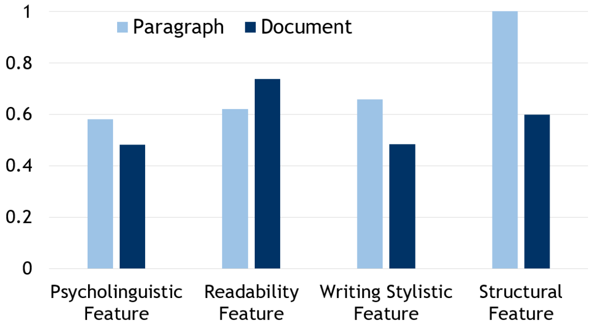

Figure 2: Comparing the importance of the four feature sets at paragraph level and document level.

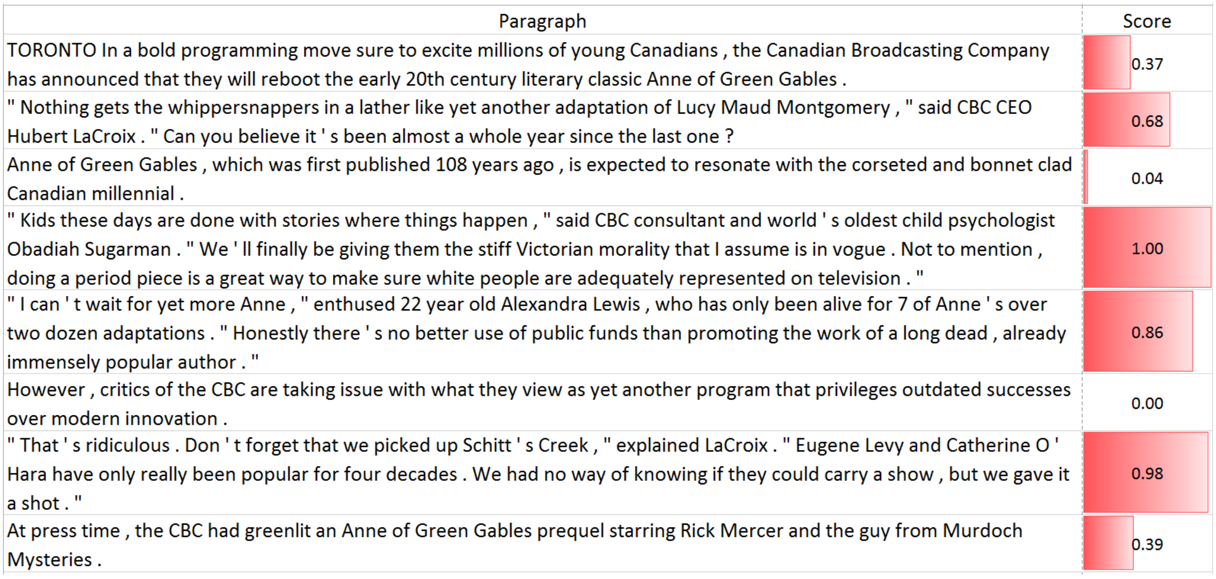
4.5.1 Comparing the Four Feature Sets

According to Figure 2, the importance of paragraph-level features is greater than document-level features except for the readability feature set. It is reasonable to use readability at the document level because readability features evaluate the understandability of a given text, which depends on the content and the presentation. The structural feature set is highly weighted for selecting attended paragraph, which inspires us to focus on individual features inside the structural feature set.

4.5.2 Comparing Individual Features

Within each set, we rank features based on the importance score and report their mean and standard deviation before being scaled in Table 6. At paragraph level, we use top three attended paragraphs for calculating. The respective p-values of all features in the table are less than 0.01 based on the t-test, indicating satirical news is statistically significantly different from true news.

Comparing Table 6 and Table 3, we find that the word count, capital letters, and punctuations in true news are larger than in satirical news at the document level, while at paragraph level these



Paragraph	Score
TORONTO In a bold programming move sure to excite millions of young Canadians , the Canadian Broadcasting Company has announced that they will reboot the early 20th century literary classic Anne of Green Gables .	0.37
" Nothing gets the whippersnappers in a lather like yet another adaptation of Lucy Maud Montgomery , " said CBC CEO Hubert LaCroix . " Can you believe it ' s been almost a whole year since the last one ?	0.68
Anne of Green Gables , which was first published 108 years ago , is expected to resonate with the corseted and bonnet clad Canadian millennial .	0.04
" Kids these days are done with stories where things happen , " said CBC consultant and world ' s oldest child psychologist Obadiah Sugarman . " We ' ll finally be giving them the stiff Victorian morality that I assume is in vogue . Not to mention , doing a period piece is a great way to make sure white people are adequately represented on television . "	1.00
" I can ' t wait for yet more Anne , " enthused 22 year old Alexandra Lewis , who has only been alive for 7 of Anne ' s over two dozen adaptations . " Honestly there ' s no better use of public funds than promoting the work of a long dead , already immensely popular author . "	0.86
However , critics of the CBC are taking issue with what they view as yet another program that privileges outdated successes over modern innovation .	0.00
" That ' s ridiculous . Don ' t forget that we picked up Schitt ' s Creek , " explained LaCroix . " Eugene Levy and Catherine O ' Hara have only really been popular for four decades . We had no way of knowing if they could carry a show , but we gave it a shot . "	0.98
At press time , the CBC had greenlit an Anne of Green Gables prequel starring Rick Mercer and the guy from Murdoch Mysteries .	0.39

Figure 3: An example of attended paragraphs.

features in true news are less than in satirical news. This indicates satire paragraph could be more complex locally. It also could be referred as "sentence complexity", that *"satirical articles tend to pack a great number of clauses into a sentence for comedic effect"* (Rubin et al., 2016). Accordingly, we hypothesize top complex paragraphs could represent the entire satire document for classification, which we leave for future examination.

In Table 6, psycholinguistic feature "Humans" is more related to emotional writing than control writing (Pennebaker et al., 2007), which indicates satirical news is emotional and unprofessional compared to true news. The same reason also applies to "Social" and "Leisure", where the former implies emotional and the latter implies control writing. The "Past" and "VBN" both have higher frequencies in true news, which can be explained by the fact that true news covers what happened. A similar reason that true news reports what happened to others explains a low "Self" and a high "VBZ" in true news.

For writing stylistic features, it is suggested that informative writing has more nouns, adjectives, prepositions and coordinating conjunctions, while imaginative writing has more verbs, adverbs, pronouns, and pre-determiners (Rayson et al., 2001). This explains higher frequencies of "RB" and "PRP" in satirical news, and higher frequency of "NN" and "CC" in true news. One exception is "JJ", adjectives, which receives the highest weight in this feature set and indicates a higher frequency in satirical news. We suspect adjective could also be related to emotional writing, but more experiments are required.

Readability suggests satirical news is easier to be understood. Considering satirical news is also deceptive (as the story is not true), this is consistent with works (Frank et al., 2008; Afroz et al., 2012) showing deceptive writings are more easily comprehended than genuine writings. Finally, true news has more digits and a higher "CD"(Cardinal number) frequency, even at the paragraph level, because they tend to be clear and accurate.

4.6 Visualization of Attended Paragraph

To explore the attention, we sample one example in the validation set and present it in Figure 3. The value at the right represents the scaled attention score. The high attended paragraphs are longer and have more capital letters as they are referring different entities. They have more double quotes, as multiple conversations are involved.

Moreover, we subjectively feel the attended paragraph with score 0.98 has a sense of humor while the paragraph with score 0.86 has a sense of sarcasm, which are common in satire. The paragraph with score 1.0 presents controversial topics, which could be misleading if the reader cannot understand the satire. This is what we expect from the attention mechanism. Based on the visualization, we also feel this work could be generalized to detect figurative languages.

5 Conclusion

In this paper, we proposed a 4-level hierarchical network and utilized attention mechanism to understand satire at both paragraph level and document level. The evaluation suggests readability features support the final classification while psycholinguistic features, writing stylistic features, and structural features are beneficial at the paragraph level. In addition, although satirical news is shorter than true news at the document level, we find satirical news generally contain paragraphs which are more complex than true news at the paragraph level. The analysis of individual features reveals that the writing of satirical news tends to be emotional and imaginative.

We will investigate efforts to model satire at the paragraph level following our conclusion and theoretical backgrounds, such as (Ermida, 2012). We plan to go beyond the binary classification and explore satire degree estimation. We will generalize our approach to reveal characteristics of figurative language (Joshi et al., 2016), where different paragraphs or sentences may reflect different degrees of sarcasm, irony, and humor.

Abstract

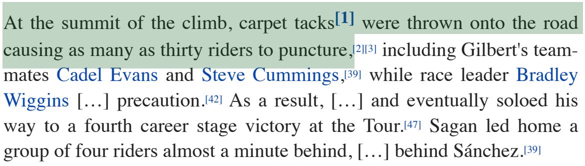
Verifiability is one of the core editing principles in Wikipedia, editors being encouraged to provide citations for the added content. For a Wikipedia article, determining the *citation span* of a citation, i.e. what content is covered by a citation, is important as it helps decide for which content citations are still missing.

We are the first to address the problem of determining the *citation span* in Wikipedia articles. We approach this problem by classifying which textual fragments in an article are covered by a citation. We propose a sequence classification approach where for a paragraph and a citation, we determine the citation span at a fine-grained level.

We provide a thorough experimental evaluation and compare our approach against baselines adopted from the scientific domain, where we show improvement for all evaluation metrics.

1 Introduction

Citations uphold the crucial policy of *verifiability* in Wikipedia. This policy requires Wikipedia contributors to support their additions with citations from authoritative external sources (web, news, journal etc.). In particular, it states that *"articles should be based on reliable, third-party, published sources with a reputation for fact-checking and accuracy"*[1]. Not only are citations essential in maintaining reliability, neutrality and authoritative assessment of content in such a collaboratively edited platform; but lack of citations are essential signals for core editors for unreliability checks.



At the summit of the climb, carpet tacks[1] were thrown onto the road causing as many as thirty riders to puncture,[2][3] including Gilbert's teammates Cadel Evans and Steve Cummings,[39] while race leader Bradley Wiggins [...] precaution.[42] As a result, [...] and eventually soloed his way to a fourth career stage victory at the Tour.[47] Sagan led home a group of four riders almost a minute behind, [...] behind Sánchez.[39]

Figure 1: Sub-sentence level span for citation [1] in a citing paragraph in a Wikipedia article.

However, there are two problems when it comes to citing facts in Wikipedia. First, there is a long tail of Wikipedia pages where citations are missing and hence facts might be unverified. Second, citations might have different span *granularities*, i.e., the text encoding the fact(s), for which a citation is intended, might span less than a sentence (see Figure 1) to multiple sentences. We denote the different *pieces of text* which contain a citation marker as *fact statements* or simply *statements*. For example, Table 1 shows different *statements* for several citations. The aim of this work is to automatically and accurately determine *citation spans* in order to improve coverage (Fetahu et al., 2015b, 2016) and to assist editors in verifying citation quality at a fine-grained level.

Earlier work on span determination is mostly concerned with scientific texts (O'Connor, 1982; Kaplan et al., 2016), operates at sentence level and exploits explicit authoring cues specific to scientific text. Although Wikipedia has well formed text, it does not follow explicit scientific guidelines for placing citations. Moreover, most statements can only be inferred from the citation text.

In this work, we operate at a sub-sentence level, loosely referred to as text fragments, and take a sequence prediction approach using a *linear chain CRF* (Lafferty et al., 2001). We limit our work to citations referring to *web* and *news* sources, as

Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

they are accessible online and present the most prominent sources in Wikipedia (Fetahu et al., 2015a). By using recent work on moving window language models (Taneva and Weikum, 2013) and the structure of the paragraph that includes a citation, we classify sequences of text fragments as text that belong to a given citation. We are able to tackle all citation span cases as shown in Table 1.

`sub sentence`	Obama was born on August 4, 1961$^{[c_1]}$, at Kapi'olani Maternity $\cdots$ Honolulu$^{[c_2]}$; he is the first $\cdots$ been born in Hawaii.$^{[c_3]}$.
`sentence`	He was reelected to the Illinois Senate in 1998, $\cdots$ in 2002.$^{[c_1]}$
`multi sentence`	On May 25, 2011, Obama $\cdots$ to address $\cdots$ UK Parliament in Westminster Hall, London. This was $\cdots$ Charles de Gaulle $\cdots$ and Pope Benedict XVI.$^{[c_1]}$

Table 1: Varying degrees of citation span granularity in Wikipedia text.

2 Problem Definition and Terminology

In this section, we describe the terminology and define the problem of determining the *citation span* in text in Wikipedia articles.

Terminology. We consider Wikipedia articles $W = \{e_1, \ldots, e_n\}$ from a Wikipedia snapshot. We distinguish *citations* to *external references* in text and denote them with $\langle p_k, c_i \rangle$, where c_i represents a citation which occurs in paragraph p_k with positional index k in an entity $e \in W$. We will refer to p_k as the *citing paragraph*. Furthermore, with *citing sentence* we refer to the sentence in $s \in p_k$, which contains c_i. Note that p_k can have more than one citation as shown in Table 1.

Problem Definition. The task of determining the *citation span* for a citation c and a paragraph p, respectively $\langle p, c \rangle$ (or simply p_c), is subject to the citing paragraph and the citation content. In particular, we refer with *citation span* to the *textual fragments* from p which are covered by c. The fragments correspond to the sequence of *sub-sentences* $\mathcal{S}(p) = \langle \delta_1^1, \delta_1^2, \ldots, \delta_1^k, \ldots, \delta_n^m \rangle$. We obtain the sequence of sub-sentences from p by splitting the sentences into sub-sentences or text fragments based on the following punctuation delimiters $(\{,!;:?\})$. These delimitors do not always provide a perfect semantic segmentation of sentences into facts. A more involved approach could be taken akin to work in text summarization, such as Zhou and Hovy (Zhou and Hovy, 2006) or (Nenkova et al., 2007) who consider *summary units* for a similar purpose.

Formally, we define the *citation span* in Equation 4 as the function of finding the subset $\mathcal{S}' \subseteq \mathcal{S}$ where the fragments in $\mathcal{S}'$ are covered by c.

$$\varphi(p, c) \rightarrow \mathcal{S}' \subseteq \mathcal{S}, \quad s.t. \;\; \delta \in \mathcal{S}' \wedge c \vdash \delta \qquad (1)$$

where $c \vdash \delta$ states that δ is covered in c.

3 Related Work

Scientific Text. One of the first attempts to determine the citation span in text (O'Connor, 1982) was carried out in the context of document retrieval. The citing statements from a document were used as an index to retrieve the *cited* document. The citing statements are extracted based on heuristics starting from the citing sentence and are expanded with sentences in a window of +/-2 sentences, depending on them containing cue words like *'this', 'these',... 'above-mentioned'*. We consider the approach in (O'Connor, 1982) as a baseline.

Kaplan et al. (2016) proposed the task of determining the *citation block* based on a set of *textual coherence* features (e.g. grammatical or lexical coherence). The citation block *starts* from the citing sentence, with succeeding sentences classified (through SVMs or CRFs) according to whether they belong to the block. Abu-Jbara and Radev (2012) determine the citation block by first segmenting the sentences and then classifying individual words as being *inside/outside* the citation. Finally, the segment is classified depending on the word labels (majority of words being inside, at least one, or all of them). This approach is not applicable in our case due to the fact that words in Wikipedia text are not domain or genre-specific as one expects in scientific text, and as such their classification does not work.

Citations in IR. The importance of determining the citation span has been acknowledged in the field of Information Retrieval (IR). The focus is on building citation indexes (Garfield, 1955) and improving the retrieval of scientific articles (Ritchie et al., 2008, 2006). Citing sentences on a fixed window size are used to index documents and aid the retrieval process.

Summarization. Citations have been successfully employed to generate summaries of scientific articles (Qazvinian and Radev, 2008; Elkiss et al., 2008). In all cases, citing statements are either extracted manually or via heuristics such as extracting only citing sentences. Similarly (Nanba and Okumura, 1999) expand the summaries in addition to the citing sentence based on cue words (e.g. *'In this', 'However'* etc.). The work in (Qazvinian and Radev, 2010) goes one step beyond and considers sentences which do not *explicitly* cite another article. The task is to assign a binary label to a sentence, indicating whether it contains context for a cited paper. We use this approach as one of our competitors. Again, the premise is that citations are marked explicitly and additional citing sentences are found dependent on them.

Comparison to our work. The language style and the composition of citations in Wikipedia and in scientific text differ significantly. Citations are *explicit* in scientific text (e.g. *author names*) and are usually the first word in a sentence (Abu-Jbara and Radev, 2012). In Wikipedia, citations are *implicit* (see Table 1) and there are no cue words in text which link to the provided citations. Therefore, the proposed methodologies and features from the scientific domain do not perform optimally in our case.

Both (Qazvinian and Radev, 2010) and (O'Connor, 1982) work at the sentence level. As, in Wikipedia, citation span detection needs to be performed at the sub-sentence level (see Table 1), their method introduces erroneous spans as we will show in our evaluation.

Related to our problem is the work on addressing quotation attribution. Pareti et al. (2013) propose an approach for *direct* and *indirect* quotation attribution. The task is mostly based on lexical cues and specific *reporting verbs* that are the signal for the majority of direct quotations. However, in the case of quotation attribution the task is to find the *source, cue*, and *content* of the quotation, whereas in our case, for a given citing paragraph and reference we simply assess which text fragment is covered by the reference. We also do normally not have access to specific lexical links between the citation and its citation span.

4 Citation Span Approach

We approach the problem of citation span detection in Wikipedia as a *sequence classification* problem. For a citation c and a citing paragraph p, we chunk the paragraph into textual fragments at the *sub-sentence* granularity, shown in Equation 4.

Figure 2 shows an overview of the sequence classification of textual fragments. We use a *linear chain CRF* (Lafferty et al., 2001), where for any fragment δ we predict the label corresponding to a random variable $\mathbf{y}$ which is either *'covered'* or *'not-covered'*. We opt for CRFs since we can encode global dependencies between the text fragments and the actual citation, thus, ensuring the coherence and accuracy of the predicted labels.

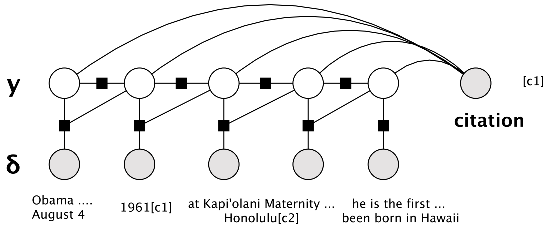

Figure 2: Linear chain CRF representing the sequence of text fragments in a paragraph. In the factors we encode the fitness to the given citation.

We now describe the features we compute for the factors $\Psi(y_i, y_{i-1}, \delta_i)$ for a fragment δ_i w.r.t the citation c. We determine the fitness of δ_i holding true or being covered by c. We denote with f_k the features for the factors $\Psi_i(y_i, y_{i-1}, \delta_i)$ for sequence δ_i for the linear-chain CRF in Figure 2.

4.1 Structural Features

An important aspect to consider for citation span detection is the structure of the citing paragraph, and correspondingly its sentences. For a textual fragment δ, we extract the following structural features shown in Table 2.

factor	description
$f_i^{c'}$	presence of other citations in δ_i where $c' \neq c$
$f^{\#s}$	the number of sentences in p
$f_i^{\lvert\delta_i\rvert}$	the length in terms of characters of the sub-sequence
f_i^{s}	check if δ_i is in the same sentence as the citation c
$f_i^{s \neq s'}$	check if δ_i is in the same sentence as δ_{i-1}
f_i^{c}	the distance of fragment δ_i to the fragment which contains citation c

Table 2: Structural features for a fragment δ_i.

From the features in Table 2, we highlight f_i^c which specifies the distance of δ to the fragment that cites c. The closer a fragment is to the citation the higher the likelihood of it being covered in c. In Wikipedia, depending on the citation and the paragraph length, the validity of a citation is densely concentrated in its nearby sub-sentences (preceding and succeeding).

Furthermore, the features $f^{\#s}$ and f_i^s (the number of sentences in p together with the feature considering if δ is in the same sentence as c) are strong indicators for accurate prediction of the label of δ. That is, it is more likely for a fragment δ to be covered by the citation if it appears in the same sentence or sentences nearby to the citation marker.

However, as shown in Table 1 there are three main citation span groups, and as such relying only on the structure of the citing paragraph does not yield optimal results. Hence, in the next group we consider features that tie the individual fragments in the citing paragraph with the citation as shown in Figure 2.

4.2 Citation Features

A core indicator as to whether a fragment δ is covered by c is based on the lexical similarity between δ and the content in c. We gather such evidence by computing two similarity measures. We compute the features f_i^{LM} and f_i^J between δ and paragraphs in the citation content c.

The first measure, f_i^{LM}, corresponds to a moving language window proposed in (Taneva and Weikum, 2013). In this case, for each word in either a paragraph in the citation c or the sequence δ, we associate a language model M_{w_i} based on its context $\phi(w_i) = \{w_{i-3}, w_{i-2}, w_{i-1}, w_i, w_{i+1}, w_{i+2}, w_{i+3}\}$ with a window of +/- 3 words. The parameters for the model M_{w_i} are estimated as in Equation 2 for all the words in the context $\phi(w_i)$ and their frequencies denoted with tf. With M_δ and M_p we denote the overall models as estimated in Equation 2 for the words in the respective fragments.

$$P(w|M_{w_i}) = \frac{tf_{w,\phi(w_i)}}{\sum_{w' \in \phi(w_i)} tf_{w',\phi(w_i)}} \tag{2}$$

Finally, we compute the similarity of each word in $w \in \delta$ against the language model of paragraph $p \in c$ in Equation 3, which corresponds to the Kullback-Leibler divergence score.

$$f_i^{LM} = \min_{p \in c} \left[- \sum_{w \in \delta} P(w|M_\delta) \log \frac{P(w|M_\delta)}{P(w|M_p)} \right] \tag{3}$$

The intuition behind f_i^{LM} is that for the fragments δ we take into account the word similarity and the similarity in the context they appear in w.r.t a paragraph in a citation. In this way, we ensure that the similarity is not by chance but is supported by the context in which the word appears. Finally, another advantage of this model is that we localize the paragraphs in c which provide evidence for δ.

As an additional feature we compute f_i^J which corresponds to the maximal *jaccard* similarity between δ_i and paragraphs $p \in c$.

Finally, as we will show in our experimental evaluation in Section 5, there is a high correlation between the citation span length and the length of citation content in terms of sentences. Hence, we add as an additional feature f^c the number of sentences in c.

4.3 Discourse Features

Sentences and fragments within a sentence can be tied together by discourse relations. We annotate sentences with explicit discourse relations based on an approach proposed in (Pitler and Nenkova, 2009), using discourse connectives as cues. The explicit discourse relations belong to one of the following: *temporal, contingency, expansion, comparison*.

After extracting a discourse connective in a sentence, we determine by its position to which fragment it belongs and mark the fragment accordingly. We denote with f_i^{disc} the discourse feature for the fragment δ_i.[2]

4.4 Temporal Features

An important aspect that we consider here is the temporal difference between two consecutive fragments δ_i and δ_{i-1}. If there exists a temporal date expression in δ_i and δ_{i-1} and they point to different time-points, this presents an indicator on the transitioning between the states y_i and y_{i-1}. That is, there is a higher likelihood of changing the state in the sequence $\mathcal{S}$ for the labels y_i and y_{i-1}.

We compute the temporal feature $f_i^{\lambda(i,i-1)}$,indicating the difference in *days* between any two temporal expression extracted from δ_i and δ_{i-1}. We extract the temporal expression through a set of hand-crafted regular expressions. We use the following expressions: (1) `DD Month YYYY`, (2) `DD MM YYYY`, (3)

[2] Note that, although discourse relations hold between at least two fragments or sentences, we only mark the individual fragment in which the connective occurs with the discourse relation type.

type	*avg.* $|s|$	*avg.* $|\delta|$	*avg 'covered'*
news	7.76	22.55	0.28
web	8.67	23.07	0.30

Table 3: Dataset statistics for citing paragraphs, distinguishing between *web* and *news* references, showing the average number of sentences, fragments, and covered fragments.

`MM DD YY(YY)`, (4) `YYYY`, with delimiters (whitespace, '-', '.').

5 Experimental Setup

We now outline the experimental setup for evaluating the citation span approach and the competitors for this task. The data and the proposed approaches are made available at the paper URL[3].

5.1 Dataset

We evaluate the citation span approaches on a random sample of Wikipedia entities (snapshot of 20/11/2016). For the sampling process, we first group entities based on the number of *web* or *news* citations.[4]). We then sample from the specific groups. This is due to the inherent differences in citation spans for entities with different numbers of citations. For instance, entities with a high number of citations tend to have shorter spans per citation. Figure 3 shows the distribution of entities from the different groups. From each sampled entity, we extract all *citing paragraphs* that contain either a *web* or *news* citation. Our sample consists of 509 citing paragraphs from 134 entities.

Furthermore, since a paragraph may have more than one citation, in our sampled citing paragraphs, we have an average of 4.4 citations per paragraph, which finally resulted in 408 unique paragraphs. Table 3 shows the stats of the dataset.

5.2 Ground Truth

Setup. For the ground truth, the citation span of c in paragraph p was manually determined by labeling each fragment in p with the binary label *covered* or *not-covered*.

We set strict guidelines that help us generate reliable ground-truth annotations. We follow two main guidelines: (i) requirement to read and comprehend the content in c, and (ii) matching of the textual fragments from p as either being supported *explicitly* or *implicitly* in c.[5]

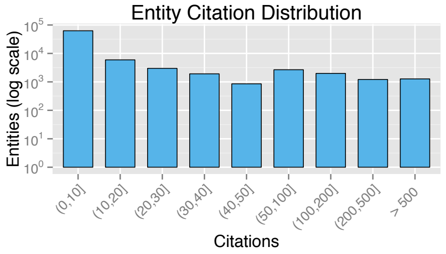

Figure 3: Entity distribution based on the number of news citations.

The entire dataset was carefully annotated by the first author. Later, a second annotator annotated a 10% sample of the dataset with an inter-rater agreement of $\kappa = .84$. We chose not to use crowd-sourcing as the task is very complex and hard to divide into small independent tasks. Since the task requires reading and comprehending the entire content in c and p, it takes on average up to 2.4 minutes to perform the evaluation for a single item. In future, it would be worthwhile to conduct more large-scale annotation exercises.

Citation Span Stats. Following the definition in Equation 4, we determine the citation span at the sub-sentence granularity level. Table 4 shows the distribution of citations falling into the specific spans for the citing paragraphs. We note that the majority of citations have a span between half a sentence and up to a sentence, yet, the remainder of more than 20% of citation span across multiple sentences in such paragraphs.

We define the citation span as the ratio of sub-sentences which are covered by a given citation over the total number of sub-sentences in the sentence, consequentially in the citing paragraph. That is, a citation is considered to have a span of one sentence if it covers all its sub-sentences.

$$span(c, p) = \sum_{s \in p} \frac{\#\delta^s \in \mathcal{S}'}{\#\delta^s} \tag{4}$$

where δ^s represents a sequence in sentence $s \in p$, which are part of the the ground-truth.

In Figure 4, we analyze a possible factor in the variance of the citation span. It is evident that for longer cited documents the span increases. This is

[3] `http://l3s.de/~fetahu/emnlp17/`

[4] Wikipedia has an internal categorization of citations based on the reference they point to.

[5] We excluded cases where the citation is not appropriate for the paragraph at all. This is, for example, the case when the language of c is not English.

	total	$\leq .5$	$(.5, 1]$	$(1, 2]$	$(2, 5]$	> 5
news	318	35	201	54	22	6
web	191	13	121	27	25	6

Table 4: Citation span distribution based on the number of sub-sentences in the citing paragraph.

intuitive since such documents carry more information and consequentially their span in the citing paragraphs can be larger. An example is the Wikipedia article `2008 US Open (tennis)` which has a citing paragraph with a citation span of 7 sentences for an article of 30k characters long[6]. We encoded this in the *citation* features f^c.

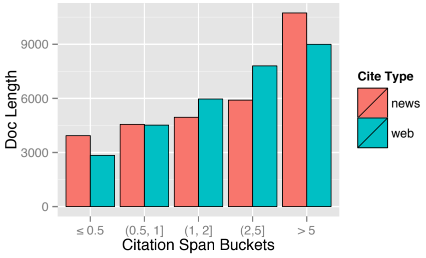

Figure 4: Average document length for the different span buckets for citation types *web* and *news*.

Additionally, within the different citation spans we analyze how many of them contain *skips* for two cases: (i) skip a fragment within a sentence, and (ii) skip sentences in p. The results for both cases are presented in Table 5.

span	*news*		*web*	
	skip δ	*skip* s	*skip* δ	*skip* s
≤ 0.5	6%	-	-	-
$(0.5, 1]$	-	-	-	1%
$(1, 2]$	-	8%	-	19%
$(2, 5]$	5%	18%	-	21%
> 5	-	20%	-	67%

Table 5: The percentage of citations in a span with *fragment skips* and *sentence skips*.

From the results in Table 4 and 5 we see that simple heuristics on selecting complete sentences or selecting consecutive sequences do not account for the different citation span cases and skips at the sentence and paragraph level. This leads to suboptimal results and introduces erroneous spans. Furthermore, we find that in 3.7% of the cases in our ground-truth, the citation spans include fragments after the citation marker.

5.3 Baselines

We consider the following baselines as competitors for our citation span approach.

Inter-Citation Text – IC. The span consists of sentences which start either at the beginning of the paragraph or at the end of a previous citation. The granularity is at the sentence level.

Citation-Sentence-Window – CSW. The span consists of sentences in a window of +/- 2 sentences from the citing sentence (O'Connor, 1982). The other sentences are included if they contain specific cue words in fixed positions.

Citing Sentence – CS. The span consists of only the *citing sentence*.

Markov Random Fields - MRF. MRFs (Qazvinian and Radev, 2010) model two functions. First, *compatibility*, which measures the similarity of sentences in p, and as such allows to extract non-citing sentences. Second, the *potential*, which measures the similarity between sentences in c with sentences in p. We use the provided implementation by the authors.

Citation Span Plain – CSPC. A plain classification setup using the features in Section 4, where the sequences are classified in isolation. We use Random Forests (Breiman, 2001) and evaluate them with 5-fold cross validation.

5.4 Citation Span Approach Setup – CSPS

For our approach $CSPS$ as mentioned in Section 4, we opt for linear-chain CRFs and use the implementation in (Okazaki, 2007). We evaluate our models using 5-fold cross validation, and learn the optimal parameters for the CRF model through the L-BFGS approach (Liu and Nocedal, 1989).

5.5 Evaluation Metrics

We measure the performance of the citation span approaches through the following metrics. We will denote with W' the sampled entities, with $\mathbf{p} = \{p_c, \ldots\}$ (p_c refers to $\langle p, c \rangle$) the set of sampled paragraphs from e, and with $|\mathbf{p}|$ the total items from e.

Mean Average Precision – MAP**.** First, we define *precision* for p_c as the ratio $P(p_c) = |\mathcal{S}' \cap \mathcal{S}^t| / |\mathcal{S}'|$ of fragments present in $\mathcal{S}' \cap \mathcal{S}^t$ over $\mathcal{S}'$. We measure MAP as in Equation 5.

$$MAP = \frac{1}{|W'|} \sum_{e \in W'} \frac{\sum_{p_c \in \mathbf{p}} P(p_c)}{|\mathbf{p}|} \qquad (5)$$

[6] `http://news.bbc.co.uk/sport1/hi/tennis/7601195.stm`

Recall – R. We measure the recall for p_c as the ratio $\mathcal{S}' \cap \mathcal{S}^t$ over all fragments in $\mathcal{S}^t$, $R(p_c) = |\mathcal{S}' \cap \mathcal{S}^t|/|\mathcal{S}^t|$. We average the individual recall scores for $e \in W'$ for the corresponding $\mathbf{p}$.

$$R = \frac{1}{|W'|} \sum_{e \in W'} \frac{\sum_{p_c \in \mathbf{p}} R(p_c)}{|\mathbf{p}|} \tag{6}$$

Erroneous Span – Δ. We measure the number of extra *words* or extra *sub-sentences* (denoted with Δ_w and Δ_δ) added by text fragments that are not part of the ground-truth $\mathcal{S}^t$. The ratio is relative to the number of words or sub-sentences in the ground-truth for p_c. We compute Δ_w and Δ_δ in Equation 7 and 8, respectively.

$$\Delta_w = \frac{1}{|W'|} \sum_{e \in W'} \frac{1}{|\mathbf{p}|} \sum_{p_c \in \mathbf{p}} \frac{\sum_{\delta \in \mathcal{S}' \setminus \mathcal{S}^t} words(\delta)}{\sum_{\delta \in \mathcal{S}^t} words(\delta)} \tag{7}$$

$$\Delta_\delta = \frac{1}{|W'|} \sum_{e \in W'} \frac{1}{|\mathbf{p}|} \sum_{p_c \in \mathbf{p}} \frac{|\mathcal{S}' \setminus \mathcal{S}^t|}{|\mathcal{S}^t|} \tag{8}$$

6 Results and Discussion

6.1 Citation Span Robustness

Table 6 shows the results for the different approaches on determining the citation span for all span cases shown in Table 4.

Accuracy. Not surprisingly, the baseline approaches perform reasonably well. CS which selects only the citing sentence achieves a reasonable $MAP = 0.86$ and similar recall. A slightly different baseline CSW achieves comparable scores with $MAP = 0.85$. This is due to the inherent span structure in Wikipedia, where a large portion of citations span up to a sentence (see Table 4). Therefore, in approximately 64% of the cases the baselines will select the correct span. For the cases where the span is more than a sentence, the drawback of these baselines is in coverage. We show in the next section a detailed decomposition of the results and highlight why even in the simpler cases, a sentence level granularity has its shortcomings due to sequence skips as shown in Table 5.

Overall, when comparing CS as the best performing baseline against our approach $CSPS$, we achieve an overall score of $MAP = 0.83$ (a slight decrease of 3.6%), whereas in term of F1 score, we have a decrease of 9%. The plain-classification approach $CSPC$ achieves similar score with $MAP = 0.86$, whereas in terms of F1 score, we have a decrease of 8%. As described above and as we will see later on in Table 7, the overall good performance of the baseline approaches can be attributed to the citation span distribution in our ground-truth.

On the other hand, an interesting observation is that sophisticated approaches, geared towards scientific domains like MRF perform poorly. We attribute this to *language style*, i.e., in Wikipedia there are no explicit citation hooks that are present in scientific articles. Comparing to $CSPS$, we outperform MRF by a large margin with an increase in MAP by 84%.

When comparing the sequence classifier $CSPS$ to the plain classifier $CSPC$, we see a marginal difference of 1.3% for *F1*. However, it will become more evident later that classifying jointly the text fragments for the different span buckets, outperforms the plain classification model.

	MAP	R	F1	Δ_w	Δ_δ
MRF	0.45	0.78	0.56	308%	278%
IC	0.72	**0.94**	0.77	113%	115%
CSW	0.85	0.84	**0.82**	38%	31%
CS	**0.86**	0.84	**0.82**	35%	27%
CSPC	**0.86**	0.68	0.76	**26**%	**23**%
CSPS	0.83	0.69	0.75	32%	24%

Table 6: Evaluation results for the different citation span approaches.

Erroneous Span. One of the major drawbacks of competing approaches is the granularity at which the span is determined. This leads to erroneous spans. From Table 4 we see that approximately in ∼10% of the cases the span is at sub-sentence level, and in 28% the span is more than a sentence.

The best performing baseline CS has an erroneous span of $\Delta_w = 35\%$ and $\Delta_\delta = 27\%$, in terms of extra words and sub-sentences, respectively. That is, nearly half of the determined span is erroneous, or in other words it is not covered in the provided citation. The MRF approach due to its poor MAP score provides the largest erroneous spans with $\Delta_w = 308\%$ and $\Delta_\delta = 278\%$. The amount of erroneous span is unevenly distributed, that is, in cases where the span is not at the sentence level granularity the amount of erroneous span increases. A detailed analysis is provided in the next section.

Contrary to the baselines, for $CSPS$ and similarly for $CSPC$, we achieve the lowest erroneous spans with $\Delta_w = 32\%$ and $\Delta_\delta = 26\%$, and $\Delta_w = 24\%$ and $\Delta_w = 23\%$, respectively.

Compared to the remaining baselines, we

achieve an overall relative decrease of 9% for $\Delta_w(CSPS)$, and 34% for $\Delta_w(CSPC)$, when compared to the best performing baseline CS.

From the *skips* in sequences in Table 5 and the unsuitability of sentence granularity for citation spans, we analyze the locality of erroneous spans w.r.t to the sequence that contains c, specifically the distribution of erroneous spans *preceding* and *succeeding* it. For the CS baseline, 71% of the total erroneous spans are added by sequences preceding the citing sequence, contrary to 35% which succeed it. In the case of $CSPS$, we have only 9% of erroneous spans (for Δ_δ) preceding the citation.

6.2 Citation Span and Feature Analysis

We now analyze how the approaches perform for the different citation spans in Table 4[7]. Additionally, we analyze how our approach $CSPS$ performs when determining the span without access to the content of c.

Citation Span. Table 7 shows the results for the approaches under comparison for all the citation span cases. In the case where the citation spans up to a sentence, that is $(0.5, 1]$, which presents the simplest citation span case, the baselines perform reasonably well. This is due to the heuristics they apply to determine the span, which in all cases includes the *citing sentence*. In terms of $F1$ score, the baseline CS achieves a highly competitive score of $F1 = 0.97$. Our approach $CSPS$ in this case has slight increase of 1% for $F1$ and an increase of 3% for MAP. $CSPC$ achieves a similar performance in this case.

However, for the cases where the span is at the sub-sentence level or across multiple sentences, the performance of baselines drops drastically. In the first bucket (≤ 0.5) which accounts for 9% of ground-truth data, we achieve the highest score with $MAP = 0.87$, though with lower recall than the competitors with $R = 0.56$. The reason for this is that the baselines take complete sentences, thus, having perfect recall at the cost of accuracy. In terms of $F1$ score we achieve 21% better results than the best performing baseline CS.

For the span of $(1, 2]$ we maintain an overall high accuracy and recall, and have the highest $F1$ score. The improvement is 8% in terms of $F1$ score. Finally, for the last case where the span is more than 2 sentences, we achieve $MAP = 0.74$, a marginal increase of 3%, however with lower recall, which results in an overall decrease of 4% for $F1$. The statistical significance tests are indicated with ** and * in Table 7.

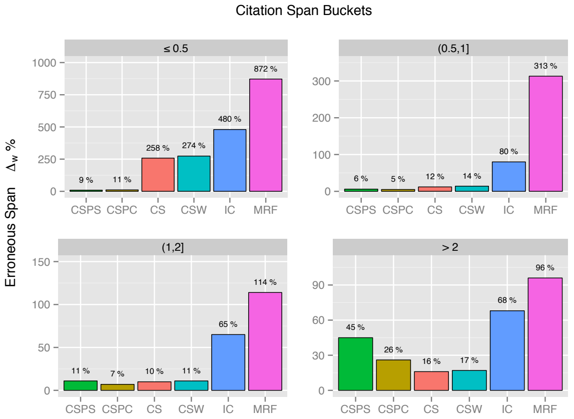

Figure 5: Erroneous spans for the different citation span buckets. The y-axis presents the Δ_w whereas in the x-axis are shown the different approaches.

Erroneous Span. Figure 5 shows the erroneous spans in terms of words for the metric Δ_w for all citation span cases. It is noteworthy that the amount of error can be well beyond 100% due to the ratio of the suggested span and the actual span in our ground-truth, which can be higher.

In the first bucket (span of ≤ 0.5) with granularity less than a sentence, all the competing approaches introduce large erroneous spans. For $CSPS$ we have a $MAP = 0.87$, and consequentially we have the lowest $\Delta_w = 9\%$, while for $CSPC$ we have only $\Delta_w = 11\%$. In contrast, the non-ML competitors introduce a minimum of $\Delta_w(CS) = 182\%$, with MRFs having the highest error. We also perform well in the bucket $(0.5, 1]$. For larger spans, for instance, for $(1, 2]$, we are still slightly better, with roughly 3% less erroneous span when comparing $CSPC$ and CS. However, only in the case of spans with > 2, we perform below the CS baseline. Despite, the smaller erroneous span, the CS baseline never includes more than one sentence, and as such it does not include many erroneous spans for the larger buckets. However, it is by definition unable to recognize any longer spans.

Feature Analysis. It is worthwhile to investigate the performance gains in determining the citation span without analyzing the content of the citation. The reason for this is that there are several cita-

[7] The models were retrained and tested for the different buckets with 5-fold cross validation.

		≤ 0.5			$(0.5, 1]$			$(1, 2]$			> 2	
	MAP	R	F1	MAP	R	F1	MAP	R	F1	MAP	R	F1
MRF	0.15	0.88	0.27	0.44	0.80	0.61	0.59	0.74	0.57	0.59	0.63	0.55
IC	0.32	**1.00**	0.45	0.77	**0.99**	0.83	0.73	**0.84**	0.74	0.72	**0.81**	**0.73**

CS	0.40	**1.00**	0.56	0.94	0.98	0.97	0.90	0.53	0.65	**0.80**	0.32	0.42
CSPC	0.85	0.53	0.65	**0.96**	0.97	0.97	**0.96**	0.68	0.79	0.71	0.65	0.68
CSPS	**0.87****	0.56	**0.68****	**0.96**	0.98	**0.98**	0.88	0.73	**0.80***	0.74	0.72	0.70
Δ_{F1} CSPS			▲21%			0%			▲8%			▼4%

Table 7: Evaluation results for the citation span approaches for the different span cases. For the results of $CSPS$ we compute the relative increase/decrease of $F1$ score compared to the best result (based on $F1$) from the competitors. We mark in bold the best results for the evaluation metrics, and indicate with ** and * the results which are highly significant ($p < 0.001$) and significant ($p < 0.05$) based on *t-test* statistics when compared to the best performing baselines (CS, IC, CSW, MRF) based on F1 score, respectively.

tion categories for which access to the source cannot be easily automated. Models which can determine the span accurately without the actual content have the advantage of generalizing to other citation sources (e.g. *books*) for which the evaluation is more challenging.[8]

Here, we disregard the citation features from Section 4.2. In terms of MAP, we have a slight decrease with $MAP = 0.82$ when compared to the model with the citation features. For recall we have a drop of 3%, resulting in $R = 0.67$.

This shows that by solely relying on the structure of the citing paragraph and other structural and discourse features we can perform the task with reasonable accuracy.

7 Conclusion

In this work, we tackled the problem of determining the fine-grained citation span of references in Wikipedia. We started from the *citing paragraph* and decomposed it into sequences consisting of sub-sentences. To accurately determine the span we proposed features that leverage the structure of the paragraph, discourse and temporal features, and finally analyzed the similarity between the citing paragraph and the citation content.

We introduce both a standard classifier as well as a sequence classifier using a linear-chain CRF model. For evaluation we manually annotated a ground-truth dataset of 509 citing paragraphs. We reported standard evaluation metrics and also introduced metrics that measure the amount of erroneous span.

We achieved a $MAP = 0.86$, in the case of the plain classification model $CSPC$, and with a marginal difference for $CSPS$ with $MAP = 0.83$, across all cases with an erroneous span of $\Delta_w = 26\%$ or $\Delta_w = 32\%$, depending on the model. Thus, we provide accurate means on determining the span and at the same time decrease the erroneous span by 34% compared to the best performing baselines. Moreover, we excel at determining citation spans at the sub-sentence level.

In conclusion, this presents an initial attempt on solving the citation span for references in Wikipedia. As future work we foresee a larger ground-truth and more robust approaches which take into account factors such as a reference being irrelevant to a citing paragraph and cases where the evidence for a paragraph is implied rather than explicitly stated in the reference.

Abstract

Most studies on human editing focus merely on syntactic revision operations, failing to capture the intentions behind revision changes, which are essential for facilitating the single and collaborative writing process. In this work, we develop in collaboration with Wikipedia editors a 13-category taxonomy of the semantic intention behind edits in Wikipedia articles. Using labeled article edits, we build a computational classifier of intentions that achieved a micro-averaged F1 score of 0.621. We use this model to investigate edit intention effectiveness: how different types of edits predict the retention of newcomers and changes in the quality of articles, two key concerns for Wikipedia today. Our analysis shows that the types of edits that users make in their first session predict their subsequent survival as Wikipedia editors, and articles in different stages need different types of edits.

1 Introduction

Many online text production communities, including Wikipedia, maintain a history of revisions made by millions of participants. As Wikipedia statistics as of January 2017 show, English Wikipedia has 5.3 million articles with an average of 162.89 revisions per article, with revisions growing at a rate of about 2 revisions per second. This provides an amazing corpus for studying the types and effectiveness of revisions. Specifically, differences between revisions contain valuable information for modeling document quality or extracting users' expertise, and can additionally support various natural language processing (NLP) tasks such as sentence compression (Yamangil and Nelken, 2008), lexical simplification (Yatskar et al., 2010), information retrieval (Aji et al., 2010), textual entailment recognition (Zanzotto and Pennacchiotti, 2010), language bias detection (Recasens et al., 2013), spelling errors and paraphrases (Zesch, 2012; Max and Wisniewski, 2010).

To avoid building different approaches to extract the information needed by different NLP tasks (Ferschke et al., 2013), a unified framework to recognize edits from revisions is needed. Prior research on revision editing primarily develop syntactic edit action categories, from which they try to understand the effects of edits on meaning (Faigley and Witte, 1981; Yang et al., 2016). For instance, Daxenberger and Gurevych (2012) categorized edits based on whether edits affect the text meaning, resulting in syntactic edit categories such as file deletion, reference modification, etc. However, simply understanding the syntactic revision operation types does not provide the information we seek: *why* do editors do what they do? *how effective* are their actions? For example, syntactic edit type taxonomies cannot tell the difference between simplifying a paragraph and maliciously damaging that paragraph, since both involve deleting a sentence.

In this work, we focus explicitly on revision intention. We introduce a fine-grained taxonomy of the reasons why an author in Wikipedia made an edit. Example edit intentions include copy editing, elaboration, verification, and simplification. Compared to taxonomies that either focus on low-level syntactic operations (Faigley and Witte, 1981) or that mix syntactic and semantic classes (Daxenberger and Gurevych, 2013), a clean higher-level semantic categorization enables us to easily identify textual meaning changes, and to connect revisions to "what happens in the mind of the revising author during the revision"

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2000–2010

(Fitzgerald, 1987; Daxenberger, 2016). In order to capture the meaning behind edits, we worked with 13 Wikipedians to build a taxonomy that captured the meaning of an revision, which we term *edit intention*, and hand-labeled a corpus of 7,177 revisions with their edit intentions. We then developed an automated method to identify these edit intentions from differences between revisions of Wikipedia articles. To explore the utility of this taxonomy, we applied this model to better understand two important issues for Wikipedia: new editor retention and article quality. Specifically, we examined whether edit intentions in newcomers' first editing sessions predict their retention, and examined how edits with different intentions lead to changes in article quality. These analyses showed that specific types of editing work were positively correlated with newcomer survival and articles in different stages of development benefited differently from different types of edits.

2 Related Work

Wikipedia revision histories have been used for a wide range of NLP tasks (Yamangil and Nelken, 2008; Aji et al., 2010; Zanzotto and Pennacchiotti, 2010; Ganter and Strube, 2009; Nelken and Yamangil, 2008). For instance, Yatskar et al. (2010) used Wikipedia comments associated with revisions to collect relevant edits for sentence simplification. Max and Wisniewski (2010) constructed a corpus of rewritings that can be used for spelling errors and paraphrases (Zesch, 2012). Similarly, Zanzotto and Pennacchiotti (2010) used edits as training data for textual entailment recognition, and Recasens et al. (2013) analyzed real instances of human edits designed to remove bias from Wikipedia articles. Most of these work employed manually defined rules or filters to collect relevant edits to the NLP task at hand.

Towards analyzing revisions and developing unified revision taxonomies (Bronner and Monz, 2012; Liu and Ram, 2011), Fong and Biuk-Aghai (2010) built machine learning models to distinguish between factual and fluency edits in revision histories. Faigley and Witte (1981) made a distinction between changes that affect meaning, called *text-base changes* and changes which do not affect meaning, called *surface changes*. The two categories are further divided into formal changes, meaning-preserving changes, micro-structure changes and macro-structure changes. This taxonomy was later extended by Jones (2008) to take into account edit categories such as significant deletion, style, image insertion, revert, etc. Pfeil et al. (2006) proposed a 13-category taxonomy based on the data and performed manual annotation to compare cultural differences in the writing process in different versions of Wikipedia. Daxenberger and Gurevych (2013) introduced a finer-grained edit taxonomy, and performed multi-label classification to extract edit categories based on unparsed source text (Daxenberger and Gurevych, 2012). However, most taxonomies of edit categories contain only syntactic actions or a mixture of syntactic and semantic actions, failing to capturing the intention of revisions.

In terms of revision intentions, Zhang and Litman (2016) incorporated both argumentative writing features and surface changes from Faigley and Witte (1981) and constructed eight categories of revision *purposes*, such as claims/ideas, warrant/reasoning/backing, rebuttal/reservation, organization, clarify, etc. Tan and Lee (2014) used revisions to understand statement strength in academic writings. There are multiple works on the detection of specific subsets of revision intentions in Wikipedia, such as vandalism detection where the goal is to classify revisions as vandalized or non-vandalized (Harpalani et al., 2011; Adler et al., 2011) and language bias/neutral point of view detection (Recasens et al., 2013). Instead of recognizing a specific type of revision intention each time, our work aims at designing a systematic and comprehensive edit intention taxonomy to capture intentions behind textual changes.

Prior work also used edit types and intentions to better understand the process of collaborative writing, such as article quality improvement (Kittur and Kraut, 2008). For example, Liu and Ram (2011) found that Wikipedia article quality correlates with different types of contributors; similarly Yang et al. (2016) pointed out articles in different quality stages need different types of editors. However, there are few studies examining the specific types of edits that are predictive of article quality. Recent research shows that the number of active contributors in Wikipedia has been steadily declining since 2007, and Halfaker et al. (2012) suggested that the semi-automated rejection of new editors' contributions is a key cause, but they did not explore whether or not specific types of newcomers' work got rejected at different rates

Label	Description	α	Before	After
Clarification	Specify or explain an existing fact or meaning by example or discussion without adding new information	0.394	0.7%	4.1%
Copy Editing	Rephrase; improve grammar, spelling, tone, or punctuation	0.800	11.8%	14.8%
Counter Vandalism	Revert or otherwise; remove vandalism	0.879	1.9%	1.5%
Disambiguation	Relink from a disambiguation page to a specific page	0.401	0.3%	1.8%
Elaboration	Extend/add substantive new content; insert a fact or new meaningful assertion	0.733	12.0%	12.0%
Fact Update	Update numbers, dates, scores, episodes, status, etc. based on newly available information	0.744	5.5%	5.2%
Point of View	Rewrite using encyclopedic, neutral tone; remove bias; apply due weight	0.629	0.3%	2.2%
Process	Start/continue a wiki process workflow such as tagging an article with cleanup, merge or deletion notices	0.786	4.4%	5.8%
Refactoring	Restructure the article; move and rewrite content, without changing the meaning of it	0.737	1.9%	2.9%
Simplification	Reduce the complexity or breadth of discussion; may remove information	0.528	1.6%	4.6%
Vandalism	Deliberately attempt to damage the article	0.894	2.5%	2.0%
Verification	Add/modify references/citations; remove unverified text	0.797	5.4%	9.8%
Wikification	Format text to meet style guidelines, e.g. add links or remove them where necessary	0.664	33.1%	33.6%
Other	None of the above.	0.952	1.2%	-
Corpus Size		4,977	4,977	7,177

Table 1: A taxonomy of edit intentions in Wikipedia revisions, Cronbach's α agreement and the distributions of edit intention before and after corpus expansion. The percentage in each row represents what percentage of revisions are labeled with this edit intention. The percentages do not sum up to 100% because one revision could belong to multiple categories. The *After* corpus is used for all our analyses.

and how that affects retention. In this paper, we take advantage of this new taxonomy to explore correlations between edit intentions, newcomers' retention, and article quality.

3 Semantic Taxonomy of Edit Intentions

A *revision* is created whenever an editor saves changes to a Wikipedia page. As one revision could contain multiple local changes, each revision can be labeled with one or more edit intentions, representing the purposes of why an editor made that change. Different from prior research (Daxenberger, 2016; Yang et al., 2016), we do not distinguish between revisions and edits. Although an edit is a coherent local change and might belong to any edit categories, it cannot be used to represent the intentions of editors during the revision. For example, it might be difficult to recognize *Refactoring* if only one single edit is present. Since relocation or reorganization might involve several changes in the article, looking at one might lose the whole picture and lead to information loss. Moreover, edit types simply extracted from an edit is inadequate in outlining the correct intentions, for instance, adding a sentence could be *Clarification*, *Elaboration*, or *Vandalism*.

3.1 Taxonomy of Edit Intentions

Our semantic taxonomy of edit intentions builds on prior literature on collaborative writing (Faigley and Witte, 1981; Fitzgerald, 1987), research on document revision analyses (Bronner and Monz, 2012), studies on edit categories (Daxenberger and Gurevych, 2012; Fong and Biuk-Aghai, 2010), and work on purpose/intention classification (Zhang and Litman, 2016). In order to ensure that our taxonomy captured the *intentions* that Wikipedians would find meaningful, we set up discussions with a group of 12 interested editors on a Wikipedia project talk page, and iteratively refined our taxonomy based on their feedback. Our discussion with Wikipedia editors is in this page[1]. We also analyzed which intentions get more confused with which and used that to guide the refinement.

We define a top level layer for the revision intention taxonomy: intentions that are common in general revisions: **General Revision Intentions**, and intentions that are specific in Wikipedia: **Wikipedia Specific Intentions**. This categorization leads to 13 distinct semantic intentions, and Table 1 provides detailed descriptions. Specifically, general revision intentions include: *Clarification*, *Copy Editing*, *Elaboration*, *Fact Update*, *Point of View*, *Refactoring*, *Simplification* and *verification*, and can be applicable to other contexts. *Counter Vandalism*, *Disambiguation*, *Process*, *Vandalism*, and *Wikification* are edit intentions related to Wikipeida. We also propose an *Other* category, intended for edits that cannot be labeled using the above taxonomy.

As the first work to model intentions of revisions, our taxonomy distills and extends existing edit type taxonomies. For instance, our intentions of "elaboration" and "verification" are extensions of "evidence" type proposed by (Zhang and Litman, 2016), and a syntactic category of "information deletion" in (Daxenberger and Gurevych, 2013) could be an instance of our "vandalism" or "simplification" depending on the context.

3.2 Corpus Construction

To construct a reliable, hand-coded dataset to serve as ground truth for automatic recognition of edit intentions, we employed four undergraduate students who had basic Wikipedia editing experience to label edits using our intention taxonomy, based on written annotation guidelines[2] vetted by Wikipedia editors and provided examples[3]. Moreover, to expose annotators to more working knowledge of Wikipedia, we provided three one-hour training sessions where annotators were asked to label a small set of revisions (around 50 each time) and to discuss their disagreements until consensus.

We randomly sampled 5,000 revisions from Jan, 2016 to June 2016 from the recent changes table[4] in the Wikipedia database. For each revision, we displayed the content difference[5] before and after the change to annotators, via a labeling interface that we developed. Because an editor could make several different types of edits within a single revision, we asked four RAs to label each revision with one or more of the possible semantic intentions. We collected four valid annotations for 4,977 revisions. We used Cronbach's α, a measure of internal consistency, to evaluate agreement among the annotators. The overall agreement α score was 0.782, indicating substantial agreement between different annotators; The rule of thumb 1993 suggests that Cronbachs alpha scores larger than 0.7 are considered as acceptable. The inter-annotator agreement per semantic intention is described in column α in Table 1.

3.3 Corpus Expansion

As shown in column *Before* in Table 1, some types of edit intentions, such as *disambiguation* and *clarification*, were very rare in the random-sample corpus. To address this under-representation problem, we used the text of editors' comments to expand the corpus by retrieving 200 more revisions for each edit intention except Vandalism and Counter-Vandalism, resulting in 2,200 revisions[6]. More precisely, as a common practice (Zanzotto and Pennacchiotti, 2010; Recasens et al., 2013), we utilized regular expressions to match the text from the comments, which editors often wrote when saving their revisions, to the edit intentions. For example, editors might be signalling that they were intending to fix problems of *Point of View* when their comments contained keywords such as "npov" or "neutral". Even though the comments sometimes signal the editors' intents, they are not infallible, editors may fail to complete the comment field, may only label one of the multiple edit intentions for a single revision, or write comments that are inaccurate, irrelevant, or incomplete. Thus the first author annotated the 2,200 revisions from the expanded corpus and

[5] en.wikipedia.org/wiki/?diff=712140761

[6] We used a practical and economic way to expand the corpus, and this made the intention distribution skewed away. We acknowledge this expansion as a limitation.

merged it with the randomly sampled corpus. The frequency of the edit intentions before and after the expansion is in Table 1. We used the majority voting to resolve the disagreement. That is, if at least 3 out of 4 annotators picked an intention for a revision, it will be selected as the ground-truth. The final corpus contains 5,777 revisions, and can be downloaded from here[7].

4 Identification of Edit Intentions

We frame automated identification of edit intentions as a multi-label classification task. We designed four sets of features for identifying edit intentions from revisions. Set I comprised two features associated with the **Editor**: *user registration* indicating whether the editor of a particular revision was registered or anonymous and *tenure*, which refers to the elapsed months between the current revision and editors' registration date. Set II comprised 16 features associated with the **Comment** written by the editor to describe the revision, including *comment length* and a set of regular expressions to match intentions such as `*pov*`, `*clarify*`, `*simplif*`, `*add link*`, etc. Set III comprised 198 features associated with the **Revision Diff**, based on content differences between current revision and the previous one. They are similar to textual features defined in Daxenberger and Gurevych (2013), but we considered a wider range of objects being modified. In particular, we computed the difference in the number of characters, uppercase words, numeric chars, white-spaces, markups, Chinese/Japanese/Korean characters, HTML entity characters, URLs, punctuations, break characters, etc. We also considered languages features, such as the use of stop words, obscene words and informal words. Set IV comprises two features associated with **Vandalism** and **Revert**. We utilized the Wikipedia API to extract whether a revision was likely to be vandalism[8] or reverting revisions[9].

4.1 Identification Result

We extracted the input features with the help of Revision Scoring package[10] and framed this task a multi-label classification problem. For multi-label classification, we considered solving them by using single-label classification algorithms and by transforming it into one or more single-label classification tasks. We used the multi-label classifiers implemented in Mulan (Tsoumakas et al., 2011), with 10-fold cross validation. We utilized Binary Relevance (**BR**) to convert our multi-label classification into 13 binary single-label problems. Similar to Daxenberger and Gurevych (2013); Yang et al. (2016), we used Random k-labelsets **RAKEL** method that randomly chooses l small subset with k categories from the overall set of categories. We set l as 26, twice the size of the categories, and set k as 3. **MLKNN** method that classifies edit intentions based on K (K=10) nearest neighbor method. We used C4.5 decision tree classifiers in BR and RAKEL, as recommended by prior work (Daxenberger and Gurevych, 2013; Potthast et al., 2013). Prior research shows that sophisticated neural network models for text-classification largely rely on factors such as dataset size (Zhang et al., 2015; Joulin et al., 2016). Due to the size of our corpus and the complexity of this task, we did not use them.

To evaluate the relative accuracy of the multi-label classifier, we compared it to several baselines. The random baseline, denoted as **Random** in Table 2, assigns labels randomly. The majority category baseline, denoted as **Majority**, assigns all edits the most frequent intention, elaboration. Since revision comments may be especially as informative in reflecting edit intentions, the comment baseline, denoted as **CMT**, is a Binary Relevance classifier that includes only the comments features from Set II. We also created a Binary Relevance classifier, denoted as **BR-**, which excludes comment features and only used features from Sets I, III and IV.

Table 2 shows the evaluation metrics for the baselines and our multi-label classifiers. The metrics include the Exact Match subset accuracy, which evaluates whether the predicted labels are the same as the actual labels. These classifiers are available upon request. Table 2 also shows example-based measures of Accuracy, Precision, Recall and F1 Score, weighting each edit equally. It also shows label-based measures of accuracy – the micro- and macro-averaged F1 scores– which weight each edit intention category equally. As a ranking based measure, we measured One Error,

Label	Macro F1	0.060	0.042	0.310	0.487	**0.597**	0.576	0.385
	Micro F1	0.074	0.370	0.528	0.583	**0.621**	0.613	0.441
Ranking	One Error	0.920	0.583	0.415	0.400	0.358	**0.320**	0.434

Table 2: Performance comparison for predicting edit intentions from revisions. Best results are bold.

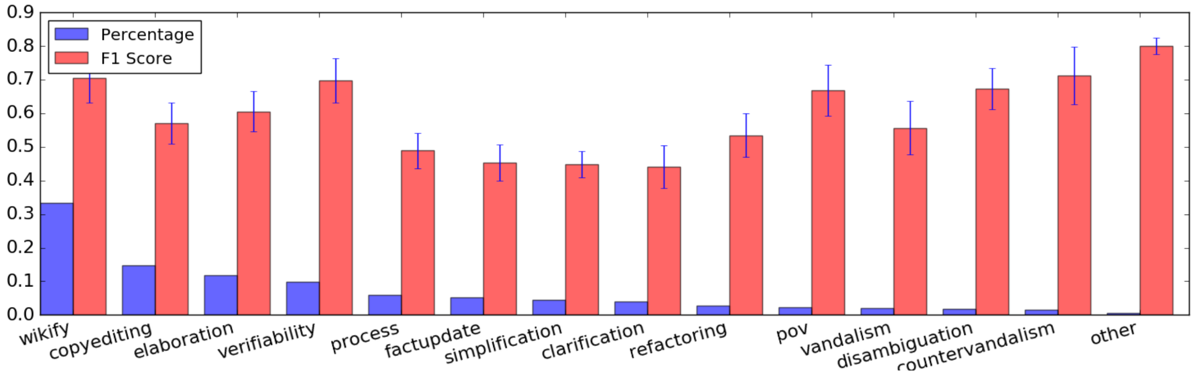

Figure 1: The relative frequency of each edit intention, and its F1 score provided by the **BR** model.

which evaluates how many times the top ranked predicted intention is not in the set of true labels of the instance.

Results show that the Binary Relevance (BR) and MLKNN classifiers, which used all our constructed features, outperformed Random and Majority baselines. Moreover, the BR and MLKNN methods show relatively similar best performances. Although multiple studies have utilized revisions' comments as "groundtruth" to collect desired edits, the CMT method, which includes only comment features, is less accurate than either the BR or MLKNN models. Note that predicting 14-category semantic intentions is more challenging compared to classifying low-level syntactic actions, such as inserting an image (Daxenberger and Gurevych, 2013).

5 Intentions, Survival and Quality

The automated measurement of edit intentions provides a general framework to analyze revisions and can facilitate a wide range of applications, such as collecting specific types of revisions (Yatskar et al., 2010; Recasens et al., 2013; Zanzotto and Pennacchiotti, 2010) and outlining the evolution of author roles (Arazy et al., 2015; Yang et al., 2016). In this section, we demonstrate two examples of how this intention taxonomy can be applied to better understand the success of online collaboration communities (Kraut et al., 2010), specifically the process of these sites to retain new contributors and create innovative products. To this end, we first investigate what newcomers are intended for in their first sessions and whether their edit intentions can account for their survival in Wikipedia. We then examine how edits carrying on different intentions at distinct times in an article's history influence changes in its quality.

5.1 How Edit Intentions Affect Survival

To explore newcomers' intentions during their first experience editing articles, we focus on users' first edit sessions in Wikipedia. Here, **Edit Session** is defined as a sequence of edits performed by a registered user with less than one hour's time gap between two adjacent edits (Halfaker et al., 2012). We then compare edit intentions of newcomers who survive - **Survivors**, and newcomers who do not - **Non-survivors**. Here, newcomers are defined as surviving if they performed an edit at

Edit Intention	***Intention Dist***		***Revert Ratio***	
	NS	**SS**	**NS**	**SS**
clarification	**0.2%**	**0.4%**	0.1%	0.1%
copy editing	**12.1%**	**14.4%**	**6.9%**	**3.8%**
counter vandalism	0.1%	0.0%	0.1%	0.0%
disambiguation	0.0%	0.0%	0.0%	0.0%
elaboration	27.7%	26.5%	**16.5%**	**6.9%**
fact update	4.2%	3.8%	**3.4%**	**1.7%**
point of view	**0.1%**	**0.2%**	0.0%	0.1%
process	2.0%	2.3%	**1.9%**	**0.7%**
refactoring	1.1%	1.3%	**0.9%**	**0.5%**
simplification	**3.7%**	**3.1%**	**3.1%**	**1.4%**
vandalism	**13.8%**	**6.1%**	**16.0%**	**4.7%**
verification	7.0%	7.4%	**3.8%**	**2.7%**
wikification	**25.8%**	**32.3%**	**14.0%**	**6.9%**

Table 3: The edit intention distribution in the first sessions (Intention Dist) and the revert ratio comparison (Revert Ratio), among non-survivors (NS) and survivors (SS). The numbers are bolded if 1-way ANOVA tests for difference between two groups are significant, with $p<0.05$.

Edit Intention	**Survival**	**Quality Changes**
clarification	0.029	0.001
copy editing	0.033	$0.011^\dagger$
counter vandalism	0.004	$-0.020^\dagger$
disambiguation	-0.003	$-0.006^\dagger$
elaboration	-0.024	$0.061^\dagger$
fact update	-0.001	0.002
point of view	0.041	-0.003
process	$0.051^\dagger$	$-0.024^\dagger$
refactoring	-0.013	$0.011^\dagger$
simplification	-0.002	$-0.008^\dagger$
vandalism	$-0.211^\dagger$	$-0.005^\dagger$
verification	0.047	$0.068^\dagger$
wikification	$0.099^\dagger$	$-0.010^\dagger$

Table 4: Regression coefficients of different edit intentions for predicting Newcomer **Survival** and Article **Quality Changes**. † means the coefficient is statistically significant ($p<0.05$)

least two months after their first edit session.

5.1.1 Intention Comparison

Among 100,000 randomly sampled Wikipedia users, 21,096 made revisions in the Main/Article namespace during their first editing session. Among these 4,407 were survivors (i.e., made an edit two months after registering) and 16,689 were non-survivors. We applied our edit intention model to 53,248 revisions in users' first sessions, and compared the percentages of different types of edit intentions between survivors and non-survivors, as shown in ***Intention Dist*** column in Table 3. We also performed 1-way ANOVA to test whether survivors and non-survivors have the same mean for each edit intention. We observed that, survivors tend to do more copy-editing (Δ_+=2.3%) and more wikification (Δ_+=6.5%), while non-survivors seem to perform more simplification and vandalism, which might provide signals for detecting vandals.

5.1.2 Revert Analysis

To explore the relationship between rejection of contributions and newcomer retention, we also visualized the revert ratios of different types of edit intentions for survivors and non-survivors in their first session. Here, **Revert** refers to whether an edit from the author was reverted or completely removed by another user, and we detect reverts using MediaWiki Reverts library[11]. We then measured the revert ratio for each edit intention by calculating the percentage of revisions belonging to a specific edit intention, among all reverted revisions in users' first sessions. As shown in the ***Revert Ratio*** column in Table 3, in general, non-survivors get reverted more compared to survivors, across all edit intentions. Interestingly, non-survivors compared to survivors get reverted more when performing *Wikification*, *verification* and *Refactoring*, suggesting that sophisticated types of work might not be suitable for beginners.

5.1.3 Newcomer Survival

As a further exploration of the relationship between edit intentions and newcomer survival, we performed a logistic regression using edits in survivors' and non-survivors' first sessions. To handle this imbalanced data (i.e., many more negative examples than positive examples in training), we performed majority-class under-sampling to make this dataset balanced. Similar to Halfaker et al. (2012), we controlled the number of revisions completed during the first session (a proxy for an editor's initial investment), and the number of revisions reverted in their first sessions. We

[11] `http://pythonhosted.org/mwreverts/`

described the regression coefficients of statistically significant edit intentions in the **Survival** column of Table 4. This logistic model achieves an Accuracy of 60.98%, Recall of 58.30%, Precision of 78.08% and F1-score of 66.76%. Editing articles for the purposes of *Process*, *Verification* and *Wikification* significantly predict the survival of newcomers, while performing vandalism is a strong negative predictor for survival.

5.2 How Intentions Affect Article Quality

Although there are over 5.5 million articles in the English Wikipedia, fewer than 0.2% have been evaluated by Wikipedians as good articles and around 92% have been evaluated as start or stub class articles, Wikipedia's two lowest quality categories. In this section, we examine how edits with different intentions at distinct times in an article's history influence changes in its quality.

This task is framed as a prediction task, i.e. using edits' intentions and a set of control variables to predict changes in article quality. We borrowed a Article Quality Prediction Dataset released in Yang et al. (2016), which consists of the quality ratings collected in January and June, 2015 of 151,452 articles. We collected 1,623,446 revisions made to these articles between January and June 2015, by randomly sampling 10% revisions that were made to these articles during that time periods. Specifically, the outcome *article quality change* is calculated by subtracting the previous quality score from the end quality score. The control variables include the previous article quality score, the total number of edits, the total number of editors, the changed bytes to an article, and the total number of edits to the article talk page during the six months. To construct edit-intention predictors, we summed the number of edits for each edit intention during the six months divided by the total number of revisions in this article.

Results of the linear regression model, shown in **Quality Changes** column of Table 4, show that our constructed regression model is significantly predictive of article quality changes ($R^2 = 0.225$). The results show that, keeping all control variables fixed, more *Copy Editing*, *Elaboration*, *Refactoring* and *Verification* are positively associated with improvements in article quality; in contrast, *Vandalism*, *Counter Vandalism*, *Disambiguation*, *Process* and *Simplification* predict declines in article quality. The first four of these edits types often occur with reducing the article content, removing or redirecting pages. Improper use of them might be detrimental to article quality.

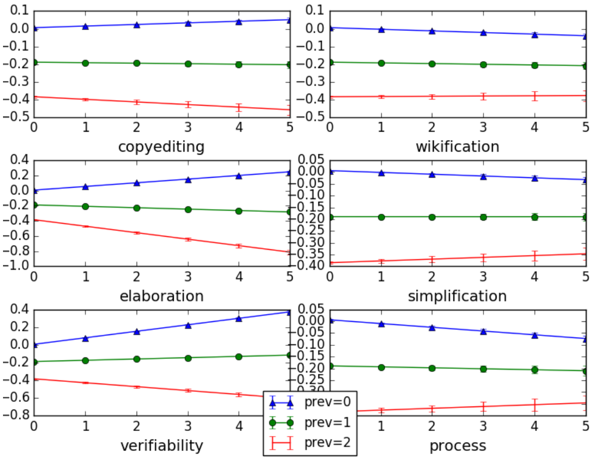

Figure 2: Interaction effect of different levels of edit intentions and different levels of previous article quality (**prev**) on article quality changes. All variables are standardized. The Y-axis measures the predictive margins and X-axis refers to different standardized levels of edit intention.

To determine if the effect of edit intentions on quality changes depends upon the initial quality of the article, we added the interaction terms between the previous quality score and edit percentages of different intentions (e.g., clarification x previous quality), and visualized interaction effects in Figure 2. When examining the interaction terms in more detail: the negative slope of *copy editing* (when prev=2) suggests that, as articles increase in quality, copy editing is needed less. We found similar trends for interactions between previous quality and *elaboration* and *verification*, which are essential for articles in the starting stages. In contrast, the positive slopes for *simplification*, *wikification* and *process* suggest that, as articles increase in quality, simplifying articles' content, adding proper links or reorganizing their structure becomes more important. Overall, these results reveal that different types of edit intentions are needed at different quality stages of articles.

6 Discussion and Conclusion

In this work, we proposed 13 semantic intentions that motivate editors' revisions in English Wikipedia. Example edit intentions include copy editing, elaboration, simplification, etc. Based in a labeled corpus of revisions, we developed machine-learning models to automatically identify these edit intentions. We then examine the relations between edit intentions, newcomers survival, and article quality improvement. We found that (1) survivors tend to do more copy editing and wikification; non-survivors seem to perform more vandalism and other sophisticated types of work, and the latter often gets reverted more; (2) Different types of contributions are needed by articles in different quality stages, with elaboration and verification are needed more for articles in the starting stages, and simplification and process become more important as article quality increases.

Our proposed edit intention taxonomy and the constructed corpus can facilitate a set of downstream NLP applications. First, classifiers based on this intention taxonomy can help retrieve large scale and high quality revisions around simplification, neutral point of view or copy editing, which provides amazing corpora for studying lexical simplification, language bias detection and paraphrases. Second, as we showed in Section 5.2, determining how different edit types influence changes in articles is of great use to better the causes of quality variance in collaborative writing, such as detecting quality flaws (Anderka et al., 2012) and providing insights on which specific aspects of an article needs improvement and what type of work should be performed. The ability to identify the need for editing, and specifically the types of editing work required, can greatly assist not only collaborative writing but also individual improvement of text. Moreover, even though our edit taxonomy is for English Wikipedia, it can be applied to other language versions of Wikipedia. We are now deploying the same edit intention taxonomy for Italian Wikipedia, and plan to apply it to other low resourced languages in Wikipedia. Finally, beyond the context of Wikipedia, similar taxonomies can be designed for analyzing the collaboration and interaction happened in other online contexts such as academic writing (e.g., Google Docs or ShareLatex, etc).

Abstract

We introduce a hierarchical architecture for machine reading capable of extracting precise information from long documents. The model divides the document into small, overlapping windows and encodes all windows in parallel with an RNN. It then attends over these window encodings, reducing them to a single encoding, which is decoded into an answer using a sequence decoder. This hierarchical approach allows the model to scale to longer documents without increasing the number of sequential steps. In a supervised setting, our model achieves state of the art accuracy of 76.8 on the WikiReading dataset. We also evaluate the model in a semi-supervised setting by downsampling the WikiReading training set to create increasingly smaller amounts of supervision, while leaving the full unlabeled document corpus to train a sequence autoencoder on document windows. We evaluate models that can reuse autoencoder states and outputs without fine-tuning their weights, allowing for more efficient training and inference.

1 Introduction

Recently, deep neural networks (DNNs) have provided promising results for a variety of reading comprehension and question answering tasks (Weston et al., 2014; Hermann et al., 2015; Rajpurkar et al., 2016), which require extracting precise information from documents conditioned on a query. While a basic sequence to sequence (seq2seq) model (Sutskever et al., 2014) can perform these tasks by encoding a question and document sequence and decoding an answer sequence (Hewlett et al., 2016), it has some disadvantages. The answer may be encountered early in the text and need to be stored across all the further recurrent steps, leading to forgetting or corruption; Attention can be added to the decoder to solve this problem (Hermann et al., 2015). Even with attention, approaches based on Recurrent Neural Networks (RNNs) require a number of sequential steps proportional to the document length to encode each document position. Hierarchical reading models address this problem by breaking the document into sentences (Choi et al., 2017). In this paper, we introduce a simpler hierarchical model that achieves state-of-the-art performance on our benchmark task without this linguistic structure, and use it as framework to explore semi-supervised learning for reading comprehension.

We first develop a hierarchical reader called Sliding-Window Encoder Attentive Reader (SWEAR) that circumvents the aforementioned bottlenecks of existing readers. SWEAR, illustrated in Figure 1, first encodes each question into a vector space representation. It then chunks each document into overlapping, fixed-length windows and, conditioned on the question representation, encodes each window in parallel. Inspired by recent attention mechanisms such as Hermann et al. (2015), SWEAR attends over the window representations and reduces them into a single vector for each document. Finally, the answer is decoded from this document vector. Our results show that SWEAR outperforms the previous state-of-the-art on the supervised WikiReading task (Hewlett et al., 2016), improving Mean F1 to 76.8 from the previous 75.6 (Choi et al., 2017).

While WikiReading is a large dataset with millions of labeled examples, many applications of machine reading have a much smaller number

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2011–2020
Copenhagen, Denmark, September 7–11, 2017.

of labeled examples among a large set of unlabeled documents. To model this situation, we constructed a semi-supervised version of WikiReading by downsampling the labeled corpus into a variety of smaller subsets, while preserving the full unlabeled corpus (i.e., Wikipedia). To take advantage of the unlabeled data, we evaluated multiple methods of reusing unsupervised recurrent autoencoders in semi-supervised versions of SWEAR. Importantly, in these models we are able to reuse all the autoencoder parameters *without fine-tuning*, meaning the supervised phase only has to learn to condition the answer on the document and query. This allows for more efficient training and online operation: Documents can be encoded in a single pass offline and these encodings reused by all models, both during training and when answering queries. Our semi-supervised learning models achieve significantly better performance than supervised SWEAR on several subsets with different characteristics. The best-performing model reaches 66.5 with 1% of the WikiReading dataset, compared to the 2016 state of the art of 71.8 (with 100% of the dataset).

2 Problem Description

Following the recent progress on end-to-end supervised question answering (Hermann et al., 2015; Rajpurkar et al., 2016), we consider the general problem of predicting an answer A given a query-document pair (Q, D). We do not make the assumption that the answer should be present verbatim in the document.

2.1 Supervised Version

Given a document $D = \{d_1, d_2, \cdots, d_{N_D}\}$ and a query $Q = \{q_1, q_2, \cdots, q_{N_Q}\}$ as sequences of words, our task is to generate a new sequence of words that matches the correct answer $A = \{a_1, a_2, \cdots, a_{N_A}\}$. Because we do not assume that A is a subsequence of D, the answer may require blending information from multiple parts of the document, or may be precisely copied from a single location. Our proposed architecture supports both of these use cases.

The WikiReading dataset (Hewlett et al., 2016), which includes a mix of categorization and extraction tasks, is the largest dataset matching this problem description. In WikiReading, documents are Wikipedia articles, while queries and answers are Wikidata properties and values, respectively. Example Wikidata property-value pairs are `(place of birth, Paris)`, `(genre, Science Fiction)`. The dataset contains 18.58M instances divided into training, validation, and test with an 85/10/5 split. The answer is present verbatim in the document only 47.1% of the time, severely limiting models that label document spans, such as those developed for the popular SQUAD dataset (Rajpurkar et al., 2016).

2.2 Semi-Supervised Version

We also consider a semi-supervised version of the task, where an additional corpus of documents without labeled (Q, A) pairs is available. Taking advantage of the large size of the WikiReading dataset, we created a series of increasingly challenging semi-supervised problems with the following structure:

- **Unsupervised:** The entire document corpus (about 4M Wikipedia articles), with queries and answers removed.
- **Supervised:** Five smaller training sets created by sampling a random (1%, 0.5%, 0.1%) of the WikiReading training set, and taking (200, 100) random samples from each property in the original training set.

3 Supervised Model Architecture

We now present our model, called Sliding-Window Encoder Attentive Reader (SWEAR), shown in Figure 1, and describe its operation in a fully supervised setting. Given a (Q, D) pair, the model encodes Q into a vector space representation with a Recurrent Neural Network (RNN). The first layer of the model chunks the document D into overlapping, fixed-length windows and encodes all windows in parallel with an RNN conditioned on the question representation. The second layer attends over the window representations, reducing them into a single vector representing the latent answer. Finally, the answer sequence A is decoded from this vector using an RNN sequence decoder.

3.1 Preliminaries and Notation

Each word w comes from a vocabulary V and is associated with a vector e_w which constitutes the rows of an embedding matrix E. We denote by e^D, e^Q, and e^A the vector sequences corresponding to

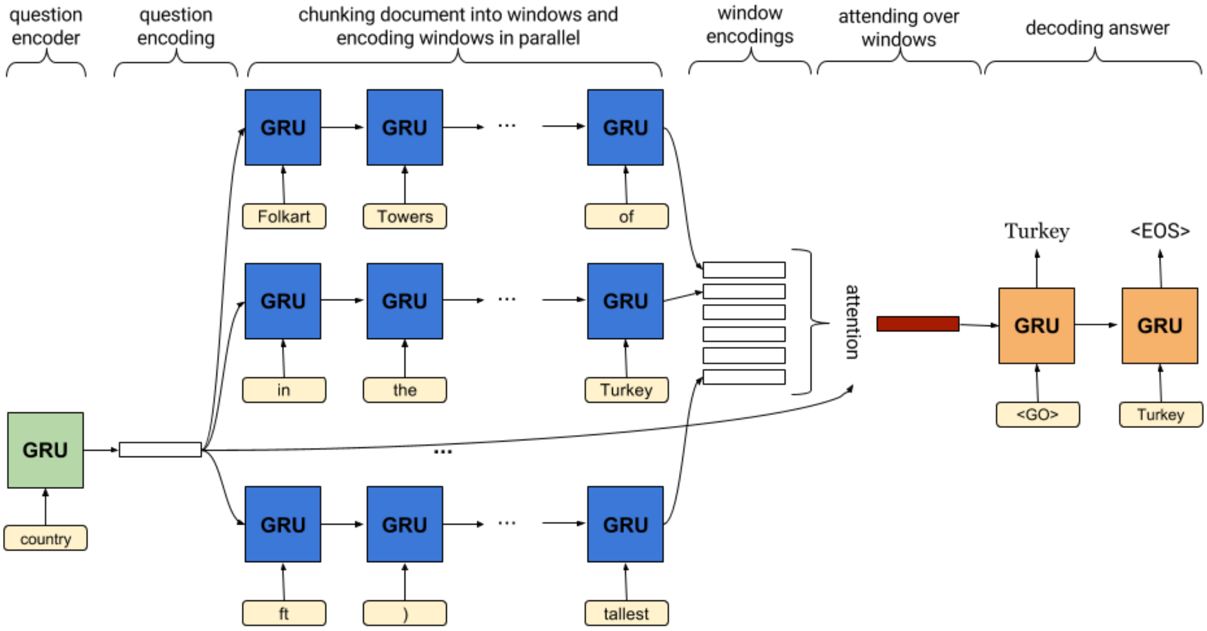

Figure 1: SWEAR model: Boxes are RNN cells, colors indicate parameter sharing.

the document, question, and answer sequences, respectively. More specifically, we aim at obtaining vector representations for documents and questions, then generating the words of the answer sequence.

Our model makes extensive use of RNN encoders to transform sequences into fixed length vectors. For our purposes, an RNN encoder consists of GRU units (Cho et al., 2014) defined as

$$h_t = f(x_t; h_{t-1}; \theta) \tag{1}$$

where h_t is hidden state at time t. f is a nonlinear function operating on input vector x_t and previous state, h_{t-1} with θ being its parameter vector. Given an input sequence, the encoder runs over the sequence of words producing the hidden vectors at each step. We refer to the last hidden state of an RNN encoder as the *encoding* of a sequence.

3.2 Sliding Window Recurrent Encoder

The core of the model is a sequence encoder that operates over sliding windows in a manner analogous to a traditional convolution. Before encoding the document, we slide a window of length l with a step size s over the document and produce $n = \lfloor \frac{N_D - l}{s} \rfloor$ document windows. This yields a sequence of sub-documents $(D_1, D_2, \cdots, D_n)$, where each D_i contains a subsequence of l words from the original document D. Intuitively, a precise answer may be present verbatim in one or more windows, or many windows may contain evidence suggestive of a more categorical answer.

Next, the model encodes each window conditioned on a question encoding. We first encode the question sequence once using a RNN (Enc) as

$$h^q = Enc(e^Q; \theta_Q) \tag{2}$$

where h^q is the last hidden state and θ_Q represents the parameters of the question encoder. Initialized with this question encoding, we employ another RNN to encode each document window as

$$\begin{aligned} h^w_{i,0} &= h^q \\ h^w_i &= Enc(e^{D_i}; \theta_W) \end{aligned} \tag{3}$$

where $h^w_{i,0}$ is the initial hidden state, h^w_i is the last hidden state, and θ_W represents the parameters of the window encoder. θ_W is shared for every window and is decoupled from θ_Q. As the windows are significantly smaller than the documents, encodings of windows will reflect the effect of question encodings better, mitigating any long-distance dependency problems.

3.3 Combining Window Encodings

SWEAR attends over the window encoder states using the question encoding to produce a single vector h^d for the document, given by

$$p_i \propto \exp(u_R^T \, tanh(W_R[h^w_i, h^q])) \tag{4}$$

$$h^d = \sum_i p_i h^w_i \tag{5}$$

Model	Mean F1
Placeholder seq2seq (HE16)	71.8
SoftAttend (CH17)	71.6
Reinforce (CH17)	74.5
Placeholder seq2seq (CH17)	75.6
SWEAR (w/ zeros)	76.4
SWEAR	**76.8**

Table 1: Results for SWEAR compared to top published results on the WikiReading test set.

	HE16 Best	SWEAR
Categorical	**88.6**	**88.6**
Relational	56.5	**63.4**
Date	73.8	**82.5**

Table 2: Mean F1 for SWEAR on each type of property compared with the best results for each type reported in Hewlett et al. (2016), which come from different models. Other publications did not report these sub-scores.

Doc length	pct	seq2seq	SWEAR	imp
$[0, 200)$	44.6	79.7	80.7	1.2
$[200, 400)$	19.5	76.7	77.8	1.5
$[400, 600)$	11.0	74.5	76.3	2.3
$[600, 800)$	6.6	72.8	74.3	2.1
$[800, 1000)$	4.3	71.5	72.8	1.8
$[1000, max)$	14.0	64.8	65.9	1.7

Table 3: Comparison of Mean F1 for SWEAR and a baseline seq2seq model on the WikiReading test set across different document length ranges. *pct* indicates the percentage of the dataset falling in the given document length range. *imp* is the percentage improvement of SWEAR over baseline.

where $[.]$ is vector concatenation, and p_i is the probability window i is relevant to answering the question. W_R and u_R are parameters of the attention model.

3.4 Answer Decoding

Given the document encoding h^d, an RNN decoder (Dec) generates the answer word sequence:

$$h_0^a = h^d$$

$$h_t^a = Dec(h_{t-1}^a; \omega_A) \quad (6)$$

$$P(a_t^* = w_j) \propto \exp(e_j^T (W_A h_t^a + b_A)) \quad (7)$$

$$a_t^* = argmax_j(P(a_t^* = w_j)) \quad (8)$$

where h_0^a is the initial hidden state and h_t^a is the hidden vector at time t. $A^* = \{a_1^*, a_2^*, \cdots, a_{N_A}^*\}$ is the sequence of answer words generated. W_A, b_A, and ω_A are the parameters of the answer decoder. The training objective is to minimize the average cross-entropy error between the candidate sequence A^* and the correct answer sequence A.

3.5 Supervised Results

Before exploring unsupervised pre-training, we present summary results for SWEAR in a fully supervised setting, for comparison to previous work on the WikiReading task, namely that of Hewlett et al. (2016) and Choi et al. (2017), which we refer to as HE16 and CH17 in tables. For further experiments, results, and discussion see Section 5.2. Table 1 shows that SWEAR outperforms the best results for various models reported in both publications, including the hierarchical models SoftAttend and Reinforce presented by Choi et al. (2017).[1] Interestingly, SoftAttend computes an attention over sentence encodings, analogous to SWEAR's attention over overlapping window encodings, but it does so on the basis of less powerful encoders (BoW or convolution vs RNN), suggesting that the extra computation spent by the RNN provides a meaningful boost to performance.

To quantify the effect of initializing the window encoder with the question state, we report results for two variants of SWEAR: In *SWEAR* the window encoder is initialized with the question encoding, while in *SWEAR w/ zeros*, the window encoder is initialized with zeros. In both cases the question encoding is used for attention over the window encodings. For SWEAR w/ zeros it is additionally concatenated with the document encoding and passed through a 2-layer fully connected neural network before the decoding step. Conditioning on the question increases Mean F1 by 0.4.

Hewlett et al. (2016) grouped properties by answer distribution: *Categorical* properties have a small list of possible answers, such as countries, *Relational* properties have an open set of answers, such as spouses or places of birth, and *Date* properties (a subset of relational properties) have date answers, such as date of birth. We reproduce this grouping in Table 2 to show that SWEAR improves performance for Relational and Date properties, demonstrating that it is better able to extract precise information from documents.

Finally, we observe that SWEAR outperforms a baseline seq2seq model on longer documents, as

[1] Document lengths differ between publications: We truncate documents to the first 600 words, while Choi et al. truncate to 1000 words or 35 sentences and Hewlett et al. truncate to 300 words.

shown in Table 3. The baseline model is roughly equivalent to the best previously-published result, Placeholder seq2seq (CH17) in Table 1, reaching a Mean F1 of 75.5 on the WikiReading testset. SWEAR improves over the baseline in every length category, but the differences are larger for longer documents.

4 Semi-Supervised Model Architecture

We now describe semi-supervised versions of the SWEAR model, to address the semi-supervised problem setting described in Section 2.2. A wide variety of approaches have been developed for semi-supervised learning with Neural Networks, with a typical scheme consisting of training an unsupervised model first, and then reusing the weights of that network as part of a supervised model. We consider each of these problems in turn, describing two types of unsupervised autoencoder models for sequences in Section 4.1 before turning to a series of strategies for incorporating the autoencoder weights into a final supervised model in Section 4.3. All of these models reuse the autoencoder weights without modification, meaning a document can be encoded once by an offline process, and the resulting encodings can be used both during training and to answer multiple queries online in a more efficient manner.

4.1 Recurrent Autoencoders for Unsupervised Pre-training

Autoencoders are models that reconstruct their input, typically by encoding it into a latent space and then decoding it back again. Autoencoders have recently proved useful for semi-supervised learning (Dai and Le, 2015; Fabius and van Amersfoort, 2014). We now describe two autoencoder models from the recent literature that we use for unsupervised learning. The Recurrent Autoencoder (RAE) is the natural application of the seq2seq framework (Sutskever et al., 2014) to autoencoding documents (Dai and Le, 2015): In seq2seq, an encoder RNN already produces a latent representation h_N, which is used to initialize a decoder RNN. In RAE, the output sequence is replaced with the input sequence, so learning minimizes the cross-entropy between the reconstructed input sequence and the original input sequence. Encoder and decoder cells share parameters θ_U.

4.1.1 Variational Recurrent Autoencoder

The Variational Recurrent Autoencoder (VRAE), introduced by Fabius et al. (2014), is a RAE with a variational Bayesian inference step where an unobserved latent random variable generates the sequential data. The encoder and decoder are exactly the same as RAE, but the latent state h_N is not directly passed to the decoder. Instead, it is used to estimate the parameters of a Gaussian distribution with a diagonal covariance matrix: The mean is given by $\mu_x = W_\mu h_N + b_\mu$ and the covariance by $\Sigma_x = W_\Sigma h_N + b_\Sigma$, where W_μ, W_Σ, b_μ, and b_Σ are new variational step parameters. The decoder is initialized with a single vector sampled from this distribution, $z_x \sim \mathcal{N}(z|\mu_x, \Sigma_x)$. For VRAE, the Kullback-Leibler divergence between trained Normal distribution and standard normal distribution, i.e., $KL(\mathcal{N}(\mu_x, \Sigma_x)|\mathcal{N}(0, I))$, is added to the loss.

4.1.2 Window Autoencoders

We take advantage of the SWEAR architecture by training autoencoders for text windows, as opposed to the standard document autoencoders. These autoencoders operate on the same sliding window subsequences as the supervised SWEAR model, autoencoding all subsequences independently and in parallel. This makes them easier to train as they only have to compress short sequences of text into a fixed-length representation. As the task of autoencoding is independent from our supervised problem, we refer to the generated encodings as *global encodings*.

4.2 Baseline: Initialization with Autoencoder Embeddings

Our baseline approach to reusing an unsupervised autoencoder in SWEAR is to initialize all embeddings with the pre-trained parameters and fix them. We call this model SWEAR-SS (for semi-supervised). The embedding matrix is fixed to the autoencoder embeddings. All other parameters are initialized randomly and trained as in the fully supervised version. We found that initializing the encoders and decoder with autoencoder weights hurts performance.

4.3 Reviewer Models

Unfortunately, this baseline approach to semi-supervised learning has significant disadvantages in our problem setting. Pre-trained RNN parameters are not fully exploited since we observed

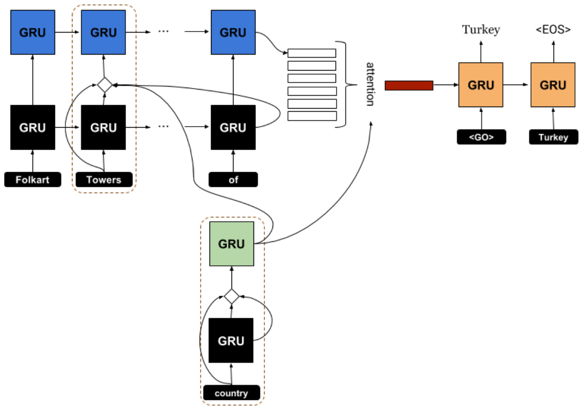

Figure 2: Multi-layer reviewer model (SWEAR-MLR), shown operating over a single window: Black boxes are RNN cells with fixed weights copied from the autoencoder, diamonds indicate vector concatenation with adapter and FC layers. For simplicity, only the cells in dashed boxes are fully illustrated (detailed in Figure 3), but the same structure is repeated for each cell.

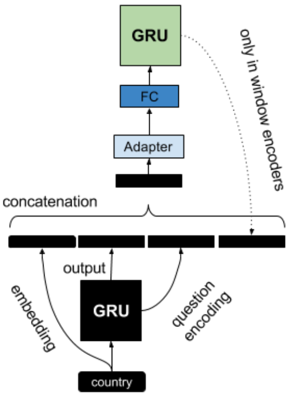

Figure 3: Detailed illustration of the dashed box in SWEAR-MLR question encoder. Black boxes are fixed parameters and encodings. The window encoder is similar, except that the output of the question reviewer layer is also added to the concatenated input (dashed line).

catastrophic forgetting when initializing and fine-tuning SWEAR with pre-trained weights. This includes fixing window encoder parameters with autoencoders and only fine-tuning question encoders. Second, conditioning the window encoders on the question eliminates the possibility to train window representations offline and utilize them later which causes a significant overhead during testing.

Inspired by recent trends in deep learning models such as Progressive Neural Networks (Rusu et al., 2016) and Reviewer Models (Yang et al., 2016), we propose multiple solutions to these problems. All of the proposed models process text input first through a fixed *autoencoder layer*: fixed pre-trained embeddings and fixed RNN encoder parameters, both initialized from the autoencoder weights. Above this autoencoder layer, we build layers of abstraction that learn to adapt the pre-trained models to the QA task.

4.3.1 Multi-Layer Reviewer (SWEAR-MLR)

The most straightforward extension to the baseline model is to fix the pretrained autoencoder RNN as the first layer and introduce a second, trainable *reviewer layer*. To make this approach more suitable for question answering, reviewer layers utilize corresponding global encodings as well as hidden states of the pre-trained autoencoders as input (Figure 2). The aim is to review both pre-trained question and window encodings to compose a single vector representing the window conditioned on the question.

Encoding questions: The question is first encoded by the autoencoder layer, $\tilde{h}^q = Enc(e^Q; \theta_U)$ where both word embeddings (E and e^Q) and encoder (θ_U) are fixed and initialized with pretrained parameters. A second, learnable RNN layer then takes the output of the autoencoder layer and corresponding input embeddings as input and produces the final question encoding, $h^q = Enc(FC([e^Q, \tilde{h}^q, \tilde{h}_t]); \theta_Q)$ where FC is a fully connected layer with ReLU activation function, and $\tilde{h}_t$ is the output of the autoencoder layer at time step t. Figure 3 illustrates a single time-step of the question encoder.

Encoding windows: Similarly, windows are encoded first by the fixed autoencoder layer and then by a reviewer layer, $\tilde{h}^w_i = Enc(e^{D_i}; \theta_U)$ and $h^w_i = Enc(FC([e^{D_i}, \tilde{h}^w_i, \tilde{h}^w_t, h^q]); \theta_W)$ where $\tilde{h}^w_t$ is the output of the autoencoder layer at time step t. Unlike supervised SWEAR, in SWEAR-MLR the window encoder is not initialized with the question encoder state. Instead, the question encoder state is an additional input to each unit in the reviewer layer (illustrated as the dashed line in Figure 3). Intuitively, the reviewer layer should reuse the global window and question information and encode only information relevant to the current question.

4.3.2 Progressive Reviewer (SWEAR-PR)

Although the reviewer layer in SWEAR-MLR has global window and question encodings as input, it requires a number of sequential steps equal to the window size, plus any additional reviewer steps. The reviewer layer also has to re-encode windows for each question, which is not ideal for online use.

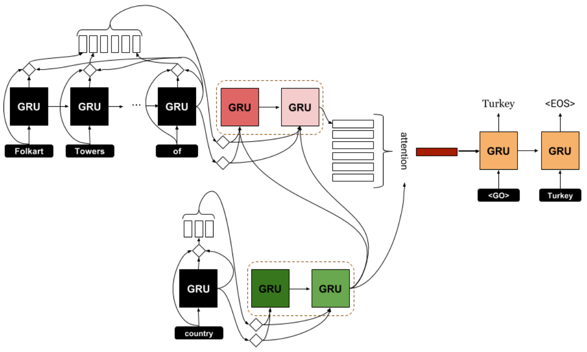

Figure 4: Progressive reviewer model (SWEAR-PR), shown operating over a single window: Black boxes are RNN cells with fixed weights copied from the autoencoder, diamonds indicate vector concatenation with adapter and FC layers. Dashed boxes contain reviewer layers. Cells within reviewer layers are decoupled as indicated by different colors.

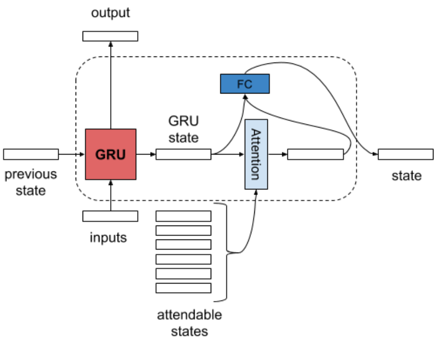

Figure 5: Illustration of attention cell: GRU state is used to attend over attendable states, then final state is computed by concatenating GRU state with context vector and passing through a fully connected neural network.

To address these issues, we now present a *Progressive Reviewer* model (SWEAR-PR) that reviews the outputs of the encoders using a separate RNN that is decoupled from the window size (Figure 4).

Encoding questions and windows: Similar to SWEAR-MLR, SWEAR-PR first encodes the questions and windows independently using autoencoder layers, $\tilde{h}^q = Enc(e^Q; \theta_U)$ and $\tilde{h}^w_i = Enc(e^{D_i}; \theta_U)$. To decouple the question and window encoders, however, SWEAR-PR does not have a second layer as a reviewer.

Reviewing questions and windows: SWEAR-PR employs two other RNNs to review the question and window encodings and to compose a single window representation conditioned on the question. Question reviewer takes the same pre-trained question encoding at each time step and attends over the hidden states and input embeddings of the pre-trained question encoder, $h^q = AttnEnc(FC(\tilde{h}^q); FC([\tilde{h}^q_t, e^Q]); \theta_Q)$ where $AttnEnc$ is an RNN with an attention cell which is illustrated in Figure 5. Outputs of the fixed autoencoder layer and fixed word embeddings, $[\tilde{h}^q_t, e^Q]$, are the attendable states. Window reviewer on the other hand takes the pre-trained window encoding and reviewed question encoding at each time step and attends over the hidden states of pre-trained window encoder, $h^w_i = AttnEnc(FC([\tilde{h}^w_i, h^q]); FC([\tilde{h}^w_t, e^{D_i}]); \theta_W)$ where outputs of the fixed autoencoder layer and fixed word embeddings, $[\tilde{h}^w_t, e^{D_i}]$, are the attendable states. As length of the windows is smaller than length of the reviewers, SWEAR-PR has significantly smaller overhead compared to other supervised and semi-supervised SWEAR variants.

4.3.3 Shared Components

Reducing window encodings and decoding: As in the supervised case described in 4, both reviewer models attend over the window encodings using the question encoding and reduce them into a single document encoding. Identical to answer decoding described in 6, the answer is decoded using another RNN taking the document state as the initial state. The parameters of this answer decoder are initialized randomly.

Adapter layer: As the distribution and scale of parameters may differ significantly between the autoencoder layer and the reviewer layer, we use an *adapter layer* similar to the adapters in Progressive Neural Networks (Rusu et al., 2016) to normalize the pre-trained parameters:

$$W_{out} = a * tanh(b * W_{in}) \tag{9}$$

where a and b are scalar variables to be learnt and W_{in} is a pre-trained input parameter. We put adapter layers after every pre-trained parameter connecting to a finetuned parameter such as on the connections from pre-trained embeddings to reviewer layer. We use dropout (Srivastava et al., 2014) regularization on both inputs and outputs of the reviewer cells.

5 Experimental Evaluation

As described in Section 2, we evaluate our models on the WikiReading task. In Section 3.5 we presented results for the supervised SWEAR on the full WikiReading dataset, establishing it as the highest-scoring method so far developed for WikiReading. We now compare our semi-supervised models SWEAR-MLR and SWEAR-

Model	1%	0.5%	0.1%
SWEAR	63.5	57.6	39.5
SWEAR-SS (RAE)	64.7	62.8	55.3
SWEAR-SS (VRAE)	**65.7**	**64.0**	**60.7**

Table 4: Mean F1 results for SWEAR (fully supervised) and SWEAR-SS (semi-supervised) trained on 1%, 0.5%, and 0.1% subsets, respectively. Variants of SWEAR-SS indicate different sources of fixed encoder weights. [2]

PR over various subsets of the WikiReading dataset, using SWEAR as a baseline.

5.1 Experimental Setup

Following Hewlett et al. (2016), we use the *Mean F1* metric for WikiReading, which assigns partial credit when there are multiple valid answers. We ran hyperparameter tuning for all models and report the result for the configuration with the highest Mean F1 on the validation set.

The supervised SWEAR model was trained on both the full training (results reported in Section 3.5) and on each subset of training data (results reported below). Unsupervised autoencoders were trained on all documents in the WikiReading training set. We selected the autoencoder with the lowest reconstruction error for use in semi-supervised experiments. After initialization with weights from the best autoencoder, learnable parameters in the semi-supervised models were trained exactly as in the supervised model.

Training Details

We implemented all models in a shared framework in TensorFlow (Abadi et al., 2016). We used the Adam optimizer (Kingma and Ba, 2014) for all training, periodically halving the learning rate according to a hyperparameter. Models were trained for a maximum of 4 epochs.

Table 7 shows which hyperparameters were tuned for each type of model, and the range of values for each hyperparameter. The parameters in the second group of the table are tuned for supervised SWEAR and the best setting (shown in bold) was used for other models where applicable. We fixed the batch size to 8 for autoencoders and 64 for semi-supervised models. We used a truncated normal distribution with a standard deviation of 0.01 for VRAE.

5.2 Results and Discussion

Model	100	200
SWEAR	25.0	33.0
SWEAR-SS (VRAE)	**39.0**	**45.0**

Table 5: Results for SWEAR and the best SWEAR-SS initialization (VRAE) trained on 100- and 200- per-property subsets, respectively.

Model	Mean F1
SWEAR-PR	**66.5**
dropout on input only	65.4
no dropout	64.6
shared reviewer cells	63.8
SWEAR-MLR	63.0
w/o skip connections	60.0

Table 6: Results for semi-supervised reviewer models trained on the 1% subset of WikiReading.

Table 4 and 5 show the results of SWEAR and semi-supervised models with pretrained and fixed embeddings. Results show that SWEAR-SS always improves over SWEAR at small data sizes, with the difference become dramatic as the dataset becomes very small. VRAE pretraining yields the best performance. As training and testing datasets have different distributions in per-property subsets, Mean F1 for supervised and semi-supervised models drops compared to uniform sampling. However, initialization with pretrained VRAE model leads to a substantial improvement on both subsamples. We further experimented by initializing the decoder (vs. only the encoder) with pretrained autoencoder weights but this resulted in a lower Mean F1.

Table 6 shows the results of semi-supervised reviewer models. When trained on 1% of the training data, SWEAR-MLR and the supervised SWEAR model perform similarly. Without using skip connections between embedding and hidden layers, the performance drops. The SWEAR-PR model further improves Mean F1 and outperforms the strongest SWEAR-SS model, even without fine-tuning the weights initialized from the autoencoder.

The success of SWEAR-PR rests on multiple design elements working together, as shown by the reduced performance caused by altering or disabling them. Using dropout only on the inputs, or not using any dropout on reviewer cells, causes a substantial decrease in Mean F1 score (by 1.1 and 1.9, respectively). Configuring the model with many more review steps (15) but with

[2] Initialization with Word2Vec (Mikolov et al., 2013) embeddings on 1% subset gives 64.0 Mean F1 score.

Parameter	**Space**

a smaller hidden vector size (128) reduced Mean F1 to 62.5. Increasing the number of review steps for the question to 5 caused a decrease in Mean F1 of 2.1.

6 Related Work

Our model architecture is one of many hierarchical models for documents proposed in the literature. The most similar is proposed by Choi et al. (2017), which uses a coarse-to-fine approach of first encoding each sentence with a cheap BoW or Conv model, then selecting the top k sentences to form a mini-document which is then processed by a standard seq2seq model. While they also evaluate their approach on WikiReading, their emphasis is on efficiency rather than model accuracy, with the resulting model performing slightly worse than the full seq2seq model but taking much less time to execute. SWEAR also requires fewer sequential steps than the document length but still computes at least as many recurrent steps in parallel.

Our model can also be viewed as containing a Memory Network (MemNet) built from a document (Weston et al., 2014; Sukhbaatar et al., 2015), where the memories are the window encodings. The core MemNet operation consists of attention over a set of vectors (memories) based on a query encoding, and then reduction of a second set of vectors by weighted sum based on the attention weights. In particular, Miller et al. (2016) introduce the Key-Value MemNet where the two sets of memories are computed from the keys and values of a map, respectively: In their QA task, each memory entry consists of a potential answer (the value) and its context bag of words (the key).

Our reviewer approach is inspired by “Encode, Review, Decode” approach introduced by Yang et al. (2016), which showed the value of introducing additional computation steps between the encoder and decoder in a seq2seq model.

The basic recurrent autoencoder was first introduced by Dai et al. (2015), a standard seq2seq model with the same input and output. Fabius et al. (2014) expanded this model into the Variational Recurrent Autoencoder (VRAE), which we describe in Section 4.1.1. VRAE is an application of the general idea of variational autoencoding, which applies variational approximation to the posterior to reconstruct the input (Kingma and Welling, 2013). While we train window autoencoders, an alternative approach is hierarchical document autoencoders (Li et al., 2015).

The semi-supervised approach of initializing the weights of an RNN encoder with those of a recurrent autoencoder was first studied by Dai et al. (2015) in the context of document classification and further studied by Ramachandran et al. (2016) for traditional sequence-to-sequence tasks such as machine translation. Our baseline semi-supervised model can be viewed as an extension of these approaches to a reading comprehension setting. Dai et al. (2015) also explore initialization from a language model, but find that the recurrent autoencoder is superior, which is why we do not consider language models in this work.

7 Conclusions

We have demonstrated the efficacy of the SWEAR architecture, reaching state of the art performance on supervised WikiReading. The model improves the extraction of precise information from long documents over the baseline seq2seq model. In a semi-supervised setting, our method of reusing (V)RAE encodings in a reading comprehension framework is effective, with SWEAR-PR reaching an accuracy of 66.5 on 1% of the dataset against last year’s state of the art of 71.8 using the full dataset. However, these methods require careful configuration and tuning to succeed, and making them more robust presents an excellent opportunity for future work.

Adversarial Examples for Evaluating Reading Comprehension Systems

Robin Jia

Abstract

Standard accuracy metrics indicate that reading comprehension systems are making rapid progress, but the extent to which these systems truly understand language remains unclear. To reward systems with real language understanding abilities, we propose an adversarial evaluation scheme for the Stanford Question Answering Dataset (SQuAD). Our method tests whether systems can answer questions about paragraphs that contain adversarially inserted sentences, which are automatically generated to distract computer systems without changing the correct answer or misleading humans. In this adversarial setting, the accuracy of sixteen published models drops from an average of 75% F1 score to 36%; when the adversary is allowed to add ungrammatical sequences of words, average accuracy on four models decreases further to 7%. We hope our insights will motivate the development of new models that understand language more precisely.

1 Introduction

Quantifying the extent to which a computer system exhibits intelligent behavior is a longstanding problem in AI (Levesque, 2013). Today, the standard paradigm is to measure average error across a held-out test set. However, models can succeed in this paradigm by recognizing patterns that happen to be predictive on most of the test examples, while ignoring deeper, more difficult phenomena (Rimell et al., 2009; Paperno et al., 2016).

Article: Super Bowl 50
Paragraph: "*Peyton Manning became the first quarterback ever to lead two different teams to multiple Super Bowls. He is also the oldest quarterback ever to play in a Super Bowl at age 39. The past record was held by John Elway, who led the Broncos to victory in Super Bowl XXXIII at age 38 and is currently Denver's Executive Vice President of Football Operations and General Manager. Quarterback Jeff Dean had jersey number 37 in Champ Bowl XXXIV.*"
Question: "*What is the name of the quarterback who was 38 in Super Bowl XXXIII?*"
Original Prediction: John Elway
Prediction under adversary: Jeff Dean

Figure 1: An example from the SQuAD dataset. The BiDAF Ensemble model originally gets the answer correct, but is fooled by the addition of an adversarial distracting sentence (in blue).

In this work, we propose adversarial evaluation for NLP, in which systems are instead evaluated on adversarially-chosen inputs. We focus on the SQuAD reading comprehension task (Rajpurkar et al., 2016), in which systems answer questions about paragraphs from Wikipedia. Reading comprehension is an appealing testbed for adversarial evaluation, as existing models appear successful by standard average-case evaluation metrics: the current state-of-the-art system achieves 84.7% F1 score, while human performance is just 91.2%.[1] Nonetheless, it seems unlikely that existing systems possess true language understanding and reasoning capabilities.

Carrying out adversarial evaluation on SQuAD requires new methods that adversarially alter reading comprehension examples. Prior work in computer vision adds imperceptible adversarial perturbations to input images, relying on the fact that such small perturbations cannot change an image's true label (Szegedy et al., 2014; Goodfellow et al., 2015). In contrast, changing even one word of a

Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

paragraph can drastically alter its meaning. Instead of relying on semantics-preserving perturbations, we create adversarial examples by adding distracting sentences to the input paragraph, as shown in Figure 1. We automatically generate these sentences so that they confuse models, but do not contradict the correct answer or confuse humans. For our main results, we use a simple set of rules to generate a raw distractor sentence that does not answer the question but looks related; we then fix grammatical errors via crowdsourcing. While adversarially perturbed images punish model *oversensitivity* to imperceptible noise, our adversarial examples target model *overstability*—the inability of a model to distinguish a sentence that actually answers the question from one that merely has words in common with it.

Our experiments demonstrate that no published open-source model is robust to the addition of adversarial sentences. Across sixteen such models, adding grammatical adversarial sentences reduces F1 score from an average of 75% to 36%. On a smaller set of four models, we run additional experiments in which the adversary adds non-grammatical sequences of English words, causing average F1 score to drop further to 7%. To encourage the development of new models that understand language more precisely, we have released all of our code and data publicly.

2 The SQuAD Task and Models

2.1 Task

The SQuAD dataset (Rajpurkar et al., 2016) contains 107,785 human-generated reading comprehension questions about Wikipedia articles. Each question refers to one paragraph of an article, and the corresponding answer is guaranteed to be a span in that paragraph.

2.2 Models

When developing and testing our methods, we focused on two published model architectures: BiDAF (Seo et al., 2016) and Match-LSTM (Wang and Jiang, 2016). Both are deep learning architectures that predict a probability distribution over the correct answer. Each model has a single and an ensemble version, yielding four systems in total.

We also validate our major findings on twelve other published models with publicly available test-time code: ReasoNet Single and Ensemble versions (Shen et al., 2017), Mnemonic Reader Single and Ensemble versions (Hu et al., 2017), Structural Embedding of Dependency Trees (SEDT) Single and Ensemble versions (Liu et al., 2017), jNet (Zhang et al., 2017), Ruminating Reader (Gong and Bowman, 2017), Multi-Perspective Context Matching (MPCM) Single version (Wang et al., 2016), RaSOR (Lee et al., 2017), Dynamic Chunk Reader (DCR) (Yu et al., 2016), and the Logistic Regression Baseline (Rajpurkar et al., 2016). We did not run these models during development, so they serve as a held-out set that validates the generality of our approach.

2.3 Standard Evaluation

Given a model f that takes in paragraph-question pairs (p, q) and outputs an answer $\hat{a}$, the *standard accuracy* over a test set D_{test} is simply

$$\text{Acc}(f) \overset{\text{def}}{=} \frac{1}{|D_{\text{test}}|} \sum_{(p,q,a)\in D_{\text{test}}} v((p, q, a), f),$$

where v is the F1 score between the true answer a and the predicted answer $f(p, q)$ (see Rajpurkar et al. (2016) for details).

3 Adversarial Evaluation

3.1 General Framework

A model that relies on superficial cues without understanding language can do well according to average F1 score, if these cues happen to be predictive most of the time. Weissenborn et al. (2017) argue that many SQuAD questions can be answered with heuristics based on type and keyword-matching. To determine whether existing models have learned much beyond such simple patterns, we introduce adversaries that confuse deficient models by altering test examples. Consider the example in Figure 1: the BiDAF Ensemble model originally gives the right answer, but gets confused when an adversarial distracting sentence is added to the paragraph.

We define an adversary A to be a function that takes in an example (p, q, a), optionally with a model f, and returns a new example (p', q', a'). The *adversarial accuracy* with respect to A is

$$\text{Adv}(f) \overset{\text{def}}{=} \frac{1}{|D_{\text{test}}|} \sum_{(p,q,a)\in D_{\text{test}}} v(A(p, q, a, f), f)).$$

While standard test error measures the fraction of the test distribution over which the model gets the correct answer, the adversarial accuracy measures

	Image Classification	Reading Comprehension
Possible Input		Tesla moved to the city of Chicago in 1880.
Similar Input		Tadakatsu moved to the city of Chicago in 1881.
Semantics	Same	Different
Model's Mistake	Considers the two to be different	Considers the two to be the same
Model Weakness	Overly sensitive	Overly stable

Table 1: Adversarial examples in computer vision exploit model oversensitivity to small perturbations. In contrast, our adversarial examples work because models do not realize that a small perturbation can completely change the meaning of a sentence. Images from Szegedy et al. (2014).

the fraction over which the model is *robustly* correct, even in the face of adversarially-chosen alterations. For this quantity to be meaningful, the adversary must satisfy two basic requirements: first, it should always generate (p', q', a') tuples that are *valid*—a human would judge a' as the correct answer to q' given p'. Second, (p', q', a') should be somehow "close" to the original example (p, q, a).

3.2 Semantics-preserving Adversaries

In image classification, adversarial examples are commonly generated by adding an imperceptible amount of noise to the input (Szegedy et al., 2014; Goodfellow et al., 2015). These perturbations do not change the semantics of the image, but they can change the predictions of models that are *oversensitive* to semantics-preserving changes. For language, the direct analogue would be to paraphrase the input (Madnani and Dorr, 2010). However, high-precision paraphrase generation is challenging, as most edits to a sentence do actually change its meaning.

3.3 Concatenative Adversaries

Instead of relying on paraphrasing, we use perturbations that do alter semantics to build *concatenative* adversaries, which generate examples of the form $(p + s, q, a)$ for some sentence s. In other words, concatenative adversaries add a new sentence to the end of the paragraph, and leave the question and answer unchanged. Valid adversarial examples are precisely those for which s does not contradict the correct answer; we refer to such sentences as being *compatible* with (p, q, a). We use semantics-altering perturbations to that ensure that s is compatible, even though it may have many words in common with the question q. Existing models are bad at distinguishing these sentences from sentences that do in fact address the question, indicating that they suffer not from oversensitivity but from *overstability* to semantics-altering edits. Table 1 summarizes this important distinction.

The decision to always append s to the end of p is somewhat arbitrary; we could also prepend it to the beginning, though this would violate the expectation of the first sentence being a topic sentence. Both are more likely to preserve the validity of the example than inserting s in the middle of p, which runs the risk of breaking coreference links.

Now, we describe two concrete concatenative adversaries, as well as two variants. AddSent, our main adversary, adds grammatical sentences that look similar to the question. In contrast, AddAny adds arbitrary sequences of English words, giving it more power to confuse models. Figure 2 illustrates these two main adversaries.

3.3.1 AddSent

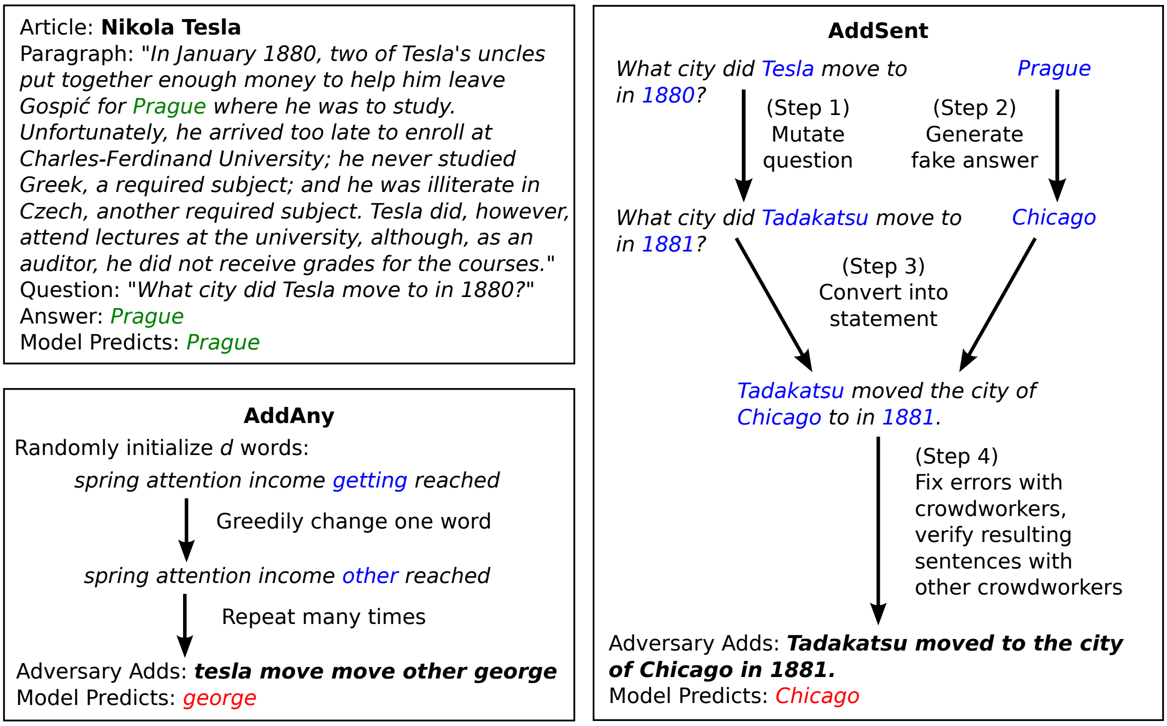
AddSent uses a four-step procedure to generate sentences that look similar to the question, but do not actually contradict the correct answer. Refer to Figure 2 for an illustration of these steps.

In Step 1, we apply semantics-altering perturbations to the question, in order to guarantee that the resulting adversarial sentence is compatible. We replace nouns and adjectives with antonyms from WordNet (Fellbaum, 1998), and change named entities and numbers to the nearest word in GloVe word vector space[2] (Pennington et al., 2014) with the same part of speech.[3] If no words are changed during this step, the adversary gives up and immediately returns the original example. For example, given the question "*What ABC division handles domestic television distribution?*", we would change "*ABC*" to "*NBC*" (a nearby word in vector space) and "*domestic*" to "*foreign*" (a WordNet antonym), resulting in the question, "*What NBC division handles foreign television distribution?*"

In Step 2, we create a fake answer that has the same "type" as the original answer. We define a set

[2] We use 100-dimensional GloVe vectors trained on Wikipedia and Euclidean distance to define nearby words.

[3] We choose the nearest word whose most common gold POS tag in the Penn Treebank (Marcus et al., 1999) matches the predicted POS tag of the original word, according to CoreNLP. If none of the nearest 100 words satisfy this, we just return the single closest word.



Article: Nikola Tesla
Paragraph: "In January 1880, two of Tesla's uncles put together enough money to help him leave Gospić for Prague where he was to study. Unfortunately, he arrived too late to enroll at Charles-Ferdinand University; he never studied Greek, a required subject; and he was illiterate in Czech, another required subject. Tesla did, however, attend lectures at the university, although, as an auditor, he did not receive grades for the courses."
Question: "What city did Tesla move to in 1880?"
Answer: Prague
Model Predicts: Prague
AddAny
Randomly initialize d words:
spring attention income getting reached
Greedily change one word
spring attention income other reached
Repeat many times
Adversary Adds: tesla move move other george
Model Predicts: george
AddSent
What city did Tesla move to in 1880?
Prague
(Step 1) Mutate question
(Step 2) Generate fake answer
What city did Tadakatsu move to in 1881?
Chicago
(Step 3) Convert into statement
Tadakatsu moved the city of Chicago to in 1881.
(Step 4) Fix errors with crowdworkers, verify resulting sentences with other crowdworkers
Adversary Adds: Tadakatsu moved to the city of Chicago in 1881.
Model Predicts: Chicago

Figure 2: An illustration of the AddSent and AddAny adversaries.

of 26 types, corresponding to NER and POS tags from Stanford CoreNLP (Manning et al., 2014), plus a few custom categories (e.g., abbreviations), and manually associate a fake answer with each type. Given the original answer to a question, we compute its type and return the corresponding fake answer. In our running example, the correct answer was not tagged as a named entity, and has the POS tag `NNP`, which corresponds to the fake answer "*Central Park.*"

In Step 3, we combine the altered question and fake answer into declarative form, using a set of roughly 50 manually-defined rules over CoreNLP constituency parses. For example, "*What ABC division handles domestic television distribution?*" triggers a rule that converts questions of the form "*what/which* $\texttt{NP}_1$ $\texttt{VP}_1$?" to "The $\texttt{NP}_1$ of `[Answer]` $\texttt{VP}_1$". After incorporating the alterations and fake answer from the previous steps, we generate the sentence, "*The NBC division of Central Park handles foreign television distribution.*"

The raw sentences generated by Step 3 can be ungrammatical or otherwise unnatural due to the incompleteness of our rules and errors in constituency parsing. Therefore, in Step 4, we fix errors in these sentences via crowdsourcing. Each sentence is edited independently by five workers on Amazon Mechanical Turk, resulting in up to five sentences for each raw sentence. Three additional crowdworkers then filter out sentences that are ungrammatical or incompatible, resulting in a smaller (possibly empty) set of human-approved sentences. The full AddSent adversary runs the model f as a black box on every human-approved sentence, and picks the one that makes the model give the worst answer. If there are no human-approved sentences, the adversary simply returns the original example.

A model-independent adversary. AddSent requires a small number of queries to the model under evaluation. To explore the possibility of an adversary that is completely model-independent, we also introduce AddOneSent, which adds a random human-approved sentence to the paragraph. In contrast with prior work in computer vision (Papernot et al., 2017; Narodytska and Kasiviswanathan, 2016; Moosavi-Dezfooli et al., 2017), AddOneSent does not require any access to the model or to any training data: it generates adversarial examples based solely on the intuition that existing models are overly stable.

3.3.2 AddAny

For AddAny, the goal is to choose any sequence of d words, regardless of grammaticality. We use local search to adversarially choose a distracting sentence $s = w_1 w_2 \dots w_d$. Figure 2 shows an example of AddAny with $d = 5$ words; in our experiments, we use $d = 10$.

We first initialize words $w_1, \dots, w_d$ randomly from a list of common English words.[4] Then, we run 6 epochs of local search, each of which iterates over the indices $i \in \{1, \dots, d\}$ in a random order. For each i, we randomly generate a set of candidate words W as the union of 20 randomly sampled common words and all words in q. For each $x \in W$, we generate the sentence with x in the i-th position and w_j in the j-th position for each $j \neq i$. We try adding each sentence to the paragraph and query the model for its predicted probability distribution over answers. We update w_i to be the x that minimizes the expected value of the F1 score over the model's output distribution. We return immediately if the model's argmax prediction has 0 F1 score. If we do not stop after 3 epochs, we randomly initialize 4 additional word sequences, and search over all of these random initializations in parallel.

AddAny requires significantly more model access than AddSent: not only does it query the model many times during the search process, but it also assumes that the model returns a probability distribution over answers, instead of just a single prediction. Without this assumption, we would have to rely on something like the F1 score of the argmax prediction, which is piecewise constant and therefore harder to optimize. "Probabilistic" query access is still weaker than access to gradients, as is common in computer vision (Szegedy et al., 2014; Goodfellow et al., 2015).

We do not do anything to ensure that the sentences generated by this search procedure do not contradict the original answer. In practice, the generated "sentences" are gibberish that use many question words but have no semantic content (see Figure 2 for an example).

Finally, we note that both AddSent and AddAny try to incorporate words from the question into their adversarial sentences. While this is an obvious way to draw the model's attention, we were curious if we could also distract the model without such a straightforward approach. To this end, we introduce a variant of AddAny called AddCommon, which is exactly like AddAny except it only adds common words.

	Match Single	Match Ens.	BiDAF Single	BiDAF Ens.
Original	71.4	75.4	75.5	80.0
AddSent	27.3	29.4	34.3	34.2
AddOneSent	39.0	41.8	45.7	46.9
AddAny	7.6	11.7	4.8	2.7
AddCommon	38.9	51.0	41.7	52.6

Table 2: Adversarial evaluation on the Match-LSTM and BiDAF systems. All four systems can be fooled by adversarial examples.

Model	Original	AddSent	AddOneSent
ReasoNet-E	**81.1**	39.4	49.8

Logistic	50.4	23.2	30.4

Table 3: AddSent and AddOneSent on all sixteen models, sorted by F1 score the original examples. S = single, E = ensemble.

4 Experiments

4.1 Setup

For all experiments, we measure adversarial F1 score (Rajpurkar et al., 2016) across 1000 randomly sampled examples from the SQuAD development set (the test set is not publicly available). Downsampling was helpful because AddAny and AddCommon can issue thousands of model queries per example, making them very slow. As the effect sizes we measure are large, this downsampling does not hurt statistical significance.

4.2 Main Experiments

Table 2 shows the performance of the Match-LSTM and BiDAF models against all four adversaries. Each model incurred a significant accuracy drop under every form of adversarial evaluation. AddSent made average F1 score across the four models fall from 75.7% to 31.3%. AddAny was even more effective, making average F1 score fall to 6.7%. AddOneSent retained much of the effectiveness of AddSent, despite being model-independent. Finally, AddCommon caused aver-

[4] We define common words as the 1000 most frequent words in the Brown corpus (Francis and Kucera, 1979).

	Human
Original	92.6
AddSent	79.5
AddOneSent	89.2

Table 4: Human evaulation on adversarial examples. Human accuracy drops on AddSent mostly due to unrelated errors; the AddOneSent numbers show that humans are robust to adversarial sentences.

age F1 score to fall to 46.1%, despite only adding common words.

We also verified that our adversaries were general enough to fool models that we did not use during development. We ran AddSent on twelve published models for which we found publicly available test-time code; we did not run AddAny on these models, as not all models exposed output distributions. As seen in Table 3, no model was robust to adversarial evaluation; across the sixteen total models tested, average F1 score fell from 75.4% to 36.4% under AddSent.

It is noteworthy that the Mnemonic Reader models (Hu et al., 2017) outperform the other models by about 6 F1 points. We hypothesize that Mnemonic Reader's self-alignment layer, which helps model long-distance relationships between parts of the paragraph, makes it better at locating all pieces of evidence that support the correct answer. Therefore, it can be more confident in the correct answer, compared to the fake answer inserted by the adversary.

4.3 Human Evaluation

To ensure our results are valid, we verified that humans are not also fooled by our adversarial examples. As AddAny requires too many model queries to run against humans, we focused on AddSent. We presented each original and adversarial paragraph-question pair to three crowdworkers, and asked them to select the correct answer by copy-and-pasting from the paragraph. We then took a majority vote over the three responses (if all three responses were different, we picked one at random). These results are shown in Table 4. On original examples, our humans are actually slightly better than the reported number of 91.2 F1 on the entire development set. On AddSent, human accuracy drops by 13.1 F1 points, much less than the computer systems.

Moreover, much of this decrease can be explained by mistakes unrelated to our adversarial sentences. Recall that AddSent picks the worst case over up to five different paragraph-question pairs. Even if we showed the same original example to five sets of three crowdworkers, chances are that at least one of the five groups would make a mistake, just because humans naturally err. Therefore, it is more meaningful to evaluate humans on AddOneSent, on which their accuracy drops by only 3.4 F1 points.

4.4 Analysis

Next, we sought to better understand the behavior of our four main models under adversarial evaluation. To highlight errors caused by the adversary, we focused on examples where the model originally predicted the (exact) correct answer. We divided this set into "model successes"—examples where the model continued being correct during adversarial evaluation—and "model failures"—examples where the model gave a wrong answer during adversarial evaluation.

4.4.1 Manual verification

First, we verified that the sentences added by AddSent are actually grammatical and compatible. We manually checked 100 randomly chosen BiDAF Ensemble failures. We found only one where the sentence could be interpreted as answering the question: in this case, AddSent replaced the word "*Muslim*" with the related word "*Islamic*", so the resulting adversarial sentence still contradicted the correct answer. Additionally, we found 7 minor grammar errors, such as subject-verb disagreement (e.g., "*The Alaskan Archipelago* ***are*** *made up almost entirely of hamsters.*") and misuse of function words (e.g., "*The gas* ***of*** *nitrogen makes up 21.8 % of* ***the*** *Mars's atmosphere.*"), but no errors that materially impeded understanding of the sentence.

We also verified compatibility for AddAny. We found no violations out of 100 randomly chosen BiDAF Ensemble failures.

4.4.2 Error analysis

Next, we wanted to understand what types of errors the models made on the AddSent examples. In 96.6% of model failures, the model predicted a span in the adversarial sentence. The lengths of the predicted answers were mostly similar to those of correct answers, but the BiDAF models occasionally predicted very long spans. The BiDAF Single model predicted an answer of more than

29 words—the length of the longest answer in the SQuAD development set—on 5.0% of model failures; for BiDAF Ensemble, this number was 1.6%. Since the BiDAF models independently predict the start and end positions of the answer, they can predict very long spans when the end pointer is influenced by the adversarial sentence, but the start pointer is not. Match-LSTM has a similar structure, but also has a hard-coded rule that stops it from predicting very long answers.

We also analyzed human failures—examples where the humans were correct originally, but wrong during adversarial evaluation. Humans predicted from the adversarial sentence on only 27.3% of these error cases, which confirms that many errors are normal mistakes unrelated to adversarial sentences.

4.4.3 Categorizing ADDSENT sentences

We then manually examined sentences generated by ADDSENT. In 100 BiDAF Ensemble failures, we found 75 cases where an entity name was changed in the adversarial sentence, 17 cases where numbers or dates were changed, and 33 cases where an antonym of a question word was used.[5] Additionally, 7 sentences had other miscellaneous perturbations made by crowdworkers during Step 4 of ADDSENT. For example, on a question about the "*Kalven Report*", the adversarial sentence discussed "*The statement Kalven cited*" instead; in another case, the question, "*How does Kenya curb corruption?*" was met by the unhelpful sentence, "*Tanzania is curbing corruption*" (the model simply answered, "*corruption*").

4.4.4 Reasons for model successes

Finally, we sought to understand the factors that influence whether the model will be robust to adversarial perturbations on a particular example. First, we found that models do well when the question has an exact n-gram match with the original paragraph. Figure 3 plots the fraction of examples for which an n-gram in the question appears verbatim in the original passage; this is much higher for model successes. For example, 41.5% of BiDAF Ensemble successes had a 4-gram in common with the original paragraph, compared to only 21.0% of model failures.

We also found that models succeeded more often on short questions. Figure 4 shows the distribution of question length on model successes and failures; successes tend to involve shorter questions. For example, 32.7% of the questions in BiDAF Ensemble successes were 8 words or shorter, compared to only 11.8% for model failures. This effect arises because ADDSENT always changes at least one word in the question. For long questions, changing one word leaves many others unchanged, so the adversarial sentence still has many words in common with the question. For short questions, changing one content word may be enough to make the adversarial sentence completely irrelevant.

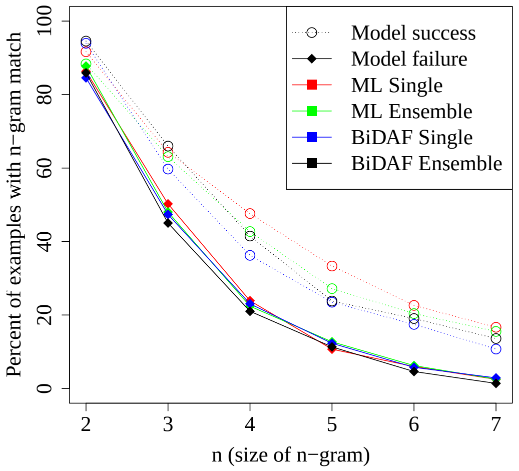

Figure 3: Fraction of model successes and failures on ADDSENT for which the question has an exact n-gram match with the original paragraph. For each model and each value of n, successes are more likely to have an n-gram match than failures.

Targeted Model	Model under Evaluation			
	ML Single	ML Ens.	BiDAF Single	BiDAF Ens.
ADDSENT				
ML Single	27.3	33.4	40.3	39.1
ML Ens.	31.6	29.4	40.2	38.7
BiDAF Single	32.7	34.8	34.3	37.4
BiDAF Ens.	32.7	34.2	38.3	34.2
ADDANY				
ML Single	7.6	54.1	57.1	60.9
ML Ens.	44.9	11.7	50.4	54.8
BiDAF Single	58.4	60.5	4.8	46.4
BiDAF Ens.	48.8	51.1	25.0	2.7

Table 5: Transferability of adversarial examples across models. Each row measures performance on adversarial examples generated to target one particular model; each column evaluates one (possibly different) model on these examples.

[5] These numbers add up to more than 100 because more than one word can be altered per example.

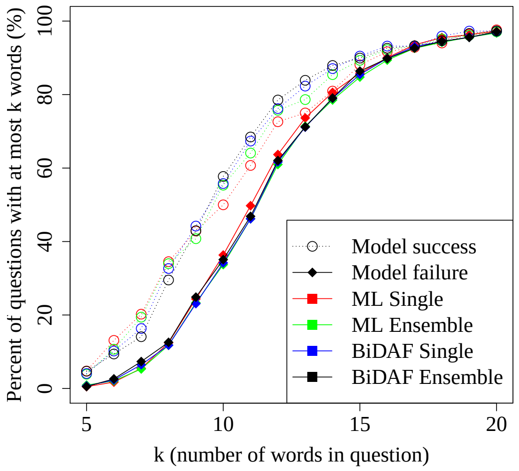

Figure 4: For model successes and failures on AddSent, the cumulative distribution function of the number of words in the question (for each k, what fraction of questions have $\leq k$ words). Successes are more likely to involve short questions.

4.5 Transferability across Models

In computer vision, adversarial examples that fool one model also tend to fool other models (Szegedy et al., 2014; Moosavi-Dezfooli et al., 2017); we investigate whether the same pattern holds for us. Examples from AddOneSent clearly do transfer across models, since AddOneSent always adds the same adversarial sentence regardless of model.

Table 5 shows the results of evaluating the four main models on adversarial examples generated by running either AddSent or AddAny against each model. AddSent adversarial examples transfer between models quite effectively; in particular, they are harder than AddOneSent examples, which implies that examples that fool one model are more likely to fool other models. The AddAny adversarial examples exhibited more limited transferability between models. For both AddSent and AddAny, examples transferred slightly better between single and ensemble versions of the same model.

4.6 Training on Adversarial Examples

Finally, we tried training on adversarial examples, to see if existing models can learn to become more robust. Due to the prohibitive cost of running AddSent or AddAny on the entire training set, we instead ran only Steps 1-3 of AddSent (everything except crowdsourcing) to generate a raw adversarial sentence for each training example. We then trained the BiDAF model from scratch on the union of these examples and the original training data. As a control, we also trained a second BiDAF model on the original training data alone.[6]

	Training data	
Test data	Original	Augmented
Original	75.8	75.1
AddSent	34.8	70.4
AddSentMod	34.3	39.2

Table 6: Effect of training the BiDAF Single model on the original training data alone (first column) versus augmenting the data with raw AddSent examples (second column).

The results of evaluating these models are shown in Table 6. At first glance, training on adversarial data seems effective, as it largely protects against AddSent. However, further investigation shows that training on these examples has only limited utility. To demonstrate this, we created a variant of AddSent called AddSentMod, which differs from AddSent in two ways: it uses a different set of fake answers (e.g., PERSON named entities map to "*Charles Babbage*" instead of "*Jeff Dean*"), and it prepends the adversarial sentence to the beginning of the paragraph instead of appending it to the end. The retrained model does almost as badly as the original one on AddSentMod, suggesting that it has just learned to ignore the last sentence and reject the fake answers that AddSent usually proposed. In order for training on adversarial examples to actually improve the model, more care must be taken to ensure that the model cannot overfit the adversary.

5 Discussion and Related Work

Despite appearing successful by standard evaluation metrics, existing machine learning systems for reading comprehension perform poorly under adversarial evaluation. Standard evaluation is overly lenient on models that rely on superficial cues. In contrast, adversarial evaluation reveals that existing models are overly stable to perturbations that alter semantics.

To optimize adversarial evaluation metrics, we may need new strategies for training models. For certain classes of models and adversaries, efficient training strategies exist: for example, Globerson and Roweis (2006) train classifiers that are optimally robust to adversarial feature deletion. Ad-

[6] All previous experiments used parameters released by Seo et al. (2016)

versarial training (Goodfellow et al., 2015) can be used for any model trained with stochastic gradient descent, but it requires generating new adversarial examples at every iteration; this is feasible for images, where fast gradient-based adversaries exist, but is infeasible for domains where only slower adversaries are available.

We contrast *adversarial evaluation*, as studied in this work, with *generative adversarial models*. While related in name, the two have very different goals. Generative adversarial models pit a generative model, whose goal is to generate realistic outputs, against a discriminative model, whose goal is to distinguish the generator's outputs from real data (Smith, 2012; Goodfellow et al., 2014). Bowman et al. (2016) and Li et al. (2017) used such a setup for sentence and dialogue generation, respectively. Our setup also involves a generator and a discriminator in an adversarial relationship; however, our discriminative system is tasked with finding the right answer, not distinguishing the generated examples from real ones, and our goal is to evaluate the discriminative system, not to train the generative one.

While we use adversaries as a way to evaluate language understanding, robustness to adversarial attacks may also be its own goal for tasks such as spam detection. Dalvi et al. (2004) formulated such tasks as a game between a classifier and an adversary, and analyzed optimal strategies for each player. Lowd and Meek (2005) described an efficient attack by which an adversary can reverse-engineer the weights of a linear classifier, in order to then generate adversarial inputs. In contrast with these methods, we do not make strong structural assumptions about our classifiers.

Other work has proposed harder test datasets for various tasks. Levesque (2013) proposed the Winograd Schema challenge, in which computers must resolve coreference resolution problems that were handcrafted to require extensive world knowledge. Paperno et al. (2016) constructed the LAMBADA dataset, which tests the ability of language models to handle long-range dependencies. Their method relies on the availability of a large initial dataset, from which they distill a difficult subset; such initial data may be unavailable for many tasks. Rimell et al. (2009) showed that dependency parsers that seem very accurate by standard metrics perform poorly on a subset of the test data that has unbounded dependency constructions. Such evaluation schemes can only test models on phenomena that are moderately frequent in the test distribution; by perturbing test examples, we can introduce out-of-distribution phenomena while still leveraging prior data collection efforts.

While concatenative adversaries are well-suited to reading comprehension, other adversarial methods may prove more effective on other tasks. As discussed previously, paraphrase generation systems (Madnani and Dorr, 2010) could be used for adversarial evaluation on a wide range of language tasks. Building on our intuition that existing models are overly stable, we could apply meaning-altering perturbations to inputs on tasks like machine translation, and adversarially choose ones for which the model's output does *not* change. We could also adversarially generate new examples by combining multiple existing ones, in the spirit of Data Recombination (Jia and Liang, 2016). The Build It, Break It shared task (Bender et al., 2017) encourages researchers to adversarially design minimal pairs to fool sentiment analysis and semantic role labeling systems.

Progress on building systems that truly understand language is only possible if our evaluation metrics can distinguish real intelligent behavior from shallow pattern matching. To this end, we have released scripts to run ADDSENT on any SQuAD system, as well as code for ADDANY. We hope that our work will motivate the development of more sophisticated models that understand language at a deeper level.

Abstract

Reasoning with commonsense knowledge is critical for natural language understanding. Traditional methods for commonsense machine comprehension mostly only focus on one specific kind of knowledge, neglecting the fact that commonsense reasoning requires simultaneously considering different kinds of commonsense knowledge. In this paper, we propose a multi-knowledge reasoning method, which can exploit heterogeneous knowledge for commonsense machine comprehension. Specifically, we first mine different kinds of knowledge (including event narrative knowledge, entity semantic knowledge and sentiment coherent knowledge) and encode them as inference rules with costs. Then we propose a multi-knowledge reasoning model, which selects inference rules for a specific reasoning context using attention mechanism, and reasons by summarizing all valid inference rules. Experiments on RocStories show that our method outperforms traditional models significantly.

1 Introduction

Commonsense knowledge is fundamental in artificial intelligence, and has long been a key component in natural language understanding and human-like reasoning. For example, to understand the relation between sentences "*Mary walked to a restaurant*" and "*She ordered some foods*", we need commonsense knowledge such as "*Mary is a girl*", "*restaurant sells food*", etc. The task of understanding natural language with commonsense knowledge is usually referred as *commonsense machine comprehension*, which has been a hot topic in recent years (Richardson et al., 2013; Weston et al., 2015; Zhang et al., 2016).

Recently, *RocStories* (Mostafazadeh et al., 2016a), a commonsense machine comprehension task, has attached many researchers' attention due to its significant difference from previous machine comprehension tasks. *RocStories* focuses on reasoning with implicit commonsense knowledge, rather than matching with explicit information in given contexts. In this task, a system requires choosing a sentence, namely *hypothesis*, to complete a given commonsense story, called as *premise document*. Table 1 shows two examples. RocStories proposes a challenging benchmark task for evaluating commonsense-based language understanding. As investigated by Mostafazadeh et al.(2016a), this dataset does not have any boundary cases and thus results in 100% human performance.

Commonsense machine comprehension, however, is an natural ability for human but could be very challenging for computers. In general, any world knowledge whatsoever in the reader's mind can affect the choice of an interpretation (Dahlgren et al., 1989). That is, a person can learn any heterogeneous commonsense knowledge and make inference of given information based on all knowledge in his mind. For example, to choose the right hypothesis for the first premise document in Table 1, we needs the event narrative knowledge that "*X does a thorough job*" will lead to "*commends X*", rather than "*fire X*". Besides, people can further confirm their judgement based on the sentimental coherence between "*finish super early*" and "*job well done*". Furthermore, in the second example, even both hypothesises are consistent with the premise document in both event and sentimental facets, we can still infer the right answer easily using the commonsense knowledge that "*puppy*" is a dog, meanwhile "*kitten*" is a cat.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2032–2043
Copenhagen, Denmark, September 7–11, 2017.

Premise Document	Right Hypothesis	Wrong Hypothesis
Ron started his new job as a landscaper today. He loves the outdoors and has always enjoyed working in it. His boss tells him to re-sod the front yard of the mayor's home. Ron is ecstatic, but **does a thorough job** and **finishes super early**.	His boss **commends** him for a **job well done**.	Ron is immediately **fired** for insubordination.
One day, my sister came over to the house to show us her **puppy**. She told us that she had just gotten the puppy across the street. My sons begged me to get them one. I told them that if they would care for it, they could have it.	My son said they would, so we got a **dog**.	We then grabbed a small **kitten**.

Table 1: Examples of RocStories Dataset.

In recent years, many methods have been proposed for commonsense machine comprehension. However, these methods mostly either focus on matching explicit information in given texts (Weston et al., 2014; Wang and Jiang, 2016a,b; Wang et al., 2016b; Zhao et al., 2017), or paid attention to one specific kind of commonsense knowledge, such as event temporal relation (Chambers and Jurafsky, 2008; Modi and Titov, 2014; Pichotta and Mooney, 2016b; Hu et al., 2017) and event causality (Do et al., 2011; Radinsky et al., 2012; Hashimoto et al., 2015; Gui et al., 2016). As discussed above, it is obvious that commonsense machine comprehension problem is far from settled by considering only explicit or a single kind of commonsense knowledge. To achieve human-like comprehension and reasoning, there exist two main challenges:

1) How to mine and represent different kinds of implicit knowledge that commonsense machine comprehension needs. For example, to complete the first example in Table 1, we need a system equipped with the event narrative knowledge that "*commends X*" can be inferred from "*X does a thorough job*", as well as the sentiment coherent knowledge that "*insubordination*" and "*finish super early*" are sentimental incoherent.

2) How to reason with various kinds of commonsense knowledge. As shown above, knowledge that reasoning process needs varies for different contexts. For human-like commonsense machine comprehension, a system should take various kinds of knowledge into consideration, decide what knowledge will be utilized in a specific reasoning contexts, and make the final decision by taking all utilized knowledge into consideration.

To address the above problems, this paper proposes a new commonsense reasoning approach, which can mine and exploit heterogeneous knowledge for commonsense machine comprehension. Specifically, we first mine different kinds of knowledge from raw text and relevant knowledge base, including event narrative knowledge, entity semantic knowledge and sentiment coherent knowledge. These heterogeneous knowledge are encoded into a uniform representation – inference rules between elements under different kinds of relations, with an inference cost for each rule. Then we design a rule selection model using attention mechanism, modeling which inference rules will be applied in a specific reasoning context. Finally, we propose a multi-knowledge reasoning model, which measures the reasoning distance from a premise document to a hypothesis as the expected cost sum of all inference rules applied in the reasoning process.

By modeling and exploiting heterogeneous knowledge during commonsense reasoning, our method can achieve more accurate and more robust performance than traditional methods. Furthermore, our method is a general framework, which can be extended to incorporate new knowledge easily. Experiments show that our method achieves a 13.7% accuracy improvement on the standard RocStories dataset, a significant improvement over previous work.

2 Commonsense Knowledge Acquisition for Machine Comprehension

As described above, various knowledge can be exploited for machine comprehension. In this section, we describe how to mine different knowledge from different sources. Specifically, we mine three types of commonly used commonsense knowledge, including: 1)*Event narrative knowledge*, which captures temporal and causal relations between events; 2)*Entity semantic knowledge*, which captures semantic relations between entities; 3)*Sentiment coherent knowledge*, which captures sentimental coherence between elements.

In this paper, we represent commonsense knowledge as a set of inference rules given in the form of $X \xrightarrow{f} Y : s$, which means that element Y can be inferred from element X under relation f, with an inference cost s. An element can stand

	Antecedent	Consequent	Relation	Cost
①	Mary	she	coreference	0.0
②	restaurant	order	narrative	0.1
③	restaurant	food	associative	0.1
④	restaurant	food	narrative	0.3
⑤	Mary	order	narrative	0.5
⑥	walk	sleep	narrative	0.8
⑦	walk	food	narrative	0.9

Table 2: Examples of Inference Rules.

for either event, entity or sentiment, and this paper represents elements using lemmatized nouns, verbs and adjectives. The lexical element representation can also be easily extended to structural representation, like the one in (Chambers and Jurafsky, 2008), if needed. However, in auxiliary experiments we found that using structural elements results in severe sparseness and noises which in turn will hurt the reasoning performance. Therefore, we think an individual work is needed to solve it. Table 2 demonstrates several examples of inference rules. In following, we describe how to mine different types of inference rules.

2.1 Mining Event Narrative Knowledge

Event narrative knowledge captures structured temporal and casual knowledge about stereotypical event sequences, which is fundamental for commonsense machine comprehension. For example, we can infer "X ordered some foods" from "X walked to a restaurant" using event narrative knowledge. Previous work (Chambers and Jurafsky, 2008; Rudinger et al., 2015) proves that event narrative knowledge can be mined from raw texts unsupervisedly. So we propose two models to encode this knowledge using inference rules.

The first one is based on ordered PMI, which is also proposed by Rudinger et al. (2015). Given two element e_1 and e_2, this model calculates the cost of inference rule $e_1 \xrightarrow{narrative} e_2$ as:

$$cost(e_1 \rightarrow e_2) = -log\frac{C(e_1, e_2)}{C(e_1, *), C(*, e_2)} \tag{1}$$

Here $C(e_1, e_2)$ is the order sensitive count that element e_1 occurs before element e_2 in different sentences of the same document.

The second model is a variant of the skip-gram model (Mikolov et al., 2013). The goal of this model is to find element representations which can accurately predict relevant elements in sentences afterwards. Formally, given n asymmetric pairs of elements $(e_1^1, e_2^1), (e_1^2, e_2^2), ..., (e_1^n, e_2^n)$ identified from training data, the objective of our model is to maximize the average log probability $\frac{1}{n}\sum_{i=1}^{n} logP(e_2^i|e_1^i)$. And the probability $P(e_2|e_1)$ is defined using the softmax function:

$$P(e_2|e_1) \propto exp(\mathbf{v}'_{e_2}{}^T \mathbf{v}_{e_1}) \tag{2}$$

where $\mathbf{v}_e$ and $\mathbf{v}'_e$ are "antecedent" and "consequent" vector representation of element e, respectively. We use the negative inner product $-\mathbf{v}'_{e_2}{}^T \mathbf{v}_{e_1}$ as the cost of inference rule $e_1 \xrightarrow{skip-gram} e_2$.

2.2 Mining Entity Semantic Knowledge

Entities, often serving as event participants or environment variables, are important components of commonsense stories. Intuitively, an entity in hypothesis is reasonable if we can identify semantic relations between it and some parts of premise document. For example, if a premise document contains "Starbucks", then "coffeehouse" and "latte" will be reasonable entities in hypothesis since "Starbucks" is a possible coreference of "coffeehouse" and it is semantically related to "latte".

Specifically, we identify mainly two kinds of semantic relations between entities for commonsense machine comprehension:

1) *Coreference relation,* which indicates that two elements refer to the same entity in environment. In stories, besides to pronouns, an entity is often referred using its hypernyms, e.g, the second example in Table 1 uses "dog" to refer to "puppy". Motivated by this observation, we mine coreference knowledge between elements using Wordnet (Kilgarriff and Fellbaum, 2000): $X \xrightarrow{coref} Y$ is an inference rule with cost 0 if X and Y are lemmas in the same Wordnet synset, or with hyponymy relation in Wordnet. Otherwise, the cost of inference rules between this element-pair under this relation will be 1.

2) *Associative relation,* which captures the semantic relatedness between two entities, i.e., "starbucks" → "latte", "restaurant" → "food", etc. This paper mines associative relations between entities from Wikipedia[1], using the method proposed by Milne and Witten(2008). Specifically, given two entities e_1 and e_2, we compute the semantic distance $dist(e_1, e_2)$ between them as:

$$dist(e_1, e_2) = \frac{log(max(|E_1|, |E_2|) - log(|E_1 \bigcap E_2|))}{log(|W|) - log(min(|E_1|, |E_2|))} \tag{3}$$

where E_1 and E_2 are the sets of all entities that link to these two entities in Wikipedia respectively,

[1] https://www.wikipedia.org/

and W is the entire Wikipedia. We set the cost of inference rule $e_1 \xrightarrow{associative} e_2$ as $dist(e_1, e_2)$.

2.3 Mining Sentiment Coherent Knowledge

Sentiment is one of the central and pervasive aspects of human experience (Ortony et al., 1990). It plays an important role in commonsense stories, i.e., a reasonable hypothesis should be sentimental coherent with its premise document. In this paper, we mine sentiment coherence rules using SentiWordnet (Baccianella et al., 2010), in which each synset of Wordnet is assigned with three sentiment scores: positivity, negativity and objectivity.

Concretely, to identify sentimental coherence rule between two element e_1 and e_2, we first compute the positivity, negativity and objectivity scores of every element by averaging the scores of all synsets it's in, then we identify an element to be subjective if its objectivity score is smaller than a threshold, and the distance between its positivity and negativity score is greater than a threshold. Finally, for an inference rule $e_1 \xrightarrow{senti} e_2$, we set its cost to 1 if e_1 and e_2 are both subjective and have opposite sentimental polarity, to -1 if they are both subjective and their sentimental polarity are the same, and to 0 for other cases. For example, we will mine inference rules "good $\xrightarrow{senti}$ happy : -1", "perfect $\xrightarrow{senti}$ sad : 1" and "young $\xrightarrow{senti}$ happy : 0".

2.4 Metric Learning to Calibrate Cost Measurement

So far, we have extracted many inference rules under different relations. However, because we extract them from different sources and estimate their costs using different measurements, the cost metrics of these rules may not be consistent with each other. To exploit different types of inference rules in a unified framework, we here propose a metric learning based method to calibrate their costs.

Given an input distance function, a metric learning method constructs a new distance function which is "better" than the original one with supervision regarding an ideal distance (Kulis, 2012). To calibrate inference rule cost, we add a nonlinear layer to the original cost s_r of inference rule r under relation f:

$$c_r = sigmoid(w_f s_r + b_f) \tag{4}$$

Here c_r is the metric-unified inference cost of inference rule r, w_f and b_f are calibration parameters for inference rules of relation f. We use sigmoid function in order to normalize costs into 0 to 1. Calibration parameters will be trained along with other parameters in our model. See Section 3.4 for detail.

2.5 Dealing with Negation

One important linguistic phenomenon needs to specifically consider is negation. Here we discuss how to solve negation in our model.

We use $\neg X$ to represent an element X modified by a negation word (the existence of negation is detected using dependency relations). Under event narrative relation and sentiment coherent relation, the existence of negation will reverse the conclusion. So we add three additional negation related inference rules for rule $X \xrightarrow{f} Y : s$ under these relations, including $\neg X \xrightarrow{f} Y : 1 - s$, $X \xrightarrow{f} \neg Y : 1 - s$ and $\neg X \xrightarrow{f} \neg Y : s$. Here s is the calibrated cost of the original inference rule. For entity semantic relations, we just ignore the negation since it will not affect the inference under these relations.

3 Machine Comprehension via Commonsense Reasoning

This section describes how to leverage acquired knowledge for commonsense machine comprehension. We first define how to infer from a premise document to a hypothesis using inference rules. Then we model how to choose inference rules for a specific reasoning context. Finally, we describe how to measure the reasoning distance from a premise document to a hypothesis by summarizing the costs of all possible inferences.

3.1 Inference from Premise Document to Hypothesis

Given a premise document $D = \{d_1, d_2, ..., d_m\}$ containing m elements, a hypothesis $H = \{h_1, h_2, ..., h_n\}$ containing n elements, a valid inference R from D to H is a set of inference rules that all elements in H can be inferred from one element in D using one and only one rule in R. This definition means that all elements in H should be covered by consequents of inference rules in R, as well as all antecedents of inference rules in R should come from D. Figure 1 shows some inference examples, where (a), (b) and (d) are valid inferences, but (c) is not a valid inference because its rules can not cover all elements in hypothesis.

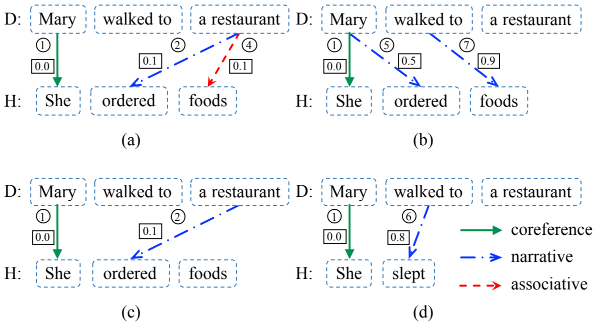

Figure 1: Examples of inferences. Numbers in circle indicates the proposed inference rules in Table 2, and values in rectangle are their costs.

By the definition, the size of R and the size of H are equal. So we use r_i to denote the inference rule in R that applied to derive element h_i in H, i.e., $R = \{r_1, r_2, ..., r_n\}$.

Based on the above definition, we can naturally define the cost of an inference R as the cost sum of all inference rules in R. In Figure 1, the cost for inference (a) is $0.0 + 0.1 + 0.1 = 0.2$, and for inference (d) is $0.0 + 0.8 = 0.8$.

3.2 Modeling Inference Probability using Attention Mechanism

Obviously, there exist multiple valid inferences for a premise document and a hypothesis. For example, in Figure 1, both (a) and (b) are valid inferences for the same premise document and hypothesis. To identify whether a hypothesis is reasonable, we need to consider all possible inferences. However, in human reasoning process, not all inference rules have the same possibility to be applied, because the more reasonable inference will be proposed more likely. In Figure 1, inference (a) should have a higher probability than inference (b) because it is more reasonable to infer "*foods*" from "*a restaurant*" with *associative relation*, rather than from "*walked to*" with *narrative relation*. Besides, the possibility of proposing an inference should not depend on its cost, e.g., inference (d) should have high possibility to be proposed despite its high cost, because we often infer event "*sleep*" from another event using inference rules under *narrative relation*. As examples mentioned above, the "cost" measures the "correctness" of an inference rule. A rule with low cost is more likely to be "reasonable", and a rule with high cost is more likely to be a contradiction with commonsense. On the other hand, the "possibility" should measure how likely a rule will be applied in a given context, which does not depend on the "cost" but on the nature of the rule and the given context. Motivated by above observations, we endow each inference a probability $P(R|D, H)$, indicating the possibility that R is chosen to infer hypothesis H from premise document D. For simplicity, we assume that each element in hypothesis is independently inferred using individual inference rule, then $P(R|D, H)$ can be written as:

$$P(R|D,H) = \prod_{i=1}^{n} P(r_i|D,H) \tag{5}$$

$$= \prod_{i=1}^{n} P(r_i|D,h_i) \tag{6}$$

$$= \prod_{i=1}^{n} \sum_{j=1}^{m} P(r_i, d_j|D, h_i) \tag{7}$$

Equation (7) clearly shows how an inference rule is selected given the premise document D and the element h_i in hypothesis. It depends on which element d_j in D will be selected and which relation f will be used to infer h_i from d_j. We then refactor the probability $P(r_i, d_j|D, h_i)$ to be:

$$P(r_i, d_j|D, h_i) = \begin{cases} 0 & , antecedent(r_i) \neq d_j \\ g(h_i, d_j, f(r_i); D) & , otherwise \end{cases} \tag{8}$$

Here $f(r)$ is the relation type of inference rule r, and $g(h, d, f; D)$ is defined as:

$$g(h, d, f; D) = \frac{s(h,d)a(h,f)a(d,f)}{\sum_{f \in \mathcal{F}} \sum_{d \in D} s(h,d)a(h,f)a(d,f)} \tag{9}$$

Here $\mathcal{F}$ denotes all relation types of inference rules, $s(e_1, e_2)$ is a matching function between two elements e_1 and e_2, measuring by cosine similarity based on GoogleNews word2vec (Mikolov et al., 2013). And $a(e, f)$ is an attention function measuring how likely an element e will be involved with rules under relation f:

$$a(e, f) = \mathbf{v_f}^T tanh(\mathbf{W_f e} + \mathbf{b_f}) \tag{10}$$

where $\mathbf{v_f} \in \mathbb{R}^K$, $\mathbf{W_f} \in \mathbb{R}^{K \times F}$ and $\mathbf{b_f} \in \mathbb{R}^K$ are attention parameters of relation f, and $\mathbf{e} \in \mathbb{R}^F$ is the feature vector of element e. Here K is the size of attention hidden layer and F is the dimension of feature vector. We consider three types of features, as shown in Table 3. Using attention mechanism, our method models the possibility that an inference rule is applied during the inference from a premise document to a hypothesis by considering the relatedness between elements and knowledge category, as well as the relatedness between two elements, which make it able to select the most reasonable inference rules to derive each part of the hypothesis.

Feature	Description
Syntax Features	
is_verb	whether this element is a verb
is_noun	whether this element is a noun
is_adj	whether this element is an adjective
Lexical Features	
is_event	whether this element belongs to hyponymy of *event sysnset* in Wordnet
is_entity	whether this element belongs to hyponymy of *physical_entity sysnset*
is_attr	whether this element belongs to hyponymy of *attribute sysnset*
named_entity	the named entity type of this element
Semantic Features	
word embeddings	300 dimension embeddings of GoogleNews word2vec model

Table 3: Features for element-relation attention.

3.3 Reasoning Distance Between Premise Document and Hypothesis

Given a premise document, this section shows how to measure whether a hypothesis is coherent using above inference model. Given all valid inferences from D to H and the probability $P(R|D,H)$ of selecting inference R to infer H from D, we measure the reasoning distance $L(D \to H)$ as the expected cost sum of all valid inferences:

$$L(D \to H) = E_{P(R|D,H)}[cost(R)] \tag{11}$$

$$= E_{P(R|D,H)}[\sum_{i=1}^{n} cost(r_i)] \tag{12}$$

Then using Equation (6) and Equation (7), we can further rewrite the equation into:

$$L(D \to H) = \sum_{R}[\prod_{i=1}^{n} P(r_i|D,h_i)] \cdot [\sum_{i=1}^{n} cost(r_i)] \tag{13}$$

$$= \sum_{i=1}^{n} P(r_i|D,h_i) \cdot cost(r_i) \tag{14}$$

$$= \sum_{i=1}^{n}\sum_{j=1}^{m} P(r_i,d_j|D,h_i) \cdot cost(r_i) \tag{15}$$

Equation (15) shows that in our framework, the final cost of inferring the element h_i in the hypothesis is the expected cost of all valid inference rules which can derive h_i from one element in the premise document.

3.4 Model Learning

Following Huang et al. (2013), our model measures the posterior probability of choosing hypothesis H as the answer of premise document D through a softmax function:

$$P(H|D) = \frac{exp(-\gamma L(D \to H))}{\sum_{H' \in \mathcal{H}_D} exp(-\gamma L(D \to H'))} \tag{16}$$

Here $\mathcal{H}_D$ is all candidate hypothesises for D, and γ is a positive smoothing factor. We train our model by maximizing the likelihood of choosing right hypothesis H^+ for D:

$$\mathcal{L}(\theta) = -log \prod_{(D,H^+)} P(H^+|D) \tag{17}$$

where θ is the parameter set of our model, including calibration parameters in Section 2.4 and attention parameters in Section 3.2. $\mathcal{L}(\theta)$ is differentiable so we can estimate θ using any gradient-based optimization algorithm.

4 Experiments

4.1 Experimental Settings

Data Preparation. We evaluated our approach on the *Test Set Spring 2016* of RocStories, which consists of 1871 commonsense stories, with each story has two candidate story endings. Because stories in the training set of RocStories do not contain wrong hypothesis, and our model has a compact size of parameters, we estimated the parameters of our model using the *Validation Set Spring 2016* of RocStories with 1871 commonsense stories.

We mined event narrative knowledge from the *Training Set Spring 2016* of RocStories, which consists of 45502 commonsense stories. We performed lemmatisation, part of speech annotation, named entity tagging, and dependency parsing using Stanford CoreNLP toolkits (Manning et al., 2014). We used the Jan. 30, 2010 English version of Wikipedia and processed it according to the method described by Hu et al. (2008).

Model Training. We used normalized initialization (Glorot and Bengio, 2010) to initialize attention parameters in our model. For calibration parameters, we initialized all $\mathbf{w_f}$ to 1 and $\mathbf{b_f}$ to 0. The model parameters were trained using minibatch stochastic gradient descent algorithm. As for hyper-parameters, we set the batch size as 32, the learning rate as 1, the dimension of attention hidden layer K as 32, and the smoothing factor γ as 0.5.

Baselines. We compared our approach with following three baselines:

1) **Narrative Event Chain** (Chambers and Jurafsky, 2008), which scores hypothesis using PMI scores between events. We used a simplified version of the original model by using only verbs as event, ignoring the dependency relation between verbs and their participants. We found such a simplified version achieved better performance than its original one whose performance was reported in (Mostafazadeh et al., 2016a).

2) **Deep Structured Semantic Model (DSS-**

M) (Huang et al., 2013), which achieved the best performance on RocStories as reported by Mostafazadeh et al.(2016a). This model measures the reasoning score between a premise document D and a hypothesis H by calculating the cosine similarity between the overall vector representations of D and H, and do not consider any other task-relevant knowledge.

3) **Recurrent Neural Network(RNN) Model** proposed by Pichotta and Mooney(2015), which transforms all events and their arguments into a sequence and predict next events and arguments using a Long Short-Term Memory network. We used the average generating probability of all elements in H as the reasoning score, and choose the hypothesis with largest reasoning score as the system answer.

4.2 Overall Performance

System	**Accuracy**
Narrative Event Chain	57.62%
DSSM	58.52%
RNN Model	58.93%
Our Model	**67.02%**

Table 4: Comparison of accuracy for our model and three baselines on RocStories Spring 2016 Test Set. The result of DSSM is adapted from (Mostafazadeh et al., 2016a).

Table 4 shows the results. From this table, we can see that:

1) Our model outperforms all baselines significantly. Compared with baselines, the accuracy improvement on test set is at least 13.7%. This demonstrates the effectiveness of our model by mining and exploiting heteregenous knowledge.

2) The event narrative knowledge only is insufficient for commonsense machine comprehension. Compared with Narrative Event Chain Model, our model achieves a 16.3% accuracy improvement by considering richer commonsense knowledge, rather than only narrative event knowledge.

3) It is necessary to distinguish different kinds of commonsense relations for machine comprehension and commonsense reasoning. Compared with DSSM and RNN, which model all relations between two elements using a single semantic similarity score, our model achieves significant accuracy improvements by modeling, distinguishing and selecting different types of commonsense relations between different kinds of elements.

4.3 Effects of Different Knowledge

To investigate the effect of different kinds of knowledge in our model, we conducted two groups of experiments.

The first group of experiments was conducted using only one kind of knowledge at a time in our model. Table 5 shows the results. We can see that using a single kind of knowledge is insufficient for commonsense machine comprehension: all single-knowledge settings cannot achieve competitive performance to the all-knowledge setting.

System	**Accuray**
Event Narrative Knowledge	60.98%
Entity Semantics Knowledge	57.14%
Sentiment Coherent Knowledge	61.30%
Our Model(All Knowledge)	**67.02%**

Table 5: Comparison of the performance using single type of knowledge.

The second group of experiments was conducted to investigate whether different knowledge can complement each other. We conducted experiments by removing one kind of knowledge from our final model at a time, and investigate the change of accuracy.

System	**Accuracy**
Our Model(All Knowledge)	**67.02%**
-w/o Event Narrative Knowledge	63.65%
-w/o Entity Semantic Knowledge	64.89%
-w/o Sentiment Coherent Knowledge	62.85%

Table 6: Comparison of the performance by removing one single type of knowledge.

Table 6 shows the results. We can find that removing any kind of knowledge will reduce the accuracy. This verified that all kinds of knowledge containing unique complementary information, which cannot be covered by other types of knowledge.

4.4 Effect of Inference Probability

This section investigates the effect of inference rule selection probability, and whether our attention mechanism can effectively model the possibility of inference rule selection. We compared our method with following two heuristic settings:

1) **Minimum Cost Mechanism**, which measures the reasoning distance by only selecting the inference rule with minimum cost for each hypothesis element.

2) **Average Cost Mechanism**, which measures the reasoning distance by setting equal probabilities to all inference rules that can infer a hypothesis element from a premise document element.

System	Accuracy
Minimum Cost Mechanism	54.84%
Average Cost Mechanism	63.01%
Our Model(Attention Mechanism)	**67.02%**

Table 7: Comparison of the performance using different inference rule selection mechanism.

Table 7 show the results. We can see that: 1) the minimum cost mechanism cannot achieve competitive performance, we believe this is because the selection of rules should not depend on the cost of them, and considering all valid inferences is critical for reasoning; 2) our attention mechanism can effectively model the inference rule selection possibility. Compared with the average cost mechanism, our method achieved a 6.36% accuracy improvement. This also verified the necessity of an effective inference rule probability model.

4.5 Effect of Negation Rules

This section investigates the effect of special handling of negation mentioned in Section 2.5. To investigate the necessity of negation rules proposed in our model, we conducted experiments by removing all negation rules from original system, and investigate the change of accuracy.

System	Accuracy
Our Model	**67.02%**
-w/o Negation Rules	63.12%

Table 8: Comparison of the performance by removing negation rules.

Table 8 show the results. We can see that removing negation rules will significantly drop the system performance, which confirm the effectiveness of our proposed negation rules.

5 Related Work

Endowing computers with the ability of understanding commonsense story has long a goal of natural language processing. There exist two big challenges: 1)Matching explicit information in the given context; 2)Incorporating implicit commonsense knowledge into human-like reasoning process. Previous machine comprehension tasks (Richardson et al., 2013; Weston et al., 2015; Hermann et al., 2015; Rajpurkar et al., 2016) mainly focus on the first challenge, leading their solutions focusing on semantic matching between texts (Weston et al., 2014; Kumar et al., 2015; Narasimhan and Barzilay, 2015; Smith et al., 2015; Sukhbaatar et al., 2015; Hill et al., 2015; Wang et al., 2015, 2016a; Cui et al., 2016; Trischler et al., 2016a,b; Kadlec et al., 2016; Kobayashi et al., 2016; Wang and Jiang, 2016b), but ignore the second issues. One notable task is SNLI (Bowman et al., 2015), which considers entailment between two sentences. This task, however, only provides shallow context and thus needs a few kinds of implicit knowledge (Rocktäschel et al., 2015; Wang and Jiang, 2016a; Angeli et al., 2016; Wang et al., 2016b; Parikh et al., 2016; Henderson and Popa, 2016; Zhao et al., 2017).

Realizing that story understanding needs commonsense knowledge, many researches have been proposed to learn structural event knowledge. Chambers and Jurafsky (2008) first proposed an unsupervised approach to learn partially ordered sets of events from raw text. Many expansions have been introduced later, including unsupervisedly learning narrative schemas and scripts (Chambers and Jurafsky, 2009; Regneri et al., 2011), event schemas and frames (Chambers and Jurafsky, 2011; Balasubramanian et al., 2013; Sha et al., 2016; Huang et al., 2016; Mostafazadeh et al., 2016b), and some generative models to learn latent structures of event knowledge (Cheung et al., 2013; Chambers, 2013; Bamman et al., 2014; Nguyen et al., 2015). Another direction for learning event-centred knowledge is causality identification (Do et al., 2011; Radinsky et al., 2012; Berant et al., 2014; Hashimoto et al., 2015; Gui et al., 2016), which tried to identify the causality relation in text.

For reasoning over these knowledge, Jans et al. (2012) extend introduced skip-grams for collecting statistics. Further improvements include incorporating more information and more complicated models (Radinsky and Horvitz, 2013; Modi and Titov, 2014; Ahrendt and Demberg, 2016). Recent researches tried to solve event prediction problem by transforming it into an language modeling paradigm (Pichotta and Mooney, 2014, 2015, 2016a,b; Rudinger et al., 2015; Hu et al., 2017).

The principal difference between previous work and our method is that we not only take various kinds of implicit commonsense knowledge into consideration, but also provide a highly extensible framework to exploit these kinds of knowledge for commonsense machine comprehension. We also notice the recent progress in RocStories (Mostafazadeh et al., 2017). Rather than inferring a possible ending generated from document, recent systems solve this task by discriminatively comparing two candidates. This enables very strong stylistic features being added explicitly (Schwartz et al., 2017; Bugert et al., 2017) or implicitly (Schenk and Chiarcos, 2017), which can select hypothesis without any consideration of given document. Also, some augmentation strategies are introduced to produce more training data (Roemmele and Gordon, 2017; Mihaylov and Frank, 2017; Bugert et al., 2017). These methods are dataset-sensitive and are not the main concentration of our paper.

6 Conclusions and Future Work

This paper proposes a commonsense machine comprehension method, which performs effective commonsense reasoning by taking heterogenous knowledge into consideration. Specifically, we mine commonsense knowledge from heterogeneous knowledge sources and simultaneously exploit them by proposing a highly extensible multi-knowledge reasoning framework. Experiment results shown that our method surpasses baselines by a large margin.

Currently, there are little labeled training instances for commonsense machine comprehension, for future work we want to address this issue by developing semi-supervised or unsupervised approaches.

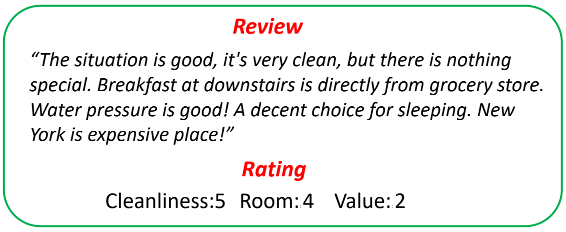
Abstract

Document-level multi-aspect sentiment classification is an important task for customer relation management. In this paper, we model the task as a machine comprehension problem where pseudo question-answer pairs are constructed by a small number of aspect-related keywords and aspect ratings. A hierarchical iterative attention model is introduced to build aspect-specific representations by frequent and repeated interactions between documents and aspect questions. We adopt a hierarchical architecture to represent both word level and sentence level information, and use the attention operations for aspect questions and documents alternatively with the multiple hop mechanism. Experimental results on the TripAdvisor and BeerAdvocate datasets show that our model outperforms classical baselines.

1 Introduction

Document-level sentiment classification is one of the pragmatical sentiment analysis tasks (Pang and Lee, 2007; Liu, 2010). There are many Web sites having platforms for users to input reviews over products or services, such as TripAdvisor, Yelp, Amazon, etc. Most of reviews are very comprehensive and thus long documents. Analyzing these documents to predict ratings of products or services is an important complementary way for better customer relationship management. Recently, neural network based approaches have been developed and become state-of-the-arts for long-document sentiment classification (Tang et al., 2015a,b; Yang et al., 2016). However, predicting an overall score for each long document is not enough, because the document can mention different aspects of the corresponding product or service. For example, in Figure 1, there could be different aspects for a review of hotel. These aspects help customer service better understand what are the major pros and cons of the product or service. Compared to the overall rating, users are less motivated to give aspect ratings. Therefore, it is more practically useful to perform document-level multi-aspect sentiment classification task, predicting different ratings for each aspect rather than an overall rating.



Review

"The situation is good, it's very clean, but there is nothing special. Breakfast at downstairs is directly from grocery store. Water pressure is good! A decent choice for sleeping. New York is expensive place!"

Rating

Cleanliness:5 Room:4 Value:2

Figure 1: Example: hotel review with aspects.

One straightforward approach for document-level multi-aspect sentiment classification is multi-task learning (Caruana, 1997). For neural networks, we can simply treat each aspect (e.g., rating from one to five) as a classification task, and let different tasks use softmax classifier to extract task-specific representations at the top layer while share the input and hidden layers to mutually enhance the prediction results (Collobert et al., 2011; Luong et al., 2016). However, such approach ignores the fact that the aspects themselves have semantic meanings. For example, as human beings, if we were asked to evaluate the aspect rating of a document, we simply read the review, and find aspect-related keywords, and see around comments. Then, we aggregate all the related snippets to make a decision.

In this paper, we propose a novel approach to treat document-level multi-aspect sentiment clas-

sification as a machine comprehension (Kumar et al., 2016; Sordoni et al., 2016) problem. To mimic human's evaluation of aspect classification, we create a list of keywords for each aspect. For example, when we work on the *Room* aspect, we generate some keywords such as "room," "bed," "view," etc. Then we can ask pseudo questions: "How is the room?" "How is the bed?" "How is the view?" and provide an answer "Rating 5." In this case, we can train a machine comprehension model to automatically attend corresponding text snippets in the review document to predict the aspect rating. Specifically, we introduce a hierarchical and iterative attention model to construct aspect-specific representations. We use a hierarchical architecture to build up different representations at both word and sentence levels interacting with aspect questions. At each level, the model consists of input encoders and iterative attention modules. The input encoder learns memories[1] of documents and questions with Bi-directional LSTM (Bi-LSTM) model and non-linear mapping respectively. The iterative attention module takes into memories as input and attends them sequentially with a multiple hop mechanism, performing effective interactions between documents and aspect questions.

To evaluate the effectiveness of the proposed model, we conduct extensive experiments on the TripAdvisor and BeerAdvocate datasets and the results show that our model outperforms typical baselines. We also analyze the effects of numbers of the hop and aspect words on performances. Moreover, a case study for attention results is performed at both word and sentence levels.

The contributions of this paper are two-fold. First, we study the document-level multi-aspect sentiment classification as a machine comprehension problem and introduce a hierarchical iterative attention model for it. Second, we demonstrate the effectiveness of proposed model on two datasets, showing that our model outperforms classical baselines. The code and data for this paper are available at `https://github.com/HKUST-KnowComp/DMSCMC`.

2 Method

In this section, we introduce our proposed method.

2.1 Problem Definition and Hierarchical Framework

We first briefly introduce the problem we work on. Given a piece of review, our task is to predict the ratings of different aspects. For example, in Figure 1, we predict the ratings of *Cleanliness*, *Room*, and *Value*. To achieve this, we assume that there are existing reviews with aspect ratings for machines to learn. Formally, we denote the review document as d containing a set of T_d sentences $\{s_1, s_2, \dots s_{T_d}\}$. For the t-th sentence s_t, we use a set of words $\{w_1, w_2, \dots w_{|s_t|}\}$ to represent it, and use $\mathbf{w}_i$, $\mathbf{w}_i^w$ and $\mathbf{w}_i^p$ as the one-hot encoding, word embedding, and phrase embedding for w_i respectively. The phrase embedding encodes the semantics of phrases where the current word w_i is the center (e.g., hidden vectors learned by Bi-LSTM shown in Section 2.2). For each q_k of K aspects

[1] Following the work (Weston et al., 2015; Sukhbaatar et al., 2015), we refer the memory to a set vectors which are stacked together and could be attended.

$\{q_1, q_2, \ldots, q_K\}$, we use N_k aspect-related keywords, $\left\{q_{k_1}, q_{k_2} \ldots q_{k_{N_k}}\right\}$, to represent it. Similarly, we use $\mathbf{q}_{k_i}$, $\mathbf{q}_{k_i}^w$ as the one-hot encoding and word embedding for q_{k_i} respectively.

There are several sophisticated methods for choosing aspect keywords (e.g., topic model). Here, we consider a simple way where five seeds were first manually selected for each aspect and then more words were obtained based on their cosine similarities with seeds[2]

As shown in Figure 2 (left), our framework follows the idea of multi-task learning, which learns different aspects simultaneously. In this case, all these tasks share the representations of words and architecture of semantic model for the final classifiers. Different from straightforward neural network based multi-task learning (Collobert et al., 2011), for each document d and an aspect q_k, our model uses both the content of d and all the related keywords $\left\{q_{k_1}, q_{k_2} \ldots q_{k_{N_k}}\right\}$ as input. Since the keywords can cover most of the semantic meanings of the aspect, and we do not know which document mentions which semantic meaning, we build an attention model to automatically decide it (introduced in Section 2.3). Assuming that the keywords have been decided, we use a hierarchical attention model to select useful information from the review documents. As shown in Figure 2 (right), the hierarchical attention of keywords is applied to both sentence level (to select meaningful words) and document level (to select meaningful sentence). Thus, our model builds aspect-specific representations in a bottom-up manner.

Specifically, we obtain sentence representations $\left\{\mathbf{s}_1^k, \mathbf{s}_2^k, \ldots \mathbf{s}_T^k\right\}$ using the input encoder (Section 2.2) and iterative attention module (Section 2.3) at the word level. Then we take sentence representations and k-th aspect as input and apply the sentence-level input encoder and attention model to generate the document representation $\mathbf{d}_k$ for final classification. As shown in Figure 2 (right), the attention model is applied twice at different levels of the representation.

2.2 Input Encoder

The input module builds memory vectors for the iterative attention module and is performed both at word and sentence levels. For a document, it converts word sequence into word level memory $\mathbf{M}_w^d$ and sentence sequence into sentence level memory $\mathbf{M}_s^d$ respectively. For an aspect question q_k, it takes a set of aspect-specific words $\{q_{k_i}\}_{1\le i\le N_k}$ as input and derives word level memory $\mathbf{M}_w^q$ and sentence level memory $\mathbf{M}_s^q$.

To construct $\mathbf{M}_w^d$, we obtain word embeddings $\left\{\mathbf{w}_1^w, \mathbf{w}_2^w, \ldots \mathbf{w}_{|s_t|}^w\right\}$ from an embedding matrix $\mathbf{E}^A$ applied to all words shown in the corpus. Then, LSTM (Hochreiter and Schmidhuber, 1997) model is used as the encoder to produce hidden vectors of words based on the word embeddings. At each step, LSTM takes input $\mathbf{w}_t^w$ and derives a new hidden vector by $\mathbf{h}_t = \text{LSTM}(\mathbf{w}_t^w, \mathbf{h}_{t-1})$. To preserve the subsequent context information for words, another LSTM is ran over word sequence in a reverse order simultaneously. Then the forward hidden vector $\overrightarrow{\mathbf{h}}_t$ and backward hidden vector $\overleftarrow{\mathbf{h}}_t$ are concatenated as phrase embedding $\mathbf{w}_t^p$. We stack these phrase embeddings together as word level memory $\mathbf{M}_w^d$. Similarly, we feed sentence representations into another Bi-LSTM to derive the sentence level memory $\mathbf{M}_s^d$. Note that, the sentence representations are obtained using the iterative attention module which is described as Eq. (5) in Section 2.3.

Since we have question keywords as input, to allow the interactions between questions and documents, we also build question memory in following way. We obtain $\mathbf{Q}_k = \left\{\mathbf{q}_{k_i}^w\right\}_{1\le i\le N_k}$ by looking up an embedding matrix [3] $\mathbf{E}^B$ applied to all question keywords. Then a non-linear mapping is applied to obtain the question memory at word level:

$$\mathbf{M}_w^{q_k} = \tanh(\mathbf{Q}_k \mathbf{W}_w^q), \tag{1}$$

where $\mathbf{W}_w^q$ is the parameter matrix to adapt q_k at word level. Similarly, we use another mapping to obtain the sentence level memory:

$$\mathbf{M}_s^{q_k} = \tanh(\mathbf{Q}_k \mathbf{W}_s^q), \tag{2}$$

where $\mathbf{W}_s^q$ is the parameter matrix to adapt q_k at sentence level.

2.3 Iterative Attention Module

The iterative attention module (IAM) attends and reads memories of questions and documents alternatively with a multi-hop mechanism, deriving

[2] For example, the words “value,” “price,” “worth,” “cost,” and “\$” are selected as seeds for aspect *Price*. The information for seeds can be found in our released resource.

[3] $\mathbf{E}^A$ and $\mathbf{E}^B$ are initialized by the same pre-trained embeddings but are different embedding matrices with different updates.

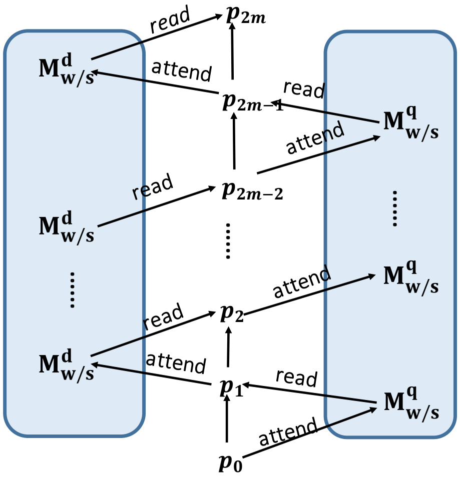

Figure 3: The iterative attention module.

aspect-specific sentence and document representations. As we discussed in the introduction, the set of selected question keywords may not best characterize the aspect for different documents. Thus, the IAM module introduces a backward attention to use document information (word or sentence) to select useful keywords of each aspect as the document-specific question to build attention model.

The illustration of IAM is shown in Figure 3. To obtain sentence representations, it takes $\mathbf{M}^d_w$ and $\mathbf{M}^q_w$ as the input and performs m iterations (hops). For each iteration, IAM conducts four operations: (1) attends the question memory by the selective vector $\mathbf{p}$ and summarizes question memory vectors into a single vector $\hat{\mathbf{q}}$; (2) updates the selective vector by the previous one and $\hat{\mathbf{q}}$; (3) attends document (content) memory based on the updated selective vector and summarizes memory vectors in to a single vector $\hat{\mathbf{c}}$; (4) updates the selective vector by the previous one and $\hat{\mathbf{c}}$.

We unify operations (1) and (3) by an attention function $\hat{\mathbf{x}} = \mathcal{A}(\mathbf{p}, \mathbf{M})$, where $\mathbf{M}$ could be $\mathbf{M}^d_w$ or $\mathbf{M}^q_w$ which corresponds $\hat{\mathbf{x}} = \hat{\mathbf{c}}$ or $\hat{\mathbf{x}} = \hat{\mathbf{q}}$. The attention function $\mathcal{A}$ is decomposed as:

$$\begin{aligned}\mathbf{H} &= \tanh(\mathbf{M}\mathbf{W}_a \odot (\mathbb{1}\mathbf{p})) \\ \mathbf{a} &= \text{softmax}(\mathbf{H}\mathbf{v}_a^T) \\ \hat{\mathbf{x}} &= \sum \mathbf{a}_i \mathbf{M}_i,\end{aligned} \tag{3}$$

where $\mathbb{1}$ is a vector with all elements are 1, which copies the selective vector to meet the dimension requirement. The $\mathbf{W}_a$ and $\mathbf{v}_a$ are parameters, $\mathbf{a}$ is attention weights for memory vectors, and $\mathbf{M}_i$ means i-th row in $\mathbf{M}$.

Operations (2) and (4) are formulated as an update function $\mathbf{p}_{2i-\{l\}} = \mathcal{U}(\hat{\mathbf{x}}, \mathbf{p}_{2i-\{l\}-1})$, where i is the hop index, l can be 0 or 1 which corresponds to $\hat{\mathbf{x}} = \hat{\mathbf{c}}$ or $\hat{\mathbf{x}} = \hat{\mathbf{q}}$ respectively. We initialize $\mathbf{p}_0$ by a zero vector. The update function $\mathcal{U}$ can be a recurrent neural network (Xiong et al., 2017) or other heuristic weighting functions. In this paper, we introduce a simple strategy:

$$\mathbf{p}_{2i-\{l\}} = \hat{\mathbf{x}}, \tag{4}$$

which ignores the previous selective vector but succeeds to obtain comparable results with other more complicated function in the initial experiments.

Multi-hop mechanism attends different memory locations in different hops (Sukhbaatar et al., 2015), capturing different interactions between documents and questions. In order to preserve the information of various kinds of interactions, we concatenate all $\hat{\mathbf{c}}$'s in each hop as the final representations of sentences:

$$\mathbf{s} = [\hat{\mathbf{c}}_1; \hat{\mathbf{c}}_2; \cdots \hat{\mathbf{c}}_m]. \tag{5}$$

After obtaining sentence representations, we feed them into the sentence-level input encoder, deriving the memories $\mathbf{M}^d_s$ and $\mathbf{M}^q_s$. Then, the aspect-specific document representation $\mathbf{d}_k$ is obtained by the sentence-level IAM in a similar way.

2.4 Objective Function

For each aspect, we obtain aspect-specific document representations $\{\mathbf{d}_k\}_{1 \le k \le K}$. All these representations are fed into classifiers, each of which includes a softmax layer. The softmax layer outputs the probability distribution over $|\mathcal{Y}|$ categories for the distributed representation, which is defined as:

$$\mathbf{p}'(d, k) = \text{softmax}(\mathbf{W}^{class}_k \mathbf{d}_k), \tag{6}$$

where $\mathbf{W}^{class}_k$ is the parameter matrix.

We define the cross-entropy objective function between gold sentiment distribution $\mathbf{p}(d, k)$ and predicted sentiment distribution $\mathbf{p}'(d, k)$ as the classification loss function:

$$-\sum_{d \in \mathcal{D}} \sum_{k=1}^{K} \sum_{i=1}^{|\mathcal{Y}|} \mathbf{p}(d, k) \log(\mathbf{p}'(d, k)), \tag{7}$$

where $\mathbf{p}(d, k)$ is a one-hot vector, which has the same dimension as the number of classes, and only the dimension associated with the ground truth label is one, with others being zeros.

Dataset	#docs	#words/doc	#words/sent
TripAdvisor	29,391	251.7	18.0
BeerAdvocate	51,020	144.5	12.1

Table 1: Statistics of the datasets. The rating scale of TripAdvisor dataset is 1-5. The rating scale of BeerAdvocate dataset is 1-10.

3 Experiment

In this section, we show experimental results to demonstrate our proposed algorithm.

3.1 Datasets

We conduct our experiments on TripAdvisor (Wang et al., 2010) and BeerAdvocate (McAuley et al., 2012; Lei et al., 2016) datasets, which contain seven aspects (*value*, *room*, *location*, *cleanliness*, *check in/front desk*, *service*, and *business service*) and four aspects (*feel*, *look*, *smell*, and *taste*) respectively. We follow the processing step (Lei et al., 2016) by choosing the reviews with different aspect ratings and the new datasets are described in Table 1. We tokenize the datasets by Stanford corenlp[4] and randomly split them into training, development, and testing sets with 80/10/10%.

3.2 Baseline Methods

To demonstrate the effectiveness of the proposed method, we compare our model with following baselines:

Majority uses the majority sentiment label in development sets as the predicted label.

SVM uses unigram and bigram as text features and uses Liblinear (Fan et al., 2008) for learning.

SLDA refers to supervised latent Dirichlet allocation (Blei and Mcauliffe, 2010) which is a statistical model of labeled documents.

NBoW is a neural bag-of-words model averaging embeddings of all words in a document and feeds the resulted embeddings into SVM classifier.

DAN is a deep averaging network model which consists of several fully connected layers with averaged word embeddings as input. One novel word dropout strategy is employed to boost model performances (Iyyer et al., 2015).

CNN continuously performs a convolution operation over a sentence to extract words neighboring features, then gets a fixed-sized representation by a pooling layer (Kim, 2014).

LSTM is one variant of recurrent neural network and has been proved to be one of state-of-the-art models for document-level sentiment classification (Tang et al., 2015a). We use LSTM to refer Bi-LSTM which captures both forward and backward semantic information.

HAN means the hierarchical attention network which is proposed in (Yang et al., 2016) for document classification. Note that, the original *HAN* depends GRU as the encoder. In our experiments, LSTM-based HAN obtains slightly better results. Thus, we report the results of HAN with LSTM as the encoder.

We extend *DAN*, *CNN*, *LSTM* with the hierarchical architecture and multi-task framework, the corresponding models are *MHDAN*, *MHCNN* and *MHLSTM* respectively. Besides, *MHAN* is also evaluated as one baseline, which is *HAN* with the multi-task learning.

3.3 Implementation Details

We implement all neural models using Theano (Theano Development Team, 2016). The model parameters are tuned based on the development sets. We learn 200-dimensional word embeddings with Skip-gram model (Mikolov et al., 2013) on in-domain corpus, which follows (Tang et al., 2015a). The pre-trained word embeddings are used to initialize the embedding matrices $\mathbf{E}^A$ and $\mathbf{E}^B$. The dimensions of all hidden vectors are set to 200. For TripAdvisor dataset, the hop numbers of word-level and sentence-level iterative attention modules are set to 4 and 2 respectively. For BeerAdvocate dataset, the hop numbers are set to 6 and 2. The number of selected keywords $N_k = N$ is set to 20. To avoid model over-fitting, we use dropout and regularization as follows: (1) the regularization parameter is set to *1e-5*; (2) the dropout rate is set to 0.3, which is applied to both sentence and document vectors. All parameters are trained by ADADELTA (Zeiler, 2012) without needing to set the initial learning rate. To ensure fair comparisons, we make baselines have same settings as the proposed model, such as word embeddings, dimensions of hidden vectors and optimization details and so on.

3.4 Results and Analyses

We use accuracy and mean squared error (MSE) as the evaluation metrics and the results are shown in Table 2.

[4] http://nlp.stanford.edu/software/corenlp.shtml

MHAN	44.72	1.294	44.94	1.210	37.98	1.783	36.82	1.813
Our	46.21	1.091	**46.56**	**1.083**	39.43	1.696	**38.06**	**1.755**

Table 2: Comparison of our model and other baseline methods.

Model	TripAdvisor		BeerAdvocate	
	Accuracy	MSE	Accuracy	MSE
MHLSTM	44.75 (0.24)	1.256 (0.05)	37.28 (0.43)	1.802 (0.17)
MHAN	45.02 (0.33)	1.221 (0.12)	37.02 (0.22)	1.810 (0.15)
Our	**46.65**†(0.29)	**1.084***(0.06)	**38.25**†(0.35)	**1.749***(0.18)

Table 3: The results of average accuracy/MSE and standard deviation of models on test sets. We choose *MHAN* and *MHLSTM* as comparison baselines for TripAdvisor and BeerAdvocate respectively. In t-tests, the marker * refers to p-value < 0.05 and the marker † refers to p-value < 0.01.

Compared to SVM and SLDA, NBoW achieves higher accuracy by 3% in both datasets, which shows that embedding features are more effective than traditional ngram features on these two datasets. All neural network models outperform NBoW. It shows the advantages of neural networks in the document sentiment classification.

From the results of neural networks, we can observe that DAN performs worse than LSTM and CNN, and LSTM achieves slightly higher results than CNN. It can be explained that the simple composition method averaging embeddings of words in a document but ignoring word order, may not be as effective as other flexible composition models, such as LSTM and CNN, on aspect classification. Additionally, we observe that the multi-task learning and hierarchical architecture are beneficial for neural networks. Among all baselines, MHAN and MHLSTM achieve comparable results and outperform others.

Compared with MHAN and MHLSTM, our method achieves improvements of 1.5% (3% relative improvement) and 1.0% (2.5% relative improvement) on TripAdvisor and BeerAdvocate respectively, which shows that the incorporation of iterative attention mechanism helps the deep neural network based model build up more discriminative aspect-aware representation. Note that BeerAdvocate is relatively more difficult since the predicted ratings are from 1 to 10 while TripAdvisor is 1 to 5. Moreover, t-test is conducted by randomly splitting datasets into train/dev/test sets and random initialization. The results on test sets are described in Table 3 which show performance of our model is stable.

3.5 Case Study for Attention Results

In this section, we sample two sentences from TripAdvisor to show the visualization of attention results for case study. Both word-level and sentence-level attention visualizations are shown in Figure 4. We normalize the word weight by the sentence weight to make sure that only important words in a document are highlighted.

From the top figures in (a) and (b), we observe that our model assigns different attention weights for each aspect. For example, in the first sentence, the words *comfortable* and *bed* are assigned higher

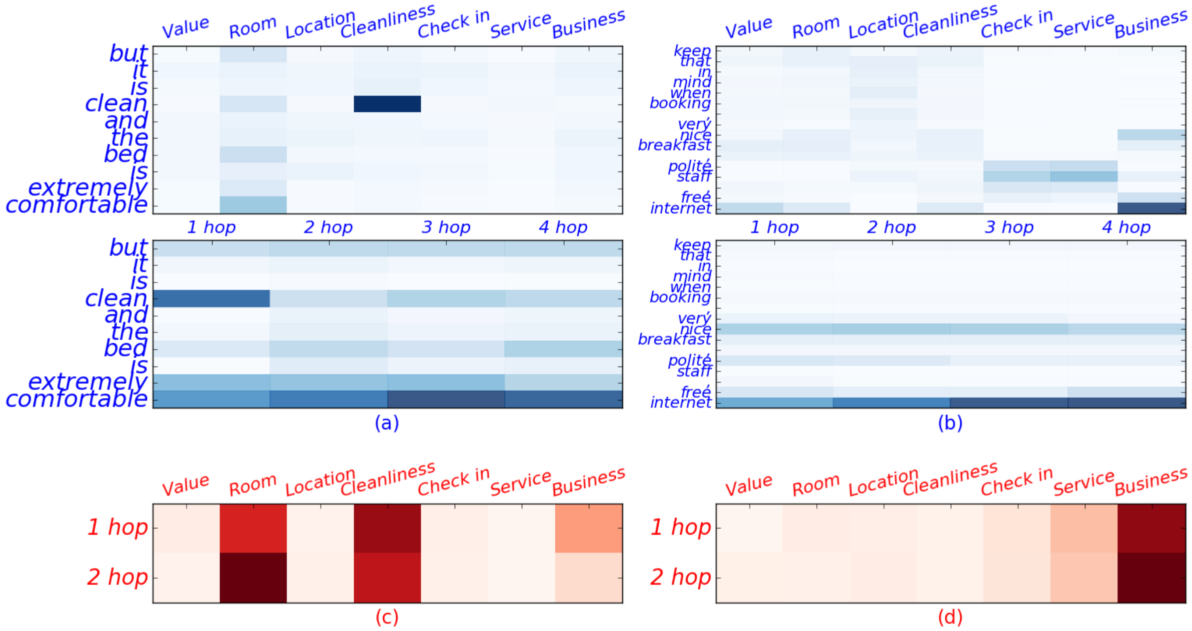

Figure 4: The attention visualization of words and sentences. Darker color means higher weight. (a) and (b) are the visualization of word weights; (c) and (d) are the visualization of sentence weights. The top figures in (a) and (b) show the word weights of fourth hop for each aspect. The bottom figures in (a) and (b) visualize the word weights of different hops for the aspects *Room* and *Business* respectively.

weights in the aspect *Room*, and the word *clean* are highlighted by the aspect *Cleaniness*. In the second sentence, the word *internet* is assigned a high attention value for *Business*. Moreover, the bottom figures in (a) and (b) show that (1) word weights of different hops are various; (2) attention values in higher hop are more reasonable. Specifically, in the first sentence, the weight of word *clean* is higher than the word *comfortable* in first hop, while *comfortable* surpasses *clean* in higher hops. In the second sentence, we observe that the value of word *internet* increases with the number of hop. Thus, we can see that the more sensible weights are obtained for words through the proposed iterative attention mechanism. Similarly, the figures (c) and (d) show that the conclusion from words is also suitable for sentences. For the first sentence, the sentence weight regarding the aspect *Room* is lower than *Cleanliness* in the first hop, but surpasses *Cleanliness* in the second hop. For the second sentence, the weight for *Business* becomes higher in the second hop.

3.6 Effects of Hop and Aspect Keywords

In this experiment, we investigate the effects of hop number m and size of aspect keywords N on performances. All the experiments are conducted on the development set. Due to lack of space, we only present the results of TripAdvisor and the results of BeerAdvocate have a similar behavior as TripAdvisor.

For the hop number, we vary m from 1 to 7 and the results are shown in Figure 5 (left). We can see that: (1) at the word level, the performance increases when $m \leq 4$, but shows no improvement after $m > 4$; (2) at the sentence level, model performs best when $m = 2$. Moreover, we can see that the hop number of word level leads to larger variation than the hop number of sentence level.

For the size of aspect keywords, we vary N from 0 to 35, incremented by 5. Note that, we set a learnable vector to represent question memory when $N = 0$. The results are shown in Figure 5 (right). We observe that the performance increases when $N \leq 20$, and has no improvement after $N > 20$. This indicates that a small number of keywords can help the proposed model achieve competitive results.

4 Related Work

Multi-Aspect Sentiment Classification. Multi-aspect sentiment classification has been studied extensively in literature. Lu et al. (2011) used support vector regression model based on hand-

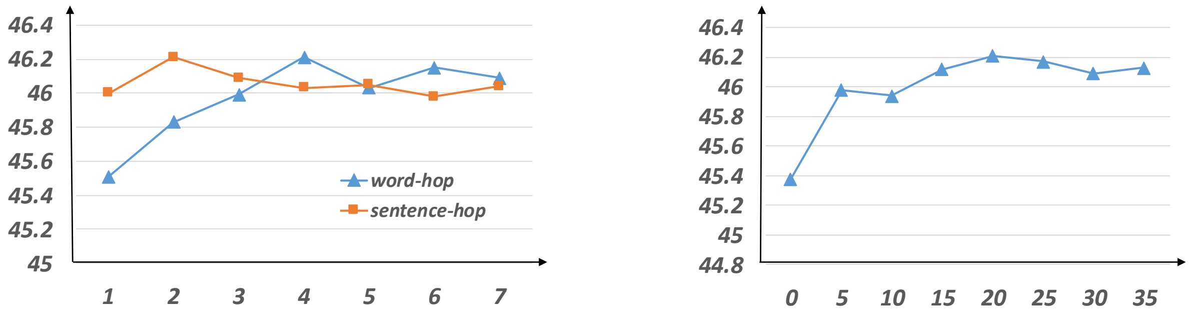

Figure 5: Results of different hops and different sizes of question keywords. Left: different the hop numbers; Right: different sizes of keywords.

crafted features to predict aspect ratings. To handle the correlation between aspects, McAuley et al. (2012) added a dependency term in final multi-class SVM objective. There were also some heuristic based methods and sophisticated topic models where multi-aspect sentiment classification is solved as a subproblem (Titov and McDonald, 2008; Wang et al., 2010; Diao et al., 2014; Pappas and Popescu-Belis, 2014). However, these approaches often rely on strict assumptions about words and sentences, for example, using the word syntax to determine if a word is an aspect or a sentiment word, or relating a sentence with an specific aspect. Another related problem is called aspect-based sentiment classification (Pontiki et al., 2014, 2016; Poria et al., 2016), which first extracts aspect expressions from sentences (Poria et al., 2014; Balahur and Montoyo, 2008; Chen et al., 2014, 2013), and then determines their sentiments. With the developments of neural networks and word embeddings in NLP, neural network based models have shown the state-of-the-art results with less feature engineering work. Tang et al. (2016) employed a deep memory network for aspect-based sentiment classification given the aspect location and Lakkaraju et al. (2014) employed recurrent neural networks and its variants for the task of extraction of aspect-sentiment pair. However, these tasks are sentence-level. Another related research field is document-level sentiment classification because we can treat single aspect sentiment classification as an individual document classification task. This line of research includes (Tang et al., 2015b; Chen et al., 2016; Tang et al., 2016; Yang et al., 2016) which are based on neural networks in a hierarchical structure. However, they did not work on multiple aspects.

Machine Comprehension. Recently, neural network based machine comprehension (or reading) has been studied extensively in NLP, with the releases of large-scale evaluation datasets (Hermann et al., 2015; Hill et al., 2016; Rajpurkar et al., 2016). Most of the related studies focus on attention mechanism (Bahdanau et al., 2014) which is firstly proposed in machine translating and aims to solve the long-distance dependency between words. Hermann et al. (2015) used Bi-LSTM to encode document and query, and proposed Attentive Reader and Impatient Reader. The first one attends document based on the query representation, and the second one attends document by the representation of each token in query with an incremental manner. Memory Networks (Weston et al., 2015; Sukhbaatar et al., 2015) attend and reason document representation in a multi-hop fashion, enriching interactions between documents and questions. Dynamic Memory Network (Kumar et al., 2016) updates memories of documents by re-running GRU models based on derived attention weights. Meanwhile, the query representation is refined by another GRU model. Gated-Attention Reader (Dhingra et al., 2016) proposes a novel attention mechanism, which is based on multiplicative interactions between the query embeddings and the intermediate states of a recurrent neural network document reader. Bi-Directional Attention Model (Xiong et al., 2017; Seo et al., 2017) fuses co-dependent representations of queries and documents in order to focus on relevant parts of both. Iterative Attention model (Sordoni et al., 2016) attends question and document sequentially, which is related to our model. Different from Iterative Attention model, our model focuses on the document-level multi-aspect sentiment classification, which is proposed in a hierarchical architecture and has different procedures in the iterative attention module. Another related research problem is visual question answering which uses an image as question context rather than a set of keywords as question. Neural network based visual question answering (Lu et al., 2016; Xiong et al., 2016) is similar as the proposed models in text comprehension.

5 Conclusion

In this paper, we model the document-level multi-aspect sentiment classification as a text comprehension problem and propose a novel hierarchical iterative attention model in which documents and pseudo aspect-questions are interleaved at both word and sentence-level to learn aspect-aware document representation in a unified model. Extensive experiments show that our model outperforms the other neural models with multi-task framework and hierarchical architecture.

Abstract

Argument mining has become a popular research area in NLP. It typically includes the identification of argumentative components, e.g. claims, as the central component of an argument. We perform a qualitative analysis across six different datasets and show that these appear to conceptualize claims quite differently. To learn about the consequences of such different conceptualizations of claim for practical applications, we carried out extensive experiments using state-of-the-art feature-rich and deep learning systems, to identify claims in a cross-domain fashion. While the divergent conceptualization of claims in different datasets is indeed harmful to cross-domain classification, we show that there are shared properties on the lexical level as well as system configurations that can help to overcome these gaps.

1 Introduction

The key component of an argument is the *claim*. This simple observation has not changed much since the early works on argumentation by Aristotle more than two thousand years ago, although argumentation scholars provide us with a plethora of often clashing theories and models (van Eemeren et al., 2014). Despite the lack of a precise definition in the contemporary argumentation theory, Toulmin's influential work on argumentation in the 1950's introduced a claim as an 'assertion that deserves our attention' (Toulmin, 2003, p. 11); recent works describe a claim as 'a statement that is in dispute and that we are trying to support with reasons' (Govier, 2010).

Argument mining, a computational counterpart of manual argumentation analysis, is a recent growing sub-field of NLP (Peldszus and Stede, 2013a). 'Mining' arguments usually involves several steps like separating argumentative from non-argumentative text units, parsing argument structures, and recognizing argument components such as claims—the main focus of this article. Claim identification itself is an important prerequisite for applications such as fake checking (Vlachos and Riedel, 2014), politics and legal affairs (Surdeanu et al., 2010), and science (Park and Blake, 2012).

Although claims can be identified with a promising level of accuracy in typical argumentative discourse such as persuasive essays (Stab and Gurevych, 2014; Eger et al., 2017), less homogeneous resources, for instance online discourse, pose challenges to current systems (Habernal and Gurevych, 2017). Furthermore, existing argument mining approaches are often limited to a single, specific domain like legal documents (Mochales-Palau and Moens, 2009), microtexts (Peldszus and Stede, 2015), Wikipedia articles (Levy et al., 2014; Rinott et al., 2015) or student essays (Stab and Gurevych, 2017). The problem of generalizing systems or features and their robustness across heterogeneous datasets thus remains fairly unexplored.

This situation motivated us to perform a detailed analysis of the concept of claims (as a key component of an argument) in existing argument mining datasets from different domains.[1] We first review and qualitatively analyze six existing publicly available datasets for argument mining (§3), showing that the conceptualizations of claims in these datasets differ largely. In a next step, we analyze the influence of these differences for cross-domain claim identification. We propose several computational models for claim identification,

[1] We take the machine learning perspective in which different *domains* mean data drawn from different distributions (Murphy, 2012, p. 297).

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2055–2066
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

including systems using linguistically motivated features (§4.1) and recent deep neural networks (§4.2), and rigorously evaluate them on and across all datasets (§5). Finally, in order to better understand the factors influencing the performance in a cross-domain scenario, we perform an extensive quantitative analysis on the results (§6).

Our analysis reveals that despite obvious differences in conceptualizations of claims across datasets, there are some shared properties on the lexical level which can be useful for claim identification in heterogeneous or unknown domains. Furthermore, we found that the choice of the source (training) domain is crucial when the target domain is unknown. We release our experimental framework to help other researchers build upon our findings.[2]

2 Related Work

Existing approaches to argument mining can be roughly categorized into (*a*) *multi-document* approaches which recognize claims and evidence across several documents and (*b*) *discourse level* approaches addressing the argumentative structure within a single document. Multi-document approaches have been proposed e.g. by Levy et al. (2014) and Rinott et al. (2015) for mining claims and corresponding evidence for a predefined topic over multiple Wikipedia articles. Nevertheless, to date most approaches and datasets deal with single-document argumentative discourse. This paper takes the discourse level perspective, as we aim to assess multiple datasets from different authors and compare their notion of 'claims'.

Mochales-Palau and Moens (2009) experiment at the discourse level using feature-rich SVM and a hand-crafted context-free grammar in order to recognize claims and premises in legal decisions. Their best results for claims achieve 74.1% F_1 using domain-dependent key phrases, token counts, location features, information about verbs, and the tense of the sentence. Peldszus and Stede (2015) present an approach based on a minimum spanning tree algorithm and model the global structure of arguments considering argumentative relations, the stance and the function of argument components. Their approach yields 86.9% F_1 for recognizing claims in English 'microtexts'. Habernal and Gurevych (2017) cast argument component identification as BIO sequence labeling and jointly model separation of argumentative from non-argumentative text units and identification of argument component boundaries together with their types. They achieved 25.1% Macro-F_1 with a combination of topic, sentiment, semantic, discourse and embedding features using structural SVM. Stab and Gurevych (2014) identified claims and other argument components in student essays. They experiment with several classifiers and achieved the best performance of 53.8% F_1 score using SVM with structural, lexical, syntactic, indicator and contextual features. Although the above-mentioned approaches achieve promising results in particular domains, their ability to generalize over heterogeneous text types and domains remains unanswered.

Rosenthal and McKeown (2012) set out to explore this direction by conducting cross-domain experiments for detecting claims in blog articles from LiveJournal and discussions taken from Wikipedia. However, they focused on relatively similar datasets that both stem from the social media domain and in addition annotated the datasets themselves, leading to an identical conceptualization of the notion of claim. Although Al-Khatib et al. (2016) also deal with cross-domain experiments, they address a different task; namely identification of argumentative sentences. Further, their goals are different: they want to improve argumentation mining via distant supervision rather than detecting differences in the notions of a claim.

Domain adaptation techniques (Daume III, 2007) try to address the frequently observed drop in classifier performances entailed by a dissimilarity of training and test data distributions. Since techniques such as learning generalized cross-domain representations in an unsupervised manner (Blitzer et al., 2006; Pan et al., 2010; Glorot et al., 2011; Yang and Eisenstein, 2015) have been criticized for targeting specific source and target domains, it has alternatively been proposed to learn *universal* representations from general domains in order to render a learner robust across *all* possible domain shifts (Müller and Schütze, 2015; Schnabel and Schütze, 2013). Our approach is in a similar vein. However, rather than trying to improve classifier performances for a specific source-target domain pair, we want to detect *differences* between these pairs. Furthermore, we are looking

3 Claim Identification in Computational Argumentation

We briefly describe six English datasets used in our empirical study; they all capture claims on the discourse level. Table 1 summarizes the dataset statistics relevant to claim identification.

3.1 Datasets

The AraucariaDB corpus (Reed et al., 2008) includes various genres (**VG**) such as newspaper editorials, parliamentary records, or judicial summaries. The annotation scheme structures arguments as trees and distinguishes between claims and premises at the clause level. Although the reliability of the annotations is unknown, the corpus has been extensively used in argument mining (Moens et al., 2007; Feng and Hirst, 2011; Rooney et al., 2012).

The corpus from Habernal and Gurevych (2017) includes user-generated web discourse (**WD**) such as blog posts, or user comments annotated with claims and premises as well as backings, rebuttals and refutations (α_U 0.48) inspired by Toulmin's model of argument (Toulmin, 2003).

The persuasive essay (**PE**) corpus (Stab and Gurevych, 2017) includes 402 student essays. The scheme comprises major claims, claims and premises at the clause level (α_U 0.77). The corpus has been extensively used in the argument mining community (Persing and Ng, 2015; Lippi and Torroni, 2015; Nguyen and Litman, 2016).

Biran and Rambow (2011a) annotated claims and premises in online comments (**OC**) from blog threads of LiveJournal (κ 0.69). In a subsequent work, Biran and Rambow (2011b) applied their annotation scheme to documents from Wikipedia talk pages (**WTP**) and annotated 118 threads. For our experiments, we consider each user comment in both corpora as a document, which yields $2,805$ documents in the OC corpus and $1,985$ documents in the WTP corpus.

Peldszus and Stede (2016) created a corpus of German microtexts (**MT**) of controlled linguistic and rhetoric complexity. Each document includes a single argument and does not exceed five argument components. The scheme models the argument structure and distinguishes between premises and claims, among other properties (such as proponent/opponent or normal/example). In the first annotation study, 26 untrained annotators annotated 23 microtexts in a classroom experiment (κ 0.38) (Peldszus and Stede, 2013b). In a subsequent work, the corpus was largely extended by expert annotators (κ 0.83). Recently, they translated the corpus to English, resulting in the first parallel corpus in computational argumentation; our experiments rely on the English version.

3.2 Qualitative Analysis of Claims

In order to investigate how claim annotations are tackled in the chosen corpora, one co-author of this paper manually analyzed 50 randomly sampled claims from each corpus. The characteristics taken into account are drawn from argumentation theory (Schiappa and Nordin, 2013) and include among other things the claim type, signaling words and discourse markers.

Biran and Rambow (2011b) do not back-up their claim annotations by any common argumentation theory but rather state that claims are *utterances which convey subjective information and anticipate the question 'why are you telling me that?'* and need to be supported by justifications. Using this rather loose definition, a claim might be any subjective statement that is justified by the author. Detailed examination of the LiveJournal corpus (OC) revealed that sentences with claims are extremely noisy. Their content ranges from a single word, (*"Bastard."*), to emotional expressions of personal regret, (*"::hugs:: i am so sorry hon .."*)

to general Web-chat nonsense (*"W-wow... that's a wicked awesome picture... looks like something from Pirates of the Caribbean...gone Victorian ...lolz."*) or posts without any clear argumentative purpose (*"what i did with it was make this recipe for a sort of casserole/stratta (i made this up, here is the recipe) [...] butter, 4 eggs, salt, pepper, sauted onions and cabbage..add as much as you want bake for 1 hour at 350 it was seriously delicious!"*). The Wikipedia Talk Page corpus (WTP) contains claims typical to Wikipedia quality discussions (*"That is why this article has NPOV issues."*) and policy claims (Schiappa and Nordin, 2013) are present as well (*"I think the gallery should be got rid of altogether."*). However, a small number of nonsensical claims remains (*"A dot."*).

Analysis of the MT dataset revealed that about half of claim sentences contain the modal verb *'should'*, clearly indicating policy claims (*"The death penalty should be abandoned everywhere."*). Such statements also very explicitly express the stance on the controversial topic of interest. In a similar vein, claims in persuasive students' essays (PE) heavily rely on phrases signaling beliefs (*"In my opinion, although using machines have many benefits, we cannot ignore its negative effects."*) or argumentative discourse connectors whose usage is recommended in textbooks on essay writing (*"Thus, it is not need for young people to possess this ability."*). Most claims are value/policy claims written in the present tense.

The mixture of genres in the AraucariaDB corpus (VG) is reflected in the variety of claims. While some are simple statements starting with a discourse marker (*"Therefore, 10% of the students in my logic class are left-handed."*), there are many legal-specific claims requiring expert knowledge (*"In considering the intention of Parliament when passing the 1985 Act, or perhaps more properly the intention of the draftsman in settling its terms, there are [...]"*), reported and direct speech claims (*"Eight-month-old Kyle Mutch's tragic death was not an accident and he suffered injuries consistent with a punch or a kick, a court heard yesterday."*), and several nonsensical claims (*"RE: Does the Priest Scandal Reveal the Beast?"*) which undercut the consistency of this dataset.

The web-discourse (WD) claims take a clear stance to the relevant controversy (*"I regard single sex education as bad."*), yet sometimes anaphoric (*"My view on the subject is no."*). The usage of discourse markers is seldom. Habernal and Gurevych (2017) investigated hedging in claims and found out that it varies with respect to the topic being discussed (10% up to 35% of claims are hedged). Sarcasm or rhetorical question are also common (*"In 2013, is single-sex education really the way to go?"*).

These observations make clear that annotating claims—the central part of all arguments, as suggested by the majority of argumentation scholars—can be approached very differently when it comes to actual empirical, data-driven operationalization. While some traits are shared, such as that claims usually need some support to make up a 'full' argument (e.g., premises, evidence, or justifications), the exact definition of a claim can be arbitrary—depending on the domain, register, or task.

4 Methodology

Given the results from the qualitative analysis, we want to investigate whether the different conceptualizations of claims can be assessed empirically and if so, how they could be dealt with in practice. Put simply, the task we are trying to solve in the following is: *given a sentence, classify whether or not it contains a claim.* We opted to model the claim identification task on sentence level, as this is the only way to make all datasets compatible to each other. Different datasets model claim boundaries differently, e.g. MT includes discourse markers within the same sentence, whereas they are excluded in PE.

All six datasets described in the previous section have been preprocessed by first segmenting documents into sentences using Stanford CoreNLP (Manning et al., 2014) and then annotating every sentence as claim, if one or more tokens within the sentence were labeled as claim (or major claim in PE). Analogously, each sentence is annotated as non-claim, if none of its tokens were labeled as claim (or major claim). Although our basic units of interest are sentences, we keep the content of the entire document to be able to retrieve information about the context of (non-)claims.[3]

We are not interested in optimizing the properties of a certain learner for this task, but rather

[3] This is true only for the feature-based learners. The neural networks do not have access to information beyond individual sentences.

want to compare the influence of different types of lexical, syntactical, and other kinds of information across datasets.[4] Thus, we used a limited set of learners for our task: a) a standard L2-regularized logistic regression approach with manually defined feature sets[5], which is a simple yet robust and established technique for many text classification problems (Plank et al., 2014; He et al., 2015; Zhang et al., 2016a; Ferreira and Vlachos, 2016); and b) several deep learning approaches, using state-of-the-art neural network architectures.

The **in-domain experiments** were carried out in a 10-fold cross-validation setup with fixed splits into training and test data. As for the **cross-domain experiments**, we train on the entire data of the source domain and test on the entire data of the target domain. In the domain adaptation terminology, this corresponds to an unsupervised setting.

To address class-imbalance in our datasets (see Table 1), we downsample the negative class (non-claim) both in-domain and cross-domain, so that positive and negative class occur approximately in an 1:1 ratio in the training data. Since this means that we discard a lot of useful information (many negative instances), we repeat this procedure 20 times, in each case randomly discarding instances of the negative class such that the required ratio is obtained. At test time, we use the majority prediction of this ensemble of 20 trained models. With the exception of very few cases, this led to consistent performance improvements across all experiments. The systems are described in more detail in the following subsections. Additionally, we report the results of two baselines. The majority baseline labels all sentences as non-claims (predominant class in all datasets), the random baseline labels sentences as claims with 0.5 probability.

4.1 Linguistically Motivated Features

For the logistic regression-based experiments (LR) we employed the following feature groups. *Structure Features* capture the position, the length and the punctuation of a sentence. *Lexical Features* are lowercased unigrams. *Syntax Features* account for grammatical information at the sentence level. We include information about the part-of-speech and parse tree for each sentence. *Discourse Features* encode information extracted with help of the Penn Discourse Treebank (PDTB) styled end-to-end discourse parser as presented by Lin et al. (2014). *Embedding Features* represent each sentence as a summation of its word embeddings (Guo et al., 2014). We further experimented with sentiment features (Habernal and Gurevych, 2015; Anand et al., 2011) and dictionary features (Misra et al., 2015; Rosenthal and McKeown, 2015) but these delivered very poor results and are not reported in this article. The full set of features and their parameters are described in the supplementary material to this article. We experiment with the full feature set, individual feature groups, and feature ablation (all features except for one group).

4.2 Deep Learning Approaches

As alternatives to our feature-based systems, we consider three deep learning approaches. The first is the Convolutional Neural Net of Kim (Kim, 2014) which has shown to perform excellently on many diverse classification tasks such as sentiment analysis and question classification and is still a strong competitor among neural techniques focusing on sentence classification (Komninos and Manandhar, 2016; Zhang et al., 2016b,c). We consider two variants of Kim's CNN, one in which words' vectors are initialized with pre-trained GoogleNews word embeddings (CNN:w2vec) and one in which the vectors are randomly initialized and updated during training (CNN:rand). Our second model is an LSTM (long short-term memory) neural net for sentence classification (LSTM) and our third model is a bidirectional LSTM (BiLSTM).

For all neural network classifiers, we use default hyperparameters concerning hidden dimensionalities (for the two LSTM models), number of filters (for the convolutional neural net), and others. We train each of the three neural networks for 15 iterations and choose in each case the learned model that performs best on a held-out development set of roughly 10% of the training data as the model to apply to unseen test data. This corresponds to an early stopping regularization scheme.

5 Results

In the following, we summarize the results of the various learners described above. Obtaining all results required heavy computation, e.g. the cross-

[4] For the same reason, we do not optimize any hyperparameters for individual learners, unless explicitly stated.

[5] Using the liblinear library (Fan et al., 2008).

validation experiments for feature-based systems took 56 days of computing. We intentionally do not list the results of previous work on those datasets. The scores are not comparable since we strictly work on sentence level (rather than e.g. clause level) and applied downsampling to the training data. All reported significance tests were conduced using two-tailed Wilcoxon Signed-Rank Test for matched pairs, i.e. paired scores of F_1 scores from two compared systems (Japkowicz and Shah, 2014).

5.1 In-Domain Experiments

The performance of the learners is quite divergent across datasets, with Macro-F_1 scores[6] ranging from 60% (WTP) to 80% (MT), average 67% (see Table 2). On all datasets, our best systems clearly outperform both baselines. In isolation, lexical, embedding, and syntax features are most helpful, whereas structural features did not help in most cases. Discourse features only contribute significantly on MT. When looking at the performance of the feature-based approaches, the most striking finding is the importance of lexical (in our setup, unigram) information.

The average performances of LR$_{-syntax}$ and CNN:rand are virtually identical, both for Macro-F_1 and Claim-F_1, with a slight advantage for the feature-based approach, but their difference is not statistically significant ($p \leq 0.05$). Altogether, these two systems exhibit significantly better average performances than all other models surveyed here, both those relying on and those not relying on hand-crafted features ($p \leq 0.05$). The absence or the different nature of inter-annotator agreement measures for all datasets prevent us from searching for correlations between agreement and performance. But we observed that the systems yield better results on PE and MT, both datasets with good inter-annotator agreement ($\alpha_u = 0.77$ for PE and $\kappa = 0.83$ for MT).

5.2 Cross-Domain Experiments

For all six datasets, training on different sources resulted in a performance drop. Table 3 lists the results of the best feature-based (*LR All features*) and deep learning (*CNN:rand*) systems, as well as single feature groups (averages over all source domains, results for individual source domains can be found in the supplementary material to this article). We note the biggest performance drops on the datasets which performed best in the in-domain setting (MT and PE). For the lowest scoring datasets, OC and WTP, the differences are only marginal when trained on a suitable dataset (VG

Table 3: Cross-domain experiments, best values per column are highlighted, in-domain results (for comparison) in italics; results only for selected systems. For each source/target combination we show two scores: *Macro-F_1* score (left-hand column) and F_1 score for claims (right-hand column).

and OC, respectively). The best feature-based approach outperforms the best deep learning approach in most scenarios. In particular, as opposed to the in-domain experiments, the difference of the Claim-F_1 measure between the feature-based approaches and the deep learning approaches is striking. In the feature-based approaches, on average, a combination of all features yields the best results for both Macro-F_1 and Claim-F_1. When comparing single features, lexical ones do the best job.

Looking at the best overall system (LR with all features), the average test results when training on different source datasets are between 54% Macro-F_1 resp. 23% Claim-F_1 (both MT) and 58% (VG) resp. 34% (OC). Depending on the goal that should be achieved, training on VG (highest average Macro-F_1) or OC (highest average Claim-F_1) seems to be the best choice when the domain of test data is unknown (we analyze this finding in more depth in §6). MT clearly gives the best results as target domain, followed by PE and VG.

We also performed experiments with mixed sources, the results are shown in Table 4. We did this in a leave-one-domain-out fashion, in particular we trained on all but one datasets and tested on the remaining one. In this scenario, the neural network systems seem to benefit from the increased amount of training data and thus gave the best results. Overall, the mixed sources approach works better than many of the single-source cross-domain systems – yet, the differences were not found to be significant, but as good as training on suitable single sources (see above).

6 Further Analysis and Discussion

To better understand which factors influence cross-domain performance of the systems we tested, we considered the following variables as potential determinants of outcome: similarity between source and target domain, the source domain itself, training data size, and the ratio between claims and non-claims.

We calculated the Spearman correlation of the top-500 lemmas between the datasets in each direction, see results in Table 5. The most similar domains are OC (source s) and WTP (target t), coming from the same authors. OC (s) and WD (t) as well OC (s) and VG (t) are also highly cor-

Table 5: Heatmap of Spearman correlations in % based on most frequent 500 lemmas for each dataset. Source domain: rows, target domain: columns.

related. For a statistical test of potential correlations between cross-domain performances and the introduced variables, we regress the cross-domain results (Table 3) on Table 5 (T4 in the following equation), on the number of claims #C (directly related to training data size in our experiments, effect of downsampling), and on the ratio of claims to non-claims R.[7] More precisely, given source/training data and target data pairs (s,t) in Table 3, we estimate the linear regression model

$$y_{st} = \alpha \cdot \mathrm{T4}_{st} + \beta \cdot \log(\#\mathrm{C}_s) + \gamma \cdot \mathrm{R}_t + \varepsilon_{st}, \quad (1)$$

where y_{st} denotes the Macro-F_1 score when training on s and testing on t. In the regression, we also include binary dummy variables $\mathbb{1}_\sigma = \mathbb{1}_{s,\sigma}$ for each domain σ whose value is 1 if $s = \sigma$ (and 0 otherwise). These help us identify "good" source domains.

The coefficient α for Table 5 is not statistically significantly different from zero in any case. Ultimately, this means that it is difficult to predict cross-domain performance from lexical similarity of the datasets. This is in contrast to e.g., POS tagging, where lexical similarity has been reported to predict cross-domain performance very well (Van Asch and Daelemans, 2010). The coefficient for training data size β is statistically significantly different from zero in three out of 15 cases. In particular, it is significantly positive in two (CNN:rand, CNN:w2vec) out of four cases for the neural networks. This indicates that the neural networks would have particularly benefited from more training data, which is confirmed by the improved performance of the neural networks in the mixed sources experiments (cf. §5.2). The ratio of claims to non-claims in t is among the best predictors for the variables considered here (coefficient γ is significant in three out of 15 cases, but consistently positive). This is probably due to our decision to balance training data (downsampling non-claims) to keep the assessment of claim identification realistic for real-world applications, where the class ratio of t is unknown. Our systems are thus inherently biased towards a higher claim ratio.

Finally, the dummy variables for OC and VG are three times significantly positive, but consistently positive overall. Their average coefficient is 2.31 and 1.90, respectively, while the average coefficients for all other source datasets is negative, and not significant in most cases. Thus, even when controlling for all other factors such as training data size and the different claim ratios of target domains, OC and VG are the best source domains for cross-domain claim classification in our experiments. OC and VG are particularly good training sources for the detection of claims (as opposed to non-claims)—the minority class in all datasets—as indicated by the average Claim-F_1 scores in Table 3.

One finding that was confirmed both in-domain as well as cross-domain was the importance of lexical features as compared to other feature groups. As mere lexical similarity between domains does not explain performance (cf. coefficient α above), this finding indicated that the learners relied on

[7] Overall, we had 15 different systems, see upper 15 rows in Table 2. Therefore, we had 15 different regression models.

a few, but important lexical clues. To go more into depth, we carried out error analysis on the CNN:rand cross-domain results. We used OC, VG and PE as source domains, and MT and WTP as target domains. By examining examples in which a model trained on OC and VG made correct predictions as opposed to a model trained on PE, we quickly noticed that lexical indicators indeed played a crucial role. In particular, the occurrence of the word "should" (and to a lower degree: "would", "article", "one") are helpful for the detection of claims across various datasets. In MT, a simple baseline labeling every sentence containing "should" as claim achieves 76.1 Macro-F_1 (just slightly below the best in-domain system on this dataset). In the other datasets, this phenomenon is far less dominant, but still observable. We conclude that a few rather simple rules (learned by models trained on OC and VG, but not by potentially more complex models trained on PE) make a big difference in the cross-domain setting.

7 Conclusion

In a rigorous empirical assessment of different machine learning systems, we compared how six datasets model claims as the fundamental component of an argument. The varying performance of the tested in-domain systems reflects different notions of claims also observed in a qualitative study of claims across the domains. Our results reveal that the best in-domain system is not necessarily the best system in environments where the target domain is unknown. Particularly, we found that mixing source domains and training on two rather noisy datasets (OC and VG) gave the best results in the cross-domain setup. The reason for this seem to be a few important lexical indicators (like the word "should") which are learned easier under these circumstances. In summary, as for the six datasets we analyzed here, our analysis shows that the essence of a claim is not much more than a few lexical clues.

From this, we conclude that future work should address the problem of vague conceptualization of claims as central components of arguments. A more consistent notion of claims, which also holds across domains, would potentially not just benefit cross-domain claim identification, but also higher-level applications relying on argumentation mining (Wachsmuth et al., 2017). To further overcome the problem of domain dependence, multi-task learning is a framework that could be explored (Søgaard and Goldberg, 2016) for different conceptualizations of claims.

Identifying Where to Focus in Reading Comprehension for Neural Question Generation

Xinya Du and **Claire Cardie**
Department of Computer Science
Cornell University
Ithaca, NY, 14853, USA
{xdu, cardie}@cs.cornell.edu

Abstract

A first step in the task of automatically generating questions for testing reading comprehension is to identify *question-worthy* sentences, i.e. sentences in a text passage that humans find it worthwhile to ask questions about. We propose a hierarchical neural sentence-level sequence tagging model for this task, which existing approaches to question generation have ignored. The approach is fully data-driven — with no sophisticated NLP pipelines or any hand-crafted rules/features — and compares favorably to a number of baselines when evaluated on the SQuAD data set. When incorporated into an existing neural question generation system, the resulting end-to-end system achieves state-of-the-art performance for paragraph-level question generation for reading comprehension.

1 Introduction and Related Work

Automatically generating questions for testing reading comprehension is a challenging task (Mannem et al., 2010; Rus et al., 2010). First and foremost, the question generation system must determine which concepts in the associated text passage are important, i.e. are worth asking a question about.

The little previous work that exists in this area currently circumvents this critical step in passage-level question generation by assuming that such sentences have already been identified. In particular, prior work focuses almost exclusively on *sentence-level* question generation: given a text passage, assume that all sentences contain a question-worthy concept and generate one or more questions for each (Heilman and Smith, 2010; Du et al., 2017; Zhou et al., 2017).

In contrast, we study the task of *passage-level question generation (QG)*. Inspired by the large body of research in text summarization on identifying sentences that contain "summary-worthy" content (e.g. Mihalcea (2005), Berg-Kirkpatrick et al. (2011), Yang et al. (2017)), we develop a method to identify the *question-worthy sentences* in each paragraph of a reading comprehension passage. Inspired further by the success of neural sequence models for many natural language processing tasks (e.g. named entity recognition (Collobert et al., 2011), sentiment classification (Socher et al., 2013), machine translation (Sutskever et al., 2014), dependency parsing (Chen and Manning, 2014)), including very recently document-level text summarization (Cheng and Lapata, 2016), we propose a hierarchical neural sentence-level sequence tagging model for question-worthy sentence identification.

We employ the SQuAD reading comprehension data set (Rajpurkar et al., 2016) for evaluation and show that our sentence selection approach compares favorably to a number of baselines including the feature-rich sentence selection model of Cheng and Lapata (2016) proposed in the context of extract-based summarization, and the convolutional neural network model of Kim (2014) that achieves state-of-the-art results on a variety of sentence classification tasks.

We also incorporate our sentence selection component into the neural question generation system of Du et al. (2017) and show, again using SQuAD, that our resulting end-to-end system achieves state-of-the-art performance for the challenging task of paragraph-level question generation for reading comprehension.

2 Problem Formulation

In this section, we define the tasks of *important* (i.e. question-worthy) *sentence selection* and *sentence-level question generation (QG)*. Our full paragraph-level QG system includes both of these components. For the sentence selection task, given a paragraph D consisting of a sequence of sentences $\{s_1, ..., s_m\}$, we aim to select a subset of k question-worthy sentences $(k < m)$. The goal is defined as finding $\overline{\mathbf{y}} = \{y_1, ..., y_m\}$, such that,

$$\begin{aligned}\overline{\mathbf{y}} &= \arg\max_{\mathbf{y}} \log P_1 (\mathbf{y}|D) \\ &= \arg\max_{\mathbf{y}} \sum_{t=1}^{|\mathbf{y}|} \log P_1 (y_t|D)\end{aligned} \quad (1)$$

where log $P(\mathbf{y}|D)$ is the conditional log-likelihood of the label sequence $\mathbf{y}$; and $y_i = 1$ means sentence i is question-worthy (contains at least one answer), otherwise $y_i = 0$.

For sentence-level QG, the goal is to find the best word sequence $\overline{\mathbf{z}}$ (a question of arbitrary length) that maximizes the conditional likelihood given the input sentence $\mathbf{x}$ and satisfies:

$$\begin{aligned}\overline{\mathbf{z}} &= \arg\max_{\mathbf{z}} \log P_2 (\mathbf{z}|\mathbf{x}) \\ &= \arg\max_{\mathbf{z}} \sum_{t=1}^{|\mathbf{z}|} \log P_2 (z_t|\mathbf{x}, z_{<t})\end{aligned} \quad (2)$$

where $P_2(\mathbf{z}|\mathbf{x})$ is modeled with a global attention mechanism (Section 3).

3 Model

Important Sentence Selection Our general idea for the hierarchical neural network architecture is illustrated in Figure 1. First, we perform the encoding using sum operation or convolution+maximum pooling operation (Kim, 2014; dos Santos and Zadrozny, 2014) over the word vectors comprising each sentence in the input paragraph. For simplicity and consistency, we denote the sentence encoding process as ENC. Given the t^{th} sentence $\mathbf{x} = \{x_1, ..., x_n\}$ in the paragraph, we have its encoding:

$$\mathbf{s}_t = \text{ENC}([x_1, ..., x_n]) \quad (3)$$

Then we use a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) to encode the paragraph,

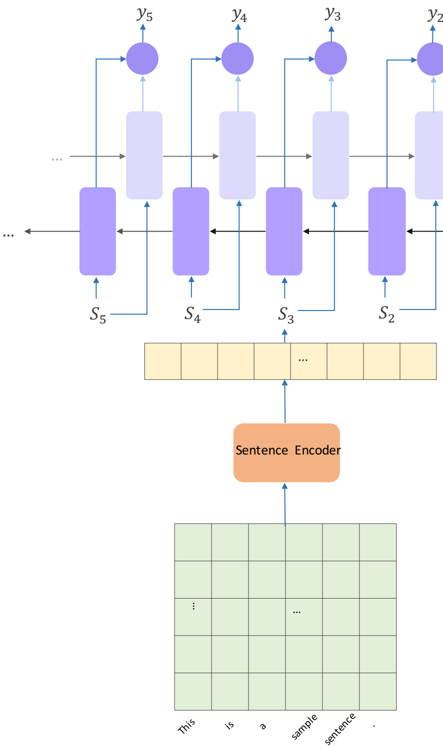

Figure 1: Hierarchical neural network architecture for sentence-level sequence labeling. The input is a paragraph consisting of sentences, whose encoded representation is fed into each hidden unit.

$$\begin{aligned}\overrightarrow{\mathbf{h}_t} &= \overrightarrow{\text{LSTM}} \left(\mathbf{s}_t, \overrightarrow{\mathbf{h}_{t-1}}\right) \\ \overleftarrow{\mathbf{h}_t} &= \overleftarrow{\text{LSTM}} \left(\mathbf{s}_t, \overleftarrow{\mathbf{h}_{t+1}}\right)\end{aligned}$$

We use the concatenation of the two, namely, $[\overrightarrow{\mathbf{h}_t}; \overleftarrow{\mathbf{h}_t}]$, as the hidden state $\mathbf{h}_t$ at time stamp t, and feed it to the upper layers to get the probability distribution of y_t $(\in \{0, 1\})$,

$$P_1 (y_t|D; \theta) = \text{softmax} \left(\text{MLP} \left(\tanh \left([\overrightarrow{\mathbf{h}_t}; \overleftarrow{\mathbf{h}_t}]\right)\right)\right)$$

where MLP is multi-layer neural network and tanh is the activation function.

Question Generation Similar to Du et al. (2017), we implement the sentence-level question generator with an attention-based sequence-to-sequence learning framework (Sutskever et al., 2014; Bahdanau et al., 2015), to map a sentence in the reading comprehension article to natural questions. It consists of an LSTM encoder and decoder. The encoder is a bi-directional LSTM network; it encodes the input sentence $\mathbf{x}$ into a sequence of hidden states $\mathbf{q}_1, \mathbf{q}_2, ..., \mathbf{q}_{|\mathbf{x}|}$.

Model	Precision	Recall	F-measure	Acc.	Paragraph-level Acc.
RANDOM	63.45	50.29	56.11	50.27	11.69
Majority Baseline	63.21	100.00	77.46	63.21	32.30
CNN (Kim, 2014)	68.35	**90.13**	77.74	67.38	24.73
LREG$_{\text{(w/ BOW)}}$	68.52	86.55	76.49	66.37	31.36
LREG$_{\text{(w/ para.-level)}}$ (Cheng and Lapata, 2016)	70.49	89.08	78.70	69.52	33.95
Ours$_{\text{SUM}}$ (no pre-trained)	73.02	89.23	80.32	72.36	36.46
Ours$_{\text{SUM}}$ (w/ pre-trained)	73.85	87.65	80.16	**72.58**	36.30
Ours$_{\text{CNN}}$ (no pre-trained)	73.15	89.29	**80.42***	72.52	35.93
Ours$_{\text{CNN}}$ (w/ pre-trained)	**74.35**	86.11	79.80	72.44	**36.87**

Table 1: Automatic evaluation results for important sentence selection. The best performing system in each column is highlighted in boldface. Paragraph-level accuracies are calculated as the proportion of paragraphs in which *all* of the sentences are predicted correctly. We show two-tailed t-test results on F-measure for our best performing method compared to the other baselines. (Statistical significance is indicated with $^*(p < 0.005)$.)

The decoder is another LSTM that uses global attention over the encoder hidden states. The entire encoder-decoder structure learns the probability of generating a question given a sentence, as indicated by equation 2. To be more specific,

$$P_2\left(z_t|\mathbf{x}, z_{<t}\right) = \text{softmax}\left(\mathbf{W}_s\text{tanh}\left(\mathbf{W}_t[\mathbf{h}_t; \mathbf{c}_t]\right)\right)$$

where $\mathbf{W}_s$, $\mathbf{W}_t$ are parameter matrices; $\mathbf{h}_t$ is the hidden state of the decoder LSTM; and $\mathbf{c}_t$ is the context vector created dynamically by the encoder LSTM — the weighted sum of the hidden states computed for the source sentence:

$$\mathbf{c}_t = \sum_{i=1,..,|\mathbf{x}|} a_{i,t}\mathbf{q}_i$$

The attention weights $a_{i,t}$ are calculated via a bilinear scoring function and softmax normalization:

$$a_{i,t} = \frac{\exp(\mathbf{h}_t^T \mathbf{W}_b \mathbf{q}_i)}{\sum_j \exp(\mathbf{h}_t^T \mathbf{W}_b \mathbf{q}_j)}$$

Apart from the bilinear score, alternative options for computing the attention can also be used (e.g. dot product). Readers can refer to Luong et al. (2015) for more details.

During inference, beam search is used to predict the question. The decoded `UNK` token at time step t, is replaced with the token in the input sentence with the highest attention score, the index of which is $\arg\max_i a_{i,t}$.

Henceforth, we will refer to our sentence-level **N**eural **Q**uestion **G**eneration system as **NQG**. Note that generating answer-specific questions would be easy for this architecture — we can append answer location features to the vectors of tokens in the sentence. To better mimic the real life case (where questions are generated with no prior knowledge of the desired answers), we do not use such location features in our experiments.

4 Experimental Setup and Results

4.1 Dataset and Implementation Details

We use the SQuAD dataset (Rajpurkar et al., 2016) for training and evaluation for both important sentence selection and sentence-level NQG. The dataset contains 536 curated Wikipedia articles with over 100k questions posed about the articles. The authors employ Amazon Mechanical Turk crowd-workers to generate questions based on the article paragraphs and to annotate the corresponding answer spans in the text. Later, to make the evaluation of the dataset more robust, other crowd-workers are employed to provide additional answers to the questions.

We split the public portion of the dataset into training ($\sim$80%), validation ($\sim$10%) and test ($\sim$10%) sets at the paragraph level. For the sentence selection task, we treat sentences that contain at least one answer span (question-worthy sentences) as positive examples ($y = 1$); all remaining sentences are considered negative ($y = 0$). Not surprisingly, the training set is unbalanced: 52332 ($\sim$60%) sentences contain answers, while 29693 sentences do not. Because of the variabil-

	Model	BLEU 1	BLEU 2	BLEU 3	BLEU 4	METEOR
Conservative	LREG(C&L) + NQG	38.30	23.15	15.64	10.97	15.09
	Ours + NQG	40.08	24.26	16.39	11.50	15.67
Liberal	LREG(C&L) + NQG	51.55	40.17	34.35	30.59	24.17
	Ours + NQG	52.89	41.16	35.15	31.25	24.76

Table 2: Results for the full QG systems using BLEU 1–4, METEOR. The first stage of the two pipeline systems are the feature-rich linear model (LREG) and our best performing selection model respectively.

ity of human choice in generating questions, it is the case that many sentences labeled as negative examples might actually contain concepts worth asking a question about. For the related important sentence detection task in text summarization, Yang et al. (2017) therefore propose a two-stage approach (Lee and Liu, 2003; Elkan and Noto, 2008) to augment the set of known summary-worthy sentences. In contrast, we adopt a conservative approach rather than predict too many sentences as being question-worthy: we pair up source sentences with their corresponding questions, and use just these sentence-question pairs to training the encoder-decoder model.

We use the `glove.840B.300d` pre-trained embeddings (Pennington et al., 2014) for initialization of the embedding layer for our sentence selection model and the full NQG model. `glove.6B.100d` embeddings are used for calculating sentence similarity feature of the baseline linear model (LREG). Tokens outside the vocabulary list are replaced by the `UNK` symbol. Hyperparameters for all models are tuned on the validation set and results are reported on the test set.

4.2 Sentence Selection Results

	conservative eval.		liberal eval.	
Gold Data System Output	w/ Q	w/o Q	w/ Q	w/o Q
w/ Q	matching	zero	matching	full
w/o Q	zero	-	zero	-

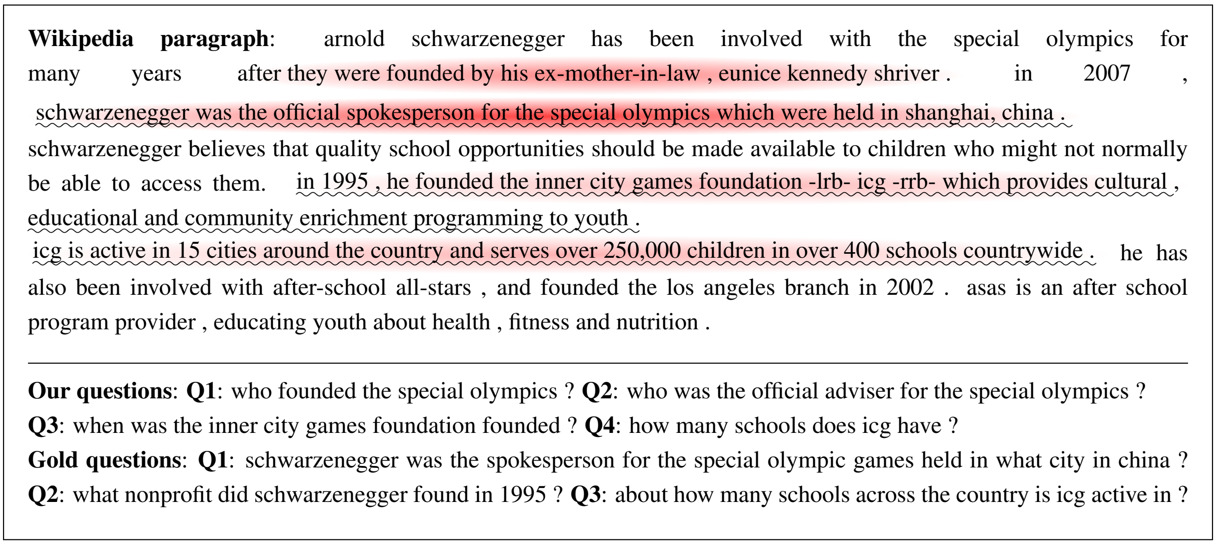
Table 3: For a source sentence in SQuAD, given the prediction from the sentence selection system and the corresponding NQG output, we provide conservative and liberal evaluations.

We compare to a number of baselines. The **Random** baseline assigns a random label to each sentence. The **Majority** baseline assumes that all sentences are question-worthy. The convolutional neural networks (**CNN**) sentence classification model (Kim, 2014) has similar structure to our CNN sentence encoder, but the classification is done only at the sentence-level rather than jointly at paragraph-level. **LREG$_{\text{w/ BOW}}$** is the logistic regression model with bag-of-words features. **LREG$_{\text{w/ para.-level}}$** is the feature-rich LREG model designed by Cheng and Lapata (2016); the features include: sentence length, position of sentence, number of named entities in the sentence, number of sentences in the paragraph, sentence-to-sentence cohesion, and sentence-to-paragraph relevance. Sentence-to-sentence cohesion is obtained by calculating the embedding space similarity between it and every other sentence in the paragraph (similar for sentence-to-paragraph relevance). In document summarization, graph-based extractive summarization models (e.g. TGRAPH Parveen et al. (2015) and URANK Wan (2010)) focus on global optimization and extract sentences contributing to topical coherent summaries. Because this does not really fit our task — a *summary-worthy* sentence might not necessarily contain enough information for generating a good question — we do not include these as comparisons.

Results are displayed in Table 1. Our models with sum or CNN as the sentence encoder significantly outperform the feature-rich LREG as well as the other baselines in terms of F-measure.

4.3 Evaluation of the full QG system

To evaluate the full systems for paragraph-level QG, we introduce in Table 3 the "conservative" and "liberal" evaluation strategies. Given an input source sentence, there will be in total four possibilities: if both the gold standard data and prediction include the sentence, then we use its n-gram matching score (by BLEU (Papineni et al., 2002) and METEOR (Denkowski and Lavie, 2014)); if neither the gold data nor prediction include the sentence, then the sentence is discarded from the evaluation; if the gold data includes the sentence while the prediction does not, we assign a score of 0 for it; and if gold data does not include the sentence while prediction does, the generated question gets a 0 for conservative, while it gets full



Wikipedia paragraph: arnold schwarzenegger has been involved with the special olympics for many years after they were founded by his ex-mother-in-law , eunice kennedy shriver . in 2007 , schwarzenegger was the official spokesperson for the special olympics which were held in shanghai, china . schwarzenegger believes that quality school opportunities should be made available to children who might not normally be able to access them. in 1995 , he founded the inner city games foundation -lrb- icg -rrb- which provides cultural , educational and community enrichment programming to youth . icg is active in 15 cities around the country and serves over 250,000 children in over 400 schools countrywide . he has also been involved with after-school all-stars , and founded the los angeles branch in 2002 . asas is an after school program provider , educating youth about health , fitness and nutrition .

Our questions: **Q1**: who founded the special olympics ? **Q2**: who was the official adviser for the special olympics ? **Q3**: when was the inner city games foundation founded ? **Q4**: how many schools does icg have ?
Gold questions: **Q1**: schwarzenegger was the spokesperson for the special olympic games held in what city in china ? **Q2**: what nonprofit did schwarzenegger found in 1995 ? **Q3**: about how many schools across the country is icg active in ?

Figure 2: Sample output from our full NQG system, the four questions correspond to the four highlighted sentences in the paragraph in the same order. Darkness indicates sentence importance, the score for deciding the darkness is obtained from the softmax results. Wave-lined sentences bear label $y = 1$, and 0 otherwise. The three gold questions also correspond to the wave-lined sentences in the same order. Please refer to the appendix for sample output on more Wikipedia articles.

score for liberal evaluation. Table 2 shows that the QG system incorporating our best performing sentence extractor outperforms its LREG counterpart across metrics. Note that to calculate the score for the matching case, similar to our earlier work (Du et al., 2017), we adapt the image captioning evaluation scripts of Chen et al. (2015) since there can be several gold standard questions for a single input sentence.

In Figure 2, we provide questions generated by the full NQG system (Q1–4) and according to the gold standard (Q1–3) for the selected Wikipedia paragraph. The sentences they were drawn from are shown with wavy lines (gold standard) and via highlighting (our system). Darkness of the highlighting is proportional to the softmax score provided by the sentence extractor.

5 Conclusion

In this work we introduced the task of identifying important sentences — good sentences to ask a question about — in the reading comprehension setting. We proposed a hierarchical neural sentence labeling model and investigated encoding sentences with sum and convolution operations. The question generation system that uses our sentence selection model consistently outperforms previous approaches and achieves state-of-the-art paragraph-level question generation performance on the SQUAD data set.

In future work, we would like to investigate approaches to identify question-worth *concepts* rather than question-worthy sentences. It would also be interesting to see if the generated questions can be used to help improve question answering systems.

Abstract

Comprehending lyrics, as found in songs and poems, can pose a challenge to human and machine readers alike. This motivates the need for systems that can understand the ambiguity and jargon found in such creative texts, and provide commentary to aid readers in reaching the correct interpretation.

We introduce the task of automated lyric annotation (ALA). Like text simplification, a goal of ALA is to rephrase the original text in a more easily understandable manner. However, in ALA the system must often include *additional* information to clarify niche terminology and abstract concepts. To stimulate research on this task, we release a large collection of crowdsourced annotations for song lyrics. We analyze the performance of translation and retrieval models on this task, measuring performance with both automated and human evaluation. We find that each model captures a unique type of information important to the task.

1 Introduction

Song lyrics and poetry often make use of ambiguity, symbolism, irony, and other stylistic elements to evoke emotive responses. These characteristics sometimes make it challenging to interpret obscure lyrics, especially for readers or listeners who are unfamiliar with the genre. To address this problem, several online lyric databases have been created where users can explain, contextualize, or discuss lyrics. Examples include MetroLyrics[1] and Genius.com[2]. We refer to such commentary as a lyric annotation (Figure 1).

How does it feel?
To be without a home
Like a complete unknown,

Like a rolling stone

↓

The proverb "A rolling stone gathers no moss" refers to people who are always on the move, never putting down roots or accumulating responsibilities and cares.

Figure 1: A lyric annotation for "Like A Rolling Stone" by Bob Dylan.

In this work we introduce the task of *automated lyric annotation* (ALA). Compared to many traditional NLP systems, which are trained on newswire or similar text, an automated system capable of explaining abstract language, or finding alternative text expressions for slang (and other unknown terms) would exhibit a deeper understanding of the nuances of language. As a result, research in this area may open the door to a variety of interesting use cases. In addition to providing lyric annotations, such systems can lead to improved NLP analysis of informal text (blogs, social media, novels and other literary works of fiction), better handling of genres with heavy use of jargon (scientific texts, product manuals), and increased robustness to textual variety in more traditional NLP tasks and genres.

Our contributions are as follows:

1. To aid in the study of ALA we present a corpus of 803,720 crowdsourced lyric annotation pairs suitable for training models for this task.[3]
2. We present baseline systems using statistical machine translation (SMT), neural trans-

# Lyric Annotation pairs	803,720
⊘ Tokens per Lyric	15
⊘ Tokens per Annotation	43
$\|V_{\text{lyrics}}\|$	124,022
$\|V_{\text{annot}}\|$	260,427

Table 1: Properties of gathered dataset (V_{lyrics} and V_{annot} denote the vocabulary for lyrics and annotations, ⊘ denotes the average amount).

lation (Seq2Seq), and information retrieval.

3. We establish an evaluation procedure which adopts measures from machine translation, paraphrase generation, and text simplification. Evaluation is conducted using both human and automated means, which we perform and report across all baselines.

2 The Genius ALA Dataset

We collect a dataset of crowdsourced annotations, generated by users of the *Genius* online lyric database. For a given song, users can navigate to a particular stanza or line, view existing annotations for the target lyric, or provide their own annotation. Discussion between users acts to improve annotation quality, as it does with other collaborative online databases like Wikipedia. This process is gamified: users earn *IQ* points for producing high quality annotations.

We collect 736,423 lyrics having a total 1,404,107 lyric annotation pairs from all subsections (rap, poetry, news, etc.) of Genius. We limit the initial release of the annotation data to be English-only, and filter out non-English annotations using a pre-trained language identifier. We also remove annotations which are solely links to external resources, and do not provide useful textual annotations. This reduces the dataset to 803,720 lyric annotation pairs. We list several properties of the collected dataset in Table 1.

2.1 Context Independent Annotation

Mining annotations from a collaborative human-curated website presents additional challenges worth noting. For instance, while we are able to generate large quantities of parallel text from Genius, users operate without a single, predefined and shared *global* goal other than to maximize their own IQ points. As such, there is no motivation to provide annotations for a song in its entirety, or independent of previous annotations.

For this reason we distinguish between two types of annotations: *context independent* (CI) annotations are independent of their surrounding context and can be interpreted without it, e.g., explain specific metaphors or imagery or provide narrative while normalizing slang language. Contrastively, *context sensitive* (CS) annotations provide broader context beyond the song lyric excerpt, e.g., background information on the artist.

To estimate contribution from both types to the dataset, we sample 2,000 lyric annotation pairs and label them as either CI or CS. Based on this sample, an estimated 34.8% of all annotations is independent of context. Table 2 shows examples of both types.

While the goal of ALA is to generate annotations of all types, it is evident from our analysis that CS annotations can not be generated by models trained solely on parallel text. That is, these annotations cannot be generated without background knowledge or added context. Therefore, in this preliminary work we focus on predicting CI lyric annotations.

3 Baselines

We experiment with three baseline models used for text simplification and paraphrase generation.

- **Statistical Machine Translation (SMT):** One approach is to treat the task as one of translation, and to use established statistical machine translation (SMT) methods (Quirk et al., 2004) to produce them. We train a standard phrase-based SMT model to translate lyrics to annotations, using GIZA++ (Josef Och and Ney, 2003) for word alignment and Moses (Koehn et al., 2007) for phrasal alignment, training, and decoding.

- **Seq2Seq:** Sequence-to-sequence models (Sutskever et al., 2014) offer an alternative to SMT systems, and have been applied successfully to a variety of tasks including machine translation. In Seq2Seq, a recurrent neural network (RNN) encodes the source sequence to a single vector representation. A separate decoder RNN generates the translation conditioned on this representation of the source sequence's semantics. We utilize Seq2Seq with attention (Bahdanau et al., 2014), which allows the model to

Type	% of annotations	Examples	
CI (Context independent)	34.8%	[L]	Gotta patch a lil kid tryna get at this cabbage
		[A]	He's trying to ignore the people trying to get at his money.
		[L]	You know it's beef when a smart brother gets stupid
		[A]	You know an argument is serious when an otherwise rational man loses rational.
CS (Context sensitive)	65.2%	[L]	Cause we ain't break up, more like broke down
		[A]	The song details Joe's break up with former girlfriend Esther.
		[L]	If I quit this season, I still be the greatest, funk
		[A]	Kendrick has dropped two classic albums and pushed the artistic envelope further.

Table 2: Examples of context independent and dependent pairs of lyrics [L] and annotations [A].

additionally condition on tokens from the input sequence during decoding.

- **Retrieval:** In practice, similar lyrics may reappear in different contexts with exchangeable annotations. We treat the training corpus as a database of lyrics' excerpts with corresponding annotations, and at test time select the annotation assigned to the most similar lyric. This baseline is referred to as the *retrieval* model. We use standard TF-IDF weighted cosine distance as similarity measure between lyrics' excerpts.

4 Evaluation

4.1 Data

We evaluate automatic annotators on a selection of 354 CI annotations and partition the rest of the annotations into 2,000 instances for development and the full remainder for training. It is important to note that the annotations used for training and development include CI as well as CS annotations.

Annotations often include multiple sentences or even paragraphs for a single lyrics excerpt (which does not include end marks), while machine translation models need aligned corpora at sentence level to perform well (Xu et al., 2016). We therefore transform training data by including each sentence from the annotation as a single training instance with the same lyric, resulting in a total of 1,813,350 sentence pairs.

We use this collection of sentence pairs (denoted as *sent.* in results) to train the SMT model. Seq2Seq models are trained using sentence pairs as well as full annotations. Interestingly, techniques encouraging alignment by matching length and thresholding cosine distance between lyric and annotation did not improve performance during development.

4.2 Measures

For automated evaluation, we use measures commonly used to evaluate translation systems (BLEU, METEOR), paraphrase generation (iBLEU) and text simplification (SARI).

BLEU (Papineni et al., 2002) uses a modified form of precision to compare generated annotations against references from Genius. METEOR (Denkowski and Lavie, 2011) is based on the harmonic mean of precision and recall and, along with exact word matching, includes stemming and synonymy matching. iBLEU (Sun and Zhou, 2012) is an extension of the BLEU metric to measure diversity as well as adequacy of the annotation, iBLEU $= 0.9 \times$ BLEU(Annotation, Reference) $- 0.1 \times$ BLEU(Annotation, Lyric). SARI (Xu et al., 2016) measures precision and recall of words that are added, kept, or deleted separately and averages their arithmetic means.

We also measure quality by crowdsourcing ratings via the online platform CrowdFlower.[4] We present collaborators with a song lyric excerpt annotated with output from the annotation generators as well as a reference annotation from Genius. Collaborators assign a 5-point rating for *Fluency* which rates the quality of the generated language, and *Information* which measures the added clarification by the annotation, a key aspect of this task. For each lyric annotation pair, we gather ratings from three different collaborators and take the average.

4.3 Hyperparameters and Optimization

Here we describe implementation and some of the optimizations used when training the models.

[4] https://www.crowdflower.com/

Lyric:	`and when I slept, I dream g's, son I need some`
Human:	he dreams about large amounts of money because he is in need of it .
SMT:	and when he slept, and he's dream, g's son, he needs some
Seq2Seq:	when he sleeps , he dreams of getting money.
Retrieval:	g's refer to the ghetto gangsters in london that the kid has become involved with
Lyric:	`Mossberg pump I'm ridin' shotgun literally`
Human:	riding shotgun means to ride up front in the passenger seat
SMT:	Mossberg pump - action shotgun, he's saying he's ridin' shotgun literally.
Seq2Seq:	Mossberg is a firearms manufacturer. He is riding shotgun with his shotgun.
Retrieval:	he fully respects the people mentioned earlier and is riding for them.
Lyric:	`and my eyes red cause of all that haze`
Human:	his eyes turn red due to lack of hydration from the weed one smokes (in this case , smoking purple haze)
SMT:	and his eyes are red because of all that haze.
Seq2Seq:	his eyes are red because of all the weed he smokes.
Retrieval:	his eyes are red as a sign of the fatigue of travel and , possibly , from drugs and alcohol .

Table 3: Lyrics excerpts with annotations from Genius ('Human') and automated annotators.

	Properties		Automated Evaluation				Human Evaluation	
	Length Ratio	Profanity/Tok.	BLEU	iBLEU	METEOR	SARI	Fluency	Information
Human	1.19	0.0027	-	-	-	-	3.93	3.53
SMT (Sent.)	1.23	0.0068	6.22	1.44	12.20	38.42	3.82	3.31
Seq2Seq (Sent.)	1.05	0.0023	5.33	3.64	9.28	36.52	3.76	3.25
Seq2Seq	1.32	0.0022	5.15	3.46	10.56	36.86	3.83	3.34
Retrieval	1.18	0.0038	2.82	2.27	5.10	32.76	3.93	2.98

Table 4: Quantitative evaluation of different automated annotators.

For Seq2Seq models, we use OpenNMT (Klein et al., 2017) and optimize for perplexity on the development set. Vocabulary for both lyrics and annotations is reduced to the 50,000 most frequent tokens and are embedded in a 500-dimensional space.

We use two layers of stacked bi-directional LSTMs with hidden states of 1024 dimensions. We regularize using dropout (keep probability of 0.7) and train using stochastic gradient descent with batches of 64 samples for 13 epochs.

The decoder of the SMT model is tuned for optimal BLEU scores on the development set using minimum error rate training (Bertoldi et al., 2009).

5 Results

To measure agreement between collaborators, we compute the kappa statistic (Fleiss, 1971). Kappa statistics for fluency and information are 0.05 and 0.07 respectively, which indicates low agreement. The task of evaluating lyric annotations was difficult for CrowdFlower collaborators as was apparent from their evaluation of the task. For evaluation in future work, we recommend recruitment of expert collaborators familiar with the Genius platform and song lyrics.

Table 3 shows examples of lyrics with annotations from Genius and those generated by baseline models.

A notable observation is that translation models learn to take the role of narrator, as is common in CI annotations, and recognize slang language while simplifying it to more standard English.

Automatic and human evaluation scores are shown in Table 4. Next to evaluation metrics, we show two properties of automatically generated annotations; the average annotation length relative to the lyric and the occurrence of profanity per token in annotations, using a list of 343 swear words.

The SMT model scores high on BLEU, METEOR and SARI but shows a large drop in performance for iBLEU, which penalizes lexical similarity between lyrics and generated annotations as apparent from the amount profanity remaining in the generated annotations.

Standard SMT rephrases the song lyric from a third person perspective but is conservative in lexical substitutions and keeps close to the grammar of the lyric. A more appropriate objective function for tuning the decoder which promotes lexical dissimilarity as done for paraphrase generation, would be beneficial for this approach.

Seq2Seq models generate annotations more dissimilar to the song lyric and obtain higher iBLEU

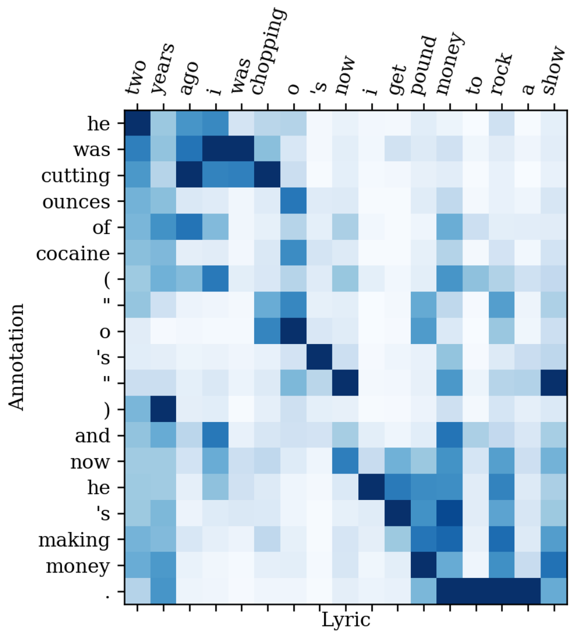

Figure 2: Attention visualization of Seq2Seq models for ALA.

and Information scores. To visualize some of the alignments learned by the translation models, Fig. 2 shows word-by-word attention scores for a translation by the Seq2Seq model.

While the retrieval model obtains quality annotations when test lyrics are highly similar to lyrics from the training set, retrieved annotations are often unrelated to the test lyric or specific to the song lyric it is retrieved from.

Out of the unsupervised metrics, METEOR obtained the highest Pearson correlation (Pearson, 1895) with human ratings for Information with a coefficient of 0.15.

6 Related Work

Work on modeling of social annotations has mainly focused on the use of topic models (Iwata et al., 2009; Das et al., 2014) in which annotations are assumed to originate from topics. They can be used as a preprocessing step in machine learning tasks such as text classification and image recognition but do not generate language as required in our ALA task.

Text simplification and paraphrase generation have been widely studied. Recent work has highlighted the need for large text collections (Xu et al., 2015) as well as more appropriate evaluation measures (Xu et al., 2016; Galley et al., 2015). They indicated that especially informal language, with its high degree of lexical variation, e.g., as used in social media or lyrics, poses serious challenges (Xu et al., 2013).

Text generation for artistic purposes, such as poetry and lyrics, has been explored most commonly using templates and constraints (Barbieri et al., 2012). In regard to rap lyrics, Wu et al. (2013) present a system for rap lyric generation that produces a single line of lyrics that is meant to be a response to a single line of input. Most recent work is that of Zhang et al. (2014) and Potash et al. (2015), who show the effectiveness of RNNs for the generation of poetry and lyrics.

The task of annotating song lyrics is also related to metaphor processing. As annotators often explain metaphors used in song lyrics, the Genius dataset can serve as a resource to study computational modeling of metaphors (Shutova and Teufel, 2010).

7 Conclusion and Future Work

We presented and released the Genius dataset to study the task of Automated Lyric Annotation. As a first investigation, we studied automatic generation of context independent annotations as machine translation and information retrieval. Our baseline system tests indicate that our corpus is suitable to train machine translation systems.

Standard SMT models are capable of rephrasing and simplifying song lyrics but tend to keep close to the structure of the song lyric. Seq2Seq models demonstrated potential to generate more fluent and informative text, dissimilar to the lyric.

A large fraction of the annotations is heavily based on context and background knowledge (CS), one of their most appealing aspects. As future work we suggest injection of structured and unstructured external knowledge (Ahn et al., 2016) and explicit modeling of references (Yang et al., 2016).

Abstract

When people recall and digest what they have read for writing summaries, the important content is more likely to attract their attention. Inspired by this observation, we propose a cascaded attention based unsupervised model to estimate the salience information from the text for compressive multi-document summarization. The attention weights are learned automatically by an unsupervised data reconstruction framework which can capture the sentence salience. By adding sparsity constraints on the number of output vectors, we can generate condensed information which can be treated as word salience. Fine-grained and coarse-grained sentence compression strategies are incorporated to produce compressive summaries. Experiments on some benchmark data sets show that our framework achieves better results than the state-of-the-art methods.

1 Introduction

The goal of Multi-Document Summarization (MDS) is to automatically produce a succinct summary, preserving the most important information of a set of documents describing a topic[1] (Luhn, 1958; Edmundson, 1969; Goldstein et al., 2000; Erkan and Radev, 2004b; Wan et al., 2007; Nenkova and McKeown, 2012). Considering the procedure of summary writing by humans, when people read, they will **remember** and **forget** part of the content. Information which is more important may make a deep impression easily. When people recall and digest what they have read to write summaries, the important information usually attracts more **attention** (*the behavioral and cognitive process of selectively concentrating on a discrete aspect of information, whether deemed subjective or objective, while ignoring other perceivable information*[2]) since it may repeatedly appears in some documents, or be positioned in the beginning paragraphs.

In the context of multi-document summarization, to generate a summary sentence for a key aspect of the topic, we need to find its relevant parts in the original documents, which may attract more attention. The semantic parts with high attention weights plausibly represent and reconstruct the topic's main idea. To this end, we propose a cascaded neural attention model to distill salient information from the input documents in an unsupervised data reconstruction manner, which includes two components: reader and recaller. The reader is a gated recurrent neural network (LSTM or GRU) based sentence sequence encoder which can map all the sentences of the topic into a global representation, with the mechanism of remembering and forgetting. The recaller decodes the global representation into significantly fewer diversified vectors for distillation and concentration. A cascaded attention mechanism is designed by incorporating attentions on both the hidden layer (dense distributed representation of a sentence) and the output layer (sparse bag-of-words representation of summary information). It is worth noting that the output vectors of the recaller can be viewed as word salience, and the attention matrix can be used as sentence salience. Both of them are automatically learned by data reconstruction in an **un-**

Copenhagen, Denmark, September 7–11, 2017.

supervised manner. Thereafter, the word salience is fed into a coarse-grained sentence compression component. Finally, the attention weights are integrated into a phrase-based optimization framework for compressive summary generation.

In fact, the notion of "attention" has gained popularity recently in neural network modeling, which has improved the performance of many tasks such as machine translation (Bahdanau et al., 2015; Luong et al., 2015). However, very few previous works employ attention mechanism to tackle MDS. Rush et al. (2015) and Nallapati et al. (2016) employed attention-based sequence-to-sequence (seq2seq) framework only for sentence summarization. Gu et al. (2016), Cheng and Lapata (2016), and Nallapati et al. (2016) also utilized seq2seq based framework with attention modeling for short text or single document summarization. Different from their works, our framework aims at conducting multi-document summarization in an unsupervised manner.

Our contributions are as follows: (1) We propose a cascaded attention model that captures salient information in different semantic representations. (2) The attention weights are learned automatically by an unsupervised data reconstruction framework which can capture the sentence salience. By adding sparsity constraints on the number of output vectors of the recaller, we can generate condensed vectors which can be treated as word salience; (3) We thoroughly investigate the performance of combining different attention architectures and cascaded structures. Experimental results on some benchmark data sets show that our framework achieves better performance than the state-of-the-art models.

2 Framework Description

2.1 Overview

Our framework has two phases, namely, information distillation for finding salient words/sentences, and compressive summary generation. For the first phase, our cascaded neural attention model consists of two components: reader and recaller as shown in Figure 1. The reader component reads in all the sentences in the document set corresponding to the topic/event. The information distillation happens in the recaller component where only the most important information is preserved. Precisely, the recaller outputs fewer vectors s than that of the input sentences x for the reader.

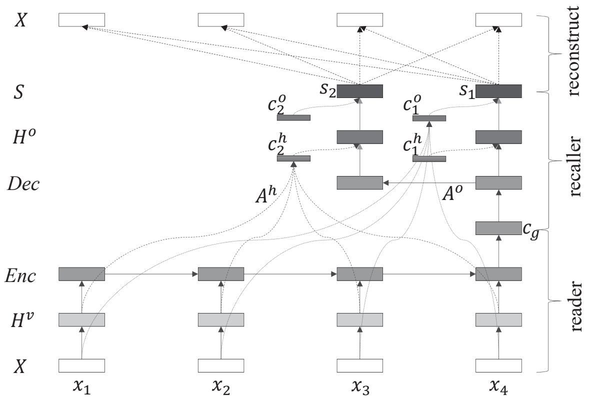

Figure 1: Our cascaded attention based unsupervised information distillation framework. X is the original input sentence sequence of a topic. H^i is the hidden vectors of sentences. "Enc" and "Dec" represent the RNN-based encoding and decoding layer respectively. c_g is the global representation for the whole topic. A^h and A^o are the distilled attention matrices for the hidden layer and the output layer respectively, representing the salience of sentences. H^o is the output hidden layer. s_1 and s_2 are the distilled condensed vectors representing the salience of words. Note that they are neither origin inputs nor golden summaries.

After the learning of the neural attention model finishes, the obtained salience information will be used in the second phase for compressive summary generation. This phase consists of two components: (i) the coarse-grained sentence compression component which can filter the trivial information based on the output vectors S from the neural attention model; (ii) the unified phrase-based optimization method for summary generation in which the attention matrix A^o is used to conduct fine-grained compression and summary construction.

2.2 Attention Modeling for Distillation

2.2.1 Reader

In the reader stage, for each topic, we extract all the sentences $X = \{x_1, x_2, \ldots, x_m\}$ from the set of input documents corresponding to a topic and generate a sentence sequence with length m. The sentence order is the same as the original order of the documents. Then the reader reads the whole sequence sentence by sentence. We employ the bag-of-words (BOW) representation as the initial semantic representation for sentences. Assume that the dictionary size is k, then $x_i \in \mathbb{R}^k$.

Sparsity is one common problem for the BOW representation, especially when each vector is generated from a single sentence. Moreover, downstream algorithms might suffer from the curse of dimensionality. To solve these problems, we add a hidden layer H^v (v for input layer) which is a densely distributed representation above the input layer as shown in Figure 1. Such distributed representation can provide better generalization than BOW representation in many different tasks (Le and Mikolov, 2014; Mikolov et al., 2013). Specifically, the input hidden layer will project the input sentence vector x_j to a new space $\mathbb{R}^h$ according to Equation 1. Then we obtain a new sentence sequence $H^v = [h_1^v, h_2^v, \ldots, h_m^v]$.

$$h_j^v = \tanh(W_{xh}^v x_j + b_h^v) \tag{1}$$

where W_{xh}^v and b_h^v are the weight and bias respectively. The superscript v means that the variables are from the input layer.

While reading the sentence sequence, the reader should have the ability of remembering and forgetting. Therefore, we employ the RNN models with various gates (input gate, forget gate, etc.) to imitate the remembering and forgetting mechanism. Then the RNN based neural encoder (the third layer in Figure 1) will map the whole embedding sequence to a single vector c_g which can be regarded as a global representation for the whole topic. Let t be the index of the sequence state for the sentence x_t, the hidden unit h_t^e (e for encoder RNN) of the RNN encoder can be computed as:

$$h_t^e = f(h_{t-1}^e, h_t^v) \tag{2}$$

where the RNN $f(\cdot)$ computes the current hidden state given the previous hidden state h_{t-1}^e and the sentence embedding h_t^v. The encoder generates hidden states $\{h_t^e\}$ over all time steps. The last state $\{h_m^e\}$ is extracted as the global representation c_g for the whole topic. The structure for $f(\cdot)$ can be either an LSTM (Hochreiter and Schmidhuber, 1997) or GRU (Cho et al., 2014).

2.2.2 Recaller

The recaller stage is a reverse of the reader stage, but it outputs less number of vectors in S as shown in Figure 1. Given the global representation c_g, the past hidden state h_{t-1}^d (d for decoder RNN) from the decoder layer, an RNN based decoder generates several hidden states according to:

$$h_t^d = f(h_{t-1}^d, c_g) \tag{3}$$

We use c_g to initialize the first decoder hidden state. The decoder will generate several hidden states $\{h_t^d\}$ over pre-defined time steps. Then, similar to the reader stage, we add an output hidden layer after the decoder layer:

$$h_t^o = \tanh(W_{hh}^o h_t^d + b_h^o) \tag{4}$$

where W_{hh}^o and b_h^o are the weight and bias respectively for the projection from h_t^d to h_t^o. Finally, the output layer maps these hidden vectors to the condensed vectors $S = [s_1, s_2, \ldots, s_n]$, Each output vector s_t has the same dimension k as the input BOW vectors and is obtained as follows:

$$s_t = \sigma(W_{hs} h_t^o + b_s) \tag{5}$$

For the purpose of distillation and concentration, we restrict n to be very small.

2.2.3 Cascaded Attention Modeling

Salience estimation for words and sentences is a crucial component in MDS, especially in the unsupervised summarization setting. We propose a cascaded attention model for information distillation to tackle the salience estimation task for MDS. We add attention mechanism not only in the hidden layer, but also in the output layer. By this cascaded attention model, we can capture the salience of sentences from two different and complementary vector spaces. One is the embedding space that provides better generalization, and the other one is the BOW vector space that captures more nuanced and subtle difference.

For each output hidden state h_t^o, we align it with each input hidden state h_i^v by an attention vector $a_{t,i}^h \in \mathbb{R}^m$ (recall that m is the number of input sentences). $a_{t,i}^h$ is derived by comparing h_t^o with each input sentence hidden state h_i^v:

$$a_{t,i}^h = \frac{\exp(score(h_t^o, h_i^v))}{\sum_{i'} \exp(score(h_t^o, h_{i'}^v))} \tag{6}$$

where $score(\cdot)$ is a content-based function to capture the relation between two vectors. Several different formulations can be used as the function $score(\cdot)$ which will be elaborated later.

Based on the alignment vectors $\{a_{t,i}^h\}$, we can create a context vector c_t^h by linearly blending the sentence hidden states $\{h_{i'}^v\}$:

$$c_t^h = \sum\nolimits_{i'} a_{t,i'}^h h_{i'}^v \tag{7}$$

Then the output hidden state can be updated based on the context vector. Let $\tilde{h}_t^o = h_t^o$, then update the original state according to the following operation:

$$h_t^o = \tanh(W_{ch}^a c_t^h + W_{hh}^a \tilde{h}_t^o) \tag{8}$$

The alignment vector $a_{t,i}^h$ captures which sentence should be attended more in the hidden space when generating the condensed representation for the whole topic.

Besides the attention mechanism on the hidden layer, we also directly add attention on the output BOW layer which can capture more nuanced and subtle difference information from the BOW vector space. The hidden attention vector $a_{t,i}^h$ is integrated with the output attention by a weight $\lambda_a \in [0, 1]$:

$$\bar{a}_{t,i}^o = \frac{\exp(score(s_t, x_i))}{\sum_{i'} \exp(score(s_t, x_{i'}))} \tag{9}$$

$$a_{t,i}^o = \lambda_a \bar{a}_{t,i}^o + (1 - \lambda_a) a_{t,i}^h \tag{10}$$

The output context vector is computed as:

$$c_t^o = \sum\nolimits_{i'} a_{t,i'}^o x_{i'} \tag{11}$$

To update the output vector s_t in Equation 5, we develop a different method from that of the hidden attentions. Specifically we use a weighted combination of the context vectors and the original outputs with $\lambda_c \in [0, 1]$. Let $\tilde{s}_t = s_t$, then the updated s_t is:

$$s_t = \lambda_c c_t^o + (1 - \lambda_c)\tilde{s}_t \tag{12}$$

The parameters λ_a and λ_c can also be learned during training.

There are several different alternatives for the function $score(\cdot)$:

$$score(h_t, h_s) = \begin{cases} {h_t}^T h_s & \textit{dot} \\ {h_t}^T W h_s & \textit{tensor} \\ v^T \tanh(W[h_t; h_s]) & \textit{concat} \end{cases} \tag{13}$$

Considering their behaviors as studied in (Luong et al., 2015), we adopt "*concat*" for the hidden attention layer, and "*dot*" for the output attention layer.

2.2.4 Unsupervised Learning

By minimizing the loss owing to using the condensed output vectors to reconstruct the original input sentence vectors, we are able to learn the solutions for all the parameters as follows.

$$\min_{\Theta} \frac{1}{2m} \sum_{i=1}^{m} \|x_i - \sum_{j=1}^{n} s_j a_{j,i}^o\|_2^2 + \lambda_s \|S\|_1 \tag{14}$$

where Θ denotes all the parameters in our model. In order to penalize the unimportant terms in the output vectors, we put a sparsity constraint on the rows of S using l_1-regularization, with the weight λ_s as a scaling constant for determining its relative importance.

Let $\bar{s}$ be the magnitude vector computed from the columns in S ($S \in \mathbb{R}^{n \times k}$). Once the training is finished, each dimension of the vector $\bar{s}$ can be regarded as the **word salience** score. According to Equation 14, $s_i \in S$ is used to reconstruct the original sentence space X, and $n \ll m$ (the number of sentences in X is much more than the number of vectors in S) Therefore a large value in $\bar{s}$ means that the corresponding word contains important information about this topic and it can serve as the word salience.

Moreover, the output layer attention matrix A^o can be regarded as containing the **sentence salience** information. Note that each output vector s_i is generated based on the cascaded attention mechanism. Assume that $a_i^o = A_{i,:}^o \in \mathbb{R}^m$ is the attention weight vector for s_i. According to Equation 9, a large value in a_i^o conveys a meaning that the corresponding sentence should contribute more when generating s_i. We also use the magnitude of the columns in A^o to represent the salience of sentences.

2.3 Compressive Summary Generation Phase

2.3.1 Coarse-grained Sentence Compression

Using the information distillation result from the cascaded neural attention model, we conduct coarse-grained compression for each individual sentence. Such strategy has been adopted in some multi-document summarization methods (Li et al., 2013; Wang et al., 2013; Yao et al., 2015). Our coarse-grained sentence compression jointly considers word salience obtained from the neural attention model and linguistically-motivated rules. The linguistically-motivated rules are designed based on the observed obvious evidence for uncritical information from the word level to the clause level, which include news headers such as "BEIJING, Nov. 24 (Xinhua) –", intra-sentential attribution such as ", police said Thursday", ", he said", etc. The information filtered by the rules will be processed according to the word salience score. Information with smaller salience score ($< \epsilon$) will be removed.

2.3.2 Phrase-based Optimization for Summary Construction

After coarse-grained compression on each single sentence as described above, we design a unified optimization method for summary generation. We refine the phrase-based summary construction model in (Bing et al., 2015) by adjusting the goal as compressive summarization. We consider the salience information obtained by our neural attention model and the compressed sentences in the coarse-grained compression component.

Based on the parsed constituency tree for each input sentence as described in Section 2.3.1, we extract the noun-phrases (NPs) and verb-phrases (VPs). The salience S_i of a phrase P_i is defined as:

$$S_i = \{\sum_{t \in P_i} tf(t) / \sum_{t \in Topic} tf(t)\} \times a_i \qquad (15)$$

where a_i is the salience of the sentence containing P_i. $tf(t)$ is the frequency of the concept t (unigram/bigram) in the whole topic. Thus, S_i inherits the salience of its sentence, and also considers the importance of its concepts.

The overall objective function of our optimization formulation for selecting salient NPs and VPs is formulated as an integer linear programming (ILP) problem:

$$\max\{\sum\nolimits_i \alpha_i S_i - \sum\nolimits_{i<j} \alpha_{ij}(S_i + S_j)R_{ij}\} \quad (16)$$

where α_i is the selection indicator for the phrase P_i, S_i is the salience scores of P_i, α_{ij} and R_{ij} is the co-occurrence indicator and the similarity of a pair of phrases (P_i, P_j) respectively. The similarity is calculated by the Jaccard Index based method. Specifically, this objective maximizes the salience score of the selected phrases as indicated by the first term, and penalizes the selection of similar phrase pairs.

In order to obtain coherent summaries with good readability, we add some constraints into the ILP framework such as sentence generation constraint: Let β_k denote the selection indicator of the sentence x_k. If any phrase from x_k is selected, $\beta_k = 1$. Otherwise, $\beta_k = 0$. For generating a compressed summary sentence, it is required that if $\beta_k = 1$, at least one NP and at lease one VP of the sentence should be selected. It is expressed as:

$$\forall P_i \in x_k, \alpha_i \leq \beta_k \wedge \sum\nolimits_i \alpha_i \geq \beta_k, \qquad (17)$$

Other constraints include sentence number, summary length, phrase co-occurrence, etc. For details, please refer to McDonald (2007), Woodsend and Lapata (2012), and Bing et al. (2015).

The objective function and constraints are linear. Therefore the optimization can be solved by existing ILP solvers such as the simplex algorithm (Dantzig and Thapa, 2006). In the implementation, we use a package called lp_solve[3].

In the post-processing, the phrases and sentences in a summary are ordered according to their natural order if they come from the same document. Otherwise, they are ordered according to the timestamps of the corresponding documents.

3 Experimental Setup

3.1 Datasets

DUC: Both DUC 2006 and DUC 2007 are used in our evaluation. DUC 2006 and DUC 2007 contain 50 and 45 topics respectively. Each topic has 25 news documents and 4 model summaries. The length of the model summary is limited to 250 words. **TAC**: We also use TAC 2010 and TAC 2011 in our experiments. TAC 2011 is the latest standard summarization benchmark data set and it contains 44 topics. Each topic falls into one of 5 predefined event categories and contains 10 related news documents and 4 model summaries. TAC 2010 is used as the parameter tuning data set of our TAC evaluation.

3.2 Settings

For text processing, the input sentences are represented as BOW vectors with dimension k. The dictionary is created using unigrams and named entity terms. The word salience threshold ϵ used in sentence compression is 0.005. For the neural network framework, we set the hidden size as 500. All the neural matrix parameters $\mathcal{W}$ in hidden layers and RNN layers are initialized from a uniform distribution between $[-0.1, 0.1]$. Adadelta (Schmidhuber, 2015) is used for gradient based optimization. Gradient clipping is adopted by scaling gradients then the norm exceeded a threshold of 10. The maximum epoch number in the optimization procedure is 200. We limit the number of distilled vectors $n = 5$. The attention cascaded parameter λ_a and λ_c can be learned by our model. The sparsity penalty λ_s in Equation 14 is

We use ROUGE score as our evaluation metric (Lin, 2004) with standard options. F-measures of ROUGE-1 (R-1), ROUGE-2 (R-2) and ROUGE-SU4 (R-SU4) are reported.

4 Results and Discussions

4.1 Effect of Existing Salience Models and Different Attention Architectures

We quantitatively evaluate the performance of different variants on the dataset of TAC 2010. The experimental results are shown in Table 1. Note that the summary generation phase for different methods are the same, and only the salience estimation methods are different. Commonly used existing methods for salience estimation include: concept weight (**CW**) (Bing et al., 2015) and sparse coding (**SC**) (Li et al., 2015). As mentioned in Section 2.2.3, there are several alternatives for the attention scoring function $score(\cdot)$: **dot**, **tensor**, and **concat**. Moreover, we also design experiments to show the benefit of our cascaded attention mechanism versus the single attention method. **AttenC** denotes the cascaded attention mechanism. **AttenH** and **AttenO** represent the attention only on the hidden layer or the output layer respectively without cascaded combination.

Among all the methods, the cascaded attention model with *dot* structure achieves the best performance. The effect of different RNN models, such as LSTM and GRU, is similar. However, there are less parameters in GRU resulting in improvements for the efficiency of training. Therefore, we choose **AttenC-dot-gru** as the attention structure of our framework in the subsequent experiments. Moreover, the results without coarse-grained sentence compression (Section 2.3.1) show that the compression can indeed improve the sumamrization performance.

4.2 Main Results of Compressive MDS

We compare our system **C-Attention** with several unsupervised summarization baselines and state-of-the-art models. **Random** baseline selects sentences randomly for each topic. **Lead** baseline (Wasson, 1998) ranks the news chronologically and extracts the leading sentences one by one. **TextRank** (Mihalcea and Tarau, 2004) and **LexRank** (Erkan and Radev, 2004a) estimate sentence salience by applying the PageRank algorithm to the sentence graph. **PKUTM** (Li et al., 2011) employs manifold-ranking for sentence scoring and selection; **ABS-Phrase** (Bing et al., 2015) generates abstractive summaries using phrase-based optimization framework. Three other unsupervised methods based on sparse coding are also compared, namely, **DSDR** (He et al., 2012), **MDS-Sparse** (Liu et al., 2015), and **RA-MDS** (Li et al., 2015).

As shown in Table 2, Table 3, and Table 4, our system achieves the best results on all the ROUGE

Table 4: Results on TAC 2011.

System	R-1	R-2	R-SU4
Random	0.303	0.045	0.090
Lead	0.315	0.071	0.103

C-Attention	**0.400***	**0.121***	**0.153***

* Statistical significance tests show that our method is better than the best baselines.

metrics. The reasons are as follows: (1) The attention model can directly capture the salient sentences, which are obtained by minimizing the global data reconstruction error; (2) The cascaded structure of attentions can jointly consider the embedding vector space and bag-of-words vector space when conducting the estimation of sentence salience; (3) The coarse-grained sentence compression based on distilled word salience, and the fine-grained compression via phrase-based unified optimization framework can generate more concise and salient summaries. It is worth noting that PKUTM used a Wikipedia corpus for providing domain knowledge. The system **SWING** (Min et al., 2012) is the best system for TAC 2011. Our results are not as good as SWING. The reason is that SWING employs category-specific features and requires supervised training. These features help them select better category-specific content for the summary. In contrast, our model is basically **unsupervised**.

4.3 Linguistic Quality Evaluation

The linguistic quality of summaries generated by ABS-Phrase, PKUTM, and our model from 20 topics of TAC 2011 is evaluated using the five linguistic quality questions on grammaticality (Q1), non-redundancy (Q2), referential clarity (Q3), focus (Q4), and coherence (Q5) in Document Understanding Conferences (DUC). A Likert scale with five levels is employed with 5 being very good with 1 being very poor. A summary was blindly evaluated by three assessors on each question. The results are given in Table 5. PKUTM is an extractive method that picks the original sentences, hence it achieves higher score in Q1 grammaticality. ABS-Phrase is an abstractive method and can generate new sentences by merging different phrases, which decreases the grammaticality. Grammaticality of our compression-based framework is better than ABS-Phrase, but not as good as PKUTM. However, our framework performs the best on some other metrics such as Q2 (non-redundancy) and Q4 (focus). The reason is that our framework can compress and remove some uncritical and redundancy content from the original sentences, which leads to better performance on Q2 and Q4.

Table 5: Evaluation of linguistic quality.

System	Q1	Q2	Q3	Q4	Q5	AVG
ABS-Phrase	3.75	3.38	3.75	3.35	3.12	3.47
PKUTM	4.13	3.45	3.83	3.33	2.92	3.53
Ours	3.96	3.50	3.79	3.50	3.25	3.60

Table 6: Top-10 terms extracted from each topic according to the word salience

Topic 1	Topic 2	Topic 3
school	heart	HIV
shooting	disease	Africa
Auvinen	study	circumcision
Finland	risk	study
police	test	infection
video	blood	trial
Wednesday	red	woman
gunman	telomere	drug
post	level	health

4.4 Case Study: Distilled Word Salience

As mentioned above, the output vectors S in our neural model contain the distilled word salience information. In order to show the performance of word salience estimation, we select 3 topics (events) from different categories of TAC 2011: “Finland Shooting”, “Heart Disease”, and “Hiv Infection Africa”. For each topic, we sort the dictionary terms according to their salience scores, and extract the top-10 terms as the salience estimation results as shown in Table 6. We can see that the top-10 terms reveal the most important information of each topic. For the topic “Finland Shooting”, there is a sentence from the golden summary “A teenager at a school in Finland went on a shooting rampage Wednesday, November 11, 2007, killing 8 people, then himself.” It is obvious that the top-10 terms from Table 6 can capture this main point.

4.5 Case Study: Attention-based Sentence Salience

In our model, the distilled attention matrix A^o can be treated as sentence salience estimation. Let $\widehat{a}$ be the magnitude of the columns in A^o and $\widehat{a} \in \mathbb{R}^m$. $\widehat{a}_i$ represents the salience of the sentence x_i. We collect all the attention vectors for 8 topics of TAC 2011, and display them as an image as shown in Figure 2. The x-axis represents the sentence id (we show at most 100 sentences), and the y-axis represents the topic id. The gray level of pixels in the image indicates different salience scores, where $dark$ represents a high salience score and $light$ represents a small score. Note that different topics seem to hold different ranges of salience scores because they have different number of sentences, i.e. m. According to Equation 9, topics containing more sentences will distribute the attention to more units, therefore, each sentence will get a relatively smaller attention weight. But this issue does not affect the performance of MDS since different topics are independently processed.

In Figure 2, there are some chunks in each topic (see Topic 3 as an example) having higher attention weights, which indeed automatically captures one characteristic of MDS: *sentence position is an important feature for news summarization*. As observed by several previous studies (Li et al., 2015; Min et al., 2012), the sentences in the beginning of a news document are usually more important and tend to be used for writing model summaries. Manual checking verified that those high-attention chunks correspond to the beginning sentences. Our model is able to automatically capture this information by assigning the latter sentences in each topic lower attention weights.

4.6 Summary Case Analysis

Table 7 shows the summary of the topic "*Hawkins Robert Van Maur*" in TAC 2011. The summary contains four sentences, which are all compressed with different compression ratio. Some uncritical information is excluded from the summary sentences, such as "*police said Thursday*" in S2, "*But*" in S3, and "*he said*" in S4. In addition, the VP "*killing eight people*" in S2 is also excluded since it is duplicate with the phrase "killed eight people" in S3. Moreover, from the case we can find that the compression operation did not harm the linguistic quality.

Table 7: The summary of the topic "*Hawkins Robert Van Maur*".

S1: The young gunman who opened fire at a mall busy with holiday shoppers appeared to choose his victims at random, according to police[~~, but a note he left behind hinted at a troubled life~~].
S2: The teenage gunman who went on a shooting rampage in a department store, [~~killing eight people,~~] may have smuggled an assault rifle into the mall underneath clothing[~~, police said Thursday~~].
S3: [~~But~~] police said it was Hawkins who went into an Omaha shopping mall on Wednesday and began a shooting rampage that killed eight people.
S4: Mall security officers noticed Hawkins briefly enter the Von Maur department store at Omaha's Westroads Mall earlier Wednesday[~~, he said~~].

5 Related Works

According to different machine learning paradigms, summarization models can be divided into supervised framework and unsupervised framework. Some previous works have been proposed based on unsupervised models. For example, Mihalcea and Tarau (2004) and Erkan and Radev (2004a) estimated sentence salience by applying the PageRank algorithm to the sentence graph. He et al. (2012), Liu et al. (2015), Li et al. (2015) and Song et al. (2017) employed sparse coding techniques for finding the salient sentences as summaries. Li et al. (2017) conducted salience estimation jointly considering reconstructions on several different vector spaces generated by a variational auto-ecoder framework.

Some recent works utilize attention modeling based recurrent neural networks to tackle the task of single-document summarization. Rush et al. (2015) proposed a sentence summarization framework based on a neural attention model using a supervised sequence-to-sequence neural machine translation model. Gu et al. (2016) combined a copying mechanism with the seq2seq framework to improve the quality of the generated summaries. Nallapati et al. (2016) also employed the typical attention modeling based seq2seq framework, but utilized a trick to control the vocabulary size to improve the training efficiency. However, few previous works employ attention mechanism to tackle the unsupervised MDS problem. In contrast, our attention-based framework can generate summaries for multi-document summarization

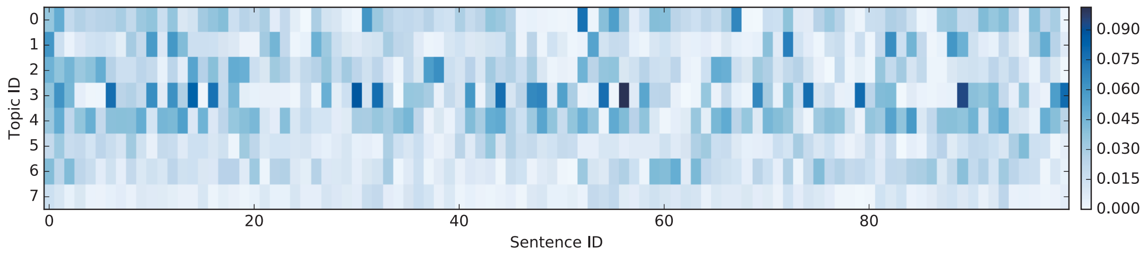

Figure 2: Visualization for sentence attention.

settings in an unsupervised manner.

6 Conclusions

We propose a cascaded neural attention based unsupervised salience estimation method for compressive multi-document summarization. The attention weights for sentences and salience values for words are both learned by data reconstruction in an unsupervised manner. We thoroughly investigate the performance of combining different attention architectures and cascaded structures. Experimental results on some benchmark data sets show that our framework achieves good performance compared with the state-of-the-art methods.

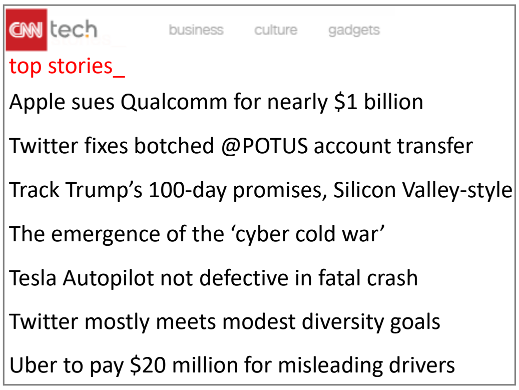
Abstract

We propose a new framework for abstractive text summarization based on a sequence-to-sequence oriented encoder-decoder model equipped with a deep recurrent generative decoder (DRGN). Latent structure information implied in the target summaries is learned based on a recurrent latent random model for improving the summarization quality. Neural variational inference is employed to address the intractable posterior inference for the recurrent latent variables. Abstractive summaries are generated based on both the generative latent variables and the discriminative deterministic states. Extensive experiments on some benchmark datasets in different languages show that DRGN achieves improvements over the state-of-the-art methods.

1 Introduction

Automatic summarization is the process of automatically generating a summary that retains the most important content of the original text document (Edmundson, 1969; Luhn, 1958; Nenkova and McKeown, 2012). Different from the common extraction-based and compression-based methods, abstraction-based methods aim at constructing new sentences as summaries, thus they require a deeper understanding of the text and the capability of generating new sentences, which provide an obvious advantage in improving the focus of a summary, reducing the redundancy, and keeping a good compression rate (Bing et al., 2015; Rush et al., 2015; Nallapati et al., 2016).



Apple sues Qualcomm for nearly $1 billion

Twitter fixes botched @POTUS account transfer

Track Trump's 100-day promises, Silicon Valley-style

The emergence of the 'cyber cold war'

Tesla Autopilot not defective in fatal crash

Twitter mostly meets modest diversity goals

Uber to pay $20 million for misleading drivers

Figure 1: Headlines of the top stories from the channel "Technology" of CNN.

Some previous research works show that human-written summaries are more abstractive (Jing and McKeown, 2000). Moreover, our investigation reveals that people may naturally follow some inherent structures when they write the abstractive summaries. To illustrate this observation, we show some examples in Figure 1, which are some top story summaries or headlines from the channel "Technology" of CNN. After analyzing the summaries carefully, we can find some common structures from them, such as "**What**", "**What-Happened**" , "**Who Action What**", etc. For example, the summary "*Apple sues Qualcomm for nearly $1 billion*" can be structuralized as "Who (Apple) Action (sues) What (Qualcomm)". Similarly, the summaries "*[Twitter] [fixes] [botched @POTUS account transfer]*", "*[Uber] [to pay] [$20 million] for misleading drivers*", and "*[Bipartisan bill] aims to [reform] [H-1B visa system]*" also follow the structure of "Who Action What". The summary "*The emergence of the 'cyber cold war'*" matches with the structure of "What", and the summary "*St. Louis' public library computers hacked*" follows

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2091–2100
Copenhagen, Denmark, September 7–11, 2017.

the structure of “What-Happened”.

Intuitively, if we can incorporate the latent structure information of summaries into the abstractive summarization model, it will improve the quality of the generated summaries. However, very few existing works specifically consider the latent structure information of summaries in their summarization models. Although a very popular neural network based sequence-to-sequence (seq2seq) framework has been proposed to tackle the abstractive summarization problem (Lopyrev, 2015; Rush et al., 2015; Nallapati et al., 2016), the calculation of the internal decoding states is entirely deterministic. The deterministic transformations in these discriminative models lead to limitations on the representation ability of the latent structure information. Miao and Blunsom (2016) extended the seq2seq framework and proposed a generative model to capture the latent summary information, but they did not consider the recurrent dependencies in their generative model leading to limited representation ability.

To tackle the above mentioned problems, we design a new framework based on sequence-to-sequence oriented encoder-decoder model equipped with a latent structure modeling component. We employ Variational Auto-Encoders (VAEs) (Kingma and Welling, 2013; Rezende et al., 2014) as the base model for our generative framework which can handle the inference problem associated with complex generative modeling. However, the standard framework of VAEs is not designed for sequence modeling related tasks. Inspired by (Chung et al., 2015), we add historical dependencies on the latent variables of VAEs and propose a deep recurrent generative decoder (DRGD) for latent structure modeling. Then the standard discriminative deterministic decoder and the recurrent generative decoder are integrated into a unified decoding framework. The target summaries will be decoded based on both the discriminative deterministic variables and the generative latent structural information. All the neural parameters are learned by back-propagation in an end-to-end training paradigm.

The main contributions of our framework are summarized as follows: (1) We propose a sequence-to-sequence oriented encoder-decoder model equipped with a deep recurrent generative decoder (DRGD) to model and learn the latent structure information implied in the target summaries of the training data. Neural variational inference is employed to address the intractable posterior inference for the recurrent latent variables. (2) Both the generative latent structural information and the discriminative deterministic variables are jointly considered in the generation process of the abstractive summaries. (3) Experimental results on some benchmark datasets in different languages show that our framework achieves better performance than the state-of-the-art models.

2 Related Works

Automatic summarization is the process of automatically generating a summary that retains the most important content of the original text document (Nenkova and McKeown, 2012). Traditionally, the summarization methods can be classified into three categories: extraction-based methods (Erkan and Radev, 2004; Goldstein et al., 2000; Wan et al., 2007; Min et al., 2012; Nallapati et al., 2017; Cheng and Lapata, 2016; Cao et al., 2016; Song et al., 2017), compression-based methods (Li et al., 2013; Wang et al., 2013; Li et al., 2015, 2017), and abstraction-based methods. In fact, previous investigations show that human-written summaries are more abstractive (Barzilay and McKeown, 2005; Bing et al., 2015). Abstraction-based approaches can generate new sentences based on the facts from different source sentences. Barzilay and McKeown (2005) employed sentence fusion to generate a new sentence. Bing et al. (2015) proposed a more fine-grained fusion framework, where new sentences are generated by selecting and merging salient phrases. These methods can be regarded as a kind of indirect abstractive summarization, and complicated constraints are used to guarantee the linguistic quality.

Recently, some researchers employ neural network based framework to tackle the abstractive summarization problem. Rush et al. (2015) proposed a neural network based model with local attention modeling, which is trained on the Gigaword corpus, but combined with an additional log-linear extractive summarization model with handcrafted features. Gu et al. (2016) integrated a copying mechanism into a seq2seq framework to improve the quality of the generated summaries. Chen et al. (2016) proposed a new attention mechanism that not only considers the important source segments, but also distracts them in the decoding step in order to better grasp the overall meaning of input documents. Nallapati et al. (2016) utilized a trick to control the vocabulary size to improve the training efficiency. The calculations in these methods are all deterministic and the representation ability is limited. Miao and Blunsom (2016) extended the seq2seq framework and proposed a generative model to capture the latent summary information, but they do not consider the recurrent dependencies in their generative model leading to limited representation ability.

Some research works employ topic models to capture the latent information from source documents or sentences. Wang et al. (2009) proposed a new Bayesian sentence-based topic model by making use of both the term-document and term-sentence associations to improve the performance of sentence selection. Celikyilmaz and Hakkani-Tur (2010) estimated scores for sentences based on their latent characteristics using a hierarchical topic model, and trained a regression model to extract sentences. However, they only use the latent topic information to conduct the sentence salience estimation for extractive summarization. In contrast, our purpose is to model and learn the latent structure information from the target summaries and use it to enhance the performance of abstractive summarization.

3 Framework Description

3.1 Overview

As shown in Figure 2, the basic framework of our approach is a neural network based encoder-decoder framework for sequence-to-sequence learning. The input is a variable-length sequence $X = \{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_m\}$ representing the source text. The word embedding $\mathbf{x}_t$ is initialized randomly and learned during the optimization process. The output is also a sequence $Y = \{\mathbf{y}_1, \mathbf{y}_2, \dots, \mathbf{y}_n\}$, which represents the generated abstractive summaries. Gated Recurrent Unit (GRU) (Cho et al., 2014) is employed as the basic sequence modeling component for the encoder and the decoder. For latent structure modeling, we add historical dependencies on the latent variables of Variational Auto-Encoders (VAEs) and propose a deep recurrent generative decoder (DRGD) to distill the complex latent structures implied in the target summaries of the training data. Finally, the abstractive summaries will be decoded out based on both the discriminative deterministic variables H and the generative latent structural information Z.

3.2 Recurrent Generative Decoder

Assume that we have obtained the source text representation $\mathbf{h}^e \in \mathbb{R}^{k_h}$. The purpose of the decoder is to translate this source code $\mathbf{h}^e$ into a series of hidden states $\{\mathbf{h}_1^d, \mathbf{h}_2^d, \dots, \mathbf{h}_n^d\}$, and then revert these hidden states to an actual word sequence and generate the summary.

For standard recurrent decoders, at each time step t, the hidden state $\mathbf{h}_t^d \in \mathbb{R}^{k_h}$ is calculated using the dependent input symbol $\mathbf{y}_{t-1} \in \mathbb{R}^{k_w}$ and the previous hidden state $\mathbf{h}_{t-1}^d$:

$$\mathbf{h}_t^d = f(\mathbf{y}_{t-1}, \mathbf{h}_{t-1}^d) \quad (1)$$

where $f(\cdot)$ is a recurrent neural network such as vanilla RNN, Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997), and Gated Recurrent Unit (GRU) (Cho et al., 2014). No matter which one we use for $f(\cdot)$, the common transformation operation is as follows:

$$\mathbf{h}_t^d = g(\mathbf{W}_{yh}^d \mathbf{y}_{t-1} + \mathbf{W}_{hh}^d \mathbf{h}_{t-1}^d + \mathbf{b}_h^d) \quad (2)$$

where $\mathbf{W}_{yh}^d \in \mathbb{R}^{k_h \times k_w}$ and $\mathbf{W}_{hh}^d \in \mathbb{R}^{k_h \times k_h}$ are the linear transformation matrices. $\mathbf{b}_h^d$ is the bias. k_h is the dimension of the hidden layers, and k_w is the dimension of the word embeddings. $g(\cdot)$ is the non-linear activation function. From Equation 2, we can see that all the transformations are deterministic, which leads to a deterministic recurrent hidden state h_t^d. From our investigations, we find that the representational power of such deterministic variables are limited. Some more complex latent structures in the target summaries, such as the high-level syntactic features and latent topics, cannot be modeled effectively by the deterministic operations and variables.

Recently, a generative model called Variational Auto-Encoders (VAEs) (Kingma and Welling, 2013; Rezende et al., 2014) shows strong capability in modeling latent random variables and improves the performance of tasks in different fields such as sentence generation (Bowman et al., 2016) and image generation (Gregor et al., 2015). However, the standard VAEs is not designed for modeling sequence directly. Inspired by (Chung et al., 2015), we extend the standard VAEs by

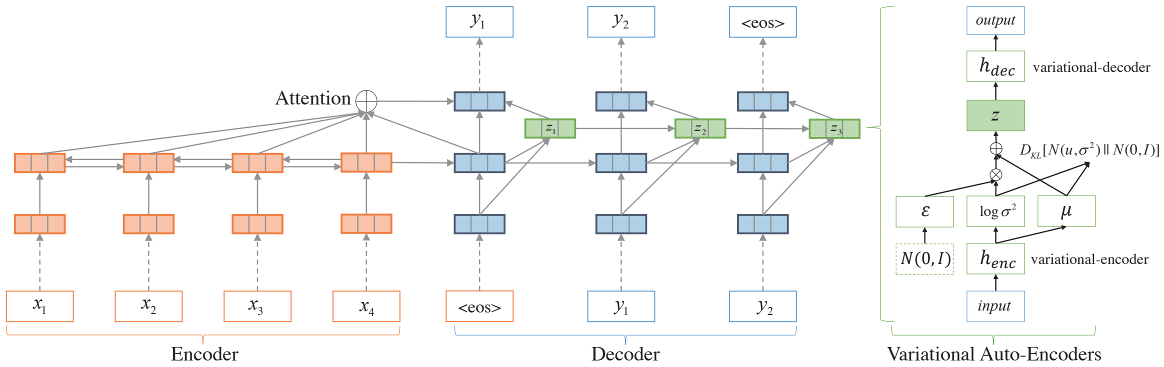

Figure 2: Our deep recurrent generative decoder (DRGD) for latent structure modeling.

introducing the historical latent variable dependencies to make it be capable of modeling sequence data. Our proposed latent structure modeling framework can be viewed as a sequence generative model which can be divided into two parts: inference (variational-encoder) and generation (variational-decoder). As shown in the decoder component of Figure 2, the input of the original VAEs only contains the observed variable $\mathbf{y}_t$, and the variational-encoder can map it to a latent variable $\mathbf{z} \in \mathbb{R}^{k_z}$, which can be used to reconstruct the original input. For the task of summarization, in the sequence decoder component, the previous latent structure information needs to be considered for constructing more effective representations for the generation of the next state.

For the inference stage, the variational-encoder can map the observed variable $\mathbf{y}_{<t}$ and the previous latent structure information $\mathbf{z}_{<t}$ to the posterior probability distribution of the latent structure variable $p_\theta(\mathbf{z}_t|\mathbf{y}_{<t}, \mathbf{z}_{<t})$. It is obvious that this is a recurrent inference process in which $\mathbf{z}_t$ contains the historical dynamic latent structure information. Compared with the variational inference process $p_\theta(\mathbf{z}_t|\mathbf{y}_t)$ of the typical VAEs model, the recurrent framework can extract more complex and effective latent structure features implied in the sequence data.

For the generation process, based on the latent structure variable $\mathbf{z}_t$, the target word y_t at the time step t is drawn from a conditional probability distribution $p_\theta(\mathbf{y}_t|\mathbf{z}_t)$. The target is to maximize the probability of each generated summary $y = \{\mathbf{y}_1, \mathbf{y}_2, \ldots, \mathbf{y}_T\}$ based on the generation process according to:

$$p_\theta(y) = \prod_{t=1}^{T} \int p_\theta(\mathbf{y}_t|\mathbf{z}_t) p_\theta(\mathbf{z}_t) d\mathbf{z}_t \tag{3}$$

For the purpose of solving the intractable integral of the marginal likelihood as shown in Equation 3, a recognition model $q_\phi(\mathbf{z}_t|\mathbf{y}_{<t}, \mathbf{z}_{<t})$ is introduced as an approximation to the intractable true posterior $p_\theta(\mathbf{z}_t|\mathbf{y}_{<t}, \mathbf{z}_{<t})$. The recognition model parameters ϕ and the generative model parameters θ can be learned jointly. The aim is to reduce the Kulllback-Leibler divergence (KL) between $q_\phi(\mathbf{z}_t|\mathbf{y}_{<t}, \mathbf{z}_{<t})$ and $p_\theta(\mathbf{z}_t|\mathbf{y}_{<t}, \mathbf{z}_{<t})$:

$$\begin{aligned} & D_{KL}[q_\phi(\mathbf{z}_t|\mathbf{y}_{<t}, \mathbf{z}_{<t}) \| p_\theta(\mathbf{z}_t|\mathbf{y}_{<t}, \mathbf{z}_{<t})] \\ & = \int_z q_\phi(\mathbf{z}_t|\mathbf{y}_{<t}, \mathbf{z}_{<t}) \log \frac{q_\phi(\mathbf{z}_t|\mathbf{y}_{<t}, \mathbf{z}_{<t})}{p_\theta(\mathbf{z}_t|\mathbf{y}_{<t}, \mathbf{z}_{<t})} dz \\ & = \mathbb{E}_{q_\phi(\mathbf{z}_t|\mathbf{y}_{<t}, \mathbf{z}_{<t})}[\log q_\phi(\mathbf{z}_t|\cdot) - \log p_\theta(\mathbf{z}_t|\cdot)] \end{aligned}$$

where $\cdot$ denotes the conditional variables $\mathbf{y}_{<t}$ and $\mathbf{z}_{<t}$. Bayes rule is applied to $p_\theta(\mathbf{z}_t|\mathbf{y}_{<t}, \mathbf{z}_{<t})$, and we can extract $\log p_\theta(\mathbf{z})$ from the expectation, transfer the expectation term $\mathbb{E}_{q_\phi(\mathbf{z}_t|\mathbf{y}_{<t}, \mathbf{z}_{<t})}$ back to KL-divergence, and rearrange all the terms. Consequently the following holds:

$$\begin{aligned} & \log p_\theta(\mathbf{y}_{<t}) = \\ & D_{KL}[q_\phi(\mathbf{z}_t|\mathbf{y}_{<t}, \mathbf{z}_{<t}) \| p_\theta(\mathbf{z}_t|\mathbf{y}_{<t}, \mathbf{z}_{<t})] \\ & + \mathbb{E}_{q_\phi(\mathbf{z}_t|\mathbf{y}_{<t}, \mathbf{z}_{<t})}[\log p_\theta(\mathbf{y}_{<t}|\mathbf{z}_t)] \\ & - D_{KL}[q_\phi(\mathbf{z}_t|\mathbf{y}_{<t}, \mathbf{z}_{<t}) \| p_\theta(\mathbf{z}_t)] \end{aligned} \tag{4}$$

Let $\mathcal{L}(\theta, \phi; y)$ represent the last two terms from the right part of Equation 4:

$$\begin{aligned} & \mathcal{L}(\theta, \varphi; y) = \\ & \mathbb{E}_{q_\phi(\mathbf{z}_t|\mathbf{y}_{<t}, \mathbf{z}_{<t})} \Big\{ \sum_{t=1}^{T} \log p_\theta(\mathbf{y}_t|\mathbf{z}_t) \\ & \quad - D_{KL}[q_\phi(\mathbf{z}_t|\mathbf{y}_{<t}, \mathbf{z}_{<t}) \| p_\theta(\mathbf{z}_t)] \Big\} \end{aligned} \tag{5}$$

Since the first KL-divergence term of Equation 4 is non-negative, we have $\log p_\theta(\mathbf{y}_{<t}) \geq \mathcal{L}(\theta, \phi; y)$ meaning that $\mathcal{L}(\theta, \phi; y)$ is a lower bound (the objective to be maximized) on the marginal likelihood. In order to differentiate and optimize the

lower bound $\mathcal{L}(\theta, \phi; y)$, following the core idea of VAEs, we use a neural network framework for the probabilistic encoder $q_\phi(\mathbf{z}_t|\mathbf{y}_{<t}, \mathbf{z}_{<t})$ for better approximation.

3.3 Abstractive Summary Generation

We also design a neural network based framework to conduct the variational inference and generation for the recurrent generative decoder component similar to some design in previous works (Kingma and Welling, 2013; Rezende et al., 2014; Gregor et al., 2015). The encoder component and the decoder component are integrated into a unified abstractive summarization framework. Considering that GRU has comparable performance but with less parameters and more efficient computation, we employ GRU as the basic recurrent model which updates the variables according to the following operations:

$$\begin{aligned}
\mathbf{r}_t &= \sigma(\mathbf{W}_{xr}\mathbf{x}_t + \mathbf{W}_{hr}\mathbf{h}_{t-1} + \mathbf{b}_r)\\
\mathbf{z}_t &= \sigma(\mathbf{W}_{xz}\mathbf{x}_t + \mathbf{W}_{hz}\mathbf{h}_{t-1} + \mathbf{b}_z)\\
\mathbf{g}_t &= \tanh(\mathbf{W}_{xh}\mathbf{x}_t + \mathbf{W}_{hh}(\mathbf{r}_t \odot \mathbf{h}_{t-1}) + \mathbf{b}_h)\\
\mathbf{h}_t &= \mathbf{z}_t \odot \mathbf{h}_{t-1} + (1 - \mathbf{z}_t) \odot \mathbf{g}_t
\end{aligned}$$

where $\mathbf{r}_t$ is the reset gate, $\mathbf{z}_t$ is the update gate. $\odot$ denotes the element-wise multiplication. *tanh* is the hyperbolic tangent activation function.

As shown in the left block of Figure 2, the encoder is designed based on bidirectional recurrent neural networks. Let $\mathbf{x}_t$ be the word embedding vector of the t-th word in the source sequence. GRU maps $\mathbf{x}_t$ and the previous hidden state $\mathbf{h}_{t-1}$ to the current hidden state $\mathbf{h}_t$ in feed-forward direction and back-forward direction respectively:

$$\begin{aligned}
\overrightarrow{\mathbf{h}}_t &= GRU(x_t, \overrightarrow{\mathbf{h}}_{t-1})\\
\overleftarrow{\mathbf{h}}_t &= GRU(x_t, \overleftarrow{\mathbf{h}}_{t-1})
\end{aligned} \tag{6}$$

Then the final hidden state $\mathbf{h}^e_t \in \mathbb{R}^{2k_h}$ is concatenated using the hidden states from the two directions: $\mathbf{h}^e_t = \overrightarrow{\mathbf{h}}_t || \overleftarrow{\mathbf{h}}$. As shown in the middle block of Figure 2, the decoder consists of two components: discriminative deterministic decoding and generative latent structure modeling.

The discriminative deterministic decoding is an improved attention modeling based recurrent sequence decoder. The first hidden state $\mathbf{h}^d_1$ is initialized using the average of all the source input states: $\mathbf{h}^d_1 = \frac{1}{T^e}\sum_{t=1}^{T^e}\mathbf{h}^e_t$, where $\mathbf{h}^e_t$ is the source input hidden state. T^e is the input sequence length. The deterministic decoder hidden state $\mathbf{h}^d_t$ is calculated using two layers of GRUs. On the first layer, the hidden state is calculated only using the current input word embedding $\mathbf{y}_{t-1}$ and the previous hidden state $\mathbf{h}^{d_1}_{t-1}$:

$$\mathbf{h}^{d_1}_t = GRU_1(\mathbf{y}_{t-1}, \mathbf{h}^{d_1}_{t-1}) \tag{7}$$

where the superscript d_1 denotes the first decoder GRU layer. Then the attention weights at the time step t are calculated based on the relationship of $\mathbf{h}^{d_1}_t$ and all the source hidden states $\{\mathbf{h}^e_t\}$. Let $a_{i,j}$ be the attention weight between $\mathbf{h}^{d_1}_i$ and $\mathbf{h}^e_j$, which can be calculated using the following formulation:

$$\begin{aligned}
a_{i,j} &= \frac{\exp(e_{i,j})}{\sum_{j'=1}^{T^e}\exp(e_{i,j'})}\\
e_{i,j} &= \mathbf{v}^T\tanh(\mathbf{W}^d_{hh}\mathbf{h}^{d_1}_i + \mathbf{W}^e_{hh}\mathbf{h}^e_j + \mathbf{b}_a)
\end{aligned}$$

where $\mathbf{W}^d_{hh} \in \mathbb{R}^{k_h \times k_h}$, $\mathbf{W}^e_{hh} \in \mathbb{R}^{k_h \times 2k_h}$, $\mathbf{b}_a \in \mathbb{R}^{k_h}$, and $\mathbf{v} \in \mathbb{R}^{k_h}$. The attention context is obtained by the weighted linear combination of all the source hidden states:

$$\mathbf{c}_t = \sum_{j'=1}^{T^e} a_{t,j'}\mathbf{h}^e_{j'} \tag{8}$$

The final deterministic hidden state $\mathbf{h}^{d_2}_t$ is the output of the second decoder GRU layer, jointly considering the word $\mathbf{y}_{t-1}$, the previous hidden state $\mathbf{h}^{d_2}_{t-1}$, and the attention context $\mathbf{c}_t$:

$$\mathbf{h}^{d_2}_t = GRU_2(\mathbf{y}_{t-1}, \mathbf{h}^{d_2}_{t-1}, \mathbf{c}_t) \tag{9}$$

For the component of recurrent generative model, inspired by some ideas in previous works (Kingma and Welling, 2013; Rezende et al., 2014; Gregor et al., 2015), we assume that both the prior and posterior of the latent variables are Gaussian, i.e., $p_\theta(\mathbf{z}_t) = \mathcal{N}(0, \mathbf{I})$ and $q_\phi(\mathbf{z}_t|\mathbf{y}_{<t}, \mathbf{z}_{<t}) = \mathcal{N}(\mathbf{z}_t; \boldsymbol{\mu}, \boldsymbol{\sigma}^2\mathbf{I})$, where $\boldsymbol{\mu}$ and $\boldsymbol{\sigma}$ denote the variational mean and standard deviation respectively, which can be calculated via a multilayer perceptron. Precisely, given the word embedding $\mathbf{y}_{t-1}$, the previous latent structure variable $\mathbf{z}_{t-1}$, and the previous deterministic hidden state $\mathbf{h}^d_{t-1}$, we first project it to a new hidden space:

$$\mathbf{h}^{e_z}_t = g(\mathbf{W}^{e_z}_{yh}\mathbf{y}_{t-1} + \mathbf{W}^{e_z}_{zh}\mathbf{z}_{t-1} + \mathbf{W}^{e_z}_{hh}\mathbf{h}^d_{t-1} + \mathbf{b}^{e_z}_h)$$

where $\mathbf{W}^{e_z}_{yh} \in \mathbb{R}^{k_h \times k_w}$, $\mathbf{W}^{e_z}_{zh} \in \mathbb{R}^{k_h \times k_z}$, $\mathbf{W}^{e_z}_{hh} \in \mathbb{R}^{k_h \times k_h}$, and $\mathbf{b}^{e_z}_h \in \mathbb{R}^{k_h}$. g is the sigmoid activation function: $\sigma(\mathbf{x}) = 1/(1 + e^{-\mathbf{x}})$. Then the

Gaussian parameters $\boldsymbol{\mu}_t \in \mathbb{R}^{k_z}$ and $\boldsymbol{\sigma}_t \in \mathbb{R}^{k_z}$ can be obtained via a linear transformation based on $\mathbf{h}_t^{e_z}$:

$$\begin{aligned} \boldsymbol{\mu}_t &= \mathbf{W}_{h\mu}^{e_z}\mathbf{h}_t^{e_z} + \mathbf{b}_{\mu}^{e_z} \\ \log(\boldsymbol{\sigma}_t^2) &= \mathbf{W}_{h\sigma}\mathbf{h}_t^{e_z} + \mathbf{b}_{\sigma}^{e_z} \end{aligned} \tag{10}$$

The latent structure variable $\mathbf{z}_t \in \mathbb{R}^{k_z}$ can be calculated using the reparameterization trick:

$$\boldsymbol{\varepsilon} \sim \mathcal{N}(\mathbf{0}, \mathbf{I}), \;\; \mathbf{z}_t = \boldsymbol{\mu}_t + \boldsymbol{\sigma}_t \otimes \varepsilon \tag{11}$$

where $\boldsymbol{\varepsilon} \in \mathbb{R}^{k_z}$ is an auxiliary noise variable. The process of inference for finding $\mathbf{z}_t$ based on neural networks can be teated as a variational encoding process.

To generate summaries precisely, we first integrate the recurrent generative decoding component with the discriminative deterministic decoding component, and map the latent structure variable $\mathbf{z}_t$ and the deterministic decoding hidden state $\mathbf{h}_t^{d_2}$ to a new hidden variable:

$$\mathbf{h}_t^{d_y} = tanh(\mathbf{W}_{zh}^{d_y}\mathbf{z}_t + \mathbf{W}_{hh}^{d_z}\mathbf{h}_t^{d_2} + \mathbf{b}_h^{d_y}) \tag{12}$$

Given the combined decoding state $\mathbf{h}_t^{d_y}$ at the time t, the probability of generating any target word y_t is given as follows:

$$\mathbf{y}_t = \varsigma(\mathbf{W}_{hy}^{d}\mathbf{h}_t^{d_y} + \mathbf{b}_{hy}^{d}) \tag{13}$$

where $\mathbf{W}_{hy}^{d} \in \mathbb{R}^{k_y \times k_h}$ and $\mathbf{b}_{hy}^{d} \in \mathbb{R}^{k_y}$. $\varsigma(\cdot)$ is the softmax function. Finally, we use a beam search algorithm (Koehn, 2004) for decoding and generating the best summary.

3.4 Learning

Although the proposed model contains a recurrent generative decoder, the whole framework is fully differentiable. As shown in Section 3.3, both the recurrent deterministic decoder and the recurrent generative decoder are designed based on neural networks. Therefore, all the parameters in our model can be optimized in an end-to-end paradigm using back-propagation. We use $\{X\}_N$ and $\{Y\}_N$ to denote the training source and target sequence. Generally, the objective of our framework consists of two terms. One term is the negative log-likelihood of the generated summaries, and the other one is the variational lower bound $\mathcal{L}(\theta, \phi; Y)$ mentioned in Equation 5. Since the variational lower bound $\mathcal{L}(\theta, \phi; Y)$ also contains a likelihood term, we can merge it with the likelihood term of summaries. The final objective function, which needs to be minimized, is formulated as follows:

$$\begin{aligned} \mathcal{J} = \frac{1}{N}\sum_{n=1}^{N}\sum_{t=1}^{T}\Bigg\{ &-\log\left[p(y_t^{(n)}|y_{<t}^{(n)}, X^{(n)})\right] \\ &+ D_{KL}\left[q_\phi(\mathbf{z}_t^{(n)}|\mathbf{y}_{<t}^{(n)}, \mathbf{z}_{<t}^{(n)})\|p_\theta(\mathbf{z}_t^{(n)})\right]\Bigg\} \end{aligned} \tag{14}$$

4 Experimental Setup

4.1 Datesets

We train and evaluate our framework on three popular datasets. **Gigawords** is an English sentence summarization dataset prepared based on Annotated Gigawords[1] by extracting the first sentence from articles with the headline to form a source-summary pair. We directly download the prepared dataset used in (Rush et al., 2015). It roughly contains 3.8M training pairs, 190K validation pairs, and 2,000 test pairs. **DUC-2004**[2] is another English dataset only used for testing in our experiments. It contains 500 documents. Each document contains 4 model summaries written by experts. The length of the summary is limited to 75 bytes. **LCSTS** is a large-scale Chinese short text summarization dataset, consisting of pairs of (short text, summary) collected from Sina Weibo[3] (Hu et al., 2015). We take Part-I as the training set, Part-II as the development set, and Part-III as the test set. There is a score in range $1 \sim 5$ labeled by human to indicate how relevant an article and its summary is. We only reserve those pairs with scores no less than 3. The size of the three sets are 2.4M, 8.7k, and 725 respectively. In our experiments, we only take Chinese character sequence as input, without performing word segmentation.

4.2 Evaluation Metrics

We use ROUGE score (Lin, 2004) as our evaluation metric with standard options. The basic idea of ROUGE is to count the number of overlapping units between generated summaries and the reference summaries, such as overlapped n-grams, word sequences, and word pairs. F-measures of ROUGE-1 (R-1), ROUGE-2 (R-2), ROUGE-L (R-L) and ROUGE-SU4 (R-SU4) are reported.

4.3 Comparative Methods

We compare our model with some baselines and state-of-the-art methods. Because the datasets are

[1] https://catalog.ldc.upenn.edu/ldc2012t21

[2] http://duc.nist.gov/duc2004

[3] http://www.weibo.com

quite standard, so we just extract the results from their papers. Therefore the baseline methods on different datasets may be slightly different.

- **TOPIARY** (Zajic et al., 2004) is the best on DUC2004 Task-1 for compressive text summarization. It combines a system using linguistic based transformations and an unsupervised topic detection algorithm for compressive text summarization.

- **MOSES+** (Rush et al., 2015) uses a phrase-based statistical machine translation system trained on Gigaword to produce summaries. It also augments the phrase table with "deletion" rulesto improve the baseline performance, and MERT is also used to improve the quality of generated summaries.

- **ABS** and **ABS+** (Rush et al., 2015) are both the neural network based models with local attention modeling for abstractive sentence summarization. ABS+ is trained on the Gigaword corpus, but combined with an additional log-linear extractive summarization model with handcrafted features.

- **RNN** and **RNN-context** (Hu et al., 2015) are two seq2seq architectures. RNN-context integrates attention mechanism to model the context.

- **CopyNet** (Gu et al., 2016) integrates a copying mechanism into the sequence-to-sequence framework.

- **RNN-distract** (Chen et al., 2016) uses a new attention mechanism by distracting the historical attention in the decoding steps.

- **RAS-LSTM** and **RAS-Elman** (Chopra et al., 2016) both consider words and word positions as input and use convolutional encoders to handle the source information. For the attention based sequence decoding process, RAS-Elman selects Elman RNN (Elman, 1990) as decoder, and RAS-LSTM selects Long Short-Term Memory architecture (Hochreiter and Schmidhuber, 1997).

- **LenEmb** (Kikuchi et al., 2016) uses a mechanism to control the summary length by considering the length embedding vector as the input.

- **ASC+FSC$_1$** (Miao and Blunsom, 2016) uses a generative model with attention mechanism to conduct the sentence compression problem. The model first draws a latent summary sentence from a background language model, and then subsequently draws the observed sentence conditioned on this latent summary.

- **lvt2k-1sent** and **lvt5k-1sent** (Nallapati et al., 2016) utilize a trick to control the vocabulary size to improve the training efficiency.

4.4 Experimental Settings

For the experiments on the English dataset Gigawords, we set the dimension of word embeddings to 300, and the dimension of hidden states and latent variables to 500. The maximum length of documents and summaries is 100 and 50 respectively. The batch size of mini-batch training is 256. For DUC-2004, the maximum length of summaries is 75 bytes. For the dataset of LCSTS, the dimension of word embeddings is 350. We also set the dimension of hidden states and latent variables to 500. The maximum length of documents and summaries is 120 and 25 respectively, and the batch size is also 256. The beam size of the decoder was set to be 10. Adadelta (Schmidhuber, 2015) with hyperparameter $\rho = 0.95$ and $\epsilon = 1e - 6$ is used for gradient based optimization. Our neural network based framework is implemented using Theano (Theano Development Team, 2016).

5 Results and Discussions

5.1 ROUGE Evaluation

Table 1: ROUGE-F1 on validation sets

Dataset	**System**	**R-1**	**R-2**	**R-L**
GIGA	StanD	32.69	15.29	30.60
	DRGD	**36.25**	**17.61**	**33.55**
LCSTS	StanD	33.88	21.49	31.05
	DRGD	**36.71**	**24.00**	**34.10**

We first depict the performance of our model DRGD by comparing to the standard decoders (StanD) of our own implementation. The comparison results on the validation datasets of Gigawords and LCSTS are shown in Table 1. From the results we can see that our proposed generative decoders DRGD can obtain obvious improvements on abstractive summarization than the standard decoders. Actually, the performance of the standard

RNN-context	29.90	17.40	27.20
CopyNet	34.40	21.60	31.30
RNN-distract	35.20	22.60	32.50
DRGD	**36.99**	**24.15**	**34.21**

decoders is similar with those mentioned popular baseline methods.

The results on the English datasets of Gigawords and DUC-2004 are shown in Table 2 and Table 3 respectively. Our model DRGD achieves the best summarization performance on all the ROUGE metrics. Although ASC+FSC$_1$ also uses a generative method to model the latent summary variables, the representation ability is limited and it cannot bring in noticeable improvements. It is worth noting that the methods lvt2k-1sent and lvt5k-1sent (Nallapati et al., 2016) utilize linguistic features such as parts-of-speech tags, named-entity tags, and TF and IDF statistics of the words as part of the document representation. In fact, extracting all such features is a time consuming work, especially on large-scale datasets such as Gigawords. lvt2k and lvt5k are not end-to-end style models and are more complicated than our model in practical applications.

The results on the Chinese dataset LCSTS are shown in Table 4. Our model DRGD also achieves the best performance. Although CopyNet employs a copying mechanism to improve the summary quality and RNN-distract considers attention information diversity in their decoders, our model is still better than those two methods demonstrating that the latent structure information learned from target summaries indeed plays a role in abstractive summarization. We also believe that integrating the copying mechanism and coverage diversity in our framework will further improve the summarization performance.

5.2 Summary Case Analysis

In order to analyze the reasons of improving the performance, we compare the generated summaries by DRGD and the standard decoders StanD used in some other works such as (Chopra et al., 2016). The source texts, golden summaries, and the generated summaries are shown in Table 5. From the cases we can observe that DRGD can indeed capture some latent structures which are consistent with the golden summaries. For example, our result for S(1) "*Wuhan wins men's soccer title at Chinese city games*" matches the "Who Action What" structure. However, the standard decoder StanD ignores the latent structures and generates some loose sentences, such as the results for S(1) "*Results of men's volleyball at Chinese city games*" does not catch the main points. The reason is that the recurrent variational auto-encoders used in our framework have better representation ability and can capture more effective and complicated latent structures from the sequence data. Therefore, the summaries generated by DRGD have consistent latent structures with the ground truth, leading to a better ROUGE evaluation.

6 Conclusions

We propose a deep recurrent generative decoder (DRGD) to improve the abstractive summarization performance. The model is a sequence-to-sequence oriented encoder-decoder framework equipped with a latent structure modeling component. Abstractive summaries are generated based on both the latent variables and the deterministic states. Extensive experiments on benchmark

Table 5: Examples of the generated summaries.

S(1): hosts wuhan won the men 's soccer title by beating beijing shunyi #-# here at the #th chinese city games on friday. **Golden**: hosts wuhan wins men 's soccer title at chinese city games. **StanD**: results of men 's volleyball at chinese city games. **DRGD**: **wuhan wins men 's soccer title at chinese city games.**
S(2): UNK and the china meteorological administration tuesday signed an agreement here on long - and short-term cooperation in projects involving meteorological satellites and satellite meteorology. **Golden**: UNK china to cooperate in meteorology. **StanD**: weather forecast for major chinese cities. **DRGD**: **china to cooperate in meteorological satellites.**
S(3): the rand gained ground against the dollar at the opening here wednesday , to #.# to the greenback from #.# at the close tuesday. **Golden**: rand gains ground. **StanD**: rand slightly higher against dollar. **DRGD**: **rand gains ground against dollar.**
S(4): new zealand women are having more children and the country 's birth rate reached its highest level in ## years , statistics new zealand said on wednesday. **Golden**: new zealand birth rate reaches ##-year high. **StanD**: new zealand women are having more children birth rate hits highest level in ## years. **DRGD**: **new zealand 's birth rate hits ##-year high.**

datasets show that DRGD achieves improvements over the state-of-the-art methods.

Abstract

The need for automatic document summarization that can be used for practical applications is increasing rapidly. In this paper, we propose a general framework for summarization that extracts sentences from a document using externally related information. Our work is aimed at single document summarization using small amounts of reference summaries. In particular, we address document summarization in the framework of multi-task learning using curriculum learning for sentence extraction and document classification. The proposed framework enables us to obtain better feature representations to extract sentences from documents. We evaluate our proposed summarization method on two datasets: financial report and news corpus. Experimental results demonstrate that our summarizers achieve performance that is comparable to state-of-the-art systems.

1 Introduction

With rapid increase in the volume of textual data that are available both online and offline, the need for automatic document summarization that can be implement in practical scenarios is increasing (Li et al., 2016; Chopra et al., 2016; Takase et al., 2016). Among the several summarization systems, extractive summarization approaches (Erkan and Radev, 2004; McDonald, 2007; Wong et al., 2008) are widely used. These techniques identify and subsequently concatenate relevant sentences automatically from a document to create its summary while preserving its original information content. Such approaches are popular and widely used for practical applications because they are computationally cost-effective and less complex. Extractive summarization approaches based on neural network-based approaches (Kågebäck et al., 2014; Cao et al., 2015; Yin and Pei, 2015; Cao et al., 2016) have advanced rapidly. Recently, an attentional encoder-decoder for extractive single-document summarization was proposed and its application to the news corpus was demonstrated (Cheng and Lapata, 2016; Nallapati et al., 2017).

The neural network-based approaches rely heavily on large amounts of reference summaries for training neural models, and consequently, for tuning a large number of parameters. The reference summaries are manually or semi-automatically created in advance. Some existing studies employ parallel corpora as artificial reference summaries (Woodsend and Lapata, 2010; Cheng and Lapata, 2016). However, preparing such large volumes of reference summaries manually is sometimes costly. Particularly, it is infeasible for humans to create hundreds of thousands of reference summaries in cases where summarization requires domain-specific or expert knowledge. Such cases include financial reports, financial and economic news (Filippova et al., 2009), and scientific articles (Parveen et al., 2016).

A fundamental requirement in extractive summarization is the identification of salient sentences from a document, i.e., sentences that represent key subjects mentioned in the document. Such subjects are often described in the form of topics, categories, sentiments, and other meta-information about a document. Sometimes they are extracted from external information related to document contents. Once one knows the subjects of a document beforehand, a straightforward strategy in extractive summarization is to select sentences that are relevant to the subjects. Importantly, subjects should be inferred from sentences identified from

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2101–2110
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

the document. For example, assume that we are about to summarize a financial report of a company with knowledge from external information sources that the company has strong earnings. In this case, we might select sentences that explain factors affecting increase of earnings so that a reader of the summary can intuitively understand the company's financial situation.

The key idea is that we regard the subjects of a document as pseudo-rough reference summaries. Then, if we are able to estimate the subjects with small amounts of documents and the external information in them, the identification of salient sentences from a document can be supported by sentence features that have been learned from document subject estimation. As a result, smaller amounts of actual reference summaries are only needed as mutually learning feature representations for both subject estimation and sentence identification from pseudo-rough reference summaries.

As described earlier, we focus on single document summarization with small amounts of reference summaries, and propose a general framework for summarization that is useful for extracting sentences from a document along with its external related information. Particularly, we formalize estimation of the above-described document subjects as a document classification task and solve document summarization in the framework of multi-task learning for sentence extraction and document classification.

Our proposed summarization framework comprises two components: one designed for sentence extraction, which selects sentences relevant to the subjects of an input document, and one for document classification, which predicts the subject of the input document. In the multi-task learning framework, document classification supports sentence extraction by learning common feature representations of salient sentences for summarization. We use recurrent neural network encoder–decoder as sentence extractor and document classifier.

We evaluate our proposed summarization method on two datasets: the NIKKEI, the leading financial news publisher in Japan and a financial report corpus; and the New York Times Annotated Corpus (Sandhaus, 2008). The results of experimental evaluations demonstrate that our summarizers achieve a performance that is comparable to those of state-of-the-art systems.

The contribution of this paper is two-fold. First, we propose a general framework for single document summarization with small amounts of reference summaries, which is important for practical implementation of summarization techniques. Second, we propose a multi-task learning method with curriculum learning that supports sentence extraction from a document while solving document classification. Here, we assume that a document is classifiable into certain subjects, which comprise the meta-information of the document. Furthermore, sentences for a summary are extracted in relation to the subjects.

2 Problem Statement and Data Preparation

In this section, we define the task of sentence extraction for document summarization as addressed in this paper. We specifically examine documents that satisfy the following requirements. (1) Reference summaries are few. (2) The document is associated with a list of subjects, $\{a_1, a_2, \cdots, a_m\}$ ($a_i \in \{0, 1\}$), that includes topics, categories, sentiments, and other meta-information. $a_j = 1$ denotes that the document is classified into the subject j. Given a document D consisting of a sequence of sentences $\{s_1, s_2, \cdots, s_n\}$, we aim to extract k sentences in relation to a document subject a_j, which is expected to be included in the summary ($k < n$) of the document. We predict both a subject a_j for the document and a label $y_i \in \{0, 1\}$ for each sentence within the document, which indicates that the i-th sentence should be extracted.

In this study, we use two datasets for our sentence extraction task: the NIKKEI financial report corpus and New York Times news corpus.

For the financial report corpus, we used financial reports published every quarter during 2013–2016 by Japanese exchange listed companies. The reports explained the economic activity and the factors affecting revenue or profits for the quarter. For the reference summary, which is the gold standard summary used for training a classifier that predicts a sentence label, we use financial news articles published by the NIKKEI [1]. The NIKKEI publishes articles summarizing financial reports of each company. It covers approximately 10 % of all the reports: 3911 reports from 2013 to 2016. The

[1] http://www.nikkei.com/

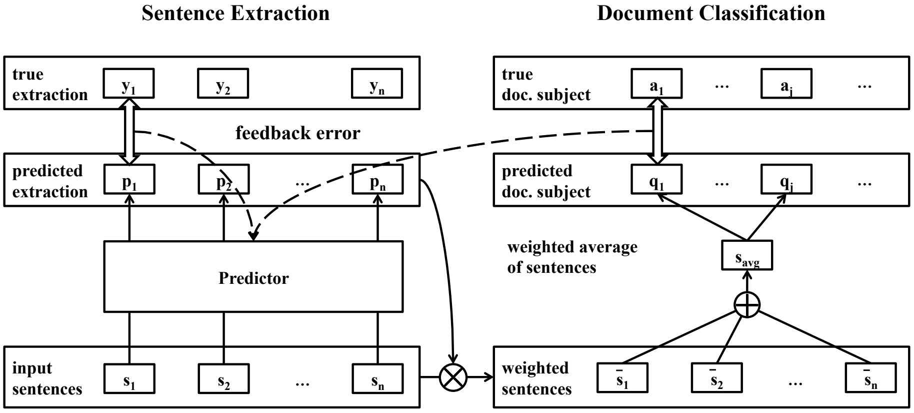

Figure 1: Proposed multi-task learning framework for sentence extraction with document classification

language of the reports and the articles is Japanese. For the document subject of a financial report, we used profit and revenue information as a subject a_j $(j = 1, 2)$, which indicates its profit and revenue increase compared to an earlier term.

Our second dataset, the New York Times Annotated Corpus (NYTAC), is a collection of articles from the New York Times. The gold standard summaries are attached to some of the articles. As the subject of a document article, we use already annotated category of the news from its metadata such as *Business* and *Arts*.

For the task of sentence extraction, the gold standard labels indicating sentences that should be extracted are needed. To attach the labels on sentences that maximize the Rouge score with respect to gold summaries, we introduce a greedy approach (Cheng and Lapata, 2016; Nallapati et al., 2017). We first select one sentence that has a maximum Rouge score with respect to the entire gold standard summary. We add it to the reference summary set and select sentences incrementally until no candidate sentence improves the score when added to the current summary set. The labels of sentences in the summary set are set as $y = 1$. The greedy approach is efficient because the computational costs associated with the identification of a global optimal summary set are too large.

The labels are attached by computing ROUGE-1 (Lin, 2004). ROUGE-1 and ROUGE-2 are reported as best for emulating evaluation by humans (Owczarzak et al., 2012). For financial reports, words apart from nouns, verbs, adjectives, and adverbs are removed for computing appropriate ROUGE scores. The accuracy between the labels attached by ROUGE-1 and humans is 81%.

3 Summarization Model

This section introduces our novel summarization framework. Figure 1 presents the proposed multi-task learning framework for sentence extraction with document classification. The left half of the figure shows the common sentence extraction part. The right half depicts a novel sentence extraction by document classification. We assume that a document is classifiable into certain subjects that represent meta-information of the document, and assume that sentences for a summary are extracted in relation to the subjects. Therefore, solving document classification supports sentence extraction from a document with multi-task learning of both tasks.

In Fig. 1, s_i denotes the embedding of sentence i. Furthermore, y_i denotes whether the sentence should be extracted and a_j is a subject of a document, which includes topics, categories, sentiments, or other meta-information. The predictor component computes $p_i \equiv p(y_i = 1 \mid D)$, the probability of sentence i extraction. Our proposed method estimates p_i by learning both sentence extraction and document classification.

We now explain how learning document classification supports sentence extraction. In Fig. 1, s_{avg} is the weighted average of s_i in terms of the probability of sentence extraction. It means that s_{avg} includes much more information about sentences with higher extraction probability. The probability that the document is related to a subject $q_j \equiv p(a_j = 1 \mid D)$ is estimated by s_{avg}. The error is larger if the contents of extracted sentences do not correspond with the document subject. By feeding back this error to the predictor, the model learns to extract sentences related to

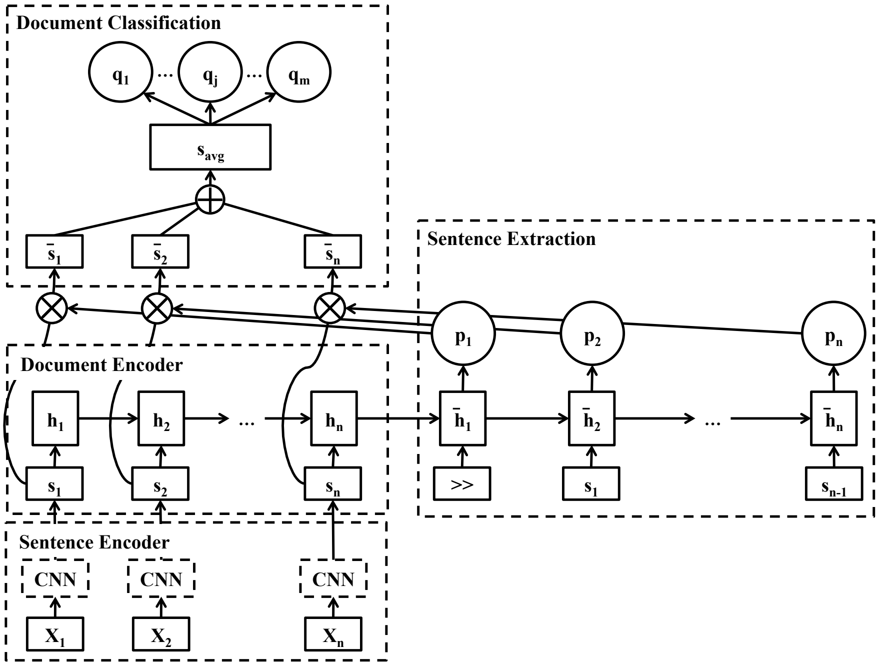

Figure 2: Sentence extraction model using LSTM-RNN with multi-task learning

the document subject. For example, in the case of a financial report, profit information indicating profit and revenue increase compared with an earlier term is used as a document subject. Positive sentences are expected to be extracted so that the extracted sentences reflect good financial results if the profit and revenue increase.

Figure. 2 shows the entire model. With respect to the predictor component in the proposed model, we use an encoder–decoder architecture modeled by recurrent neural networks (Kim et al., 2016) based on recent neural extractive summarization approaches (Cheng and Lapata, 2016; Nallapati et al., 2017). However, our summarization framework is applicable to all models of sentence extraction using distributed representation as inputs. We explain four sub-modules of the summarization model: sentence encoder, document encoder, sentence extraction, and document classification.

3.1 Sentence Encoder

We use Convolutional Neural Network (CNN) to obtain a sentence embedding from word embeddings. The training speed of single-layer CNN is high. It is effective for sentence-level classification such as sentiment analysis (Kim, 2014). Actually, CNN is suitable for use because our model requires a high computational cost. Sentence embeddings are used for both sentence extraction and document classification.

Let $x_i \in \mathcal{R}^d$ denote the embedding of the i-th word in the sentence, and $x_{i:i+q-1} \in \mathcal{R}^{dq}$ represent a concatenated vector that represents a sequence of q words. Convolutional filter $w \in \mathcal{R}^{dq}$ is applied as

$$s_w^i = f(w \cdot x_{i:i+q} + b), \qquad (1)$$

where f is a nonlinear function such as the hyperbolic tangent and b is the bias. Max pooling over time is applied to obtain a single feature s_w representing the sentence under filter w.

3.2 Document Encoder and Extractor

The LSTM-RNN Encoder–Decoder model is used for sentence extraction. First, on the encoder part, all sentences of a document are input into the hidden layers of RNN. LSTM assigns the input gate, forget gate, output gate, and memory cells as activation functions of RNN.

In Fig. 2, $h_n \in \mathcal{R}^k$ is the output of the encoder part, for which information of all sentences is input. The extraction probability is estimated based on the encoder part output. The hidden layer of the decoder part $\bar{h}_t \in \mathcal{R}^k$ is updated by LSTM equal to the encoder part. The initial value $\bar{h}_0$ is h_n. The input is the prior sentence s_{t-1} multiplied by the extraction probability p_{t-1}. Therefore, more information about sentences that are likely to be extracted is input to the hidden layer. Based on each hidden layer, the extraction probability of sentence t is computed as shown below.

$$h_t = \mathrm{LSTM}(s_t, h_{t-1}) \tag{2}$$

$$\bar{h}_t = \mathrm{LSTM}(p_{t-1} \cdot s_{t-1}, \bar{h}_{t-1}) \tag{3}$$

$$p_t = \sigma(w_y \cdot [h_t : \bar{h}_t] + b_y) \tag{4}$$

Here, $w_y \in \mathcal{R}^{2k}$ represents the weight vector, b_y stands for the bias, and : is the concatenation operator of vectors. By concatenating the hidden layers of the decoder part with the encoder part, the extraction probability is computed by referencing the information of input sentences more directly. It seems reasonable to pay attention to the input sentence directly when deciding whether the sentence should be extracted or not.

3.3 Document Classification

Using the embeddings and estimated extraction probability of sentences, the probability distribution of input document subjects is estimated. The probability that a document is classified into the subject j, q_j, is computed as shown below.

$$q_j = \sigma(w_a \cdot s_{avg} + b_a) \tag{5}$$

$$s_{avg} = \frac{\sum_t p_t \cdot s_t}{\sum_i p_i} \tag{6}$$

Here, w_a signifies the weight vector and b_a is the bias. Additionally, s_{avg} represents the weighted average of sentence embeddings. Each sentence is weighted by the estimated extraction probability. The predictor computes the probability distribution of a document subject from s_{avg}, which means that the predictor pays more attention to sentences that are likely to be extracted.

3.4 Multi-Task Learning with Curriculum Learning

This section presents an explanation of the procedure followed to train the summarization model. The model parameters are updated to maximize the likelihood of all sentence labels and document subject labels. This is equivalent to minimization of the following error terms.

$$\begin{aligned} E_y(\theta) = &-\sum_{t=1}^{n} (y_t \log p_t + (1-y_t)\log(1-p_t)) \\ &+ \lambda_\theta \|\theta\|^2 \end{aligned} \tag{7}$$

$$\begin{aligned} E_a(\theta) = &-\sum_{j=1}^{m} (a_j \log q_j + (1-a_j)\log(1-q_j)) \\ &+ \lambda_\theta \|\theta\|^2 \end{aligned} \tag{8}$$

In these equations, $\|\theta\|^2$ is the L2 norm, and λ_θ is the regularization term. L2 regularization is introduced to avoid overfitting.

Multi-task learning is generally complicated because the parameter is optimized simultaneously for sentence extraction and document classification. We introduce curriculum learning (Bengio et al., 2009) to overcome this difficulty. Curriculum learning is a learning method that aims to improve the performance of a complicated model or data. The model starts by learning a simple model or data, and gradually adapts to more complicated ones.

We introduce two kinds of curriculum learning for multi-task learning. We apply baby step curriculum learning (Cirik et al., 2016), which demonstrates the effectiveness of the LSTM-RNN architecture. In this, the dataset is categorized based on the difficulty and added to the order of ease.

We divide the dataset into three subsets based on the combination of document type and objective function. The first subset has documents with an attached reference summary. The model is trained for optimizing sentence extraction. The second uses the same documents as the first. However, the objective function is document classification. The last one has documents with no reference summary. Only the likelihood of document subjects as pseudo-rough reference summaries is maximized in the last dataset. For sentence extraction task, it is more difficult to train from the last dataset than the first dataset because information related to document subjects are more truncated than the reference summary. The second dataset is the bridge between the first and the last.

For document classification, sentences are weight-averaged by the estimated sentence extraction probability p_t. In the second dataset, sentences are weighted not only by p_t, but also the true label y_t. p_t in Eq.(6) is replaced by $\bar{p}_t$ as follows.

$$\bar{p}_t = \kappa p_t + (1-\kappa) y_t \tag{9}$$

Here, κ is the mixing rate of extraction probability and the true label. At the beginning of training,

p_t is not predicted accurately. This will affect document classification adversely, therefore κ is set to nearly zero so that the true label y_t is used for document classification. By using the true label, training for sentence extraction and document classification does not mutually interfere. As training progress, κ gets larger and document classification supports sentence extraction.

We believe that our basic idea of curriculum learning, with some modifications depending on the task applied, can be applied for other kinds of multi-task learning in general.

4 Experimental Setup

4.1 Dataset

The NIKKEI Financial Report Corpus

For training and evaluation, we used financial reports published from April 2013 through September 2016. The reports used for evaluation and validation were published in the last and the second to last quarter. All other reports were used for training. The numbers of reports used for training, validation, and evaluation were $12,262$, 191, and 183. In the training dataset, $8,725$ reports with no reference summary were included and used only for training of document classification, which predicts document subjects. As for document subjects, we used subjects of two kinds as $a_j \in \{0,1\}$ $(j = 1,2)$, indicating that the profit and revenue increases compared with the prior term. $a_j = 1$ denotes that the value increases.

New York Times Annotated Corpus

For the experiment using NYTAC, we evaluated our model using different amounts of reference summary. The numbers of articles used for both validation and evaluation were 200. For training, we prepared 125, 250, and 500 articles. For training of document classification, we used 3000 articles for which the reference summary was not attached. As document subjects, we used the category of a news article $a_j \in \{0,1\}$ $(j = 1,2,\cdots,C)$ as a subject. Each subject corresponded to a news article category, such as ”Business” and ”Arts.” $a_j = 1$ denotes that a document is classified into the category j. C is the number of categories, which is 26 in our experiment.

4.2 Implementation Details

The word embeddings were pre-trained using Skip-gram (Mikolov et al., 2013) on all $1,043,064$ articles in the Japanese version of Wikipedia. The dimensions of word embedding were 200. Those of the hidden layer in LSTM-RNN were 400. For CNN, the list of kernel sizes was $\{1,2,3,4,5,6\}$. The number of feature maps was 50. Adadelta (Zeiler, 2012) was used for updating parameters. The initial learning rate was 10^{-6}. The hyper parameters were optimized using grid search. We extracted three sentences with the highest scores in the manner described in an earlier report (Cheng and Lapata, 2016).

4.3 Baselines

For the NIKKEI financial report dataset, we used LEAD, which extracts the leading three sentences of a document as a baseline. We also built a baseline classifier LREG using logistic regression and human engineered features. The features were sentence length, position in the document, number of entities, nouns, verbs, adverbs, and adjectives in the sentence. We also added the sentiment of sentence to the features. For the financial report summarization, sentiment information is important because positive/negative sentences are frequently included in the summary when the revenue increases/decreases. The sentiment is computed by the frequency of words that appear in the articles when the revenue increases/decreases. For both datasets, we assigned NN-SE(Cheng and Lapata, 2016) as the baseline. The difference between NN-SE and our model is the introduction of multi-task learning and curriculum learning. The hyper-parameters are the same as those of our model. Through comparison with NN-SE, we can validate the effectiveness of the proposed framework.

5 Results

5.1 Results obtained from the NIKKEI Financial Report Corpus

Table1 presents the results for financial reports using F-measure. The precision and recall are calculated based on binary classification setup. LEAD, LREG, and NN-SE are used as the baselines. The proposed neural multi-task learning model, NN-ML, is significantly inferior to NN-SE and LREG. However, NN-ML-CL, the proposed model with curriculum learning, is superior to all

Table 1: F-measure evaluation (%) on financial reports

Models	F-measure	Precision	Recall
LEAD	42.1	39.1	50.4
LREG	60.5	**67.6**	66.5
NN-SE	59.9	58.0	68.8
NN-ML	55.2	52.1	64.6
NN-ML-CL	**60.6**	54.6	**74.9**

Table 2: F-measure evaluation (%) depending on the amount of reference summary

Models	125	250	500	1000	2000
NN-SE	55.2	56.1	58.0	58.0	58.1
NN-ML-CL	**58.1**	**58.4**	**59.4**	**59.3**	**59.2**

other models. This result shows that merely introducing multi-task learning does not positively influence on sentence extraction. However, curriculum learning overcomes the difficulty of multi-task learning; thus, document classification has positive effects on sentence extraction.

We confirmed the relation between the effectiveness of our model and the amount of reference summaries. We compared NN-ML-CL (our model) and NN-SE in several cases for which the amounts of reference summaries were 125, 250, 500, 1000, and 2000; the results are shown in Table 2. As observed, NN-ML-CL is superior to NN-SE in all cases. The margin between NN-ML-CL and NN-SE grows as the amount decreases, which means that document classification is more effective in cases with fewer reference summaries.

We also reported the results of human evaluation for summaries generated by the respective systems. Referring to the gold summary, participants ranked the generated summaries generated by four systems: NN-ML-CL(our system), NN-SE, LEAD, and LREG. The judging criteria was informativeness, which indicates how a generated summary covers information in the gold summary. From the test documents, we remove summaries for which the same sentences were extracted by different systems and randomly sampled 20 documents. 6 persons participated in the evaluation.

Table 3 presents the distribution of ranking and the average. Our NN-ML-CL model is ranked first in more than half the tests and markedly surpasses other models. Comparison with NN-SE verifies the effectiveness of multi-task learning for human evaluation.

Table 3: Ranking distributions (%) and the average evaluated by humans

Models	1st	2nd	3rd	4th	Ave.
LEAD	21.7	20.0	28.3	30.0	2.67
LREG	20.0	28.3	26.7	25.0	2.45
NN-SE	31.7	21.7	16.7	30.0	2.57
NN-ML-CL	51.7	20.0	21.7	6.7	**1.83**

Table 4: ROUGE scores (%) for various amounts of reference summaries in NYTAC

Model	Ref.	ROUGE-1	ROUGE-2
NN-SE	125	17.2	12.1
	250	16.8	11.3
	500	18.0	12.5
NN-ML-CL	125	18.1	12.7
	250	18.3	12.7
	500	18.5	12.9

5.2 Results on NYTAC

Table 4 presents our results for NYTAC using ROUGE-1 and ROUGE-2. In all cases, NN-ML-CL outperforms NN-SE on both metrics. When the amount of reference summary is 250, the margin between NN-ML-CL and NN-SE is the largest on each metric. For cases with 125 and 500 reference summaries, improvement is observed, but the margin is smaller than in the case for financial reports.

5.3 Discussion

In this section, we discuss how document classification contributes to the improvement of sentence extraction performance on the financial report dataset.

As mentioned above, NN-ML, the model that uses multi-task learning, exhibits a performance that is worse than that of NN-SE, the model that does not use multi-task learning. One possible explanation would be that it is difficult to optimize the parameters to maximize the likelihood of both sentence extraction and document classification simultaneously. If the learning task of sentence extraction does not proceed well enough, the task of document classification may also not work well. The reason is that the classification task relies on the estimated probability for sentence extraction in our proposed summarization framework.

However, curriculum learning improves the performance of the model with multi-task learning. By introducing curriculum learning into the framework, we are able to start training the model

Table 5: Rates (%) of extracted sentences corresponding with a document subject

	Correspond	Not	Others
NN-SE	**40.0**	40.0	20.0
NN-ML-CL	**85.7**	14.3	0.0

Table 6: Example of gold summary and sentences extracted using NN-ML-CL and NN-SE

Sentences extracted by NN-ML-CL
The rapid progress of the strong yen adversely influenced financial results, but the growth of revenue in areas such as Europe, Asia, and Oceania increased the revenue to 535 billion yen. The demand for air conditioners increased because of the intense July heat.
Sentences extracted by NN-SE
As for fluorine resin, the demand for semiconductors rose steadily. However, competing Chinese companies gained power, and revenue for electrical wire use declined. The revenue of parts for guided missiles increase year-on-year, but the revenue of medical equipment decrease.
News Article (Gold summary)
In Southeast Asia and Europe, high-end models of air conditioners sold well. In China and US, revenue rose and overcame the adverse influence of strong yen. The corporate tax ratio reduction also supported business performance. The revenue of air-conditioners, a leading product of Daikin, rose 9% in Southeast Asia. The revenue network in Vietnam and Indonesia expanded. revenue of air-conditioners rose at a higher pace than market scale. In China, the revenue of air conditioners for business use recovered. High-end models were also selling well.

only for sentence extraction. Then, the training for document classification is started gradually. Eventually, it contributes to the improvement of the performance of sentence extraction through the multi-task learning approach.

From the results for the financial report corpus, we confirmed that the contents of sentences extracted by our model corresponded with revenue and profit changes. Before validation, the sentences were categorized as corresponding to or not corresponding to others. We compared the results of sentence extraction with NN-ML-CL and NN-SE and checked the category distribution of sentences extracted using NN-ML-CL or NN-SE.

Table 5 shows that 85.7% of sentences extracted using NN-ML-CL correspond to changes of revenues and profits. However, only 40.0% of sentences extracted by NN-SE correspond to these parameters, which indicates that document classification supports extraction of sentences related to the revenue and profit change, and contributes to the improvement.

Table 6 shows sentences extracted from financial reports published by Daikin, Ltd., the leading air-conditioner manufacturer in Japan. During this term, the air conditioner revenue increased; moreover, revenues and profits increased considerably year-on-year. NN-ML-CL extracted sentences that mention the good revenue performance of air-conditioners in Asia and Europe, which is the same as that in the gold summary. In contrast, NN-SE extracts sentences mentioning the bad revenue performance of fluorine resin and medical equipment, which are not described in the gold summary. NN-SE is badly affected owing to training on past reports and articles. Our model extracts sentences with words that appear frequently in a positive context. Therefore, sentences related to good revenue performance are extracted.

There are two main ways of applications for our summarization approach with document classification. In the first case, the text collection has explicitly annotated document labels, which includes the collection of news articles with their category information, product reviews with their rating, scholarly paper abstracts with their discipline information, etc. In the second case, a document label can be acquired from external information sources about the text collection. For financial reports, the information about financial situation of a target company is extracted from the financial statement, which in turn can be used for a label of document classification.

6 Related Work

Based on the recent advances of neural network-based approaches (Kågebäck et al., 2014; Cao et al., 2015; Yin and Pei, 2015; Cao et al., 2016), an attentional encoder-decoder for extractive single-document summarization and its application to the news corpus was proposed (Cheng and Lapata, 2016; Nallapati et al., 2017). Although we employ an encoder-decoder architecture in the predictor component of our summarization framework, the framework can be applied to all models of sentence extraction using distributed representation as inputs, including recently advanced other attention-based encoder-decoder networks (Wang et al., 2016; Yang et al., 2016)

(Cheng and Lapata, 2016; Nallapati et al., 2017) argue that a stumbling block to applying neural network models to extractive summarization is the lack of training data and documents with sentences labeled as summary-worthy. To overcome this, several studies have used artificial reference summaries (Sun et al., 2005; Svore et al., 2007; Woodsend and Lapata, 2010; Cheng and Lapata, 2016) compiled by collecting documents and corresponding highlights from other sources. However, preparing such a parallel corpus often requires domain-specific or expert knowledge depending on the domain (Filippova et al., 2009; Parveen et al., 2016). Our summarization uses document-associated information as pseudo rough reference summaries, which enables us to learn feature representations for both document classification and sentence identification with smaller amounts of actual reference summaries.

Neural networks based multi-task learning has recently proven effective in many NLP problems (Liu et al., 2015, 2016; Firat et al., 2016; Dong et al., 2015). Aiming at single document summarization with relatively small amounts of reference summaries, we demonstrated document summarization in the framework of multi-task learning with curriculum learning for sentence extraction and document classification. This enabled us to obtain better feature representations to extract sentences from documents.

7 Conclusion

In this paper, we proposed a general framework for extractive summarization using document subjects. Our key idea is to use a multi-task learning method that supports sentence extraction while enabling document classification, assuming that a document can be classified into certain subjects, and sentences for a summary are extracted in relation to the subjects.

This framework enables single document summarization with relatively small amounts of reference summaries since document subjects can be used as pseudo-rough reference summaries. Our proposed method can be widely applied for actual documents attached with meta-information such as product reviews, sports news and so on.

Experimental results showed that our model is less effective on the news corpus. For higher performance, more information such as the embeddings of news descriptors for document classification must be used.

Towards Automatic Construction of News Overview Articles by News Synthesis

Abstract

In this paper we investigate a new task of automatically constructing an overview article from a given set of news articles about a news event. We propose a news synthesis approach to address this task based on passage segmentation, ranking, selection and merging. Our proposed approach is compared with several typical multi-document summarization methods on the Wikinews dataset, and achieves the best performance on both automatic evaluation and manual evaluation.

1 Introduction

There are usually many news articles about a news event, and news summaries can be used for readers to quickly learn the most salient information of the news articles. News summaries in previous studies are usually very short, and most of them consist of about one or two hundred words. However, in many circumstances, readers want to learn more about an event, but the news summary is insufficient to read, and people are reluctant to read each news article one by one. A possible solution to this problem is constructing a long and comprehensive news overview article to summarize and present all important facts about the news event in an unbiased way. The news overview articles can be considered long summaries, however, news overview articles are more comprehensive and the article texts are harder to arrange and organize.

In this paper, we conduct a pilot study to investigate the new task of automatic construction of a news overview article from a set of news articles about an event. We argue that traditional multi-document summarization methods can be applied to this task, but they do not perform well because sentence-based extraction used in these methods is not suitable for constructing and organizing a long article. Instead, we propose a news synthesis approach to address this task. Our approach uses passage as the basic unit. In this study, passage does not mean a natural paragraph, but means a block of text (maybe multiple paragraphs) about a subtopic of an event. Our approach first segments news articles into passages with the SenTiling algorithm, and then ranks the passages with the DivRank algorithm. Finally, it selects and merges a few passages to construct the long news overview article.

We automatically build an evaluation dataset based on English Wikinews [1]. Most Wikinews articles are synthesis articles and they are written using information from other online news sources. All the important facts available from all sources about a news event are combined into a single article for the reader's convenience, and the information is presented in a neutral manner avoiding the bias that may be present in other news sources. Therefore, we treat a Wikinews article as an ideal overview article (i.e., reference) of the source news articles.

We compare our proposed approach with several typical multi-document summarization methods based on the Wikinews dataset. The results are very promising and our approach achieves the best performance on both automatic evaluation and manual evaluation. In this study, we demonstrate the feasibility of automatic construction of long overview articles from a set of news articles.

The contributions of this paper are summarized as follows: 1) we are the first to investigate the task of automatic construction of news overview articles from a set of source news articles; 2) we automatically build an evaluation dataset based on Wikinews; 3) we propose a news passage-based

synthesis approach to address this task; 4) evaluation results verify the efficacy of our approach.

2 Our News Synthesis Approach

We propose a news synthesis approach to automatic construction of news overview articles from a set of source news articles. Our approach uses passage as the basic unit, and consists of three main steps: passage segmentation, passage ranking, and passage selection and merging. The rationale of using passage rather than sentence lies in that 1) the sentences in a passage are more complete and coherent than multiple sentences selected from different places in different documents; 2) it is easier to arrange several passages than to arrange a large number of sentences.

2.1 Passage Segmentation

In this step, we aim to segment each source news article into several passages, where each passage represents a subtopic of the event. In order to achieve this goal, we adopt the TextTiling algorithm (Hearst, 1997), which is a popular algorithm for discovering subtopic structure using term repetition. The original TextTiling algorithm usually splits a sentence into different passages, and in order to remedy this problem, we slightly modify the TextTiling algorithm and our new SenTiling algorithm consists of three steps:

Tokenization refers to the division of the input text into individual lexical units, and the tokens are converted to lower-case characters and stemmed using the Porter stemmer.

Lexical score determination refers to assigning a lexical score of each gap between text blocks. To avoid the incomplete sentence in the segmentation result, we regard a sentence as a text block and calculate a lexical score for the gap at the end of each sentence by the cosine similarity value between 100 words before and after the gap. We do not use natural paragraphs as blocks because their lengths are highly irregular.

Boundary identification assigns a depth score to each sentence gap and then determines the passages to assign to a document. The depth score is computed in the same way as in (Hearst, 1997) and it corresponds to how strongly the cues for a subtopic changed on both sides of a given gap and is based on the distance from the peaks on both sides of the valley to that valley. Since every gap is a potential segment boundary. We select a boundary only if the depth score exceeds the average depth scores $\overline{s}$ minus the standard deviation σ of their scores (thus assuming that the scores are normally distributed), as $\overline{s} - \sigma$.

2.2 Passage Ranking

We use DivRank (Mei et al., 2010) to rank passages, because DivRank automatically balances the prestige and the diversity of the top ranked passages in a principled way. It is motivated from a general time-variant random walk process known as the vertex-reinforced random walk. Let $p_T(v)$ be the probability that the walk is at state v at time T, and $p_T(u, v)$ be the transition probability from any state u to any state v at time T.

$$p_T(v) = \textstyle\sum_{u \in V} p_{T-1}(u, v) p_{T-1}(u)$$

$$p_T(u, v) = (1 - \lambda) \cdot p^*(v) + \lambda \cdot \frac{p_0(u,v) \cdot p_T(v)}{D_T(u)}$$

where $D_T(u) = \sum_{v \in V} p_0(u, v) p_T(v)$. And $p^*(v)$ is a uniform distribution which represents the prior preference of visiting vertex v. $p_0(u, v)$ is the organic transition probability prior to any reinforcement, which is estimated as in a regular time-homogenous random walk by the normalized cosine similarity value between u and v.

After a sufficiently large T, the reinforced random walk will converge to a stationary distribution, and each passage node will be assigned with a rank score.

2.3 Passage Selection and Merging

We aim to select several important but non-redundant passages to form the overview article. The selection can be done according to the DivRank scores because the scores balance the prestige and the diversity of most of the top ranked passages, but it occasionally happens that two relevant passages both get high scores. In order to remedy this problem and make the content for each subtopic more comprehensive and complete, we further merge relevant passages by adding informative sentences from relevant passages into the selected passage. The greedy selection process is illustrated in Algorithm 1.

The function $merge(g_{i*}, g_{j*})$ merges the sentences of g_{i*} into g_{j*} one by one. If the average similarity between a sentence $s_{i*,k}$ in g_{i*} and each sentence in g_{j*} is less than ξ, we insert the sentence $s_{i*,k}$ into g_{j*} and find the insertion position between two sentences $s_{j*,m}$ and $s_{j*,n}$ in g_{j*}, where the average of the similarity between $s_{i*,k}$ and $s_{j*,m}$, and the similarity between $s_{i*,k}$

Algorithm 1 Passage Selection and Merging

```
Input:
    Passage set $G = g_1, ..., g_n$ and each passage $g_i$ is assigned with a DivRank score $p(g_i)$;
    The cosine similarity value $gSim_{i,j}$ between any two passages $g_i$ and $g_j$;
Output:
    The passage set $O$ in the overview article;
Initialize $O = \phi$
while $G \neq \phi$ and $O$ does not reach the length limit do
    $g_{i*} = \text{argmax}_{g_i \in G}\, p(g_i)$;
    $G = G - g_{i*}$
    $g_{j*} = \text{argmax}_{g_j \in O}\, gSim_{i*,j}$;
    if $gSim_{i*,j*} > \tau$ then
        $g_{j*} = merge(g_{i*}, g_{j*})$
    else
        $O = O \cup g_{i*}$
    end if
end while
return $O$
```

and $s_{j*,n}$ is the largest.

Finally, we arrange the passages in O with topological sorting to form the overview article. We follow two principles: 1) If passages u and v are from the same news article and u is before v, they should be adjacent and have the same order in the overview article; 2) If passages u and v are from different news articles and u has higher DivRank score than v, u and the passages coming from the same news article with u should be placed before v in the overview article.

3 Evaluation Dataset and Baselines

As mentioned in the introduction section, we used Wikinews to construct the evaluation dataset. We first crawled 18121 English Wikinews and their source news articles via the associated URLs. However, many Wikinews articles have very few source news articles and they are very short, and moreover, the URLs for many of the source news are out of date. We filtered the Wikinews articles for which the number of available source news articles are less than 5. Finally, we selected 100 longest Wikinews from the remaining set for testing [2]. The average number of words of Wikinews in the test set is 598 and the average number of total words of their source news articles is 2136. Accordingly, the length limit of overview articles produced by different methods is 600 words.

Our approach is compared with several typical multi-document summarization methods: **Lead**, **Coverage**, **Centroid** (Radev et al., 2004), **TextRank** (Mihalcea and Tarau, 2004), **ClusterCMRW** (Wan and Yang, 2008), **ILP** (Gillick and Favre, 2009) and **Submodular** (Li et al., 2012). We also implement **SenDivRank** that applies the DivRank algorithm on sentences.

For our approach, τ is set to 0.4 and ξ is set to 0.5 based on an additional small development set chosen from the remaining Wikinews set. λ in the DivRank algorithm is set to 0.85 by default. Under the control of these thresholds, we only merge a very small number of passages and insert very few sentences from one passage to another passage, so the influence of passage merging on the coherence is very subtle.

4 Evaluation Results and Analysis

Automatic Evaluation: Similar to traditional summarization tasks, we use the ROUGE metrics (Lin and Hovy, 2003) to automatically evaluate the quality of peer overview articles against the gold-standard references. We use ROUGE-1.5.5 and report the F-scores of ROUGE-1 (R-1), ROUGE-2 (R-2) and ROUGE-SU4 (R-SU4).

Firstly, we perform evaluation on the whole articles and Table 1 shows the comparison results. We can see that our approach outperforms all the baseline methods with respect to ROUGE-2 and ROUGE-SU4. The Submodular method achieves the highest ROUGE-1 score, but our approach also achieves very high ROUGE-1 score, which is very close to that of the Submodular method.

Table 3: Comparison results on two-part evaluation II

tent organization in long articles, we split each article (both peer article and reference article) into two parts with equal length, and compare the first parts in the peer and reference articles, and then compare the second parts in the peer and reference articles. Lastly, the ROUGE scores are averaged across the two parts. Table 2 shows the comparison results based on this evaluation protocol (two-part evaluation I). Furthermore, we allow the first part in a reference article to match with the second part in a peer article, and vice versa. We allow one-to-one matching and find the optimal matching between the two sets of parts, which refers to the matching with the largest sum of the similarity values of the matched parts. We then compute and average the ROUGE scores of the matched parts. Table 3 shows the comparison results based on this evaluation protocol (two-part evaluation II). We can see from Tables 2 and 3 that our proposed approach performs much better than the baseline methods over all three metrics.

Method	Cov.	Read.	Overall
TextRank	2.86	2.34	2.50
Centroid	2.83	2.17	2.33
ILP	2.17	1.17	2.27
ClusterCMRW	3.33	2.34	2.83

SenDivRank	3.51	2.47	2.86
Our Approach	**3.85**	**3.32**	**3.47**

Table 4: Manual evaluation results

Manual Evaluation: We randomly select 30 test cases for manual evaluation. We employ three students as human judges and each judge is asked to read the reference Wikinews and the peer overview article produced by each method, and then give a rating score between 1 and 5 with respect to three aspects: content coverage, readability and overall responsiveness. 5 means “very good”, 3 means “acceptable”, and 1 means “very bad”. The methods producing the articles are blind to the judges. Finally, the rating scores with respect to each aspect across different test cases are averaged, and then averaged across the three judges. Table 4 shows the manual evaluation results. We can see that our proposed approach can produce news overview articles with better content coverage, readability and overall responsiveness than baseline methods. The quality of the news overview articles is generally acceptable by the human judges.

In all, our proposed approach are more effective than typical multi-document summarization methods for addressing this challenging task. It is feasible to automatically construct news overview articles with news synthesis.

5 Related Work

The most closely related work is multi-document summarization, which aims to produce a concise (or short) summary to deliver the major information for a given document set. Most summarization methods rank and select a few existing sentences in the documents or compose new sentences with phrases to form a summary. Typical summarization methods include graph-based ranking methods (Erkan and Radev, 2004; Mihalcea and Tarau, 2005; Berg-Kirkpatrick et al., 2011; Wan and Zhang, 2014; Wan and Yang, 2008), sentence classification or regression based methods (Conroy and O’leary, 2001; Shen et al., 2007; Ouyang et al., 2007), ILP-based methods (McDonald, 2007; Gillick and Favre, 2009; Xie et al., 2009; Berg-Kirkpatrick et al., 2011; Woodsend and Lapata, 2012; Bing et al., 2015), submodular maximization based methods (Lin and Bilmes, 2010, 2011; Sipos et al., 2012), DPP (Determinantal Point Process) based methods (Kulesza et al., 2012), and neural model based methods (Rush et al., 2015; Chopra et al., 2016; Nallapati et al., 2016), etc.

Other related work includes automatic generation of well-structured Wikipedia articles (Sauper and Barzilay, 2009; Yao et al., 2011). Different from Wikinews, Wikipedia articles usually have domain-dependent templates for content filling and organization.

6 Conclusion

In this pilot study we proposed a news synthesis approach to address the challenging task of automatic generation of news overview articles. Evaluation results on Wikinews verified the efficacy and feasibility of the proposed approach. In future work, we will investigate supervised learning methods for passage ranking and selection, and try to paraphrase the selected passages.

Joint Syntacto-Discourse Parsing and the Syntacto-Discourse Treebank [*]

Abstract

Discourse parsing has long been treated as a stand-alone problem independent from constituency or dependency parsing. Most attempts at this problem are pipelined rather than end-to-end, sophisticated, and not self-contained: they assume gold-standard text segmentations (Elementary Discourse Units), and use external parsers for syntactic features. In this paper we propose the first end-to-end discourse parser that jointly parses in both syntax and discourse levels, as well as the first syntacto-discourse treebank by integrating the Penn Treebank with the RST Treebank. Built upon our recent span-based constituency parser, this joint syntacto-discourse parser requires no preprocessing whatsoever (such as segmentation or feature extraction), achieves the state-of-the-art end-to-end discourse parsing accuracy.

1 Introduction

Distinguishing the semantic relations between segments in a document can be greatly beneficial to many high-level NLP tasks, such as summarization (Louis et al., 2010; Yoshida et al., 2014), sentiment analysis (Voll and Taboada, 2007; Somasundaran et al., 2009; Bhatia et al., 2015), question answering (Ferrucci et al., 2010; Jansen et al., 2014), and textual quality evaluation (Tetreault et al., 2013; Li and Jurafsky, 2016).

There has been a variety of research on discourse parsing (Marcu, 2000a; Soricut and Marcu, 2003; Pardo and Nunes, 2008; Hernault et al., 2010; da Cunha et al., 2012; Joty et al., 2013; Joty and Moschitti, 2014; Feng and Hirst, 2014; Ji and Eisenstein, 2014; Li et al., 2014a,b; Heilman and Sagae, 2015; Wang et al., 2017). But most of them suffer from the following limitations:

1. *pipelined rather than end-to-end*: they assume pre-segmented discourse, and worse yet, use gold-standard segmentations, except Hernault et al. (2010);
2. *not self-contained*: they rely on external syntactic parsers and pretrained word vectors;
3. *complicated*: they design sophisticated features, including those from parse-trees.

We argue for the first time that discourse parsing should be viewed as an extension of, and be performed in conjunction with, constituency parsing. We propose the first *joint syntacto-discourse treebank*, by unifying constituency and discourse tree representations. Based on this, we propose the first *end-to-end* incremental parser that jointly parses at both constituency and discourse levels. Our algorithm builds up on the span-based parser (Cross and Huang, 2016); it employs the strong generalization power of bi-directional LSTMs, and parses efficiently and robustly with an extremely simple span-based feature set that does not use any tree structure information.

We make the following contributions:

1. We develop a combined representation of constituency and discourse trees to facilitate parsing at both levels without explicit conversion mechanism. Using this representation, we build and release a joint treebank based on the Penn Treebank (Marcus et al., 1993) and RST Treebank (Marcu, 2000a,b) (Section 2).
2. We propose a novel joint parser that parses at both constituency and discourse levels. Our

(a) A discourse tree with 3 EDUs (●: nucleas; ○: satellite) in the RST treebank (Marcu, 2000b)

(b) The corresponding RST-PTB tree (our work)

Figure 1: Examples of the RST discourse treebank and our syntacto-discourse treebank (PTB-RST).

parser performs discourse parsing in an end-to-end manner, which greatly reduces the efforts required in preprocessing the text for segmentation and feature extraction, and, to our best knowledge, is the first end-to-end discourse parser in literature (Section 3).

3. Even though it simultaneously performs constituency parsing, our parser does *not* use any explicit syntactic feature, nor does it need any binarization of discourse trees, thanks to the powerful span-based framework of Cross and Huang (2016) (Section 3).

4. Empirically, our end-to-end parser outperforms the existing pipelined discourse parsing efforts. When the gold EDUs are provided, our parser is also competitive to other existing approaches with sophisticated features (Section 4).

2 Combined Representation & Treebank

We first briefly review the discourse structures in Rhetorical Structure Theory (Mann and Thompson, 1988), and then discuss how to unify discourse and constituency trees, which gives rise to our syntacto-discourse treebank PTB-RST.

2.1 Review: RST Discourse Structures

In an RST discourse tree, there are two types of branchings. Most of the internal tree nodes are binary branching, with one *nucleus* child containing the core semantic meaning of the current node, and one *satellite* child semantically decorating the nucleus. Like dependency labels, there is a *relation* annotated between each satellite-nucleus pair, such as "Background" or "Purpose". Figure 1(a) shows an example RST tree. There are also non-binary-branching internal nodes whose children are conjunctions, e.g., a "List" of semantically similar EDUs (which are all nucleus nodes); see Figure 2(a) for an example.

2.2 Syntacto-Discourse Representation

It is widely recognized that lower-level lexical and syntactic information can greatly help determining both the boundaries of the EDUs (i.e., discourse segmentation) (Bach et al., 2012) as well as the semantic relations between EDUs (Soricut and Marcu, 2003; Hernault et al., 2010; Joty and Moschitti, 2014; Feng and Hirst, 2014; Ji and Eisenstein, 2014; Li et al., 2014a; Heilman and Sagae, 2015). While these previous approaches rely on pre-trained tools to provide both EDU segmentation and intra-EDU syntactic parse trees, we instead propose to directly determine the low-level segmentations, the syntactic parses, and the high-level discourse parses using a single joint parser. This parser is trained on the combined trees of constituency and discourse structures.

We first convert an RST tree to a format similar

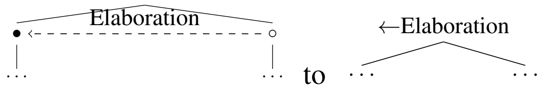
to those constituency trees in the Penn Treebank (Marcus et al., 1993). For each binary branching node with a nucleus child and a satellite child, we use the relation as the label of the converted parent node. The nucleus/satellite relation, along with the direction (either ← or →, pointing from satellite to nucleus) is then used as the label. For example, at the top level in Figure 2, we convert



For a conjunctive branch (e.g. "List"), we simply use the relation as the label of the converted node.

After converting an RST tree into the constituency tree format, we then replace each leaf node (i.e., EDU) with the corresponding syntactic (sub)tree from PTB. Given that the sentences in the RST Treebank (Marcu, 2000b) is a subset of that of PTB, we can always find the corresponding constituency subtrees for each EDU leaf node. In most cases, each EDU corresponds to one single (sub)tree in PTB, since the discourse boundaries generally do not conflict with constituencies. In other cases, one EDU node may correspond to multiple subtrees in PTB, and for these EDUs we use the lowest common ancestor of those subtrees in the PTB as the label of that EDU in the converted tree. E.g., if C–D is one EDU in the PTB tree  it might be converted to 
if the relation annonated in RST is B $\xrightarrow{\text{Purpose}}$ C–D.

Figures 1–2 are two examples of discourse trees and their combined syntacto-discourse trees.

2.3 Joint PTB-RST Treebank

Using the conversion strategy described above we build the first joint syntacto-discourse treebank based on the Penn Treebank and RST Treebank. This PTB-RST treebank is released as a set of tools to generate the joint trees given Penn Treebank and RST Treebank data. During the alignment between the RST trees and the PTB trees, we only keep the common parts of the two trees.

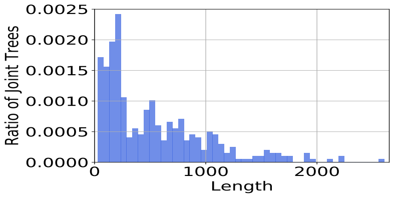


Figure 3: PTB-RST: length distribution (# tokens).

We follow the standard training/testing split of the RST Treebank. In the training set, there are 347 joint trees with a total of 17,837 tokens, and the lengths of the discourses range from 30 to 2,199 tokens. In the test set, there are 38 joint trees with a total of 4,819 tokens, and the lengths vary from 45 to 2,607. Figure 3 shows the distribution of the discourse lengths over the whole dataset, which on average is about 2x of PTB sentence length, but longest ones are about 10x the longest lengths in the Treebank.

3 Joint Syntacto-Discourse Parsing

Given the combined syntacto-discourse treebank, we now propose a joint parser that can perform end-to-end discourse segmentation and parsing.

3.1 Extending Span-based Parsing

As mentioned above, the input sequences are substantially longer than PTB parsing, so we choose linear-time parsing, by adapting a popular greedy constituency parser, the span-based constituency parser of Cross and Huang (2016).

As in span-based parsing, at each step, we maintain a a stack of spans. Notice that in conventional incremental parsing, the stack stores the subtrees

$$\begin{array}{ll}
\text{input} & w_0 \ldots w_{n-1} \\[6pt]
\text{axiom} & \langle\, {}_{-1}\triangle_0 \rangle\text{: } (0, \emptyset) \qquad \text{goal} \quad \langle\, {}_{-1}\triangle_0\triangle_n \rangle\text{: } (\_, t) \\[6pt]
\mathsf{sh} & \dfrac{\langle \ldots\, {}_i\triangle_j \rangle : (c, t)}{\langle \ldots\, {}_i\triangle_j \overset{j}{\triangle}_{j+1} \rangle : (c + sc_{\mathsf{sh}}(i, j), t)}\; j < n \\[12pt]
\mathsf{comb} & \dfrac{\langle \ldots\, {}_i\triangle_k\triangle_j \rangle : (c, t)}{\langle \ldots\, {}_i\overset{k}{\triangle}{}_j \rangle : (c + sc_{\mathsf{comb}}(i, k, j), t)} \\[12pt]
\mathsf{label}_X & \dfrac{\langle \ldots\, {}_i\overset{k}{\triangle}{}_j \rangle : (c, t)}{\langle \ldots\, {}_i\triangle_j \rangle : (c + sc_{\mathsf{label}_X}(i, k, j), t \cup \{{}_iX_j\})} \\[12pt]
\mathsf{nolabel} & \dfrac{\langle \ldots\, {}_i\overset{k}{\triangle}{}_j \rangle : (c, t)}{\langle \ldots\, {}_i\triangle_j \rangle : (c + sc_{\mathsf{nolabel}}(i, k, j), t)}
\end{array}$$

Figure 4: Deductive system for joint syntactic and discourse parsing. $sc_{\mathsf{sh}}(\cdot, \cdot)$, $sc_{\mathsf{comb}}(\cdot, \cdot, \cdot)$, $sc_{\mathsf{label}_X}(\cdot, \cdot, \cdot)$, and $sc_{\mathsf{nolabel}}(\cdot, \cdot, \cdot)$ are scoring functions evaluated in the neural network.

constructed so far, but in span-based constituency parsing, the stack only stores the boundaries of subtrees, which are just a list of indices $\ldots{}_i\triangle_k\triangle_j$. In other words, quite shockingly, no tree structure is represented anywhere in the parser. Please refer Cross and Huang (2016) for details.

Similar to span-based constituency parsing, we alternate between structural (either shift or combine) and label (label_X or nolabel) actions in an odd-even fashion. But different from Cross and Huang (2016), after a structural action, we choose to keep the last branching point k, i.e., ${}_i\overset{k}{\triangle}{}_j$ (mostly for combine, but also trivially for shift). This is because in our parsing mechanism, the discourse relation between two EDUs is actually determined after the previous combine action. We need to keep the splitting point to clearly find the spans of the two EDUs to determine their relations. This midpoint k disappears after a label action; therefore we can use the shape of the last span on the stack (whether it contains the split point, i.e., ${}_i\overset{k}{\triangle}{}_j$ or ${}_i\triangle_j$) to determine the parity of the step and thus no longer need to carry the step z in the state as in Cross and Huang (2016).

The nolabel action makes the binarization of the discourse/constituency tree unnecessary, because nolabel actually combines the top two spans on the stack σ into one span, but without annotating the new span a label. This greatly simplifies the preprocessing and post-processing efforts needed.

	Prec.	Recall	F1
Constituency	87.6	86.9	87.2
Discourse	46.5	40.2	43.0
Overall	83.5	81.6	82.5

Table 1: Accuracies on PTB-RST at constituency and discourse levels.

3.2 Recurrent Neural Models and Training

The scoring functions in the deductive system (Figure 4) are calculated by an underlying neural model, which is similar to the bi-directional LSTM model in Cross and Huang (2016) that evaluates based on span boundary features. Again, it is important to note that no discourse or syntactic tree structures are represented in the features.

During the decoding time, a document is firstl passed into a two-layer bi-directional LSTM model, then the outputs at each text position of the two layers of the bi-directional LSTMs are concatenated as the positional features. The spans at each parsing step can be represented as the feature vectors at the boundaries. The span features are then passed into fully connected networks with softmax to calculate the likelihood of performing the corresponding action or marking the corresponding label.

We use the "training with exploration" strategy (Goldberg and Nivre, 2013) and the dynamic oracle mechanism described in Cross and Huang (2016) to make sure the model can handle unseen parsing configurations properly.

4 Empirical Results

We use the treebank described in Section 2 for empirical evaluation. We randomly choose 30 documents from the training set as the development set.

We tune the hyperparameters of the neural model on the development set. For most of the hyperparameters we settle with the same values suggested by Cross and Huang (2016). To alleviate the overfitting problem for training on the relative small RST Treebank, we use a dropout of 0.5.

One particular hyperparameter is that we use a value β to balance the chances between training following the exploration (i.e., the best action chosen by the neural model) and following the correct path provided by the dynamic oracle. We find that $\beta = 0.8$, i.e., following the dynamic oracle with a probability of 0.8, achieves the best performance. One explanation for this high chance to follow the oracle is that, since our combined trees are signif-

Table 3: Experiments using gold segmentations. The column of "syntactic feats" shows how the syntactic features are calculated in the corresponding systems. Note that our parser predicts solely based on the span features from bi-directionaly LSTM, instead of any explicitly designed syntactic features.

icantly larger than the constituency trees in Penn Treebank, lower β makes the parsing easily divert into wrong trails that are difficult to learn from.

Since our parser essentially performs both constituency parsing task and discourse parsing task. We also evaluate the performances on sentence constituency level and discourse level separately. The result is shown in Table 1. Note that in constituency level, the accuracy is not directly comparable with the accuracy reported in Cross and Huang (2016), since: a) our parser is trained on a much smaller dataset (RST Treebank is about 1/6 of Penn Treebank); b) the parser is trained to optimize the discourse-level accuracy.

Table 2 shows that, in the perspective of end-to-end discourse parsing, our parser first outperforms the state-of-the-art segmentator of Bach et al. (2012), and furthermore, in end-to-end parsing, the superiority of our parser is more pronounced comparing to the previously best parser of Hernault et al. (2010).

On the other hand, the majority of the conventional discourse parsers are not end-to-end: they rely on gold EDU segmentations and pre-trained tools like Stanford parsers to generate features. We perform an experiment to compare the performance of our parser with them given the gold EDU segments (Table 3). Note that most of these parsers do not handle multi-branching discourse nodes and are trained and evaluated on binarized discourse trees (Feng and Hirst, 2014; Li et al., 2014a,b; Ji and Eisenstein, 2014; Heilman and Sagae, 2015), so their performances are actually not directly comparable to the results we reported.

5 Conclusion

We have presented a neural-based incremental parser that can jointly parse at both constituency and discourse levels. To our best knowledge, this is the first end-to-end parser for discourse parsing task. Our parser achieves the state-of-the-art performance in end-to-end parsing, and unlike previous approaches, needs little pre-processing effort.

Event Coreference Resolution by Iteratively Unfolding Inter-dependencies among Events

Abstract

We introduce a novel iterative approach for event coreference resolution that gradually builds event clusters by exploiting inter-dependencies among event mentions within the same chain as well as across event chains. Among event mentions in the same chain, we distinguish within- and cross-document event coreference links by using two distinct pairwise classifiers, trained separately to capture differences in feature distributions of within- and cross-document event clusters. Our event coreference approach alternates between WD and CD clustering and combines arguments from both event clusters after every merge, continuing till no more merge can be made. And then it performs further merging between event chains that are both closely related to a set of other chains of events. Experiments on the ECB+ corpus show that our model outperforms state-of-the-art methods in joint task of WD and CD event coreference resolution.

1 Introduction

Event coreference resolution is the task of identifying event mentions and clustering them such that each cluster represents a unique real world event. The capability of resolving links among coreferring event identities is vital for information aggregation and many NLP applications, including topic detection and tracking, information extraction, question answering and text summarization (Humphreys et al., 1997; Allan et al., 1998; Daniel et al., 2003; Narayanan and Harabagiu, 2004; Mayfield et al., 2009; Zhang et al., 2015). Yet, studies on event coreference are few compared to the well-studied entity coreference resolution.

Event mentions that refer to the same event can occur both within a document (WD) and across multiple documents (CD). One common practice (Lee et al., 2012) to approach CD coreference task is to resolve event coreference in a mega-document created by concatenating topic-relevant documents, which essentially does not distinguish WD and CD event links.

However, intuitively, recognizing CD coreferent event pairs requires stricter evidence compared to WD event linking because it is riskier to link two event mentions from two distinct documents rather than the same document. In a perfect scenario where all WD event mentions are properly clustered and their participants and arguments are combined within a cluster, CD clustering can be performed with ease as sufficient evidences are collected through initial WD clustering. Therefore, another very common practice for event coreference is to first group event mentions within a document and then group WD clusters across documents (Yang et al., 2015).

Nonetheless, WD coreference chains are equally hard to resolve. Event mentions in the same document can look very dissimilar (”killed/ VB” and ”murder/ NN”), have event arguments (i.e., participants and spatio-temporal information of an event (Bejan and Harabagiu, 2010)) partially or entirely omitted, or appear in distinct contexts compared to their antecedent event mentions, partially to avoid repetitions. Under this irresolute state, approaching WD and CD individually is incompetent.

While CD coreference resolution is overall difficult, we observe that some CD coreferent event mentions, especially the ones that appear at the beginning of documents, share sufficient contexts and are relatively easier to resolve. At the same

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2124–2133
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

time, many of them bear sufficient differences that can bring in new information and further lead to more WD merges and consequently more CD merges.

Guided by these observations, we present an event coreference approach that exploits interdependencies among event mentions within an event chain both within a document and across documents, by sequentially applying WD and CD merges in an alternating manner until no more merge can be made. We combine argument features of event mentions after each CD (WD) merge in order to resolve more difficult WD (CD) merges in the following iterations. Furthermore, our model uses two distinct pairwise classifiers that are separately trained with features intrinsic to each type. Specifically, the WD classifier uses features based on event mentions and their arguments while the CD classifier relies on features characterizing surrounding contexts of event mentions as well.

We further exploit second-order interdependencies across event clusters in order to resolve additional WD and CD coreferent event pairs. Intuitively, if two event mentions are related to the same set of events, it is likely that the two event mentions refer to the same real world event, even when their word forms and local contexts are distinct. Specifically, we merge event clusters if their event mentions are tightly associated (i.e., having the same dependency relations) or loosely associated (i.e., co-occurring in the same sentential context) with enough (i.e., passing a threshold) other events that are known coreferent.

Experimental results on the benchmark event coreference dataset, ECB+ (Cybulska and Vossen, 2014b,a), show that our model extensively exploits inter-dependencies between events and outperforms the state-of-the-art methods for both WD and CD event coreference resolution.

2 Related Work

Different approaches, focusing on either of WD or CD coreference chains, have been proposed for event coreference resolution. Works specific to WD event coreference includes pairwise classifiers (Ahn, 2006; Chen et al., 2009) graph based clustering method (Chen and Ji, 2009), information propagation (Liu et al., 2014), and markov logic networks Lu et al. (2016). As to only CD event coreference, Cybulska and Vossen (2015a) created pairwise classifiers using features indicating granularities of event slots and in another work (2015b), grouped events based on compatibilities of event contexts.

Like this work, several studies have considered both WD and CD event coreference resolution task together. However to simplify the problem, they (Lee et al., 2012; Bejan and Harabagiu, 2010, 2014) created a meta-document by concatenating topic-relevant documents and treated both as an identical task. Most recently, Yang et al. (2015) applied a two-level clustering model that first groups event mentions within a document and then groups WD clusters across documents in a joint inference process. Our approach advances these works and emphasizes on different natures of WD and CD clusters along with the benefits of distinguishing WD merges from CD merges and exploiting their mutual dependencies.

Iterative models, in general, have been applied to both entity coreference resolution (Singh et al., 2009; Clark and Manning, 2015, 2016; Wiseman et al., 2016) and prior event coreference resolution (Lee et al., 2012) works, which gradually build clusters and enable later merges to benefit from earlier ones. Especially, Lee et al. (2012) used an iterative model to jointly build entity and event clusters and showed the advantages of information flow between entity and event clusters through semantic role features. Our model, by alternating between WD and CD merges, allows the multi-level flow of first order interdependencies. Moreover, additional cross cluster merges based on 2nd order interdependencies effectively exploits the semantic relations among events, in contrast to only semantic roles (between events and arguments) used in previous work.

3 System Overview and A Worked Example

Inter-dependencies among event mentions can be effectively exploited by conducting sequential WD and CD merges in an iterative manner. In addition, recognizing second order relations between event chains relies on adequate number of event mentions that are already linked. Therefore, our model conducts event coreference in two stages. In the first stage, it iteratively conducts WD and CD merges as suggested by pairwise WD and CD merging classifiers respectively. Argument features of individual event mentions are propagated

[S2] A shocking video presented for the first time in court hearing captures the moment Horton, a Brooklyn mother of 12 was murdered in a gang shooting.

[D2]

[S1] Gangbangers who allegedly killed mom of 12 in shootout begin trial.

[S2] Prosecutors presented the tragic footage at the trial of the two youths charged with murdering Horton.

Figure 1: An example of Event Coreference using the iterative two stage model. All event mentions are boldfaced; solid arrow line between event mentions show second order relations between them; dashed lines link coreferent event mentions and are tagged with the type of merge.

within a cluster after each merge operation. In the second stage, it explores second order relations across event clusters w.r.t context event mentions in order to carefully generate candidate event clusters and perform further merging.

The example in Figure 1 illustrates the two stages of our proposed approach. It shows two iterations of WD and CD merges. In iteration 1, relatively easy coreferent event mentions were linked, including the two *shooting* and two *trial* event mentions in doc_1 and doc_2 as well as the event mentions *presented*, *trial* and *murder* across the two documents. Argument propagation was conducted after each merge and *murder*'s argument "mother of 12" in doc_1 is combined with the *murder* event in doc_2 after iteration 1. Then in iteration 2, more merges were made by recognizing additional coreferent event mentions including event mentions in one document (e.g., *murdering* and *killed* in doc_2) and event mentions across the two documents (e.g., *shooting* in doc_1 and shootout in doc_2). Next, two additional merges were made by leveraging second-order inter-dependencies. Specifically, both the event mentions *released* in doc_1 and *presented* in doc_2 are in the same dependency relation ("nmod") with a mention of the *trial* event cluster, therefore, a new merge was made between clusters containing the two mentions. Following this, the event mentions *court hearing* in doc_1 and *trial* in doc_2 were identified to have multiple coreferent events in their sentential contexts, therefore, the clusters containing these two event mentions were merged as well.

4 Detailed System Description: Exploiting Interdependencies between Events

4.1 Document Clustering

Our approach starts with a pre-processing step that clusters input documents ($\mathcal{D}$) into a set of document clusters ($\mathcal{C}$). This is meant to reduce search space and mitigate errors (Lee et al., 2012). In our experiments, we used the Affinity Propagation algorithm (Buitinck et al., 2013) on $tf - idf$ vectors, where terms are only proper nouns and verbs (excludes reporting and auxiliary verbs) in the document. While it is interesting to understand the influences of wrong document clusters to event coreference, this algorithm yielded perfect document clusters on the benchmark ECB+

dataset (Cybulska and Vossen, 2014b,a). This is consistent with the prior study (Lee et al., 2012) on the related ECB dataset (Bejan and Harabagiu, 2010) [1], which shows that document clustering in the ECB dataset is trivial.

```
Algorithm 1:
  input: set of Documents $\mathcal{D}$
         Within-Document Classifier: $\Theta_{\mathcal{WD}}$
         Cross-Document Classifier: $\Theta_{\mathcal{CD}}$
  // clusters of event mentions
1  $\mathcal{EM} = \{\}$
  // clusters of Documents
2  $\mathcal{C}$ = ClusterDocument($\mathcal{D}$)
3  for each document cluster $c$ in $\mathcal{C}$ do
4    $\mathcal{EM}' = \{$Singleton Clusters$\}$
     // Iterative WD and CD Merging
6    while $iterate$ do
7      $iterate$ = False
8      for each two clusters $E_1, E_2 \in \mathcal{EM}'$ s.t. $\exists e_1 \in E_1, e_2 \in E_2$, $(e_1, e_2) \in$ a Doc, and score$(\Theta_{\mathcal{WD}}, e_1, e_2) > 0.60$ do
9          Merge$(E_1, E_2, \mathcal{EM}')$
10         $iterate$ = True
11     if not $iterate$ break
12     $iterate$ = False
13     for each two clusters $E_1, E_2 \in \mathcal{EM}'$ s.t. $\exists e_1 \in E_1, e_2 \in E_2$, $(e_1, e_2) \notin$ a Doc, and score$(\Theta_{\mathcal{CD}}, e_1, e_2) > 0.90$ do
14         Merge$(E_1, E_2, \mathcal{EM}')$
15         $iterate$ = True
   // Exploiting Second-Order Inter-dependencies Across Event Chains
16   while $\exists$ two clusters $E_1, E_2 \in \mathcal{EM}'$ s.t. GovernorModifierRelated$(E_1, E_2, \Theta_{\mathcal{CD}})$ do
17     $\mathcal{EM}'$ = Merge$(E_1, E_2, \mathcal{EM}')$
18   while $\exists$ two clusters $E_1, E_2 \in \mathcal{EM}'$ s.t. ContextSimilarity$(E_1, E_2, \Theta_{\mathcal{CD}})$ do
19     $\mathcal{EM}'$ = Merge$(E_1, E_2, \mathcal{EM}')$
20   $\mathcal{EM} = \mathcal{EM} + \mathcal{EM}'$
21 output: $\mathcal{EM}$
```

4.2 Iterative WD and CD Merging

We iteratively conduct WD merges and CD merges until no more merge can be done. We train pairwise classifiers for identifying event clusters to merge. Specifically for WD merges as indicated in lines 8-10 in Algorithm 1, we iteratively go through pairs of clusters that contain a pair of within-document event mentions, one mention from each cluster. If the similarity score between the two event mentions is above a tuned threshold of 0.6 [2], we merge the two clusters. Similarly, for CD merges described in lines 13-15 of Algorithm 1, we iteratively go through pairs of clusters that contain a pair of cross-document event mentions and merge the two clusters if the similarity score between the two event mentions is above another tuned threshold of 0.9 [3]. Following each cluster pair merge, arguments are combined for the two merged clusters.

4.3 Merging by Exploiting Second-Order Inter-dependencies Across Event Chains

Intuitively, two event mentions that share events in their contexts are likely to be coreferent. Similarly, if their context events are coreferent, the two events are likely to be coreferent as well.

First, if two event mentions are in the same dependency relation with two other event mentions that are known coreferent, then the first two event mentions are likely to describe the same real world event as well. In steps 16-17 of Algorithm 1, we perform event cluster merges by collecting evidence pertaining to dependency relations. The subroutine $GovernorModifierRelated$ $(E_1, E_2, \Theta_{\mathcal{CD}})$ checks whether two event mentions e_1 and e_2, from clusters E_1 and E_2 respectively, have a related event e_3 from another cluster E_3, such that $E_3 \notin \{E_1, E_2\}$ and pairs $(e_1, e_3), (e_2, e_3)$ are linked with the same dependency relation. Note that observing shared event mentions in the contexts will increase the likelihood that the two event mentions are coreferent, but we can not sufficiently infer the coreference relation yet, we still need to look at features describing the event mentions. Therefore, if the condition was satisfied, the subroutine eventually makes merges based on the CD confidence score assigned to the event pair (e_1, e_2) but using a lower threshold of 0.8.

In addition, seeing coreferent event mentions in the sentential contexts of two events will increase the likelihood that the two events are coreferent as well. Then as shown in steps 18-19, we fur-

[1] The ECB+ dataset is an extended version of the ECB dataset. Both datasets have documents for the same 43 topics.

[2] all tunings are performed on Validation dataset (topics 23-25)

[3] Note that these high threshold for WD- and CD- classifiers are meant to retain high precision and avoid error propagation in subsequent stages. Output from each classifier is a number bounded in [0,1].

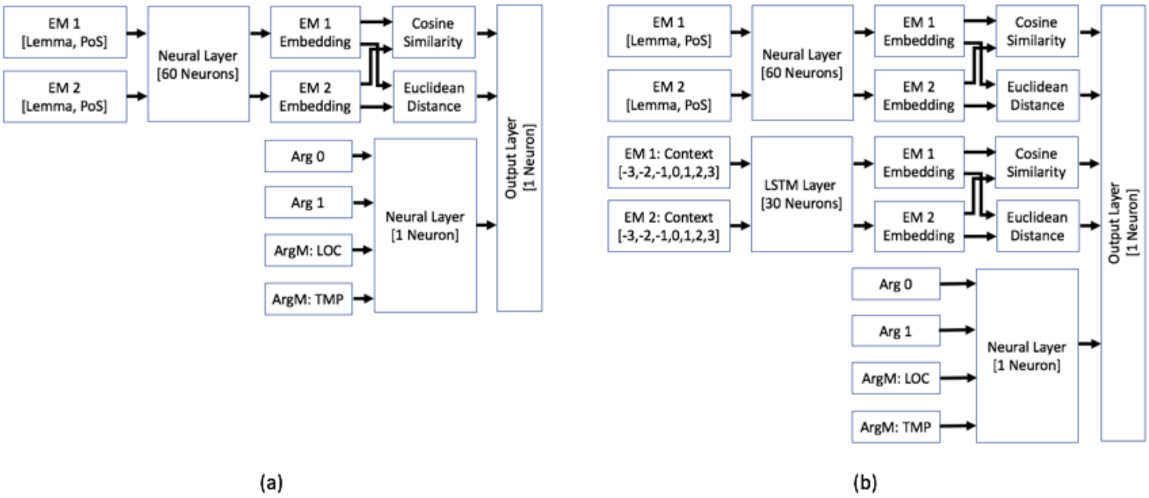

Figure 2: Pairwise Classifiers for resolving (a) Within-Document Coreference Links (b) Cross-Document Coreference Links. *EM*: event mentions; *Arg0, Arg1, ArgM:LOC, ArgM:TMP*: semantic roles.

ther use context events co-occurring in the same sentence as another parameter to perform additional clustering. Subroutine $ContextSimilarity$ $(E_1, E_2, \Theta_{\mathcal{CD}})$ generates a context vector ($\mathcal{CV}$) for each event cluster and check whether cosine similarity between context vectors of two clusters E_1 and E_2 $(cos(\vec{\mathcal{CV}}^1, \vec{\mathcal{CV}}^2))$ is above 0.7. Specifically, we define *context clusters* for an event mention as the different event clusters that have event mentions co-occurring in the same sentence. Then the context vector of an event cluster has an entry for each of its context clusters, with the value to be the number of sentences where event mentions from the two clusters co-occur. This subroutine also makes merges based on the CD confidence score using the same lower threshold of 0.8.

5 Distinguishing WD and CD Merging

We implement two distinct pairwise classifiers to effectively utilize the distributional variations in WD and CD clusters. The first classifier (WD) is used for calculating a similarity between two event mentions within a document and recognizing coreferent event mention pairs. The second classifier (CD) is used for calculating a similarity between two event mentions across two documents and then identifying coreferent event mention pairs across documents. Both classifiers were implemented as neural nets (Chollet, 2015). The architectures of the two classifiers are shown in Figure 2.

WD Classifier: the neural network based WD classifier essentially inherits the features that have been shown effective in previous event coreference studies (Ahn, 2006; Chen et al., 2009), including both features for event words and features for their arguments. Specifically, the classifier includes a common neural layer shared by two event mentions to embed event lemma and parts-of-speech features. Then the classifier calculates cosine similarity and euclidean distance between two event embeddings, one per event mention. In addition, the classifier includes a neural layer component to embed event arguments that are overlapped between the two event mentions. Its output layer takes the calculated cosine similarity and euclidean distance between event mention embeddings as well as the embedding of the overlapped event arguments as input, and output a confidence score to indicate the similarity of the two event mentions.

CD Classifier: the CD classifier mimics the WD classifier except that the CD classifier contains an additional LSTM layer (Hochreiter and Schmidhuber, 1997) to embed context words. The LSTM layer is shared by both event mentions in order to calculate context word embeddings for both event mentions. Specifically, three words to each side of an event word together with the event word itself are used to calculate the context embedding for each event mention. The classifier then calculates cosine similarity and euclidean distance between two context embeddings as well. The output neural net layer will take two sets of cosine similarity and euclidean distance scores that have been calculated w.r.t. context embeddings and event word embeddings, as well as the embedding of the overlapped event arguments as input, and further calculate a confidence score indicating the similarity of two event mentions across documents.

5.1 Characteristics of WD and CD Event Linking

In order to further understand characteristics of within- and cross-document event linking, we trained two classifiers having the same CD classifier architecture (Figure 2(b)) but with different sets of event pairs, within-document or cross-document event pairs, then analyzed the impacts of features on each type of event linking by comparing the neural net learned weights for each feature. Table 1 shows the comparisons of feature weights.

Features	**WD**	**CD**
Event Word Embedding: Euc	1.017	0.207
Event Word Embedding: Cos	1.086	1.142
Context Embedding: Euc	0.038	0.422
Context Embedding: Cos	0.004	3.910
Argument Embedding	0.349	3.270

Table 1: Comparisons of Feature Weights Learned Using In-doc or Cross-doc Coreferent Event Pairs, Euc: Euclidean Distance, Cos: Cosine Similarity

We can see that within-document event linking mainly relies on the euclidean distance and cosine similarity scores calculated using event word features, with a reasonable amount of weight assigned to overlapped arguments' embedding as well. However, only very small weights were assigned to the similarity and distance scores calculated using context embeddings. In contrast, in the classifier trained with cross-doc coreferent event mention pairs, the highest weight was assigned to the cosine similarity score calculated using context embeddings of two event mentions. Additionally, both the cosine similarity score calculated using event word embeddings and the overlapped argument features were assigned high weights as well. The comparisons clearly demonstrate the significantly different nature of WD and CD event coreference.

5.2 Neural Net Classifiers and Training

In both WD and CD classifiers, we use neural network layer with 60 neurons for embedding event word features and another layer with 1 neuron for embedding argument features. Additionally, in CD classifier, we use an LSTM layer with 30 neurons to embed context features. Dropout of 0.25 was applied to both the event word neural net layer and the context layer. We used sigmoid activation function for the dense layers and tanh activation for the LSTM layer. We used 300-dimensional word embeddings and one hot 37[4] dimensional pos tag embeddings in all our experiments. Therefore, input to word embedding layer is a 337-dimensional vector and to LSTM layer is 300*7 dimensional vectors.

We train both classifiers using the ECB+ corpus (Cybulska and Vossen, 2014b,a). We train the WD classifier using all pairs of WD event mentions that are in an annotated event chain as positive instances and using all pairs of WD event mentions that are not in an annotated event chain as negative instances. However, there are significantly more CD coreferent event mention pairs annotated in the ECB+ corpus, therefore, we randomly sampled 70% of all the CD coreferent event mention pairs as positive instances and randomly sampled from non-coreferent CD event mention pairs as negative instances. Specifically, number of negative instances are kept 5 times of positive instances.

Note that the pairwise classifiers will be used throughout the iterative merging stage. However, after each merge, argument propagation is conducted to enrich features for each event mention in the merged cluster and the number of arguments of an event mention will grow after several merges. In order to account for the growing number of arguments in iterative merging, we augment arguments for each event mention in training instances with arguments derived from other event mentions in the same pair. The augmenting was performed randomly for only 50% of event mentions.

6 Evaluation

We perform all the experiments on the ECB+ corpus (Cybulska and Vossen, 2014b,a), which is an extension to the earlier EventCorefBank (ECB) (Bejan and Harabagiu, 2010) dataset. We have adopted the settings used in Yang et al. (2015). We divide the dataset into training set (topics 1-20), validation set (topics 21-23) and test

[4] Corresponding to the unique 36 POS tags based on the Stanford POS tagger (Toutanova et al., 2003) and an additional 'padding'.

set (topics 24-43). Table 2 shows the distribution of the corpus.

	Train	**Dev**	**Test**	**Total**
#Documents	462	73	447	982
#Sentences	7,294	649	7,867	15,810
#Event Mentions	3,555	441	3,290	7,286
#CD Chains	687	47	486	1,220
#WD Chains	2,499	316	2,137	4,952
Avg. WD chain length	2.835	2.589	2.553	2.686
Avg. CD chain length	5.17	9.39	6.77	5.98

Table 2: ECB+ Corpus Statistics.

We used event mentions identified by CRF based event extractor used in Yang et al. (2015) and extracted event arguments by applying state-of-the-art semantic role labeling system (SwiRL (Surdeanu et al., 2007)). In addition, we used the Stanford parser (Chen and Manning, 2014) for generating dependency relations, parts-of-speech tags and lemmas. We use pre-trained Glove vectors (Pennington et al., 2014)[5] for word representation and one-hot vectors for parts-of-speech tags.

We evaluate our model using four commonly adopted event coreference evaluation metrics, namely, **MUC** (Vilain et al., 1995), $\mathbf{B^3}$ (Bagga and Baldwin, 1998), $\mathbf{CEAF_e}$ (Luo, 2005) and **CoNLL F1** (Pradhan et al., 2014). We used the publicly available official implementation of revised coreference scorer (**v8.01**).[6]

6.1 Baseline Systems

We compare our iterative event coreference resolution model with five baseline systems.

LEMMA: The Lemma match baseline links event mentions within- or cross- documents which have the same lemmatized head word. It is often considered a strong baseline for this task.

HDDCRP (Yang et al., 2015): The second baseline is the supervised Hierarchical Distance Dependent Bayesian Model, the most recent event coreference system evaluated on the same ECB+ dataset. This model uses distances between event mentions, generated using a feature-rich learnable distance function, as Bayesian priors for single pass non-parametric clustering.

HDP-LEX[7]: A reimplementation of the unsupervised hierarchical bayesian model by Bejan and Harabagiu (2010, 2014).

Agglomerative[7]: A Reimplementation of two-step agglomerative clustering model, WD clustering followed by CD clustering (Chen et al., 2009).

We have trained our systems using the same ECB+ dataset and the same set of event mentions as these prior systems.

6.2 Our Systems

We evaluate several variation systems of our proposed model.

Common Classifier (WD or CD): the system implementing only the first stage of iterative WD & CD merging. In addition, the same neural net classifier with the architecture as shown in Figure 2(a) (the WD classifier) or in Figure 2(b) (the CD classifier) was applied for both WD and CD merging. The neural net classifiers were trained using all coreferent event mention pairs including both within-document and cross-document ones.

WD and CD Classifiers: distinguishes WD from CD merges by using two distinct classifiers (Figure 2(a), 2(b)) in the first stage of the algorithm.

+ 2nd Order Relations: after iterative WD and CD merges within each individual chain as suggested by pairwise classifiers (the first stage), further merges (the second stage) were conducted leveraging second order event inter-dependencies across event chains.

6.3 Results

Table 3 shows the comparison results for both within-document and cross-document event coreference resolution. In the first stage of iterative merging, using two distinct WD and CD classifiers for corresponding WD and CD merges yields clear improvements for both WD and CD event coreference resolution tasks, compared with using one common classifier for both types of merges. In addition, the second stage of iterative merging further improves both WD and CD event coreference resolution performance stably by leveraging second order event inter-dependencies. The improvements are consistent when measured using various coreference resolution evaluation metrics.

Our full model achieved more than 8% of improvements when compared with the lemma matching baseline, using the CoNLL F1-score for both WD and CD coreference resolution tasks. Furthermore, it outperforms state-of-the-art HDDCRP model for both WD and CD event coreference resolution by 2.1% and 4.9% respectively.

7 Discussion and Analysis

Cross-Document Coreference Results				
$F_{measure}$	B^3	MUC	$CEAFE_e$	CoNLL
1 Iteration	56	69.3	50.3	58.5
2 Iterations	57.9	69.9	52.4	60.1
3 Iterations	58.3	70.6	53.1	60.7
Within-Document Coreference Results				
1 Iteration	69.7	55.8	68.8	64.8
2 Iterations	70.2	60.3	69.4	66.6
3 Iterations	70.9	61.2	69.5	67.2

Table 4: Per-iteration Performance Analysis for the First Stage of Iterative WD & CD Merging.

Stage I: The first stage of our algorithm, iterative WD and CD merging, went for three iterations (See Table 4). Our analysis of merges in each iteration shows that most of the merges in the initial iteration are between event mentions with the same lemma or shared arguments. In the second and third iterations, more merges were between event mentions with synonymous lemmas or shared arguments that have been accumulated in previous iterations. Example merges between synonymous event mentions include *(nominate, nominations)*, *(die, death)*, *(murder, killing)*, *(hit, strike)*, *(attack, bomb)* etc.

Stage II: It is even more intriguing to discuss the clusters that were merged in stage 2 of merging, that leverages second order event interdependencies across event chains. We found that almost all of the 81 merges happening in the second stage are between event mentions that are quite dissimilar including *(take over, replace)*, *(unveil, announce)*, *(win, victory, comeback)*, *(downtime, problem, outage)*, *(cut, damage)*, *(spark, trigger)* etc. Most interestingly, two event pairs which are antonymous to each other, *(win, beat)* and *(defeat, victory)*, were also correctly merged.

Errors: while our iterative algorithm has gradually resolved coreference relations between event mentions that are synonyms or distant by surface forms, many coreference links were overlooked and many unrelated events were wrongly predicted as coreferential. We analyzed our system's final predictions in order to identify the most common sources of errors.

Missed Coreference Links: We found that many event mentions have few or no argument in their local context, and our event coreference resolution system often failed to link these event mentions with their coreferential mentions. For instance, in the following event mention pairs that were overlooked by the system, *(operations, raids), (operations, sweep), (suicide, hang), (prosecution, jail), and (participating, role)*, one or both event mentions do not have an argument in their local context. This is mainly because the base WD and CD classifiers heavily rely on features extracted from the local context of two event mentions, including event words and event arguments, in resolving the coreference relation. For these event mentions having few arguments identified, the iterative algorithm may get stuck from the beginning.

While it is a grand challenge to further resolve coreferential relations between event mentions that do not have sufficient local features, these missed coreference links easily break a long and influential event chain into several sub-chains, which makes event coreference resolution results less useful for many potential applications, such as text summarization.

Wrongly Predicted Coreference Links: The majority of this type of errors are between non-coreferent event mentions that have the same lemma. This is especially common among reporting event mentions and light verb mentions. For instance, we found that 24 non-coreferent event clusters corresponding to reporting events, e.g., *said, told* and *reported*, and 13 non-coreferent clusters corresponding to light verbs, e.g., *take, give* and *get*, were incorrectly merged by the system.

8 Conclusions and Future Work

We presented a novel approach for event coreference resolution that extensively exploits event inter-dependencies between event mentions in the same chain and event mentions across chains. The approach iteratively conducts WD and CD merges followed by further merges leveraging second order event inter-dependencies across chains. We further distinguish WD and CD merges using two distinct classifiers that capture differences of within- and cross-document event clusters in feature distributions. Our system was shown effective in both WD and CD event coreference and has outperformed the previous best event coreference system in both tasks.

Note that our approach is flexible to incorporate different strategies for conducting WD and CD merges. In the future, we plan to continue to investigate the distinct characteristics of WD and CD coreferent event mentions in order to further improve event coreference performance. Especially, we are interested in including additional discourse-level features for improving WD coreference merge performance, such as, features indicating the distance between two event mentions in a document.

When to Finish? Optimal Beam Search for Neural Text Generation (modulo beam size)

Abstract

In neural text generation such as neural machine translation, summarization, and image captioning, beam search is widely used to improve the output text quality. However, in the neural generation setting, hypotheses can finish in different steps, which makes it difficult to decide when to end beam search to ensure optimality. We propose a provably optimal beam search algorithm that will always return the optimal-score complete hypothesis (modulo beam size), and finish as soon as the optimality is established (finishing no later than the baseline). To counter neural generation's tendency for shorter hypotheses, we also introduce a bounded length reward mechanism which allows a modified version of our beam search algorithm to remain optimal. Experiments on neural machine translation demonstrate that our principled beam search algorithm leads to improvement in BLEU score over previously proposed alternatives.

1 Introduction

In recent years, neural text generation using recurrent networks have witnessed rapid progress, quickly becoming the state-of-the-art paradigms in machine translation (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2014), summarization (Rush et al., 2015; Ranzato et al., 2016), and image captioning (Vinyals et al., 2015; Xu et al., 2015). In the decoder of neural generation, beam search is widely employed to boost the output text quality, often leading to substantial improvement over greedy search (equivalent to beam size 1) in metrics such as BLEU or ROUGE; for example, Ranzato et al. (2016) reported +2.2 BLEU (on single reference) in translation and +3.5 ROUGE-2 in summarization, both using a beam of 10. Our own experiments on machine translation (see Sec. 5) show +4.2 BLEU (on four references) using a beam of 5.

However, unlike traditional beam search in phrase-based MT or shift-reduce parsing where all hypotheses finish in the same number of steps, here in neural generation, hypotheses can finish in vastly different numbers of steps. Once you find a completed hypothesis (by generating the </s> symbol), there are still other active hypotheses in the beam that can continue to grow, which might lead to better scores. Therefore when can you end the beam search? How (and when) can you guarantee that the returned hypothesis has the optimal score modulo beam size?

There have not been satisfying answers to these questions, and existing beam search strategies are heuristic methods that do not guarantee optimality. For example, the widely influential RNNsearch (Bahdanau et al., 2014) employs a "shrinking beam" method: once a completed hypothesis is found, beam size shrinks by 1, and beam search would finish if beam size shrinks to 0 or if the number of steps hits a hard limit. The best scoring completed hypothesis among all completed ones encountered so far is returned. On the other hand, OpenNMT (Klein et al., 2017), whose PyTorch version will be the baseline in our experiments, uses a very different strategy: beam search terminates whenever the highest-ranking hypothesis in the current step is completed (which is also the one returned), without considering any other completed hypotheses. Neither of these two methods guarantee optimality of the returned hypothesis.

We therefore propose a novel and simple beam search variant that will always return the optimal-score complete hypothesis (modulo beam size), and finish as soon as the optimality is established.

Copenhagen, Denmark, September 7–11, 2017.

However, another well-known problem remains, that the generated sentences are often too short, compared to previous paradigms such as SMT (Shen et al., 2016). To alleviate this problem, previous efforts introduce length normalization (as a switch in RNNsearch) or length reward (He et al., 2016) borrowed from SMT (Koehn et al., 2007). Unfortunately these changes will invalidate the optimal property of our proposed algorithm. So we introduce a *bounded* length reward mechanism which allows a modified version of our beam search algorithm to remain optimal. Experiments on neural machine translation demonstrate that our principled beam search algorithm leads to improvement in BLEU score over previously proposed alternatives.

2 Neural Generation and Beam Search

Here we briefly review neural text generation and then review existing beam search algorithms.

Assume the input sentence, document, or image is embedded into a vector $\mathbf{x}$, from which we generate the output sentence $\mathbf{y}$ which is a *completed* hypothesis:[1]

$$\begin{aligned}\mathbf{y}^* &= \mathop{\mathbf{argmax}}_{\mathbf{y}:comp(\mathbf{y})} p(\mathbf{y} \mid \mathbf{x}) \\ &= \mathop{\mathbf{argmax}}_{\mathbf{y}:comp(\mathbf{y})} \prod_{i \le |\mathbf{y}|} p(y_i \mid \mathbf{x}, \mathbf{y}_{<i})\end{aligned}$$

where $\mathbf{y}_{<i}$ is a popular shorthand notation for the prefix $y_0 y_1 ... y_{i-1}$. We say that a hypothesis $\mathbf{y}$ is **completed**, notated $comp(\mathbf{y})$, if its last word is `</s>`, i.e.,

$$comp(\mathbf{y}) \triangleq (\mathbf{y}_{|\mathbf{y}|} = \texttt{</s>})$$

in which case it will not be further expanded.

A crucial difference in RNN-based neural generation compared to previous paradigms such as phrase-based MT is that we no longer decompose $p(y_i \mid \mathbf{x}, \mathbf{y}_{<i})$ into the translation model, $p(y_i \mid \mathbf{x})$, and the language model, $p(y_i \mid \mathbf{y}_{<i})$, and more importantly, we no longer approximate the latter by n-gram models. This ability to model arbitrarily-lengthed history using RNNs is an important reason for NMT's substantially improved fluency compared to SMT.

To (approximately) search for the best output $\mathbf{y}^*$, we use beam search, where the beam B_i at step i is an *ordered* list of size (at most) b, and expands to the next beam B_{i+1} of the same size:

$$B_0 = [\langle \texttt{<s>},\ p(\texttt{<s>} \mid \mathbf{x})\rangle]$$

$$B_i = \overset{b}{\mathbf{top}}\{\langle \mathbf{y}' \circ y_i,\ s \cdot p(y_i | \mathbf{x}, \mathbf{y})\rangle \mid \langle \mathbf{y}', s\rangle \in B_{i-1}\}$$

where the notation $\mathbf{top}^b\, S$ selects the top b scoring items from the set S, and each item is a pair $\langle \mathbf{y}, s\rangle$ where $\mathbf{y}$ is the current prefix and s is its accumulated score (i.e., product of probabilities).

3 Optimal Beam Search (modulo beam size)

We propose a very simple method to optimally finish beam search, which guarantees the returned hypothesis is the highest-scoring completed hypothesis modulo beam size; in other words, we will finish as soon as an "optimality certificate" can be established that future hypotheses will never score better than the current best one.

Let $best_{\le i}$ be the *best completed hypothesis so far* up to step i, i.e.,

$$best_{\le i} \triangleq \max\{\mathbf{y} \in \cup_{j \le i} B_j \mid comp(\mathbf{y})\} \quad (1)$$

We update it every time we find a completed hypothesis (if there is none yet, then it remains undefined). Now at any step i, if $best_{\le i}$ is defined, and the highest scoring item $B_{i,1}$ in the current beam B_i scores worse than or equal to $best_{\le i}$, i.e., when

$$B_{i,1} \le best_{\le i} \quad (2)$$

we claim the optimality certificate is established, and terminate beam search, returning $best_{\le i}$ (here smaller means worse, since we aim for the highest-probability completed hypothesis).

Theorem 1 (optimality)**.** *When our beam search algorithm terminates, the current best completed hypothesis (i.e., $best_{\le i}$) is the highest-probability completed hypothesis (modulo beam size).*

Proof. If $B_{i,1} \le best_{\le i}$ then $B_{i,j} \le B_{i,1} \le best_{\le i}$ for all items $B_{i,j}$ in beam B_i. Future descendants grown from these items will only be no better, since probability ≤ 1, so all items in current and future steps are no better than $best_{\le i}$. □

Theorem 2 (early stopping)**.** *Our beam search algorithm terminates no later than OpenNMT's termination criteria (when $B_{i,1}$ is completed).*

Proof. When $B_{i,1}$ is itself completed, $best_{\le i} = \max\{B_{i,1}, \cdots\} \ge B_{i,1}$, so our stopping criteria is also met. □

[1] For simplicity reasons we do not discuss bidirectional LSTMs and attentional mechanisms here but our algorithms still work with those encoders (we have tested them).

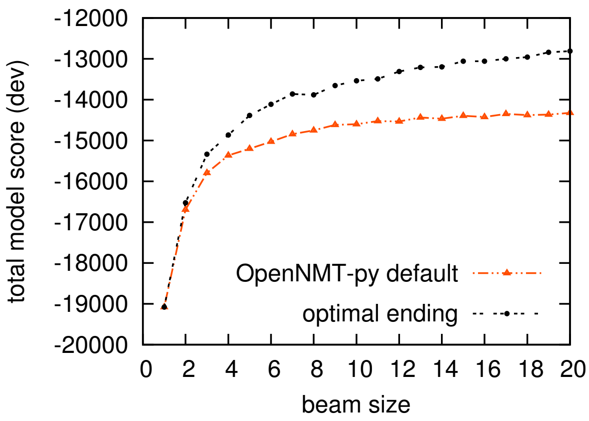

Figure 1: Comparison between optimal beam search and OpenNMT-py's default search, in terms of search quality (model score, ↑ is better).

This above Theorem shows that our search is stopping earlier once the optimality certificate is established, exploring fewer items than OpenNMT's default search. Also note that the latter, even though exploring more items than ours, still can return suboptimal solutions; e.g., when $B_{i,1}$ is worst than $best_{\leq i}$ (they never stored $best_{\leq i}$). In practice, we noticed our search finishes about 3–5 steps earlier than OpenNMT at a beam of 10, and this advantage widens as beam size increases, although the overall speedup is not too noticeable, given the target language sentence length is much longer. Also, our model scores (i.e., log-probabilities) are indeed better (see Fig. 1), where the advantage is also more pronounced with larger beams (note that OpenNMT baseline is almost flat after $b = 10$, while our optimal beam search still steadily improves). Combining these two Theorems, it is interesting to note that our method is not just optimal but also faster.

4 Optimal Beam Search for Bounded Length Reward

However, optimal-score hypothesis, though satisfying in theory, is not ideal in practice, since neural models are notoriously bad in producing very short sentences, as opposed to older paradigms such as SMT (Shen et al., 2016). To alleviate this problem, two methods have been proposed: (a) length normalization, used in RNNsearch as an option, where the revised score of a hypothesis is divided by its length, thus favoring longer sentences; and (b) explicit length reward (He et al., 2016) borrowed from SMT, rewarding each generated word by a constant tuned on the dev set.

Unfortunately, each of these methods breaks the optimality proof of our beam search algorithm in Section 3, since a future hypothesis, being longer, might end up with a higher (revised) score. We therefore devise a novel mechanism called "bounded length reward", that is, we reward each word until the length of the hypothesis is longer than the "estimated optimal length". In machine translation and summarization, this optimal length l can be $ratio \cdot |\mathbf{x}|$ where $|\mathbf{x}|$ is the source sentence length, and $ratio$ is the average ratio of reference translation length over source sentence length on the dev set (in our Chinese-to-English NMT experiments, it is 1.27 as the English side is a bit longer). Note that we use the same $ratio$ estimated from dev on test, assuming that the optimal length ratio for test (which we do not know) should be similar to those of dev ones. We denote $\tilde{sc}(\mathbf{y})$ to be the revised score of hypothesis $\mathbf{y}$ with the bounded length reward, i.e.,

$$\tilde{sc}(\mathbf{y}) \triangleq sc(\mathbf{y}) + r \cdot \min\{l, |\mathbf{y}|\}.$$

We also define $\tilde{best}_{\leq i}$ to be the revised version of $best_{\leq i}$ that optimizes the revised instead of the original score, i.e.,

$$\tilde{best}_{\leq i} \triangleq \mathop{\mathbf{argmax}}_{\mathbf{y} \in \cup_{j \leq i} B_j, comp(\mathbf{y})} \tilde{sc}(\mathbf{y})$$

Now with bounded length reward, we can modify our beam search algorithm a little bit and still guarantee optimality. First we include in the revised cost a reward r for each generated word, as long as the length is less than l, the estimated optimal length. If at step i, the highest scoring item $B_{i,1}$'s revised score (i.e., including bounded length reward) plus the heuristic "future" extra length reward of a descendant, $r \cdot \max\{l - i, 0\}$, is worse than (or equal to) the similarly revised version of $best_{\leq i}$, i.e.,

$$\tilde{sc}(B_{i,1}) + r \cdot \max\{l - i, 0\} \leq \tilde{sc}(\tilde{best}_{\leq i}) \quad (3)$$

at which time we claim the revised optimality certificate is established, and terminate the beam search and return $\tilde{best}_{\leq i}$.

Actually with some trivial math we can simplify the stopping criteria to

$$sc(B_{i,1}) + r \cdot l \leq \tilde{sc}(\tilde{best}_{\leq i}). \quad (4)$$

This much simplified but still equivalent criteria can speed up decoding in practice, since this

	sents	tokens	vocab.	w/ BPE

means we actually do not need to compute the revised score for every hypothesis in the beam; we only need to add the bounded length reward when one is finished (i.e., when updating $\widetilde{best}_{\leq i}$), and the simplified criteria only compares it with the original score of a hypothesis plus a constant reward $r \cdot l$.

Theorem 3 (modified optimality)**.** *Our modified beam search returns the highest-scoring completed hypothesis where the score of an item is its log-probability plus a bounded length reward.*

Proof. trivial. □

5 Experiments: Neural Translation

5.1 Data Preparation, Training, and Baselines

We conduct experiments on Chinese-to-English neural machine translation, using OpenNMT-py,[2] the PyTorch port of the Lua-based OpenNMT (Klein et al., 2017). We choose this library because PyTorch's combination of Python with Torch's dynamic computation graphs made it much easier to implement various search algorithms on it than on Theano-based implementations derived from RNNsearch (Bahdanau et al., 2014) (such as the widely used GroundHog[3] and Laulysta[4] codebases) as well as the original LuaTorch version of OpenNMT. We use 1M Chinese/English sentence pairs for training (see Table 1 for statistics); we also trained on 2M sentence pairs and only saw a minor improvement so below we report results from 1M training. To alleviate the vocabulary size issue we employ byte-pair encoding (BPE) (Sennrich et al., 2015) which reduces the source and target language vocabulary sizes to 18k and 10k, respectively; we found BPE to significantly improve BLEU scores (by at least +2 BLEU) and reduce training time. Following other papers on Chinese-English translation such as Shen et al. (2016), we use NIST 06 newswire portion (616 sentences) for development and NIST 08 newswire portion (691 sentences) for testing; we will report case-insensitive 4-reference BLEU-4 scores (using original segmentation).

Following OpenNMT-py's default settings, we train our NMT model for 20 epochs to minimize perplexity on the training set (excluding 15% sentences longer than 50 source tokens), with a batch size of 64, word embedding size of 500, and dropout rate of 0.3. The total number of parameters is 29M. Training takes about an hour per epoch on Geforce 980 Ti GPU, and the model at epoch 15 reaches the lowest perplexity on the dev set (9.10) which is chosen as the model for testing.

On dev set, the default decoder of OpenNMT-py reaches 29.2 BLEU with beam size 1 (greedy) and 33.2 BLEU with the default beam size of 5. To put this in perspective, the most commonly used SMT toolkit Moses (Koehn et al., 2007) reaches 30.1 BLEU (with beam size 70) using the same 1M sentence training set (trigram language model trained on the target side). With 2.56M training sentence pairs, Shen et al. (2016) reported 32.7 BLEU on the same dev set using Moses and 30.7 BLEU using the baseline RNNsearch (GroundHog) with beam size 10 (without BPE, without length normalization or length reward). So our OpenNMT-py baseline is extremely competitve.

5.2 Beam Search & Bounded Length Reward

We compare the following beam search variants:

1. OpenNMT-py's default beam search, finishing only when the top hypothesis in a step is completed (see Section 2);

2. The "shrinking beam" method in RNNsearch with two variants to encourage longer translations:

   (a) length normalization; Google NMT (Wu et al., 2016) also adopted a similar

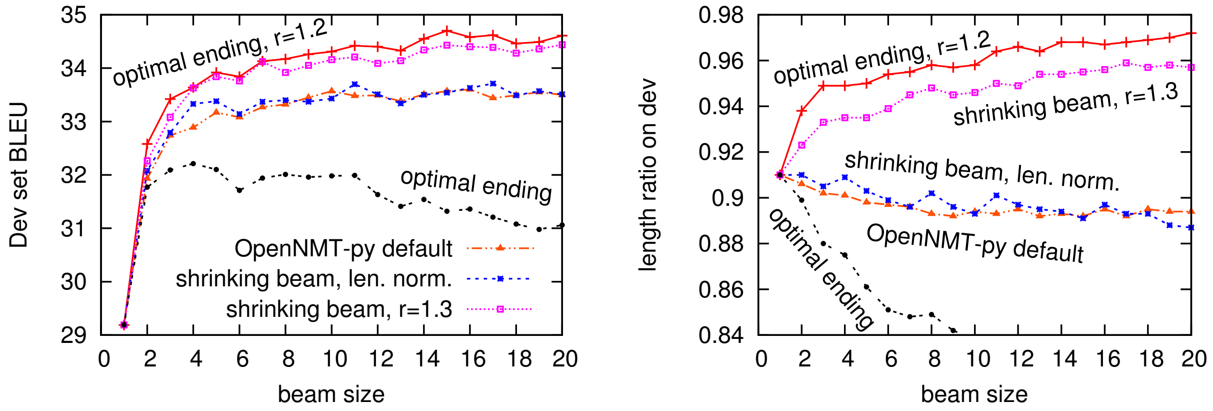
[4] https://github.com/laulysta/nmt/



(a) BLEU vs. beam size

(b) length ratio vs. beam size

Figure 2: BLEU score and length ratio against beam size (on dev) of various beam search algorithms for neural machine translation.

mechanism.

(b) unbounded length reward (tuned on dev set) in Baidu NMT (He et al., 2016).

3. Our optimal-ending beam search (Section 3);

4. Our modified optimal-ending beam search for bounded length reward (Section 4).

Notice that length reward has no effect on both methods 1 and 2(a) above. To tune the optimal length reward r we run our modified optimal-ending beam search algorithm with all combinations of $r = 0, 0.5, 1, 1.1, 1.2, 1.3, 1.4$ with beam sizes $b = 1 \ldots 20$ on the dev set, since different beam sizes might prefer different length rewards. We found $r = 1.2$ to be the best among all length rewards (see Table 2) which is used in Figure 2 and $b = 15$ is the best for $r = 1.2$.

We can observe from Figure 2 that (a) our optimal beam search with bounded length reward performs the best, and at b=15 it is +5 BLEU better than b=1; (b) pure optimal beam search degrades after b=4 due to extremely short translations; (c) both the shrinking beam method with length normalization and OpenNMT-py's default search alleviate the shortening problem, but still produce very short translations (length ratio ~0.9). (d) the shrinking beam method with length reward works well, but still 0.3 BLEU below our best method. These are confirmed by the test set (Tab. 3).

6 Conclusions

We have presented a beam search algorithm for neural sentence generation that always returns optimal-score completed hypotheses. To counter neural generation's natural tendancy for shorter hypotheses, we introduced a *bounded length reward* mechanism which allows a modified version of our beam search algorithm to remain optimal. Experiments on top of strong baselines have confirmed that our principled search algorithms (together with our bounded length reward mechanism) outperform existing beam search methods in terms of BLEU scores. We will release our implementations (which will hopefully be merged into OpenNMT-py) when this paper is published. [5]

Abstract

We propose simple and flexible training and decoding methods for influencing output style and topic in neural encoder-decoder based language generation. This capability is desirable in a variety of applications, including conversational systems, where successful agents need to produce language in a specific style and generate responses steered by a human puppeteer or external knowledge. We decompose the neural generation process into empirically easier sub-problems: a faithfulness model and a decoding method based on selective-sampling. We also describe training and sampling algorithms that bias the generation process with a specific language style restriction, or a topic restriction. Human evaluation results show that our proposed methods are able to to restrict style and topic without degrading output quality in conversational tasks.

chat context	Where are you?

1 Introduction

Neural encoder-decoder models have demonstrated great promise in many sequence generation tasks, including neural machine translation (Sutskever et al., 2014; Cho et al., 2014; Bahdanau et al., 2014; Luong et al., 2015; Wu et al., 2016), image captioning (Xu et al., 2015), summarization (Rush et al., 2015; Gu et al., 2016; Kikuchi et al., 2016), and conversation generation (Vinyals and Le, 2015; Sordoni et al., 2015; Shang et al., 2015; Shao et al., 2017; Li et al., 2015). These encouraging early successes have motivated research interest in training more natural-sounding conversational systems based on large volumes of open-domain human-to-human interactions. In order to create more human-like patterns of conversation, the agents need to have recognizable (and tunable) style, just as individual humans do, and also need to accept guidance from separate information processing modules in order to increase quality of responses. In an extreme case, an agent may be micro-managed by a human user who uses the neural model to enforce grammar and style (e.g., a level of politeness, or a type of humor), while driving the content directly (e.g., by expressing In this manner, the neural model becomes an authoring tool, rather than an independent chat-bot. On the other hand, in fully automated agent systems, the agent may be influenced by a knowledge database, or some other artificial information system, while running in a pre-set style or a style deemed best based on the course of the conversation.

One obstacle to achieving this with neural language generation models is that the sentence representation is distributed across all coordinates of

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2140–2150
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

the embedding vector in a way that is hard to disentangle, and thus control. In order to gain insight into the full distribution of what a decoder might produce given the prompt sentence as input, the model has to be heavily (and sometimes cleverly) sampled. The second problem is that neural models only become highly functional after training with very large amounts of data, while the strongly recognizable style usually must be defined by a relatively tiny corpus of examples (e.g., all Seinfeld episodes, or all popular song lyrics).

In this paper, we address the challenge of how to enforce the decoder models to mimic a specific language style with only thousands of target sentences, as well as generating specific content in that style. We developed and experimented with several training and decoding procedures to allow the model to adapt to target language style and follow additional content guidance. Our experiments, conducted on an open-domain corpus of Twitter conversations and small persona corpora, show that our methods are capable of responding to queries in a transferred style without significant loss of relevance, and can respond within a specific topic as restricted by a human. Some examples of 'scenting' the base conversation model with particular styles are shown in Table 1. More can be found in the Supplementary Material.

2 Related Work

Recurrent neural network based encoder-decoder models have been applied to machine translation and quickly achieved state-of-the-art results (Bahdanau et al., 2014; Luong et al., 2015). As an extension, the attention mechanism enables the decoder to revisit the input sequence's hidden states and dynamically collects information needed for each decoding step. Specifically, our conversation model is established based on a combination of the models of (Bahdanau et al., 2014) and (Luong et al., 2015) that we found to be effective. In section 3, we describe the attention-based neural encoder-decoder model we used in detail.

This work follows the line of research initiated by (Ritter et al., 2011) and (Vinyals and Le, 2015) who treat generation of conversational dialog as a data-drive statistical machine translation (SMT) problem. Sordoni et al. (2015) extended (Ritter et al., 2011) by re-scoring SMT outputs using a neural encoder-decoder model conditioned on conversation history. Recently, researchers have used neural encoder-decoder models to directly generate responses in an end-to-end fashion without relying on SMT phrase tables(Vinyals and Le, 2015; Sordoni et al., 2015; Shang et al., 2015; Shao et al., 2017; Li et al., 2015).

Li et al. (2016) defined a "persona" as the character that an artificial agent, as actor, plays or performs during conversational interactions. Their dataset requires user identification for all speakers in the training set, while our methods treat the base data (millions of twitter conversations) as unlabeled, and the target persona is defined simply by a relatively small sample of their speech. In this sense, the persona can be any set of text data. In our experiments, for example, we used a generic Star Wars character that was based on the entire set of Star Wars scripts (in addition to 46 million base conversations from Twitter). This provides us with a system that can talk about almost anything, being able to respond to most prompts, but in a recognizable Star Wars style. Other possibilities include training (styling) on famous personalities, or certain types of poetry, or song lyrics, or even mixing styles by providing two or more datasets for styling. Thus our targets are highly recognizable styles, and use of these for emphasis (or caricature) by human puppeteers who can choose from multiple options and guide neural models in a direction they like. We expect that these tools might not only be useful in conversational systems, but could also be popular in social media for text authoring that goes well beyond spelling/grammar auto correction.

3 Neural Encoder-Decoder Background

In general, neural encoder-decoder models aim at generating a target sequence $Y = (y_1, \ldots, y_{T_y})$ given a source sequence $X = (x_1, \ldots, x_{T_x})$. Each word in both source and target sentences, x_t or y_t, belongs to the source vocabulary V_x, and the target vocabulary V_y respectively.

First, an encoder converts the source sequence X into a set of context vectors $C = \{\mathbf{h}_1, \mathbf{h}_2, \ldots, \mathbf{h}_{T_x}\}$, whose size varies with regard to the length of the source passage. This context representation is generated using a multi-layered recurrent neural network (RNN). The encoder RNN reads the source passage from the first token until the last one, where $\mathbf{h}_i = \Psi\left(\mathbf{h}_{i-1}, \mathbf{E}_x\left[x_t\right]\right)$. Here $\mathbf{E}_x \in \mathbb{R}^{|V_x|\times d}$ is an embedding matrix containing vector representations of words, and Ψ is a recurrent activation unit that we employ in the Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997).

The decoder, which is also implemented as an RNN, generates one word at a time, based on the context vector set returned by the encoder. The decoder's hidden state $\bar{\mathbf{h}}_t$ is a fixed-length continuous vector that is updated in the same way as encoder. At each time step t in the decoder, a time-dependent attentional context vector $\mathbf{c}_t$ is computed based on the current hidden state of the decoder $\bar{\mathbf{h}}_t$ and the whole context set C.

Decoding starts by computing the content-based score of each context vector as: $e_{t,i} = \bar{\mathbf{h}}_t^\top W_a \mathbf{h}_i$. This relevance score measures how helpful the i-th context vector of the source sequence is in predicting next word based on the decoder's current hidden state $\bar{\mathbf{h}}_t^\top$. Relevance scores are further normalized by the softmax function: $\alpha_{t,i} = \frac{\exp(e_{t,i})}{\sum_{j=1}^{T_x}\exp(e_{t,j})}$, and we call $\alpha_{t,i}$ the attention weight. The time-dependent context vector $\mathbf{c}_t$ is then the weighted sum of the context vectors with their attention weights from above: $\mathbf{c}_t = \sum_{i=1}^{T_x} \alpha_{t,i}\mathbf{h}_i$.

With the context vector $\mathbf{c}_t$ and the hidden state $\mathbf{h}_t$, we then combine the information from both vectors to produce an attentional hidden state as follow: $\mathbf{z}_t = \tanh(\mathbf{W}_c[\mathbf{c}_t;\mathbf{h}_t])$. The probability distribution for the next target symbol is computed by $p(y_t = k|\tilde{y}_{<t}, X) \propto \exp(\mathbf{W}_s\mathbf{z}_t + \mathbf{b}_t)$.

4 Decoding with Selective Sampling

The standard objective function for neural encoder-decoder models is the log-likelihood of target T given source S, which at test time yields the statistical decision problem:

$$\hat{T} = \arg\max_T \big\{ \log p(T|S)\big\}. \quad (1)$$

However, as discussed in (Li et al., 2015; Shao et al., 2017), simply conducting beam search over the above objective will tend to generate generic and safe responses that lack diversity, such as *"I am not sure"*. In section 7.3, we present a ranking experiment in which we verify that an RNN-based neural decoder provides a poor approximation of the above conditional probability, and instead biases towards the target language model $p(T)$. Fortunately, the backward model $p(S|T)$ empirically perform much better than $p(T|S)$ on the relevance ranking task. Therefore, we directly apply Bayes' rule to Equation 1, as in statistical machine translation (Brown et al., 1993), and use:

$$\hat{T} = \arg\max_T \big\{ \log p(S|T) + \log p(T)\big\}. \quad (2)$$

Since $p(T|S)$ is empirically biased towards $p(T)$, in practice, this objective also resembles the Maximum Mutual Information (MMI) objective function in (Li et al., 2015).

The challenge now is to develop an effective search algorithm for a target words sequence that maximize the product in Equation 2. Here, we follow a similar process as in (Wen et al., 2015) which generates multiple target hypotheses with stochastic sampling based on $p(T|S)$, and then ranks them with the objective function 2 above. However, as also observed by (Shao et al., 2017), step-by-step naive sampling can accumulate errors as the sequence gets longer.

To reduce language errors of stochastic sampling, we introduce a sample selector to choose the next token among N stochastically sampled tokens based on the predicted output word distributions. The sample selector, which is a multilayer perceptron in our experiments, takes the following features: 1) the log-probability of current sample word in $p(w_t|S)$; 2) the entropy of current predicted word distribution, $\sum_{w_t} P(w_t|S)\log P(w_t|S)$ for all w_t in the vocabulary; 3) the log-probability of current sample word in $p(w_t|\emptyset)$, which we found effective in ranking task. The selector outputs a binary variable that indicates whether the current sample should be accepted or rejected.

At test time, if none of the N sampled tokens are above the classification threshold, we choose the highest scored token. If there are more than 1 acceptable samples among N stochastically sampled tokens, we randomly choose one among them. Ideally, this permits us to safely inject diversity while maintaining language fluency. We also use the sample acceptor's probabilities as the language model score $P(T)$ for objective in equation 2.

As regards directly integrating beam-search, we found (a) that beam-search often produces a set of similar top-N candidates, and (b) that decoding with only the objective $p(Y|X)$ can easily lead to irrelevant candidates. (See section 7.3) Therefore, we use the selective-sampling method to generate candidates for all our experiments; this (a) samples stochastically then (b) selects using a learned objective from data. The sample-then-select approach encourages more diversity (v.s. MMI's beam-search) while still maintain language fluency (v.s. naive-sampling).

5 Output style restriction using a small 'scenting' dataset

In this section, we propose three simple yet effective methods of influencing the language style of the output in the neural encoder-decoder framework. Our language style restricting setup assumes that there is a large open-domain parallel corpus that provides training for context-response relevance, and a smaller monologue speaker corpus that reflects the language characteristics of the target speaker. We will refer to this smaller set as a 'scenting' dataset, since it hints at, or insinuates, the characteristics of the target speaker.

5.1 $Rank$: Search in the Target Corpus

Our first approach to scenting is to simply use the all sentences in the target speaker's corpus as generation candidates, ranked by the objective (2) for a given prompt. Since these sentences are naturally-occurring instead of generated word-by-word, we can safely assume $p(T)$ is constant (and high), and so the objective only requires sorting the sentences based on the backward model $p(S|T)$.

RNN-based ranking methods are among the most effective methods for retrieving relevant responses (Wang and Nyberg, 2015, 2016). Thus this approach is a very strong baseline. Its limitation is also obvious: by limiting all possible responses to a fixed finite set of sentences, this method cannot provide a good response if such a response is not already in the scenting dataset.

5.2 $Multiply$: Mixing the base model and the target language model during generation

In our second method we use both the vanilla encoder-decoder model trained on open-domain corpus and the target domain language model trained on the corpus while decoding output sentence. The idea is to use a speaker's language model, which is also RNN-based in our experiments, to restrict the open-domain encoder-decoder model's step-by-step word prediction. Similar ideas have been tested in domain adaptation for statistical machine translation (Koehn and Schroeder, 2007), where both in-domain and open-domain translation tables were used as candidates for generating target sentence. Because open-domain encoder-decoder models are trained with various kinds of language patterns and topics, choosing a sequence that satisfies both models may produce relevant responses that are also in the target language style. We found that a straightforward way of achieving this is to multiply the two models' distributions $p_1(t|S)^{\lambda_1} p_2(t)^{\lambda_2}$ at each point and then re-normalize before sampling. The weights can be tuned either by the perplexity on the validation set, or through manually controlling the trade-off between style restriction and answer accuracy.

5.3 $Finetune$: Over-training on Target Corpus with Pseudo Context

Fine-tuning is a widely used in the neural network community to achieve transfer learning. This strategy permits us to train the neural encoder-decoder on a larger general parallel corpus, and then use the learned parameters to initialize the training of a styled model. Most of the time, however, the target speaker's corpus will lack training data in parallel form. For example, if we train on song lyrics or movie scripts, or political speeches, the data will not be in a question-answer form. To make encoder-decoder overtraining possible, we treat every sentence in the scenting corpus as a target sentence T generated a pseudo context from the backward model $p(S|T)$ trained on the open-domain corpus. Over-training on such pairs imparts the scenting dataset's language characteristics, while retaining the generality of the original model. We also found that the previous sentence in the styled corpus (i.e., previous sentence in the speech) provides helpful context for the current sentence, analogous with a question-answer link. Thus we use both pseudo context and the previous sentence as possible sources S to fine-tune the in-domain decoder. To avoid overfitting, we stop overtraining when the perplexity on the in-domain validation set starts to increase. A corresponding sample acceptor is also trained for the fine-tuned model: we found it helpful to initialize this from the open-domain model's sample acceptor.

6 Restricting the Output Topic

We further introduce a topic restricting method for neural decoders based on the Counting Grid (Jojic and Perina, 2011) model, by treating language guidance as a topic embedding. Our model extension provides information about the output topic in the form of an additional topic embedding vector to the neural net at each time step.

6.1 CG: Counting Grids

The basic counting grid $\pi_{\mathbf{k}}$ is a set of distributions on the d-dimensional toroidal discrete grid $\mathbf{E}$ indexed by $\mathbf{k}$. The grids in this paper are bi-dimensional and typically from $(E_x = 32) \times (E_y = 32)$ to $(E_x = 64) \times (E_y = 64)$ in size. The index z indexes a particular word in the vocabulary $z = [1 \dots Z]$. Thus, $\pi_{\mathbf{i}}(z)$ is the probability of the word z at the d-dimensional discrete location $\mathbf{i}$, and $\sum_z \pi_{\mathbf{i}}(z) = 1$ at every location on the grid. The model generates bags of words, each represented by a list of words $\mathbf{w} = \{w_n\}_{n=1}^N$ with each word w_n taking an integer value between 1 and Z. The modeling assumption in the basic CG model is that each bag is generated from the distributions in a single window $\mathbf{W}$ of a preset size, e.g., $(W_x = 5) \times (W_y = 5)$. A bag can be generated by first picking a window at a d-dimensional location ℓ, denoted as W_ℓ, then generating each of the N words by sampling a location $\mathbf{k}_n$ for a particular micro-topic $\pi_{\mathbf{k}_n}$ uniformly within the window, and sampling from that micro-topic.

Because the conditional distribution $p(\mathbf{k}_n|\ell)$ is a preset uniform distribution over the grid locations inside the window placed at location ℓ, the variable $\mathbf{k}_n$ can be summed out (Jojic and Perina, 2011), and the generation can directly use the grouped histograms

$$h_\ell(z) = \frac{1}{|\mathbf{W}|} \sum_{\mathbf{j} \in W_\ell} \pi_{\mathbf{j}}(z), \tag{3}$$

where $|\mathbf{W}|$ is the area of the window, e.g. 25 when 5×5 windows are used. In other words, the position of the window ℓ in the grid is a latent variable given which we can write the probability of the bag as

$$P(\mathbf{w}|\ell) = \prod_{w_n \in \mathbf{w}} h_\ell(w_n) = \prod_{w_n \in \mathbf{w}} \Big(\frac{1}{|\mathbf{W}|} \cdot \sum_{\mathbf{j} \in W_\ell} \pi_{\mathbf{j}}(w_n) \Big) \tag{4}$$

As the grid is toroidal, a window can start at any position and there is as many h distributions as there are π distributions. The former will have a considerably higher entropy as they are averages of many π distributions. Although the basic CG model is essentially a simple mixture assuming the existence of a single source (one window) for all the features in one bag, it can have a very large number of (highly related) choices h to choose from. Topic models (Blei et al., 2003; Lafferty and Blei, 2006), on the other hand, are admixtures that capture word co-occurrence statistics by using a much smaller number of topics that can be more freely combined to explain a single document (and this makes it harder to visualize the topics and pinpoint the right combination of topics to use in influencing the output).

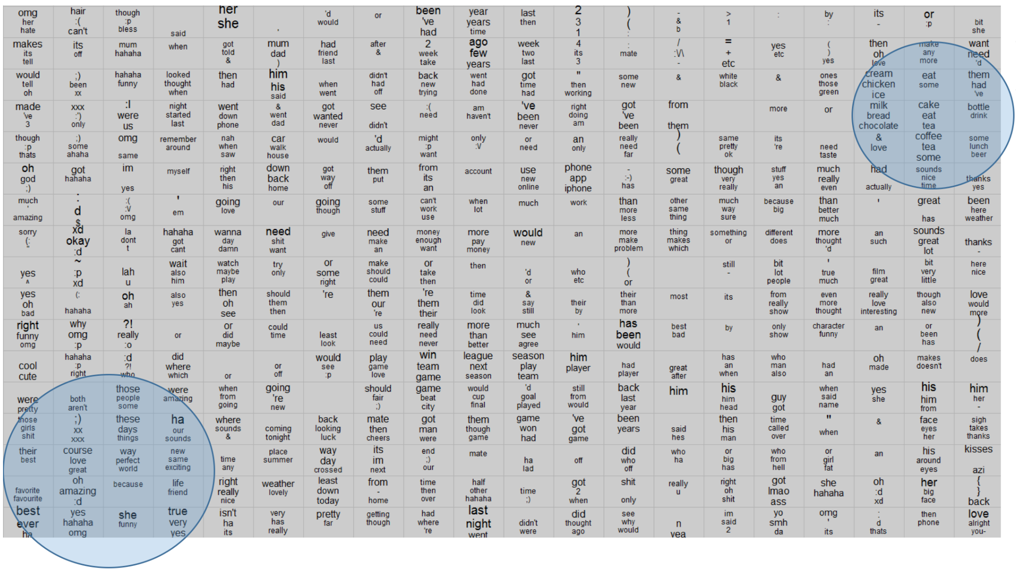
In a well-fit CG model, each data point tends to have a rather peaky posterior location distribution because the model is a mixture. The CG model can be learned efficiently using the EM algorithm because the inference of the hidden variables, as well as updates of π and h can be performed using summed area tables (Crow, 1984), and are thus considerably faster than most of the sophisticated sampling procedures used to train other topic models. The use of overlapping windows helps both in controlling the capacity of the model and in organizing topics on the grid automatically: Two overlapping windows have only slighly different h distributions, making CGs especially useful in visualization applications where the grid is shown in terms of the most likely words in the component distributions π (Perina et al., 2014).[1]

Having trained the grid on some corpus (in our case a sample of the base model's corpus), the mapping of either a source S and/or target T sentence can be obtained by treating the sentences as bags of words. By appending one or both of these mappings to the decoder's embedding of the target T, the end-to-end encoder-decoder learning can be performed in a scenario where the decoder is expected to get an additional hint through a CG mapping. In our experiments, we only used the embedding of the target T as the decoder hint, and we appended the full posterior distribution over CG locations to the encoder's embedding. At test time, we only have the S and need to generate T without knowing where it may map in the counting grid. We considered two ways of providing a mapping:

- The user provides a hint sentence H (could be just a few words in any order), and the CG mapping of the user's hint, i.e. the full posterior distribution $p(\ell|H)$, is used in the decoding. The posterior probabilities over 32 × 32 grid locations are unwrapped into a vector

[1] (Chen et al., 2017) have recently proposed using LDA for topic modeling in Sequence-To-Sequence response generation models. We believe that the CG embedding used here will prove easier to apply and interpret through visualization.

S: I am so hungry!



T1: Have leftover cake, come over!
T2: Let's have cream chicken for lunch.

T1: Of course, ;)
T2: Omg, hahaha. I am very hungry, too

Figure 1: A part of a Counting Grid trained on Twitter data and its use in providing topical hints in decoding. For the source sentence at the top, the decoder may produce the two target samples on the right, if the circled locations are used as a hint, or the two sentences at the bottom if the locations in the lower right are picked.

with a size of $|L| = 1024$, and then concatenated with the word embedding as the input at each time-step. That acts to expand the user's hint into a sentence with similar content (and style if the model is also styled).

- The CG is scanned and a variety of mappings are tested as inputs to provide a diverse set of possible answers. In our experiments, instead of scanning over all 1024 possible locations in the grid, we retrieved several possible answers using information retrieval (ranking of the data samples in the training set based on the source S and picking the top ten). Then the CG mapping $p(\ell|H)$ of these retrieved hints is used to decode several samples from each.

As an example, Figure 1 shows a portion of a CG trained on randomly chosen 800k tweets from the twitter corpus. In each cell of the grid, we show the top words in the distribution $\pi_{\mathbf{j}}(z)$ over words (z) in that location $(\mathbf{j})$. (Each cell has a distribution over the entire vocabulary). As a response to "I am hungry," using two highlighted areas as hints, we can generate either a set of empathic responses, such as 'Me too,' or food suggestions, such as 'Let's have cake.' It will also be evident that some areas of the grid may produce less sensical answers. These can later be pruned by likelihood criteria or by user selection.

7 Experiments

7.1 Datasets

Yahoo! Answer Dataset. We use the Comprehensive Questions and Answers dataset[2] to train and validate the performances of different decoding setups with ranking experiments described in section 7.3. This dataset contains 4.4 million Yahoo! Answers questions and the user-selected best answers. Unlike the conversational datasets, such as the Twitter dataset described below, it contains more relevant and specific responses for each question, which leads to less ambiguity in ranking.

Twitter Conversation Dataset. We trained our base encoder-decoder models on the Twitter Conversation Triple Dataset described in (Sordoni et al., 2015), which consists of 23 million conversational snippets randomly selected from a collection of 129M context-message-response triples extracted from the Twitter Firehose over the 3-month

[2] http://webscope.sandbox.yahoo.com/catalog.php?datatype=l

period from June through August 2012. For the purposes of our experiments, we split the triples into context-message and message-response pairs yielding 46M source-target pairs. For tuning and evaluation, we used the development dataset of size 200K conversation pairs and the test dataset of 5K examples. The corpus is preprocessed using a Twitter specific tokenizer (O'Connor et al., 2010). The vocabulary size is limited to 50,000 excluding the special boundary symbol and the unknown word tag.

Scenting datasets. A variety of persona characters have been trained and tested, including Hillary Clinton, Donald Trump, John F. Kennedy, Richard Nixon, singer-songwriters, stand-up comedians, and a generic Star Wars character. In experiments, we evaluated on a diverse set of representative target speakers:

JFK. We mainly tested our models on John F. Kennedy's speeches collected from American Presidency Project[3], which contains 6474 training and 719 validation sentences.

Star Wars. Movie subtitles of three Star Wars movies are also tested[4]. They are extracted from Cornell Movie-Dialogs Corpus (Danescu-Niculescu-Mizil and Lee, 2011), and have 495 training and 54 validation sentences.

Singer-Songwriter. We also evaluated our approach on a lyric corpus from a collective of singers: Coldplay, Linkin Park, and Green Day. The lyric dataset is collected from mldb.org and has 9182 training and 1020 validation lines.

Debate Chat Contexts. We designed testing questionnaires with 64 chat contexts spanning a range of topics in politic, science, and technology: the sort of questions we might ask in an entertaining political debate.[5] To test the model's ability to control output topic in section 7.4.3, we also created one hint per question.

7.2 Network Setup and Implementation

Our encoder and decoder RNNs contains two-layer stacked LSTMs. Each LSTM layer has a memory size of 500. The network weights are randomly initialized using a uniform distribution $(-0.08, 0.08)$, and are trained with the ADAM optimizer (Kingma and Ba, 2014), with an initial learning rate of 0.002. Gradients were clipped so their norm does not exceed 5. Each mini-batch contains 200 answers and their questions. The words of input sentences were first converted to 300-dimensional vector representations learned from the RNN based language modeling tool word2vec (Mikolov et al., 2013). The beginning and end of each passage are also padded with a special boundary symbol. During decoding, our model generates 500 candidate samples in parallel, then ranks them. As these are processed in batches on GPU, generation is very efficient. We also experimented incorporating an information retrieval (IR) module to automatically collect topic hints for CG-based decoder. Specifically, a full-text index of twitter corpus is built using solr[6], and the top 10 searched results based on the source sentence are be used to generate posterior CG distributions as hints.

7.3 Validating the Decoding Setup with Ranking

We performed a ranking evaluation applying different decoding setups on the Yahoo! Answers dataset. Here we wanted to test the relevance judgment capacities of different setups, and validate the necessity of the new decoding method discussed in section 4. Yahoo! Answers question is used as source S, and its answer is treated as target T. Each test question is associated with one true answer and 19 random answers from the test set. MRR (Mean Reciprocal Rank) and P@1 (precision of top1) were then used as evaluation metrics.

Table 2 shows the answer ranking evaluation results: the forward model $P(T|S)$, by itself is close to the performance of random selection in distinguishing true answer from wrong answers. This implies that a naive beam search over only the forward model may generate irrelevant outputs. One hypothesis was that $P(T|S)$ is biased toward $P(T)$, and performance indeed improves after normalizing by $P(T)$. However, it is difficult to directly decode with objective $P(T|S)/P(T|\emptyset)$, because this objective removes the influence of the target-side language model. Decoding only according to this function will thus result in only low-frequency words and ungrammatical sentences, behavior also noted by (Li et al., 2015; Shao et al., 2017).

Ranking Methods	MRR	P@1
$P_{rnn}(T\|S)$	0.224	0.075
$P_{rnn}(T\|S)/P_{rnn}(T\|\emptyset)$	0.652	0.524
$P_{rnn}(S\|T)$	0.687	0.556

Table 2: Ranking the true target answer among random answers on Yahoo! Answers test set.

7.4 Human Evaluations

7.4.1 Systems

We tested 10 different system configurations to evaluate the overall output quality, and their abilities of influencing output language style and topic:

- ***vanilla-sampling*** each word in the target.
- ***selective-sampling*** as described in section 4; all the following systems are using it as well.
- ***cg-ir*** uses IR results to create counting grid topic hints (sections 6.1 and 7.2).
- ***rank*** uses proposals from the full JFK corpus as in section 5.1.
- ***multiply*** with a JFK language model as in section 5.2.
- ***finetune*** with JFK dataset as in section 5.3.
- ***finetune-cg-ir*** uses IR results as topic hints for fine-tuned JFK.
- ***finetune-cg-topic*** forced to use the given topic hint for fine-tuned JFK.
- ***singer-songwriter*** fine-tuned cg-topic.
- ***starwars*** fine-tuned cg-topic.

7.4.2 Evaluation Setup

Owing to the low consistency between automatic metrics and human perception on conversational tasks (Liu et al., 2016; Stent et al., 2005) and the lack of true reference responses from persona models, we evaluated the quality of our generated text with a set of judges recruited from Amazon Mechanical Turk (AMT). Workers were selected based on their AMT prior approval rate (>95%). Each questionnaire was presented to 3 different workers. We evaluated our proposed models on the 64 debate chat contexts. Each of the evaluated methods generated 3 samples for every chat context. To ensure calibrated ratings between systems, we show the human judges all system outputs (randomly ordered) for each particular test case at the same time. For each chat context, we conducted three kinds of assessments:

Methods	Quality (MOS)	Style
vanilla-sampling	2.286 ± 0.046	—
selective-sampling	2.681 ± 0.049	10.42%
cg-ir	2.566 ± 0.048	10.24%
rank	2.477 ± 0.048	21.88%
multiply	2.627 ± 0.048	13.54%
finetune	2.597 ± 0.046	20.83%
finetune-cg-ir	2.627 ± 0.049	20.31%
finetune-cg-topic	2.667 ± 0.045	21.09%
singer-songwriter	2.373 ± 0.045	—
starwars	2.677 ± 0.048	—

Table 3: Results of quality assessments with 5-scale mean opinion scores (MOS) and JFK style assessments with binary ratings. Style results are statistically significant compared to the *selective-sampling* by paired t-tests ($p < 0.5\%$).

Quality Assessment Workers were provided with the following guidelines: "Given the chat context, a chat-bot needs to continue the conversation. Rate the potential answers based on your own preference on a scale of 1 to 5 (the highest):"

- 5-Excellent: "Very appropriate response, and coherent with the chat context."
- 4-Good: "Coherent with the chat context."
- 3-Fair: "Interpretable and related. It is OK for you to receive this chat response."
- 2-Poor: "Interpretable, but not related."
- 1-Bad: "Not interpretable."

In this test, the outputs of all 10 systems evaluated are then provided to worker together for a total of 30 responses. In total, we gathered $64 \cdot 30 \cdot 3 = 5760$ ratings for quality assessments, and 47 different workers participated.

Style Assessment. We provided following instructions: "Which candidate responses are likely to have come from or are related to [Persona Name]?". Checkboxes were provided for the responses from style-influenced systems and from *selective-sampling* as a baseline.

Topic Assessment. The instruction was: "Which candidate answers to the chat context above are similar or related to the following answer: '[a hint topic provided by us]'?". This was also a checkbox questionnaire. Candidates are from both style- and topic-influenced systems (fine-tuned cg-topic), and from *selective-sampling* as a baseline.

Persona	Style		Topic	
	Ours	Base	Ours	Base
John F. Kennedy	21%	10%	33%	22%
Star Wars	27%	3%	14%	8%
Singer-Songwriter	31%	23%	17%	9%

Table 4: The style and topic assessments (both binary) of three models with different personas and with restriction of specific target topic for each chat context. All style and topic results are statistically significant compared to the Base (*selective-sampling*) by paired t-tests with $p < 0.5\%$.

7.4.3 Results

Overall Quality. We conducted mean opinion score (MOS) tests for overall quality assessment of generated responses with questionnaires described above. Table 3 shows the MOS results with standard error. It can be seen that all the systems based on selective sampling are significantly better than vanilla sampling baseline. When restricting output's style and/or topic, the MOS score results of most systems do not decline significantly except *singer-songwriter*, which attempts to generate lyrics-like outputs in response to to political debate questions, resulting in uninterpretable strings.

Our *rank* method uses $p(S|T)$ to pick the answer from the original persona corpus, and is thus as good at styling as the person themselves. Because most of our testing questionnaire is political, the *rank* was indeed often able to find related answers in the dataset (JFK). Also, unlike generation-based approaches, *rank* has oracle-level language fluency and it is expected to have quality score of at least 2 ("Interpretable, but not related"). Overall, however, the quality score of *rank* is still lower than other approaches. Note that a hybrid system can actually chose between rank and the decoder's outputs based on likelihood, as shown in the example of bJFk-bNixon debate in the supplemental material.

Influencing the Style. Table 3 also shows the likelihood of being labeled as JFK for different methods. It is encouraging that *finetune* based approaches have similar chances as the *rank* system which retrieves sentences directly from JFK corpus, and are significantly better than the *selective-sampling* baseline.

Influencing both Style and Topic. Table 4 summarizes the results in terms of style (the fraction of answers labeled as in-style for the target persona), and topic (the percentage of answers picked as related to the human-provided topic hint text). We used the last three of the ten listed systems, which are both styled and use specific topic hints to generate answers. These results demonstrate that it is indeed possible to provide simple prompts to a styled model and drive their answers in a desired direction while picking up the style of the persona. It also shows that the style of some characters is harder to recreate than others. For example, workers are more likely to label baseline results as lyrics from a singer-songwriter than lines from Star Wars movies, which might be because lyrics often take significant freedom with structure and grammar. We also found that it is harder for Star Wars and Singer-Songwriter bots to follow topic hints than it is for the John F. Kennedy model, largely because the political debate questions we used overlap less with the topics found in the scenting datasets for those two personas.

8 Conclusions

In this study we investigated the possibility of steering the style and content in the output of a neural encoder-decoder model[7]. We showed that acquisition of highly recognizable styles of famous personalities, characters, or professionals, is achievable, and that it is even possible to allow users to influence the topic direction of conversations. The tools described in the paper are not only useful in conversational systems (e.g., chatbots), but can also be useful as authoring tools in social media. In the latter case, the social media users might use neural models as consultants to help with crafting responses to any post the user is reading. The AMT tests show that these models do indeed provide increased recognizability of the style, without sacrificing quality or relevance.

Preserving Distributional Information in Dialogue Act Classification

Abstract

This paper introduces a novel training/decoding strategy for sequence labeling. Instead of greedily choosing a label at each time step, and using it for the next prediction, we retain the probability distribution over the current label, and pass this distribution to the next prediction. This approach allows us to avoid the effect of label bias and error propagation in sequence learning/decoding. Our experiments on dialogue act classification demonstrate the effectiveness of this approach. Even though our underlying neural network model is relatively simple, it outperforms more complex neural models, achieving state-of-the-art results on the MapTask and Switchboard corpora.

1 Introduction

Dialogue Act (DA) classification is a sequence-labeling task, where a sequence of utterances is mapped into a sequence of DAs. The DAs are semantic classifications of the utterances, and different corpora usually have their own DA labels.

Two of the most popular DA classification datasets are Switchboard (Godfrey et al., 1992; Jurafsky et al., 1997) and MapTask (Anderson et al., 1991). There have been many works on DA classification applied to these two datasets; some focus on textual data (Kalchbrenner and Blunsom, 2013; Stolcke et al., 2000), while others explore speech data (Julia et al., 2010). The classification methods used can be broadly divided into *instance-based methods* (Julia et al., 2010; Gambäck et al., 2011) and *sequence-labeling methods* (Stolcke et al., 2000; Kalchbrenner and Blunsom, 2013; Ji et al., 2016; Shen and Lee, 2016; Tran et al., 2017). Instance-based methods treat each utterance as an independent data point, which allows the application of general machine learning models, such as Support Vector Machines. Sequence-labeling methods include methods based on Hidden Markov Models (HMMs) (Stolcke et al., 2000) and neural networks (Kalchbrenner and Blunsom, 2013; Ji et al., 2016; Shen and Lee, 2016; Tran et al., 2017).

Stolcke *et al.* employed an HMM, using a Language Model to produce emission probabilities. The neural models are particularly successful, posting a higher accuracy on Switchboard than the HMM. Specifically, Kalchbrenner and Blunsom (2013) model a DA sequence with a recurrent neural network (RNN) where sentence representations are constructed by means of a convolutional neural network (CNN); Ji *et al.* (2016) treat the labels as latent variables in a generative RNN; Shen and Lee (2016) employ attentional RNNs for the independent prediction of DAs; and Tran *et al.* (2017) model the DAs in a conversation by means of a hierarchical RNN. In this paper, we also rely on RNNs, but our architecture is much simpler than the above neural models, while posting competitive results.

Most neural network models for DA classification employ greedy decoding (Tran et al., 2017; Ji et al., 2016), as its speed and simplicity support an on-line decoding process (i.e., producing a label immediately after receiving an utterance). For sequential labeling, the DA label in the current time step is very important (Tran et al., 2017). However, using a greedy approach to connect the current label directly to the next label may degrade

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2151–2156
Copenhagen, Denmark, September 7–11, 2017.

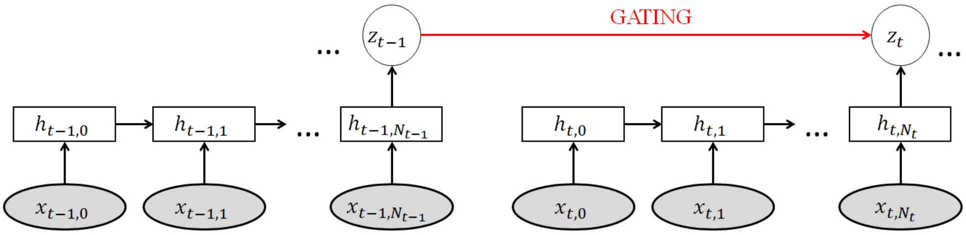

Figure 1: Model architecture.

performance, because the current predicted label may be noisy, which in turn leads to the propagation of errors through the sequence (Tran et al., 2017; Ranzato et al., 2015).

Recently, Bengio *et al.* (2015) proposed a technique called *Scheduled Sampling* that tries to solve the label-bias problem by alternating between the predicted label and the correct label during training. This makes the model gradually adapt to the noisiness of the predicted label. However, this method still relies upon a single current label, and, by omitting the distribution over the possible labels, this model loses information about the current stage. In contrast, we propose to condition the next label on a predicted distribution of the current label. Specifically, we introduce two variants of this idea: the *Uncertainty Propagation* model and the *Average Embedding* model.

2 Sequential DA Prediction

We are interested in predicting DAs $\{z_1, \ldots, z_t\}$ in a conversation as we receive textual utterances $\{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_t\}$ sequentially. Importantly, we do not have access to future utterances when predicting a DA at time t.

Model. We propose a discriminative model, where the probability of DAs conditioned on utterances is decomposed as follows (Figure 1):

$$p(\boldsymbol{z}_{1:t}|\boldsymbol{x}_{1:t}) = \prod_{i=1}^{t} p_{\boldsymbol{\theta}}(z_i|z_{i-1}, \boldsymbol{x}_i) \qquad (1)$$

where $\boldsymbol{z}_{1:t}$ and $\boldsymbol{x}_{1:t}$ respectively denote the sequence of DAs and utterances up to time step t. Our model resembles a maximum entropy Markov model, as it conditions the label of the next time step on the label of the current step and the next received utterance. The conditional distribution term $p_{\boldsymbol{\theta}}(z_i|z_{i-1}, \boldsymbol{x}_i)$ is realised by neural models as follows:

$$z_i|z_{i-1}, \boldsymbol{x}_i \sim \mathit{softmax}(\boldsymbol{W}^{(z_{i-1})}\boldsymbol{c}(\boldsymbol{x}_i) + \boldsymbol{b}^{(z_{i-1})}) \qquad (2)$$

where $\boldsymbol{c}(\boldsymbol{x}_i)$ is the distributed representation of utterance $\boldsymbol{x}_i$ (discussed below), and $\{\boldsymbol{W}^{(z_{i-1})}, \boldsymbol{b}^{(z_{i-1})}\}$ are DA-specific parameters gated on the current DA z_{i-1}.

The encoding function for an utterance is an RNN with long-short term memory (LSTM) units (Graves, 2013; Hochreiter and Schmidhuber, 1997), where the final hidden state of the RNN is taken as the representation of the whole sequence of text:

$$\boldsymbol{h}_{t,n} = \boldsymbol{f}_{\boldsymbol{\phi}}(\boldsymbol{h}_{t,n-1}, \boldsymbol{e}(x_{t,n})) \ \ , \ \ \boldsymbol{c}(\boldsymbol{x}_t) = \boldsymbol{h}_{t,N_t} \qquad (3)$$

where $x_{t,n}$ is the n-th token in the t-th utterance, and N_t is the length of the utterance.

The parameter set of our model $\boldsymbol{\theta}$ includes $\{\boldsymbol{W}^{(\ell)}, \boldsymbol{b}^{(\ell)}\}_{\ell=1}^{L}$ for the gating component (where L is the number of DAs), as well as the LSTM parameters $\boldsymbol{\phi}$ and the word-embedding table $\{\boldsymbol{e}(w)\}_{w \in \mathcal{W}}$, where $\mathcal{W}$ is the dictionary.

Uncertainty Propagation. In this model, the distribution over the labels at the current time step is passed to the next time step. Specifically, the quantity of interest is the posterior probability of the DA of the next time step given all the utterances observed so far. This posterior probability can be rewritten as

$$\begin{aligned} p_{\boldsymbol{\theta}}(z_t|\boldsymbol{x}_{1:t}) &= \sum_{z_1,\ldots,z_{t-1}} p_{\boldsymbol{\theta}}(\boldsymbol{z}_{1:t}|\boldsymbol{x}_{1:t}) \\ &= \sum_{z_{t-1}} p_{\boldsymbol{\theta}}(z_t|z_{t-1}, \boldsymbol{x}_t) p_{\boldsymbol{\theta}}(z_{t-1}|\boldsymbol{x}_{1:t-1}) \qquad (4) \end{aligned}$$

According to Equation 4, the label uncertainty at the next time step t can be computed by a dynamic programming algorithm based on the label uncertainty of the current time step combined with the local potentials $p_{\boldsymbol{\theta}}(z_t|z_{t-1}, \boldsymbol{x}_t)$.

The use of posterior probability for prediction is also motivated by the minimum Bayes risk decoding (MBR). In the sequential setting, we are interested in predicting the next DA that minimizes the expected loss

$$\begin{aligned} & \arg\min_{\hat{z}_t} \sum_{z_1,\dots,z_{t-1}} p_{\boldsymbol{\theta}}(\boldsymbol{z}_{1:t}|\boldsymbol{x}_{1:t}) \mathit{loss}(z_t, \hat{z}_t) \\ = \quad & \arg\min_{\hat{z}_t} p_{\boldsymbol{\theta}}(z_t|\boldsymbol{x}_{1:t}) \mathit{loss}(z_t, \hat{z}_t) \end{aligned} \tag{5}$$

where $\hat{z}_t$ is the predicted label, z_t is the actual label, and $\mathit{loss}(z_t, \hat{z}_t) = 1_{z_t \neq \hat{z}_t}$.

In addition to decoding, we use posterior probability when training the model. That is, our training objective is

$$\sum_{(\boldsymbol{x}_{1:T}, \boldsymbol{z}_{1:T}) \in \mathcal{D}} \sum_{t=1}^{T} \log p_{\boldsymbol{\theta}}(z_t|\boldsymbol{x}_{1:t}) \tag{6}$$

where $\mathcal{D}$ is the set of conversations in the training set, each consisting of a sequence of utterances $\boldsymbol{x}_{1:T}$ annotated with its gold sequence of DAs $\boldsymbol{z}_{1:T}$.

Average Embedding. This model offers a new perspective where a neural net combines an inference machine and a model (rather than simply encoding a model). Specifically, this model represents in its architecture, through a weighted sum of embeddings, the inference procedure encoded in Equation 4 for the Uncertainty Propagation model:

$$\mathit{softmax}(E_{q(z_{t-1})}[\boldsymbol{W}^{(z_{t-1})}]\boldsymbol{c}(\boldsymbol{x}_t) + E_{q(z_{t-1})}[\boldsymbol{b}^{(z_{t-1})}]) \tag{7}$$

where $q(z_t)$ is an embedding that represents the uncertainty at time step t. $q(z_t)$ is computed sequentially as new utterances are received, and used in both decoding and training.

This formulation contrasts with Uncertainty Propagation, where the expectation is over the distributions:

$$E_{p_{\boldsymbol{\theta}}(z_{t-1}|\boldsymbol{x}_{1:t-1})}[\mathit{softmax}(\boldsymbol{W}^{(z_{t-1})}\boldsymbol{c}(\boldsymbol{x}_t) + \boldsymbol{b}^{(z_{t-1})})] \tag{8}$$

It is worth noting that Equations 7 and 8 yield the same result if the distributions involved in calculating the expectations are point-mass distributions and they are equal.

Although we could have used a more elaborate neural architecture as the inference machine for the Average Embedding model, we employed a simple *softmax* architecture to make this model comparable with the principled inference algorithm for our Uncertainty Propagation model, which is based on Equation 4.

Comparison to traditional graphical models Our models have several similarities with the traditional HMM model and inference algorithms, such as Forward-Backward decoding and the Viterbi algorithm. However, there are some key differences. Firstly, our model is discriminative, whereas HMM is generative. Secondly, our method is designed for online decoding (the future inputs to a specific classification decision are unknown), whereas both Forward-Backward decoding and Viterbi require access to the whole sequence. Thirdly, Viterbi's objective is to decode for the most probable sequence of labels, whereas our decoding algorithm's objective is to find the sequence of most probable labels (conditioned on the inputs observed so far). Lastly, our Uncertainty Propagation model is not only a basis for decoding, but also for training (the training objective in Equation 6 requires the calculation of the posterior probability in Equation 4). Overall, the best analogue of our Uncertainty Propagation model to methods used in HMMs and other graphical models is the forward message calculation in the Forward-Backward algorithm.

3 Experiments

3.1 Data sets

For our experiments, we use the MapTask and Switchboard corpora.

The MapTask Dialog Act corpus (Anderson et al., 1991) consists of 128 conversations tagged with 13 DAs. The MapTask conversations focus on instructions and clarifications — in the MapTask experiment, there is one instruction giver and one instruction follower. The task of the instruction giver is to guide the instruction follower to follow a pre-determined path, and the instruction follower must draw this path on his/her map. We use 12 conversations for validation, 13 for testing, and the rest for training.

The Switchboard Dialog Act corpus (Godfrey et al., 1992; Jurafsky et al., 1997) consists of 1155 transcribed telephone conversations about general topics, encoded into 42 DAs. We use the experimental setup proposed by Stolcke *et al.* (2000): 1115 conversations for training and 19 for testing.

3.2 Baselines

Our first baseline is the model without any current label information. Next, we compare our models with other strategies for incorporating the current

	Accuracy	
Models	**Switchboard**	**MapTask**
No current label	72.93%	61.27%
True current label	73.15%	63.36%
Predicted current label	73.91%	64.53%
Scheduled Sampling	74.43%	64.50%
Average Embedding	75.04%	65.09%
Uncertainty Propagation	**75.61%**	**65.87%**

Table 1: Results of different strategies to leverage the current label.

Baseline models	**Accuracy**
Julia *et al.* (2010)	55.4 %
Surendran and Levow (2006)	59.1%
Tran *et al.* (2017)	61.6%
Our models:	
Average Embedding	62.6%
Uncertainty Propagation	**62.9%**

Table 2: Results on MapTask data.

Baseline models	**Accuracy**
Stolcke *et al.* (2000)	71.0%
Shen and Lee (2016)	72.6%
Kalchbrenner and Blunsom (2013)	73.9%
Tran *et al.* (2017)	74.5%
Ji *et al.* (2016)	(77.0%) 72.5%
Our models:	
Average Embedding	75.0%
Uncertainty Propagation	**75.6%**

Table 3: Results on Switchboard data.

labels, viz those that use *predicted label* in training, and those that use *correct label*. These models simply employ the predicted/correct label to gate the parameters in Equation 2 during training. During testing, both models can only use the predicted label.

Another baseline is Bengio *et al.*'s (2015) Scheduled Sampling technique, where the training model uses the current correct label with probability p and the predicted label with probability $1 - p$, and p is scheduled to decrease over time. This strategy tries to solve the label-bias problem by making the model gradually adapt to the noisy predicted current label.

Finally, we consider the results obtained by corpus-specific baselines, viz (Julia et al., 2010; Surendran and Levow, 2006; Tran et al., 2017) for MapTask, and (Stolcke et al., 2000; Kalchbrenner and Blunsom, 2013; Ji et al., 2016; Shen and Lee, 2016; Tran et al., 2017) for Switchboard.

3.3 Results

Table 1 compares our results with those obtained by the baselines. Our two models, Uncertainty Propagation and Average Embedding, outperform all the baselines. Among these two models, Uncertainty Propagation, which is more analytically grounded, outperforms the Average Embedding model. Using the true current label during training seems to degrade performance compared to using the predicted label, which is expected, since the true label is not available during testing. The Scheduled Sampling method performs similarly to the predicted-label method for the MapTask corpus, and outperforms this method for the Switchboard corpus.

Tables 2 and 3 compare our models' performance on the MapTask and Switchboard corpora respectively with that of several strong baselines. On MapTask, we achieved the best results for textual input, using the four-fold cross-validation setup used by Surendran and Levow (2006) and Julia *et al.* (2010). On Switchboard, we also obtained the best results among the systems with the same experimental setting. It is worth noting that Ji *et al.* (2016) reported a higher accuracy of 77.0%, but the paper does not provide enough information about the experimental setup to replicate this result, and we only got 72.5% accuracy using the paper's publicly available code.

3.4 Analysis

To quantify the effectiveness of the different models on reducing the label-bias problem, we calculate the probability of the models making a correct prediction after they have made a sequence of n mistakes. We expect our models, Uncertainty Propagation and Average Embedding, to be more robust than the label-sensitive baselines in recovering from errors.

The results in Table 4 confirm our expectations. The simple model with no current label, while performing worse than all other models in accuracy, does not suffer from the label-bias problem. Among the models with current label information, Uncertainty Propagation suffers the least from label bias. It even outperforms the model with no current label on Switchboard for all values of n, and on MapTask for $n = 2$. Interestingly, Average Embedding performs quite well for $n = 1$, but

	MapTask			Switchboard		
	$n = 1$	$n = 2$	$n = 3$	$n = 1$	$n = 2$	$n = 3$
Not affected by label bias:						
No Previous label	60.29%	56.90%	55.67%	66.99%	63.10%	56.52%
Affected by label bias:						
True current label	53.12%	50.38%	47.89%	61.74%	60.93%	60.71%
Predicted current label	55.89%	53.65%	49.10%	64.38%	62.21%	62.59%
Scheduled Sampling	54.28%	53.32%	50.00%	64.67%	63.49%	60.87%
Average Embedding	56.50%	53.76%	52.56%	66.51%	61.71%	55.22%
Uncertainty Propagation	**57.13%**	**57.37%**	**53.93%**	**67.78%**	**66.57%**	**66.36%**

Table 4: Probability that the models recover from a sequence of n prediction mistakes.

its ability to recover from errors drops quickly as the length of the erroneous conditioning sequence increases, especially on Switchboard, where the number of labels is higher. This may explain its slightly lower accuracy compared to the Uncertainty Propagation model. However, in general, the difference in accuracy between these two models is small, because they are rather unlikely to make several consecutive errors.

4 Conclusion

In this paper, we proposed two strategies to encode current label uncertainty in sequence-labeling RNN models. The experimental results show that our models achieve a very strong performance on the MapTask and Switchboard corpora using a simple underlying RNN architecture.

Although we experimented with DA classification, the idea presented in this paper is general, and can be applied to many sequence-labeling tasks. Our approach is particularly suitable for tasks involving streaming data where the model only has access to current and previous observations.

In the future, we plan to combine our strategies with more complex neural architectures, and explore their application to other sequence-labeling problems.

Abstract

In this paper, drawing intuition from the Turing test, we propose using adversarial training for open-domain dialogue generation: the system is trained to produce sequences that are indistinguishable from human-generated dialogue utterances. We cast the task as a reinforcement learning (RL) problem where we jointly train two systems, a generative model to produce response sequences, and a discriminator—analagous to the human evaluator in the Turing test— to distinguish between the human-generated dialogues and the machine-generated ones. The outputs from the discriminator are then used as rewards for the generative model, pushing the system to generate dialogues that mostly resemble human dialogues.

In addition to adversarial training we describe a model for adversarial *evaluation* that uses success in fooling an adversary as a dialogue evaluation metric, while avoiding a number of potential pitfalls. Experimental results on several metrics, including adversarial evaluation, demonstrate that the adversarially-trained system generates higher-quality responses than previous baselines.

1 Introduction

Open domain dialogue generation (Ritter et al., 2011; Sordoni et al., 2015; Xu et al., 2016; Wen et al., 2016; Li et al., 2016b; Serban et al., 2016c, 2017) aims at generating meaningful and coherent dialogue responses given the dialogue history. Prior systems, e.g., phrase-based machine translation systems (Ritter et al., 2011; Sordoni et al., 2015) or end-to-end neural systems (Shang et al., 2015; Vinyals and Le, 2015; Li et al., 2016a; Yao et al., 2015; Luan et al., 2016) approximate such a goal by predicting the next dialogue utterance given the dialogue history using the maximum likelihood estimation (MLE) objective. Despite its success, this over-simplified training objective leads to problems: responses are dull, generic (Sordoni et al., 2015; Serban et al., 2016a; Li et al., 2016a), repetitive, and short-sighted (Li et al., 2016d).

Solutions to these problems require answering a few fundamental questions: what are the crucial aspects that characterize an ideal conversation, how can we quantitatively measure them, and how can we incorporate them into a machine learning system? For example, Li et al. (2016d) manually define three ideal dialogue properties (ease of answering, informativeness and coherence) and use a reinforcement-learning framework to train the model to generate highly rewarded responses. Yu et al. (2016b) use keyword retrieval confidence as a reward. However, it is widely acknowledged that manually defined reward functions can't possibly cover all crucial aspects and can lead to suboptimal generated utterances.

A good dialogue model should generate utterances indistinguishable from human dialogues. Such a goal suggests a training objective resembling the idea of the Turing test (Turing, 1950). We borrow the idea of adversarial training (Goodfellow et al., 2014; Denton et al., 2015) in computer vision, in which we jointly train two models, a generator (a neural SEQ2SEQ model) that defines the probability of generating a dialogue sequence, and a discriminator that labels dialogues as human-generated or machine-generated. This discriminator is analogous to the evaluator in the Turing test. We cast the task as a reinforcement learning problem, in which the quality of machine-generated utterances is measured by its ability to fool the discriminator into believing that it is a

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2157–2169
Copenhagen, Denmark, September 7–11, 2017.

human-generated one. The output from the discriminator is used as a reward to the generator, pushing it to generate utterances indistinguishable from human-generated dialogues.

The idea of a Turing test—employing an evaluator to distinguish machine-generated texts from human-generated ones—can be applied not only to training but also testing, where it goes by the name of adversarial evaluation. Adversarial evaluation was first employed in Bowman et al. (2016) to evaluate sentence generation quality, and preliminarily studied for dialogue generation by Kannan and Vinyals (2016). In this paper, we discuss potential pitfalls of adversarial evaluations and necessary steps to avoid them and make evaluation reliable.

Experimental results demonstrate that our approach produces more interactive, interesting, and non-repetitive responses than standard SEQ2SEQ models trained using the MLE objective function.

2 Related Work

Dialogue generation Response generation for dialogue can be viewed as a source-to-target transduction problem. Ritter et al. (2011) frame the generation problem as a machine translation problem. Sordoni et al. (2015) improved Ritter et al.'s system by rescoring the outputs of a phrasal MT-based conversation system with a neural model incorporating prior context. Recent progress in SEQ2SEQ models have inspired several efforts (Vinyals and Le, 2015; Serban et al., 2016a,d; Luan et al., 2016) to build end-to-end conversational systems that first apply an encoder to map a message to a distributed vector representing its meaning and then generate a response from the vector.

Our work adapts the encoder-decoder model to RL training, and can thus be viewed as an extension of Li et al. (2016d), but with more general RL rewards. Li et al. (2016d) simulate dialogues between two virtual agents, using policy gradient methods to reward sequences that display three useful conversational properties: informativity, coherence, and ease of answering. Our work is also related to recent efforts to integrate the SEQ2SEQ and reinforcement learning paradigms, drawing on the advantages of both (Wen et al., 2016). For example, Su et al. (2016) combine reinforcement learning with neural generation on tasks with real users. Asghar et al. (2016) train an end-to-end RL dialogue model using human users.

Dialogue quality is traditionally evaluated (Sordoni et al., 2015, e.g.) using word-overlap metrics such as BLEU and METEOR scores used for machine translation. Some recent work (Liu et al., 2016) has started to look at more flexible and reliable evaluation metrics such as human-rating prediction (Lowe et al., 2017) and next utterance classification (Lowe et al., 2016).

Adversarial networks The idea of generative adversarial networks has enjoyed great success in computer vision (Radford et al., 2015; Chen et al., 2016a; Salimans et al., 2016). Training is formalized as a game in which the generative model is trained to generate outputs to fool the discriminator; the technique has been successfully applied to image generation.

However, to the best of our knowledge, this idea has not achieved comparable success in NLP. This is due to the fact that unlike in vision, text generation is discrete, which makes the error outputted from the discriminator hard to backpropagate to the generator. Some recent work has begun to address this issue: Lamb et al. (2016) propose providing the discriminator with the intermediate hidden vectors of the generator rather than its sequence outputs. Such a strategy makes the system differentiable and achieves promising results in tasks like character-level language modeling and handwriting generation. Yu et al. (2016a) use policy gradient reinforcement learning to backpropagate the error from the discriminator, showing improvement in multiple generation tasks such as poem generation, speech language generation and music generation. Outside of sequence generation, Chen et al. (2016b) apply the idea of adversarial training to sentiment analysis and Zhang et al. (2017) apply the idea to domain adaptation tasks.

Our work is distantly related to recent work that formalizes sequence generation as an action-taking problem in reinforcement learning. Ranzato et al. (2016) train RNN decoders in a SEQ2SEQ model using policy gradient to obtain competitive machine translation results. Bahdanau et al. (2017) take this a step further by training an actor-critic RL model for machine translation. Also related is recent work (Shen et al., 2016; Wiseman and Rush, 2016) to address the issues of exposure bias and loss-evaluation mismatch in neural translation.

3 Adversarial Training for Dialogue Generation

In this section, we describe in detail the components of the proposed adversarial reinforcement learning model. The problem can be framed as follows: given a dialogue history x consisting of a sequence of dialogue utterances,[1] the model needs to generate a response $y = \{y_1, y_2, ..., y_T\}$. We view the process of sentence generation as a sequence of actions that are taken according to a policy defined by an encoder-decoder recurrent neural network.

3.1 Adversarial REINFORCE

The adversarial REINFORCE algorithm consists of two components: a generative model G and a discriminative model D.

Generative model The generative model G defines the policy that generates a response y given dialogue history x. It takes a form similar to SEQ2SEQ models, which first map the source input to a vector representation using a recurrent net and then compute the probability of generating each token in the target using a softmax function.

Discriminative model The discriminative model D is a binary classifier that takes as input a sequence of dialogue utterances $\{x, y\}$ and outputs a label indicating whether the input is generated by humans or machines. The input dialogue is encoded into a vector representation using a hierarchical encoder (Li et al., 2015; Serban et al., 2016b),[2] which is then fed to a 2-class softmax function, returning the probability of the input dialogue episode being a machine-generated dialogue (denoted $Q_-(\{x, y\})$) or a human-generated dialogue (denoted $Q_+(\{x, y\})$).

Policy Gradient Training The key idea of the system is to encourage the generator to generate utterances that are indistinguishable from human generated dialogues. We use policy gradient methods to achieve such a goal, in which the score of current utterances being human-generated ones assigned by the discriminator (i.e., $Q_+(\{x, y\})$) is used as a reward for the generator, which is trained to maximize the expected reward of generated utterance(s) using the REINFORCE algorithm (Williams, 1992):

$$J(\theta) = \mathbb{E}_{y \sim p(y|x)}(Q_+(\{x, y\})|\theta) \tag{1}$$

Given the input dialogue history x, the bot generates a dialogue utterance y by sampling from the policy. The concatenation of the generated utterance y and the input x is fed to the discriminator. The gradient of (1) is approximated using the likelihood ratio trick (Williams, 1992; Glynn, 1990; Aleksandrov et al., 1968):

$$\begin{aligned} \nabla J(\theta) \approx & [Q_+(\{x, y\}) - b(\{x, y\})] \\ & \nabla \log \pi(y|x) \\ = & [Q_+(\{x, y\}) - b(\{x, y\})] \\ & \nabla \sum_t \log p(y_t|x, y_{1:t-1}) \end{aligned} \tag{2}$$

where π denotes the probability of the generated responses. $b(\{x, y\})$ denotes the baseline value to reduce the variance of the estimate while keeping it unbiased.[3] The discriminator is simultaneously updated with the human generated dialogue that contains dialogue history x as a positive example and the machine-generated dialogue as a negative example.

3.2 Reward for Every Generation Step (REGS)

The REINFORCE algorithm described has the disadvantage that the expectation of the reward is approximated by only one sample, and the reward associated with this sample (i.e., $[Q_+(\{x, y\}) - b(\{x, y\})]$ in Eq(2)) is used for all actions (the generation of each token) in the generated sequence. Suppose, for example, the input history is *what's your name*, the human-generated response is *I am John*, and the machine-generated response is *I don't know*. The vanilla REINFORCE model assigns the same negative reward to all tokens within the human-generated response (i.e., *I*, *don't*, *know*), whereas proper credit assignment in training would give separate rewards, most likely a neutral reward for the token *I*, and negative rewards to *don't* and *know*. We call this *reward for every generation step*, abbreviated *REGS*.

Rewards for intermediate steps or partially decoded sequences are thus necessary. Unfortunately, the discriminator is trained to assign scores to fully

[1] We approximate the dialogue history using the concatenation of two preceding utterances. We found that using more than 2 context utterances yields very tiny performance improvements for SEQ2SEQ models.

[2] To be specific, each utterance p or q is mapped to a vector representation h_p or h_q using LSTM (Hochreiter and Schmidhuber, 1997). Another LSTM is put on sentence level, mapping the context dialogue sequence to a single representation.

[3] Like Ranzato et al. (2016), we train another neural network model (the critic) to estimate the value (or future reward) of current state (i.e., the dialogue history) under the current policy π. The critic network takes as input the dialogue history, transforms it to a vector representation using a hierarchical network and maps the representation to a scalar. The network is optimized based on the mean squared loss between the estimated reward and the real reward.

generated sequences, but not partially decoded ones. We propose two strategies for computing intermediate step rewards by (1) using Monte Carlo (MC) search and (2) training a discriminator that is able to assign rewards to partially decoded sequences.

In (1) Monte Carlo search, given a partially decoded s_P, the model keeps sampling tokens from the distribution until the decoding finishes. Such a process is repeated N (set to 5) times and the N generated sequences will share a common prefix s_P. These N sequences are fed to the discriminator, the average score of which is used as a reward for the s_P. A similar strategy is adopted in Yu et al. (2016a). The downside of MC is that it requires repeating the sampling process for each prefix of each sequence and is thus significantly time-consuming.[4]

In (2), we directly train a discriminator that is able to assign rewards to both fully and partially decoded sequences. We break the generated sequences into partial sequences, namely $\{y^+_{1:t}\}_{t=1}^{N_{Y+}}$ and $\{y^-_{1:t}\}_{t=1}^{N_{Y-}}$ and use all instances in $\{y^+_{1:t}\}_{t=1}^{N_{Y+}}$ as positive examples and instances $\{y^-_{1:t}\}_{t=1}^{N_{Y-}}$ as negative examples. The problem with such a strategy is that earlier actions in a sequence are shared among multiple training examples for the discriminator (for example, token y_1^+ is contained in all partially generated sequences, which results in overfitting. To mitigate this problem, we adopt a strategy similar to when training value networks in *AlphaGo* (Silver et al., 2016), in which for each collection of subsequences of Y, we randomly sample only one example from $\{y^+_{1:t}\}_{t=1}^{N_{Y+}}$ and one example from $\{y^-_{1:t}\}_{t=1}^{N_{Y-}}$, which are treated as positive and negative examples to update the discriminator. Compared with the Monte Carlo search model, this strategy is significantly more time-effective, but comes with the weakness that the discriminator becomes less accurate after partially decoded sequences are added in as training examples. We find that the MC model performs better when training time is less of an issue.

For each partially-generated sequence $Y_t = y_{1:t}$, the discriminator gives a classification score $Q_+(x, Y_t)$. We compute the baseline $b(x, Y_t)$ using a similar model to the vanilla REINFORCE model. This yields the following gradient to update the generator:

$$\nabla J(\theta) \approx \sum_t (Q_+(x, Y_t) - b(x, Y_t)) \nabla \log p(y_t|x, Y_{1:t-1}) \quad (3)$$

Comparing (3) with (2), we can see that the values for rewards and baselines are different among generated tokens in the same response.

Teacher Forcing Practically, we find that updating the generative model only using Eq. 1 leads to unstable training for both vanilla Reinforce and REGS, with the perplexity value skyrocketing after training the model for a few hours (even when the generator is initialized using a pre-trained SEQ2SEQ model). The reason this happens is that the generative model can only be indirectly exposed to the gold-standard target sequences through the reward passed back from the discriminator, and this reward is used to promote or discourage its (the generator's) own generated sequences. Such a training strategy is fragile: once the generator (accidentally) deteriorates in some training batches and the discriminator consequently does an extremely good job in recognizing sequences from the generator, the generator immediately gets lost. It knows that its generated sequences are bad based on the rewards outputted from the discriminator, but it does not know what sequences are good and how to push itself to generate these good sequences (the odds of generating a good response from random sampling are minute, due to the vast size of the space of possible sequences). Loss of the reward signal leads to a breakdown in the training process.

To alleviate this issue and give the generator more direct access to the gold-standard targets, we propose also feeding human generated responses to the generator for model updates. The most straightforward strategy is for the discriminator to automatically assign a reward of 1 (or other positive values) to the human generated responses and for the generator to use this reward to update itself on human generated examples. This can be seen as having a teacher intervene with the generator some fraction of the time and force it to generate the true responses, an approach that is similar to the professor-forcing algorithm of Lamb et al. (2016).

A closer look reveals that this modification is the same as the standard training of SEQ2SEQ mod-

[4] Consider one target sequence with length 20, we need to sample 5*20=100 full sequences to get rewards for all intermediate steps. Training one batch with 128 examples roughly takes roughly 1 min on a single GPU, which is computationally intractable considering the size of the dialogue data we have. We thus parallelize the sampling processes, distributing jobs across 8 GPUs.

```

Figure 1: A brief review of the proposed adversarial reinforcement algorithm for training the generator G and discriminator D. The reward r from the discriminator D can be computed using different strategies according to whether using REINFORCE or REGS. The update of the generator G on $(X, \hat{Y})$ can be done by either using Eq.2 or Eq.3. D-steps is set to 5 and G-steps is set to 1.

els, making the final training alternately update the SEQ2SEQ model using the adversarial objective and the MLE objective. One can think of the professor-forcing model as a regularizer to regulate the generator once it starts deviating from the training dataset.

We also propose another workaround, in which the discriminator first assigns a reward to a human generated example using its own model, and the generator then updates itself using this reward on the human generated example only if the reward is larger than the baseline value. Such a strategy has the advantage that different weights for model updates are assigned to different human generated examples (in the form of different reward values produced by the generator) and that human generated examples are always associated with nonnegative weights.

A sketch of the proposed model is shown in Figure 1.

3.3 Training Details

We first pre-train the generative model by predicting target sequences given the dialogue history. We trained a SEQ2SEQ model (Sutskever et al., 2014) with an attention mechanism (Bahdanau et al., 2015; Luong et al., 2015) on the OpenSubtitles dataset. We followed protocols recommended by Sutskever et al. (2014), such as gradient clipping, mini-batch and learning rate decay. We also pre-train the discriminator. To generate negative examples, we decode part of the training data. Half of the negative examples are generated using beam-search with mutual information reranking as described in Li et al. (2016a), and the other half is generated from sampling.

For data processing, model training and decoding (both the proposed adversarial training model and the standard SEQ2SEQ models), we employ a few strategies that improve response quality, including: (2) Remove training examples with length of responses shorter than a threshold (set to 5). We find that this significantly improves the general response quality.[5] (2) Instead of using the same learning rate for all examples, using a weighted learning rate that considers the average tf-idf score for tokens within the response. Such a strategy decreases the influence from dull and generic utterances.[6] (3) Penalizing intra-sibling ranking when doing beam search decoding to promote N-best list diversity as described in Li et al. (2016c). (4) Penalizing word types (stop words excluded) that have already been generated. Such a strategy dramatically decreases the rate of repetitive responses such as *no. no. no. no. no.* or contradictory responses such as *I don't like oranges but i like oranges*.

4 Adversarial Evaluation

In this section, we discuss strategies for successful adversarial evaluation. Note that the proposed adversarial training and adversarial evaluation are separate procedures. They are independent of each other and share no common parameters.

The idea of adversarial evaluation, first proposed by Bowman et al. (2016), is to train a discriminant function to separate generated and true sentences, in an attempt to evaluate the model's sentence generation capability. The idea has been preliminarily studied by Kannan and Vinyals (2016) in the context of dialogue generation. Adversarial evaluation also resembles the idea of the Turing test, which

[5] To compensate for the loss of short responses, one can train a separate model using short sequences.

[6] We treat each sentence as a document. Stop words are removed. Learning rates are normalized within one batch. For example, suppose t_1, t_2, ..., t_i, ... ,t_N denote the tf-idf scores for sentences within current batch and lr denotes the original learning rate. The learning rate for sentence with index i is $N \cdot lr \cdot \frac{t_i}{\sum_{i'} t_{i'}}$. To avoid exploding learning rates for sequences with extremely rare words, the tf-idf score of a sentence is capped at L times the minimum tf-idf score in the current batch. L is empirically chosen and is set to 3.

requires a human evaluator to distinguish machine-generated texts from human-generated ones. Since it is time-consuming and costly to ask a human to talk to a model and give judgements, we train a machine evaluator in place of the human evaluator to distinguish the human dialogues and machine dialogues, and we use it to measure the general quality of the generated responses.

Adversarial evaluation involves both training and testing. At training time, the evaluator is trained to label dialogues as machine-generated (negative) or human-generated (positive). At test time, the trained evaluator is evaluated on a held-out dataset. If the human-generated dialogues and machine-generated ones are indistinguishable, the model will achieve 50 percent accuracy at test time.

4.1 Adversarial Success

We define Adversarial Success (*AdverSuc* for short) to be the fraction of instances in which a model is capable of fooling the evaluator. *AdverSuc* is the difference between 1 and the accuracy achieved by the evaluator. Higher values of *AdverSuc* for a dialogue generation model are better.

4.2 Testing the Evaluator's Ability

One caveat with the adversarial evaluation methods is that they are model-dependent. We approximate the human evaluator in the Turing test with an automatic evaluator and assume that the evaluator is perfect: low accuracy of the discriminator should indicate high quality of the responses, since we interpret this to mean the generated responses are indistinguishable from the human ones. Unfortunately, there is another factor that can lead to low discriminative accuracy: a poor discriminative model. Consider a discriminator that always gives random labels or always gives the same label. Such an evaluator always yields a high *AdverSuc* value of 0.5. Bowman et al. (2016) propose two different discriminator models separately using *unigram* features and *neural* features. It is hard to tell which feature set is more reliable. The standard strategy of testing the model on a held-out development set is not suited to this case, since a model that overfits the development set is necessarily superior.

To deal with this issue, we propose setting up a few manually-invented situations to test the ability of the automatic evaluator. This is akin to setting up examinations to test the ability of the human evaluator in the Turing test. We report not only the *AdverSuc* values, but also the scores that the evaluator achieves in these manually-designed test cases, indicating how much we can trust the reported *AdverSuc*. We develop scenarios in which we know in advance how a perfect evaluator should behave, and then compare *AdverSuc* from a discriminative model with the gold-standard *AdverSuc*. Scenarios we design include:

- We use human-generated dialogues as both positive examples and negative examples. A perfect evaluator should give an *AdverSuc* of 0.5 (accuracy 50%), which is the gold-standard result.
- We use machine-generated dialogues as both positive examples and negative examples. A perfect evaluator should give an *AdverSuc* of 0.5 (accuracy 50%).
- We use original human-generated dialogues as positive examples and dialogues consisting of random utterances as negative examples. A perfect evaluator should give an *AdverSuc* of 0 (accuracy 100%).
- We use original human-generated dialogues as positive examples and dialogues with responses replaced by the utterances immediately following the true responses. A perfect evaluation should give an *AdverSuc* of 0 (accuracy 100%).

The *evaluator reliability error* (ERE) is the average deviation of an evaluator's adversarial error from the gold-standard error in the above tasks, with equal weight for each task. The smaller the error, the more reliable the evaluator is.

4.3 Machine-vs-Random Accuracy

Evaluator reliability error uses scenarios constructed from human-generated dialogues to assess feature or hyper-parameter choice for the evaluator. Unfortunately, no machine-generated responses are involved in the ERE metric. The following example illustrates the serious weakness resulting from this strategy: as will be shown in the experiment section, when inputs are decoded using greedy or beam search models, most generation systems to date yield an adversarial success less than 10 percent (evaluator accuracy 90 percent). But when using sampling for decoding, the adversarial success skyrockets to around 40 percent,[7] only 10 percent less than what's needed to pass the Turing test. A close look at the decoded sequences using sampling tells a different story: the responses from

[7] Similar results are also reported in Kannan and Vinyals (2016).

Input	tell me ... how long have you had this falling sickness ?
Vanilla-MLE	i 'm not a doctor .
Vanilla-Sample	well everything you did was totally untrue .
REINFORCE	i don 't know how long it 's been .
REGS Monte Carlo	A few months, I guess .
Input	so i had the doctors test sammy 's response to conditioning .
Vanilla-MLE	sammy wrote the test sammy wrote the test .
Vanilla-Sample	objects pick objects up objects objects objects objects objects
REINFORCE	i 'm not sure that 's relevant .
REGS Monte Carlo	so he took the pills .
Input	what are you going to do ?
Vanilla-MLE	i 'm going to the movies .
Vanilla-Sample	get him outta here first !
REINFORCE	i 'm going to get you .
REGS Monte Carlo	i 'm going to get you a new car .
Input	they fear your power your intellect .
Vanilla-MLE	you 're the only one who knows what 's going on .
Vanilla-Sample	when they are conquered and you surrender they will control all of us .
REINFORCE	i 'm afraid i 'm not ready yet .
REGS Monte Carlo	i 'm not afraid of your power .

Table 1: Sampled responses from different models. More in Appendix Tables 5 and 6.

sampling are sometimes incoherent, irrelevant or even ungrammatical.

We thus propose an additional sanity check, in which we report the accuracy of distinguishing between machine-generated responses and randomly sampled responses (*machine-vs-random* for short). This resembles the N-choose-1 metric described in Shao et al. (2017). Higher accuracy indicates that the generated responses are distinguishable from randomly sampled human responses, indicating that the generative model is not fooling the generator simply by introducing randomness. As we will show in Sec. 5, using sampling results in high *AdverSuc* values but low *machine-vs-random* accuracy.

5 Experimental Results

In this section, we detail experimental results on adversarial success and human evaluation.

Setting	ERE
SVM+Unigram	0.232
Concat Neural	0.209
Hierarchical Neural	0.193
SVM+Neural+multil-features	0.152

Table 2: ERE scores obtained by different models.

5.1 Adversarial Evaluation

ERE We first test adversarial evaluation models with different feature sets and model architectures for reliability, as measured by evaluator reliability error (ERE). We explore the following models: (1) *SVM+Unigram*: SVM using unigram features.[8] A multi-utterance dialogue (i.e., input messages and responses) is transformed to a unigram representation; (2) *Concat Neural*: a neural classification model with a softmax function that takes as input the concatenation of representations of constituent dialogues sentences; (3) *Hierarchical Neural*: a hierarchical encoder with a structure similar to the discriminator used in the reinforcement; and (4) *SVM+Neural+multi-lex-features*: a SVM model that uses the following features: unigrams, neural representations of dialogues obtained by the neural model trained using strategy (3),[9] the forward likelihood $\log p(t|s)$ and backward likelihood $p(s|t)$.

ERE scores obtained by different models are reported in Table 2. As can be seen, the *hierarchical neural* evaluator (model 3) is more reliable than simply concatenating the sentence-level representations (model 2). Using the combination of neural features and lexicalized features yields the most reliable evaluator. For the rest of this section, we report results obtained by the *Hierarchical Neural* setting due to its end-to-end nature, despite its inferiority to *SVM+Neural+multil-features*.

Table 3 presents *AdverSuc* values for different models, along with *machine-vs-random* accuracy described in Section 4.3. Higher values of *AdverSuc* and *machine-vs-random* are better.

Baselines we consider include standard SEQ2SEQ models using greedy decoding (*MLE-greedy*), beam-search (*MLE+BS*) and sampling, as well as the mutual information reranking model of Li et al. (2016a) with two algorithmic variations: (1) MMI+$p(t|s)$, in which a large N-best list is first

[8] Trained using the SVM-Light package (Joachims, 2002).

[9] The representation before the softmax layer.

Model	*AdverSuc*	*machine-vs-random*
MLE-BS	0.037	0.942
MLE-Greedy	0.049	0.945
MMI+$p(t\|s)$	0.073	0.953
MMI-$p(t)$	0.090	0.880
Sampling	0.372	0.679
Adver-Reinforce	0.080	0.945
Adver-REGS	0.098	0.952

Table 3: *AdverSuc* and *machine-vs-random* scores achieved by different training/decoding strategies.

generated using a pre-trained SEQ2SEQ model and then reranked by the backward probability $p(s|t)$ and (2) MMI$-p(t)$, in which language model probability is penalized during decoding.

Results are shown in Table 3. What first stands out is decoding using sampling (as discussed in Section 4.3), achieving a significantly higher *AdverSuc* number than all the rest models. However, this does not indicate the superiority of the sampling decoding model, since the *machine-vs-random* accuracy is at the same time significantly lower. This means that sampled responses based on SEQ2SEQ models are not only hard for an evaluator to distinguish from real human responses, but also from randomly sampled responses. A similar, though much less extreme, effect is observed for MMI$-p(t)$, which has an *AdverSuc* value slightly higher than *Adver-Reinforce*, but a significantly lower *machine-vs-random* score.

By comparing different baselines, we find that MMI+$p(t|s)$ is better than *MLE-greedy*, which is in turn better than *MLE+BS*. This result is in line with human-evaluation results from Li et al. (2016a). The two proposed adversarial algorithms achieve better performance than the baselines. We expect this to be the case, since the adversarial algorithms are trained on an objective function more similar to the evaluation metric (i.e., adversarial success). *REGS* performs slightly better than the vanilla REINFORCE algorithm.

5.2 Human Evaluation

For human evaluation, we follow protocols defined in Li et al. (2016d), employing crowdsourced judges to evaluate a random sample of 200 items. We present both an input message and the generated outputs to 3 judges and ask them to decide which of the two outputs is better (*single-turn* general quality). Ties are permitted. Identical strings are assigned the same score. We also present the judges with *multi-turn* conversations simulated between the two agents. Each conversation consists of 3 turns. Results are presented in Table 4. We observe a significant quality improvement on both single-turn quality and multi-turn quality from the proposed adversarial model. It is worth noting that the reinforcement learning system described in Li et al. (2016d), which simulates conversations between two bots and is trained based on manually designed reward functions, only improves multi-turn dialogue quality, while the model described in this paper improves both single-turn and multi-turn dialogue generation quality. This confirms that the reward adopted in adversarial training is more general, natural and effective in training dialogue systems.

Setting	adver-win	adver-lose	tie
single-turn	0.62	0.18	0.20
multi-turn	0.72	0.10	0.18

Table 4: The gain from the proposed adversarial model over the mutual information system based on pairwise human judgments.

6 Conclusion and Future Work

In this paper, drawing intuitions from the Turing test, we propose using an adversarial training approach for response generation. We cast the model in the framework of reinforcement learning and train a generator based on the signal from a discriminator to generate response sequences indistinguishable from human-generated dialogues. We observe clear performance improvements on multiple metrics from the adversarial training strategy.

The adversarial training model should theoretically benefit a variety of generation tasks in NLP. Unfortunately, in preliminary experiments applying the same training paradigm to machine translation, we did not observe a clear performance boost. We conjecture that this is because the adversarial training strategy is more beneficial to tasks in which there is a big discrepancy between the distributions of the generated sequences and the reference target sequences. In other words, the adversarial approach is more beneficial on tasks in which entropy of the targets is high. Exploring this relationship further is a focus of our future work.

Vanilla-MLE	they 're not the only ones who have been in the system .
Vanilla-Sample	it 's the new priority only .
Reinforce	they 're not the only ones who can help us .
MC	can we find someone else ?
Input	and he carried them all the time wherever he went .
Vanilla-MLE	i don 't know who he is .
Vanilla-Sample	the church ... suffered the winds of 900 meters with horse aid .
Reinforce	he was a good man .
MC	he was a very good man .
Input	somebody probably flushed their pet snake down the toilet .
Vanilla-MLE	i 'm sure the dog will be here soon .
Vanilla-Sample	i could at least think .
Reinforce	i don 't think so .
MC	i don 't think so .
Input	excuse me but how did we pay for these suits ?
Vanilla-MLE	i 'm not a beggar .
Vanilla-Sample	is this the money eugene ?
Reinforce	i don 't know what to do .
MC	how much money you owe me ?
Input	... while the beautiful and happy world was madly destroyed ;
Vanilla-MLE	i was born in the world of the world
Vanilla-Sample	as in childhood i took you to one tenth of a postcard
Reinforce	and the world was full of joy .
MC	and the world was full of joy .
Input	i was kinda hoping that you were my dad .
Vanilla-MLE	i 'm just a little bit of a little bit of a little bit of a little bit of a
Vanilla-Sample	shiny gold gold and silver in the mountains .
Reinforce	i 'm not gonna be a baby .
MC	i 'm not going to be a father .
Input	the man who does that is not afraid to die .
Vanilla-MLE	he 's not afraid of the dark .
Vanilla-Sample	even the program is the only truth
Reinforce	he 's also not afraid of me .
MC	he 's such a brave man !
Input	do you have any idea what caused the explosion ?
Vanilla-MLE	i think it 's the same thing .
Vanilla-Sample	i 'm still very nervous .
Reinforce	maybe it 's just a coincidence .
MC	i don 't know if it 's a coincidence .
Input	don 't bother the citizens in hong kong island anymore
Vanilla-MLE	i 'll be back in a few days
Vanilla-Sample	you wiii be transferred to the target court
Reinforce	i 'm not sure if you can handle it without bothering them .
MC	i 'm not going to be a nuisance
Input	you know you ought to find yourself a girl .
Vanilla-MLE	you know what i mean ?
Vanilla-Sample	it 's full of crime ...
Reinforce	i don 't know what you 're talking about .
MC	i don 't want to be a girl .
Input	i got you the big screen tv deluxe UNknown machine
Vanilla-MLE	i 'm gonna be a little late for the movie .
Vanilla-Sample	you mean you 're living ?
Reinforce	i 'm gonna get you a new one .
MC	i 'm gonna get you a new tv set .
Input	we won 't give her the chance to surprise us .
Vanilla-MLE	she 's not going to be a party member .
Vanilla-Sample	the timing 's good and bad .
Reinforce	we 'll have to get her back .
MC	i don 't think we have to worry about her .
Input	does it live in this matter we call dna ?
Vanilla-MLE	i don 't think so .
Vanilla-Sample	and it requires time to be wrong and no one believes it .
Reinforce	it 's a genetic disorder .
MC	i don 't think so .

Using Context Information for Dialog Act Classification in DNN Framework

Yang Liu and **Kun Han** and **Zhao Tan** and **Yun Lei**
Applied Machine Learning, Facebook

Abstract

Previous work on dialog act (DA) classification has investigated different methods, such as hidden Markov models, maximum entropy, conditional random fields, graphical models, and support vector machines. A few recent studies explored using deep learning neural networks for DA classification, however, it is not clear yet what is the best method for using dialog context or DA sequential information, and how much gain it brings. This paper proposes several ways of using context information for DA classification, all in the deep learning framework. The baseline system classifies each utterance using the convolutional neural networks (CNN). Our proposed methods include using hierarchical models (recurrent neural networks (RNN) or CNN) for DA sequence tagging where the bottom layer takes the sentence CNN representation as input, concatenating predictions from the previous utterances with the CNN vector for classification, and performing sequence decoding based on the predictions from the sentence CNN model. We conduct thorough experiments and comparisons on the Switchboard corpus, demonstrate that incorporating context information significantly improves DA classification, and show that we achieve new state-of-the-art performance for this task.

1 Introduction

Dialog act (DA) represents a function of a speaker's utterance in either human-to-human or human-to-computer conversations. Correct identification of DAs is important for understanding human conversations, as well as for developing intelligent human-to-computer dialog systems (either written or spoken dialogs). For example, recognizing DAs can help identify questions and answers in meetings, customer service, online forum, etc. Many machine learning techniques have been investigated and shown reasonable performance for DA classification, for example, (Ang et al., 2005; Ji and Bilmes, 2005; Kalchbrenner and Blunsom, 2013; Ribeiro et al., 2015), just to name a few. Intuitively we would expect that leveraging dialog context can help classify the current utterance. For example, if the previous sentence is a question, then there is a high probability that the current sentence is a response to that question. Such context information has been explored in some previous methods, for example, hidden Markov models (HMM), conditional random fields (CRF), dynamic Bayesian networks (DBN). Given the recent success of the deep learning framework in various language processing tasks, in this work we also employ neural networks for DA classification. In fact, such models have been used in some recent studies for DA classification, e.g., (Rojas-Barahona et al., 2016; Kalchbrenner and Blunsom, 2013; Zhou et al., 2015); however, previous work has not thoroughly evaluated the use of context information for this task, and there is still a lack of good understanding about how we can use context information and how useful it is. This is the question we aim to answer in this work.

The contributions of this paper are: 1) We propose several ways to incorporate context information for DA classification over the baseline method of using convolutional neural networks (CNN) for sentence classification, including: (a) a hierarchical RNN/LSTM and CNN to model the utterance sequence in the conversation, where the input to the higher level LSTM and CNN unit is the sentence vector from the sentence level CNN model;

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2170–2178
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

(b) a two-step approach where the predicted DA results for the previous utterances, either labels or probability distributions, are concatenated with the sentence CNN vector for the current utterance as the new input for classification; (c) sequence level decoding based on the predicted DA probabilities and the transition probabilities between DA labels. Some of these methods have not been exploited previously for this task. 2) We perform a detailed and thorough analysis of different modeling approaches and some impacting factors in the models (such as the context length, representations and quality of the predictions). This is the first study with such kind of comparisons. 3) We achieve new state-of-the-art results.

2 Related work

Previous work has investigated different machine learning techniques for DA classification such as Maximum entropy, DBN, HMM, and SVM (Ang et al., 2005; Ji and Bilmes, 2005; Venkataraman et al., 2003; Webb et al., 2005; Fernandez and Picard, 2002; Mast et al., 1996; Liu, 2006; Kral and Cerisara, 2014). Different features have been explored in these models, including lexical, syntactic features, prosodic cues, and speaker interactions. In particular, context information has been previously used in some methods. For example, some early studies used HMMs (Venkataraman et al., 2003; Stolcke et al., 2000), where the "hidden" states are the DA tags, which generate the sequence of words as observations. The observation probabilities are obtained by DA specific word-based language models, and a DA tag based n-gram language model provides the transition probabilities between the DA tags. (Ji and Bilmes, 2005; Dielmann and Renals, 2008) used DBN for sequence decoding and examined both the generative and the conditional modeling approaches. CRF, as a powerful sequence labeling method, has also been widely used to incorporate context information for DA classification (Kim et al., 2010; Quarteroni et al., 2011; Chen and Eugenio, 2013; Dielmann and Renals, 2008). It is worth noting that (Ribeiro et al., 2015) used different configurations to capture information from previous context in the SVM classifiers, such as n-grams or DA predictions. This is similar to our work in that we also evaluate using the previous utterances, and the predicted DAs for them. However, our modeling approaches are all based on DNNs, as described in more details in Section 3, and the interaction between utterances and DA labels is modeled in the hierarchical models in a more principled way.

Recently deep learning has been widely adopted in many language processing tasks, including DA classification. Context or sequence information is also explored in this framework. For example, (Rojas-Barahona et al., 2016) proposed to use DNN for DA classification and slot filling, and evaluated on two different sets. They showed that their proposed CNN+LSTM model has negligible gain on one data set, and significant improvement on the other one for the joint DA classification and slot filling task. (Kalchbrenner and Blunsom, 2013) proposed methods for discourse decomposition, and investigated using recurrent CNN for DA classification, reporting some positive results, e.g., 2.9% improvement over the LM-HMM baseline. In this paper we propose different methods in the deep learning framework to incorporate context information. Our hierarchical LSTM and CNN method has some similarities to that used in (Rojas-Barahona et al., 2016; Kalchbrenner and Blunsom, 2013), but unlike those that focus on just one method, we propose a few approaches and perform comparisons among them for a deeper understanding of different methods and their contributing factors.

The discussions above are limited to DA classification using speech/text data. Other knowledge sources have also been used in a multimodal setting (e.g., haptic actions in (Chen and Eugenio, 2013)). In this study we just rely on textual information. Also note that in some scenarios, for example, speech conversations where transcripts are from speech recognition systems, DA segmentation is also needed. This problem has been addressed in some previous work, for example, (Lendvai, 2007; Quarteroni et al., 2011; Ang et al., 2005), which often uses a classification or sequence labeling setup for the segmentation task, or performs joint DA segmentation and classification. We use pre-segmented utterances and focus just on the DA classification task in this work.

3 DA Classification Methods

3.1 Task

Our task is to classify each utterance in a conversation into a predefined DA tag set. We use Switchboard data in our experiments (see Section 4.1 for

DA type	speaker	sentence
statement-opinion	B	I always kind of think it would be neat to be able to watch them and be there for them all the time
back-channel	A	Uh-huh
question-yes-no	B	Is that what you do?
yes-answer	A	Uh yeah
statement	A	Actually I teach my kids at home
statement	A	so I'm here all the time
summarize/reformulate	B:	Oh so they don't go to school

Table 1: An example of Switchboard conversation with the DA labels.

additional information on the data). There are different granularities of the tag sets. In this work we use 42 tags (Jurafsky et al., 1997), which has been widely used in previous studies of DA classification on this data set. Table 1 shows an example of some utterances in a Switchboard conversation. We can see that the 'answer' DA follows the 'question' one, which is quite intuitive. Our goal is thus to model such sequential information for DA classification. Again in this work we only use the transcriptions of the utterances along with the speaker information (i.e., if the current utterance is from the same or different speaker as the previous one), without any speech related features.

3.2 CNN for utterance classification

All of our methods are built based on the basic CNN sentence representation, which has been widely used recently in sentence as well as document classification (Collobert et al., 2011; Kim, 2014), therefore we first briefly describe this baseline. Figure 1 shows the context independent CNN-based classification method. Let $\mathbf{w}_{[1...n]}$ represent the word embedding sequence for a sentence with n words, where $\mathbf{w}_i \in \mathbf{R}^d$ is the d-dimensional embedding vector for the i^{th} word. A temporal convolution operation is applied to the sentence:

$$c_{[1...n]} = \tilde{\mathbf{w}}_{[1...n]} * \mathbf{f}$$

where $\tilde{\mathbf{w}}_{[1...n]}$ denotes the sequence $\mathbf{w}_{[1...n]}$ with zero padding, and f is a filter map for the convolution operation. A max pooling layer is then applied over the resulting sequence $c_{[1...n]}$ to obtain one value for the sentence. If we use l window sizes and k filters for each window, then $l \times k$ convolutional sequences are generated for each sentence, and after max pooling, we obtain a fixed-length vector $\mathbf{s}$ with a dimension of $l \times k$. This is the feature vector representation for the sentence, which is then used as the input in a multi-layer perceptron (MLP) or feedforward neural network for sentence classification. We only use one layer MLP in this work.

This baseline CNN model learns textual information in each sentence for DA classification. We can incorporate additional features into this model, for example, if the current sentence is from the same speaker as the previous one. Figure 1 shows the use of such additional features – they are concatenated with the CNN-based textural vector, and then fed to the MLP for DA classification. In the rest of the paper, when there is no confusion, we also use CNN for the cases when additional features are concatenated with the standard CNN for sentence-level representation. We use this CNN model as a baseline, and in the following will explore several methods using context information for DA classification.

3.3 Use history DA information

As discussed earlier, we expect there is valuable sequential information among the DA tags, therefore in the first approach, we combine the history DA information with the current utterance to classify its DA tag. This is represented as additional features concatenated with the CNN sentence representation, as shown in Figure 1. We evaluate different configurations in this framework.

- Use DA labels. We compare using reference and system predicted DA labels in training and testing. Note that using reference labels in testing is not a real testing setup. This is just meant to provide an upper bound and understand the performance degradation due to prediction errors.
- Use probabilities for system predictions. Instead of taking the hard decisions from the system's predictions, we evaluate using the

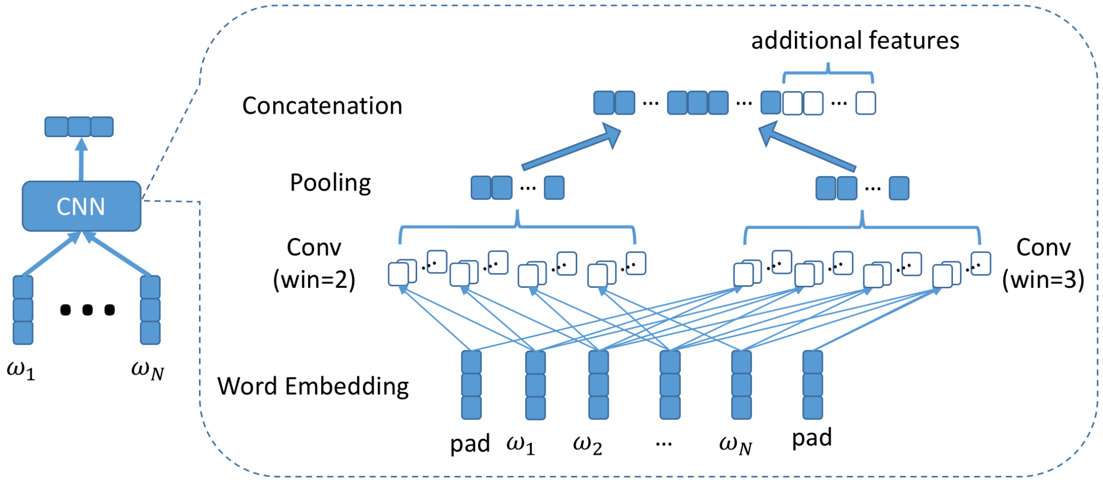

Figure 1: Baseline context-independent CNN-based DA classification method.

posterior probabilities from the system in order to capture more information.

- History length. We compare using DA information from different number of previous utterances.

Note that for most of these setups above when system's predicted DA information is used, we need to go through the following procedure:

- train a context-independent sentence CNN model
- use it to generate predictions, for training and test data
- add the corresponding history DA information in the training set to retrain a model
- add the history DA information in the test set and apply the new model

The only scenario where these steps are not required is when reference DA tags are used in both training and testing. There is one additional caveat that is worth pointing out – when generating the DA predictions for the training data, ideally we need to perform cross validation for the training set such that all the training sentences are labeled by a model trained from data that does not include this sentence, and thus we have matched information used in training and testing; however, we noticed that our model does not overfit the training data very much, and the training accuracy is not significantly different from the test accuracy, therefore we simply apply the trained CNN model to the training set itself to obtain the DA predictions for all the training sentences, and train the new model.

3.4 CNN + DA transition decoding

In this approach, we perform conversation level decoding that combines the probabilities from the context-independent CNN model and the DA tag transition probabilities. The DA classification problem can be represented as:

$$\hat{Y} = argmaxP(Y|X) = argmaxP(Y)P(X|Y)$$
$$= argmaxP(Y)\prod_i P(x_i|y_i)$$

where Y is the DA tag sequence, and X contains the entire conversation, i.e., sequence of sentences. $P(Y)$ can be computed for the DA tag sequence (similar to word-based n-gram language model, here "words" are DA tags), and the probability of a tag given the utterance ($P(x_i|y_i)$) can be obtained from the rescaled probability from the CNN model (that is $P(y_i|x_i)$). For decoding, we can use either Viterbi decoding to find the most likely DA sequence (as shown above) or forward-backward decoding to determine the best tag for each utterance in the sequence. This model is similar to the HMM model used previously for this task (Stolcke et al., 2000), and the difference is in that the probability of a DA given the sentence is estimated by the CNN model, a discrim-

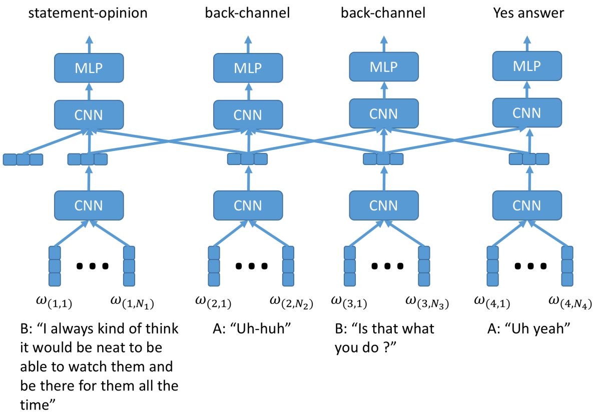

Figure 2: Hirarchical CNN: sequence CNN on top of sentence CNN for DA classification.

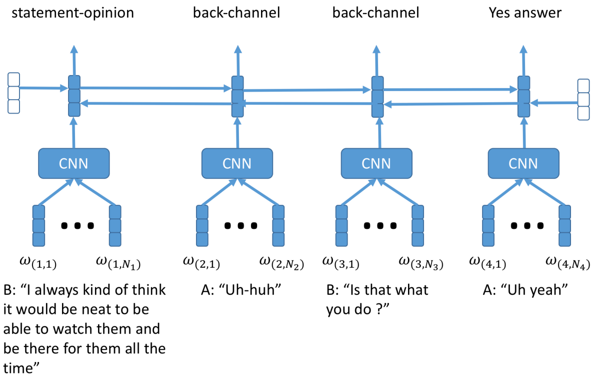

Figure 3: RNN/Bi-LSTM on top of sentence CNN for DA classification.

inative model, in contrast to the word-based language model that is a generative model.

3.5 Hierarchical model: CNN+CNN

Once we have the sentence vector representation built based on the baseline CNN model, we use another CNN to incorporate context information of an utterance for its classification. Figure 2 shows this method. The sequence of sentences is represented by a sequence of fixed length vectors $\mathbf{s}_{[1...m]}$, where m is the number of sentences in the conversation, and s_i is the vector representation for sentence i from the baseline CNN model. Similar to the CNN model for word sequence, we apply a temporal convolutional layer with different filters to $\mathbf{s}_{[1...m]}$. Different from the sentence CNN model for word sequences, here we do not perform pooling for the entire dialog sequence, as the classification task is for each sentence, not the whole conversation (sentence sequence). Instead, for each sentence, the output of every convolutional filter is concatenated to form the sentence's representation, and then an MLP is used for its classification. This approach can be thought as a hierarchical neural network, where the high level CNN is used to capture context information.

3.6 Hierarchical model: CNN+RNN

The hierarchical CNN method uses the neighboring sentences to learn the dependencies among consecutive utterances. A different method to model the sequential information is via an RNN that is intrinsically capable of learning the temporal dynamics, which is suitable for the problem. In this hierarchical model, the representation for each sentence is still learned by the CNN as in the baseline, while the dialog-level sequence information among sentences is modeled by the RNN. Here, we use bidirectional-LSTM (BLSTM) to learn the context before and after the current sentence. The left-to-right LSTM output and the one from the reverse direction are concatenated and input to a hidden layer for classification. BLSTM has been widely used recently for various sequence labeling problems (such as part-of-speech tagging, named entity recognition) and achieved state-of-the-art performance. Figure 3 shows the structure of the model. Note that the difference between these last two models and the one using history DA information is in that DA labels are not explicitly represented in these hierarchical models.

4 Experiments

4.1 Data

We use Switchboard data in our experiments. This corpus has been widely used in the community for DA classification. In this data, two people talked over the phone about a given topic for several minutes. 1155 conversations have been manually labeled with DAs. 40 conversations were held out for testing and development. However, there is no standard as to what are the test ones (it is unknown from the earliest paper using this data (Stolcke et al., 2000)). Therefore we randomly split the set into two, 20 conversations in each, with similar amount of utterances. We use one set as the development set and evaluate on the other set. As mentioned earlier, we do not use speech features, and only use textual information and speaker change feature in this study. For all the experiments, we use human transcripts. This setup is expected to be applicable to written conversations/dialogs. Table 2 shows the basic statistics of the data.

	conversations	sentences
training	1115	196,753
test set 1	20	3,764
test set 2	20	3,771

Table 2: Data information.

4.2 Results

4.2.1 Baseline CNN

For all the DNN models, we did not tune model parameters very much. Most of the parameters were chosen based on literature or our experience with other DNN-based text classification tasks. We used pretrained embeddings (dimension 200) to initialize word vectors to use in CNN, and then update them during training.[1] To avoid overfitting, we use a dropout of 0.5. The baseline CNN uses three windows: 1, 2, and 3, and 100 filter maps for each. The output hidden layer dimension is 100. For learning, we use Adagrad with a learning rate of 0.01.

Table 3 shows the baseline classification accuracy results when no context information is used, for three setups: the baseline sentence CNN model with the pretrained embeddings, when speaker change information is added, and when no pretrained embeddings are used. We can see the slight performance change because of the added speaker change feature. When no pretrained embeddings are used, i.e., no additional information is used from other resources, there is a performance degradation of 2-3%. Note that these results are better or at least comparable to state-of-the-art performance. In fact, we also implemented a CRF tagging model for this data set, where we used bag-of-word features for each utterance, therefore the information is similar to that used in the DNN framework (but the CRF does model DA tag sequential information). This CRF model has an accuracy of about 74% for the two sets combined. The CNN model without using pretrained embeddings has worse results than the CRF system that is trained just using the Switchboard data, confirming that when using word embeddings as word representations, pretrained embeddings are beneficial when the training size is small. However, the CNN model can effectively leverage word embedding information (obtained from unlabeled data), whereas it is not straightforward to use such information in the CRF classifiers. This shows an advantage of the DNN-based method.

	set 1	set 2
CNN	74.47	76.88
+ speaker change	74.73	77.12
no pretrained embedding	71.81	74.49

Table 3: DA classification accuracy (%) when using the baseline CNN without context information.

4.2.2 Hierarchical models: CNN+CNN/RNN

For the hierarchical models described in Section 3.5 and 3.6, i.e., adding CNN and BLSTM on top of the baseline sentence CNN, we kept the same model parameters in the sentence CNN part. The dimension is 64 for both the higher level CNN and LSTM. For these sequence labeling tasks, we use stochastic gradient descent (SGD), with a learning rate of 0.01. We observed this yielded better performance than Adagrad learning. Table 4 shows the results for different setups in these two models to evaluate the impact of context information. For LSTM, we compare using LSTM and BLSTM; for CNN, we show results when using different context window sizes in the top layer.

		set 1	set 2
baseline CNN		74.73	77.12
CNN+CNN	window 2	76.2	79.16
	window 3	76.78	79.05
	window 4	77.15	79.74
CNN+RNN	BLSTM	76.91	79.71
	LSTM	76.35	79.71

Table 4: DA classification results (%) when using the hierarchical structure: sentence CNN followed by dialog sequence level CNN or RNN/BLSTM.

From the table we can see that using LSTM and CNN to model context information for DA classification is effective, both models significantly outperforming the baseline. Regarding the effect of context, in general there is slightly more gain when more context is used, as in BLSTM, or larger windows in CNN. For CNN, when we increase the window more, to beyond 4, there is no further improvement. The greatest difference comes from using context vs. not using it at all.

[1] The embeddings we used are generated based on our collected web data. We compared it to other embeddings, e.g., Senna, and found the performance difference is very small.

history	DA = ref or sys		DA representation	set 1	set 2
	training	testing			
one	ref	ref	label	78.19	80.96
	ref	sys	label	75.72	77.94
	sys	sys	label	76.78	79.26
	sys	sys	probabilities	76.62	79.45
two	ref	ref	label	78.93	81.54
	sys	sys	label	76.41	79.98
	sys	sys	probabilities	76.51	80.14
three	ref	ref	label	79.62	81.76
	sys	sys	label	76.54	80.06
	sys	sys	probabilities	76.73	79.9
baseline CNN				74.73	77.12

Table 5: DA classification results (%) when incorporating history DA information in the current utterance in the CNN method. Three factors are examined: context history length, DA representations, and where DA information is from.

4.2.3 CNN + DA prediction

As described in Section 3.3, another method to incorporate context information is to use the DAs from previous utterances. We perform a detailed analysis to examine three factors under this framework:

- context history: we use a window of up to 3, i.e., information from the previous one, two, or three utterances;
- representation of the DA information, whether it is DA label or probabilities;
- reference vs. system predicted DA labels during training and testing.

Using the reference DA labels in testing is expected to give an oracle or upper bound performance for this set of experiments. Table 5 shows the results for these setups. The predictions for the utterances are generated using the baseline CNN model, with the pretrained embeddings and speaker information (i.e., the best utterance classification model). The model parameters in the second-round CNN training (when additional history DA information is included) are the same as the baseline CNN.

From Table 5 we can see that in terms of the representation of the history DA information, using hard labels and soft predictions achieves similar performance. For model training, it is better to have matched information in training and testing. Using reference DA labels during training and system predictions in testing (second row in the results) is less effective compared to using both system predictions in training and testing. The quality of the prediction also affects the usefulness of the DA prediction information, as demonstrated by the better performance when the reference labels are used compared to using system predicted DAs, which is expected. The immediate previous utterance has the largest impact on the prediction of the current utterance (comparing to not using context at all), and adding longer context helps less. In addition, using the reference previous DA labels (ref train and ref test condition) benefits more than using system predicted DA labels when longer history is used, suggesting that more predicted DAs, when used together, become more noisy and bring less gain.

4.2.4 Overall results

Table 6 summarizes the results for different systems, including the baseline CNN model without using context information (this baseline uses pretrained embeddings and speaker change feature), and four different ways of using context: (a) predicted DA information (posterior probabilities) is combined with the current sentence's CNN-based representation; (b) applying a BLSTM on top of the sentence CNN representation; (c) hierarchical CNN that combines the current sentence's CNN representation with its neighbors; (d) sequence decoding by combining CNN posteriors with DA transition scores.

From the results, we can see the positive effect

	set 1	set 2
CNN baseline, no context	74.73	77.12
CNN + DA predictions	76.73	79.9
CNN + RNN/BLSTM	76.91	79.7
CNN + CNN	77.15	79.74
CNN prob + DA transition	76.70	79.69

Table 6: DA classification results (%) using different systems.

when context information is used. All the methods using context yield significant improvement over the baseline (statistically significant based on t-test). Comparing representing context information via the DA labels of the previous utterances vs. using the hierarchical CNN or RNN model, we see there is not much difference. This observation is somewhat different from that found in (Ribeiro et al., 2015; Kim et al., 2010) where using previous DA predictions yields more gain than adding n-gram features from the previous utterances. We believe one reason for this difference is the use of the DNN framework to model the utterance sequences. Given the current data size and the oracle performance in Table 5, we expect that when more data is available, using larger neural networks will further improve the performance. Furthermore, we want to mention that overall these results represent new state-of-the-art performance for this task ((Kalchbrenner and Blunsom, 2013) reported 73.9% accuracy using recurrent CNN, though the results are not directly comparable since they only evaluated on 19 test conversations).

4.2.5 Final remarks

As expected, our experimental results demonstrate that we can effectively incorporate context information to improve DA classification. We conducted some analyses to see what errors are corrected when we use the context models compared to the baseline results. Due to space limit, we show one positive example below where adding context changes the prediction from 'backchannel' to 'answer'.

- Example:
  - Is this a mail order parts house that specializes in parts for parts for uh old imports?
  - right

It is clear that using context can help disambiguate and better predict the DAs for the current utterance. In fact, we noticed that close to 5% of errors are correctly changed from 'back channel' to 'reply' when context information is used.

One of the most frequent errors we notice the system makes is the mislabels between 'statement' and 'statement-opinion'. To correctly identify statement-opinion DAs, we can perform some opinion or subjectivity recognition, but that is out of the scope of this study. Another frequent error is the confusion between backchannel and agreement. For example, 'right' and 'yeah' are common words for both categories, and even with context information, they are still hard to disambiguate for the current models.

Finally it is worth pointing out that our work uses an offline setting where we perform DA tagging for the entire conversation. In real world applications, an online setting may be needed; however, information from previous utterances can still be used there. In fact, most of the performance gain from incorporating context information comes from the previous utterances (e.g., the difference between the hierarchical LSTM and BLSTM is very small). Our findings about the effectiveness of context information are applicable to the online setting.

5 Conclusions

We proposed several approaches to incorporate context information in the deep learning framework for DA classification in conversations, including expanding the sentence CNN vector with the predicted DA information from previous utterances to train another model, hierarchical models based on CNN or LSTM to model the DA sequence on top of the sentence CNN representation, or dialog level decoding once the sentence CNN generates its hypothesis. Compared to the baseline using CNN for utterance classification, our proposed methods effectively leverage context information and achieve significantly better performance. We observe that there is very small difference among different approaches. Our results represent the state-of-the-art for DA classification on the Switchboard data. We conducted thorough evaluations to understand the impact of different factors, and our results shed lights on the use of context information for similar tasks. In our future work, we plan to apply these approaches to other tasks, such as intent recognition and slot filling in language understanding.

Acknowledgments

The authors thank Yandi Xia for preparing the Switchboard data, Xian Qian, Antoine Raux and Benoit Dumoulin for various discussions.

Abstract

We present an unsupervised model of dialogue act sequences in conversation. By modeling topical themes as transitioning more slowly than dialogue acts in conversation, our model de-emphasizes content-related words in order to focus on conversational function words that signal dialogue acts. We also incorporate speaker tendencies to use some acts more than others as an additional predictor of dialogue act prevalence beyond temporal dependencies. According to the evaluation presented on two dissimilar corpora, the CNET forum and NPS Chat corpus, the effectiveness of each modeling assumption is found to vary depending on characteristics of the data. De-emphasizing content-related words yields improvement on the CNET corpus, while utilizing speaker tendencies is advantageous on the NPS corpus. The components of our model complement one another to achieve robust performance on both corpora and outperform state-of-the-art baseline models.

1 Introduction

Dialogue acts (DAs), or speech acts, represent the intention behind an utterance in conversation to achieve a conversational goal (Austin, 1975). Modeling conversations as structured DA sequences is a step toward the automated understanding of dialogue, useful for dialogue agents (Traum, 1999; Louwerse et al., 2002) and the processing of informal online conversational data (Misra and Walker, 2013; Vosoughi and Roy, 2016). Distributions of DAs can also be used as predictors of conversational outcome measures such as student learning in tutoring systems (Litman and Forbes-Riley, 2006) and engagement in meetings (Wrede and Shriberg, 2003). Unsupervised models for DA recognition may substitute or aid costly human annotation. We present an unsupervised model of DA sequences in conversation that overcomes limitations of prior models.

The first improvement our model offers is separating out content-related words to emphasize words more relevant to DAs. DAs are associated more closely with style and function words such as discourse markers and light verbs than with content words, which are more related to the propositional content (Erkens and Janssen, 2008; O'Shea et al., 2012). However, separating out content words is not standard in our field. For example, in some rule-based semantic and pragmatic parsing, the content and function of dialogue acts are not formally distinguished in the formalization (Becker et al., 2011), especially in domain-specific applications in dialogue systems (Gavaldà, 2004). A separation between content and function is useful for making cross-domain or cross-task generalizations about conversational processes.

Our model filters out content words by implementing the assumption that conversations proceed against a backdrop of underlying topics that transition more slowly than DAs or that are constant throughout. Based on a difference in transition speed, two types of language models are learned: foreground language models that capture DA-related words and background language models for content words. Although some existing models assume a background or domain-specific language model to filter out words unrelated to DAs (Lee et al., 2013; Paul, 2012; Ritter et al., 2010), they either require domain labels or do not learn topics underlying conversations.

The second improvement offered by our model is inclusion of speaker preferences, or tendencies to use some DAs more than others. Prior mod-

els of DAs in conversation often rely on the discourse property of conditional relevance (Levinson, 1983; Martin and Rose, 2003), i.e., tendencies for sequences of conversational DAs such as questions followed by answers, greetings followed by greetings, and invitations followed by acceptances (Sidnell, 2011). Though conditional relevance, which motivates the use of Markov models for inducing DA representations, is one stable signal to discover DAs in discourse data (Brychcín and Král, 2017; Lee et al., 2013), there are reasons that it is a less strong signal than ultimately desired. One of the reasons is that the DA of an utterance depends not only on the preceding DA, but also on the speaker's personal style (Appling et al., 2013) or preferences for certain DAs. Our model explicitly accounts for speaker preferences as a factor in determining the DA of an utterance.

Our model also includes additional structure to account for assumptions about distribution and packaging of observed DAs in running discourse. First, one utterance can involve more than one DA (Levinson, 1983); for example, asking a question in a forum may involve introducing the speaker, explaining the problem, etc. Hence, we assume that DAs operate on more than one level simultaneously, and an utterance-level DA is a mixture of finer-grained sentence-level DAs. Second, online conversations often have multi-level structure, branching into multiple conversational threads using replies. Our model supports conversations that have such multi-level structure.

To illustrate the generalizability of our model, we evaluate it on two corpora with very different characteristics in terms of utterance length, the number of speakers per conversation, and the domain: CNET and NPS Chat Corpus. We evaluate the DA recognition accuracy of our model and compare the result with other latest models. As we tune the model parameters for each corpus, we use our model as a lens to understand the relationship between the nature of conversations and effective model components for identifying DAs, which may inform future model design.

For the remainder of the paper, we will discuss prior work on dialogue acts and existing models (Section 2) and explain our model design (Section 3). Then we will describe our evaluation method and corpora (Section 4) and discuss the lessons learned from our empirical investigation (Section 5). We conclude the paper in Section 6.

2 Related Work

Austin (1975) makes a distinction between the illocutionary, social intention of an utterance (as seen in the indirect sentence "Can you pass the salt?") and the locutionary act of an utterance, which includes the ostensible surface-level meaning of the words. DAs are commonly thought of as describing illocutionary actions in talk. Example DAs used in computational systems include *yes-no question*, *statement*, *backchannel*, and *opinion* (Jurafsky et al., 1998).

Winograd and Flores (1986) were some of the first to conceptualize DAs with state transitions as a model for conversation. Similarly, contemporary unsupervised DA models often use a hidden Markov model (HMM) to structure a generative process of utterance sequences (Ritter et al., 2010). It is commonly assumed that each hidden state corresponds to a DA, but different approaches use different representations for states.

One common representation of a state is a multinomial distribution over words, from which words related to DAs are generated. Often, this generative process includes domain- or content-related language models that are independent of states and used to filter out words unrelated to DAs (Lee et al., 2013; Ritter et al., 2010). However, these language models have some limitations. For instance, Lee et al. (2013) rely on domain labels for learning domain-specific language models, which may require human annotation, whereas our model learns them without labels. Ritter et al. (2010) learn conversation-specific language models to filter out content words. We take a different approach, simultaneously learning content-related topics underlying the entire corpus and filtering out these content words. Although most models incorporate a general language model to separate out common words (Lee et al., 2013; Paul, 2012; Ritter et al., 2010), we do not learn it because we assume that common words are relevant to DAs.

Word embedding vector representations have also been researched as the outputs of latent states. For example, Brychcín and Král (2017) represent an utterance as a weighted sum of word vectors from GloVe[1]. Each utterance vector is generated from a Gaussian distribution that parameterizes a latent state. This model has been shown to capture

[1] https://nlp.stanford.edu/projects/glove/

DAs effectively for short utterances.

DAs are not completely determined by preceding DAs (Levinson, 1983), and this difficulty can be overcome partly by modeling speaker style, as there is evidence that each speaker has preferences for certain DAs (Appling et al., 2013). Joty et al. (2011) model speakers as outputs generated by an HMM, but this structure makes it hard to adjust the contribution of speaker preferences and may overestimate the influence of speakers. We model speaker preferences more directly such that the preceding DA and the speaker together determine an utterance's probability distribution over DAs.

One reason for the nondeterministic nature of DAs is that one utterance can involve more than one DA (Levinson, 1983); this suggests that one language model per DA may not be enough. Paul (2012) represents latent states as mixtures of topics, but there is no one-to-one relationship between states and DAs. Joty et al. (2011) assume that words are drawn individually from a fixed number of language models specific to each DA. However, we observe that one sentence usually performs a consistent finer-grained act, so we constrain each sentence in an utterance to one language model. Thus, utterances, which may consist of multiple sentences, are represented as a mixture of finer-grained sentence-level DAs.

Word order in an utterance may play an important role in determining a DA, as in the difference between "I am correct" and "am I correct". Ezen-Can and Boyer (2015) compute the similarity between utterances based on word order using a Markov random field and cluster similar utterances to identify DAs. This model, however, does not consider transitions between clusters.

Online conversations often have asynchronous, multi-level structure (e.g., nested replies). In Joty et al. (2011)'s model, individual reply structure paths from the first utterance to terminal utterances are teased apart into separate sequential conversations by duplicating utterances. However, this method counts the same utterance multiple times and requires an aggregation method for making a final decision of the DA for each utterance. We address multi-level structure without duplicating utterances.

The properties of the models explained so far are summarized in Table 1.

The relative importance of each structural component in a model may not be identical across all corpora. Differences, especially as they are attributed to meaningful contextual variables, can be interesting both practically and theoretically. One contribution of our work is considering how differences in these kinds of contextual variables lead to meaningful differences in the utility of our different modeling assumtions. More typical work in the field has emphasized methodological concerns such as minimization of parameter tuning, for example, by using a hierarchical Dirichlet process to determine the number of latent DAs automatically (Lee et al., 2013; Ritter et al., 2010) or by simply assuming that a word is equally likely to be DA-related or general (Paul, 2012). While these efforts are useful, especially when maximizing the likelihood of the data, searching for the optimal values of parameters for DA recognition may allow us to better understand the contribution of each model component depending on the characteristics of the dialogue, which in turn can inform future model design.

3 Model

Our model, CSM (content word filtering and speaker preferences model), is based on an HMM combined with components for content word filtering and speaker preferences. In the model, each latent state represents an utterance-level DA as a mixture of *foreground topics*, each of which represents a sentence-level DA. Each sentence in an utterance is assigned one foreground topic. To filter content words, there is a set of *background topics* shared across conversations, and each conversation is assigned a background topic that underlies the whole conversation.

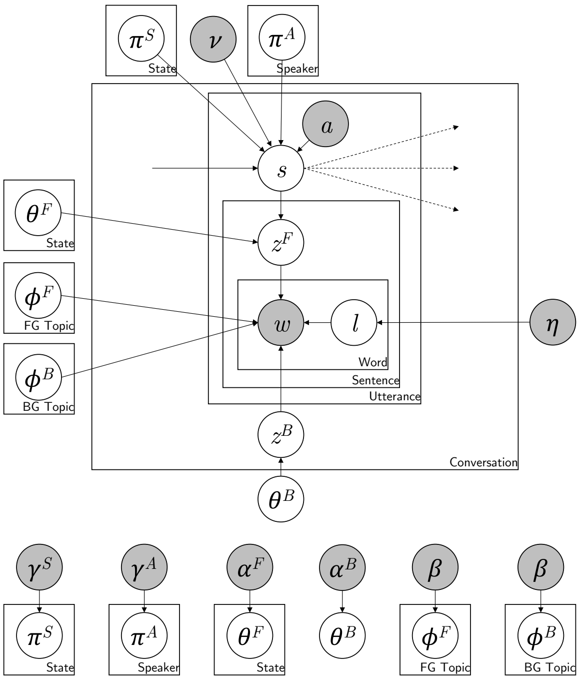

Figure 1: Graphical representation. Shaded nodes represent observable variables.

A transition between states is defined on every parent-child utterance pair, supporting multi-level structure. The state of an utterance is dependent on both its parent's state and its speaker. Speakers are specific to each conversation, i.e., a speaker participating in multiple conversations is treated as different speakers for different conversations. The graphical representation of CSM is in Figure 1.

The formal generative process of conversations is as follows:

- For each speaker a, draw a preference distribution over states $\pi_a^A \sim \text{Dir}(\gamma^A)$.
- For each state s
  - ▹ Draw a transition probability distribution over states $\pi_s^S \sim \text{Dir}(\gamma^S)$.
  - ▹ Draw a probability distribution over foreground topics $\theta_s^F \sim \text{Dir}(\alpha^F)$.
- For each foreground topic t, draw a probability distribution over words $\phi_t^F \sim \text{Dir}(\beta)$.
- For each background topic t, draw a probability distribution over words $\phi_t^B \sim \text{Dir}(\beta)$.
- For the corpus, draw a distribution over background topics $\theta^B \sim \text{Dir}(\alpha^B)$.
- For each conversation
  - ▹ Draw a background topic $z^B \sim \text{Cat}(\theta^B)$.
  - ▹ For each utterance u, with its speaker a_u, its parent p, and the parent's state s_p,
    - ♦ Draw a state $s_u \sim \text{Cat}(\nu\pi_{s_p}^S + (1-\nu)\pi_{a_u}^A)$.
    - ♦ For each sentence
      - □ Draw a foreground topic $z^F \sim \text{Cat}(\theta_{s_u}^F)$.
      - □ For each word
        - · Draw an indicator of "foreground" or "background" $l \sim \text{Cat}((\eta, 1-\eta))$.
        - · If l is "foreground", draw a word $w \sim \text{Cat}(\phi_{z^F}^F)$.
        - · If l is "background", draw a word $w \sim \text{Cat}(\phi_{z^B}^B)$.

According to this model, content words are separated out into background topics in several ways. A background topic does not transition as frequently as foreground topics within a conversation. Accordingly, words that are consistently used across utterances in a conversation are likely to be clustered into the background topic z^B, whereas words whose use is sensitive to the previous state and the speaker are likely to be clustered into foreground topics z^F. However, common function words, such as pronouns, prepositions, and punctuations, may also be separated out. Hence, η, the probability of a word being foreground, adjusts the degree of filtering. The higher the η value, the more words are likely to be generated from a foreground topic, and thus the more function words are included in foreground topics, leaving background topics with content words. Hence, we may set η high if we believe function words play an important role in DAs in a corpus and low otherwise. Note that $\eta = 0.5$ is equivalent to the assumption of existing models that a word is equally likely to be foreground or background (Lee et al., 2013; Paul, 2012). Background topics capture content words underlying the corpus, as they are shared across conversations.

Speaker preferences are captured as a probability distribution over DAs (π^A), which, along with the preceding state, affects the probability of the current state. ν adjusts the contribution of the speaker's preferences; the higher ν, the weaker the contribution. So, we may set ν low if the role or conversational style of each speaker is believed to be invariant and each speaker is expected to conduct specific DAs. If there is not enough such evidence and the conversation is driven without specific roles of the speakers, then we may set ν high. We find that corpora have different optimal values

N_{ij}^{SS}	Transition from state i to state j
N_{ij}^{AS}	Assignment of speaker i to state j
N_{ij}^{SF}	Assignment of state i to foreground topic j
N_{j}^{B}	Assignment to background topic j
N_{ij}^{FW}	Assignment of foreground topic i to word j
N_{ij}^{BW}	Assignment of background topic i to word j

Table 2: Descriptions of counter matrices.

of ν depending on the conversational characteristics.

We use collapsed Gibbs sampling for inference to integrate out π^S, π^A, θ^F, θ^B, ϕ^F, and ϕ^B. Given conversation text with speakers for each utterance, along with the hyperparameters, ν, and η, the Gibbs sampler estimates the following variables using counter matrices explained in Table 2:

$$\pi_{ij}^{S} = \frac{N_{ij}^{SS} + \gamma^S}{\sum_{j'}(N_{ij'}^{SS} + \gamma^S)}, \pi_{ij}^{A} = \frac{N_{ij}^{AS} + \gamma^A}{\sum_{j'}(N_{ij'}^{AS} + \gamma^A)}$$

$$\theta_{ij}^{F} = \frac{N_{ij}^{SF} + \alpha^F}{\sum_{j'}(N_{ij'}^{SF} + \alpha^F)}, \theta_{j}^{B} = \frac{N_{j}^{B} + \alpha^B}{\sum_{j'}(N_{j'}^{B} + \alpha^B)}$$

$$\phi_{ij}^{F} = \frac{N_{ij}^{FW} + \beta}{\sum_{j'}(N_{ij'}^{FW} + \beta)}, \phi_{ij}^{B} = \frac{N_{ij}^{BW} + \beta}{\sum_{j'}(N_{ij'}^{BW} + \beta)}.$$

We may use slice sampling (Neal, 2003) to estimate ν and η too, but the estimated values of ν and η may not be optimal for DA recognition. We can also obtain state assignments for utterances by taking a sample from the Gibbs sampler. Detailed derivation for Gibbs sampling and the code are available online[2].

4 Evaluation

This section describes our evaluation method and settings.

4.1 Task and Metrics

We evaluate our model in terms of accuracy in utterance-level DA recognition. Since the output of the model is assignments to discovered states for utterances, not pre-determined DA labels, we use a clustering evaluation method, as adopted by previous work on unsupervised DA modeling. Specifically, we use homogeneity, completeness, and v-measure as metrics (Rosenberg and Hirschberg, 2007). Homogeneity represents the degree to which utterances assigned to the same cluster by the model share the same DA in the labeled corpus. Completeness represents the degree to which utterances that have the same DA according to the gold standard are assigned to the same cluster. V-measure is the harmonic mean of homogeneity and completeness. These metrics are easy to interpret and have been demonstrated to be invariant to dataset size and number of clusters. This enables a meaningful comparison of accuracy across different corpora.

Table 4: Dialogue act tags in the corpora.

4.2 Corpora and Preprocessing

We evaluate on two corpora: CNET and NPS Chat (see Table 3 for statistics).

CNET (Kim et al., 2010) is a set of post threads from the Operating System, Software, Hardware, and Web Development sub-forums of CNET. This corpus is tagged with 12 DAs, including *Question-Question*, *Question-Confirmation*, *Answer-Add*, *Resolution*, and *Other* (Table 4). Note that question- and answer-related DAs are two-level. Most posts are tagged with one DA; in case a post is tagged with multiple DAs, we choose the first DA in the meta-data[3]. Each post is considered an

[2] https://github.com/yohanjo/Dialogue-Acts

[3] Some tagging systems, such as the DAMSL-style, break down an utterance that has multiple DAs.

utterance and each thread as a conversation. Each thread has only a few posts (median 3) and involves a few speakers (median 2). Since there are many URLs, email addresses, and numbers in text, we replace them with special tokens using regular expressions, and tokenize with the Stanford PTBTokenizer included in Stanford Parser 3.7.0[4].

NPS Chat (Forsythand and Martell, 2007) is a set of conversations from various online chat services. This corpus is tagged with 15 DAs, including *Emotion*, *System*, and *whQuestion* (Table 4). Every turn is tagged with a DA and considered an utterance. Each conversation is long (median 706 utterances) and involves many speakers (median 94). This corpus has already been tokenized, so we only replace usernames with a special token. Conversations in NPS have no reply structure, but we build in multi-level structure, simply treating an utterance that mentions another user as a child of the nearest utterance of the mentioned user. We compare the DA accuracy of the multi-level structure and the original linear structure in Section 5.

4.3 Models and Parameters

We set the numbers of states and background topics to the numbers of DAs and domains, respectively, if these numbers are available. For NPS, we search for the optimal number of background topics between 1 and 2, because there are only a few conversations. The optimal number of foreground topics is chosen among multiples of five between the number of states and four times the number of states, and the weights for state transition (ν) and foreground topics (η) are chosen among multiples of 0.1. For Dirichlet hyperparameters, we use $\alpha^F = 0.1, \gamma^A = 0.1, \beta = 0.001$ to induce sparsity, and $\gamma^S = 1, \alpha^B = 1$ for the uniform distribution over all configurations.

We randomly split each corpus into five groups and use three groups for training, one for parameter tuning, and one for testing. We run 5-fold cross-validation and report the average optimal parameter values and accuracy across the folds. The number of sampling iterations was chosen such that the log-likelihood of the data has converged. For each fold, we take 10 samples during inference on the test data with interval of 10 iterations and compute the mean and standard deviation of the 50 samples from all folds.

We compare our model with the three most recent unsupervised models we surveyed. The baseline models and settings are as follows.

Gaussian mixture HMM (Brychcín and Král, 2017), based on an HMM, has a characteristic output representation: utterance vectors. These vectors are generated from Gaussian distributions instead of using language models as in most existing models. After following their same preprocessing steps, we trained a model on the training data, chose the optimal word vector dimensionality on the validation data (among 50, 100, 200, and 300, as used in the original model), and performed inference on the test data. We used the original source code from the authors for training and modified the code for inference.

MRF-based clustering (Ezen-Can and Boyer, 2015) considers word order within an utterance to calculate similarity between utterances using an MRF. Then k-medoids clustering is conducted based on the similarity scores, resulting in clusters that represent DAs. The similarity score between two utterances is asymmetric, so we took the average value of each direction and inversed it to obtain the distance between two utterances. We trained a model on the training data, chose the optimal parameter values ($\lambda_i, \lambda_t, \alpha_d$ in the original paper) on the validation data, and assigned clusters to the test data. We implemented the algorithm since the original code was not available.

HDP-HMM (Lee et al., 2013) is based on an HMM, and each word comes from either the state-specific, general background, or domain-specific language model. HDP-HMM automatically decides the number of states using a hierarchical Dirichlet process, but we manually set the number of DAs in our experiment, assuming that we know the number of DAs of interest. We trained a model on the training data and performed inference on the test data; the validation data was not used since there are no parameters to tune. We used the original source code from the authors for training and modified the code for inference.

5 Results

Accuracy of DA recognition in terms of homogeneity, completeness, and v-measure on both corpora is summarized in Table 5. We also tested the following configurations:

- **CSM + Domain** uses true domain labels when learning background topics by force-

fully assigning a conversation the background topic corresponding to the true label.

- **CSM - Speaker** does not use speaker preferences by setting $\nu = 1$.
- **CSM - Multi-level** ignores multi-level structure; that is, utterances in each conversation are ordered by time.
- **CSM - Background Topics** uses only one background topic.

Overall, our model performs significantly better than the baselines for CNET and marginally better for NPS. The baseline models show a large variance in performance depending on the characteristics of the corpus. In contrast, our model has a low variance between the corpora, because the content word filtering, distinction between utterance-level and sentence-level DAs, and speaker preferences complement one another to adapt to different corpora. For example, content word filtering and DA level distinction play more significant roles than speaker preferences on CNET, whereas their effects are reversed on NPS. The details will be described later with qualitative analyses.

There may be several reasons for the poor performance of the baseline models on CNET. First, in our model, each utterance-level DA (latent state) is a probability distribution over sentence-level DAs (foreground topics), which better captures multiple sentence-level DAs in long utterances as in CNET. The utterances in CNET are long and may be too complex for the baseline models, which use a simpler representation for utterance-level DAs. Another reason for the low performance could be that the baseline models do not filter out content words as our model does.

Table 6: Background topics learned from CNET. **(Columns)** Left: topic index, right: top 5 words.

In the remainder of this section, we describe our qualitative analysis on the results. All examples shown in the analysis are from the result with the optimal parameter values for the first fold.

Filtering content words Our model effectively separates content words from DA-related words without using the domain label of each conversation. As an example, the background topics learned by our model from CNET are shown in Table 6. These topics are clearly related to the subjects of the forum, rather than reflecting DAs, and the topics are distinctive from one another and cohesive in themselves.

The main purpose of learning background topics is to filter out content words and retain DA-related words as foreground. The learned background topics serve this purpose well, as these topics increase v-measure by 0.17 (CSM vs. CSM - Background Topics). It is also promising that the background topics learned without domain labels perform as well as when they are learned with domain labels (CSM vs. CSM + Domain), because domain labels may not always be available.

Function words play an important role in DAs in CNET as indicated by the high optimal value of $\eta = 0.86$ (the probability of a word being foreground). The higher η means more function words are included in foreground topics, leaving background topics with content words (Section 3). The high η is evidence contrary to the common practice of designating a general background topic to filter out common words and assuming that a word is equally likely to be foreground or background (Lee et al., 2013; Paul, 2012).

The effectiveness of our method of separating background topics turns out to diminish when there are no consistent conversational topics within and across conversations as in NPS. Our model learns not to use background topics ($\eta = 1$) for NPS, because background topics may filter out function words and DA-related words that occur more consistently throughout a conversation than content words do.

(b) Foreground topics learned from NPS.

Table 7: Foreground topics learned from the corpora. **(Columns)** Left: interpretation (topic index), right: top words truncated for clarity.

Mixture of foreground topics As a consequence of filtering out content words, the foreground topics reflect various acts in conversation. Some of the learned foreground topics from CNET are shown in Table 7a. These topics capture important sentence-level DAs that constitute utterance-level DAs that are assigned to each post in CNET. For example, *Question-Question* is an utterance-level DA that often starts a conversation, and conducting this DA typically includes multiple finer-grained acts, such as explaining the environment and situation, asking a question, and thanking, as shown in the post:

> I am currently running Windows XP Media Edition on a 500G hard drive. (FT20) / I want to move my XP to it's own partition, move all of my files(music, games, work) to another, and then install the Windows 7 beta on another partition. (FT10) / I don't know if this is possible or not, but I have access to Partition Magic 8, and am wondering if I can do it with that or not. (FT10) / I am not worried about installing 7 on another partition, but am not sure if I can move my files onto a separate one while keeping XP intact. (FT10) / Any help is great, thank you. (FT17)

Likewise, the *Answer-Answer* DA includes finer acts such as wishes or URLs, as in the posts:

> Simple - Download and install the Vista Rebel XT drivers from canon usa.com. (FT10) / Once installed...........go to camera menu and switch the communication to Print/PTP. (FT10) / Don't forget to switch it back if you're connecting to an XP machine. (FT10) / Good Luck (FT14)

> http://forums.microsoft.com/MSDN/ShowPost.aspx?PostID=1996406&amp;SiteID=1 (FT5)

When a problem is resolved, the *Resolution* DA may be performed with thanking and praising:

> Excellent summary Thank you. (FT1) / Sounds like at some point it's worth us making the transition to a CMS... (FT10)

FT10 covers explanations and statements, as well as long sentences. The distinction between two levels DAs is effective for CNET, as our model beats the baselines significantly.

The foreground topics learned from NPS also reflect DAs in the corpus (Table 7b). The distinction between utterance-level and sentence-level DAs is not beneficial for NPS because each utterance is short and usually conducts only one DA. As a consequence, the model has difficulty grouping foreground topics (i.e., sentence-level DAs) that are related to one another into the same utterance-level DAs (i.e., states); for CNET, on the other hand, foreground topics that co-occur in the same utterance tend to cluster to the same state.

The DAs of some foreground topics not shown in Table 7 are difficult to interpret, and those topics possibly capture aspects of sentences other than DAs. However, they do not have undue influence in our model.

Speaker preferences Speaker preferences substantially increase the v-measure by 0.13 for NPS (CSM vs. CSM - Speaker). Notably, speaker preferences complement the mixture of sentence-level DAs, which is not good at clustering related sentence-level DAs into the same utterance-level DA for short utterances. More specifically, each speaker is modeled to have sparse preferences for utterance-level DAs (i.e., states), so foreground topics used by the same speaker, often representing the same utterance-level DA, tend to cluster to the same state.

Speaker preferences also capture the characteristic styles of some speakers. Among speakers who are found to have sparse preferences by our model, some actively express reactions and often mark laughter (FT12). Others frequently agree (FT0), greet everyone (FT5), or have many questions (FT7, FT27). Accordingly, the model finds a relatively high optimal weight for speaker preferences in NPS ($\nu = 0.58$).

In contrast, CNET benefits little from speaker preferences ($\nu = 1$), partly because there is not enough information about each speaker in such short conversations. Speakers also show little preference for DAs as defined in the corpus. For instance, while a conversation initiator tends to ask questions in successive posts, these questions are annotated as different DAs (e.g., *Question-Question*, *Question-Add*, *Question-Confirmation*, etc.) depending on the position of the post within the conversation.

Multi-level structure Our model's ability to account for multi-level structure improves the accuracy of DA recognition for both corpora (CSM vs. CSM - Multi-level). For NPS, where multi-level structure is not explicit, this improvement comes from simple heuristics for inferring multi-level structure based on user mentions.

Sentence length and foreground topics In our model, all words in the same sentence are assigned to the same foreground topic, just as many existing models assign one utterance one topic. Topic assignment is based on similarity of words in a sentence to other sentences in that topic, and short sentences often find similar sentences more easily than long sentences do. Therefore, learned topics tend to be characteristic of short sentences that are similar enough to form the separate topics, and as a result, long sentences may be assigned the same topic regardless of the DA actually performed.

6 Conclusion

We have presented an unsupervised model of DAs in conversation that separates out content words to better capture DA-related words and that incorporates speaker preferences. Our model also uses a mixture of sentence-level DAs for utterance-level DAs and supports multi-level thread structure. We find that different characteristics of conversation require different modeling assumptions for DA recognition. Unlike the baseline models, which show a large variance in performance across corpora, our model is robust for both corpora used in the evaluation due to the model components complementing one another. Specifically, content word filtering is found to be effective when each conversation has a consistent conversational topic, and the separation between sentence-level and utterance-level DAs is beneficial for long utterances. Speaker preferences are found to be helpful when speakers have characteristic styles of conversation. These findings in addition to the fact that many function words are not filtered out as background may help inform future model design.

Abstract

The study on human-computer conversation systems is a hot research topic nowadays. One of the prevailing methods to build the system is using the generative Sequence-to-Sequence (Seq2Seq) model through neural networks. However, the standard Seq2Seq model is prone to generate trivial responses. In this paper, we aim to generate a more meaningful and informative reply when answering a given question. We propose an implicit content-introducing method which incorporates additional information into the Seq2Seq model in a flexible way. Specifically, we fuse the general decoding and the auxiliary cue word information through our proposed hierarchical gated fusion unit. Experiments on real-life data demonstrate that our model consistently outperforms a set of competitive baselines in terms of BLEU scores and human evaluation.

1 Introduction

To establish a conversation system with adequate artificial intelligence is a long-cherished goal for researchers and practitioners. In particular, automatic conversation systems in open domains are attracting increasing attention due to its wide applications, such as virtual assistants and chatbots. In open domains, researchers mainly focus on data-driven approaches, since the diversity and uncertainty make it impossible to prepare the interaction logic and domain knowledge. Basically, there are two mainstream ways to build an open-domain conversation system: 1) to search pre-established database for candidate responses by query retrieval (Isbell et al., 2000; Wang et al., 2013; Yan et al., 2016; Song et al., 2016), and 2) to generate a new, tailored utterance given the user-issued query (Shang et al., 2015; Vinyals and Le, 2015; Serban et al., 2016; Mou et al., 2016; Song et al., 2016). In these studies, generation-based conversation systems have shown impressive potential. Especially, the Sequence-to-Sequence (Seq2Seq) model (Sutskever et al., 2014) based on neural networks has been extensively used in practice; the idea is to encode a query as a vector and to decode the vector into a reply. Inspired by (Mou et al., 2016), we mainly focus on the generative short-text conversation without context information.

Despite this, the performance of Seq2Seq generation-based conversation systems is far from satisfactory because its generation process is not controllable; it responses to a query according to the pattern learned from the training corpus. As a result, the system is likely to generate an unexpected reply even with little semantics, e.g, “I don’t know” and “Okay” due to the high frequency of these patterns in training data (Li et al., 2016a; Mou et al., 2016). To address this issue, Li et al. (2016a) proposed to increase diversity in the Seq2Seq model so that more informative utterances have a chance to stand out. Mou et al. (2016) provided a content-introducing approach that generates a reply based on a predicted word. The word is usually enlightening and drives the generated response to be more meaningful. However, this method is to some extent rigid; it requires the predicted word to explicitly occur in the generated utterance. As shown in Table 1, sometimes, it is better to generate a semantic related sentence based on the cue word rather than including it in the reply directly.

As for such content-introducing method, there are two aspects that need to be taken into consid-

Cue Word	审美(Aesthetics)
Reply	好恶心啊! (It's disgusting!)
Query	先放个大招(Let me use my ultimate power.)
Cue Word	技能(Skill)
Reply	新技能？(New skill?)

Table 1: The content-introducing conversation examples.

eration. 1) How to add the additional cue words during the generation process? One of the prevailing methods is modifying the neural cell with various gating mechanisms (Wen et al., 2015a,b; Xu et al., 2016). However, we need careful operation to ensure the neuron works as expected. 2) How to display the cue words in replies? As mentioned above, the explicit content-introducing approach in (Mou et al., 2016) does not fit well with all situations.

In this paper, we present an implicit content-introducing method for generative conversation systems, which incorporates cue words using our proposed hierarchical gated fusion unit (HGFU) in a flexible way. Our main contributions are as follows:

- We propose the cue word GRU, another neural cell, to deal with the auxiliary information. Compared with other gating methods, our cue word GRU is more flexible.
- We focus on the implicit content-introducing method during generation: the information of the cue word will be fused into the generation process but not necessarily occur explicitly. In this way, we change the "hard" content-introducing method into a new "soft" schema.

The rest of paper is organized as follows. We start by introducing the technical background. In Section 3, we describe our proposed method. In Section 4, we illustrate the experimental setup and evaluations against a variety of baselines. Section 5 briefly reviews related work. Finally, we conclude our paper in Section 6.

2 Technical Background

2.1 Seq2Seq Model and Attention Mechanism

Seq2Seq model was first introduced in statistical machine translation; the idea is to encode a source sentence as a vector by a recurrent neural network (RNN) and to decode the vector to a target sentence by another RNN. Now, the conversational generation is treated as a monolingual translation task (Ritter et al., 2011; Shang et al., 2015). Given a query $Q = (x_1, ..., x_n)$, the encoder represents it as a context vector C and then the decoder generates a response $R = (y_1, ..., y_m)$ word by word by maximizing the generation probability of R conditioned on Q. The objective function of Seq2Seq can be written as:

$$\begin{aligned} & p(y_1, ..., y_m | x_1, ..., x_n) \\ =& p(y_1|C) \prod_{t=2}^{T} p(y_t|C, y_1, ..., y_{t-1}) \end{aligned} \tag{1}$$

To be specific, the encoder RNN calculates the context vector by:

$$h_t = f(x_t, h_{t-1}); C = h_T \tag{2}$$

where h_t is the hidden state of encoder RNN at time t and f is a non-linear transformation which can be a long-short term memory unit (LSTM) (Hochreiter and Schmidhuber, 1997) or a gated recurrent unit (GRU) (Cho et al., 2014). In this work, we implement f using GRU.

The decoder RNN generates each reply word conditioned on the context vector C. The probability distribution p_t of candidate words at every time step t is calculated as:

$$s_t = f(y_{t-1}, s_{t-1}, C); p_t = \mathit{softmax}(s_t, y_{t-1}) \tag{3}$$

where s_t is the hidden state of decoder RNN at time t and y_{t-1} is the generated word in the reply at time $t-1$.

Attention mechanisms (Bahdanau et al., 2014) have been proved effective to improve the generation quality. In Seq2Seq with attention, each y_i corresponds to a context vector C_i; it is weighted average of all hidden states of the encoder. Formally, C_i is defined as $C_i = \sum_{j=1}^{T} \alpha_{ij} h_j$, where α_{ij} is given by:

$$\alpha_{ij} = \frac{exp(e_{ij})}{\sum_{k=1}^{T} exp(e_{ik})}; e_{ij} = \eta(s_{i-1}, h_j) \tag{4}$$

where η is usually implemented as a multi-layer perceptron (MLP) with tanh as an activation function.

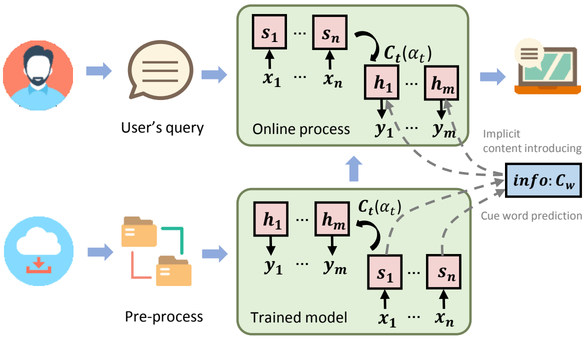

Figure 1: The architecture of our system. Based on the constructed corpus, we train our implicit content-introducing conversation system. Given a user-issued query, we first predict the cue word. Then, we incorporate the cue word into decoding process to generate a meaningful response.

2.2 Pointwise Mutual Information

Pointwise mutual information (PMI) (Church and Hanks, 1990) is a measure of association ratio based on the information theoretic concept of mutual information. Given a pair of outcomes x and y belonging to discrete random variables $\mathcal{X}$ and $\mathcal{Y}$, the PMI quantifies the discrepancy between the probability of their coincidence based on their joint distribution and their individual distributions. Mathematically:

$$\mathrm{PMI}(x,y) = \log \frac{p(x,y)}{p(x)p(y)} = \log \frac{p(x|y)}{p(x)} \tag{5}$$

This quantity is zero if x and y are independent, positive if they are positively correlated, and negative if they are negatively correlated.

3 Implicit Content-Introducing Conversation System

Figure 1 provides an overview of our system architecture. We crawl conversational data from social media which are publicly available. After filtering and cleaning procedures, we establish the conversational parallel dataset, which consists of a large number of aligned $\langle query - reply \rangle$ pairs. Based on the entire set, we first predict the cue word for the given query in Subsection 3.1. Next, we propose the new implicit content-introducing process, which explores when to incorporate the predicted cue word in Subsection 3.2 and how to apply such information in Subsection 3.3.

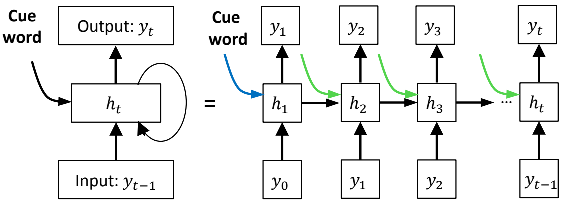

Figure 2: The information fusion patterns. The local information initialization is presented by the blue arrowhead and the global information inception includes both the blue arrowhead and the green arrowhead.

3.1 Cue Word Prediction

In computational linguistics, PMI has been used for finding collocations and associations between words. As mentioned in Mou et al. (2016), it is an appropriate statistic for cue words prediction, which is also adopted in this paper to predict a cue word C_w for the given query. Formally, given a query word w_q and a reply word w_r, the PMI is computed as:

$$\mathrm{PMI}(w_q, w_r) = \log \frac{p(w_q|w_r)}{p(w_q)} \tag{6}$$

Then, we choose the cue word C_w with highest PMI score against the query words $w_{q1}, ..., w_{qn}$ during the prediction, i.e., $C_w = \mathrm{argmax}_{w_r}\, \mathrm{PMI}(w_{q1}, ..., w_{qn}, w_r)$, where

$$\mathrm{PMI}(w_{q1}, ..., w_{qn}, w_r) \approx \log \frac{\prod_i p(w_{qi}|w_r)}{\prod_i p(w_{qi})}$$
$$= \sum_i \log \frac{p(w_{qi}|w_r)}{p(w_{qi})} = \sum_i \mathrm{PMI}(w_{qi}, w_r) \tag{7}$$

The approximation is based on the independence assumptions of both the prior distribution $p(w_{qi})$ and posterior distributions $p(w_{qi}|w_r)$. Even the two assumptions may not be true, we use them in a pragmatic way so that the word-level P-MI is additive for a whole utterance. PMI penalizes a common word by dividing its prior probability; hence, it prefers a word which is most "mutually informative" with the query.

3.2 Information Fusion Patterns

To implant the specific information in conversation system, we consider two types of information fusion patterns, namely 1) Local information initialization 2) Global information inception.

Local information initialization. In the local pattern, we fuse the cue word C_w as the auxiliary

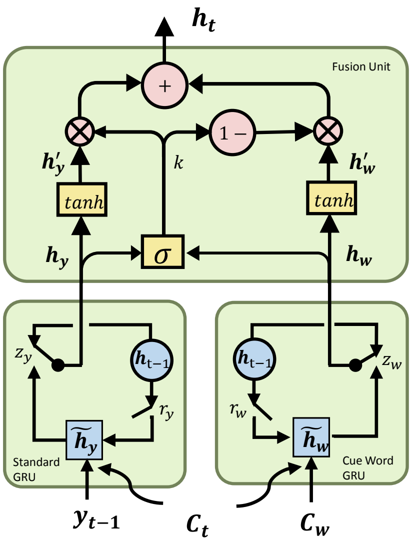

Figure 3: The structure of a HGFU. The bottom of two GRUs deal with corresponding input source, i.e., the last generated word y_{t-1} and the cue word C_w. After that, fusion unit combines the output of two GRUs to compute current hidden state h_t.

.

information only in the beginning of decoding. We describe this kind of pattern by the blue arrowhead in Figure 2. Recurrent neural networks(RNNs) such as gated recurrent units (GRUs) have the ability to keep the information from the beginning to the end to some extent. Therefore, the cue word added on the first step of the neural networks can still influence the generation of the later steps.

Global information inception. However, we observe that, although the network is capable of deciding what to keep in the cell state to affect the later generation, the influence of the added information in the beginning of decoding is becoming weaker and weaker over time. Therefore, to provide the model a broader and more flexible space for learning, we propose a global information inception pattern, which fuses the cue word C_w as the auxiliary information at every step of decoding. This process is presented by both the blue arrowhead and the green arrowheads in Figure 2.

3.3 Hierarchical Gated Fusion Unit

In this subsection, we propose our Hierarchical Gated Fusion Unit (HGFU), which incorporates cue words into the generation process and relaxes the constraint from the "hard" content-introducing method into a new "soft" schema. Figure 3 provides an overview of the structure of a HGFU. As seen, the framework consists of three components: the standard GRU, the cue word GRU, and the fusion unit. Among them, standard GRU and cue word GRU take the last generated word y_{t-1} and cue word C_w respectively as the decoder GRU's input; the fusion unit combines the hidden states of both GRUs to predict the next word y_t. In the following, we will illustrate these components in detail.

3.3.1 Standard GRU

We adopt the standard gated recurrent unit (GRU) with the attention mechanism at the decoder part. Let h_{t-1} be the last hidden state, y_{t-1} be the embedding of the last generated word, and C_t be the current attention-based context. The current hidden state of the general decoding, h_y, is defined as:

$$\begin{aligned} r_y &= \sigma(W_r y_{t-1} + U_r h_{t-1} + U_{cr} C_t + b_r) \\ z_y &= \sigma(W_z y_{t-1} + U_z h_{t-1} + U_{cz} C_t + b_z) \\ \widetilde{h_y} &= \tanh(W_h y_{t-1} + U_h(r_y \circ h_{t-1}) + U_{ch} C_t + b_h) \\ h_y &= (1 - z_y) \circ h_{t-1} + z_y \circ \widetilde{h_y} \end{aligned} \tag{8}$$

where W's $\in \mathbb{R}^{dim \times E}$ and U's $\in \mathbb{R}^{dim \times dim}$ are weight matrices; b's $\in \mathbb{R}^{dim}$ are bias terms; E denotes the word embedding dimensionality and dim denotes the number of hidden state units. This general decoding process is presented by the "Standard GRU" in Figure 3.

3.3.2 Cue word GRU

To generate more meaningful and informative replies, we introduce cue words as the additional information during generation. Naturally, the key point lies in how to incorporate such information. One of the prevailing methods is modifying the neural cell by various gating mechanisms. However, these approaches are designed specially for a specific scenario, and not effective as expected when they are employed to other tasks. To tackle this issue, we propose the cue word GRU, another independent neural cell, to deal with the auxiliary information. Since this neural cell can be replaced easily by other units, it greatly improves the flexibility and reusability.

Given the last hidden state h_{t-1} , the additional cue word C_w and the current attention-based context C_t, the new hidden state of the auxiliary decoding h_w is computed by following equations:

$$\begin{aligned} r_w &= \sigma(W_r C_w + U_r h_{t-1} + U_{cr} C_t + b_r) \\ z_w &= \sigma(W_z C_w + U_z h_{t-1} + U_{cz} C_t + b_z) \\ \widetilde{h_w} &= \tanh(W_h C_w + U_h(r_w \circ h_{t-1}) + U_{ch} C_t + b_h) \\ h_w &= (1 - z_w) \circ h_{t-1} + z_w \circ \widetilde{h_w} \end{aligned} \tag{9}$$

where W's and U's are weights and b's are bias terms like those in the standard GRU. Note that the standard GRU does not share parameter matrixes with the cue word GRU. The "Cue word GRU" in Figure 3 describes the auxiliary decoding process.

3.3.3 Fusion unit

To combine both the general decoding information and the auxiliary decoding information, we apply the fusion unit (Arevalo et al., 2017) integrating the hidden states of both standard GRU, i.e., h_y, and the cue word GRU, i.e., h_w, to compute the current hidden state h_t. The equations are as follows:

$$\begin{aligned} h_y^{'} &= \tanh(W_1 h_y) \\ h_w^{'} &= \tanh(W_2 h_w) \\ k &= \sigma(W_k[h_y^{'}, h_w^{'}]) \\ h_t &= k \circ h_y + (1 - k) \circ h_w \\ \theta &= \{W_1, W_2, W_k\} \end{aligned} \tag{10}$$

with θ the parameters to be learned. From the equations above we can see that, the gate neuron k controls the contribution of the information calculated from h_y and h_w to the overall output of the unit.

3.4 Model Training

When training on the aligned corpus, we randomly sample a noun in the reply as the cue word. The objective function was the cross entropy error between the generated word distribution p_t and the actual word distribution y_t in the training corpus.

4 Experiments

In this section, we compare our method with the-state-of-art response generation models based on a huge conversation resource. The objectives of our experiments are to 1) evaluate the effectiveness of our proposed HGFU model, and 2) explore how cue words affect the process of reply generation.

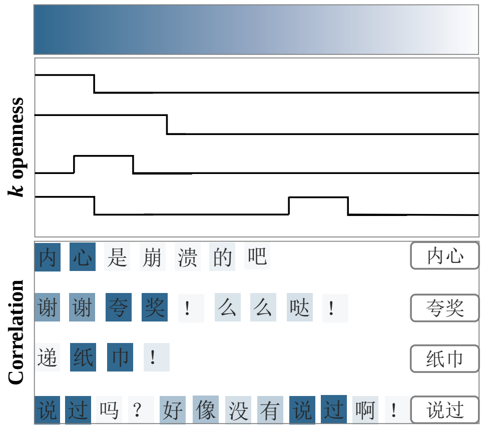

Figure 4: Heat map and the k gate openness. Bottom: The correlation between the generated reply words and the cue word. Top: The openness of k gate in fusion unit.

4.1 Experimental setup

We evaluated our model on a massive Chinese dataset of human conversation crawled from the Baidu Tieba[1] forum. There are 500,000 $\langle query - reply \rangle$ pairs for training, 2,000 for validation, and another unseen 27,871 samples for testing. In total, we kept about 63,000 distinct words.

In our experiments, the encoder, the standard decoder and the cue word decoder have 1,000 hidden units; the word embedding dimensionality is 610 which were initialized randomly and learned during training. We applied AdaDelta with a mini-batch size of 80 for optimization. These values were mostly chosen empirically. In order to prevent overfitting, early stopping was implemented using a held-out validation set.

4.2 Comparison Methods

In this paper, we conduct extensive experiments to compare our proposed method against several representative baselines. All the methods actually are implemented in two ways to utilize the cue word, which are local information initialization and global information inception.

rGRU: Through a specially designed Recall gate (Xu et al., 2016), domain knowledge was transformed into the extra global memory of a deep neural network.

SCGRU: In SCGRU (Wen et al., 2015b), an additional control cell was introduced to gate the dia-

Query (**Cue word**)	班主任还拍了我超级丑的照片已被笑死.(上镜) The teacher took a photo of me; it was really ugly and people laughed at me. (**Photogenic**)	Related Criterion	Labels
Reply1	谁的照片？ Whose photo?	Logic Consistency	Unsuitable
Reply2	什么时候拍的？ When did he took the photo?	Implicit Relevance	Neutral
Reply3	抱抱。Give you a hug.	Implicit Relevance	Neutral
Reply4	我拍照也都是巨丑的！ My photos are also ugly!	——	Suitable

Table 2: An example query, corresponding cue word in **bold** and its candidate replies with human annotation. The query states that people laughed at the author's photo, it is unsuitable to ask the ownership of this photo in Reply1. Generally, Reply2 and Reply3 apply to this scenario, but they do not reflect semantic relevance with the cue word. Reply4 talks about the respondent's situation and related to "Photogenic", thus it is a suitable response.

Method		BLEU-1	BLEU-2	BLEU-3	Human score
Local	rGRU	1.087	0.419	0.249	
	SCGRU	2.135	0.622	0.255	
	SLGD	1.678	0.508	0.209	
	FGRU	2.262	0.598	0.208	
	HGFU	1.861	0.545	0.209	
Global	rGRU	1.793	0.676	0.277	0.542
	SCGRU	3.637	0.981	0.369	0.73
	SLGD	4.146	1.059	0.367	0.71
	FGRU	4.197	1.013	0.282	0.677
	HGFU	**4.893**	**1.225**	**0.393**	**0.942**

Table 4: Performance of evaluated methods.

logue act (DA) features during the generation process.

SLGD: We implemented the Stochastic Language Generation in Dialogue (SLGD) method (Wen et al., 2015a), which added additional features in each gate of the neural cell.

FGRU: To explore more fusion strategies, intuitively, we fused the cue word and hidden states by vector concatenation during the decoding process.

Note that rGRU and SCGRU incorporate additional information by gating mechanisms, while SLGD and FGRU fuse the information into each gate of the neural cell directly.

4.3 Experiment Evaluation

Objective metrics. To evaluate the performance of different methods for the conversation generation task, we leverage BLEU (Papineni et al., 2002) as the automatic evaluation metric, which is originally designed for machine translation and evaluates the output by using n-gram matching between the output and the reference. Here, we use BLEU-1, BLEU-2 and BLEU-3 in our experiments.

Subjective metrics. Since automatic metrics may not consistently agree with human perception (Stent et al., 2005), human testing is essential to assess subjective quality. Hence, we randomly sampled 150 queries in the test set, then we invited five annotators to offer a judgment. For fairness, all of our human evaluation was conducted in a random, blind fashion, i.e., replies obtained from the five evaluated models are pooled and randomly permuted for each annotator. Three levels are assigned to a reply with scores from 0 to 2: 0 = Unsuitable reply, 2 = Suitable reply, and 1 = Neutral reply.

To make the annotation task operable, the suitability of the generated reply is judged not only based on *Grammar and Fluency, Logic Consistency and Semantic Relevance* following (Shang et al., 2015), but also *Implicit Relevance*, i.e., the generated reply should be semantically relevant to the predicted cue word, no matter the cue word explicitly appears in the reply or not. If any of the first three criteria is contradicted, the reply should be labeled as "Unsuitable". Only the replies conforming to all requirements are labeled as "Suitable". Table 2 shows an example of the annotation results of a query and its replies. The first reply is labeled as "Unsuitable" because of the logic consistency. Reply2 and Reply3 are not semantically related to the cue word, and is therefore annotated as "Neutral".

4.4 Overall Performance

The overall results against all baseline methods are listed in Table 4. Our proposed HGFU model in global schema obviously shows better performance than the baseline methods; it obtains the

	Chinese Sentence	English Tranlation
Query	写的真心棒！(**夸奖**)	What a nice written! (**Appreciation**)
Reply	谢谢夸奖！么么哒！	Thanks for your appreciation! Love you!
Query	还是无法淡定。(**内心**)	Still cannot calm down. (**Heart**)
Reply	内心是崩溃的吧。	Your heart must be broken.
Query	我先去哭一会。(**纸巾**)	I am going to cry for a while. (**Tissue**)
Reply	递纸巾！	Offer you a tissue!
Query	当初你们不是说过他是诺维斯基吗？(**说过**)	Didn't you say that he was $Nowitzki^{\dagger}$? (**Say**)
Reply	说过吗？好像没有说过啊！？	Did I say it? I don't seem to say it!?

Table 3: The explicit introducing-content cases of our HGFU model. The predicted cue word in **bold** explicitly occurs in the generated reply. $Nowitzki^{\dagger}$ is a NBA basketball player.

highest BLEU scores as well as the highest human score.

In terms of automatic evaluations, the global-based methods perform much better than a set of local-based methods, which demonstrates the effectiveness of global information inception. As mentioned above, the global schema provides the model a broader and more flexible space for learning, which is benefit for information fusion. When it comes to human scores (For the sake of convenience, we only conducted human evaluation in global schema), there are similar conclusions to BLEU results.

From Table 4, we can see that the performance of rGRU is not as good as the other systems, while SCGRU outperforms the others in the local pattern and shows comparative performance in the global schema. These two methods both augment the standard neural network with specially designed gate to control the cue word, but the results vary greatly. It is the limitation of gating mechanisms that is lacking in adaptiveness. Besides, SLGD adding cue word term in each gate of the neural cell has the similar result as FGRU method, which concatenates cue word with hidden state. Basically, our proposed HGFU has a significant improvement against the baseline systems. The most probable credits come from the cue word GRU: we apply the extra GRU unit to control the auxiliary information instead of fusion in the standard GRU, which is more flexible.

Till now, we have elaborated the overall performance of all methods. Next we will come to a closer look at some representative cases of our HGFU model for further analysis and discussions.

4.5 Analysis and Case Studies

Given a query and the cue word, our HGFU model generates a meaningful and informative response. In Table 3, the predicted cue word occurs in the generated response and we treat this kind of generation as the explicit introducing-content. However, we do not strictly restrict tothis. As shown in Table 5,our HGFUmodel also generates the replies without containing the cue word, while the responsesare still somehow related to the cue word and the query. This reflects our expectation: the information of the cue word will be fused into the generation process but not necessarily occur explicitly. It provesthe characteristics of our proposed new "soft" schema, whichare more flexible, extensible, and controllable.

We further analyze these explicit cases using a heat map as shown in Figure 4. We use various shades of blue to present the extent of correlation between the cue word and the generated reply. The darker the blue is, the higher correlation they have. For the added information in the reply (Here is exactly the cue word in darkblue), its position and occurrence times are not fixed, which are autonomously controlled by our model.

Besides, the rectangular pulse is also a significant presentation of this correlation, which indicates how the k gate in fusion unit balance the influence of h_y and h_w. When in the high level of the rectangular pulse, k "opens" the switch of h_w to generate the current word; when in the low level, the fusion unit mainly takes h_y for generation. We observe that the switch corresponds with the heat map: the generated word is more correlated with the cue word when the switch is open.

	Chinese Sentence	English Tranlation
Query	在微博看到这样一个评论真的是完全无法反驳。(**观点**)	I saw such a comment in the microblog which cannot be refused completely. (**View**)
Reply	路人表示不服啊！	As an outsider, I am not convinced!
Query	怎么突然就下雨了？(**委屈**)	Why is it raining suddenly? (**Grievance**)

5 Related work

5.1 Conversation Systems

Automatic human-computer conversation has attractedincreasing attention over the past few years. At the very beginning, people start the research using hand-crafted rules and templates (Walker et al., 2001; Misu and Kawahara, 2007; Williams et al., 2013). These approaches require no data or little data for trainingbuthuge manual effort to build the model, which is very time-consuming. For now, buildinga conversation systemmainly falls into two categories: retrieval-based and generation-based. As information retrieval techniques are developing fast, Leuski et al. (2009) build systems to select the most suitable response from the query-reply pairs using a statistical language model in cross-lingual information retrieval. Yan et al. (2016) propose a retrieval-based conversation system with the deep learning-to-respond schema through a deep neural network framework driven by web data. Recently, generation-based conversation systems have shownimpressive potential. Shang et al. (2015) generate replies for short-text conversation by Seq2Seq-basedneural networks with local and global attentions.

5.2 Content Introducing

In vertical domains, Wen et al. (2015b) apply an additional control cell to gate the dialogue act (DA) features during the generation process to ensure the generated repliesexpressthe intended meaning. Also, the Stochastic Language Generation in Dialogue method (Wen et al., 2015a) adds additional features in each gate of the neural cell. Xu et al. (2016) introduce a new trainable gate to recall the global domain memory to enhance the ability of modeling the sequence semantics. Different from the above work, our paper addresses the problem of content introducing in the open-domain generative conversation systems.

In open domains, Xing et al. (2016) incorporate topic information into Seq2Seq framework to generate informative and interesting responses. To provide informative clues for content introducing, Li et al. (2016b) detect entities from previous utterances and search for more related entities in a large knowledge graph. A very recent study similar to ours is Mou et al. (2016), where the predicted word explicitly occurs in the generated utterance. Unlike the existing work, we explore an implicit content-introducing method for neural conversation systems, which utilizes the additional cue word in a "soft" manner to generate a more meaningful response given a user-issued query.

6 Conclusion

In this paper, we explore an implicit content-introducing method for generative short-text conversation system. Given a user-issued query, our proposed HGFU incorporates an additional cue word in a "soft" manner to generate a more meaningful response. The HGFU model consists of three components: the standard GRU, the cue word GRU and the fusion unit. The standard GRU operates a general decoding process, and the cue word GRU imitates this process but treats the predicted cue word as the current input. As for the fusion unit, it combines both the hidden states of the standard GRU and the cue word GRU to generate the current output word. The experimental results demonstrate the effectiveness of our approach.

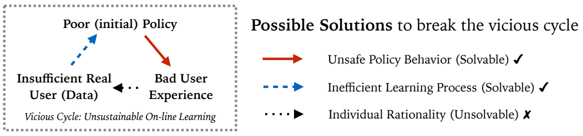
Abstract

The key to building an evolvable dialogue system in real-world scenarios is to ensure an affordable on-line dialogue policy learning, which requires the on-line learning process to be safe, efficient and economical. But in reality, due to the scarcity of real interaction data, the dialogue system usually grows slowly. Besides, the poor initial dialogue policy easily leads to bad user experience and incurs a failure of attracting users to contribute training data, so that the learning process is unsustainable. To accurately depict this, two quantitative metrics are proposed to assess safety and efficiency issues. For solving the unsustainable learning problem, we proposed a complete *companion teaching* framework incorporating the guidance from the human teacher. Since the human teaching is expensive, we compared various *teaching schemes* answering the question *how* and *when* to teach, to economically utilize teaching budget, so that make the online learning process affordable.

1 Introduction

A *task-oriented* dialogue system is designed for interacting with humans users to accomplish several predefined domains or tasks (Young et al., 2013; Daubigney et al., 2012). *Dialogue Manager* is the core component in a typical dialogue system, which controls the flow of dialogue by a *state tracker* and a *policy module* (Levin et al., 1997). The state tracker tracks the internal state of the system while the policy module decides the response to the user according to the status of states (Sun et al., 2014a; Thomson and Young, 2010). The approaches of constructing a policy module can be divided into two categories: rule-based and statistical. Rule-based policies are usually hand-crafted by domain experts which means they are inconvenient and difficult to be optimized (Williams and Young, 2007; Wang and Lemon, 2013). In recent mainstream statistical studies, *Partially Observable Markov Decision Process* (POMDP) framework has been applied to model dialogue management with unobservable states, where policy training can be formulated as a *Reinforcement Learning* (RL) problem, which enables the policy to be optimized automatically (Kaelbling et al., 1998; Arnold, 1998; Young et al., 2013).

Though RL-based approaches have the potential to improve themselves as they interact more with human users and achieve better performance than rule-based approaches, they are rarely used in real-world applications, especially in on-line scenarios, since the training process is unsustainable.



Poor (initial) Policy
Insufficient Real User (Data)
Bad User Experience
Vicious Cycle: Unsustainable On-line Learning
Possible Solutions to break the vicious cycle
Unsafe Policy Behavior (Solvable) ✓
Inefficient Learning Process (Solvable) ✓
Individual Rationality (Unsolvable) ✗

The main causes of unsustainable on-line dialogue policy learning are two-fold:

- *Safety issue:* the initial policy trained from scratch may lead to terrible user experience at the early training period, thus fail to attract sufficient users for more dialogues to do further policy training.
- *Efficiency issue:* if the progress of policy learning is not so efficient, it will exhaust users' patience before the policy reaches a desirable performance level.

[*] Both authors contributed equally to this work.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2200–2209
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

Prior works have mainly focused on improving *efficiency*, such as Gaussian Processes RL (Gašić et al., 2010), deep RL (Fatemi et al., 2016), etc. For deep RL approaches, recent researches on the *student-teacher RL framework* have shown prominent acceleration to policy learning process (Torrey and Taylor, 2013; Williams and Zweig, 2016; Amir et al., 2016). In such framework, the *teacher agent* instructs the *student agent* by providing suggestions on what actions should be taken next (Clouse, 1996).

For the *safety* issue, Chen et al. (2017) developed several teaching strategies answering "how" the human teacher guide the learning process.

However, those previous teaching methods exclude "when" to teach from concern. They simply exhaust all the budget continuously from the beginning, which is wasteful and causes a heavy workload of the human teacher. An *affordable* dialogue policy learning with human teaching should require a lighter workload and economically utilize teaching budget.

Furthermore, as for safety and efficiency evaluation, previous works have been observing the training curves and testing curves to tell which one is better, or evaluate policy performance after certain dialogues of training, which are subjective and error prone (Chen et al., 2015a; Su et al., 2016; Chen et al., 2017).

Our contribution is to address the above problems. We propose a complete framework of companion teaching, and develop various *teaching schemes* which combine different *teaching strategies* and *teaching heuristics* together, to answer the questions of "how" and "when" to teach to achieve affordable dialogue policy learning (section 2). Specifically, a novel *failure prognosis* based teaching heuristic is proposed, where MultiTask Learning (MTL) is utilized to predict the dialogue success reward (section 3). To avoid the drawbacks of traditional subjective measurements, we propose two evaluation metrics, called *Risk Index* (RI) and *Hitting Time* (HT), to quantify the safety and efficiency of on-line policy learning respectively (section 4). Simulation experiments showed, with the proposed companion teaching schemes, sustainable and affordable on-line dialogue policy learning has been achieved (section 5).

2 Companion Teaching Framework

The *companion teaching* framework is an on-line policy training framework with three intelligent participants: machine dialogue manager, human user, and human teacher (Chen et al., 2017). Under this framework, the human teacher is able to accompany the dialogue manager to guide policy learning with a limited teaching budget. By investigating the real work mode in a call center, this framework makes a reasonable assumption that human teacher has access to the extracted dialogue states from the dialogue state tracker as well as the system's dialogue act, and can also reply in the same format.

However, there are two major problems in the previous framework. First, the system will judge whether a dialogue session succeeds by several simple rules and then determine whether to feed a success reward signal to dialogue manager for reinforcement learning. Actually, the success feedback made by the system lacks flexibility and credibility, and it could mislead the policy learning. A more suitable judge should be the user or the human teacher. Second, the previous framework only answers in which way the human teacher can guide the online dialogue policy learning, but another essential question, *when* should the human teacher give guidance, remains undiscussed.

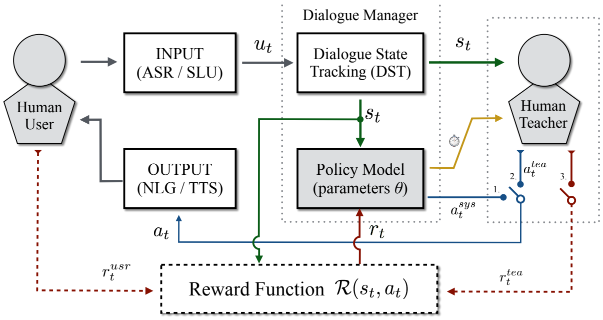


Figure 1: Companion Teaching Framework for On-line Policy Learning

In this paper, we proposed a complete framework of *companion teaching*, depicted as Figure 1. At each turn, the input module receives a speech input from the human user, then produces possible utterances u_t of the speech in text. After that, the dialogue state tracker extracts the dialogue state s_t from possible utterances. This dialogue state will be shared with policy model and human teacher if needed. When the final response a_t, has been determined, the output module will translate this dialogue act to the natural language and reply to the human user. The success signal will be fed back by the user or the human teacher as an important part of system reward, at the end of each session. The human teacher can take the initiative or be activated by *student initiated heuristic* to give the dialogue guidance with strategies corresponding to different configurations of switches in the illustration. We call the combination of strategy and heuristic as *teaching scheme*.

2.1 Teaching Strategies

The teacher can choose among three teaching strategies corresponding to different configurations of switches in a wiring diagram as Figure 1 shows: The left switch is a Single-Pole, Double-Throw (SPDT) switch, which controls whether the answer is made by the system (connected to 1) or given by the teacher as an example (connected to 2). The right switch is a simple on-off switch, which represents whether there is an extra reward signal from the teacher (ON) or not (OFF). The strategy related to the right switch is called *teaching via Critic Advice* (CA), also known as turn-level reward shaping (Thomaz and Breazeal, 2008; Judah et al., 2010). When the switch at position 3 is turned on, the teacher will give the policy model extra turn-level reward to distinguish the student's actions between good and bad actions. Besides, the left switch corresponds to *teaching via Example Action* (EA), which means the teacher gives example action for the student to take according to the student's state.

The other strategy is proposed by Chen et al. (2017), which take the advantages of both EA and CA, named *teaching via Example Action with Predicted Critique* (EAPC). With this strategy, the human teacher gives example actions, meanwhile, a weak action predictor is trained using this teaching information to provide the extra reward even in teacher's absence.

2.2 Teaching Heuristics

The strategies only answer how the human teacher can offer companion teaching to the system. However, the timing of teaching should not be ignored for the sake of utilizing the limited teaching budget better. Exhausting all the budget at early training stage, named *Early teaching heuristic* (Early), is simple and straightforward but wastes teaching opportunities on unnecessary cases. Thus, it is imperative to design some effective heuristics to instruct when the teacher should give a hand to the student.

In addition to early teaching, the teaching heuristics can be broadly divided into two categories: *teacher-initiated* heuristics and *student-initiated* heuristics (Amir et al., 2016). However, the teacher-initiated approaches require the constant long-term attention of the teacher to monitor the dialogue process (Torrey and Taylor, 2013; Amir et al., 2016), which is costly and impractical for real applications. Therefore, in this paper, we only discuss student-initiated heuristics, shown as the line with a stopwatch in Figure 1, which means that the student agent decides when to ask for the teacher's help.

Previous works have presented several effective heuristics based on *state importance*, $I(s)$, which is determined by the Q-values of the RL agent:

$$I(s) = max_a Q_{(s,a)} - min_a Q_{(s,a)}$$

Torrey and Taylor (2013) proposed *State Importance based Teaching heuristic* (SIT) which make the student ask for advice only when the current state is important:

$$I(s) > t_{si}, \tag{1}$$

where t_{si} is a fixed threshold for importance. And Clouse (1996) proposed an *State Uncertainty based Teaching heuristic* (SUT) which ask for advice when the student is uncertain about which action to take:

$$I(s) < t_{su}, \tag{2}$$

where t_{su} is a given threshold for uncertainty.

Though teaching effort can be conserved by only applying to those important or uncertain states, it may end up wasting advice if the dialogue is likely to be successful without teaching. In this paper, we propose a novel *Failure Prognosis based Teaching heuristic* (FPT) for on-line policy learning to reduce that unnecessary advice. The details are given in section 3. For comparison, we will also investigate *Random teaching heuristic* (Rand) which means the student seek for advice with a fixed probability p_r.

3 Failure Prognosis Based Teaching Heuristic

To make better use of teaching advice, we propose to use an on-line turn-level *task success predictor* to predict whether the ongoing dialogue will end in success and ask for advice only when the current prediction is a failure. The proposed approach utilizes MultiTask Learning (MTL) for the policy model to estimate future dialogue success reward and is compatible with various RL algorithms. In this paper, we implement the policy model with a Deep Q-Network (DQN), in which a neural network function approximator, named *Q-network*, is used to estimate the action-value function (Mnih et al., 2013).

3.1 Multitask Deep Q-Network

The goal of the policy model is to interact with human user by choosing actions in each turn to maximize future rewards. We define the dialogue state shared by dialogue state tracker in the t-th turn as s_t, the action taken by policy model under current policy π_θ with parameters θ in the t-th turn as a_t, and $a_t \sim \pi_\theta(\cdot|s_t)$. In an ideal dialogue environment, once the policy model emit an action a_t, the human user will give an explicit feedback, like a normal response or a feedback of whether the dialogue is successful, which will be converted to a reward signal r_t delivering to the policy model immediately, and then the policy model will transit to next state s_{t+1}. The reward r_t is composed of two parts:

$$r_t = r_t^{turn} + r_t^{\mathtt{succ}},$$

where r_t^{turn} is the turn penalty reward and $r_t^{\mathtt{succ}}$ is the dialogue success reward. Typically, r_t^{turn} is fixed for each turn as a negative constant R^{turn}, while $r_t^{\mathtt{succ}}$ equals to a predefined positive constant $R^{\mathtt{succ}}$ only when the dialogue terminates and receives a successful user feedback otherwise zero.

In DQN algorithm, all these transitions (s_t, a_t, r_t, s_{t+1}) will be stored in a replay memory $\mathcal{D}$. And the objective is to optimize MSE between *Q-network* $Q(s, a; \theta)$ and *Q-learning target* Q_e. The loss function $L(\theta)$ is defined as:

$$L(\theta) = \mathbb{E}_{s,a\sim\pi_\theta}\left[(Q_e - Q(s, a; \theta))^2\right]. \qquad (3)$$

During the training period, Q_e is estimated with old fixed parameter θ^- and sampled transitions $e \sim \mathcal{D}$:

$$Q_e = r + \gamma \max_{a_{t+1}} Q(s_{t+1}, a_{t+1}; \theta^-), \qquad (4)$$

where γ is the discount factor.

The reward $Q(s, a)$ estimated by original Q-learning algorithm is essentially a combination of future turn penalty reward $Q^{\mathtt{turn}}(s, a)$ and future dialogue success reward $Q^{\mathtt{succ}}(s, a)$. For a task-oriented dialogue system, the prediction of $Q^{\mathtt{succ}}(s, a)$ is much more important because it reflects the possibility of the dialogue to be successful. If these two rewards are estimated separately, the objective of $Q^{\mathtt{succ}}(s, a)$ can be optimized explicitly, and we can get more insights into the estimated future. We found that in practice, optimizing these two objectives with *MultiTask Learning* (MTL) converges faster and more stable compared with two separate models, the reason of which may lie in that MTL can learn different related tasks in parallel using shared representations, which will be helpful for each task to be learned better (Caruana, 1997). The structure of proposed MTL-DQN is depicted in Figure 2.

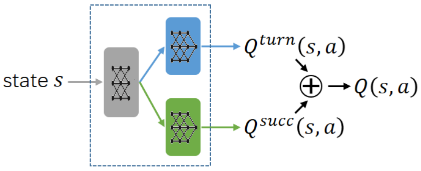

Figure 2: MTL-DQN structure

3.2 Failure Prognosis

In the proposed multitask DQN, we define *on-line task success predictor* $T(s_t)$ as:

$$T(s_t) = Q^{\mathtt{succ}}(s_t, a_t),$$

where a_t is the action taken under state s_t. It is reasonable to assume that the dialogue is going to fail if $T(s_t)$ is relatively small. Based on the task success predictor, we propose a novel student-initiated heuristic, named *Failure Prognosis based Teaching heuristic* (FPT).

The key to the proposed heuristic is to define *failure prognosis* quantitatively. A straight way is to set a ratio threshold α, and consider it to be *failure prognosis* when $T(s_t) < \alpha R^{\mathtt{succ}}$. However, this assumes that the numerical scale of $Q^{\mathtt{succ}}$ is consistent through the training period, which is not always the case. And the student's noisy estimation of $Q^{\mathtt{succ}}$ at early training period will make the learning process unstable. To smooth the teaching, we consider using a turn-level sliding window near the current state to calculate an average value as the replacement of the fixed R^{succ}. So in the t-th turn, the *failure prognosis* for the student to be *true* is equivalent to:

$$T(s_t) < \alpha \frac{1}{w} \sum_{j=t-w}^{t-1} T(s_j), \tag{5}$$

where w is the size of the sliding window.

4 Quantitative Measurements for Safety and Efficiency

The performance of different teaching strategies and heuristics should be measured in both the *safety* and *efficiency* dimension. However, the measurements in these two dimensions are subjective and error prone in the previous work (Chen et al., 2017). Especially for assessing the degree of safety of various teaching strategies and heuristics, we simply obverse the training curves so that we cannot tell of two interleaving curves which training process is safer. Thus, it is imperative to set up some quantitive measurements for both *safety* and *efficiency* evaluations. In this paper, we propose two scalar criteria: *Risk Index* (RI) and *Hitting Time* (HT).

4.1 Risk Index

The *Risk Index* is a nonnegative index designed to indicate how risky the training process could be for evaluating the safety issue during the whole online dialogue policy learning process. Because we expect that the system satisfies the quality-of-service requirement in the early training period, specifically, we hope it can keep a relatively acceptable success rate. It is straightforward to set a success rate *threshold* for the training process. In a real application scenario, this threshold can be obtained by an appropriate user study.

If the success rate over a training process keeps above this threshold all the time, we will think this training process is absolutely safe. Therefore, its RI should equal to zero.

On the other hand, if the success rate over a training process rises and falls and sometimes is below the threshold, it is risky. The riskiness consists of two parts:

- **Disruptiveness**: Sometimes the success rate during a certain period will fall much lower than the threshold, which could be very disruptive. To quantify the disruptiveness, we consider the function

  $$\texttt{dis}(t) = \texttt{threshold} - \%\texttt{succ}(t)$$

  over the training process. The higher the value of $\texttt{dis}(t')$ is, the riskier the training process could be during the period of a certain length centered with time t'.

- **Persistence**: Another thing we should take into account is the duration of the time at high risk. Let $\delta_{\texttt{risk}}(t)$ be the indicator of whether $\texttt{threshold} \geq \%\texttt{succ}(t)$. Then the persistence can be quantified as total risky time

  $$\texttt{per}(T) = \int_{t=0}^{T} \delta_{\texttt{risk}}(t) dt$$

  The longer the danger persists over the training process, the value of persistence of the training process will be, and the riskier it is.

Our *Risk Index* integrate these two contents of riskiness. That is, a nonnegative scalar

$$\texttt{RI} = \int_{t=0}^{T} \texttt{dis}(t)\delta_{\texttt{risk}}(t) dt,$$

which measures the integrated riskiness for the online training process of total length T. The RI also has an intuitive interpretation as the area of the region which is below the threshold line and above training curve. Straightforwardly, high RI indicates poor safety.

4.2 Hitting Time

To measure the efficiency, we proposed the *Hitting Time* in order to show how fast the system learns and reaches the satisfactory performance.

The difficulty of designing such a criterion lies in the dramatic and undamped fluctuation of the test curves, which is inherent in the instability dialogue task. Therefore, many popular criteria for the evaluating dynamic performance in control theory, such as “settling time” and “rise time”, cannot be applied to evaluate efficiency here.

We use *Hitting Time* to evaluate efficiency over the fluctuant testing curve first by fitting it to the empirical learning curve

$$f(t) = a - b \cdot e^{-(t/c)^2},$$

where the parameter a is the stationary performance which is predicted as the asymptotic goal of the system, b relates to the initial performance, and c relates to the climbing speed. This empirical model forces our fitted learning curve be an "S" shape curve satisfying constraints $f'(0) = 0$ and $f''(c/2) = 0$. Then we observe when this fitted learning curve hits the target performance τ and this time (measured in sessions) is *Hitting Time*. It can be calculated analytically as follow

$$\mathrm{HT} = c\sqrt{\ln\left(\frac{b}{a-\tau}\right)}.$$

Ideally, the ultimate success rate a should be very close under different settings because of the sufficient training. However, if the success rate keeps very poor during the given sessions, the fitted a will be very low, and even less than the target satisfactory performance τ. In this situation, a is meaningless, and HT becomes a complex number. And this indicates the real hitting time is far larger than given number of sessions T. We will note the HT in this case as **ULT** (Unacceptably Large Time).

In this way, we overcome the fluctuation and make the HT tell us how much time the system takes to hit and surpass the target success rate.

5 Experiments and Results

Three objectives are set for our experiments: (1) Observing the effect of multitask DQN; (2) Contrasting the performances of different teaching schemes (strategies and heuristics) under the companion teaching framework; (3) Observing the safety and efficiency issues under sparse user feedback scenarios.

5.1 Experimental Setup

Our experiments are conducted with the Dialogue State Tracking Challenge 2 (DSTC2) dataset, which is on restaurant information domain (Henderson and Thomson, 2014). The human user is emulated by an agenda-based user simulator with error model (Schatzmann et al., 2007), while the human teacher is emulated by a pre-trained policy model with success rate of about 0.78 through multitask DQN approach without teaching. A rule-based tracker is used for dialogue state tracking (Sun et al., 2014b). The semantic parser is implemented according to an SVM-based method proposed by Henderson et al. (2012). The natural language generator is implemented and modified based on an RNNLG toolkit (Wen et al., 2016, 2015a,c,b).

Early	Rand	SIT	SUT	FPT
None	$p_r = 0.6$	$t_{si} = 5$	$t_{su} = 10$	$\alpha = 1.2$ $w = 25$

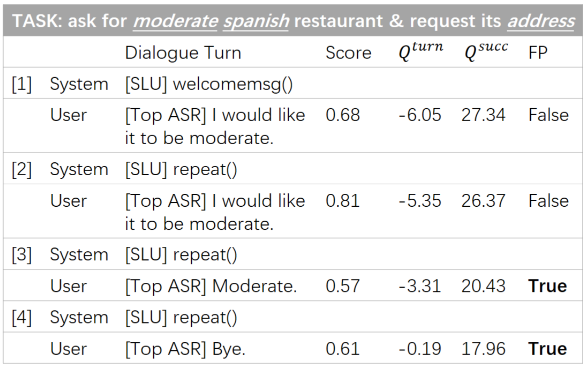
Table 1: Experimental configurations of teaching heuristics introduced in section 2.2 and 3.2.

In our experiments, all dialogues are limited to twenty turns. The "dialogue success" is judged by the user simulator according to whether all user goals are satisfied. And for policy learning, we set a small per-turn penalty of one to encourage short interactions, i.e. $R^{\mathtt{turn}} = -1$, and a large dialogue success reward of thirty to appeal to successful interactions, i.e. $R^{\mathtt{succ}} = 30$, and the discount factor γ is set to one. Table 1 summarizes the heuristics studied in our experiments, together with corresponding configurations which are chosen empirically.

5.2 Observing the Effect of MTL-DQN

The MTL-DQN described in section 3.1 can estimate the prediction of Q^{turn} and Q^{succ} respectively. In our experiments, it was implemented with one shared hidden layer and two dependent hidden layers for two different tasks using MXNet (Chen et al., 2015b).

Figure 3 shows a typical failure in dialogue policy training. The policy showed in the example hasn't been trained well, and it tends to ask the user to repeat over and over again when the confidence score of the user utterance is not high, which causes the user to terminate the dialogue impatiently.



TASK: ask for *moderate spanish* restaurant & request its *address*

		Dialogue Turn	Score	Q^{turn}	Q^{succ}	FP
[1]	System	[SLU] welcomemsg()				
	User	[Top ASR] I would like it to be moderate.	0.68	-6.05	27.34	False
[2]	System	[SLU] repeat()				
	User	[Top ASR] I would like it to be moderate.	0.81	-5.35	26.37	False
[3]	System	[SLU] repeat()				
	User	[Top ASR] Moderate.	0.57	-3.31	20.43	**True**
[4]	System	[SLU] repeat()				
	User	[Top ASR] Bye.	0.61	-0.19	17.96	**True**

Figure 3: An example of failed dialogue while training without teaching. The labels "Score" and "FP" represent for the confidence score of user utterance and the value of *failure prognosis* of the current turn respectively.

This kind of failure can be predicted and corrected in advance. By equation 5, the third turn will be estimated to be *failure prognosis*, which can be a sign for the teacher to intervene and correct the following actions to avoid dialogue failure. Besides, the explicit separate estimation of Q^{turn} and Q^{succ} provides a better understanding of the state of the current turn. For example, although the first turn and second turn have similar Q-values ($Q^{turn}+Q^{succ}$), the latter turn is predicted with less future turns and less possibility to lead to dialogue success. See appendix A for additional successful example.

5.3 Comparing Different Teaching Schemes

Our proposed complete companion teaching framework allows us to teach dialogue systems with different teaching schemes, which consists various strategies and heuristics. In our experiments, we compared 18 schemes consisting of three teaching strategies (CA, EA and EAPC), and six teaching heuristics (Early, Rand, SIT, SUT, FPT and SUT&FPT). The *SUT&FPT* heuristic means the student only ask for advice when equation 2 and 5 are both satisfied. For comparison, we use *No Teaching* (NoTeaching) as the baseline.

To verify the effects of different companion *teaching schemes*, we conduct a set of experiments to see their performances on safety and efficiency dimensions. During training, the teacher can only teach for a limited budget of 1000 turns. All the training curves shown in this paper are moving average curves with a window of size 250 dialogues and over eight runs with an endurable standard error.

5.3.1 Safety Evaluation

To compare effects of different teaching schemes on safety dimension, we use the *Risk Index* (RI) in section 4.1 to quantitatively measure each training process. We set the empirical safety threshold as 65% here. The results are shown in Table 2.

As RIs implies, schemes composed with EAPC strategy is much safer than those composed with other strategies. As for teaching heuristics, FPT, SUT and SUT&FPT are three relatively safer heuristic accompanying different strategies. One exception is that Early teaching looks more suitable for CA. A possible explanation is that when the teacher gives critique earlier, the student will mind its behavior earlier so that increase safety. Figure 4 shows the training curves of on-line learning process under EAPC with various heuristics. Among all 18 teaching schemes, EAPC+SUT is the safest teaching scheme which reduces about 78% risk of no-teaching learning.

	CA	EA	EAPC
Early	**98.5**	110.6	56.1
Rand	193.4	102.4	65.5
FPT	154.4	**86.2**	**53.6**
SIT	230.8	121.7	66.0
SUT	183.5	**95.8**	**44.5***
SUT&FPT	**131.6**	101.8	54.6
NoTeaching	202.9		

Table 2: RIs of learning processes under different teaching schemes. The least risky teaching scheme is annotated with *. For comparing different teaching heuristics with fixed teaching strategy, the smallest RIs in each column are bold and underlined, the 2^{nd} smallest ones are bold only, and the 3^{rd} smallest ones are underlined only. See abbreviations of schemes in section 2.1 and 2.2.

5.3.2 Efficiency Evaluation

We use *Hitting Time* (HT) in section 4.2 to measure the efficiency of learning process under different teaching schemes. The empirical satisfactory target success rate for the student is 70% in our experimental settings.

	CA	EA	EAPC
Early	3390.9	3479.4	4354.7
Rand	3669.0	3518.5	2979.2
FPT	**3089.4**	**2921.1**	**2798.4**
SIT	3576.4	4339.7	3768.7
SUT	3230.4	**2954.5**	3300.2
SUT&FPT	**2890.7**	3393.0	**2702.2***
NoTeaching	3204.1		

Table 3: HTs of test curves of different teaching schemes. The most efficient teaching scheme is annotated with *. For comparing different teaching heuristics with fixed strategy on efficiency issue, the smallest HTs in each column are bold and underlined, and the 2^{nd} smallest bold only. See abbreviations of schemes in section 2.1 and 2.2.

Table 3 contains all HTs of learning process under 18 teaching schemes. Intuitively, The number in the table reflect the number of sessions at which the model achieves target success rate. As it shows, not any teaching scheme will improve the learning efficiency. If the teacher intervenes at an improper time, it will distract system or confuse system even with a right guidance. But teaching when a potential failure exists (F-

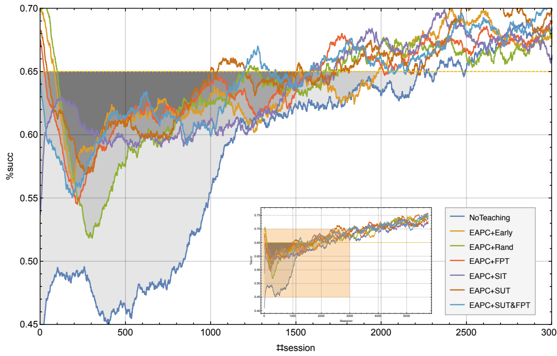


Figure 4: On-line learning process under different teaching schemes (EAPC + different heuristics). The yellow dashed line indicates safe success rate threshold. The area in gray indicates how risky a training process is. See abbreviations of schemes in section 2.1 and 2.2.

PT) is always good for improving learning efficiency. EAPC+SUT&FPT is the teaching scheme that leads to the most efficient learning process in our experiments. Figure 6 gives some example test curves and fitted empirical learning curves of learning process under EAPC with various heuristics.

5.3.3 Teacher's Workload

We also observe teacher's workload of all the teaching schemes since economically utilizing teaching budget is one of our goals.

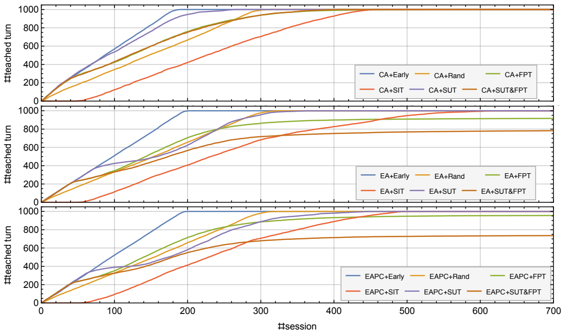

Figure 5: Cumulative usage of teaching budget. The total teaching budget is 1000 for every teaching scheme. See abbreviations of schemes in section 2.1 and 2.2.

Figure 5 illustrates the cumulative usage of teaching budget of 18 teaching schemes. It shows that early teaching is the most costly teaching heuristic so that the teaching budget is soon used up. SIT looks a bit lazy at the beginning and consumes teaching budget slowly. When the teaching strategy is EA or EAPC, FPT-based schemes do not use up full teaching budget in our experiments. Combine SUT and FPT, the workload is relatively lighter than that of teaching in other heuristics. And through proper teaching schemes, we can make better use of the teaching budget and reduce teacher's workload.

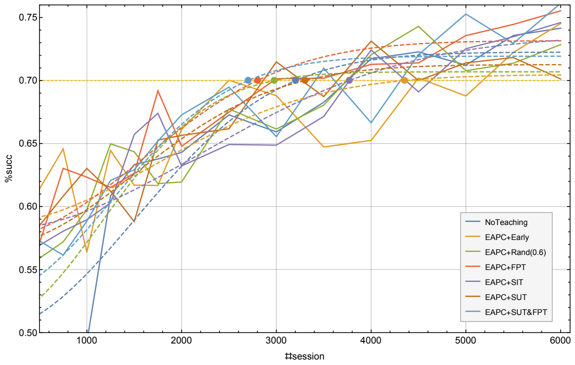

Figure 6: Test curves and fitted empirical learning curves of learning process with different teaching schemes (EAPC+different heuristic). See abbreviations of schemes in section 2.1 and 2.2.

5.4 Safety and Efficiency Issues under Sparse User Feedback Scenarios

In real application scenarios, the user rarely provides feedback at the end of the dialogue, so that safety and efficiency issues are even more serious. To observe the effectiveness of different teaching schemes under sparse user feedback, we conducted experiments with sparse user feedback.

The user feedback rate is set to 30% empirically and experiments are carried out under teaching schemes consisting of EAPC strategies and different heuristics, since EAPC is much safer and more efficient than other teaching strategies.

	RIs	**HTs**
NoTeaching	608.2	ULT
Early	223.0	6881.8
Rand	226.6	ULT
FPT	**171.5**	**6753.0**
SIT	308.8	7868.4
SUT	183.3	**5876.9**
SUT&FPT	**155.4**	8420.9

Table 4: RIs & HTs of learning processes under EAPC strategy and different heuristics when user feedback rate is 30%. See abbreviations of schemes in section 2.1 and 2.2.

Table 4 records the RIs and HTs of those different learning process when user feedback is sparse.

We can see that when the user feedback rate drops from 100% to 30%, the RIs and HTs increase dramatically. The NoTeaching baseline is very risky and inefficient (its hitting time is even unpredictable within 10000 sessions learning). However, with teaching scheme such as EAPC+FPT, both safety and efficiency can be improved a lot.

6 Conclusions and Future Work

This paper addressed the *safety* and *efficiency* issues of sustainable on-line dialogue policy learning with different teaching schemes, which answer both "how" and "when" to teach, within the complete companion teaching framework. To evaluate the policy learning process precisely, we proposed two measurements, Risk Index (RI) and Hitting Time (HT), to quantify the degree of safety and efficiency. Particularly, through multitask learning, we managed to optimize the predicted remaining turns and dialogue success reward explicitly, based on which we developed a novel *Failure Prognosis based Teaching* (FPT) heuristic to better utilize the fixed teaching budget and make the teaching affordable.

Experiments showed that different teaching schemes have different effects on safety and efficiency dimension. And they also require different workload of the teacher. Among 18 compared teaching schemes, FPT-based heuristics combined with EAPC strategy achieved promising performance on RI and HT, and required relatively slight workload. This result indicates a proper teaching scheme under the companion teaching framework is able to guarantee a sustainable and affordable on-line dialogue policy learning process.

There are several directions for our future work. We expect to deploy our proposed framework in real-world scenarios collaborating with real human teachers to verify the results presented in this paper and discover more potential challenges of on-line dialogue system development. Furthermore, the current study is focused on dialogue success rate, which is a simplification of the human satisfaction evaluation. So future work is needed to take more qualities into consideration to achieve better user experience.

Abstract

Sequence-to-sequence models have been applied to the conversation response generation problem where the source sequence is the conversation history and the target sequence is the response. Unlike translation, conversation responding is inherently creative. The generation of long, informative, coherent, and diverse responses remains a hard task. In this work, we focus on the single turn setting. We add self-attention to the decoder to maintain coherence in longer responses, and we propose a practical approach, called the glimpse-model, for scaling to large datasets. We introduce a stochastic beam-search algorithm with segment-by-segment reranking which lets us inject diversity earlier in the generation process. We trained on a combined data set of over 2.3B conversation messages mined from the web. In human evaluation studies, our method produces longer responses overall, with a higher proportion rated as acceptable and excellent as length increases, compared to baseline sequence-to-sequence models with explicit length-promotion. A back-off strategy produces better responses overall, in the full spectrum of lengths.

1 Introduction

Building computer systems capable of general-purpose conversation is a challenging problem. However, it is a necessary step toward building intelligent agents that can interact with humans via natural language, and for eventually passing the Turing test. The sequence-to-sequence (*seq2seq*) model has proven very popular as a purely data-driven approach in domains that can be cast as learning to map to and from variable-length sequences, with state-of-the art results in many domains, including machine translation (Cho et al., 2014; Sutskever et al., 2014; Wu et al., 2016). Neural conversation models are the latest development in the domain of conversation modeling, with the promise of training computers to converse in an end-to-end fashion (Vinyals and Le, 2015; Shang et al., 2015; Sordoni et al., 2015; Wen et al., 2016). Despite promising results, there are still many challenges with this approach. In particular, these models produce short, generic responses that lack diversity (Sordoni et al., 2015; Li et al., 2015). Even when longer responses are explicitly encouraged (e.g. via length normalization), they tend to be incoherent (*"The sun is in the center of the sun."*), redundant (*"i like cake and cake"*), or contradictory (*"I don't own a gun, but I do own a gun."*).

In this paper, we provide two methods to address these issues with minimal modifications to the standard seq2seq model. First, we present a *glimpse model* that only trains on fixed-length segments of the target-side at a time, allowing us to scale up training to larger data sets. Second, we introduce a *segment-based stochastic decoding technique* which injects diversity earlier in the generated responses. Together, we find that these two methods lead to both longer responses and higher ratings, compared to a baseline seq2seq model with explicit length and diversity-promoting heuristics integrated into the generation procedure (see Table 1 for examples generated using our model).

In Section 2, we present a high-level overview of these two techniques. We then discuss each

technique in more detail in Sections 3 and 4. Finally, we report small and large-scale experimental evaluations of the proposed techniques in Section 5.

2 Overview and Motivation

A major difference between translation and responding to conversations is that, in the former, the high-level semantic content to generate in the target sequence $\mathbf{y}$ is completely given by the source sequence, *i.e.*, given the source $\mathbf{x}$, there is low conditional entropy in the target distribution $P(\mathbf{y}|\mathbf{x})$. In the seq2seq approach, the decoder network therefore only has to keep track of where it is in the output, and the content to generate can be transformed from the relevant parts in the source via the attention mechanism (Bahdanau et al., 2014). In contrast, in conversation response generation, the prompt turn may be short and general (e.g., *"what do you have planned tonight"*), while an appropriate response may be long and informative.

The standard seq2seq model struggles with generating long responses, since the decoder has to keep track of everything output so far in its fixed-length hidden state vector, which leads to incoherent or even contradictory outputs. To combat this, we propose to integrate *target-side attention* into the decoder network, so it can keep track of what has been output so far. This frees up capacity in the hidden state for modeling the higher-level semantics required during the generation of coherent longer responses. We were able to achieve small perplexity gains using this idea on the small OpenSubtitles 2009 data set (Tiedemann, 2009). However, we found it to be too memory-intensive when scaling up to larger data sets.

As a trade-off, we propose a technique (called the 'glimpse model') which interpolates between source-side-only attention on the encoder, and source and target-side attention on the encoder and decoder, respectively. Our solution simply trains the decoder on fixed-length *glimpses* from the target side, while having both the source sequence and the part of the target sequence before the glimpse on the encoder, thereby sharing the attention mechanism on the encoder. This can be implemented as a simple data-preprocessing technique with an unmodified standard seq2seq implementation, and allows us to scale training to very large data sets without running into any memory issues. See Figure 1 for a graphical overview, where we illustrate this idea with a glimpse-model of length 3.

Given such a trained model, the next challenge is how to generate long, coherent, and diverse responses with the model. As observed in the previous section and in other work, standard maximum a posteriori (MAP) decoding using beam search often yields short, uninformative, and high-frequency responses. One approach to produce longer outputs is to employ length-promoting heuristics (such as length-normalization (Wu et al., 2016)) during decoding. We find this increases the length of the outputs, however often at the expense of coherence. Another approach to explicitly create variation in the generated responses is to rerank the N-best MAP-decoded list of responses from the model using diversity-promoting heuristics (Li et al., 2015) or a backward RNN (Wen et al., 2015). We find this works for shorter responses, but not for long responses, primarily for two reasons: First, the method relies on the MAP-decoding to produce the N-best list, and as mentioned above, MAP-decoding prefers short, generic responses. Second, it is too late to delay reranking in the beam search until the whole sequence has been generated, since beam-search decoding tends to yield beams with low diversity per given prompt, even when the number of beams is high. Instead, our solution is to break up the reranking over shorter segments, and to rerank segment-by-segment, thereby injecting diversity earlier during the decoding process, where it has the most impact on the resulting diversity of the generated beams.

To further improve variation in the generated responses, we replace the deterministic MAP-decoding of the beam search procedure with sampling. If a model successfully captures the distribution of responses given targets, one can expect simple greedy sampling to produce reasonable responses. However, due to model underfitting, the learned distributions are often not sharp enough, causing step-by-step sampling to accumulate errors along the way, manifesting as incoherent outputs. We find that integrating sampling into the beam-search procedure yields responses that are more coherent and with more variation overall.

In summary, the contributions of this work are the following:

1. We propose to integrate target-side attention in neural conversation models, and provide a

PROMPT:	**RESPONSE FROM BASELINE (A) vs OUR METHOD (B)**
what do you have planned tonight	**A:** I have no idea what I want to do with my life. I have no idea what I want to (Bad, Mediocre, Bad) **B:** I was planning on doing a few of these, but I'm not sure what to choose. I need to find a place to camp, and I don't have a lot of time to make a plan. (Excellent, Good, Mediocre)
I'd like to read a good science fiction novel. Haven't read scifi in a while.	**A:** If you like sci fi you should check out The Name of the Wind by Patrick Rothfuss (Excellent, Excellent, Excellent) **B:** If you want to know what sci-fi is, read the first book by Neil Gaiman. It's a sci-fi sci-fi sci-fi novel. It is really good and I recommend it to all of you. It has a great premise. (Acceptable, Excellent, Acceptable)
Got any big weekend plans?	**A:** I have plans for the weekend but I don't know if I will be able to make it to the (Bad, Mediocre, Bad) **B:** I don't really have much to do on Saturday. But I plan on going to the movies at the mall and going to the show. (Good, Good, Bad)
Sometimes flying messes my ears, because of the air pressure. Especially if I have a cold or something, flying gets me messed up.	**A:** I don't know why, but when I was a kid I used to do this all the time when I was younger. (Good, Bad, Bad) **B:** I have no idea why, but I feel exactly the same way. I don't know why, but my brain is so sensitive to air that it makes my nose twitch. (Excellent, Mediocre, Good)
Yeah. I have this friend, and we get bored just hanging out here sometimes, so we take little trips to places. We went to Seattle a couple of months ago.	**A:** What kind of things do you like to do? (Excellent, Excellent, Excellent) **B:** That sounds like a great time. I have a lot of friends that go to Seattle, so I was wondering if you could share any of the locations? (Excellent, Excellent, Excellent)
have you seen Suicide Squad?	**A:** I have not, but I will check it out. (Good, Good, Good) **B:** I saw it in a theater once and it was great. It was very... I don't know, a little dark. I like the psychological effects and the way it portrays the characters in the movie. (Excellent, Excellent, Excellent)
Actually I like the snow too, except for today. It's all slushy and it's all over the sidewalks and it's gross.	**A:** I hate the snow. I hate the snow. I hate the snow. I hate the snow. I hate the snow. I hate the snow. I hate the snow. I hate the snow. (Acceptable, Good, Good) **B:** I'm in the same boat as you. I hate it when it's snowy and I don't like to shovel it all day. :(So this is a perfect excuse to not get out of bed and go somewhere else. (Excellent, Good, Acceptable)
What do you hope to see in the future?	**A:** I want to be able to go back in time to when I was born. I want to be (Mediocre, Bad, Mediocre) **B:** I want to see an actual movie where the characters have the ability to hide the fact that they are actually in the movie. (Good, Acceptable, Acceptable)
what dangers could happen with the singularity?	**A:** I don't think it would be that big of a deal. (Acceptable, Mediocre, Acceptable) **B:** If you look at it from the perspective of an alien, you can't say that there aren't any alternative ways to deal with it. (Acceptable, Mediocre, Acceptable)
I think you're a little crazy.	**A:** I don't think you know what that word means. (Acceptable, Good, Good) **B:** I am, actually. I don't think I'm crazy though. I certainly am. (Acceptable, Mediocre, Acceptable)

Table 1: Some example responses generated from the baseline (**A**) compared to our model (**B**), with human ratings in parentheses. These were selected for quality. See the appendix for an unbiased sample.

practical approach, referred to as the **glimpse model**, which scales well and is easy to implement on top of the standard sequence-to-sequence model.

2. We introduce a **stochastic beam-search procedure** with segment-by-segment reranking which improves the diversity of the generated responses.

3. We present large-scale experiments with human evaluations showing the proposed techniques improve over strong baselines.

4. We release our collection of context-free conversation prompts used in our evaluations as a benchmark for future open-domain conversation response research.

3 Seq2Seq Model with Attention on Target

We discuss conversation response generation in the sequence-to-sequence problem setting. In this setting, there is a source sequence $\mathbf{x} = (x_1, x_2, ..., x_M)$, and a target sequence $\mathbf{y} = (y_0, y_1, y_2, ..., y_N)$. We assume y_0 is always the start-of-sequence token and y_N is the end-of-sequence token. In a typical sequence-to-sequence model, the encoder gets its input from the source sequence $\mathbf{x}$ and the decoder models the conditional language model $P(\mathbf{y}|\mathbf{x})$ of the target sequence $\mathbf{y}$, given $\mathbf{x}$.

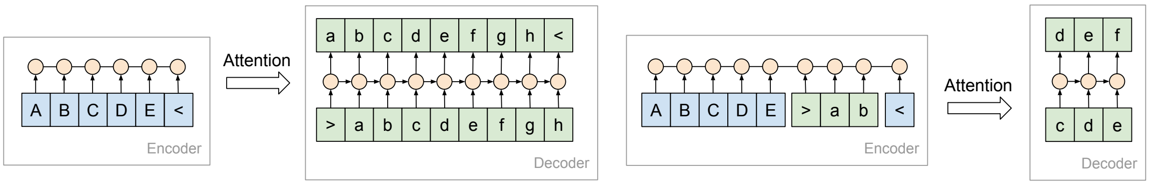
Seq2seq models with attention (Bahdanau et al., 2014) parameterize the per-symbol conditional probability as:

$$P\left(y_i|\mathbf{y}_{[0:i-1]};\mathbf{x}\right) = \mathrm{DecoderRNN}\,(\\ y_{i-1}, h_{i-1}, \mathrm{Attention}\left(h_{i-1}, \mathbf{x}\right)) \quad (1)$$

for $1 \leq i \leq N$, where DecoderRNN() is a recurrent neural network that map the sequence of decoder symbols into fixed-length vectors, and Attention() is a function that yields a fixed-size vector summary of the encoder symbols $\mathbf{x}$ (the 'focus') most relevant to predicting y_i, given the previous recurrent state of the network h_{i-1} (the 'context'). The full conditional probability follows from the product rule, as:

$$P\left(\mathbf{y}|\mathbf{x}\right) = \prod_{i=1}^{N} P\left(y_i|\mathbf{y}_{[0:i-1]};\mathbf{x}\right) \quad (2)$$

We propose to implement **target-side attention** by augmenting the attention mechanism to include the part of the target sequence already generated, *i.e.*, we include $\mathbf{y}_{[0:i-2]}$ in the arguments to the attention function: Attention$(h_{i-1}, \mathbf{y}_{[0:i-2]}, \mathbf{x})$. We implemented this in TensorFlow (Abadi et al., 2015) using 3 LSTM layers on both the encoder and the decoder, with 1024 units per layer. We experimented on the OpenSubtitles 2009 data set, and obtained a small perplexity gain from the target-side attention: 24.6 without versus 24.2 with. However, OpenSubtitles is a small data set,



(a) The vanilla sequence-to-sequence model.

(b) Length-3 Target-glimpse Model

Figure 1: The vanilla seq2seq with attention on the left, and our proposed target-glimpse model on the right. The symbol ">" and "<" are start-of-sequence and end-of-sequence, respectively.

and the majority of its response sequences are shorter than 10 tokens. This may prevent us from seeing bigger gains, since our method is designed to help with longer outputs. In order to train on the much larger Reddit data set, we implemented this method on top of the GNMT model (Wu et al., 2016). Unfortunately, we met with frequent out-of-memory issues, as the 8-layer GNMT model is already very memory-intensive, and adding target-side attention made it even more so. Ideally, we would like to retain the model's capacity in order to train a rich response model, and therefore a more efficient approach is necessary.

To this end, we propose the **target-glimpse model** which has a fixed-length decoder. The target-glimpse model is implemented as a standard sequence-to-sequence model with attention, where the decoder has a fixed length K. During training, we split the target sequence into non-overlapping, contiguous segments (*glimpses*) with fixed length K, starting from the beginning. We then train on each of these glimpses, one at a time on the decoder, while putting all target-side symbols before the glimpse on the encoder. For example, if a sequence $\mathbf{y}$ is split into two glimpses $\mathbf{y}_1$ and $\mathbf{y}_2$, each with length K ($\mathbf{y}_2$ may be shorter than K), then we will train the model with two examples, $(\mathbf{x} \rightarrow \mathbf{y}_1)$, and $(\mathbf{x}, \mathbf{y}_1 \rightarrow \mathbf{y}_2)$. Each time the concatenated sequence on the left of the arrow is put on the encoder and the sequence on the right is put on the decoder. Figure 1(b) illustrates the training of $(\mathbf{x}, \mathbf{y}_1 \rightarrow \mathbf{y}_2)$ when $K = 3$. In our implementation, we always put the source-side end-of-sequence token at the end of the whole encoder sequence, and we split the glimpses according to the decoder time steps. For example, if the sequence $\mathbf{y}$ is $y_0, y_1, y_2, ..., y_{10}$, and $K = 3$, the first example will have y_0, y_1, y_2 on the input layer of the decoder, and y_1, y_2, y_3 on the output layer of the decoder. The second example has y_3, y_4, y_5 as input of the decoder and y_4, y_5, y_6 as the output of the decoder, and so on. In our experiments, we use $K = 10$.

While decoding each glimpse, the decoder therefore attends to both the source sequence and the part of the target sequence that precedes the glimpse, thereby benefiting from the GNMT encoder's bidirectional RNN. Through generalization, the decoder should learn to decode a glimpse of length K in any arbitrary position of the target sequence (which we will exploit in our decoding technique discussed in Section 4). One drawback of this model, however, is that the context inputs to the attention mechanism only include the words that have been generated so far in this glimpse, rather than the words from the full target side. The workaround that we use is to simply connect the last hidden state of the GNMT-encoder to the initial hidden state of the decoder[1], thereby giving the decoder access to all previous symbols regardless of the starting position of the glimpse.

4 Stochastic Decoding with Segment-by-Segment Reranking

We now turn our attention from training to inference (decoding). Our strategy is to perform reranking with a normalized score at the segment level, where we generate the candidate segments using a trained glimpse-model and using a stochastic beam search procedure, which we discuss next. The full decoding algorithm proceeds segment by segment.

The standard beam search algorithm generates symbols step-by-step by keeping a set of the B highest-scoring beams generated so far at each step[2]. The algorithm adds all possible single-token extensions to every existing beam, and then selects

[1] This is the default in standard seq2seq models, but not in the GNMT model.

[2] Beams are also called 'hypotheses', and B is referred to as the 'beam width'.

the top B beams. In our stochastic beam search algorithm, we replace this deterministic top-B selection by a stochastic sampling operation in order to encourage variation. Further, to discourage a single beam from dominating the search and decreasing the final response diversity, we perform a two-step sampling procedure: 1) For each single-token extension of an individual beam we don't enumerate all possibilities, but instead sample a fixed number of D candidate tokens to be added to the beam. This yields a total of $B \times D$ beams, each with one additional symbol. 2) We then compute the accumulated conditional log-probabilities for each beam (normalized across all $B \times D$ beams), and treat these as the logits for sub-sampling B beams for the next step. We repeat this procedure until we reach the desired segment-length H, or until a segment ends with the end-of-sequence token.

For a given source sequence, we can use this stochastic beam search algorithm to generate B candidate H-length segments as the beginning of the target sequence. We then perform a reranking step (described below), and keep one of these. The concatenation of the source and the first target segment is then used as the input for generating the next B candidate segments. The algorithm continues until the segment selected ends with an end-of-sequence token.

This algorithm behaves similarly to standard beam search when the categorical distribution used during the process is sharp ('peaked'), since the samples are likely to be the top categories (words) . However, when the distribution is smooth, many of the choices are likely. In conversation response generation we are dealing with a conditional probability model with high entropy, so this is what often happens in practice.

For the reranking, we normalize the scores using random prompts. In particular, suppose $\mathbf{y}_k = y_1, ..., y_{k-1}$ is a candidate segment, and $(\mathbf{x}, \mathbf{y}_{1:k-1})$ is the input to the stochastic beam search. The normalized score is then computed as follows:

$$S\left(\mathbf{y}_k|\mathbf{x}, \mathbf{y}_{1:k-1}\right) = \frac{P\left(\mathbf{y}_k|\mathbf{x}, \mathbf{y}_{1:k-1}\right)}{\sum_{\mathbf{x}' \in \Phi} P\left(\mathbf{y}_k|\mathbf{x}', \mathbf{y}_{1:k-1}\right)} \tag{3}$$

In this equation, the set Φ is a collection of randomly sampled source sequences (prompts). In our experiments, we randomly select Q prompts from the context-free evaluation set (introduced in the Experiments section).

It is worth noting that when Φ is an unbiased sample from $P(\mathbf{x})$, the summation in the denominator is a Monte-Carlo approximation of $P(\mathbf{y}_k|\mathbf{y}_{1:k-1})$. In the case of reranking whole target sequences $\mathbf{y}$, this becomes the marginal $P(\mathbf{y})$, which corresponds to the same diversity-promoting objective used in (Li et al., 2015). However, we found that our approximation works better in terms of N-choose-1 accuracy (see Section 5.2), which suggests that its value may be closer to the true conditional probability.

In our experiments, we set number of random prompts Q to 15, segment length H to 10, number of beams B to 2, and samples per beam D to 10. We select a small value for B, since we find that larger values makes the algorithm behave more like standard beam search.

5 Experimental Results

In this section we present experimental results for evaluating the target-glimpse model and the stochastic decoding method that we presented. We train the model using the Google neural machine translation model (GNMT, (Wu et al., 2016)), on a data set that combines multiple sources mined from the Web:

1. The full Reddit data[3] that contains 1.7 billion messages (221 million conversations).
2. The 2009 Open Subtitles data (0.5 million conversations, (Tiedemann, 2009)).
3. The Stack Exchange data (0.8 million conversations).
4. Dialogue-like texts that we recognized and extracted from the web (17 million conversations).

For all these data sets, we extract pairs of messages where one can be considered as a response to the other. For example, in the Reddit data set, the messages belonging to the same post are organized as a tree. A child node is a message that replies to its parent. This may not necessarily be true as people may be replying to other messages that are also visually close. However, for our current single-turn experiments, we treat these as a single exchange.

[3] Download links are at https://redd.it/3bxlg7

In this setting, the GNMT model trained on prompt-to-response pairs works surprisingly well without modification when generating short responses with beam search. Similar to previous work on neural conversation models, we find that the generated responses are almost always grammatical, and sometimes even interesting. They are also usually on topic. In addition, we found that even greedy sampling from the 8-layer GNMT model produces grammatical responses most of the time, although these responses are more likely to be semantically-broken than responses generated using standard beam search. We would like to leverage the benefits of greedy sampling, because the induced variation generates more surprises and may potentially help improve user-engagement, and we found that our proposed segment-based beam sampling procedure accomplishes this to some extent.

5.1 Evaluation Metric

It is difficult to come up with an objective evaluation metric for conversation response generation that can be computed automatically. The conditional distribution $P(\mathbf{y}|\mathbf{x})$ is supposed to have high entropy in order to be interesting (many possible valid responses to a given prompt). Therefore BLEU scores used in translation are not a good fit (also see (Liu et al., 2016)). Other than looking at the evaluation set perplexity, we use two metrics, the **N-choose-1 accuracy** and **5-scale side-by-side human evaluation**. In the N-choose-K metric, we use the model as a retriever. Given a prompt, we ask the model to rank N candidate responses, where one is the ground truth and the other $N-1$ are random responses from the same data set. We then calculate the N-choose-K accuracy as the proportion of trials where the true response is in the top K. The prompts used for evaluation are selected randomly from the same data set. This metric isn't necessarily correlated well with the true response quality, but provides a useful first diagnostic for faster experimental iteration. It takes about a day to train a small model on a single GPU that reaches 2-choose-1 accuracies of around 70% or 80%, but it is much harder to make progress on the 50-choose-1 accuracy. As a reference, human performance on the 10-choose-1 task is around 45% accuracy.

In the 5-scale human evaluation, we use a collection of 200 context-free prompts[4]. These prompts are collected from the following sources, and filtered to prompts that are context-free (*i.e.* do not depend on previous turns in the conversation), general enough, and by eliminating near duplicates:

1. The questions and statements that users asked an internal testing bot.
2. The Fisher corpus (David et al., 2004).
3. User inputs to the Jabberwacky chatbot[5].

These can be either generic or specific. Some example prompts from this collection are shown in Table 1. These prompts are open-domain (not about any specific topic), and include a wide range of topics. Many require some creativity for answering, such as *"Tell me a story about a bear."* Our evaluation set is therefore not from the same distribution as our training set. However, since our goal is to produce good general conversation responses, we found it to be a good general purpose evaluation set.

The evaluation itself is done by human raters. They are well-trained for the purpose of ensuring rating quality, and they are native English speakers. The A 5-scale rating is produced for each prompt-response pair: *Excellent*, *Good*, *Acceptable*, *Mediocre*, and *Bad*. For example, the instructions for rating *Excellent* is "On topic, interesting, shows understanding, moves the conversation forward. It answers the question." The instruction for *Acceptable* is "On topic but with flaws that make it seem like it didnt come from a human. It implies an answer." The instruction for *Bad* is "A completely off-topic statement or question, nonsensical, or grammatically broken. It does not provide an answer."

In our experiments, we perform the evaluations side-by-side, each time using responses generated from two methods. Every prompt-response pair is rated by three raters. We rate 200 pairs in total for every method, garnering 600 ratings overall. After the evaluation, we report aggregated results from each method individually.

5.2 Motivating Experiments

To see whether generating long responses is indeed a challenging problem, we trained the plain

[4] This list will be released to the community.

[5] http://www.jabberwacky.com/

seq2seq with the GNMT model where the encoder holds the source sequence and the decoder holds the target sequence. We experimented with the standard beam search and the beam search with length normalization $\alpha = 0.8$ similar to (Wu et al., 2016). With this length normalization the generated responses are indeed longer. However, they are more often semantically incoherent. It produces *"I have no idea what you are talking about."* more often, similarly observed in (Li et al., 2016). The human evaluation results are summarized in Figure 2(b). Methods that generate longer responses have more *Bad* and less *Excellent* / *Good* ratings.

We also performed the N-choose-1 evaluation on the baseline model using different normalization schemes. The results are shown in Table 2(a). *No Normalization* means that we use $P(\mathbf{y}|\mathbf{x})$ for scoring, *Normalize by Marginal* uses $P(\mathbf{y}|\mathbf{x})/P(\mathbf{y})$, as suggested in (Li et al., 2015), and *Normalize by Random Prompts* is our scoring objective described in Section 4. The significant boost when using both normalization schemes indicates that the conditional log probability predicted by the model may be biased towards the language model probability of $P(\mathbf{y})$. After adding the normalization, the score may be closer to the true conditional log probability.

Overall, this *reranking* evaluation indicates that our heuristic is preferred to scoring using the marginal. However, it is unfortunately hard to directly make use of this score during beam search decoding (*i.e., generation*), since the resulting sequences are usually ungrammatical, as also observed by (Li et al., 2015). This is the motivation for using a segment-by-segment reranking procedure, as described in Section 4.

5.3 Large-Scale Experiments

For our large-scale experiments, we train our target-glimpse model on the full combined data set. Figure 2(d) shows the training progress curve. In this figure, we also include the curve for $K = 1$, that is, the glimpse model with decoder-length 1. It is clear enough that this model progresses much slower, so we terminated it early. However, it is surprising that the glimpse model with $K = 10$ progresses faster than the baseline model with only source-side attention, because the model is trained on examples with decoder-length fixed at 10, while the average response length is 38 in our data set. This means it takes on average 3.8x training steps for the glimpse model to train on the same number of raw training-pairs as the baseline model. Despite this, the faster progress indicates that target-side attention indeed helps the model generalize better.

The human evaluation results shown in Figure 2 compare our proposed method with the baseline seq2seq model. For this, we trained a length-10 target-glimpse model and decoded with stochastic beam-search using segment-by-segment reranking. In our experiments, we were unable to generate better long, coherent responses using the whole-sequence level reranking method from (Li et al., 2015) compared to using standard beam search with length-normalization[6]. We therefore choose the latter as our baseline, because it is the only method which generates responses that are long enough that we can compare to.

Figure 2 shows that our proposed method generates more long responses overall. One third of all responses are longer than 100 characters, while the baseline model produces only a negligible fraction. Although we do not employ any length-promoting objectives in our method, length-normalization is used for the baseline. For responses generated by our method, the proportion of *Acceptable* and *Excellent* responses remains constant or even increases as the responses grow longer. Conversely, human ratings decline sharply with length for the baseline model.

The percentage of test cases with major agreement is high for both methods. We consider a test to have major agreement if two ratings out of the three are the same. For the baseline method, 80% of the responses have major agreements, and for our method it is 70%.

However, shorter responses have a much smaller search space, and we find that standard beam search tends to generate better ("safer") short responses. To maximize cumulative response quality, we therefore implemented a back-off strategy that combines the strengths of the two methods. We choose to fallback to the baseline model without length normalization when the latter produces a response shorter than 40 characters, otherwise we use the response from our method. This corresponds to the white histogram in Figure 2(b). Compared to the other methods in the fig-

[6] This is because the method reranks the responses in the N-best list resulting from the beam search, which tend to be short with not much variation to begin with.

ure, the combined strategy results in more ratings of *Excellent*, *Good*, *Acceptable*, and *Mediocre*, and fewer *Bad* ratings. With this strategy, among the responses generated for the same 200 prompts, 133 were from the standard beam search and 67 were from our model. Out of the 67 long responses, two thirds were longer than 60 characters and half were longer than 75 characters. To compare the combined model's performance with the baseline, we generated responses from both models using the same 200 prompts. For 20 of the response pairs, human raters had no preference, but for the remaining 180, human raters preferred the combined model's response in 103 cases and the baseline's in only 77, indicating a significant win.

6 Conclusion

The research of building end-to-end systems that can engage in general-purpose conversation is still in its infancy. More significant progress is expected to be made with more advanced neural architectures. However, our results reported in this paper show that minimal modeling change and a slightly more advanced decoding technique, combined with training over very large data sets, can still lead to noticeable improvements in the quality of responses generated using neural conversation models. Overall, we found using fixed-lengths in the decoder to make it easier to train on large data sets, as well as to allow us to improve the diversity and coherence of the generated responses earlier during generation, when it has most impact. While the focus of this work has been on conversation modeling, we expect some of these results to carry over to other sequence-to-sequence settings, such as machine translation or image-captioning.

Acknowledgments

We would like to thank Quoc Le, Oriol Vinyals and Jakob Uszkoreit for many helpful discussions, and Scott Benson, Fuchun Peng for collecting the context-free prompt set, and Amin Ahmad for setting up the human evaluation, and Rami Eid, Daniel Cer for collecting training data sets, and Yonghui Wu, Zhifeng Chen, Mike Schuster for help on training the GNMT model.

Abstract

We investigate an end-to-end method for automatically inducing task-based dialogue systems from small amounts of unannotated dialogue data. It combines an incremental semantic grammar - Dynamic Syntax and Type Theory with Records (DS-TTR) - with Reinforcement Learning (RL), where language generation and dialogue management are a joint decision problem. The systems thus produced are *incremental*: dialogues are processed word-by-word, shown previously to be essential in supporting natural, spontaneous dialogue. We hypothesised that the rich linguistic knowledge within the grammar should enable a combinatorially large number of dialogue variations to be processed, even when trained on very few dialogues. Our experiments show that our model can process 74% of the Facebook AI bAbI dataset even when trained on only 0.13% of the data (5 dialogues). It can *in addition* process 65% of bAbI+, a corpus[1] we created by systematically adding incremental dialogue phenomena such as restarts and self-corrections to bAbI. We compare our model with a state-of-the-art retrieval model, MEMN2N (Bordes et al., 2017). We find that, in terms of semantic accuracy, MEMN2N shows very poor robustness to the bAbI+ transformations even when trained on the full bAbI dataset.

1 Introduction

There are currently several key problems for the practical data-driven (rather than hand-crafted) development of task-oriented dialogue systems, among them: (1) large amounts of dialogue data are needed, i.e. thousands of examples in a domain; (2) this data is usually required to be annotated with task-specific semantic/pragmatic information for the domain (e.g. various dialogue act schemes); and (3) the resulting systems are generally turn-based, and so do not support natural spontaneous dialogue which is processed *incrementally*, word-by-word, with many characteristic phenomena that arise from this incrementality.

In overcoming issue (2), a recent advance made in research on (non-task) chat dialogues has been the development of so-called "end-to-end" systems, in which all components are trained from textual dialogue examples, e.g. (Sordoni et al., 2015; Vinyals and Le, 2015). However, as Bordes and Weston (2017) argued, these end-to-end methods may not transfer well to task-based settings (where the user is trying to achieve a domain goal, such as booking a flight or finding a restaurant, resulting in an API call). Bordes and Weston (2017) then presented an end-to-end method using Memory Networks (MEMN2NS), which achieves 100% performance on a test-set of 1000 dialogues, after being trained on 1000 dialogues. This method processes dialogues turn-by-turn, and so does not have the advantages of more natural incremental systems (Aist et al., 2007; Skantze and Hjalmarsson, 2010); nor does it really perform language generation, rather it's based on a retrieval model that selects from a set of candidate system responses seen in the data.

This paper investigates an approach to these challenges - dubbed BABBLE - using an incremental, semantic parser and generator for dialogue (Eshghi et al., 2011; Eshghi, 2015), based around the Dynamic Syntax grammar formalism (DS, Kempson et al. (2001); Cann et al. (2005)).

Our advance in this paper, for end-to-end systems, is therefore twofold: (a) the BABBLE method

[1] Dataset available at https://bit.ly/babi_plus

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2220–2230
Copenhagen, Denmark, September 7–11, 2017.

overcomes the requirement for large amounts of dialogue data (i.e. 1000s of dialogues in a domain); (b) resulting systems are word-by-word incremental, in both parsing, generation and dialogue management. We show that using only 5 example dialogues from the bAbI, Task 1 dataset (i.e. 0.13% of the training data used by (Bordes et al., 2017)) BABBLE can automatically induce dialogue systems which process 74% of the bAbI testset in an incremental manner. We then introduce an extended incremental version of the bAbI dataset, which we call bAbI+ (see section 4.1), which adds some characteristic incremental phenomena - such as mid-utterance self-corrections - to the bAbI dialogues (this new dataset is freely available). Using this, we demonstrate that the BABBLE system can in addition generalise to, and process 65% of the bAbI+ dataset, still when trained *only on 5 dialogues from bAbI*. We compare this method to (Bordes et al., 2017)'s MEMN2N, which, in terms of semantic accuracy (reflected in how well `api-calls` are predicted at the end of bAbI Task 1), shows very poor robustness to the bAbI+ transformations, even when it is trained on *the full bAbI dataset*.

This overall method is portable to other task-based domains. Furthermore, as we use a semantic parser, the semantic/contextual representations of the dialogue can be used directly for large-scale inference, required in more complex tasks (e.g. interactive QA and search).

1.1 Dimensions of Pragmatic Synonymy

There are two important dimensions along which dialogues can vary, but nevertheless, lead to identical contexts: interactional, and lexical. Interactional synonymy is analogous to syntactic synonymy - when two distinct sentences are parsed to identical logical forms - except that it occurs not only at the level of a single sentence, but at the dialogue or discourse level. Fig. 1 shows examples of interactional variants that lead to very similar final contexts, in this case, that the user wants to buy an LG phone. These dialogues can be said to be *pragmatically synonymous* for this domain. Arguably, a good computational model of dialogue processing, and interactional dynamics should be able to capture this synonymy.

Lexical synonymy relations, on the other hand, hold among utterances, or dialogues, when different words (or sequences of words) express meanings that are sufficiently similar in a particular domain. What is striking about lexical synonymy relations is that unlike syntactic/interactional ones, they can often break down when one moves to another domain: lexical synonymy relations are domain specific.

Eshghi & Lemon (2014) developed a method similar in spirit to Kwiatkowski et al. (2013) for capturing lexical synonymy relations by creating clusters of semantic representations based on observations that they give rise to similar or identical extra-linguistic actions observed within a domain (e.g. a data-base query, a flight booking, or any API call). Distributional methods could also be used for this purpose (see e.g. Lewis & Steedman (2013)). In general, this kind of clustering is achieved when the domain-general semantics resulting from semantic parsing is grounded in a particular domain.

We note that while interactional synonymy relations in dialogue should be accounted for by semantic grammars or formal models of dialogue structure (such as DS-TTR (Eshghi et al., 2012), or KoS (Ginzburg, 2012)), lexical synonymy relations have to be learned from data.

2 Why a grammar-based approach?

Recent end-to-end data-driven machine learning approaches treat dialogue as a sequence-to-sequence generation problem, and train their models from large datasets e.g. (Sordoni et al., 2015; Wen et al., 2016b,a; Vinyals and Le, 2015). The systems resulting from these types of approach are in principle able to handle variations/patterns that they have encountered (sufficiently often) in the training data, but not beyond.

This large-data constraint is problematic for developers but is also strange when we consider the structural knowledge that we have about language and dialogue that can be encoded in grammars and computational models of interaction. Indeed, it is often stated that for humans to learn how to perform adequately in a domain, one example is enough from which to learn (e.g. Li et. al (2006)).

Furthermore, as these systems do not parse to logical forms, they do not allow for explicit inference, which further limits their application.

We therefore develop a method combining learning from data with an incremental semantic grammar of dialogue that is able to generalise from small number of observations in a domain –

Interactional Variation	USR: I would like an LG laptop sorry uhm phone SYS: okay.	USR: I would like a phone by LG. SYS: sorry a what? USR: a phone by LG. SYS: okay.	SYS: what would you like? USR: an LG phone SYS: okay.
	SYS: what would you like? USR: a phone SYS: by which brand? USR: LG SYS: okay	SYS: you'd like a ...? USR: a phone SYS: by what brand? USR: LG. SYS: okay	SYS: so would you like a computer? USR: no, a phone. SYS: okay. by which brand? USR: LG. SYS: okay.

Figure 1: Some Interactional Variations in a Shopping Domain

in fact even from just a few examples of successful dialogues – to a large range of interactional and syntactic variations, including everyday natural incremental phenomena.

3 Inducing Dialogue Systems

Our overall method involves incrementally parsing dialogues, and encoding the resulting semantics as state vectors in a Markov Decision Process (MDP), which is then used for Reinforcement Learning (RL) of word-level actions for system output (i.e. a combined incremental DM and NLG module for the resulting dialogue system).

3.1 Dynamic Syntax and Type Theory with Records (DS-TTR)

Dynamic Syntax (DS) is an action-based, word-by-word incremental and semantic grammar formalism (Kempson et al., 2001; Cann et al., 2005), especially suited to the highly fragmentary and context-dependent nature of dialogue. In DS, words are conditional actions - semantic updates; and dialogue is modelled as the interactive and incremental construction of contextual and semantic representations (Eshghi et al., 2015) - see Fig. 2. The contextual representations afforded by DS are of the fine-grained semantic content that is jointly negotiated/agreed upon by the interlocutors, as a result of processing questions and answers, clarification interaction, acceptances, self-/other-corrections, restarts, and other characteristic incremental phenomena in dialogue - see 3 for a sketch of how self-corrections and restarts are processed via a backtrack and search mechanism over the parse search graph (see Hough (2011); Hough and Purver (2014); Eshghi et al. (2015) for details of the model, and how this parse search graph is effectively the context of the conversation). Generation/linearisation in DS is defined using trial-and-error parsing (see Section 3.2, with the provision of *a generation goal*, viz. the semantics of the utterance to be generated. Generation thus proceeds, just as with parsing, on a word-by-word basis (see Purver et al. (2014); Hough (2015) for details). The upshot of this is that using DS, we can not only track the semantic content of some current turn as it is being constructed (parsed or generated) word-by-word, but also the context of the conversation as whole, with the latter also encoding the grounded/agreed content of the conversation (see e.g. Fig. 4, and see Eshghi et al. (2015); Purver et al. (2010) for details). Crucially for our model below, the inherent incrementality of DS-TTR together with the word-level, as well as cross-turn, parsing constraints it provides, enables the word-by-word exploration of the space of grammatical dialogues, and the semantic and contextual representations that result from them.

Type Theory with Records (TTR) is an extension of standard type theory shown to be useful in semantics and dialogue modelling (Cooper, 2005; Ginzburg, 2012). To accommodate dialogue processing, and allow for richer representations of the dialogue context recent work has integrated DS and the TTR framework to replace the logical formalism in which meanings are expressed (Purver et al., 2010, 2011; Eshghi et al., 2012). In TTR, logical forms are specified as *record types* (RTs), sequences of *fields* of the form $[\, l : T \,]$ containing a label l and a type T. RTs can be witnessed (i.e. judged as true) by *records* of that type, where a record is a sequence of label-value pairs $[\, l = v \,]$, and $[\, l = v \,]$ is of type $[\, l : T \,]$ just in case v is of type T (see Fig. 2 for example record types).

Importantly for us here, the standard *subtype* relation $\sqsubseteq$ can be defined for record types: $R_1 \sqsubseteq R_2$ if for all fields $[\, l : T_2 \,]$ in R_2, R_1 contains $[\, l : T_1 \,]$ where $T_1 \sqsubseteq T_2$. A record type can thus be indefinitely extended, and is therefore always underspecified by definition. This allows for incrementally growing meanings to be expressed in a natural way as more words are parsed or generated in

$$\begin{bmatrix} event & : & e_s \\ p1_{=today(event)} & : & t \end{bmatrix} \mapsto \begin{bmatrix} event_{=arrive} & : & e_s \\ p1_{=today(event)} & : & t \\ p2_{=pres(event)} & : & t \\ x_{=robin} & : & e \\ p3_{=subj(event,x)} & : & t \end{bmatrix} \mapsto \begin{bmatrix} event_{=arrive} & : & e_s \\ p1_{=today(event)} & : & t \\ p2_{=pres(event)} & : & t \\ x_{=robin} & : & e \\ p3_{=subj(event,x)} & : & t \\ x1 & : & e \\ p3_{=from(event,x1)} & : & t \end{bmatrix} \mapsto \begin{bmatrix} event_{=arrive} & : & e_s \\ p1_{=today(event)} & : & t \\ p2_{=pres(event)} & : & t \\ x_{=robin} & : & e \\ p_{=subj(event,x)} & : & t \\ x1_{=Sweden} & : & e \\ p3_{=from(event,x1)} & : & t \end{bmatrix}$$

"A: Today" ↦ *"..Robin arrives"* ↦ *"B: from?"* ↦ *"A: Sweden"*

Figure 2: Incremental parsing using DS-TTR

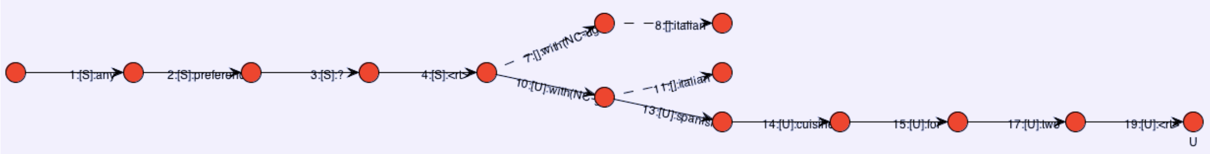

Figure 3: DS-TTR: Incremental Parsing of self-corrections and restarts

turn. In addition, as will become clear below, this subtype checking operation is the key mechanism used in our system below for feature checking.

3.2 Overall Method: BABBLE

In this section we describe our method for combining incremental dialogue parsing with Reinforcement Learning for Dialogue Management (DM) and Natural Language Generation (NLG) where these are treated as a joint decision/optimisation problem.

We start with two resources: a) a DS-TTR parser *DS* (either learned from data (Eshghi et al., 2013a), or constructed by hand), for incremental language processing, but also, more generally, for tracking the context of the dialogue using Eshghi et al.'s model of feedback (Eshghi et al., 2015; Eshghi, 2015; Eshghi et al., 2011); b) a set D of transcribed successful dialogues in the target domain.

We perform the following steps overall to induce a fully incremental dialogue system from D:

1. Automatically induce the MDP state space, S, and the dialogue goal, G_D, from D;
2. Automatically define the state encoding function $F : C \rightarrow S$; where $s \in S$ is a (binary) state vector, designed to extract from the current context of the dialogue, the semantic features observed in the example dialogues D; and $c \in C$ is a DS context, viz. a pair of TTR Record Types: $\langle c_p, c_g \rangle$, where c_p is the content of the current, *PENDING* clause as it is being constructed, but not necessarily fully grounded yet; and c_g is the content already jointly built and *GROUNDED* by the interlocutors (loosely following the DGB model of (Ginzburg, 2012)).
3. Define the MDP action set as the *DS* lexicon L (i.e. actions are words);
4. Define the reward function R as reaching G_D, while minimising dialogue length.

We then solve the generated MDP using Reinforcement Learning, with a standard Q-learning method, implemented using BURLAP (McGlashan, 2016): train a policy $\pi : S \rightarrow L$, where L is the DS Lexicon, and S the state space induced using F. The system is trained in interaction with a (semantic) simulated user, also automatically built from the dialogue data and described in the next section.

The state encoding function, F As shown in figure 4 the MDP state is a binary vector of size $2 \times |\Phi|$, i.e. twice the number of the RT features. The first half of the state vector contains the grounded features (i.e. agreed by the participants) ϕ_i, while the second half contains the current semantics being incrementally built in the current dialogue utterance. Formally: $s = \langle F_1(c_p), \ldots, F_m(c_p), F_1(c_g), \ldots, F_m(c_g) \rangle$; where $F_i(c) = 1$ if $c \sqsubseteq \phi_i$, and 0 otherwise. (Recall that $\sqsubseteq$ is the RT subtype relation).

3.2.1 Semantic User Simulation

The simulator is in charge of two key tasks during training: (1) generating user turns in the right dialogue contexts; and (2) word-by-word monitoring of the utterance so far generated by the sys-

Grounded Semantics

$$\left[\begin{array}{lcl} x2 & : & e \\ e2_{=like} & : & es \\ x1_{=USR} & : & e \\ p2_{=pres(e2)} & : & t \\ p5_{=subj(e2,x1)} & : & t \\ p4_{=obj(e2,x2)} & : & t \\ p11_{=phone(x2)} & : & t \end{array}\right]$$

Current Turn Semantics

$$\left[\begin{array}{lcl} x2 & : & e \\ e2_{=like} & : & es \\ x1_{=USR} & : & e \\ p2_{=pres(e2)} & : & t \\ p5_{=subj(e2,x1)} & : & t \\ p4_{=obj(e2,x2)} & : & t \\ p11_{=phone(x2)} & : & t \\ x3 & : & e \\ p10_{=by(x2,x3)} & : & t \\ p9_{=brand(x3)} & : & t \\ p10_{=question(x3)} & : & t \end{array}\right]$$

Dialogue so far

SYS: What would you like?
USR: a phone
SYS: by which brand?

RT Feature:

$$\left[\begin{array}{lcl} x10 & : & e \\ p15_{=brand(x10)} & : & t \end{array}\right]\left[\begin{array}{lcl} e3_{=like} & : & es \\ p2_{=pres(e3)} & : & t \end{array}\right]\left[\begin{array}{lcl} x10 & : & e \\ x8 & : & e \\ p14_{=by(x8,x10)} & : & t \end{array}\right]\left[\begin{array}{lcl} e3_{=like} & : & es \\ x5_{=usr} & : & e \\ p7_{=subj(e3,x5)} & : & t \end{array}\right]\left[\begin{array}{lcl} x8 & : & e \\ e3_{=like} & : & es \\ p6_{=obj(e3,x8)} & : & t \end{array}\right]$$

$$\text{State: } \left\langle \begin{array}{lccccc} & F_1\downarrow & F_2\downarrow & F_3\downarrow & F_4\downarrow & F_5\downarrow \\ \text{Current Turn:} & 1, & 1, & 1, & 1, & 1, \\ \text{Grounded:} & 0, & 1, & 0, & 1, & 1 \end{array} \right\rangle$$

Figure 4: Semantics to MDP state encoding with RT features

tem during exploration (i.e. babbling grammatical word sequences) by the system. To exploit (and evaluate) the full generalisation properties of the *DS* dialogue model, both (1) and (2) use the full machinery of the *DS* parser, as well the state encoding function F, described above. They are thus performed based on the *semantic context* of the dialogue so far, as tracked by *DS* (rather than, e.g. being based on string or template matching). Since this includes not just the semantic features of the current turn, but also of *the history of the conversation*, our simulator respects the turn orderings encountered in the data, i.e. it is sensitive to the order in which information is gathered from the user.

The rules required for (1) & (2) are extracted *automatically* from the raw dialogue data, D, using *DS* and F. The dialogues in D are parsed and encoded using F incrementally. For (1), all the states that trigger the user into action, $s_i = F(c)$ – where c is a DS context – immediately prior to any user turn are recorded, and mapped to what the user ends up saying in those contexts - for more than one training dialogue there may be more than one candidate (in the same context/state). The rules thus extracted will be of the form:
$s_{trig} \rightarrow \{u_1, \ldots, u_n\}$, where u_i are user turns.

Now note that the s_i's prior to the user turns also immediately follow system turns. And thus to perform (2), i.e. to monitor the system's behaviour during training, we only need to check further that the current state resulting from processing a word generated by the system, subsumes - is extendible to - one of the s_i. We perform this through a simple bitmask operation (recall that the states are binary). The simulation can thus semantically identify erroneous/out-of-domain actions (words) by the system. It would then terminate the learning episode and penalise the system immediately, aiding speed of training significantly.

4 Evaluation

We have so far induced two prototype dialogue systems, one in an 'electronics shopping' domain (see Kalatzis et al. (2016) and Fig. 1) and another in a 'restaurant-search' domain, showing that fully incremental dialogue systems can be automatically induced from small amounts of unannotated dialogue transcripts (Kalatzis et al., 2016; Eshghi et al., 2017) - in this case both systems were bootstrapped from a *single* successful example dialogue. We are in the process of evaluating these systems with real users.

In this paper, however, our focus is not on building dialogue systems *per se*, but on: **(1)** studying and quantifying the interactional and structural generalisation power of the DS-TTR grammar formalism (see Section 2), and that of symbolic, grammar-based approaches to language processing more generally. We focus here on specific dialogue phenomena, such as mid-sentence self-corrections, hesitations, and restarts (see below); **(2)** doing the same for Bordes and Weston's (2017) state-of-the-art, bottom up response retrieval model, without use of linguistic knowledge of any form; and **(3)** comparing (1) and (2).

In order to test and quantify the interactional and structural generalisation power/robustness of the two models, BABBLE and MEMN2N, we need contrasting dialogue data-sets that control for interactional vs. lexical variations in the input dialogues. Furthermore, to make our results comparable to the existing approach of Bordes and Weston (2017), we need to use the same dataset that they have used. We therefore use Facebook AI Research's bAbI dialogue tasks dataset (Bordes et al., 2017). These are goal-oriented dialogues in the domain of restaurant search. Here we tackle Task 1, where in each dialogue the system asks the user about their preferences for the properties of a restaurant, and each dialogue results in an API call which contains values of each slot obtained. Other than the explicit API call notation, there are no annotations in the data whatsoever.

4.1 The bAbI+ dataset

While containing some lexical variation, the original bAbI dialogues significantly lack interactional variation vital for natural real-life dialogue. In order to obtain such variation while holding lexical variation constant, we created the bAbI+ dataset by systematically transforming the bAbI dialogues.

bAbI+ is an extension of the original bAbI Task 1 dialogues with everyday incremental dialogue phenomena (hesitations, restarts, and corrections – see below). While the original bAbI tasks 2—7 increase the user's goal complexity, modifications introduced in bAbI+ can be thought of as orthogonal to this: we instead increase the complexity of surface forms of dialogue utterances, while keeping every other aspect of the task fixed.

The variations introduced in bAbI+ are: **1. Hesitations**, e.g. as in "we will be `uhm` eight"; **2. Restarts**, e.g. "can you make a restaurant `uhm yeah can you make a restaurant` reservation for four people with french cuisine in a moderate price range"; and **3. Corrections** affecting task-specific information - both short-distance ones correcting one token, e.g. "with french `oh no spanish` food", and long-distance NP/PP-level corrections, e.g. "with french food `uhm sorry with spanish food`".

The phenomena above are mixed in probabilistically from the fixed sets of templates to the original data[2]. The modifications affect a total of **11336** utterances in the **3998** dialogues. Around **21%** of user turns contain corrections, **40%** hesitations, and **5%** restarts (they are not mutually exclusive, so that an utterance can contain up to 3 modifications). Our modifications, with respect to corrections in particular, are more conservative than those observed in real-world data: Hough (2015) reports that self-corrections appear in **20%** of all turns of natural conversations from the British National Corpus, and in **40%** of turns in the Map Task, a corpus of human-human goal-oriented dialogues. Here's part of an example dialogue in the bAbI+ corpus:

sys:	hello what can I help you with today?
usr:	I'd like to book a uhm yeah I'd like to book a table in a expensive price range
sys:	I'm on it. Any preference on a type of cuisine?
usr:	with indian food no sorry with spanish food please

4.2 Memory Network setup

In all the experiments we describe below, we follow Bordes and Weston's setup by using a MEMN2N (we took an open source Tensorflow implementation for bAbI QA tasks and modified it[3] according to their setup – see details below). In order to adapt the data for the MEMN2N, we transform the dialogues into <*story, question, answer*> triplets. The number of triplets for a single dialogue is equal to the number of the system's turns, and in each triplet, the answer is the current system's turn, the question is the user's turn preceding it, and the story is a list of all the previous turns among both sides.

The MEMN2N hyperparameters are set as follows: **1** hop, and **128** as the size of embeddings; we train it for **100** epochs with a learning rate of **0.01** and a batch size of **8** – in this we follow the best bAbI Task 1 setup reported by (Bordes et al., 2017).

4.3 Testing the DS-TTR parser

Dynamic Syntax (DS) lexicons are learnable from data (Eshghi et al., 2013a,b). But since the lexicon was induced from a corpus of child-directed utterances in this prior work, there were some constructions as well as individual words that it did not include[4]. One of the authors therefore extended this induced grammar manually to cover the bAbI dataset, which, despite not being very diverse,

[2] See `https://github.com/ishalyminov/babi_tools`

[3] See `https://github.com/ishalyminov/memn2n`

[4] We are currently looking into applying Eshghi et al.'s (2013a) model to induce DS grammars from larger semantic corpora such as the Groningen Meaning Bank, leading to much more wide-coverage lexicons

contains a wide range of complex grammatical constructions, such as long sequences of prepositional phrases, adjuncts, short answers to yes/no and wh-questions, appositions of NPs, causative verbs etc.

We parsed all dialogues in the bAbI train and test sets, as well as on the bAbI+ corpus word-by-word, including both user and system utterances, in context. The grammar parses 100% of the dialogues, i.e. it does not fail on any word in any of the dialogues. We assess the semantic accuracy of the parser on bAbI & bAbI+ using the dialogue-final `api-calls` in section 4.5 below.

4.4 Experiment 1: Generalisation from small data

We have now set out all we need to perform the first experiment. Our aim here is to assess the generalisation power that results from the grammar and our state encoding method (section 3.1) - we dub our overall model BABBLE - and compare this to the state of the art results of Bordes et al. (2017). The method in Bordes et al. (2017) is not generative, rather it is based on retrieval of system responses, based on the history of the dialogue up to that point. Therefore, for direct comparison, and for simplicity of exposition, we do the same here: we apply the method described for creating a user simulation (section 3.2.1), this time *for the system side*, resulting in a 'system simulation'. We then use this to predict a system response, by parsing and encoding the containing test dialogue up to the point immediately prior to the system turn. This results in a triggering state, s_{trig}, which is then used as the key to look up the system's response from the rules constructed as per section 3.2.1. The returned response is then parsed word-by-word as normal, and this same process continues for the rest of the dialogue. This method uses the full machinery of DS-TTR & our state-encoding method - the BABBLE model - and will thus reflect the generalisation properties that we are interested in.

Cross-Validation Since we are here interested in data efficiency and generalisation we use all the bAbI and bAbI+ data - the train, dev, and test sets - as follows: we train Bordes & Weston's MEMN2N and BABBLE from 1-5 examples selected at random from *the longest dialogues* in bAbI – note **bAbI+ data is never used for training in these experiments**. This process is repeated across 10 folds. The models are then tested on sets of 1000 examples selected at random, in each fold. Both the training and test sets constructed in this way are kept constant in each fold across the BABBLE & MEMN2N models. The test sets are selected either exclusively from bAbI or exclusively from bAbI+.

4.4.1 Results: Predicting system turns

Table 1 shows per utterance accuracies for the BABBLE & MEMN2N models. Per utterance accuracy is the percentage of all system turns in the test dialogues that were correctly predicted. The table shows that BABBLE can generalise to a remarkable 74% of bAbI and 65% of bAbI+ with only 5 input dialogues from bAbI. It also shows that MEMN2NS can also generalise remarkably well. Although as discussed below, this result is misleading on its own as the MEMN2NS are very poor at generating the final `api-calls` correctly on both the bAbI & bAbI+ data, and are thus making too many semantic mistakes.

4.5 Experiment 2: Semantic Accuracy

The results from Experiment 1 on their own can be misleading, as correct prediction of system responses does not in general tell us enough about how well the models are interpreting the dialogues, or whether they are doing this with a sufficient level of granularity. To assess this, in this second experiment, we measure the semantic accuracy of each model by *looking exclusively* at how accurately they predict the final `api-calls` in the bAbI & bAbI+ datasets. For the MEMN2N model, we follow the same overall procedure as in the previous experiment: train on bAbI data, and test on bAbI+.

4.5.1 Results: Prediction of `api-calls`

BABBLE Mere successful parsing of all the dialogues in the bAbI and bAbI+ datasets as shown above doesn't mean that the semantic representations compiled for the dialogues were in fact correct. To measure the semantic accuracy of the DS-TTR parser we programmatically checked that the correct slot values – those in the `api-call` annotations – were in fact present in the semantic representations produced by the parser for each dialogue (see Fig. 2 for example semantic representations). We further checked that there is no other incorrect slot value present in these representations. The results showed that the parser has 100% se-

# of training dialogues:	1	2	3	4	5
BABBLE on bAbI	67.12	73.36	72.63	73.32	74.08
MEMN2N on bAbI	2.77	59.15	70.94	71.68	72.6
BABBLE on bAbI+	59.42	65.27	63.45	64.34	65.2
MEMN2N on bAbI+	0.22	56.75	68.65	71.84	73.2

Table 1: Mean per utterance accuracies (%) for MEMN2N & BABBLE models across the bAbI & bAbI+ datasets (10 folds)

mantic accuracy on both bAbI and bAbI+[5]. This result is not surprising, given that DS-TTR is a general model of incremental language processing, including phenomena such as self-corrections and restarts (see Hough (2015) for details of the model).

MEMN2N Given just 1 to 5 training instances from bAbI as in the previous experiment, the mean `api-call` prediction accuracy of the MEMN2N model is **nearly 0 on both bAbI and bAbI+**. This is not at all unexpected, since prediction of the `api-calls` is a *generative* process, unlike the prediction of system turns which can be done on a retrieval/look-up basis alone. For this, the model needs to observe the different word sequences that might determine each parameter (slot) value, and observe them with sufficient frequency and variation. This is unlike a semantic parser like DS-TTR, that produces semantic representations for the dialogues as a result of the structural, linguistic knowledge that it embodies.

Nevertheless, we were also interested in the general semantic robustness of the MEMN2N model, to the transformations in bAbI+, i.e. how well does the MEMN2N model interpret bAbI+ dialogues, when trained *on the full bAbI dataset*? Does it then learn to generalise to (process) the bAbI+ dialogues with sufficient semantic accuracy?

Table 2 shows that we can fully replicate the results reported in Bordes et al. (2017): the MEMN2N model can predict the `api-calls` with 100% accuracy, when trained on the bAbI train-set and tested on the bAbI test-set. But when this same model is tested on bAbI+, the accuracy drops to a very poor 28%, making any dialogue system built using this model unusable in the face of natural, spontaneous dialogue data. This is further discussed below.

testing configuration	accuracy
MEMN2N on bAbI	100
MEMN2N on bAbI+	28

Table 2: `api-call` prediction accuracies (%) for the MEMN2N model trained on the bAbI trainset

5 Discussion

5.1 BABBLE

The method described above has the following advantages over previous approaches to dialogue system development:

– incremental (and thus more natural) language understanding, dialogue management, and generation;

– “end-to-end" method for task-based systems: no Dialogue Act annotations are required (i.e. reduced development time and effort);

– a complete dialogue system for a new task can be automatically induced, using only ‘raw’ data – i.e. successful dialogue transcripts;

– the MDP state and action spaces are automatically induced, rather than having to be designed by hand (as in prior work);

– wide-coverage, task-based dialogue systems can be built from much smaller amounts of data as shown in section 4 .

This final point bears further examination. As an empirically adequate model of incremental language processing in dialogue, the DS-TTR grammar is required to capture interactional variants such as question-answer pairs, over- and under-answering, self- and other-corrections, clarification, split-utterances, and ellipsis more generally. As we showed in section 4, even if most of these structures are not present in the training exam-

[5] A helpful reviewer points out that the DS-TTR setup is a carefully tuned rule-based system, thus perhaps rendering these results trivial. But we note that the results here are not due to ad-hoc constructions of rules/lexicons, but due to the generality of the grammar model, and its attendant incremental, left-to-right properties; and that the same parser can be used in other domains. Furthermore, the ability to process self-corrections, restarts, etc. “comes for free”, without the need to add or posit new machinery

ple(s), the resulting trained system is able to handle them, thus resulting in a very significant generalisation around the original data.

We also note that since we were in this instance interested in a direct comparison with MEMN2NS over the bAbI & bAbI+ datasets, we didn't exploit the power of Reinforcement Learning and exploration as we described above - as we have done before with other systems (Kalatzis et al., 2016). Therefore the generalisation results we report above for BABBLE follow entirely from the knowledge present within the grammar as a computational model of dialogue processing and contextual update, rather than this having been learned from data. Applying the full RL method described above would have meant that the system would actually discover many interactional and syntactic variations that are not present in bAbI, nor in bAbI+.

5.2 MEMN2N

Even when trained on very few training instances, the MEMN2N model was able to predict system responses remarkably well. But results from Experiment 2 above showed that this was misleading: the MEMN2NS were making a drastic number of semantic mistakes when interpreting the dialogues, both in the bAbI and bAbI+ datasets. Even when trained on the full bAbI data-set, the model performed badly on bAbI+ in terms of semantic accuracy. We diagnose these results as follows:

Problem complexity: The first thing to notice is that in bAbI dialogue Task 1, the responses are highly predictable and stay constant regardless of the actual task details (slot values) up to the point of the final `api-calls`; and further, that the prediction of `api-calls` is a *generative* process, unlike the prediction of the system turns, which is retrieval-based. This, in our view, explains the very large difference in MEMN2N performance across the two prediction tasks.

Model robustness to the bAbI+ transformations:. The variations introduced in bAbI+ are repetitions of both content and non-content words, as well additional incorrect slot values. The model was working in the same setup as BABBLE, therefore none of those variations could be treated as unknown tokens for either system. Although in the case of MEMN2N, some of the mixed-in words never appeared in the training data, and bAbI+ utterances were augmented significantly with those words – so it was interesting to see how such untrained embeddings would affect the latent memory representations inside MEMN2N. The resulting performance suggests that there was no significant impact on MEMN2N from these variations as far as the predicting system responses was concerned. But the incorrect slot values introduced in self-corrections affect the system's task completion performance significantly, only appearing at the point of `api-call` predictions.

We note also that none of our experiments in this paper involved training MEMN2N on bAbI+ data. There is a very interesting question here: is the MEMN2N model in principle able to learn to process the bAbI+ structures if it is in fact trained on it? And how much bAbI+ data would it require to do so? These issues are address in detail in Shalyminov et al. (2017).

6 Conclusions

Our main advances are in a) training end-to-end dialogue systems from small amounts of data, b) incremental processing for wider coverage of more natural everyday dialogues (e.g. containing self-repairs).

We compared our grammar-based approach to dialogue processing (DS-TTR) with a state-of-the-art, end-to-end response retrieval model (MEMN2NS) (Bordes et al., 2017), when training on small amounts of dialogue data.

Our experiments show that our model can process 74% of the Facebook AI bAbI dataset even when trained on only 0.13% of the data (5 dialogues). It can *in addition* process 65% of bAbI+, a corpus we created by systematically adding incremental dialogue phenomena such as restarts and self-corrections to bAbI. We find on the other hand that the MEMN2N model is not robust to the structures we introduced in bAbI+, even when trained on the full bAbI dataset.

Abstract

Building a dialogue agent to fulfill complex tasks, such as travel planning, is challenging because the agent has to learn to *collectively* complete multiple subtasks. For example, the agent needs to reserve a hotel and book a flight so that there leaves enough time for commute between arrival and hotel check-in. This paper addresses this challenge by formulating the task in the mathematical framework of *options* over Markov Decision Processes (MDPs), and proposing a hierarchical deep reinforcement learning approach to learning a dialogue manager that operates at different temporal scales. The dialogue manager consists of: (1) a top-level dialogue policy that selects among subtasks or options, (2) a low-level dialogue policy that selects primitive actions to complete the subtask given by the top-level policy, and (3) a global state tracker that helps ensure all cross-subtask constraints be satisfied. Experiments on a travel planning task with simulated and real users show that our approach leads to significant improvements over three baselines, two based on handcrafted rules and the other based on flat deep reinforcement learning.

1 Introduction

There is a growing demand for intelligent personal assistants, mainly in the form of dialogue agents, that can help users accomplish tasks ranging from meeting scheduling to vacation planning. However, most of the popular agents in today's market, such as Amazon Echo, Apple Siri, Google Home and Microsoft Cortana, can only handle very simple tasks, such as reporting weather and requesting songs. Building a dialogue agent to fulfill complex tasks remains one of the most fundamental challenges for the NLP community and AI in general.

In this paper, we consider an important type of complex tasks, termed *composite task*, which consists of a set of subtasks that need to be fulfilled collectively. For example, in order to make a travel plan, we need to book air tickets, reserve a hotel, rent a car, etc. in a collective way so as to satisfy a set of cross-subtask constraints, which we call *slot constraints*. Examples of slot constraints for travel planning are: hotel check-in time should be later than the flight's arrival time, hotel check-out time may be earlier than the return flight depart time, the number of flight tickets equals to that of hotel check-in people, and so on.

It is common to learn a task-completion dialogue agent using reinforcement learning (RL); see Su et al. (2016); Cuayáhuitl (2017); Williams et al. (2017); Dhingra et al. (2017) and Li et al. (2017a) for a few recent examples. Compared to these dialogue agents developed for individual domains, the composite task presents additional challenges to commonly used, *flat* RL approaches such as DQN (Mnih et al., 2015). The first challenge is reward sparsity. Dialogue policy learning for composite tasks requires exploration in a much larger state-action space, and it often takes many more conversation turns between user and agent to fulfill a task, leading to a much longer trajectory. Thus, the reward signals (usually provided by users at the end of a conversation) are delayed and sparse. As we will show in this paper, typical flat RL methods such as DQN with naive ϵ-greedy exploration is rather inefficient. The second challenge is to satisfy slot constraints across subtasks. This requirement makes most of the existing methods of learning *multi-domain dialogue* agents (Cuayáhuitl, 2009; Gasic et al., 2015b) inapplicable: these methods train a

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2231–2240
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

collection of policies, one for each domain, and there is no cross-domain constraints required to successfully complete a dialogue. The third challenge is improved user experience: we find in our experiments that a flat RL agent tends to switch between different subtasks frequently when conversing with users. Such incoherent conversations lead to poor user experience, and are one of the main reasons that cause a dialogue session to fail.

In this paper, we address the above mentioned challenges by formulating the task using the mathematical framework of *options over MDPs* (Sutton et al., 1999), and proposing a method that combines deep reinforcement learning and hierarchical task decomposition to train a composite task-completion dialogue agent. At the heart of the agent is a dialogue manager, which consists of (1) a top-level dialogue policy that selects subtasks (options), (2) a low-level dialogue policy that selects primitive actions to complete a given subtask, and (3) a global state tracker that helps ensure all cross-subtask constraints be satisfied.

Conceptually, our approach exploits the structural information of composite tasks for efficient exploration. Specifically, in order to mitigate the reward sparsity issue, we equip our agent with an evaluation module (internal critic) that gives intrinsic reward signals, indicating how likely a particular subtask is completed based on its current state generated by the global state tracker. Such intrinsic rewards can be viewed as heuristics that encourage the agent to focus on solving a subtask before moving on to another subtask. Our experiments show that such intrinsic rewards can be used inside a hierarchical RL agent to make exploration more efficient, yielding a significantly reduced state-action space for decision making. Furthermore, it leads to a better user experience, as the resulting conversations switch between subtasks less frequently.

To the best of our knowledge, this is the first work that strives to develop a composite task-completion dialogue agent. Our main contributions are three-fold:

- We formulate the problem in the mathematical framework of options over MDPs.
- We propose a hierarchical deep reinforcement learning approach to efficiently learning the dialogue manager that operates at different temporal scales.
- We validate the effectiveness of the proposed approach in a travel planning task on simulated as well as real users.

2 Related Work

Task-completion dialogue systems have attracted numerous research efforts. Reinforcement learning algorithms hold the promise for dialogue policy optimization over time with experience (Scheffler and Young, 2000; Levin et al., 2000; Young et al., 2013; Williams et al., 2017). Recent advances in deep learning have inspired many deep reinforcement learning based dialogue systems that eliminate the need for feature engineering (Su et al., 2016; Cuayáhuitl, 2017; Williams et al., 2017; Dhingra et al., 2017; Li et al., 2017a).

All the work above focuses on single-domain problems. Extensions to composite-domain dialogue problems are non-trivial due to several reasons: the state and action spaces are much larger, the trajectories are much longer, and in turn reward signals are much more sparse. All these challenges can be addressed by hierarchical reinforcement learning (Sutton et al., 1999, 1998; Singh, 1992; Dietterich, 2000; Barto and Mahadevan, 2003), which decomposes a complicated task into simpler subtasks, possibly in a recursive way. Different frameworks have been proposed, such as Hierarchies of Machines (Parr and Russell, 1997) and MAXQ decomposition (Dietterich, 2000). In this paper, we choose the *options framework* for its conceptual simplicity and generality (Sutton et al., 1998); more details are found in the next section. Our work is also motivated by hierarchical-DQN (Kulkarni et al., 2016) which integrates hierarchical value functions to operate at different temporal scales. The model achieved superior performance on a complicated ATARI game "Montezuma's Revenge" with a hierarchical structure.

A related but different extension to single-domain dialogues is multi-domain dialogues, where each domain is handled by a separate agent (Lison, 2011; Gasic et al., 2015a,b; Cuayáhuitl et al., 2016). In contrast to composite-domain dialogues studied in this paper, a conversation in a multi-domain dialogue normally involves one domain, so completion of a task does *not* require solving sub-tasks in different domains. Consequently, work on multi-domain dialogues focuses on different technical challenges such as transfer learning across different domains (Gasic et al., 2015a) and domain selection (Cuayáhuitl et al., 2016).

3 Dialogue Policy Learning

Our composite task-completion dialogue agent consists of four components: (1) an LSTM-based language understanding module (Hakkani-Tür et al., 2016; Yao et al., 2014) for identifying user intents and extracting associated slots; (2) a state tracker for tracking the dialogue state; (3) a dialogue policy which selects the next action based on the current state; and (4) a model-based natural language generator (Wen et al., 2015) for converting agent actions to natural language responses. Typically, a dialogue manager contains a state tracker and a dialogue policy. In our implementation, we use a *global* state tracker to maintain the dialogue state by accumulating information across all subtasks, thus helping ensure all inter-subtask constraints be satisfied. In the rest of this section, we will describe the dialogue policy in details.

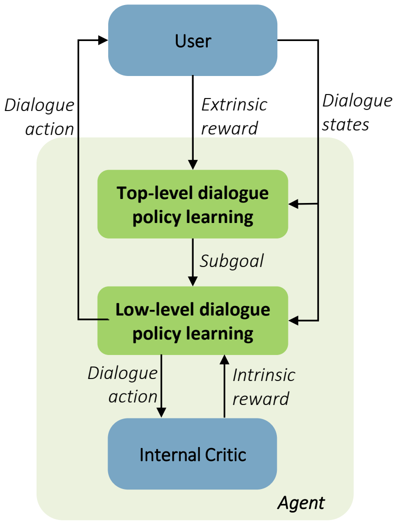

Figure 1: Overview of a composite task-completion dialogue agent.

3.1 Options over MDPs

Consider the following process of completing a composite task (e.g., travel planning). An agent first selects a subtask (e.g., book-flight-ticket), then takes a sequence of actions to gather related information (e.g., departure time, number of tickets, destination, etc.) until all users' requirements are met and the subtask is completed, and finally chooses the next subtask (e.g., reserve-hotel) to complete. The composite task is fulfilled after all its subtasks are completed collectively. The above process has a natural hierarchy: a top-level process selects which subtasks to complete, and a low-level process chooses primitive actions to complete the selected subtask. Such hierarchical decision making processes can be formulated in the *options* framework (Sutton et al., 1999), where options generalize primitive actions to higher-level actions. Different from the traditional MDP setting where an agent can only choose a primitive action at each time step, with options the agent can choose a "multi-step" action which for example could be a sequence of primitive actions for completing a subtask. As pointed out by Sutton et al. (1999), options are closely related to actions in a family of decision problems known as semi-Markov decision processes.

Following Sutton et al. (1999), an option consists of three components: a set of states where the option can be initiated, an intra-option policy that selects primitive actions while the option is in control, and a termination condition that specifies when the option is completed. For a composite task such as travel planning, subtasks like *book-flight-ticket* and *reserve-hotel* can be modeled as options. Consider, for example, the option *book-flight-ticket*: its initiation state set contains states in which the tickets have not been issued or the destination of the trip is long away enough that a flight is needed; it has an intra-option policy for requesting or confirming information regarding departure date and the number of seats, etc.; it also has a termination condition for confirming that all information is gathered and correct so that it is ready to issue the tickets.

3.2 Hierarchical Policy Learning

The intra-option is a conventional policy over primitive actions, we can consider an inter-option policy over sequences of options in much the same way as we consider the intra-option policy over sequences of actions. We propose a method that combines deep reinforcement learning and hierarchical value functions to learn a composite task-completion dialogue agent as shown in Figure 1. It is a two-level hierarchical reinforcement learning agent that consists of a top-level dialogue policy π_g and a low-level dialogue policy $\pi_{a,g}$, as shown in Figure 2. The top-level policy π_g perceives state s from the environment and selects a subtask $g \in \mathcal{G}$, where $\mathcal{G}$ is the set of all possible subtasks. The low-level policy $\pi_{a,g}$ is shared by all options. It takes as input a state s and a subtask g, and outputs a primitive action $a \in \mathcal{A}$, where $\mathcal{A}$ is the set of primitive actions of all subtasks. The subtask g remains a constant input to $\pi_{a,g}$, until a terminal state is reached to terminate g. The internal critic in the dialogue manager provides intrinsic reward $r_t^i(g_t)$, indicating whether the subtask g_t at hand has been solved; this signal is used to optimize $\pi_{a,g}$. Note that the state s contains global information, in that it keeps track of information for all subtasks.

Naturally, we aim to optimize the low-level policy $\pi_{a,g}$ so that it maximizes the following cumulative intrinsic reward at every step t:

$$\max_{\pi_{a,g}} \mathbb{E}\Big[\sum_{k \geq 0} \gamma^k r_{t+k}^i \Big| s_t = s, g_t = g, a_{t+k} = \pi_{a,g}(s_{t+k})\Big]$$

where r_{t+k}^i denotes the reward provided by the internal critic at step $t+k$. Similarly, we want the top-level policy π_g to optimize the cumulative extrinsic reward at every step t:

$$\max_{\pi_g} \mathbb{E}\Big[\sum_{k \geq 0} \gamma^k r_{t+k}^e \Big| s_t = s, a_{t+k} = \pi_g(s_{t+k})\Big] \,,$$

where r_{t+k}^e is the reward received from the environment at step $t+k$ when a new subtask starts.

Both the top-level and low-level policies can be learned with deep Q-learning methods, like DQN. Specifically, the top-level dialogue policy estimates the optimal Q-function that satisfies the following:

$$\begin{aligned} Q_1^*(s,g) = \mathbb{E}\Big[& \sum_{k=0}^{N-1} \gamma^k r_{t+k}^e + \\ & \gamma^N \cdot \max\nolimits_{g'} Q_1^*(s_{t+N}, g') | s_t = s, g_t = g\Big], \quad (1) \end{aligned}$$

where N is the number of steps that the low-level dialogue policy (intra-option policy) needs to accomplish the subtask. g' is the agent's next subtask in state s_{t+N}. Similarly, the low-level dialogue policy estimates the Q-function that satisfies the following:

$$\begin{aligned} Q_2^*(s,a,g) = \mathbb{E}\Big[& r_t^i + \\ & \gamma \cdot \max_{a_{t+1}} Q_2^*(s_{t+1}, a_{t+1}, g) | s_t = s, g_t = g\Big] \,. \end{aligned}$$

Both $Q_1^*(s,g)$ and $Q_2^*(s,a,g)$ are represented by neural networks, $Q_1(s,g;\theta_1)$ and $Q_2(s,a,g;\theta_2)$, parameterized by θ_1 and θ_2, respectively.

The top-level dialogue policy tries to minimize the following loss function at each iteration i:

$$\begin{aligned} \mathcal{L}_1(\theta_{1,i}) = \mathbb{E}_{(s,g,r^e,s') \sim \mathcal{D}_1}[(y_i - Q_1(s,g;\theta_{1,i}))^2] \\ y_i = r^e + \gamma^N \max_{g'} Q_1(s', g', \theta_{1,i-1}) \,, \end{aligned}$$

where, as in Equation (1), $r^e = \sum_{k=0}^{N-1} \gamma^k r_{t+k}^e$ is the discounted sum of reward collected when subgoal g is being completed, and N is the number of steps g is completed.

The low-level dialogue policy minimizes the following loss at each iteration i using:

$$\begin{aligned} \mathcal{L}_2(\theta_{2,i}) &= \mathbb{E}_{(s,g,a,r^i,s') \sim \mathcal{D}_2}[(y_i - \\ & \qquad Q_2(s,g,a;\theta_{2,i}))^2] \\ y_i &= r^i + \gamma \max_{a'} Q_2(s', g, a', \theta_{2,i-1}) \,. \end{aligned}$$

We use SGD to minimize the above loss functions. The gradient for the top-level dialogue policy yields:

$$\begin{aligned} \nabla_{\theta_{1,i}} L_1(\theta_{1,i}) = \mathbb{E}_{(s,g,r^e,s') \sim \mathcal{D}_1}[(r^e + \\ \gamma^N \max_{g'} Q_2(s', g', \theta_{1,i-1}) - Q_1(s,g,\theta_{1,i})) \\ \nabla_{\theta_{1,i}} Q_1(s,g,\theta_{1,i})] \end{aligned} \tag{2}$$

The gradient for the low-level dialogue policy yields:

$$\begin{aligned} \nabla_{\theta_{2,i}} L_2(\theta_{2,i}) = \mathbb{E}_{(s,g,a,r^i,s') \sim \mathcal{D}_2}[(r^i + \\ \gamma \max_{a'} Q_2(s', g, a', \theta_{2,i-1}) - Q_2(s,g,a,\theta_{2,i})) \\ \nabla_{\theta_{2,i}} Q_2(s,g,a,\theta_{2,i})] \end{aligned} \tag{3}$$

Following previous studies, we apply two most commonly used performance boosting methods: target networks and experience replay. Experience replay tuples (s, g, r^e, s') and (s, g, a, r^i, s'), are sampled from the experience replay buffers $\mathcal{D}_1$ and $\mathcal{D}_2$ respectively. A detailed summary of the learning algorithm for the hierarchical dialogue policy is provided in Appendix B.

4 Experiments and Results

To evaluate the proposed method, we conduct experiments on the composite task-completion dialogue task of travel planning.

4.1 Dataset

In the study, we made use of a human-human conversation data derived from a publicly available multi-domain dialogue corpus[1] (El Asri et al., 2017), which was collected using the Wizard-of-Oz approach. We made a few changes to the schema of the data set for the composite task-completion dialogue setting. Specifically, we added inter-subtask constraints as well as user preferences (soft constraints). The data was mainly used to create simulated users, as will be explained below shortly.

4.2 Baseline Agents

We benchmark the proposed *HRL agent* against three baseline agents:

- A *Rule Agent* uses a sophisticated hand-crafted dialogue policy, which requests and informs a hand-picked subset of necessary slots, and then confirms with the user about the reserved tickets.
- A *Rule+ Agent* requests and informs all the slots in a pre-defined order exhaustedly, and then confirms with the user about the reserved tickets. The average turn of this agent is longer than that of the *Rule* agent.
- A *flat RL Agent* is trained with a standard flat deep reinforcement learning method (DQN) which learns a flat dialogue policy using extrinsic rewards only.

4.3 User Simulator

Training reinforcement learners is challenging because they need an environment to interact with. In the dialogue research community, it is common to use simulated users as shown in Figure 3 for this purpose (Schatzmann et al., 2007; Asri et al., 2016). In this work, we adapted the publicly-available user simulator, developed by Li et al. (2016), to the composite task-completion dialogue setting using the human-human conversation data described in Section 4.1.[2] During training, the simulator provides the agent with an (extrinsic) reward signal at the end of the dialogue. A dialogue is considered to be successful only when a travel plan is made successfully, and the information provided by the agent satisfies user's constraints. At the end of each dialogue, the agent receives a positive reward of $2{*}max\_turn$ ($max\_turn = 60$ in our experiments) for success, or a negative reward of $-max\_turn$ for failure. Furthermore, at each turn, the agent receives a reward of -1 so that shorter dialogue sessions are encouraged.

User Goal A user goal is represented by a set of slots, indicating the user's request, requirement and preference. For example, an *inform slot*, such as dst_city="Honolulu", indicates a user requirement, and a *request slot*, such as price="?", indicates a user asking the agent for the information.

In our experiment, we compiled a list of user goals using the slots collected from the human-human conversation data set described in Section 4.1, as follows. We first extracted all the slots that appear in dialogue sessions. If a slot has multiple values, like "or_city=[San Francisco, San Jose]", we consider it as a user preference (soft constraint) which the user may later revise its value to explore different options in the course of the dialogue. If a slot has only one value, we treat it as a user requirement (hard constraint), which is unlikely negotiable. If a slot is with value "?", we treat it as a user request. We removed those slots from user goals if their values do not exist in our database. The compiled set of user goals contains 759 entries, each containing slots from at least two subtasks: *book-flight-ticket* and *reserve-hotel*.

User Type To compare different agents' ability to adapt to user preferences, we also constructed three additional user goal sets, representing three different types of (simulated) users, respectively:

- *Type A*: All the informed slots in a user goal have a single value. These users have hard constraints for both the flight and hotel, and have no preference on which subtask to accomplish first.
- *Type B*: At least one of informed slots in the *book-flight-ticket* subtask can have multiple values, and the user (simulator) prefers to start with the *book-flight-ticket* subtask. If the user receives "no ticket available" from the agent during the conversation, she is willing to explore alternative slot values.

[1] https://datasets.maluuba.com/Frames

[2] A detailed description of the user simulator is presented in Appendix A.

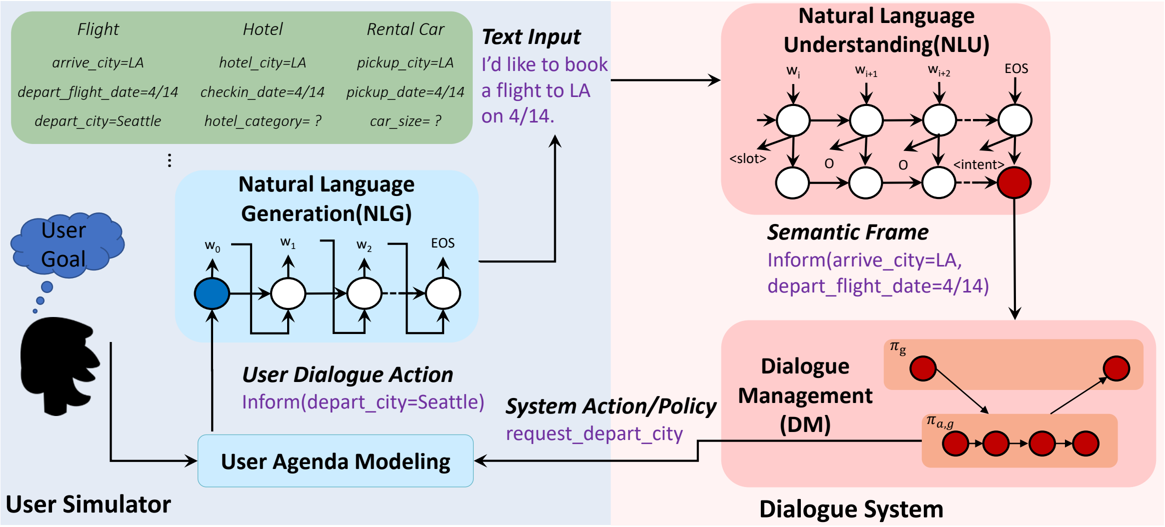

Figure 3: Illustration of the Composite Task-Completion dialogue System

- *Type C*: Similar to *Type B*, at least one of informed slots of the *reserve-hotel* subtask in a user goal can have multiple values. The user prefers to start with the *reserve-hotel* subtask. If the user receives a "no room available" response from the agent, she is willing to explore alternative slot values.

4.4 Implementation

For the RL agent, we set the size of hidden layer to 80. For the HRL agent, both top-level and low-level dialogue policies had a hidden layer size of 80. RMSprop was applied to optimize the parameters. We set batch size to 16. During training, we used the ϵ-greedy strategy for exploration. For each simulation epoch, we simulated 100 dialogues and stored these state transition tuples in an experience replay buffer. At the end of each simulation epoch, the model was updated with all the transition tuples in the buffer in a batch manner.

The experience replay strategy is critical to the success of deep reinforcement learning. In our experiments, at the beginning, we used a rule-based agent to run N ($N = 100$) dialogues to populate the experience replay buffer, which was an implicit way of imitation learning to initialize the RL agent. Then, the RL agent accumulated all the state transition tuples and flushes the replay buffer only when the current RL agent reached a success rate threshold no worse than that of the *Rule* agent.

This strategy was motivated by the following observation. The initial performance of an RL agent was often not strong enough to result in dialogue sessions with a reasonable success rate. With such data, it was easy for the agent to learn the locally optimal policy that "failed fast"; that is, the policy would finish the dialogue immediately, so that the agent could suffer the least amount of per-turn penalty. Therefore, we provided some rule-based examples that succeeded reasonably often, and did not flush the buffer until the performance of the RL agent reached an acceptable level. Generally, one can set the threshold to be the success rate of the *Rule* agent. To make a fair comparison, for the same type of users, we used the same *Rule* agent to initialize both the RL agent and the HRL agent.

4.5 Simulated User Evaluation

On the composite task-completion dialogue task, we compared the HRL agent with the baseline agents in terms of three metrics: success rate[3], average rewards, and the average number of turns per dialogue session.

Figure 4 shows the learning curves of all four agents trained on different types of users. Each learning curve was averaged over 10 runs. Table 1 shows the performance on test data. For all types of users, the HRL-based agent yielded more robust dialogue policies outperforming the hand-crafted rule-based agents and flat RL-based agent measured on success rate. It also needed fewer turns per dialogue session to accomplish a task than the rule-based agents and flat RL agent. The results

[3] Success rate is the fraction of dialogues where the tasks are successfully accomplished within the maximum turns.

	Type A			Type B			Type C		
Agent	Succ.	Turn	Reward	Succ.	Turn	Reward	Succ.	Turn	Reward
Rule	.322	46.2	-24.0	.240	54.2	-42.9	.205	54.3	-49.3
Rule+	*.535*	*82.0*	*-3.7*	*.385*	*110.5*	*-44.95*	*.340*	*108.1*	*-51.85*

across all three types of simulated users suggest the following conclusions.

First, he HRL agent significantly outperformed the RL agent. This, to a large degree, was attributed to the use of the hierarchical structure of the proposed agent. Specifically, the top-level dialogue policy selected a subtask for the agent to focus on, one at a time, thus dividing a complex task into a sequence of simpler subtasks. The selected subtasks, combined with the use of intrinsic rewards, alleviated the sparse reward and long-horizon issues, and helped the agent explore more efficiently in the state-action space. As a result, as shown in Figure 4 and Table 1, the performance of the HRL agent on types B and C users (who may need to go back to revise some slots during the dialogue) does not drop much compared to type A users, despite the increased search space in the former. Additionally, we observed a large drop in the performance of the RL Agent due to the increased complexity of the task, which required more dialogue turns and posed a challenge for temporal credit assignment.

Second, the HRL agent learned much faster than the RL agent. The HRL agent could reach the same level of performance with a smaller number of simulation examples than the RL agent,

Table 2: Sample dialogue by RL and HRL agents with real user: Left column shows the dialogue with the RL agent; Right column shows the dialogue with the HRL agent; bolded slots are the joint constraints between two subtasks.

demonstrating that the hierarchical dialogue policies were more sample-efficient than flat RL policy and could significantly reduce the sample complexity on complex tasks.

Finally, we also found that the *Rule+* and *flat* RL agents had comparable success rates, as shown in Figure 4. However, a closer look at the correlation between success rate and the average number of turns in Table 1 suggests that the *Rule+* agent required more turns which adversely affects its success, whilst the *flat* RL agent achieves similar success with much less number of turns in all the user types. It suffices to say that our hierarchical RL agent outperforms all in terms of success rate as depicted in Figure 4.

4.6 Human Evaluation

We further evaluated the agents, which were trained on simulated users, against real human users, recruited from the authors’ affiliation. We conducted the study using the HRL and RL agents, each tested against two types of users: *Type A* users who had no preference for subtask, and *Type B* users who preferred to complete the *book-flight-ticket* subtask first. Note that *Type C* users were symmetric to Type B ones, so were not included in the study. We compared two (agent, user type) pairs: {RL A, HRL A} and {RL B, HRL B}; in other words, four agents were trained against their specific user types. In each dialogue session, one of the agents was randomly picked to converse with a user. The user was presented with a user goal sampled from our corpus, and was instructed to converse with the agent to complete the task. If one of the slots in the goal had multiple values, the user had multiple choices for this slot and might revise the slot value when the agent replied with a message like "No ticket is available" during the conversation. At the end of each session, the user was asked to give a rating on a scale from 1 to 5 based on the naturalness and coherence of the dialogue. (1 is the worst rating, and 5 the best). We collected a total of 225 dialogue sessions from 12 human users.

Figure 5 presents the performance of these agents against real users in terms of success rate. Figure 6 shows the comparison in user rating. For all the cases, the HRL agent was consistently better than the RL agent in terms of success rate and user rating. Table 2 shows a sample dialogue session. We see that the HRL agent produced a more coherent conversation, as it switched among subtasks much less frequently than the *flat* RL agent.

5 Discussion and Conclusions

This paper considers composite task-completion dialogues, where a set of subtasks need to be fulfilled collectively for the entire dialogue to be successful. We formulate the policy learning problem using the options framework, and take a hierarchical deep RL approach to optimizing the policy. Our experiments, both on simulated and real users, show that the hierarchical RL agent significantly outperforms a flat RL agent and rule-based agents. The hierarchical structure of the agent also improves the coherence of the dialogue flow.

The promising results suggest several directions for future research. First, the hierarchical RL approach demonstrates strong adaptation ability to tailor the dialogue policy to different types of users. This motivates us to systematically investigate its use for dialogue *personalization*. Second, our hierarchical RL agent is implemented using a two-level dialogue policy. But more complex tasks might require multiple levels of hierarchy. Thus, it is valuable to extend our approach to handle such deep hierarchies, where a subtask can invoke another subtask and so on, taking full advantage of the options framework. Finally, designing task hierarchies requires substantial domain knowledge and is time-consuming. This challenge calls for future work on automatic learning of hierarchies for complex dialogue tasks.

Why We Need New Evaluation Metrics for NLG

Jekaterina Novikova, Ondřej Dušek, Amanda Cercas Curry and **Verena Rieser**

Abstract

The majority of NLG evaluation relies on automatic metrics, such as BLEU. In this paper, we motivate the need for novel, system- and data-independent automatic evaluation methods: We investigate a wide range of metrics, including state-of-the-art word-based and novel grammar-based ones, and demonstrate that they only weakly reflect human judgements of system outputs as generated by data-driven, end-to-end NLG. We also show that metric performance is data- and system-specific. Nevertheless, our results also suggest that automatic metrics perform reliably at system-level and can support system development by finding cases where a system performs poorly.

1 Introduction

Automatic evaluation measures, such as BLEU (Papineni et al., 2002), are used with increasing frequency to evaluate Natural Language Generation (NLG) systems: Up to 60% of NLG research published between 2012–2015 relies on automatic metrics (Gkatzia and Mahamood, 2015). Automatic evaluation is popular because it is cheaper and faster to run than human evaluation, and it is needed for automatic benchmarking and tuning of algorithms. The use of such metrics is, however, only sensible if they are known to be sufficiently correlated with human preferences. This is rarely the case, as shown by various studies in NLG (Stent et al., 2005; Belz and Reiter, 2006; Reiter and Belz, 2009), as well as in related fields, such as dialogue systems (Liu et al., 2016), machine translation (MT) (Callison-Burch et al., 2006), and image captioning (Elliott and Keller, 2014; Kilickaya et al., 2017). This paper follows on from the above previous work and presents another evaluation study into automatic metrics with the aim to firmly establish the need for new metrics. We consider this paper to be the most complete study to date, across metrics, systems, datasets and domains, focusing on recent advances in data-driven NLG. In contrast to previous work, we are the first to:

- Target end-to-end data-driven NLG, where we compare 3 different approaches. In contrast to NLG methods evaluated in previous work, our systems can produce ungrammatical output by (a) generating word-by-word, and (b) learning from noisy data.
- Compare a large number of 21 automated metrics, including novel grammar-based ones.
- Report results on two different domains and three different datasets, which allows us to draw more general conclusions.
- Conduct a detailed error analysis, which suggests that, while metrics can be reasonable indicators at the system-level, they are not reliable at the sentence-level.
- Make all associated code and data publicly available, including detailed analysis results.[1]

2 End-to-End NLG Systems

In this paper, we focus on recent end-to-end, data-driven NLG methods, which jointly learn sentence planning and surface realisation from non-aligned data (Dušek and Jurčíček, 2015; Wen et al., 2015; Mei et al., 2016; Wen et al., 2016; Sharma et al., 2016; Dušek and Jurčíček, 2016, Lampouras and Vlachos, 2016). These approaches do not require costly semantic alignment between Meaning Representations (MR) and human references (also referred to as "ground truth" or "targets"), but are

System	Dataset			Total
	BAGEL	SFREST	SFHOTEL	
LOLS	202	581	398	1,181
RNNLG	-	600	477	1,077
TGEN	202	-	-	202
Total	404	1,181	875	2,460

Table 1: Number of NLG system outputs from different datasets and systems used in this study.

based on parallel datasets, which can be collected in sufficient quality and quantity using effective crowdsourcing techniques, e.g. (Novikova et al., 2016), and as such, enable rapid development of NLG components in new domains. In particular, we compare the performance of the following systems:

- **RNNLG:**[2] The system by Wen et al. (2015) uses a Long Short-term Memory (LSTM) network to jointly address sentence planning and surface realisation. It augments each LSTM cell with a gate that conditions it on the input MR, which allows it to keep track of MR contents generated so far.
- **TGEN:**[3] The system by Dušek and Jurčíček (2015) learns to incrementally generate deep-syntax dependency trees of candidate sentence plans (i.e. which MR elements to mention and the overall sentence structure). Surface realisation is performed using a separate, domain-independent rule-based module.
- **LOLS:**[4] The system by Lampouras and Vlachos (2016) learns sentence planning and surface realisation using Locally Optimal Learning to Search (LOLS), an imitation learning framework which learns using BLEU and ROUGE as non-decomposable loss functions.

3 Datasets

We consider the following crowdsourced datasets, which target utterance generation for spoken dialogue systems. Table 1 shows the number of system outputs for each dataset. Each data instance consists of one MR and one or more natural language references as produced by humans, such as the following example, taken from the BAGEL dataset:[5]

MR: inform(name=X, area=X, pricerange=moderate, type=restaurant)
Reference: *"X is a moderately priced restaurant in X."*

- **SFHOTEL & SFREST** (Wen et al., 2015) provide information about hotels and restaurants in San Francisco. There are 8 system dialogue act types, such as *inform*, *confirm*, *goodbye* etc. Each domain contains 12 attributes, where some are common to both domains, such as *name, type, pricerange, address, area,* etc., and the others are domain-specific, e.g. *food* and *kids-allowed* for restaurants; *hasinternet* and *dogs-allowed* for hotels. For each domain, around 5K human references were collected with 2.3K unique human utterances for SFHOTEL and 1.6K for SFREST. The number of unique system outputs produced is 1181 for SFREST and 875 for SFHOTEL.
- **BAGEL** (Mairesse et al., 2010) provides information about restaurants in Cambridge. The dataset contains 202 aligned pairs of MRs and 2 corresponding references each. The domain is a subset of SFREST, including only the *inform* act and 8 attributes.

4 Metrics

4.1 Word-based Metrics (WBMs)

NLG evaluation has borrowed a number of automatic metrics from related fields, such as MT, summarisation or image captioning, which compare output texts generated by systems to ground-truth references produced by humans. We refer to this group as word-based metrics. In general, the higher these scores are, the better or more similar to the human references the output is.[6] The following order reflects the degree these metrics move from simple n-gram overlap to also considering term frequency (TF-IDF) weighting and semantically similar words.

- **Word-overlap Metrics (WOMs):** We consider frequently used metrics, including TER (Snover et al., 2006), BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), NIST (Doddington, 2002), LEPOR (Han et al., 2012), CIDER (Vedantam et al., 2015), and METEOR (Lavie and Agarwal, 2007).
- **Semantic Similarity (SIM):** We calculate the Semantic Text Similarity measure designed by Han et al. (2013). This measure is based on distributional similarity and Latent Semantic Analysis

[2] https://github.com/shawnwun/RNNLG

[3] https://github.com/UFAL-DSG/tgen

[4] https://github.com/glampouras/JLOLS_NLG

[5] Note that we use lexicalised versions of SFHOTEL and SFREST and a partially lexicalised version of BAGEL, where proper names and place names are replaced by placeholders ("X"), in correspondence with the outputs generated by the systems, as provided by the system authors.

[6] Except for TER whose scale is reversed.

(LSA) and is further complemented with semantic relations extracted from WordNet.

4.2 Grammar-based metrics (GBMs)

Grammar-based measures have been explored in related fields, such as MT (Giménez and Màrquez, 2008) or grammatical error correction (Napoles et al., 2016), and, in contrast to WBMs, do not rely on ground-truth references. To our knowledge, we are the first to consider GBMs for sentence-level NLG evaluation. We focus on two important properties of texts here – readability and grammaticality:

- **Readability** quantifies the difficulty with which a reader understands a text, as used for e.g. evaluating summarisation (Kan et al., 2001) or text simplification (Francois and Bernhard, 2014). We measure readability by the Flesch Reading Ease score (RE) (Flesch, 1979), which calculates a ratio between the number of characters per sentence, the number of words per sentence, and the number of syllables per word. Higher RE score indicates a less complex utterance that is easier to read and understand. We also consider related measures, such as characters per utterance (**len**) and per word (**cpw**), words per sentence (**wps**), syllables per sentence (**sps**) and per word (**spw**), as well as polysyllabic words per utterance (**pol**) and per word (**ppw**). The higher these scores, the more complex the utterance.

- **Grammaticality:** In contrast to previous NLG methods, our corpus-based end-to-end systems can produce ungrammatical output by (a) generating word-by-word, and (b) learning from noisy data. As a first approximation of grammaticality, we measure the number of misspellings (**msp**) and the parsing score as returned by the Stanford parser (**prs**). The lower the **msp**, the more grammatically correct an utterance is. The Stanford parser score is not designed to measure grammaticality, however, it will generally prefer a grammatical parse to a non-grammatical one.[7] Thus, lower parser scores indicate less grammatically-correct utterances. In future work, we aim to use specifically designed grammar-scoring functions, e.g. (Napoles et al., 2016), once they become publicly available.

5 Human Data Collection

To collect human rankings, we presented the MR together with 2 utterances generated by different systems side-by-side to crowdworkers, which were asked to score each utterance on a 6-point Likert scale for:

- **Informativeness:** *Does the utterance provide all the useful information from the meaning representation?*
- **Naturalness:** *Could the utterance have been produced by a native speaker?*
- **Quality:** *How do you judge the overall quality of the utterance in terms of its grammatical correctness and fluency?*

Each system output (see Table 1) was scored by 3 different crowdworkers. To reduce participants' bias, the order of appearance of utterances produced by each system was randomised and crowdworkers were restricted to evaluate a maximum of 20 utterances. The crowdworkers were selected from English-speaking countries only, based on their IP addresses, and asked to confirm that English was their native language.

To assess the reliability of ratings, we calculated the intra-class correlation coefficient (ICC), which measures inter-observer reliability on ordinal data for more than two raters (Landis and Koch, 1977). The overall ICC across all three datasets is 0.45 ($p < 0.001$), which corresponds to a moderate agreement. In general, we find consistent differences in inter-annotator agreement per system and dataset, with lower agreements for LOLS than for RNNLG and TGEN. Agreement is highest for the SFHOTEL dataset, followed by SFREST and BAGEL (details provided in supplementary material).

6 System Evaluation

Table 2 summarises the individual systems' overall corpus-level performance in terms of automatic and human scores (details are provided in the supplementary material).

All WOMs produce similar results, with SIM showing different results for the restaurant domain (BAGEL and SFREST). Most GBMs show the same trend (with different levels of statistical significance), but RE is showing inverse results. System performance is dataset-specific: For WBMs, the LOLS system consistently produces better results on BAGEL compared to TGEN, while for SFREST and SFHOTEL, LOLS is outperformed by RNNLG in

[7] http://nlp.stanford.edu/software/parser-faq.shtml

quality	**4.77**(Sd=1.19)	4.54(Sd=1.28)	**4.54** (Sd=1.18)	4.53(Sd=1.26)	4.51 (Sd=1.14)	**4.58**(Sd=1.33)

Table 2: System performance per dataset (summarised over metrics), where "*" denotes $p < 0.05$ for all the metrics and "(*)" shows significance on $p < 0.05$ level for the majority of the metrics.

terms of WBMs. We observe that human *informativeness* ratings follow the same pattern as WBMs, while the average similarity score (sim) seems to be related to human *quality* ratings.

Looking at GBMs, we observe that they seem to be related to *naturalness* and *quality* ratings. Less complex utterances, as measured by readability (re) and word length (cpw), have higher *naturalness* ratings. More complex utterances, as measured in terms of their length (len), number of words (wps), syllables (sps, spw) and polysyllables (pol, ppw), have lower *quality* evaluation. Utterances measured as more grammatical are on average evaluated higher in terms of *naturalness*.

These initial results suggest a relation between automatic metrics and human ratings at system level. However, average scores can be misleading, as they do not identify worst-case scenarios. This leads us to inspect the correlation of human and automatic metrics for each MR-system output pair at utterance level.

7 Relation of Human and Automatic Metrics

7.1 Human Correlation Analysis

We calculate the correlation between automatic metrics and human ratings using the Spearman coefficient (ρ). We split the data per dataset and system in order to make valid pairwise comparisons. To handle outliers within human ratings, we use the median score of the three human raters.[8] Following Kilickaya et al. (2017), we use the Williams' test (Williams, 1959) to determine significant differences between correlations. Table 3 summarises the utterance-level correlation results between automatic metrics and human ratings, listing the best (i.e. highest absolute ρ) results for each type of metric (details provided in supplementary material). Our results suggest that:

- In sum, no metric produces an even moderate correlation with human ratings, independently of dataset, system, or aspect of human rating. This contrasts with our initially promising results on the system level (see Section 6) and will be further discussed in Section 8. Note that similar inconsistencies between document- and sentence-level evaluation results are observed in MT (Specia et al., 2010).
- Similar to our results in Section 6, we find that WBMs show better correlations to human ratings of *informativeness* (which reflects content selection), whereas GBMs show better correlations to *quality* and *naturalness*.
- Human ratings for *informativeness*, *naturalness* and *quality* are highly correlated with each other, with the highest correlation between the latter two ($\rho = 0.81$) reflecting that they both target surface realisation.
- All WBMs produce similar results (see Figure 1 and 2): They are strongly correlated with each other, and most of them produce correlations with human ratings which are *not* significantly different from each other. GBMs, on the other hand, show greater diversity.
- Correlation results are system- and dataset-specific (details provided in supplementary material). We observe the highest correlation for TGen on Bagel (Figures 1 and 2) and LOLS on SFRest, whereas RNNLG often shows low correlation between metrics and human ratings. This lets us conclude that WBMs and GBMs are sensitive to different systems and datasets.
- The highest positive correlation is observed between the number of words (wps) and *informative-*

[8] As an alternative to using the median human judgment for each item, a more effective way to use all the human judgments could be to use Hovy et al. (2013)'s MACE tool for inferring the reliability of judges.

		Bagel		SFHotel		SFRest	
		TGen	LOLS	RNNLG	LOLS	RNNLG	LOLS
Best WBM	inform.	0.30* (BLEU-1)	0.20* (ROUGE)	0.09 (BLEU-1)	0.14* (LEPOR)	0.13* (SIM)	0.28* (LEPOR)
	natural.	-0.19* (TER)	-0.19* (TER)	0.10* (METEOR)	-0.20* (TER)	0.17* (ROUGE)	0.19* (METEOR)
	quality	-0.16* (TER)	0.16* (METEOR)	0.10* (METEOR)	-0.12* (TER)	0.09* (METEOR)	0.18* (LEPOR)

	quality	-0.19* (cpw)	0.31* (prs)	-0.16* (ppw)	-0.17* (spw)	0.11* (prs)	-0.16* (sps)

Table 3: Highest absolute Spearman correlation between metrics and human ratings, with "*" denoting $p < 0.05$ (metric with the highest absolute value of ρ given in brackets).

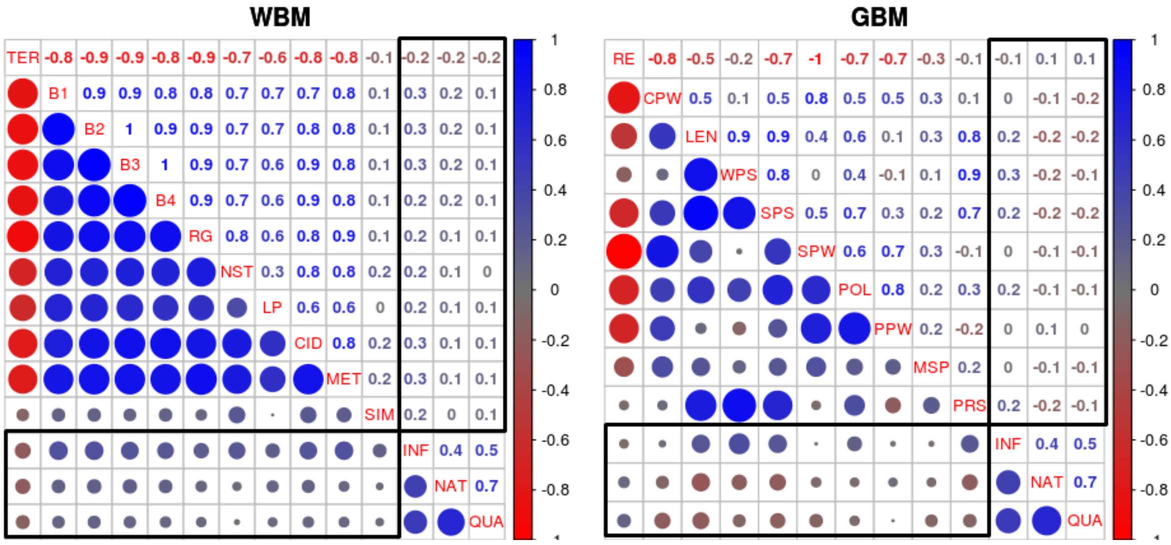

Figure 1: Spearman correlation results for TGen on Bagel. Bordered area shows correlations between human ratings and automatic metrics, the rest shows correlations among the metrics. Blue colour of circles indicates positive correlation, while red indicates negative correlation. The size of circles denotes the correlation strength.

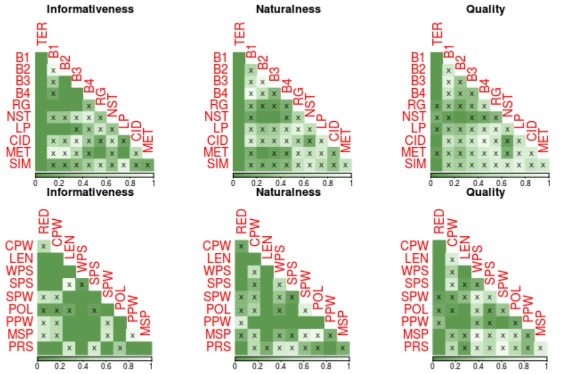

Figure 2: Williams test results: X represents a *non*-significant difference between correlations ($p < 0.05$; top: WBMs, bottom: GBMs).

ness for the TGen system on Bagel ($\rho = 0.33$, $p < 0.01$, see Figure 1). However, the wps metric (amongst most others) is not robust across systems and datasets: Its correlation on other datasets is very weak, ($\rho \leq .18$) and its correlation with informativeness ratings of LOLS outputs is insignificant.

- As a sanity check, we also measure a random score $[0.0, 1.0]$ which proves to have a close-to-zero correlation with human ratings (highest $\rho = 0.09$).

7.2 Accuracy of Relative Rankings

We now evaluate a more coarse measure, namely the metrics' ability to predict relative human ratings. That is, we compute the score of each metric for two system output sentences corresponding to the same MR. The prediction of a metric is correct if it orders the sentences in the same way as median human ratings (note that ties are allowed). Following previous work (Vedantam et al., 2015; Kilickaya et al., 2017), we mainly concentrate on WBMs. Results summarised in Table 4 show that most metrics' performance is not significantly different from that of a random score (Wilcoxon signed rank test). While the random score fluctuates between 25.4–44.5% prediction accuracy, the metrics achieve an accuracy of between 30.6–49.8%. Again, the performance of the metrics is dataset-specific: Metrics perform best on BAGEL data; for SFHOTEL, metrics show mixed performance while for SFREST, metrics perform worst.

		informat.	**naturalness**	**quality**
BAGEL	raw data	TER, BLEU1-4, ROUGE, NIST, LEPOR, CIDEr, METEOR, SIM	TER, BLEU1-4, ROUGE, NIST, LEPOR, CIDEr, METEOR, SIM	TER, BLEU1-4, ROUGE, NIST, LEPOR, CIDEr, METEOR, SIM

SFREST	raw data	SIM	LEPOR	N/A
	quant. data	TER, BLEU1-4, ROUGE, NIST, LEPOR, CIDEr, METEOR SIM	N/A	N/A

Table 4: Metrics predicting relative human rating with significantly higher accuracy than a random baseline.

Discussion: Our data differs from the one used in previous work (Vedantam et al., 2015; Kilickaya et al., 2017), which uses explicit relative rankings ("*Which output do you prefer?*"), whereas we compare two Likert-scale ratings. As such, we have 3 possible outcomes (allowing ties). This way, we can account for equally valid system outputs, which is one of the main drawbacks of forced-choice approaches (Hodosh and Hockenmaier, 2016). Our results are akin to previous work: Kilickaya et al. (2017) report results between 60-74% accuracy for binary classification on machine-machine data, which is comparable to our results for 3-way classification.

Still, we observe a mismatch between the ordinal human ratings and the continuous metrics. For example, humans might rate system A and system B both as a 6, whereas BLEU, for example, might assign 0.98 and 1.0 respectively, meaning that BLEU will declare system B as the winner. In order to account for this mismatch, we quantise our metric data to the same scale as the median scores from our human ratings.[9] Applied to SFREST, where we previously got our worst results, we can see an improvement for predicting *informativeness*, where all WBMs now perform significantly better than the random baseline (see Table 4). In the future, we will investigate related discriminative approaches, e.g. (Hodosh and Hockenmaier, 2016; Kannan and Vinyals, 2017), where the task is simplified to distinguishing correct from incorrect output.

8 Error Analysis

In this section, we attempt to uncover why automatic metrics perform so poorly.

8.1 Scales

We first explore the hypothesis that metrics are good in distinguishing extreme cases, i.e. system outputs which are rated as clearly good or bad by the human judges, but do not perform well for utterances rated in the middle of the Likert scale, as suggested by Kilickaya et al. (2017). We 'bin' our data into three groups: *bad*, which comprises low ratings ($\leq$2); *good*, comprising high ratings ($\geq$5); and finally a group comprising *average* ratings.

We find that utterances with low human ratings of *informativeness* and *naturalness* correlate significantly better ($p < 0.05$) with automatic metrics than those with average and good human ratings. For example, as shown in Figure 3, the correlation between WBMs and human ratings for utterances with low *informativeness* scores ranges between $0.3 \leq \rho \leq 0.5$ (moderate correlation), while the highest correlation for utterances of average and high informativeness barely reaches $\rho \leq 0.2$ (very weak correlation). The same pattern can be observed for correlations with *quality* and *naturalness* ratings.

This discrepancy in correlation results between low and other user ratings, together with the fact that the majority of system outputs are rated "good" for informativeness (79%), naturalness (64%) and quality (58%), whereas low ratings do not exceed 7% in total, could explain why the overall correlations are low (Section 7) despite the observed trends in relationship between average system-level performance scores (Section 6). It also explains why the RNNLG system, which contains very few instances of low user ratings, shows poor correlation between human ratings and automatic metrics.

[9] Note that this mismatch can also be accounted for by continuous rating scales, as suggested by Belz and Kow (2011).

No.	system	MR	system output	human reference	WOMs	SIM	humans
1	LOLS	inform(name = the donatello, hasinternet = yes)	well there is a hotel with internet access called the donatello	the donatello has internet	1.4	5	6
2	LOLS	inform_nomatch(area = embarcadero, kidsallowed= yes, pricerange = expensive)	i but i but i but i but i but i but i but i but i	unfortunately i could not find any expensive restaurants in embarcadero that allow kids.	1.1	1	1
3	TGen	inform(name = X, area = riverside, eattype = restaurant, food = fastfood, pricerange = cheap)	x is a restaurant on the riverside called located at the riverside and at is	x is a cheap fastfood restaurant located near the riverside	2.4	4	1
4	RNNLG	inform_nomatch(kidsallowed = yes, food = moroccan)	i am sorry, i did not find any restaurants that allows kids and serve moroccan.	sorry, there are no restaurants allowing kids and serving moroccan food	1.85	4	5

Table 5: Example pairs of MRs and system outputs from our data, contrasting the average of word-overlap metrics (normalised in the 1-6 range) and semantic similarity (SIM) with human ratings (median of all measures).

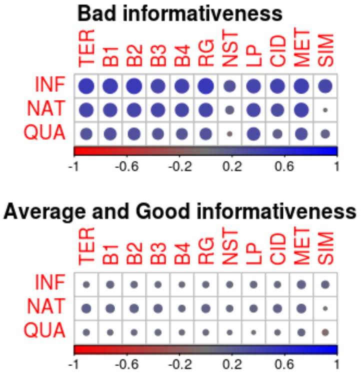

Figure 3: Correlation between automatic metrics (WBMs) and human ratings for utterances of bad informativeness (top), and average and good informativeness (bottom).

8.2 Impact of Target Data

Characteristics of Data: In Section 7.1, we observed that datasets have a significant impact on how well automatic metrics reflect human ratings. A closer inspection shows that BAGEL data differs significantly from SFREST and SFHOTEL, both in terms of grammatical and MR properties. BAGEL has significantly shorter references both in terms of number of characters and words compared to the other two datasets. Although being shorter, the words in BAGEL references are significantly more often polysyllabic. Furthermore, BAGEL only consists of utterances generated from *inform* MRs, while SFREST and SFHOTEL also have less complex MR types, such as *confirm*, *goodbye*, etc. Utterances produced from *inform* MRs are significantly longer and have a significantly higher correlation with human ratings of *informativeness* and *naturalness* than *non-inform* utterance types. In other words, BAGEL is the most complex dataset to generate from. Even though it is more complex, metrics perform most reliably on BAGEL here (note that the correlation is still only weak). One possible explanation is that BAGEL only contains two human references per MR, whereas SFHOTEL and SFREST both contain 5.35 references per MR on average. Having more references means that WBMs naturally will return higher scores (‘anything goes’). This problem could possibly be solved by weighting multiple references according to their quality, as suggested by (Galley et al., 2015), or following a reference-less approach (Specia et al., 2010).

Quality of Data: Our corpora contain crowdsourced human references that have grammatical errors, e.g. “*Fifth Floor does not allow childs*” (SFREST reference). Corpus-based methods may pick up these errors, and word-based metrics will rate these system utterances as correct, whereas we can expect human judges to be sensitive to ungrammatical utterances. Note that the parsing score (while being a crude approximation of grammaticality) achieves one of our highest correlation results against human ratings, with $|\rho| = .31$. Grammatical errors raise questions about the quality of the training data, especially when being crowdsourced. For example, Belz and Reiter (2006) find that human experts assign low rankings to their original corpus text. Again, weighting (Galley et al., 2015) or reference-less approaches (Specia et al., 2010) might remedy this issue.

8.3 Example-based Analysis

As shown in previous sections, word-based metrics moderately agree with humans on bad quality output, but cannot distinguish output of good or medium quality. Table 5 provides examples from

Study	Dimension of human ratings		Domain
	Sentence Planning	Surface Realisation	
this paper	weak positive ($\rho = 0.33$, WPS)	weak negative ($\rho = 0. - 31$, parser)	NLG, restaurant/hotel search
(Reiter and Belz, 2009)	none	strong positive (Pearson's $r = 0.96$, NIST)	NLG, weather forecast

Table 6: Best correlation results achieved by our and previous work. Dimensions targeted towards Sentence Planning include 'accuracy', 'adequacy', 'correctness', 'informativeness'. Dimensions for Surface Realisation include 'clarity', 'fluency', 'naturalness'.

our three systems.[10] Again, we observe different behaviour between WOMs and SIM scores. In Example 1, LOLS generates a grammatically correct English sentence, which represents the meaning of the MR well, and, as a result, this utterance received high human ratings (median = 6) for *informativeness, naturalness* and *quality*. However, WOMs rate this utterance low, i.e. scores of BLEU1-4, NIST, LEPOR, CIDEr, ROUGE and METEOR normalised into the 1-6 range all stay below 1.5. This is because the system-generated utterance has low overlap with the human/corpus references. Note that the SIM score is high (5), as it ignores human references and computes distributional semantic similarity between the MR and the system output. Examples 2 and 3 show outputs which receive low scores from both automatic metrics and humans. WOMs score these system outputs low due to little or no overlap with human references, whereas humans are sensitive to ungrammatical output and missing information (the former is partially captured by GBMs). Examples 2 and 3 also illustrate inconsistencies in human ratings since system output 2 is clearly worse than output 3 and both are rated by human with a median score of 1. Example 4 shows an output of the RNNLG system which is semantically very similar to the reference (SIM=4) and rated high by humans, but WOMs fail to capture this similarity. GBMs show more accurate results for this utterance, with mean of readability scores 4 and parsing score 3.5.

9 Related Work

Table 6 summarises results published by previous studies in related fields which investigate the relation between human scores and automatic metrics. These studies mainly considered WBMs, while we are the first study to consider GBMs. Some studies ask users to provide separate ratings for surface realisation (e.g. asking about 'clarity' or 'fluency'), whereas other studies focus only on sentence planning (e.g. 'accuracy', 'adequacy', or 'correctness'). In general, correlations reported by previous work range from weak to strong. The results confirm that metrics can be reliable indicators at system-level (Reiter and Belz, 2009), while they perform less reliably at sentence-level (Stent et al., 2005). Also, the results show that the metrics capture realization better than sentence planning. There is a general trend showing that best-performing metrics tend to be the more complex ones, combining word-overlap, semantic similarity and term frequency weighting. Note, however, that the majority of previous works do not report whether any of the metric correlations are significantly different from each other.

10 Conclusions

This paper shows that state-of-the-art automatic evaluation metrics for NLG systems do not sufficiently reflect human ratings, which stresses the need for human evaluations. This result is opposed to the current trend of relying on automatic evaluation identified in (Gkatzia and Mahamood, 2015).

A detailed error analysis suggests that automatic metrics are particularly weak in distinguishing outputs of medium and good quality, which can be partially attributed to the fact that human judgements and metrics are given on different scales. We also show that metric performance is data- and system-specific.

Nevertheless, our results also suggest that automatic metrics can be useful for error analysis by helping to find cases where the system is performing poorly. In addition, we find reliable results on

[10] Please note that WBMs tend to match against the reference that is closest to the generated output. Therefore, we only include the closest match in Table 5 for simplicity.

system-level, which suggests that metrics can be useful for system development.

11 Future Directions

Word-based metrics make two strong assumptions: They treat human-generated references as a gold standard, which is *correct* and *complete*. We argue that these assumptions are invalid for corpus-based NLG, especially when using crowdsourced datasets. Grammar-based metrics, on the other hand, do not rely on human-generated references and are not influenced by their quality. However, these metrics can be easily manipulated with grammatically correct and easily readable output that is unrelated to the input. We have experimented with combining WBMs and GBMs using ensemble-based learning. However, while our model achieved high correlation with humans within a single domain, its cross-domain performance is insufficient.

Our paper clearly demonstrates the need for more advanced metrics, as used in related fields, including: assessing output quality within the dialogue context, e.g. (Dušek and Jurčíček, 2016); extrinsic evaluation metrics, such as NLG's contribution to task success, e.g. (Rieser et al., 2014; Gkatzia et al., 2016; Hastie et al., 2016); building discriminative models, e.g. (Hodosh and Hockenmaier, 2016), (Kannan and Vinyals, 2017); or reference-less quality prediction as used in MT, e.g. (Specia et al., 2010). We see our paper as a first step towards reference-less evaluation for NLG by introducing grammar-based metrics. In current work (Dušek et al., 2017), we investigate a reference-less quality estimation approach based on recurrent neural networks, which predicts a quality score for a NLG system output by comparing it to the source meaning representation only.

Finally, note that the datasets considered in this study are fairly small (between 404 and 2.3k human references per domain). To remedy this, systems train on de-lexicalised versions (Wen et al., 2015), which bears the danger of ungrammatical lexicalisation (Sharma et al., 2016) and a possible overlap between testing and training set (Lampouras and Vlachos, 2016). There are ongoing efforts to release larger and more diverse data sets, e.g. (Novikova et al., 2016, 2017).

Abstract

Recent neural models have shown significant progress on the problem of generating short descriptive texts conditioned on a small number of database records. In this work, we suggest a slightly more difficult data-to-text generation task, and investigate how effective current approaches are on this task. In particular, we introduce a new, large-scale corpus of data records paired with descriptive documents, propose a series of extractive evaluation methods for analyzing performance, and obtain baseline results using current neural generation methods. Experiments show that these models produce fluent text, but fail to convincingly approximate human-generated documents. Moreover, even templated baselines exceed the performance of these neural models on some metrics, though copy- and reconstruction-based extensions lead to noticeable improvements.

1 Introduction

Over the past several years, neural text generation systems have shown impressive performance on tasks such as machine translation and summarization. As neural systems begin to move toward generating longer outputs in response to longer and more complicated inputs, however, the generated texts begin to display reference errors, intersentence incoherence, and a lack of fidelity to the source material. The goal of this paper is to suggest a particular, long-form generation task in which these challenges may be fruitfully explored, to provide a publically available dataset for this task, to suggest some automatic evaluation metrics, and finally to establish how current, neural text generation methods perform on this task.

A classic problem in natural-language generation (NLG) (Kukich, 1983; McKeown, 1992; Reiter and Dale, 1997) involves taking structured data, such as a table, as input, and producing text that adequately and fluently describes this data as output. Unlike machine translation, which aims for a complete transduction of the sentence to be translated, this form of NLG is typically taken to require addressing (at least) two separate challenges: *what to say*, the selection of an appropriate subset of the input data to discuss, and *how to say it*, the surface realization of a generation (Reiter and Dale, 1997; Jurafsky and Martin, 2014). Traditionally, these two challenges have been modularized and handled separately by generation systems. However, neural generation systems, which are typically trained end-to-end as conditional language models (Mikolov et al., 2010; Sutskever et al., 2011, 2014), blur this distinction.

In this context, we believe the problem of generating multi-sentence summaries of tables or database records to be a reasonable next-problem for neural techniques to tackle as they begin to consider more difficult NLG tasks. In particular, we would like this generation task to have the following two properties: (1) it is relatively easy to obtain fairly clean summaries and their corresponding databases for dataset construction, and (2) the summaries should be primarily focused on conveying the information in the database. This latter property ensures that the task is somewhat congenial to a standard encoder-decoder approach, and, more importantly, that it is reasonable to *evaluate* generations in terms of their fidelity to the database.

One task that meets these criteria is that of generating summaries of sports games from associated box-score data, and there is indeed a long history of NLG work that generates sports game

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2253–2263
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

summaries (Robin, 1994; Tanaka-Ishii et al., 1998; Barzilay and Lapata, 2005). To this end, we make the following contributions:

- We introduce a new large-scale corpus consisting of textual descriptions of basketball games paired with extensive statistical tables. This dataset is sufficiently large that fully data-driven approaches might be sufficient.
- We introduce a series of extractive evaluation models to automatically evaluate output generation performance, exploiting the fact that post-hoc information extraction is significantly easier than generation itself.
- We apply a series of state-of-the-art neural methods, as well as a simple templated generation system, to our data-to-document generation task in order to establish baselines and study their generations.

Our experiments indicate that neural systems are quite good at producing fluent outputs and generally score well on standard word-match metrics, but perform quite poorly at content selection and at capturing long-term structure. While the use of copy-based models and additional reconstruction terms in the training loss can lead to improvements in BLEU and in our proposed extractive evaluations, current models are still quite far from producing human-level output, and are significantly worse than templated systems in terms of content selection and realization. Overall, we believe this problem of data-to-document generation highlights important remaining challenges in neural generation systems, and the use of extractive evaluation reveals significant issues hidden by standard automatic metrics.

2 Data-to-Text Datasets

We consider the problem of generating descriptive text from database records. Following the notation in Liang et al. (2009), let $\boldsymbol{s} = \{r_j\}_{j=1}^{J}$ be a set of records, where for each $r \in \boldsymbol{s}$ we define $r.t \in \mathcal{T}$ to be the *type* of r, and we assume each r to be a binarized relation, where $r.e$ and $r.m$ are a record's entity and value, respectively. For example, a database recording statistics for a basketball game might have a record r such that $r.t$ = POINTS, $r.e$ = RUSSELL WESTBROOK, and $r.m$ = 50. In this case, $r.e$ gives the player in question, and $r.m$ gives the number of points the player scored. From these records, we are interested in generating descriptive text, $\hat{y}_{1:T} = \hat{y}_1, \ldots, \hat{y}_T$ of T words such that $\hat{y}_{1:T}$ is an adequate and fluent summary of $\boldsymbol{s}$. A dataset for training data-to-document systems typically consists of $(\boldsymbol{s}, y_{1:T})$ pairs, where $y_{1:T}$ is a document consisting of a gold (i.e., human generated) summary for database $\boldsymbol{s}$.

Several benchmark datasets have been used in recent years for the text generation task, the most popular of these being WEATHERGOV (Liang et al., 2009) and ROBOCUP (Chen and Mooney, 2008). Recently, neural generation systems have show strong results on these datasets, with the system of Mei et al. (2016) achieving BLEU scores in the 60s and 70s on WEATHERGOV, and BLEU scores of almost 30 even on the smaller ROBOCUP dataset. These results are quite promising, and suggest that neural models are a good fit for text generation. However, the statistics of these datasets, shown in Table 1, indicate that these datasets use relatively simple language and record structure. Furthermore, there is reason to believe that WEATHERGOV is at least partially machine-generated (Reiter, 2017). More recently, Lebret et al. (2016) introduced the WIKIBIO dataset, which is at least an order of magnitude larger in terms of number of tokens and record types. However, as shown in Table 1, this dataset too only contains short (single-sentence) generations, and relatively few records per generation. As such, we believe that early success on these datasets is not yet sufficient for testing the desired linguistic capabilities of text generation at a document-scale.

With this challenge in mind, we introduce a new dataset for data-to-document text generation, available at `https://github.com/harvardnlp/boxscore-data`. The dataset is intended to be comparable to WEATHERGOV in terms of token count, but to have significantly longer target texts, a larger vocabulary space, and to require more difficult content selection.

The dataset consists of two sources of articles summarizing NBA basketball games, paired with their corresponding box- and line-score tables. The data statistics of these two sources, ROTOWIRE and SBNATION, are also shown in Table 1. The first dataset, ROTOWIRE, uses professionally written, medium length game summaries targeted at fantasy basketball fans. The writing is colloquial, but relatively well structured, and targets an audience primarily interested in game

The Atlanta Hawks defeated the Miami Heat , 103 - 95 , at Philips Arena on Wednesday . Atlanta was in desperate need of a win and they were able to take care of a shorthanded Miami team here . Defense was key for the Hawks , as they held the Heat to 42 percent shooting and forced them to commit 16 turnovers . Atlanta also dominated in the paint , winning the rebounding battle , 47 - 34 , and outscoring them in the paint 58 - 26.The Hawks shot 49 percent from the field and assisted on 27 of their 43 made baskets . This was a near wire - to - wire win for the Hawks , as Miami held just one lead in the first five minutes . Miami (7 - 15) are as beat - up as anyone right now and it 's taking a toll on the heavily used starters . Hassan Whiteside really struggled in this game , as he amassed eight points , 12 rebounds and one blocks on 4 - of - 12 shooting ...

Figure 1: An example data-record and document pair from the ROTOWIRE dataset. We show a subset of the game's records (there are 628 in total), and a selection from the gold document. The document mentions only a select subset of the records, but may express them in a complicated manner. In addition to capturing the writing style, a generation system should select similar record content, express it clearly, and order it appropriately.

statistics. The second dataset, SBNATION, uses fan-written summaries targeted at other fans. This dataset is significantly larger, but also much more challenging, as the language is very informal, and often tangential to the statistics themselves. We show some sample text from ROTOWIRE in Figure 1. Our primary focus will be on the ROTOWIRE data.

3 Evaluating Document Generation

We begin by discussing the evaluation of generated documents, since both the task we introduce and the evaluation methods we propose are motivated by some of the shortcomings of current approaches to evaluation. Text generation systems are typically evaluated using a combination of automatic measures, such as BLEU (Papineni et al., 2002), and human evaluation. While BLEU is perhaps a reasonably effective way of evaluating short-form text generation, we found it to be unsatisfactory for document generation. In particular, we note that it primarily rewards fluent text generation, rather than generations that capture the most important information in the database, or that report the information in a particularly coherent way. While human evaluation, on the other hand, is likely ultimately necessary for evaluating generations (Liu et al., 2016; Wu et al., 2016), it is much less convenient than using automatic metrics. Furthermore, we believe that current text generations are sufficiently bad in sufficiently obvious ways that automatic metrics can still be of use in evaluation, and we are not yet at the point of needing to rely solely on human evaluators.

3.1 Extractive Evaluation

To address this evaluation challenge, we begin with the intuition that assessing document quality is easier than document generation. In particular, it is much easier to automatically extract information from documents than to generate documents that accurately convey desired information. As such, simple, high-precision information extraction models can serve as the basis for assessing and better understanding the quality of automatic generations. We emphasize that such an evaluation scheme is most appropriate when evaluating generations (such as basketball game summaries) that are primarily intended to summarize information. While many generation problems do not fall into this category, we believe this to be an interesting category, and one worth focusing on *because* it is amenable to this sort of evaluation.

To see how a simple information extraction system might work, consider the document in Figure 1. We may first extract candidate entity (player, team, and city) and value (number and certain string) pairs $r.e, r.m$ that appear in the text, and then predict the type $r.t$ (or none) of each candidate pair. For example, we might extract the entity-value pair ("Miami Heat", "95") from the first sentence in Figure 1, and then predict that the *type* of this pair is POINTS, giving us an extracted record r such that $(r.e, r.m, r.t) = (\text{MIAMI HEAT}, 95, \text{POINTS})$. Indeed, many relation extraction systems reduce relation extraction to multi-class classification precisely in this way (Zhang, 2004; Zhou et al., 2008; Zeng et al., 2014; dos Santos et al., 2015).

More concretely, given a document $\hat{y}_{1:T}$, we consider all pairs of word-spans in each sentence that represent possible entities e and values m. We then model $p(r.t \mid e, m; \boldsymbol{\theta})$ for each pair, using $r.t = \epsilon$ to indicate unrelated pairs. We use architectures similar to those discussed in Collobert et al. (2011) and dos Santos et al. (2015) to parameterize this probability; full details are given in the Appendix.

Importantly, we note that the $(\boldsymbol{s}, y_{1:T})$ pairs typically used for training data-to-document systems are also sufficient for training the information extraction model presented above, since we can obtain (partial) supervision by simply checking whether a candidate record lexically matches a record in $\boldsymbol{s}$.[1] However, since there may be multiple records $r \in \boldsymbol{s}$ with the same e and m but with different types $r.t$, we will not always be able to determine the type of a given entity-value pair found in the text. We therefore train our classifier to minimize a latent-variable loss: for all document spans e and m, with observed types $t(e,m) = \{r.t : r \in \boldsymbol{s}, r.e = e, r.m = m\}$ (possibly $\{\epsilon\}$), we minimize

$$\mathcal{L}(\boldsymbol{\theta}) = -\sum_{e,m} \log \sum_{t' \in t(e,m)} p(r.t = t' \mid e, m; \boldsymbol{\theta}).$$

We find that this simple system trained in this way is quite accurate at predicting relations. On the ROTOWIRE data it achieves over 90% accuracy on held-out data, and recalls approximately 60% of the relations licensed by the records.

3.2 Comparing Generations

With a sufficiently precise relation extraction system, we can begin to evaluate how well an automatic generation $\hat{y}_{1:T}$ has captured the information in a set of records $\boldsymbol{s}$. In particular, since the predictions of a precise information extraction system serve to align entity-mention pairs in the text with database records, this alignment can be used both to evaluate a generation's content selection ("what the generation says"), as well as content placement ("how the generation says it").

We consider in particular three induced metrics:

- Content Selection (CS): precision and recall of unique relations r extracted from $\hat{y}_{1:T}$ that are also extracted from $y_{1:T}$. This measures how well the generated document matches the gold document in terms of selecting which records to generate.
- Relation Generation (RG): precision and number of unique relations r extracted from $\hat{y}_{1:T}$ that also appear in $\boldsymbol{s}$. This measures how well the system is able to generate text containing factual (i.e., correct) records.
- Content Ordering (CO): normalized Damerau-Levenshtein Distance (Brill and Moore, 2000)[2] between the sequences of records extracted from $y_{1:T}$ and that extracted from $\hat{y}_{1:T}$. This measures how well the system orders the records it chooses to discuss.

We note that CS primarily targets the "what to say" aspect of evaluation, CO targets the "how to say it" aspect, and RG targets both.

We conclude this section by contrasting the automatic evaluation we have proposed with recently proposed *adversarial evaluation* approaches, which also advocate automatic metrics backed by classification (Bowman et al., 2016; Kannan and Vinyals, 2016; Li et al., 2017). Unlike adversarial evaluation, which uses a black-box classifier to determine the quality of a generation, our metrics are defined with respect to the

[1] Alternative approaches explicitly align the document with the table for this task (Liang et al., 2009).

[2] DLD is a variant of Levenshtein distance that allows transpositions of elements; it is useful in comparing the ordering of sequences that may not be permutations of the same set (which is a requirement for measures like Kendall's Tau).

predictions of an information extraction system. Accordingly, our metrics are quite interpretable, since by construction it is always possible to determine which fact (i.e., entity-value pair) in the generation is determined by the extractor to not match the database or the gold generation.

4 Neural Data-to-Document Models

In this section we briefly describe the neural generation methods we apply to the proposed task. As a base model we utilize the now standard attention-based encoder-decoder model (Sutskever et al., 2014; Cho et al., 2014; Bahdanau et al., 2015). We also experiment with several recent extensions to this model, including copy-based generation, and training with a source reconstruction term in the loss (in addition to the standard per-target-word loss).

Base Model For our base model, we map each record $r \in \boldsymbol{s}$ into a vector $\tilde{\boldsymbol{r}}$ by first embedding $r.t$ (e.g., POINTS), $r.e$ (e.g., RUSSELL WESTBROOK), and $r.m$ (e.g., 50), and then applying a 1-layer MLP (similar to Yang et al. (2016)).[3] Our source data-records are then represented as $\tilde{\boldsymbol{s}} = \{\tilde{\boldsymbol{r}}_j\}_{j=1}^{J}$. Given $\tilde{\boldsymbol{s}}$, we use an LSTM decoder with attention and input-feeding, in the style of Luong et al. (2015), to compute the probability of each target word, conditioned on the previous words and on $\boldsymbol{s}$. The model is trained end-to-end to minimize the negative log-likelihood of the words in the gold text $y_{1:T}$ given corresponding source material $\boldsymbol{s}$.

Copying There has been a surge of recent work involving augmenting encoder-decoder models to copy words directly from the source material on which they condition (Gu et al., 2016; Gülçehre et al., 2016; Merity et al., 2016; Jia and Liang, 2016; Yang et al., 2016). These models typically introduce an additional binary variable z_t into the per-timestep target word distribution, which indicates whether the target word $\hat{y}_t$ is copied from the source or generated:

$$p(\hat{y}_t \mid \hat{y}_{1:t-1}, \boldsymbol{s}) = \sum_{z \in \{0,1\}} p(\hat{y}_t, z_t = z \mid \hat{y}_{1:t-1}, \boldsymbol{s}).$$

In our case, we assume that target words are copied from the *value* portion of a record r; that is, a copy implies $\hat{y}_t = r.m$ for some r and t.

Joint Copy Model The models of Gu et al. (2016) and Yang et al. (2016) parameterize the *joint* distribution table over $\hat{y}_t$ and z_t directly:

$$p(\hat{y}_t, z_t \mid \hat{y}_{1:t-1}, \boldsymbol{s}) \propto \begin{cases} \mathrm{copy}(\hat{y}_t, \hat{y}_{1:t-1}, \boldsymbol{s}) & z_t = 1, \hat{y}_t \in \boldsymbol{s} \\ 0 & z_t = 1, \hat{y}_t \notin \boldsymbol{s} \\ \mathrm{gen}(\hat{y}_t, \hat{y}_{1:t-1}, \boldsymbol{s}) & z_t = 0, \end{cases}$$

where copy and gen are functions parameterized in terms of the decoder RNN's hidden state that assign scores to words, and where the notation $\hat{y}_t \in \boldsymbol{s}$ indicates that $\hat{y}_t$ is equal to $r.m$ for some $r \in \boldsymbol{s}$.

Conditional Copy Model Gülçehre et al. (2016), on the other hand, decompose the joint probability as:

$$p(\hat{y}_t, z_t \mid \hat{y}_{1:t-1}, \boldsymbol{s}) = \begin{cases} p_{\mathrm{copy}}(\hat{y}_t \mid z_t, \hat{y}_{1:t-1}, \boldsymbol{s})\, p(z_t \mid \hat{y}_{1:t-1}, \boldsymbol{s}) & z_t{=}1 \\ p_{\mathrm{gen}}(\hat{y}_t \mid z_t, \hat{y}_{1:t-1}, \boldsymbol{s})\, p(z_t \mid \hat{y}_{1:t-1}, \boldsymbol{s}) & z_t{=}0, \end{cases}$$

where an MLP is used to model $p(z_t \mid \hat{y}_{1:t-1}, \boldsymbol{s})$.

Models with copy-decoders may be trained to minimize the negative log marginal probability, marginalizing out the latent-variable z_t (Gu et al., 2016; Yang et al., 2016; Merity et al., 2016). However, if it is known which target words y_t are copied, it is possible to train with a loss that does not marginalize out the latent z_t. Gülçehre et al. (2016), for instance, assume that any target word y_t that also appears in the source is copied, and train to minimize the negative joint log-likelihood of the y_t and z_t.

In applying such a loss in our case, we again note that there may be multiple records r such that $r.m$ appears in $\hat{y}_{1:T}$. Accordingly, we slightly modify the p_{copy} portion of the loss of Gülçehre et al. (2016) to sum over all matched records. In particular, we model the probability of relations $r \in \boldsymbol{s}$ such that $r.m = y_t$ and $r.e$ is in the same sentence as $r.m$. Letting $r(y_t) = \{r \in \boldsymbol{s} : r.m = y_t, \mathrm{same{-}sentence}(r.e, r.m)\}$, we have:

$$p_{\mathrm{copy}}(y_t \mid z_t, y_{1:t-1}, \boldsymbol{s}) = \sum_{r \in r(y_t)} p(r \mid z_t, y_{1:t-1}, \boldsymbol{s}).$$

We note here that the key distinction for our purposes between the Joint Copy model and the Conditional Copy model is that the latter *conditions* on whether there is a copy or not, and so in p_{copy} the

[3] We also include an additional feature for whether the player is on the home- or away-team.

source records compete only with each other. In the Joint Copy model, however, the source records also compete with words that cannot be copied. As a result, training the Conditional Copy model with the supervised loss of Gülçehre et al. (2016) can be seen as training with a word-level reconstruction loss, where the decoder is trained to choose the record in $\boldsymbol{s}$ that gives rise to y_t.

Reconstruction Losses Reconstruction-based techniques can also be applied at the document- or sentence-level during training. One simple approach to this problem is to utilize the hidden states of the decoder to try to reconstruct the database. A fully differentiable approach using the decoder hidden states has recently been successfully applied to neural machine translation by Tu et al. (2017). Unlike copying, this method is applied only at training, and attempts to learn decoder hidden states with broader coverage of the input data.

In adopting this reconstruction approach we segment the decoder hidden states $\boldsymbol{h}_t$ into $\lceil \frac{T}{B} \rceil$ contiguous blocks of size at most B. Denoting a single one of these hidden state blocks as $\boldsymbol{b}_i$, we attempt to predict each field value in some record $r \in \boldsymbol{s}$ from $\boldsymbol{b}_i$. We define $p(r.e, r.m \mid \boldsymbol{b}_i)$, the probability of the entity and value in record r given $\boldsymbol{b}_i$, to be $\mathrm{softmax}(f(\boldsymbol{b}_i))$, where f is a parameterized function of $\boldsymbol{b}_i$, which in our experiments utilize a convolutional layer followed by an MLP; full details are given in the Appendix. We further extend this idea and predict K records in $\boldsymbol{s}$ from $\boldsymbol{b}_i$, rather than one. We can train with the following reconstruction loss for a particular $\boldsymbol{b}_i$:

$$\begin{aligned}\mathcal{L}(\boldsymbol{\theta}) &= -\sum_{k=1}^{K} \min_{r \in \boldsymbol{s}} \log p_k(r \mid \boldsymbol{b}_i; \boldsymbol{\theta}) \\ &= -\sum_{k=1}^{K} \min_{r \in \boldsymbol{s}} \sum_{x \in \{e,m,t\}} \log p_k(r.x \mid \boldsymbol{b}_i; \boldsymbol{\theta}),\end{aligned}$$

where p_k is the k'th predicted distribution over records, and where we have modeled each component of r independently. This loss attempts to make the *most* probable record in $\boldsymbol{s}$ given $\boldsymbol{b}_i$ more probable. We found that augmenting the above loss with a term that penalizes the total variation distance (TVD) between the p_k to be helpful.[4] Both $\mathcal{L}(\boldsymbol{\theta})$ and the TVD term are simply added to the standard negative log-likelihood objective at training time.

5 Experimental Methods

In this section we highlight a few important details of our models and methods; full details are in the Appendix. For our ROTOWIRE models, the record encoder produces $\tilde{\boldsymbol{r}}_j$ in $\mathbb{R}^{600}$, and we use a 2-layer LSTM decoder with hidden states of the same size as the $\tilde{\boldsymbol{r}}_j$, and dot-product attention and input-feeding in the style of Luong et al. (2015). Unlike past work, we use two identically structured attention layers, one to compute the standard generation probabilities (gen or p_{gen}), and one to produce the scores used in copy or p_{copy}.

We train the generation models using SGD and truncated BPTT (Elman, 1990; Mikolov et al., 2010), as in language modeling. That is, we split each $y_{1:T}$ into contiguous blocks of length 100, and backprop both the gradients with respect to the current block as well as with respect to the encoder parameters for each block.

Our extractive evaluator consists of an ensemble of 3 single-layer convolutional and 3 single-layer bidirectional LSTM models. The convolutional models concatenate convolutions with kernel widths 2, 3, and 5, and 200 feature maps in the style of (Kim, 2014). Both models are trained with SGD.

Templatized Generator In addition to neural baselines, we also use a problem-specific, template-based generator. The template-based generator first emits a sentence about the teams playing in the game, using a templatized sentence taken from the training set:

> The `<team1>` (`<wins1>`-`<losses1>`) defeated the `<team2>` (`<wins2>`-`<losses2>`) `<pts1>`-`<pts2>`.

Then, 6 player-specific sentences of the following form are emitted (again adapting a simple sentence from the training set):

> `<player>` scored `<pts>` points (`<fgm>`-`<fga>` FG, `<tpm>`-`<tpa>` 3PT, `<ftm>`-`<fta>` FT) to go with `<reb>` rebounds.

[4] Penalizing the TVD between the p_k might be useful if, for instance, K is too large, and only a smaller number of records can be predicted from $\boldsymbol{b}_i$. We also experimented with *encouraging*, rather than penalizing the TVD between the p_k, which might make sense if we were worried about ensuring the p_k captured different records.

The 6 highest-scoring players in the game are used to fill in the above template. Finally, a typical end sentence is emitted:

> The `<team1>`' next game will be at home against the Dallas Mavericks, while the `<team2>` will travel to play the Bulls.

Code implementing all models can be found at `https://github.com/harvardnlp/data2text`. Our encoder-decoder models are based on OpenNMT (Klein et al., 2017).

6 Results

We found that all models performed quite poorly on the SBNATION data, with the best model achieving a validation perplexity of 33.34 and a BLEU score of 1.78. This poor performance is presumably attributable to the noisy quality of the SBNATION data, and the fact that many documents in the dataset focus on information not in the box- and line-scores. Accordingly, we focus on ROTOWIRE in what follows.

The main results for the ROTOWIRE dataset are shown in Table 2, which shows the performance of the models in Section 4 in terms of the metrics defined in Section 3.2, as well as in terms of perplexity and BLEU.

6.1 Discussion

There are several interesting relationships in the development portion of Table 2. First we note that the Template model scores very poorly on BLEU, but does quite well on the extractive metrics, providing an upper-bound for how domain knowledge could help content selection and generation. All the neural models make significant improvements terms of BLEU score, with the conditional copying with beam search performing the best, even though all the neural models achieve roughly the same perplexity.

The extractive metrics provide further insight into the behavior of the models. We first note that on the gold documents $y_{1:T}$, the extractive model reaches 92% precision. Using the Joint Copy model, generation only has a record generation (RG) precision of 47% indicating that relationships are often generated incorrectly. The best Conditional Copy system improves this value to 71%, a significant improvement and potentially the cause of the improved BLEU score, but still far below gold.

> The Utah Jazz (38 - 26) defeated the Houston Rockets (38 - 26) 117 - 91 on Wednesday at Energy Solutions Arena in Salt Lake City . The Jazz got out to a quick start in this one , out - scoring the Rockets 31 - 15 in the first quarter alone . Along with the quick start , the Rockets were the superior shooters in this game , going 54 percent from the field and 43 percent from the three - point line , while the Jazz went 38 percent from the floor and a meager 19 percent from deep . The Rockets were able to out - rebound the Rockets 49 - 49 , giving them just enough of an advantage to secure the victory in front of their home crowd . The Jazz were led by the duo of Derrick Favors and James Harden . Favors went 2 - for - 6 from the field and 0 - for - 1 from the three - point line to score a game - high of 15 points , while also adding four rebounds and four assists ....

Figure 2: Example document generated by the Conditional Copy system with a beam of size 5. Text that accurately reflects a record in the associated box- or line-score is highlighted in blue, and erroneous text is highlighted in red.

Notably, content selection (CS) and content ordering (CO) seem to have no correlation at all with BLEU. There is some improvement with CS for the conditional model or reconstruction loss, but not much change as we move to beam search. CO actually gets worse as beam search is utilized, possibly a side effect of generating more records (RG#). The fact that these scores are much worse than the simple templated model indicates that further research is needed into better copying alone for content selection and better long term content ordering models.

Test results are consistent with development results, indicating that the Conditional Copy model is most effective at BLEU, RG, and CS, and that reconstruction is quite helpful for improving the joint model.

6.2 Human Evaluation

We also undertook two human evaluation studies, using Amazon Mechanical Turk. The first study attempted to determine whether generations considered to be more precise by our metrics were also considered more precise by human raters. To accomplish this, raters were presented with a particular NBA game's box score and line score, as well as with (randomly selected) sentences from summaries generated by our different models for those games. Raters were then asked to count how many facts in each sentence were supported by records in the box or line scores, and how many were contradicted. We randomly selected 20 distinct games to present to raters, and a total of 20 generated sentences per game were evaluated by raters. The left two columns of Table 3 contain the

		Development						
		RG		CS		CO	PPL	BLEU
Beam	Model	P%	#	P%	R%	DLD%		
	Gold	91.77	12.84	100	100	100	1.00	100

B=1	Joint Copy	47.55	7.53	20.53	22.49	8.28	7.46	10.41
	Joint Copy + Rec	57.81	8.31	23.65	23.30	9.02	7.25	10.00
	Joint Copy + Rec + TVD	60.69	8.95	23.63	24.10	8.84	7.22	12.78
	Conditional Copy	68.94	9.09	25.15	22.94	9.00	7.44	13.31
B=5	Joint Copy	47.00	10.67	16.52	26.08	7.28	7.46	10.23
	Joint Copy + Rec	62.11	10.90	21.36	26.26	9.07	7.25	10.85
	Joint Copy + Rec + TVD	57.51	11.41	18.28	25.27	8.05	7.22	12.04
	Conditional Copy	71.07	12.61	21.90	27.27	8.70	7.44	14.46
		Test						
	Template	99.30	49.61	18.50	64.70	8.04	N/A	6.78
	Joint Copy + Rec (B=5)	61.23	11.02	21.56	26.45	9.06	7.47	10.88
	Joint Copy + Rec + TVD (B=1)	60.27	9.18	23.11	23.69	8.48	7.42	12.96
	Conditional Copy (B=5)	71.82	12.82	22.17	27.16	8.68	7.67	14.49

Table 2: Performance of induced metrics on gold and system outputs of RotoWire development and test data. Columns indicate Record Generation (RG) precision and count, Content Selection (CS) precision and recall, Count Ordering (CO) in normalized Damerau-Levenshtein distance, perplexity, and BLEU. These first three metrics are described in Section 3.2. Models compare Joint and Conditional Copy also with addition Reconstruction loss and Total Variation Distance extensions (described in Section 4).

average numbers of supporting and contradicting facts per sentence as determined by the raters, for each model. We see that these results are generally in line with the RG and CS metrics, with the Conditional Copy model having the highest number of supporting facts, and the reconstruction terms significantly improving the Joint Copy models.

Using a Tukey HSD post-hoc analysis of an ANOVA with the number of contradicting facts as the dependent variable and the generating model and rater id as independent variables, we found significant ($p < 0.01$) pairwise differences in contradictory facts between the gold generations and all models except "Copy+Rec+TVD," as well as a significant difference between "Copy+Rec+TVD" and "Copy". We similarly found a significant pairwise difference between "Copy+Rec+TVD" and "Copy" for number of supporting facts.

Our second study attempted to determine whether generated summaries differed in terms of how natural their *ordering* of records (as captured, for instance, by the DLD metric) is. To test this, we presented raters with random summaries generated by our models and asked them to rate the naturalness of the ordering of facts in the summaries on a 1-7 Likert scale. 30 random summaries were used in this experiment, each rated 3 times by distinct raters. The average Likert ratings are shown in the rightmost column of Table 3.

	# Supp.	# Cont.	Order Rat.
Gold	2.04	0.70	5.19
Joint Copy	1.65	2.31	3.90
Joint Copy + Rec	2.33	1.83	4.43
Joint Copy + Rec +TVD	2.43	1.16	4.18
Conditional Copy	3.05	1.48	4.03

Table 3: Average rater judgment of number of box score fields supporting (left column) or contradicting (middle column) a generated sentence, and average rater Likert rating for the naturalness of a summary's ordering (right column). All generations use B=1.

While it is encouraging that the gold summaries received a higher average score than the generated summaries (and that the reconstruction term again improved the Joint Copy model), a Tukey HSD analysis similar to the one presented above revealed no significant pairwise differences.

6.3 Qualitative Example

Figure 2 shows a document generated by the Conditional Copy model, using a beam of size 5. This particular generation evidently has several nice properties: it nicely learns the colloquial style of the text, correctly using idioms such as "19 percent from deep." It is also partially accurate in its use of the records; we highlight in blue when it generates text that is licensed by a record in the associated box- and line-scores.

At the same time, the generation also contains major logical errors. First, there are basic copying mistakes, such as flipping the teams' win/loss records. The system also makes obvious semantic errors; for instance, it generates the phrase "the Rockets were able to out-rebound the Rockets." Finally, we see the model hallucinates factual statements, such as "in front of their home crowd," which is presumably likely according to the language model, but ultimately incorrect (and not supported by anything in the box- or line-scores). In practice, our proposed extractive evaluation will pick up on many errors in this passage. For instance, "four assists" is an RG error, repeating the Rockets' rebounds could manifest in a lower CO score, and incorrectly indicating the win/loss records is a CS error.

7 Related Work

In this section we note additional related work not noted throughout. Natural language generation has been studied for decades (Kukich, 1983; McKeown, 1992; Reiter and Dale, 1997), and generating summaries of sports games has been a topic of interest for almost as long (Robin, 1994; Tanaka-Ishii et al., 1998; Barzilay and Lapata, 2005).

Historically, research has focused on both content selection ("what to say") (Kukich, 1983; McKeown, 1992; Reiter and Dale, 1997; Duboue and McKeown, 2003; Barzilay and Lapata, 2005), and surface realization ("how to say it") (Goldberg et al., 1994; Reiter et al., 2005) with earlier work using (hand-built) grammars, and later work using SMT-like approaches (Wong and Mooney, 2007) or generating from PCFGs (Belz, 2008) or other formalisms (Soricut and Marcu, 2006; White et al., 2007). In the late 2000s and early 2010s, a number of systems were proposed that did both (Liang et al., 2009; Angeli et al., 2010; Kim and Mooney, 2010; Lu and Ng, 2011; Konstas and Lapata, 2013).

Within the world of neural text generation, some recent work has focused on conditioning language models on tables (Yang et al., 2016), and generating short biographies from Wikipedia Tables (Lebret et al., 2016; Chisholm et al., 2017). Mei et al. (2016) use a neural encoder-decoder approach on standard record-based generation datasets, obtaining impressive results, and motivating the need for more challenging NLG problems.

8 Conclusion and Future Work

This work explores the challenges facing neural data-to-document generation by introducing a new dataset, and proposing various metrics for automatically evaluating content selection, generation, and ordering. We see that recent ideas in copying and reconstruction lead to improvements on this task, but that there is a significant gap even between these neural models and templated systems. We hope to motivate researchers to focus further on generation problems that are relevant both to content selection and surface realization, but may not be reflected clearly in the model's perplexity.

Future work on this task might include approaches that process or attend to the source records in a more sophisticated way, generation models that attempt to incorporate semantic or reference-related constraints, and approaches to conditioning on facts or records that are not as explicit in the box- and line-scores.

Abstract

In this paper, we present a set of computational methods to identify the likeliness of a word being borrowed, based on the signals from social media. In terms of Spearman's correlation values, our methods perform more than two times better (~ 0.62) in predicting the borrowing likeliness compared to the best performing baseline (~ 0.26) reported in literature. Based on this likeliness estimate we asked annotators to re-annotate the language tags of foreign words in predominantly native contexts. In 88% of cases the annotators felt that the foreign language tag should be replaced by native language tag, thus indicating a huge scope for improvement of automatic language identification systems.

1 Introduction

In social media communication, multilingual people often switch between languages, a phenomenon known as *code-switching* or *code-mixing* (Auer, 1984). This makes *language identification and tagging*, which is perhaps a prerequisite for almost all other language processing tasks that follow, a challenging problem (Barman et al., 2014). In code-mixing people are subconsciously aware of the foreign origin of the code-mixed word or the phrase. A related but linguistically and cognitively distinct phenomenon is *lexical borrowing* (or simply, *borrowing*), where a word or phrase from a foreign language say L_2 is used as a part of the vocabulary of native language say L_1. For instance, in Dutch, the English word "sale" is now used more frequently than the Dutch equivalent "uitverkoop". Some English words like "shop" are even inflected in Dutch as "shoppen" and heavily used. While it is difficult in general to ascertain whether a foreign word or phrase used in an utterance is borrowed or just an instance of code-mixing (Bali et al., 2014), one tell tale sign is that only proficient multilinguals can code-mix, while even monolingual speakers can use borrowed words because, by definition, these are part of the vocabulary of a language. In other words, just because an English speaker understands and uses the word "tortilla" does not imply that she can speak or understand Spanish. A borrowed word from L_2 initially appears frequently in speech, then gradually in print media like newspaper and finally it loses its origin's identity and is used in L_1 resulting in an inclusion in the dictionary of L_1 (Myers-Scotton, 2002; Thomason, 2003). Borrowed words often take several years before they formally become part of L_1 dictionary. This motivates our research question "is early-stage automatic identification of likely to be borrowed words possible?". This is known to be a hard problem because (i) it is a socio-linguistic phenomenon closely related to acceptability and frequency, (ii) borrowing is a dynamic process; new borrowed words enter the lexicon of a language as old words, both native and borrowed, might slowly fade away from usage, and (iii) it is a population level phenomenon that necessitates data from a large portion of the population unlike standard natural language corpora that typically comes from a very small set of authors. Automatic identification of borrowed words in social media content (SMC) can improve language tagging by recommending the tagger to tag the language of the borrowed words as L_1 instead

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2264–2274

of L_2. The above reasons motivate us to resort to the social media (in particular, Twitter), where a large population of bilingual/multilingual speakers are known to often tweet in code-mixed colloquial languages (Carter et al., 2013; Solorio et al., 2014; Vyas et al., 2014; Jurgens et al., 2017; Rijhwani et al., 2017). We designed our methodology to work for any pair of languages L_1 and L_2 subject to the availability of sufficient SMC. In the current study, we consider Hindi as L_1 and English as L_2.

The main stages of our research are as follows:

Metrics to quantify the likeliness of borrowing from social media signals: We define three novel and closely similar metrics that serve as social signals indicating the likeliness of borrowing. We compare the likeliness of borrowing as predicted by our model and a baseline model with that from the ground truth obtained from human judges.

Ground truth generation: We launch an extensive survey among 58 human judges of various age groups and various educational backgrounds to collect responses indicating if each of the candidate foreign word is likely borrowed.

Application: We randomly selected some words that have a high, low and medium borrowing likeliness as predicted by our metrics. Further, we randomly selected one tweet for each of the chosen words. The chosen words in almost all of these tweets have L_2 as their language tag while a majority of the surrounding words have a tag L_1. We asked expert annotators to re-evaluate the language tags of the chosen words and indicate if they would prefer to switch this tag from L_2 from L_1.

Finally, our key results are outlined below:

1. We obtained the Spearman's rank correlation between the ground-truth ranking and the ranking based on our metrics as ~ 0.62 for all the three variants which is more than double the value (~ 0.26) if we use the most competitive baseline (Bali et al., 2014) available in the literature.

2. Interestingly, the responses of the judges in the age group below 30 seem to correspond even better with our metrics. Since language change is brought about mostly by the younger population, this might possibly mean that our metrics are able to capture the early signals of borrowing.

3. Those users that mix languages the least in their tweets present the best signals of borrowing in case they do mix the languages (correlation of our metrics estimated from the tweets of these users with that of the ground truth is ~ 0.65).

4. Finally, we obtain an excellent re-annotation accuracy of 88% for the words falling in the surely borrowed category as predicted by our metrics.

2 Related work

In linguistics *code-mixing* and *borrowing* have been studied under the broader scope of language change and evolution. Linguists have for a long time focused on the sociological and the conversational necessity of borrowing and mixing in multilingual communities (see Auer (1984) and Muysken (1996) for a review). In particular, Sankoff et al. (1990) describes the complexity of choosing features that are indicative of borrowing. This work further showed that it is not always true that only highly frequent words are borrowed; nonce words could also be borrowed along with the frequent words. More recently, (Nzai et al., 2014) analyzed the formal conversation of Spanish-English multilingual people and found that code mixing/borrowing is not only restricted to daily speech but is also prevalent in formal conversations. (Hadei, 2016) showed that phonological integration could be evaluated to understand the phenomenon of word borrowing. Along similar lines, (Sebonde, 2014) showed morphological and syntactic features could be good indicators for numerical borrowings. (Senaratne, 2013) reported that in many languages English words are likely to be borrowed in both formal and semi-formal text.

Mixing in computer mediated communication and social media: (Sotillo, 2012) investigated various types of code-mixing in a corpora of 880 SMS text messages. The author observed that most often mixing takes place at the beginning of a sentence as well as through simple insertions. Similar observations about chat and email messages have been reported in (Bock, 2013; Negrón, 2009). However, studies of code-mixing with Chinese-English bilinguals from Hong Kong (Li, 2009) and Macao (San, 2009) brings forth results that contrast the aforementioned findings and indicate that in these societies code-mixing is driven more by linguistic than social motivations.

Recently, the advent of social media has immensely propelled the research on code-mixing and borrowing as a dynamic social phenomena. (Hidayat, 2012) noted that in Facebook, users mostly preferred inter-sentential mixing and showed that 45% of the mixing originated from real lexical needs, 40% was used for conversations on a particular topic and the rest 5% for content clarification. In contrast, (Das and Gambäck, 2014) showed that in case of Facebook messages, intra-sentential mixing accounted for more than half of the cases while inter-sentential mixing accounted only for about one-third of the cases. In fact, in the First Workshop on *Computational Approaches to Code Switching* a shared task on code-mixing in tweets was launched and four different code-mixed corpora were collected from Twitter as a part of the shared task (Solorio et al., 2014). Language identification task has also been handled for English-Hindi and English-Bengali code-mixed tweets in (Das and Gambäck, 2013). Part-of-speech tagging have been recently done for code-mixed English-Hindi tweets (Solorio and Liu, 2008; Vyas et al., 2014).

Diachronic studies: As an aside, it is interesting to note that the availability of huge volumes of timestamped data (tweet streams, digitized books) is now making it possible to study various linguistic phenomena quantitatively over different timescales. For instance, (Sagi et al., 2009) uses latent semantic analysis for detection and tracking of changes in word meaning, whereas (Fremann and Lapata, 2016) presents a Bayesian approach for the same problem. (Peirsman et al., 2010) presents a distributed model for automatic identification of lexical variation between language varieties. (Bamman and Crane, 2011) discusses a method for automatically identifying word sense variation in a dated collection of historical books . (Mitra et al., 2014) presents a computational method for automatic identification of change in word senses across different timescales. (Cook et al., 2014) presents a method for novel sense identification of words over time.

Despite these diverse and rich research agendas in the field of code-switching and lexical dynamics, there has not been much attempt to quantify the likeliness of borrowing of foreign words in a language. The only work that makes an attempt in this direction is (Bali et al., 2014), which is described in detail in Sec 3.1. One of the primary challenges faced by any quantitative research on lexical borrowing is that borrowing is a social phenomenon, and therefore, it is difficult to identify suitable indicators of such a lexical diffusion process unless one has access to a large population-level data. In this work, we show for the first time how certain simple and closely related signals encoding the language usage of social media users can help us construe appropriate metrics to quantify the likeliness of borrowing of a foreign word.

3 Methodology

In this section, we present the baseline metric and propose three new metrics that quantify the likeliness of borrowing.

3.1 Baseline metric

Baseline metric – We consider the $log(\frac{F_{L_2}}{F_{L_1}})$ value proposed in (Bali et al., 2014) as the baseline metric. Here F_{L_2} denotes the frequency of the L_1 transliterated form of the word w in the standard L_1 newspaper corpus. F_{L_1}, on the other hand, denotes the frequency of the L_1 translation of the word w in the same newspaper corpus. For our experiments discussed in the later sections, both the transliteration and the translation of the words have been done by a set of volunteers who are native L_1 speakers. The authors in (Bali et al., 2014) claim that the more positive the value of this metric is for a word w, the higher is the likeliness of its being borrowed. The more negative the value is, the higher are the chances that the word w is an instance of code-mixing.
Ranking – Based on the values obtained from the above metric for a set of target words, we rank these words; words with high positive values feature at the top of the rank list and words with high negative values feature at the bottom of the list. For two words having the same $log(\frac{F_{L_2}}{F_{L_1}})$ value, we resolve the conflict by assigning each of these the average of their two rank positions. In a subsequent section, we shall compare this rank list with the one obtained from the ground truth responses.

3.2 Proposed metric

In this section, we present three novel and closely related metrics based on the language usage patterns of the users of social media (in specific, Twitter). In order to define our metrics, we need all the words to be language tagged. The different tags that a word can have are: L_1, L_2, *NE* (Named Entity) and *Others*. Based on the word level tag, we also create a tweet level tag as follows:

1. L_1: Almost every word ($> 90\%$) in the tweet is tagged as L_1.
2. L_2: Almost every word ($> 90\%$) in the tweet is tagged as L_2.

3. CML_1: Code-mixed tweet but majority (i.e., $> 50\%$) of the words are tagged as L_1.
4. CML_2: Code-mixed tweet but majority (i.e., $> 50\%$) of the words are tagged as L_2.
5. *CMEQ*: Code-mixed tweet having very similar number of words tagged as L_1 and L_2 respectively.
6. *Code Switched*: There is a trail of L_1 words followed by a trail of L_2 words or vice versa.

Using the above classification, we define the following metrics:

Unique User Ratio (UUR) – The Unique User Ratio for word usage across languages is defined as follows:

$$UUR(w) = \frac{U_{L_1} + U_{CML_1}}{U_{L_2}} \tag{1}$$

where U_{L_1} (U_{L_2}, U_{CML_1}) is the number of unique users who have used the word w in a L_1 (L_2, CML_1) tweet at least once.

Unique Tweet Ratio (UTR) – The Unique Tweet Ratio for word usage across languages is defined as follows:

$$UTR(w) = \frac{T_{L_1} + T_{CML_1}}{T_{L_2}} \tag{2}$$

where T_{L_1} (T_{L_2}, T_{CML_1}) is the total number of L_1 (L_2, CML_1) tweets which contain the word w.

Unique Phrase Ratio (UPR) – The Unique Phrase Ratio for word usage across languages is defined as follows:

$$UPR(w) = \frac{P_{L_1}}{P_{L_2}} \tag{3}$$

where P_{L_1} (P_{L_2}) is the number of L_1 (L_2) phrases which contain the word w. Note that unlike the definitions of UUR and UTR that exploit the word level language tags, the definition of UPR exploits the phrase level language tags.

Ranking – We prepare a separate rank list of the target words based on each of the three proposed metrics – UUR, UTR and UPR. The higher the value of each of this metric the higher is the likeliness of the word w to be borrowed and higher up it is in the rank list. In a subsequent section, we shall compare these rank lists with the one prepared from the ground truth responses.

4 Experiments

In this section we discuss the dataset for our experiments, the evaluation criteria and the ground truth preparation scheme.

4.1 Datasets and preprocessing

In this study, we consider code-mixed tweets gathered from Hindi-English bilingual Twitter users in order to study the effectiveness of our proposed metrics. The native language L_1 is Hindi and the foreign language L_2 is English. To bootstrap the data collection process, we used the language tagged tweets presented in (Rudra et al., 2016). In addition to this, we also crawled tweets (between Nov 2015 and Jan 2016) related to 28 hashtags representing different Indian contexts covering important topics such as sports, religion, movies, politics etc. This process results in a set of 811981 tweets. We language-tag (see details later in this section) each tweet so crawled and find that there are 3577 users who use mixed language for tweeting. Next, we systematically crawled the time lines of these 3577 users between Feb 2016 and March 2016 to gather more mixed language tweets. Using this two step process we collected a total of 1550714 distinct tweets. From this data, we filtered out tweets that are not written in romanized script, tweets having only URLs and tweets having empty content. Post filtering we obtained 725173, tweets which we use for the rest of the analysis. The datasets can be downloaded from `http://cnerg.org/borrow`

Language tagging: We tag each word in a tweet with the language of its origin using the method outlined in (Gella et al., 2013). *Hi* represents a predominantly Hindi tweet, *En* represents a predominantly English tweet, *CMH* (*CME*) represents code-mixed tweets with more Hindi (English) words, *CMEQ* represents code-mixed tweets with almost equal number of Hindi and English words and *CS* represents code-switched tweets (the number and % of tweets in each of the above six categories are presented in the supplementary material). Like the word level, the tagger also provides a phrase level language tag. Once again, the different tags that an entire phrase can have are: *En*, *Hi* and *Oth* (Other). The metrics defined in the previous section are computed using these language tags.

Newspaper dataset for the baseline: As we had discussed in the previous section, for the construction of the baseline ranking we need to resort to counting the frequency of the foreign words (i.e., English words) and their Hindi translations in a newspaper corpus as has been outlined in (Bali et al., 2014). For this purpose, we use the FIRE dataset built from the Hindi Jagaran newspaper corpus[1] which is written in Devanagari script.

4.2 Target word selection

We first compute the most frequent foreign (i.e., English words) in our tweet corpus. Since we are interested in the frequency of the English word only when it appears as a foreign word we do not consider the (i) *Hi* tweets since they do not have any foreign word, (ii) *En* tweets since here the English words are not foreign words and the (iii) code-switched tweets. Based on the frequency of usage of English as a foreign word, we select the top 1000 English words. Removal of stop words and text normalization leaves beyond 230 nouns (see supplementary material for the list of words).

Final selection of target words: In language processing, context plays an important role in understanding different properties of a word. For our study, we also attempt to use the language tags as features of the context words for a given *target word*. Our hypothesis here is that there should exist classes of words that have similar context features and the likelihood of being borrowed in each class should be different. For example, when an English word is surrounded by mostly Hindi words it seems to be more likely borrowed. We present two examples in the box below to illustrate this.

Example I:
@****** Welcome. ***Film*** *jaroor dekhna. Nahi to injection ready hai.*
Example II:
@*****_Trust @*****
Kuch to ache se karo sirji....
Har jagah bhaagte rehna is not a good ***thing***.

In *Example I* the English word “film” is surrounded by mostly Hindi words. On the other hand, in *Example II* the English word “thing” is surrounded mostly by English words. Note that the word “film” is very commonly used by Hindi monolingual speakers and is therefore highly likely to have been borrowed unlike the English word “thing” which is arguably an instance of mixing. This socio-linguistic difference seems to be very appropriately captured by the language tag of the surrounding words of these two words in the respective tweets. Based on this hypothesis we arrange the 230 words into contextually similar groups (see supplementary material for the grouping details). Finally, using the baseline metric $log(\frac{F_E}{F_H})$ (E: English, H: Hindi), we proportionately choose words from these groups as follows:

Words with very high or very low values of $log(\frac{F_E}{F_H})$ ($hlws$) – we select words having the highest and the lowest values of $log(\frac{F_E}{F_H})$ from each of the context groups. This constitutes a set of 30 words. Note that these words are baseline-biased and therefore the metric should be able to discriminate them well.

Words with medium values of $log(\frac{F_E}{F_H})$ (mws) – we selected 27 words having not so high and not so low $log(\frac{F_E}{F_H})$ at uniformly at random.

Full set of words ($full$) – Thus, in total we selected 57 target words for the purpose of our evaluation. We present these words in the box below.

Baseline-biased words – ’thing’, ’way’, ’woman’, ’press’, ’wrong’, ’well’, ’matter’, ’reason’, ’question’, ’guy’, ’moment’, ’week’, ’luck’, ’president’, ’body’, ’job’, ’car’, ’god’, ’gift’, ’status’, ’university’, ’lyrics’, ’road’, ’politics’, ’parliament’, ’review’, ’scene’, ’seat’, ’film’, ’degree’
Randomly selected words – ’people’, ’play’, ’house’, ’service’, ’rest’, ’boy’, ’month’, ’money’, ’cool’, ’development’, ’group’, ’friend’, ’day’, ’performance’, ’school’, ’blue’, ’room’, ’interview’, ’share’, ’request’, ’traffic’, ’college’, ’star’, ’class’, ’superstar’, ’petrol’, ’uncle’

4.3 Evaluation criteria

We present a four step approach for evaluation as follows. We measure (i) how well the UUR, UTR and UPR based ranking of the $hlws$ set, the mws set and the $full$ set correlate with the ground truth ranking (discussed in the next section) in comparison to the rank given by the baseline metric, (ii) how well the different rank ranges obtained from our metric align with the ground truth as compared to the baseline metric, (iii) whether there are some systematic effects of the age group of the survey participants on the rank correspondence, (iv) how our metrics if computed from the tweets of users who (a) rarely mix languages, (b) almost always mix languages and (c) are in between (a) and (b), align with the ground truth.

Rank correlation: We measure the standard Spearman’s rank correlation (ρ) (Zar, 1972) pairwise between rank lists generated by (i) UUR (ii) UTR (iii) UPR (iv) baseline metric and the ground truth.

We shall describe the next four measurements

[1] Jagaran corpus: http://fire.irsi.res.in/fire/static/data

taking UUR as the running example. The same can be extended verbatim for the other two similar metrics.

Rank ranges: We split each of the three rank lists (UUR, ground truth and baseline) into five different equal-sized ranges as follows – (i) surely borrowed (SB) containing top 20% words from each list, (ii) likely borrowed (LB) containing the next 20% words from each list, (iii) borderline (BL) constituting the subsequent 20% words from each list, (iv) likely mixed (LM) comprising the next 20% words from each list and (v) surely mixed (SM) having the last 20% words from each rank list. Therefore, we have three sets of five buckets, one set each for UUR, the ground truth and the baseline based rank list.

Next we calculate the bucket-wise correspondence between (i) the UUR and the ground truth set and (ii) the baseline and the ground truth set in terms of standard *precision* and *recall* measures. For our purpose, we adapt these measures as follows.

G: ground truth bucket set, B_b: baseline bucket set, U_b: UUR bucket set;

$BS \in \{B_b, U_b\}$, T (type of bucket) = {SB, LB, BL, LM, SM};

b_t = words in type t bucket from BS, g_t = words in type t bucket from G, $t \in T$;

tp_t (no. of true positives) = $|b_t \cap g_t|$, fp_t (no. of false positives) = $|b_t - g_t|$, tn_t (no. of true negatives) = $|g_t - b_t|$;

Bucket-wise *precision* and *recall* therefore:

$precision(b_t) = \frac{tp_t}{fp_t + tp_t}$; $recall(b_t) = \frac{tp_t}{tn_t + tp_t}$

For a given set, we obtained the overall *macro precision* (*recall*) by averaging the *precision* (*recall*) values over the five buckets. For a given set, we also obtained the overall *micro precision* by first adding the true positives across all the buckets and then normalizing by the sum of the true and the false positives over all the buckets. We take an equivalent approach for obtaining the *micro recall*.

Age group effect: Here we construct two ground truth rank lists one using the responses of the participants with age below 30 (young population) and the other using the responses of the rest of the participants (elderly population). Next we repeat the above two evaluations considering each of the new ground truth rank lists.

Extent of language mixing: Here we divide all the 3577 users into three categories – (i) High (users who have more than 20% of tweets as code-mixed), (ii) Mid (users who have 7–20% of their tweets as code-mixed, and (iii) Low (users who have less than 7% of their tweets as code-mixed). We create three UUR based rank lists for each of these three user categories and respectively compare them with the ground truth rank list.

4.4 Ground truth preparation

Since it is very difficult to obtain a suitable ground truth to validate the effectiveness of our proposed ranking scheme, we launched an online survey to collect human judgment for each of the 57 *target words*.

Online survey We conducted the online survey[2] among 58 volunteers majority of whom were either native language(Hindi) speakers or had very high proficiency in reading and writing in that language. The participants were selected from different age groups and different educational backgrounds. Every participant was asked to respond to a multiple choice question about each of the 57 *target words*. Therefore, for every single *target word*, 58 responses were gathered. The multiple choice question had the following three options and the participants were asked to select the one they preferred the most and found more natural – (i) a Hindi sentence with the *target word* as the only English word, (ii) the same Hindi sentence in (i) but with the *target word* replaced by its Hindi translation and (iii) none of the above two options. There were no time restrictions imposed while gathering the responses, i.e., the volunteers theoretically had unlimited time to decide their responses for each *target word*.

Language preference factor For each *target word*, we compute a *language preference factor* (LPF) defined as ($Count_{En} - Count_{Hi}$), where $Count_{Hi}$ refers to the number of survey participants who preferred the sentence containing the Hindi translation of the *target word* while $Count_{En}$ refers to the number of survey participants who preferred the sentence containing the *target word* itself. More positive values of LPF denotes higher usage of *target word* as compared to its Hindi translation and therefore higher likeliness of the word being borrowed.

Ground truth rank list generation We generate the ground truth rank list based on the LPF score of a *target word*. The word with the highest value

[2] Survey portal: https://goo.gl/forms/L0kJm8BNMhRj0jA53

Rank-List$_1$	Rank-List$_2$	$\rho - hlws$	$\rho - mws$	$\rho - full$
UUR	Ground truth	**0.67**	**0.64**	**0.62**
UTR	Ground truth	**0.66**	**0.63**	**0.63**
UPR	Ground truth	**0.66**	**0.64**	**0.62**
Baseline	Ground truth	0.49	0.14	0.26

Table 1: Spearman's rank correlation coefficient (ρ) among the different rank lists. Best result is marked in bold.

of LPF appears at the top of the ground truth rank list and so on in that order. Tie breaking between *target words* having equal LPF values is done by assigning average rank to each of these words.

Age group based rank list: As discussed in the previous section, we prepare the age group based rank lists by first splitting the responses of the survey participants in two groups based on their age – (i) young population (age < 30) and (ii) elderly population (age $\geq$ 30). For each group we then construct a separate LPF based ranking of the *target words*.

5 Results

5.1 Correlation among rank lists

The Spearman's rank correlation coefficient (ρ) of the rank lists for the $hlws$ set, the mws set and the $full$ set according to the baseline metric, UUR, UTR and UPR with respect to the ground truth metric LPF are noted in table 1. We observe that for the $full$ set, the ρ between the rank lists obtained from all the three metrics UUR, UTR, and UPR with respect to the ground truth is ~ 0.62 which is more than double the ρ (~ 0.26) between the baseline and the ground truth rank list. This clearly shows that the proposed metrics are able to identify the likeliness of borrowing quite accurately and far better than the baseline. Further, a remarkable observation is that our metrics outperform the baseline metric even for the $hlws$ set that is baseline-biased. Likewise, for the mws set, our metrics outperform the baseline indicating a superior recall on arbitrary words. The ranking of the $full$ set of words obtained from the ground truth, the baseline and the UUR metric is available in the supplementary material.

We present the subsequent results for the $full$ set and the UUR metric. The results obtained for the other two metrics UTR and UPR are very similar and therefore not shown.

Bucket type	Ground truth bucket	Baseline bucket	UUR bucket
SB	11	11	11
LB	11	11	11
BL	12	12	12
LM	11	11	11
SM	12	12	12

Bucket type	*prec./rec.* Baseline	*prec./rec.* UUR
SB	**0.27**	**0.27**
LB	0.09	**0.18**
BL	0.08	**0.33**
LM	0.18	**0.36**
SM	0.33	**0.50**

Table 3: Bucket-wise *precision/recall*. Best results are marked in bold.

5.2 Rank list alignment across rank ranges

The number of *target words* falling in each bucket across the three rank lists are the same and are noted in table 2. Thus, the *precision* and *recall* as per the definition are also the same. The bucket-wise *precision/recall* for the baseline and UUR with respect to the ground truth are noted in table 3. We observe that while in the SB bucket both the baseline and UUR perform equally well, for all the other buckets UUR massively outperforms the baseline. This implies that for the case where the likeliness of borrowing is the strongest, the baseline does as good as UUR. However, as one moves down the rank list, UUR turns out to be a considerably better predictor than the baseline. The overall *macro* and *micro precision/recall* as shown in table 4 further strengthens our observation that UUR is a better metric than the baseline.

5.3 Age group based analysis

As already discussed earlier, we split the ground truth responses based on the age group of the survey participants. We split the responses into two groups – (i) young population (age < 30) and (ii) elderly population (age ≥ 30) so that there are almost equal number of responses in both the groups (see supplementary material for the exact distribution).

Rank correlation: The Spearman's rank correlation of UUR and the baseline rank lists with these

Bucket	Number of users	ρ
High	302	0.52
Mid	744	0.60
Low	2531	**0.65**

Table 8: Spearman's correlation between UUR and the ground truth in the different user buckets. Best results are marked in bold.

two ground truth rank lists are shown in table 5. Interestingly, the correlation between UUR rank list and the young population ground truth is better than the elderly population ground truth. This possibly indicates that UUR is able to predict recent borrowings more accurately. However, note that the UUR rank list has a much higher correlation with both the ground truth rank lists as compared to the baseline rank list.

Rank ranges: Table 6 shows the bucket-wise *precision* and *recall* for UUR and the baseline metrics with respect to two new ground truths. For the young population once again the number of words in each bucket for all the three sets is the same thus making the values of the *precision* and the *recall* same. In fact, the *precision*/*recall* for this ground truth is exactly same as in the case of the original ground truth.

In contrast, when we consider the ground truth based on the responses of the elderly population, the number of words across the different buckets are different across the three sets. In this case, we observe that the *precision*/*recall* values are better for the UUR metric in SB, LB and LM buckets.

Finally, the overall *macro* and *micro precision* and *recall* for both the age groups are noted in table 7. Once again, for both the young and the elderly population based ground truths, the *macro* and *micro precision* and *recall* values for the UUR metric are higher compared to that of the baseline.

5.4 Extent of language mixing

As mentioned earlier, we divide the set of 3577 users into three categories. The Spearman's correlation between UUR and the ground truth for each of these buckets are given in table 8. As we can see, for Low bucket the ρ value is maximum. This points to the fact that the signals of borrowing is strongest from the users who rarely mix languages.

6 Re-annotation results

In order to conduct the re-annotation experiments we performed the following. To begin with, we ranked all the 230 English nouns in non-increasing order of their UUR values. We then randomly selected 20 words each having (i) high UUR (top 20%) values (call TOP), (ii) low UUR (bottom 20%) values (call BOT), and (iii) middle UUR (middle 20%) values (call MID). This makes a total of 60 words. Using this word list we extracted one tweet each that contained the (foreign) word from this list along with all other words in the tweet tagged in Hindi (H_{all}). We similarly prepared another such list of 60 words and extracted one tweet each in which most of the other words were tagged in Hindi (H_{most}).

We presented the selected words and the corresponding tweets to a set of annotators and asked them to annotate these selected words once again. Over all the words, we calculated the mean ($\mu_{E\rightarrow H}$) and the standard deviation ($\sigma_{E\rightarrow H}$) of the fraction of cases where the annotators altered the tag of the selected word from English to Hindi. The average inter-annotator agreement (Fleiss, 1971) for our experiments was found to be as high as 0.64. For the words in the TOP list, the fraction of times the tag is altered is **0.91** (**0.85**) with an inter-annotator agreement of 0.84 (0.80) for the

Word-rank	Context	$\mu_{E \to H}$	$\sigma_{E \to H}$
TOP	H_{all}	**0.91**	0.15
TOP	H_{most}	**0.85**	0.23
MID	H_{all}	0.58	0.28
MID	H_{most}	0.61	0.34
BOT	H_{all}	0.13	0.18
BOT	H_{most}	0.16	0.21

Table 9: Re-annotation results

H_{all} (H_{most}) category. In other words, on average, in as high as 88% of cases the annotators altered the tags of the words that are highly likely to be borrowed (i.e., TOP) in a largely Hindi context (i.e., H_{all} or H_{most}). Table 9 shows the fractional changes for all the other possible cases. An interesting observation is that the annotators rarely flipped the tags for the words in the BOT list (i.e., the sure mixing cases) in either of the H_{all} or the H_{most} contexts. These results strongly support the inclusion of our metric in the design of future automatic language tagging tasks.

7 Discussion and conclusion

In this paper, we proposed a few new metrics for estimating the likliness of borrowing that rely on signals from large scale social media data. Our best metric is two-fold better than the previous metric in terms of the accuracy of the prediction. There are some interesting linguistic aspects of borrowing as well as certain assumptions regarding the social media users that have important repercussions on this work and its potential extensions, which are discussed in this section.

Types of borrowing: Linguists define broadly three forms of borrowing, (i) *cultural*, (ii) *core*, and (iii) *therapeutic* borrowings. In *cultural borrowing*, a foreign word gets borrowed into native language to fill a lexical gap. This is because there is no equivalent native language word present to represent the same foreign word concept. For instance, the English word 'computer' has been borrowed in many Indian languages since it does not have a corresponding term in those languages[3]. In *core borrowing*, on the other hand, a foreign word replaces its native language translation in the native language vocabulary. This occurs due to overwhelming use of the foreign word over native language translation as a matter of prestige, ease of use etc. For example, the English word 'school' has become much more prevalent than its corresponding Hindi translation '*vidyalaya*' among the native Hindi speakers. Finally, therapeutic borrowing refers to borrowing of words to avoid taboo and homonomy in the native language. In this paper, although we did not perform any category based studies, most of our focus was on core borrowing.

Language of social media users: We assumed that if a user is predominantly using Hindi words in a tweet then the chances of him/her being a native Hindi speaker should be high, since, while the number of English native speakers in India is 0.02%, the number of Hindi native speakers is 41.03%[4]. This assumption has also been made in earlier studies (Rudra et al., 2016). Note that even if a user is not a native Hindi speaker but a proficient (or semi-proficient) Hindi speaker, the main results of our analysis should hold. For instance, consider two foreign words 'a' and 'b'. If 'a' is frequently borrowed in the native language, then the proficient speaker would also tend to borrow 'a' similar to a native speaker. Even if due to lack of adequate native vocabulary, the non-native speaker borrows the word 'b' in some cases, these spurious signals should get eliminated since we are making an aggregate level statistics over a large population.

Future directions: It would be interesting to understand and develop theoretical justification for the metrics. Further, it would be useful to study and classify various other linguistic phenomena closely related to core borrowing, such as: (i) *loanword*, where a form of a foreign word and its meaning or one component of its meaning gets borrowed, (ii) *calques*, where a foreign word or idiom is translated into existing words of native language, and (iii) *semantic loan*, where the word in the native language already exists but an additional meaning is borrowed from another language and added to existing meaning of the word.

Finally, we would also like to incorporate our findings into other standard tasks of multilingual IR and multilingual speech synthesis (for example to render the appropriate native accent to the borrowed word).

[3] Words for "computer" were coined in many Indian languages through morphological derivation from the term for "compute", however, none of these words are used in either formal or informal contexts.

Abstract

In this paper, we demonstrate how the state-of-the-art machine learning and text mining techniques can be used to build effective social media-based substance use detection systems. Since a substance use ground truth is difficult to obtain on a large scale, to maximize system performance, we explore different unsupervised feature learning methods to take advantage of a large amount of unsupervised social media data. We also demonstrate the benefit of using multi-view unsupervised feature learning to combine heterogeneous user information such as Facebook "likes" and "status updates" to enhance system performance. Based on our evaluation, our best models achieved 86% AUC for predicting tobacco use, 81% for alcohol use and 84% for illicit drug use, all of which significantly outperformed existing methods. Our investigation has also uncovered interesting relations between a user's social media behavior (e.g., word usage) and substance use.

1 Introduction

A substance use disorder (SUD) is defined as a condition in which recurrent use of substances such as alcohol, drugs and tobacco causes clinically and functionally significant impairment in an individual's daily life (SAMHSA, 2015). According to the 2014 National Survey on Drug Use and Health, 1 in 10 Americans age 12 and older had a substance use disorder. Substance use also costs Americans more than $700 billion a year in increased health care costs, crimes and lost productivity (NIDA, 2015).

These days, people also spend a significant amount of time on social media such as Twitter, Facebook and Instagram to interact with friends and families, exchange ideas and thoughts, provide status updates and organize events and activities. The ubiquity and widespread use of social media underlines the needs to explore its intersection with substance use and its potential as a scalable and cost-effective solution for screening and preventing substance misuse and abuse.

In this research, we employ the state-of-the-art machine learning and text mining algorithms to build automated substance use prediction systems, which can be used to identify people who are at risk of SUD. Since SUD data are often expensive to obtain at a large scale, to maximize system performance, we focus on methods that employ unsupervised feature learning to take advantage of a large amount of unsupervised social media data. Previous research in Machine Learning, Image Processing, Speech and Natural language Processing has shown that to be able to utilize a large amount of unsupervised data is one of the most reliable ways to achieve good performance (Le et al., 2011; Lee et al., 2009; Le and Mikolov, 2014). Moreover, by analyzing rich human behavior data on social media, we can also gain insight into patterns of use and risk factors associated with substance use. The main contributions of this work include:

1. We have explored a comprehensive set of single-view feature learning methods to take advantage of a large amount of unsupervised social media data. Our results have shown significant improvement over baseline systems that only use supervised training data.

2. We have explored several multi-view learning algorithms to take advantage of heteroge-

neous user data such as Facebook “likes” and “status updates”. Our results have demonstrated significant improvement over baselines that only use a single data type.

3. We have uncovered new insight into the relationship between a person’s social media activities and substance use such as the relationship between word usage and SUD.

2 Related Work

Substance use disorder (SUD) encompasses a complex pattern of behaviors. Many studies have been conducted to discover factors interacting with SUD. A growing number of studies have confirmed a strong association between personal traits and substance use. For example, (Campbell et al., 2014) found that smokers have significantly higher *openness to experience* and lower *conscientiousness*, a personality trait related to a tendency to show self-discipline, act dutifully, and aim for achievement. (Cook et al., 1998) examined the links between alcohol consumption and personality and found that alcohol use is correlated positively with sociability and extraversion. (Terracciano et al., 2008) conducted a study involving 1102 participants and found a link between drug use and low *conscientiousness*. (Carroll et al., 2009) revealed risk factors related to addiction such as age, sex, impulsivity, sweet-liking, novelty reactivity, proclivity for exercise, and environmental impoverishment. Additionally, addiction is also linked to environmental and social factors such as neighborhood environment (Crum et al., 1996), family environment (Cadoret et al., 1986; Brent, 1995) and social norms (Botvin, 2000; Oetting and Beauvais, 1987).

Traditionally, in behavior science research, data are collected from surveys or interviews with a limited number of people. The advent of social media makes a large volume of diverse user data available to researchers, which makes it possible to study SUD based on online user behaviors in a natural setting. Typical data from social media include demographics (age, gender etc.), status updates (text posts etc.), social networks (follower and following graph etc.) and likes (thumb up/down etc.). Recently, social media analytics has increasingly become a powerful tool to help understand the traits and behaviors of millions of social media users such as personal traits (Golbeck et al., 2011; Volkova and Bachrach, 2015; Youyou et al., 2015; Kiliç and Pan, 2016), brand preferences (Yang et al., 2015), communities and events (Sayyadi et al., 2009), influenza trend (Aramaki et al., 2011) and crime (Li et al., 2012). So far, however, there has been limited work that directly applies large scale social media analytics to automatically predict SUD. Among the work known to us, (Zhou et al., 2016) identified common drug consumption behaviors with regard to the time of day and week. They also discovered common interests shared by drug users such as celebrities (e.g, Chris Tucker) and comedians (e.g., cheechandchong). In addition, (Kosinski et al., 2013) automatically predicted SUD based on social media likes. Since their dataset is very similar to ours, we will use the Kosinski model as one of our baselines.

3 Dataset

The data for the study was collected from 2007 to 2012 as a part of the myPersonality project (Kosinski et al., 2015). myPersonality was a popular Facebook application that offered to its users psychometric tests and feedback on their scores. The data were gathered with an explicit opt-in consent for reuse for research purposes. Our study uses three separate datasets from myPersonality: Facebook status updates (a.k.a. posts), Facebook likes and SUD status.

The *status update dataset* contains 22 million textual posts authored by 153,000 users. The average posts per user is 143 and the average words per user is 1730. We removed users who only have non-English posts and those who have written less than 500 words. Our final status update dataset includes 106,509 users with 21 million posts. After filtering out low frequency words (those appear less than 50 times in our corpus), the vocabulary size of the status update dataset is 73,935.

The *likes dataset* contains the Facebook likes used to express positive sentiment toward various targets such as products, movies, books, expressions, websites and people (they are called *Like Entities* or LEs). Previous studies have demonstrated that social media likes speak volumes about who we are. In addition to directly signaling interests and preferences, social media likes are indicative of ethnicity, intelligence and personality (Kosinski et al., 2013). The like dataset includes the likes of 11 million Facebook users.

Overall, there are 9.9 million unique LEs and 1.8 billion user-like pairs in this dataset. The average likes per user is 161 and the average Likes each LE received is 182. We filter out users who have a small number of likes as well as LEs receiving a small number of likes. The filtering threshold for users is 50 and is 800 for LEs. After the filtering, our like dataset contains 5,138,857 users and 253,980 unique LEs.

The SUD dataset contains a total of 13,557 participants (Stillwell and Tunney, 2012). Users were asked to answer questions like “Do you smoke?”, with answers “daily or more”, “less than daily” or “never”. They also completed the Cigarette Dependence Scale (CDS-5) (Etter et al., 2003), Alcohol Use Questionnaire(AUQ) (Townshend and Duka, 2005) and the Assessment of Substance Misuse Questionnaire (ASMA) (Willner, 2000). Based on these assessments, the participants were divided into groups for each SUD type. For example, based on the assessment of tobacco use, a person is categorized as “daily or more” (group 3), “less than daily” (group 2), or “never” (group 1). The validity of the grouping was confirmed by the CDS-5 scores of the groups. Similarly, based on the assessment of alcohol use, participants were categorized as “weekly or more” (group 3), “less than once a week” (group 2) or “never” (group 1). Finally, based on the assessment of drug use, a person is assigned to “weekly or more” (group 3), “less than once a week” (group 2), or “never” (group 1). Among all the SUD participants, 37% of them are males and 63% are females. Their average age is 23 years old.

Since the like, status update and SUD datasets are only partially overlapping, their intersections are usually much smaller. Table 1 summarizes the sizes and usage of these datasets. Table 2 shows additional details of the SUD dataset including the distributions of each SUD class.

In summary, among all the datasets we have, the unsupervised like dataset is the largest (5 million+ people). We also have a significant amount of unsupervised status update data (100k+ users). In contrast, the supervised datasets which have the SUD ground truth are pretty small, ranging from 896 for the intersection of the likes, status updates and SUD (LikeStatusSUD in Table 1) to 3508, which is the intersection of the likes and SUD (LikesSUD in Table 1). Thus, the main focuses of this research include (1) employing unsupervised feature learning to take advantage of a large amount of unsupervised data (2) employing multi-view learning to combine heterogeneous user data for better prediction.

4 Single-View Post Embedding (SPE)

The main purpose of this study is to demonstrate the usefulness of employing unsupervised feature learning to derive a feature representation of a user’s Facebook posts to take advantage of a large amount of unsupervised data. Since we only use Facebook status updates (a.k.a. posts) in this study, we call the process Single-view user Post Embedding (SPE).

4.1 SPE Feature Learning Methods

Since each user is associated with a sequence of textual posts, we have explored the following methods to learn a SPE for the user.

Singular Value Decomposition (SVD) is a mathematical technique that is frequently used for dimension reduction (De Lathauwer et al., 2000). Given any $m * n$ matrix A, the algorithm will find matrices U, V and W such that $A = UWV^T$. Here U is an orthonormal $m * n$ matrix, W is a diagonal $n * n$ metrix and V is an orthonormal $n * n$ matrix. Dimensionality reduction is done by computing $R = U * W_r$ where W_r neglects all but the r largest singular values in the diagonal matrix W. In our study, the m is the number of users, n is the number of unique words in the vocabulary. $A_{ij} = k$ where k is how many times $word_j$ appears in $user_i$’s posts.

Latent Dirichlet Allocation (LDA) is a generative graphical model that allows sets of documents to be explained by unobserved latent topics (Blei et al., 2003). For each document, LDA outputs a multinomial distribution over a set of latent topics. For each topic, LDA also outputs a multinomial distribution over the vocabulary.

To learn an SPE for each user based on all his/her posts, we have tried several methods (1) UserLDA: it treats all the posts from each user as one big document and trains an LDA model to drive the topic distribution for this document. The per-document topic distribution is then used as the SPE for this user. (2) PostLDA_Doc: it treats each post as a separate document and trains an LDA model to derive a topic distribution for each post. To derive the SPE for each user, we aggregate

Table 1: Dataset Descriptions

Dataset	users	AvgUserLikes	AvgUserPosts	Usage
Likes	5,138,857	184	NA	Single View Feature Learning
LikesSUD	3,508	267	NA	Single View SUD Prediction
Status Update	106,509	NA	143	Single View Feature Learning
StatusSUD	1,231	NA	195	Single View SUD Prediction
LikeStatus	54,757	232	220	Multi-View Feature Learning
LikeStatusSUD	896	277	219	Multi-View SUD Predication

Table 2: Class Distribution of Different SUD Datasets

Dataset	Tabacco Use			Alcohol Use			Drug Use		
	3	2	1	3	2	1	3	2	1
LikeSUD	498	290	2603	469	1174	1716	171	276	1965
StatusSUD	226	95	880	179	416	596	76	102	671
LikeStatusSUD	147	69	660	123	290	453	262	53	75

all the per-post topic distribution vectors from the same user by averaging them. (3) PostLDA_Word: instead of using the $average$ of post-based topic distribution vectors, we used a word-based aggregation method suggested in (Schwartz et al., 2013):

$$p(topic|user) = \sum_{w \in voc} P(topic|w) * p(w|user)$$

where voc represents the vocabulary, $p(w|user)$ is the probability that word w appears in the posts of $user$ and $p(topic|w)$ is the topic distribution of a word w, which is available internally in an LDA model. For the UserLDA model, all the hyper parameters were set to default values. For all the PostLDA models, since Facebook posts are usually short and have a small number of topics in each post, we set the hyper parameter α to 0.3, as suggested in (Schwartz et al., 2013)

Document Embedding with Distributed Memory (D-DM) Given a document, D-DM simultaneously learns a vector representation for each word and a vector for the entire document (Le and Mikolov, 2014). During training, the document vector and one or more word vectors are aggregated to predict a target word in the context. To learn an SPE for each user, we have explored two methods (1) User-D-DM: it treats all the posts by the same user as one document and trains a document vector to represent the user. (2) Post-D-DM: it treats each post as a document and train a D-DM to learn a vector for each post. To derive the SPE for a user, we aggregate all the post vectors from the same person using "average".

Table 3: SPE: Prediction Results

Methods	Tobacco	Alcohol	Drug
Unigram	0.663	0.672	0.644
LIWC	0.731	0.689	0.758
SVD	0.779	0.724	0.764
UserLDA	0.641	0.603	0.599
PostLDA_Word	0.733	0.617	0.628
PostLDA_Doc	0.768	0.687	0.721
Post-D-DM	0.536	0.622	0.520
User-D-DM	0.775	0.730	0.767
Post-D-DBOW	0.531	0.606	0.526
User-D-DBOW	**0.802**	**0.768**	**0.819**

Document Embedding with Distributed Bag of Words (D-DBOW) D-DBOW learns a global document vector to predict words randomly sampled from the document (Le and Mikolov, 2014). Unlike D-DM, D-DBOW only learns a vector for the entire document. It does not learn vectors for individual words. Neither does it use a local context window since the words for prediction are randomly sampled from the entire document. Similar to D-DM, to derive the SPE for a user, we used two methods (1) User-D-DBOW and (2) Post-D-DBOW.

4.2 SUD Prediction with SPE

In our experiments, to search for the best model, we systematically varied the output SPE dimension from 50, 100, 300, to 500. We used the Gensim implementation of SVD, LDA, D-DM and D-DBOW in our experiments. For D-DM, the context window size was set to 5.

We compared our models with two baselines that use only supervised learning (1) a unigram model which uses unigrams as the predicting features. Since we have a large number of unigrams, we performed supervised feature selection to lower the total number of input features. Finally since all our SUD variables have three values, we employed SVM in 3-way classifications. (2) a LIWC model which uses human engineered LIWC features for SUD prediction. LIWC is a psycholinguistic lexicon (Pennebaker et al., 2015) that has been frequently used in text-based human behavior prediction. Since the number of LIWC features is relatively small, no feature selection was performed. Here, we only used the *Status Update* dataset in Table 1 as the training data for SPE learning and the *StatusSUD* dataset for supervised SUD prediction .

We evaluate the performance of our models using 10-fold cross validation. The evaluation results shown in Table 3 are based on weighted ROC AUC of the best models. Among all the feature learning methods for Facebook status updates, User-D-DBOW performed the best. It significantly outperformed all the baseline systems that only rely on supervised training ($p < 0.01$ based on t-tests). It also significantly outperformed all the traditional feature learning methods such as LDA and SVD ($p < 0.01$ based on t-tests). Moreover, in terms of whether to treat all the posts by the same user as one big document or separate documents, LDA prefers one post one document (models with a "post" prefix) while all the document vector-based methods prefer one user one document (models with a "User" prefix). Moreover, to use post-level LDA to derive the SPE of a user, the document-based aggregation method (PostLDA_Doc) performed better than the word-based method (PostLDA_Word).

5 Single-View Like Embedding (SLE)

In addition to textual posts, each user account is also associated with a set of likes. Since the like dataset is very sparse (e.g., among the millions of unique likes on Facebook, each user only has a small number of likes), we conduct experiments to learn a dense vector representation for all the likes by a user. We call this process Single-view user Like Embedding (SLE).

5.1 SLE Feature Learning Methods

The input to SLE is simply a set of LEs liked by a user. Each LE is represented by its id. To map such a representation to a dense user like vector, we have tried multiple methods.

Singular Value Decomposition (SVD) is similar to the one used in SPE except $A_{ij} = 1$ if $user_i$ likes LE_j. Otherwise, it is 0. Here A is a $m * n$ matrix where m is the number of users and n is the number of unique LEs in the like dataset.

Latent Dirichlet Allocation (LDA). To apply LDA to the like data, each individual LE is treated as a word token and all the LEs liked by the same person form a document. The order of the LEs in the document is random. For each user, LDA outputs a multinomial distribution over a set of latent "Like Topics". For example, a "Like Topic" about "hip hop music" may include famous hip hop songs and musicians.

Autoencoder (AE) is a neural network-based method for self-taught learning (Hinton and Salakhutdinov, 2006). It learns an identity function so that the output is as close to the input as possible. Although an identity function seems a trivial function to learn, by placing additional constraints (e.g,, to make the number of neurons in the hidden layer much smaller than that of the input), we can still force the system to uncover structures in the data. Architecturally, the AE we used has one input layer, one hidden layer and one output layer. For each user, we construct a training instance (X, Y) where the input vector X and output vector Y are the same. The size of X and Y is the total number of unique LEs in our dataset. X_i and Y_i equal to 1 if the user likes LE_i. Otherwise they are 0.

Document Vector with Distributed Memory (D-DM) We also applied D-DM to the like data. Given all the likes of a user, D-DM learns a vector representation for each LE as well as a document vector for all the LEs from the same user. We use the learned document vector as the output SLE.

Document Vector with Distributed Bag of Words (D-DBOW) Similarly, we applied D-DBOW to the like dataset. Since D-DBOW does not use a local context window and the words for prediction are randomly sampled from the entire document, it is more appropriate for the like dataset than D-DM. where the relative positions of LEs do matter.

5.2 SUD Prediction with SLE

Similarly, we systematically varied the output SLE dimension from 50, 100, 300, to 500 in order to search for the best model. We used the Gensim implementation of SVD, LDA, D-DM and D-

Table 4: SLE: Prediction Results

Method	Tobacco	Alcohol	Drug
Unigram	0.687	0.651	0.673
Kosinski⋆	0.730*	0.700*	0.650*
AE	0.678	0.648	0.672
SVD	0.757	0.756	0.753
LDA	0.723	0.737	0.704
D-DM	0.688	0.713	0.687
D-DBOW	**0.787**	**0.795**	**0.791**

⋆:2-way classification, 3-way for the others

DBOW in our experiments. For D-DM, the context window size was set to 20. We used Keras with Theano backend to implement AE.

We used SVM to perform 3-way classification. We compared our results with a unigram baseline. We also compared our results with that of the Kosinski model reported in (Kosinski et al., 2013). The Kosinski model was trained on the same Facebook like dataset. However, its results were based on two-way classification, a simpler task than 3-way classification. All the results are based on weighted ROC AUC.

As shown in Table 4, among all the SLE methods, the D-DBOW model performed the best. It significantly outperformed the unigram baseline that does not use any unsupervised data ($p < 0.01$ based on t-tests). It also significantly outperformed all the traditional feature learning method such as SVD and LDA (The Kosinski model used SVD for feature learning) ($p < 0.01$ based on t-tests). Between the two document vector-based methods, D-DBOW outperformed D-DM. We think this is due to the fact that D-DBOW does not use local context window, thus is not sensitive to the positions of LEs in a document. Since LE positions are randomly decided in our like data, D-DBOW seems to be a better fit for this dataset.

6 Multi-View User Embedding (MUE)

The main purpose of this study is to demonstrate the usefulness of combining heterogeneous user data such as likes and posts to learn a dense vector representation for each user. Since we employ unsupervised multi-view feature learning to combine these data, we call this process Multi-view User Embedding (MUE).

6.1 MUE Feature Learning Methods

We have explored two multi-view feature learning algorithms: Canonical Correlation Analysis (CCA) and Deep Canonical Correlation Analysis (DCCA).

Canonical Correlation Analysis (CCA) CCA is a statistical method for exploring the relationships between two multivariate sets of variables (vectors) (Hardoon et al., 2004). Given two vectors X and Y, CCA tries to find aX, bY that are maximally correlated:

$$(a^*, b^*) = \arg\max_{a,b} corr(a^{'}X, b^{'}Y) \qquad (1)$$

$$= \arg\max_{a,b} \frac{a^{'} \sum_{XY} b}{\sqrt{a^{'} \sum_{XX} ab^{'} \sum_{YY} b}} \qquad (2)$$

where (X, Y) denote random vectors with covariances $\sum_{XX} = Cov(X, X)$, $\sum_{YY} = Cov(Y, Y)$ and cross-covariance $\sum_{XY} = Cov(X, Y)$. CCA has been used frequently in unsupervised data analysis (Sargin et al., 2006; Chaudhuri et al., 2009; Kumar and Daumé, 2011; Sharma et al., 2012).

Deep Canonical Correlation Analysis (DCCA) DCCA aims to lean highly correlated deep architectures, which can be a non-linear extension of CCA (Andrew et al., 2013). The intuition is to find a maximally correlated representation of the two views by passing them through multiple stacked layers of nonlinear transformation (Andrew et al., 2013). Typically, there are three steps to train DCCA: (1) using a denoising autoencoder to pretrain each single view. In our experiments, we pretrain each single view using SPE or SLE. (2) computing the gradient of the correlation of top-level representation. (3) tuning parameters using back propagation to optimize the total correlation. Previously, DCCA was found to be more effective than CCA in image processing (Andrew et al., 2013).

6.2 SUD Prediction With MUE

The input to MUE are the two single views obtained earlier (i.e. SPE or SLE). Here, we choose the outputs from D-DBOW since it consistently outperformed all the other methods in learning SPEs and SLEs. We have run CCA and DCCA in two settings (1) balanced setting in which the SPE and SLE dimensions are always the same (2) imbalanced setting in which the dimension of SPE may be different from that of SLE. Since we varied the output dimensions of SPE and SLE from 50, 100, 300, to 500 systematically, the input dimension to MUE under the balanced setting are 100, 200, 600 and 1000. When running CCA

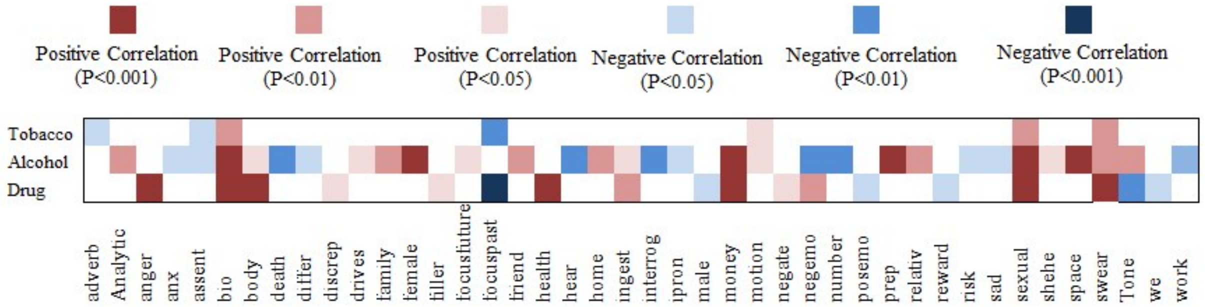

Figure 1: LIWC Features that are Most Significantly Correlated with Substance Use.

and DCCA under the imbalanced setting, we only chose the best SPE (with 50 dimensions) and the best SLE (with 300 dimensions). We also varied the number of MUE output dimensions systematically from 20,50,100,200,300,400,500 to 1000 (up to the total input MUE dimensions). We used the *LikeStatus* dataset in Table 1 as the training data for multi-view unsupervised feature learning. For MUE-based supervised SUD predication, we used the *LikeStatusSUD data*. In our experiments, we use a variant of CCA called *wGCCA* implemented by (Benton et al., 2016) where we set the weights for both views to be equal [1]. We used the DCCA implementation by (Andrew et al., 2013) which uses Keras and Theano as the deep learning platform [2]. We also varied the number of hidden layers from 1 to 3 to tune the performance.

We compared our multi-view learning results with 3 baselines: BestSPE and BestSLE are the best single view models. We also used a 3rd baseline called *Unigram_combine*, which simply concatenates all the post and like unigrams together and then applies supervised feature selection before uses the remaining features in a SVM-based classification. As shown in Table 5, both wGCCA and DCCA significantly outperformed the unigram-based baseline ($p < 0.01$ based on t-test). The difference between the best multi-view models (wGCCA_balanced for Alcohol and drug, wGCCA_imbalanced for illicit drugs) and the best single view models are also significant ($p < 0.01$). wGCCA also performed significantly better than DCCA on our tasks ($p < 0.01$ based on t-tests).

Table 5: MUE: Prediction Results

	Tobacco	Alcohol	Drug
BestSPE	0.802	0.768	0.819
BestSLE	0.787	0.795	0.791
Unigram_combine	0.685	0.669	0.662
wGCCA_balanced	0.848	**0.811**	**0.844**
wGCCA_imbalanced	**0.855**	0.799	0.832
DCCA_balanced	0.774	0.778	0.742
DCCA_imbalanced	0.760	0.781	0.737

7 Social Media and Substance Use

In addition to building models that predict SUD, we are also interested in understanding the relationship between a person's social media activities and substance use behavior. Since many of the SPEs and SLEs are not easily interpretable, in this section, we focus on the LIWC features from status updates and the LDA topics from both Likes and status updates. Since the SUD ground truth is an ordinal variable and the LIWC/LDA features are numerical, we used Spearman's rank correlation analysis to identify features that are most significantly correlated with SUD. Figure 1 shows the LIWC features that are significantly correlated with at least one type of SUD ($p < 0.05$). The color red represents a positive correlation while blue represents a negative correlation. In addition, the saturation of the color indicates the significance of the correlation. The darker the color is, the more significant the correlation is.

As shown in Figure 1, swear words such as "fuck" and "shit", sexual words such as "horny" and "sex", words related to biological process such as "blood" and "pain" are positively correlated with all three types of SUD. In addition, words related to money such as "cash", words related to body such as "hands" and "legs", words related to ingestion such as "eat" and "drink" are positively correlated with both alcohol and drug use; words related to motion such as "car" and "go" are positively correlated with both alcohol and tobacco use. In addition, female references such as "girl" and "woman", prepositions, space reference words such as "up" and "down" are positively cor-

related with alcohol use, while words related to anger such as "hate" and "kill", words related to health such as "clinic" and "pill" are positively correlated with drug use.

In terms of LIWC features that are negatively correlated with SUD, words associated with the past such as "did" and "ago" are negatively correlated with both tobacco and drug use; assent words such as "ok", "yes" and "agree" are negatively correlated to both alcohol and tobacco use. In addition, male references such as "boy" and "man", words related to reward such as "prize" and "benefit", words related to positive emotions such as "nice" and "sweet", first person pronouns (plural) such as "we" and "our" are negatively correlated to drug use. Moreover, impersonal pronouns such as "it", differentiation words such as "but" and "else", and work-related words such as "job" and "work" are negatively correlated with alcohol use. Surprisingly, risk related words such as "danger", words related to sadness, death and negative emotions are also negatively correlated with alcohol use.

There are a few surprising correlations in our results. For example, female references such as "girl" and "woman" are positively related to alcohol use while male references such as "man" and "boy" are negatively related to drug use. To interpret this, previous research has shown (Schwartz et al., 2013) that female references actually are used more often by male authors and vice versa. Thus, our findings suggest that males are more likely to use alcohol while females are less likely to use illicit drugs.

We have also used Spearman's correlation analysis to identify SUD-related "Like Topics" and "Status update Topics" learned by LDA. Since the number of significant topics is quite large, in Table 6, we only show a few samples. Based on a user's status updates, "swear topics" (T1, T9) are positively correlated with both tobacco and drug use, which is consistent with our LIWC findings. The "night life topic" (T5) is positively related to alcohol use. In addition, school related topics (T2, T6) are negatively correlated with tobacco and alcohol use. Positive family-related activities (T10) are negatively correlated with drug use. In addition, based on the LDA topics learned from "likes", a preference for rock music (T3,T11) is positive correlated with tobacco and drug use. A preference for movies such as "V For Vendetta" and "Boondock Saints" (T7) is positively correlated with alcohol use, while having a hobby (T12), liking cartoons and shows favored by kids (T8) or liking movies and brands favored by girls (T4) are negatively correlated with drug, alcohol and tobacco use.

8 Discussion and Future Work

Currently, our multi-view unsupervised features learning methods only learn from the intersection of the like and status update data, which is much smaller than either the like or the status update data. Similarly, MUE-based supervised prediction used only the intersection of all three datasets which is very small (only contains 896 users).

Thus, it would be useful if a future multi-view feature learning algorithm is capable of using all the available data (e.g., the union of all the supervised and unsupervised training data). Moreover, our best SPE model only has 50 dimensions while our best SLE model has 300 dimensions. This might be because the supervised training data used by SPE is almost three times smaller than that used by SLE . But surprisingly, SPE-based models performed better than SLE-based models. We expect that with more training data, the performance of SPE-based methods can be further improved.

9 Conclusion

We believe social media is a promising platform for both studying SUD-related human behaviors as well as engaging the public for substance abuse prevention and screening. In this study, we have focused on four main tasks (1) employing unsupervised features learning to take advantage of a large amount of unsupervised social media data (2) employing multi-view feature learning to combine heterogeneous user information such as "likes" and "status updates" to learn a comprehensive user representation (3) building SUD prediction models based on learned user features (4) employing correlation analysis to obtain human-interpretable results. Our investigation has not only produced models with the state-of-the-art prediction performance (e.g., for all three types of SUD, our models achieved over 80% prediction accuracy based on AUC), but also demonstrated the benefits of incorporating unsupervised heterogeneous user data for SUD prediction.

Demographic-Aware Word Associations

Aparna Garimella, Carmen Banea, and Rada Mihalcea

{gaparna,carmennb,mihalcea}@umich.edu

Abstract

Variations of word associations across different groups of people can provide insights into people's psychologies and their world views. To capture these variations, we introduce the task of demographic-aware word associations. We build a new gold standard dataset consisting of word association responses for approximately 300 stimulus words, collected from more than 800 respondents of different gender (male/female) and from different locations (India/United States), and show that there are significant variations in the word associations made by these groups. We also introduce a new demographic-aware word association model based on a neural net skip-gram architecture, and show how computational methods for measuring word associations that specifically account for writer demographics can outperform generic methods that are agnostic to such information.

1 Introduction

Understanding the associations that are formed in the mind is paramount to understanding the way humans acquire language throughout a lifetime of learning (Elman et al., 1997; Rogers and McClelland, 2004). Furthermore, word associations are believed to mirror the mental model of the conceptual connections in a human mind, and constitute a direct path to assessing one's semantic knowledge (Nelson et al., 2004; Mollin, 2009).

Word associations start forming early in life, as language is acquired and one learns based on the environment where concepts lie in relation to each other. For example, we may learn to associate "mother" with "warmth," or "fire" with "burn." Yet, this mental model is not static but highly dynamic, and is shaped by new experiences over a lifetime. For instance, (Tresselt and Mayzner, 1964) showed that word associations change with time, and that for respondents in younger age groups their variability is lower, while for those in older age groups the variability is higher, as their life experiences modify the commonality between respondents from the same group.

Computational linguistics has traditionally taken the "one-size-fits-all" approach, with most models being agnostic to the language of the speakers behind the language. With the introduction and adoption of Web 2.0, there has been an exponential increase in the availability of digital user-centric data in the form of blogs, microblogs and other forms of online participation. Such data often times can be augmented with demographic or other user-focused attributes, whether these are user-provided (e.g., from a user's online profile) or labeled using an automatic system. This enables computational linguists to go beyond generic corpus-based metrics of word associations, and attempt to extract associations that pertain to given demographic groups that would not have been possible without administering time consuming and resource intensive word association surveys.

While current NLP methods generally deal with more advanced tasks (relation extraction, text similarity, etc.), at their very core many of these tasks assume some way of drawing connections (or associations) between words. Therefore, as a step toward demographic-aware NLP, we choose to work on the core task of "word association." The algorithms we introduce can be immediately applied to demographic-aware word similarity, and with some minor changes to demographic-aware text similarity. Future stages could also include demographic-aware labeled associations, and more advanced applications such as information retrieval (which relies heavily on word associations/similarity), demographic-aware keyword extraction, dialogue personalization, and so forth.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2285–2295
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

Note that a few other researchers have explored demographic-aware NLP models with promising results, primarily focusing on the use of demographics for various forms of text classification (Hovy, 2015) or sentiment and subjectivity classification (Volkova et al., 2013).

The paper makes several main contributions. First, we create a novel dataset of demographic-aware word associations, consisting of approximately 300 stimulus words along with 800 responses per word collected from a demographically-diverse group of respondents, for a total of 228,800 responses. Removing spam responses resulted in 176,097 responses. Analyses that we perform on this dataset demonstrate that indeed word associations vary across user dimensions.[1] Second, we show that the associations we obtained follow the same pattern as those elicited during traditional classroom surveys. Third, we propose an evaluation metric suited for the free association norms task. Fourth, we introduce a demographic-aware model based on a skip-gram architecture and through several comparative experiments, we show that we are able to surpass the performance attainable on demographic agnostic models.

We specifically focus on two demographic dimensions: location and gender. For location, we consider India and United States (US), choice made primarily because these two countries have a large English-speaking population, represented both on social media and on crowdsourcing platforms.

2 Related Work

Word associations have captured the attention of psychologists since at least the early 1900. In (1910), Kent and Rosanoff proposed the use of a set of 100 emotionally neutral words for word associations surveys. A psycholinguistics study that looked at the impact that the nationality of respondents may have on formed word associations was carried out by Rosenzweig (1961), employing the stimulus word list proposed by Kent and Rosanoff (1910) manually translated into several West European languages. Based on the primary responses coming from native speakers of English, French, German and Italian, which were mapped back into English, the author concludes that the associations formed by speakers of the four languages are very similar, with "almost half the comparisons in any pair of languages yielding agreements," where the most frequent responses are encountered across pairs of languages. Given that the primary responses were compared across languages and people with a relatively common origin (West European), our work seeks to investigate whether similar results are encountered when looking at different locations (namely US versus India). Furthermore, our study is conducted in English from the beginning, to eliminate a third party's subjectivity in mapping primary responses from one language to another.

There have also been attempts in computational linguistics to derive associations not based on survey results (which are static and resource intensive), but based on statistics derived from large corpora (Church et al., 1989; Wettler and Rapp, 1989; Church and Hanks, 1990). Research in semantic similarity can also be used to model associations based on several directions: (1) co-occurrence metrics that rely on large corpora such as PMI (Church and Hanks, 1990), second order PMI (Islam and Inkpen, 2008), or Dice (Dice, 1945); (2) distributional similarity-based measures, that characterize a word by its surrounding context such as LSA (Landauer and Dumais, 1997), ESA (Gabrilovich and Markovitch, 2007), or SSA (Hassan and Mihalcea, 2011); and (3) knowledge-based metrics that rely on resources such as lexica or thesauri (Leacock and Chodorow, 1998; Lesk, 1986; Jarmasz and Szpakowics, 2003; Hughes and Ramag, 2007). However, most of these metrics have so far been applied to model the relatedness between two words, namely given a word pair, to score how similar the two words are; as such, they have not been used to predict free association norms, namely given a word, to attempt to determine the most likely word that a human would associate with that stimulus.

Large word association databases exist, such as the one collected by Deyne et al. (2013), who used a set of 12,000 stimulus words and surveyed 70,000 participants. Yet to our knowledge, no concerted attempt has been made to gather word associations jointly with the demographic characteristics of the people behind them.

While not directly seeking to extract word associations but rather trying to represent language meaning through a locality lens, (Bamman et al., 2014) have proposed using distributed representations to model words employed by social media

[1] This work is not centered around comparing different word forms, as one would encounter for example in British English and American English, but rather around different word associations that people with a particular demographic characteristic are inclined to make, e.g., "health" in India is more strongly associated with "wealth", while in the United States it is more strongly associated with "sick."

users from different US states. They were able to show that the regional meaning of words can successfully be carried by word embeddings, for example the word “wicked” was most similar to the word “evil” in Kansas, while in Massachusetts, it was most similar to “super” (based on the cosine similarity of the words’ vectorial representation). In contrast, our rationale in this article is to explore if word associations can be automatically derived from large corpora annotated with user-centered attributes such as location or gender.

3 Word Associations Dataset

Word association data collection typically consists of providing participants with a list of words, also known in the psycholinguistics literature as *stimulus words*, and asking them to provide the first word that comes to mind in response to each stimulus. For instance, given a stimulus word such as *cat*, one would expect answers such as *dog* or *mouse*. Earlier work on word associations administered the tests in classroom settings, with 100 words per survey, and the results were compiled into tables of norms of word associations (Kent and Rosanoff, 1910; Nelson et al., 2004).

Since our goal is to explore the effect of demographics on word associations, we created a task on Amazon Mechanical Turk (AMT) able to reach a wide and demographically diverse audience. The survey was structured into two sections: the word association part, followed by a demographic survey. Given the online nature of the survey, and since we aimed for a high quality dataset, each participant was presented with a set of 50 stimulus words at a time (instead of 100). The demographic section consisted of seven questions covering gender, age, location, occupation, ethnicity, education, and income.

Stimuli. The stimulus list consists of a set of approximately 300 words. Among these, 99 words are sourced from the word list proposed by Kent and Rosanoff (1910) (*standard* list).[2] The remaining words are identified using the method for finding word-usage differences between two groups introduced in (Garimella et al., 2016), which relies on large collections of texts authored by the two groups to identify words that can be accurately classified by an automatic classifier as belonging to one group versus another. Using their method, we obtain 100 words as the top most different words between US and India (*culture* list), and another set of 100 words as the top most different words between male and female (*gender* list). The reunion of these three lists results in 286 stimulus words for which we collect word associations. Examples are shown in Table 1.

Responses. The task was published separately for respondents from US and India, as AMT has an option of only presenting the survey to people from a preselected geographical location. Six different surveys, each including approximately 50 stimulus words, were administered for each region. The survey was conducted in English for both countries, noting that one of the official languages of India is English (alongside Hindi). Each survey also included four spam-checking questions with previously known answers (e.g., *What is the color of the sky?*, with five options *blue*, *red*, *pink*, *green*, *yellow*), which were used to filter out respondents who were filling out the survey without reading the questions.

For each set, we gathered 400 responses per region, resulting in 800 responses for both US and India. After removing the respondents who did not pass the spam-checking questions, we were left with an average of 752 responses per word, which we then balanced by gender, to retain an equal number of Indian women, Indian men, US women, and US men. This resulted in 492 and 480 responses for the two sets of 50 *standard* stimulus words, 436 and 468 for the *culture* words, and 440 and 432 for the *gender* words. Similar to (Rosenzweig, 1961), all the responses were normalized (i.e. plural was mapped to singular, gerund to infinitive, etc.); in our case we used the Stanford CoreNLP Lemmatizer (Manning et al., 2014), ultimately aggregating the responses into a gold standard.

Table 1 shows the top associations for a few sample stimuli, as collected from India and US, and males and females. Finer-grained qualitative analyses also reveal interesting distinctions. For instance *bath* is overwhelmingly associated by men with *water*, while US women associate it with *bubble*, and Indian women with *soap*. Interestingly, US men seem to provide responses based on collocations, e.g., they answer *Kane* for *citizen* (citizen Kane), *weight* for *heavy* (heavyweight), or *lion* for *mountain* (mountain lion); on the contrary, women more often provide responses that consist of synonym or antonym words, e.g., *person* for *citizen*, *health* for *sick*, or *light* for *heavy*.

For further insight, Table 2 shows the average

[2] Note that this list originally included 100 words. The word “foot” was however misspelled in our survey, and instead we gathered answers for “food.”

	Gender		Location	
Word	Male	Female	India	US
beautiful	girl, woman, pretty	pretty, girl, ugly	girl, nature, flower	pretty, girl, ugly
cheese	pizza, bread, milk	butter, mouse, pizza	pizza, butter, bread	cracker, swiss, cheddar
hard	soft, rock, work	soft, work, rock	work, stone, rock	soft, rock, time
health	good, wealth, care	good, wealth, sick	wealth, good, fitness	good, sick, care
range	distance, gun, shooting	gun, rover, mountain	price, rover, wide	gun, distance, rover
admit	hospital, guilt, card	hospital, confess, one	hospital, card, accept	guilt, one, confess
mix	tape, match, juice	cake, tape, stir	juice, tape, match	stir, tape, cake
organize	clean, arrange, party	clean, arrange, meeting	arrange, meeting, party	clean, sort, neat
stack	pile, book, box	book, pile, hay	book, queue, pile	pile, book, pancake

Table 1: Top three most frequent responses for sample stimulus words.

number of different responses obtained for a given stimulus word, with the lowest variability word, and the highest variability word.[3] The second column lists the correlations between the frequency of the primary response and the number of different responses, as also reported by (Jenkins and Palermo, 1965). This correlation is negative, as the more people agree on the primary response, the fewer overall unique answers for a stimulus word are provided. Additionally, Figure 1 shows the Zipfian distribution of average norm frequency; the most frequent response is given on average by 24% of the respondents, while the third most frequent response is given by 7% of them.

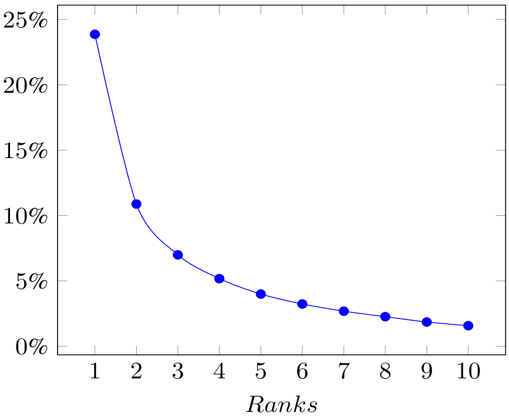

Figure 1: Primary response frequency (in percent) versus rank for the Standard word list.

Demographic	Avg.	Correlation	Lowest Variability	Highest Variability
Standard				
India	60.88	-0.52	stove	city
US	51.19	-0.53	bath	trouble
Male	61.63	-0.45	stove	city
Female	56.75	-0.55	stove	city
All				
India	72.27	-0.59	stove	regardless
US	57.03	-0.56	east	basically
Male	70.33	-0.52	stove	regardless
Female	66.54	-0.59	east	respectively

Table 2: Average number of responses obtained for a given stimulus word, correlation between frequency of primary response and number of different responses, words exhibiting the lowest variability, and words with the highest variability.

Analyses of Demographic Variations. To model norm strength within a given demographic group or across groups, we tabulate how often respondents from a group match the most frequent answer (*Primary*) or one of the most frequent ten answers for that group (*Top10*). That is, given the response for one stimulus word as provided by one held-out survey respondent at a time, we determine whether that response matches the most frequent association of the *remaining* members of the same group (Table 3, *Primary* columns), or one of the top 10 associations pertaining to that same group (Table 3, *Top10* columns). Similarly, we measure the match with the most frequent or the top 10 responses from the other group, as shown in Table 4. As expected, the intra-group similarities are significantly higher than the inter-group similarities, which supports our hypothesis that different groups make different word associations, which tend to be more coherent within a group than across groups. While males and females have similar ranges for their agreement figures, we notice that on average US respondents have stronger intra-group agreements. Note also that inter-group similarities are asymmetrical, as multiple words may have the same association frequency for one group, yet for the complementary group that may not be the case.

[3] In several of our data analyses, in order to allow for a direct comparison with the word list from (Kent and Rosanoff, 1910), in addition to showing statistics for the entire dataset (*All*), we also show statistics separately compiled for the list from (Kent and Rosanoff, 1910) (*Standard*).

As an additional analysis of demographic variations in the responses received, for each respondent, we predict his / her demographic group using a majority vote conducted across all the user's responses using a simple rule-based system that assigns each response to the group having the highest frequency for that particular association. For instance, given the response *sun* obtained from a respondent for the stimulus *yellow*, we assign the respondent to either India or US depending on the highest normalized frequency of the response *sun* for the same stimulus in each of those groups. A similar rule-based assignment is also used for gender. Thus, we compute the response words and their normalized frequencies based on the responses from 80% of the users chosen randomly, and accordingly predict the demographic group for the remaining 20% of the users based on a decision across the entire set of a user's responses. Table 5 shows the results of these predictions, which indicate high location variability (i.e., we can predict with high accuracy the location of a respondent), and medium gender variability.

Demo-	Standard		All	
graphic	Primary	Top10	Primary	Top10
India-India	0.23	0.77	0.18	0.78
US-US	0.29	0.82	0.25	0.81
Male-Male	0.23	0.79	0.19	0.79

4 Computational Models of Word Associations

We first introduce a new model for measuring word associations that leverages a shallow neural net architecture to embed demographically-enriched words. We then compare the performance of the predicted associations to those resulting from other approaches, including traditional corpus-based measures such as mutual information or vector-space models, as well as a recent distributed learning model with word embeddings. For each of these methods, we predict, evaluate, and compare generic associations (devoid of any demographic information), as well as demographic-aware associations.

4.1 Composite Skip-gram Models

We introduce a new word association model, which relies on the skip-gram neural net architecture (Mikolov et al., 2013), and leverages its efficiency and ability to deal with less frequent words.

The skip-gram model tries to predict the context given a word, that is, for each word w_i in the input sequence $w_1, \ldots, w_T$, the model tries to predict w_{i-2}, w_{i-1}, w_{i+1} and w_{i+2}, assuming, for example, a sliding window of five words. Mathematically, the model maximizes the objective function

$$J = \frac{1}{T} \sum_{i=1}^{T} \sum_{j=-c, j \neq 0}^{c} \log P(w_{i+j}|w_i) \qquad (1)$$

where T is the number of tokens in the data set, c is the number of context words on each side of the target word w_i and $P(w_{i+j}|w_i)$ is the probability to observe word w_{i+j} in the context of word w_i.

To make this model demographic-aware, we propose two variations, which we refer to as composite skip-gram models ($C - SGM$). In the first one ($EMB1$), the target word w_i is tagged with a demographic label L (e.g., gender). For example, for the target word "formula$^{L=\text{female}}$" we try to predict a high probability for "baby" and "milk" occurring in the neighboring context. The underlying reasoning is that tagged words that appear in similar contexts will be nudged toward each other, while those that do not, will further distance themselves. This allows discrepancies to emerge between how the words are embedded given a demographic dimension.

In the second variation ($EMB2$), we also include the demographic label in the context. That is, for each skip-gram $(c_{i,\text{left}}, w_i, c_{i,\text{right}})$ we generate three skip-grams

$$\begin{array}{lll} (c^{\text{label}}_{i,\text{left}}, & w_i, & c_{i,\text{right}}) \\ (c_{i,\text{left}}, & w^{\text{label}}_i, & c_{i,\text{right}}) \\ (c_{i,\text{left}}, & w_i, & c^{\text{label}}_{i,\text{right}}) \end{array} \qquad (2)$$

The two models seek to capture different scenarios. In the first model, where we only add the demographic label to the target word, the embedding of the labeled word is optimized with respect to the generic embedding of the context. In the second model, the optimization is rather symmetric, allowing tagged and generic embeddings to influence each other. Thus, the optimization function seeks to predict both tagged and untagged words in the vicinity given a target word, instead of only focusing on predicting untagged words like EMB1. The embeddings resulting from such a model should allow for more accurate representations across the tagged and untagged vocabulary, where for example the word "mother" uttered by a female would be close to the word "mother" (regardless of author gender). In both scenarios, the embeddings space accommodates both tagged and untagged words at the same time, being very computationally robust, and allowing comparisons across the tagged version of words, as well as between generic words and their tagged surrogates. For both variations, we compute the cosine similarity between the stimulus word and each of the vocabulary words (whether generic or demographic-enhanced), and retain the closest unique candidates (after dropping their demographic tag).

4.2 Other Word Association Models

Mutual Information (MI). We implement the information theoretic measure proposed by Church and Hill (1990). It is defined as follows:

$$I(x, y) = log_2 \frac{P(x, y)}{P(x)P(y)} \tag{3}$$

This measure compares the probability of observing words x and y together (the joint probability) with the probabilities of observing x and y independently. The joint probability, $P(x, y)$, is generally estimated by counting the number of times x is followed by y in a window of w words, and normalizing this count with the size of the corpus. We follow Church and Hill and set the window size w to five, as it is large enough to capture verb-argument constraints, and not so large to restrict to strict adjacency. For a given stimulus word, (1) we use the entire corpus and compute the generic MI word association with the rest of the vocabulary, and get the top associations according to their MI scores; and (2) we use the section of the corpus obtained for a given demographic, and determine the top demographic-aware MI word associations.

Vector-Space Model (VSM). We also implement the traditional vector-space model, where each word is represented by a $tf.idf$ weighted vector inside the term-document matrix (representing term occurrences inside the documents in the corpus), with a length equal to the number of documents D in the corpus (Salton and McGill, 1986). For a given stimulus word, cosine similarities are computed with all the remaining word vectors in the vocabulary, and those words having the highest similarity are considered as the top responses. Similar to MI, we use all the documents in the corpus to produce generic word associations, while only those documents pertaining to a specific demographic value are utilized to derive demographic-aware associations.

Skip-gram Language Model. We also use the distributional representation technique of word embeddings ($SGLM$) proposed by Bamman et al. (2014). Specifically, information about the speaker (geography, in their case) is used while learning the vector-space representations of word meanings from textual data that is supplemented with metadata about the authors. In addition to the *global* embedding matrix W_{main} that contains low-dimensional representations for every word in the vocabulary (Mikolov et al., 2013), this approach has an additional $|C|$ matrices $\{W_c\}$ of the same size as W_{main}, where $|C|$ denotes the number of values the demographic variable has in the data (e.g., if gender is the demographic variable, $C = \{female, male\}$ and $|C| = 2$). Each of these $|C|$ matrices captures the effect that each demographic variable value has on each word in the vocabulary. To index the embedding of a stimulus word $w \in \mathbb{R}^{|V| \times k}$, the hidden layer h is computed as the sum of the matrix multiplications with each of the independent embeddings:

$$h = w^T W_{main} + \Sigma_{c \in C} w^T W_c \tag{4}$$

It then predicts the value of the context word y using another parameter matrix $X \in \mathbb{R}^{|V| \times k}$ based on a softmax function $o = softmax(Xh)$, where $o \in \mathbb{R}^{|V| \times k}$. Backpropagation using (input x, output y) word tuples learns the values of the various embedding matrices W and parameter matrix X, which maximize the likelihood of context words y conditioned on the stimulus word x.

We use this approach in its original implementation provided by (Bamman et al., 2014) to compute the word embedding vectors for all the words in the vocabulary. Given a stimulus word, the closest vocabulary words with the highest cosine similarity are retained as the top association predictions for the given stimulus word.

5 Experiments

All our models require textual data with demographic information. We introduce below the data we used and the metrics we adopted for evaluation.

Data. Given the requirement of having gender and location information associated with the data, we resort to blogs, and collect from Google Blogger[4] a large set of blog posts authored between 1999 and 2016. Table 6 shows the breakdown of the raw blog counts per demographic category. From these, we retain only those posts with non-empty content, and preprocess the data by removing HTML tags, converting all the tokens to their lemmatized forms,[5] and discarding those lemmas with a frequency less than 10, in order to avoid misspellings and other noise characteristic to social media content.

Demo-	Raw		Balanced		
graphic	Profiles	Posts	Profiles	Posts	Tokens
India	1,520	339,624	1,520	34,987	16,884K
US	3,273	825,093	1,520	32,782	11,706K
Male	2,031	597,935	1,818	44,299	21,971K
Female	1,818	321,779	1,818	45,980	17,070K

Table 6: Raw and balanced blog dataset statistics.

From the above pool of blog posts, we create two datasets with complementary demographic classes (1) location: India-US and (2) gender: male-female.

We process each of these datasets so that they are profile-balanced with no peaks for any specific years, by applying several heuristics: **(1)** Compute the minimum number of users n over all the classes (e.g., Indian and US authors in the case of the location dataset). **(2)** From each class, select the top n users based on the number of years they were blogging and the number of posts they wrote.[6] This ensures that the maximum amount of data will be available for the selected users. **(3)** For each of these n users, pick at most 50 posts in a round-robin fashion from the years in which they blogged. **(4)** Let M be the total number of posts collected in this manner from all the classes. In order to avoid having most of the posts coming from a small number of years, set a cutoff X as a fraction of M. For each year, a maximum of X posts will be chosen from the set of M posts ($X = 0.1M$). **(5)** To ensure that all the users get to contribute posts, and that the contribution of prolific writers is kept in check, maintain user participation scores:

$$p(user) = \frac{\text{posts collected from user}}{\text{total number of posts collected}} \quad (5)$$

These scores are updated after every year is processed, as explained further. **(6)** Sort the years in increasing order of number of posts and iterate through them; identify the lowest number of posts contributed by the least prolific writer, then collect the minimum number of posts from all users who published in that year in a round-robin manner. Then, select additional posts from users in increasing order of participation scores, until the number of posts for the year reaches the cutoff X. **(7)** After each year, update the user participation scores. Table 6 shows the number of users and posts retained after balancing. This particular composition is used in our *location* data set (consisting of India and US posts) and *gender* data set (consisting of females and males posts).

Metrics. Given that the word association task is relatively similar to the lexical substitution task, in terms of open vocabulary and lack of a "right" answer, we decided to borrow the *best* and out-of-ten (*oo10*) evaluation metrics traditionally used for the latter (McCarthy and Navigli, 2009), yet corrected for weight (Jabbari et al., 2010). Briefly, these measures take the best (or top ten) responses from a system, and compare them against the gold standard, while accounting for the frequencies of the responses in the gold standard. In addition, since Figure 1 shows that the top three ranking norms are provided as answers by approximately 42% of the respondents, with the remaining norms following a long Zipfian distribution in terms of frequency of appearance, we also compute out-of-three (*oo3*), which represents a more focused approximation of our ability to predict human associations (note that out-of-ten covers 62% of the responses). Several recent papers on word associations evaluated their models indirectly via Pearson or Spearman correlation performance on a word similarity task (Chaudhari et al., 2011; Deyne et al., 2016); we choose instead to evaluate word associations directly, by using metrics that more closely align with the evaluations performed in the field of psychology where the best output of a system is compared against the most frequent human response (Bel-Enguix, 2014; Mohammad, 2011).

For a given stimulus word w with human responses H_w, suppose a system returns a set of answers S_w. We estimate how well this system

[4] www.blogger.com

[5] We normalize the word forms using the Stanford CoreNLP lemmatizer (Manning et al., 2014).

[6] Prolific users will be chosen first. For a class with exactly n users, all users will be chosen.

can find a *best* substitute for w using Equation 6, where the function $freq_w(s)$ returns the count of a system response s in H_w, and $maxfreq_w$ returns the maximum count of any response in H_w.

$$best(w) = \frac{\Sigma_{s \in S_w} freq_w(s)}{maxfreq_w \times |S_w|} \qquad (6)$$

$$oo\mathbf{n}(w) = \frac{\Sigma_{s \in S_w^n} freq_w(s)}{|H_w|} \qquad (7)$$

Equation 7 measures the coverage of a system by allowing it to offer a set S_w^n of n responses for w, where each response s is weighted by its frequency $freq_w(s)$ in H_w.

6 Evaluations and Discussions

We conduct evaluations using all the word association models described in Section 4. The results using the *best*, *out-of-three*, and *out-of-ten* evaluation metrics are listed in Table 7. For all the embeddings experiments, we use 300 latent dimensions. The Gen variation uses the demographic-blind dataset, whereas the DA variation uses the demographic-aware dataset.[7]

The MI and VSM models do not perform well in the word association prediction task, whether considering the generic or the demographic-aware data. We should emphasize, however, that the generic version of these models is able to consider co-occurrences across the entire generic datasets, while the demographic-aware co-occurrences can only be computed from the section of the dataset that matches a particular demographic; as such, these latter models are placed at a disadvantage.

Perhaps not surprisingly, the neural network skip-gram-based architectures, whether SGLM or our C-SGM, always achieve better results when compared to MI or VSM. The demographic-aware variation proposed by (Bamman et al., 2014) uses an extended skip-gram architecture that encodes a generic embedding, and several demographic-based filters per class, which in our case translates into three matrices of 300 dimensions each, the first for the generic words, and the subsequent ones for skews to be applied to the generic words in order to render the embedding through the lens of a given demographic. $SGLM - Gen$ in our case are the predictions based on the generic matrix, while $SGLM - DA$ are the predictions modified along the lines of a particular demographic.

Our composite skip-gram models encode a single matrix that contains a mix of demographic-aware and generic words expressed as 300 latent dimensions. For both gender and location, our gender-aware models ($EMB1$ and $EMB2$) surpass the SGLM gender-aware model. Surprisingly, while SGLM was never meant to be generic, the predictions based on its generic embedding matrix prove to be a difficult baseline to surpass, similar to C-SGM generic. Nonetheless, the composite skip-gram models ($EMB1$ and $EMB2$) do achieve best and second best rankings in the vast majority of cases (when compared to the best among all the other methods), with $EMB1$ being the more robust variation performing well both for gender and for location. Focusing on the performance of $EMB1$, the highest gains are observed for India-based predictions, for best (from 0.05 to 0.08) and out-of-three (from 0.07 to 0.12); for male-based predictions increasing from 0.11 to 0.13 for best, and from 0.17 to 0.20 for out-of-three; and for female-based predictions, increasing from 0.13 to 0.14 for best, and from 0.17 to 0.20 for out-of-three. US-based associations are the hardest to predict, probably because of the diverse makeup of society; additional evaluations are needed to pinpoint the exact cause.

To determine how susceptible the embedding model is to skewed, but larger training data, we also run a separate experiment on the entire raw set of blogs we collected (described on the left of Table 6), where we re-generate the $EMB1$ and $EMB2$ models. While the entire dataset is significantly larger than the balanced set, it is also significantly skewed: the data in the India:US dataset was skewed in a proportion of 1:0.48 tokens, while for Female:Male the proportion was 1:0.41 tokens. As was the case for the balanced dataset, the $EMB1$ model is still the most robust (see the bottom section in Table 7), and it achieves significant gains when compared to its balanced counterpart, in particular for *best* (for the US demographic from 0.03 to 0.13, and for India from 0.08 to 0.11), and for *out-of-three* (for US from 0.07 to 0.15, and for India from 0.12 to 0.17), which suggests that as an avenue for future research, we can explore the use of significantly larger even if unbalanced datasets to train our models.

7 Conclusion

In this paper, we introduced the task of demographic-aware word associations. To understand the various ways in which people associate words, we collected a new large demographics-

[7] To place the results in this table in perspective, it is important to note that results for this task are traditionally low. Given that the most frequent response is selected on average by 24% of respondents (see Figure 1), we can see that even for humans, the highest score would be around 0.24.

enhanced dataset of approximately 300 stimulus words and their associated norms compiled from 800 respondents for a total of 176,097 non-spam responses, and show that for people of different demographics, associations do differ with gender and location.

We proposed a new demographic-aware word association method based on composite skip-gram models that are able to jointly embed generic and gender tagged words. We showed that this method improves over its generic counterpart, and also outperforms previously proposed models of word association, thus demonstrating that it is useful to account for the demographics of the people behind the language when performing the task of automatic word association. We regard this as a first step toward demographic-aware NLP, and in future work we plan to address other more advanced NLP tasks while accounting for demographics.

The word association dataset introduced in this paper is publicly available from http://lit.eecs.umich.edu/downloads.html.

A Factored Neural Network Model for Characterizing Online Discussions in Vector Space

Hao Cheng **Hao Fang** **Mari Ostendorf**
University of Washington
{chenghao,hfang,ostendorf}@uw.edu

Abstract

We develop a novel factored neural model that learns comment embeddings in an unsupervised way leveraging the structure of distributional context in online discussion forums. The model links different context with related language factors in the embedding space, providing a way to interpret the factored embeddings. Evaluated on a community endorsement prediction task using a large collection of topic-varying Reddit discussions, the factored embeddings consistently achieve improvement over other text representations. Qualitative analysis shows that the model captures community style and topic, as well as response trigger patterns.

1 Introduction

Massive user-generated content on social media has drawn interests in predicting community reactions in the form of virality (Guerini et al., 2011), popularity (Suh et al., 2010; Hong et al., 2011; Lakkaraju et al., 2013; Tan et al., 2014), community endorsement (Jaech et al., 2015; Fang et al., 2016), persuasive impact (Althoff et al., 2014; Tan et al., 2016; Wei et al., 2016), etc. Many of these studies have analyzed content-agnostic factors such as submission timing and author social status, as well as language factors that underlie the textual content, e.g., the topic and idiosyncrasies of the community. In particular, there is an increasing amount of work on online discussion forums such as Reddit that exploits the conversational and community-centric nature of the user-generated content (Lakkaraju et al., 2013; Althoff et al., 2014; Jaech et al., 2015; Tan et al., 2016; Wei et al., 2016; He et al., 2016a; Fang et al., 2016), which contrasts with Twitter where the author's social status seems to play a larger role in popularity. This paper focuses on Reddit, using the karma score[1] as a readily available measure of community endorsement.

Some of the prior work on Reddit investigates specific linguistic phenomena (e.g. politeness, topic relevance, community style matching) using feature engineering to understand their role in predicting community reactions (Althoff et al., 2014; Jaech et al., 2015). In contrast, this paper explores methods for unsupervised text embedding learning using a model structured so as to provide some interpretability of the results when used in comment endorsement prediction. The model aims to characterize the interdependence of comment on its global context and subsequent responses that is characteristic of multi-party discussions. Specifically, we propose a factored neural model with separate mechanisms for representing global context, comment content and response generation. By factoring the model, we hope unsupervised learning will pick up different components of interactive language in the resulting embeddings, which will improve prediction of community reactions.

Distributed representations of text, or text embeddings, have achieved great success in many language processing applications, using both supervised and unsupervised methods. Unsupervised learning, in particular, has been successful at different levels, including words (Mikolov et al., 2013b), sentences (Kiros et al., 2015), and documents (Deerwester et al., 1990; Le and Mikolov, 2014). Studies have also shown that the learned embedding captures both syntactic and semantic functions of words (Mikolov et al., 2013a; Pennington et al., 2014; Levy and Goldberg, 2014; Faruqui et al., 2015a). At the same time, em-

beddings are often viewed as uninterpretable – it is difficult to align embedding dimensions to existing semantic or syntactic classes. This concern has triggered attempts in developing more interpretable embedding models (Faruqui et al., 2015b), which is also a goal of our work. We leverage the fact that the structure of the distributional context impacts what is learned in an unsupervised way and include multiple objectives for separating different types of context.

Here, we are interested in linking two types of context with corresponding language factors learned in the embedding space that may impact comment reception. First, conformity to the topic and the language use of the community tends to make the content better accepted (Lakkaraju et al., 2013; Tan et al., 2014; Tran and Ostendorf, 2016). Those global *modes* typically influence the author's generation of local *content*. Second, characteristics of a comment can influence the *responses* it triggers. Clearly, questions and statements will elicit different responses, and comments directed at a particular discussion participant may prompt that individual to respond. Of more interest here are aspects of comments that might elicit minimal response or responses with different sentiments, which are relevant for eventual endorsement.

The primary contribution of this work is the development of a factored neural model to jointly learn these aspects of multi-party discussions from a large collection of Reddit comments in an unsupervised fashion. Extending the recent neural attention model (Bahdanau et al., 2015), the proposed model can interpret the learned latent global modes as community-related topic and style. A comment-response generation model component captures aspects of the comment that are response triggers. The multi-factored comment embedding is evaluated on the task of predicting the comment endorsement for three online communities different in topic trends and writing style. The representation of textual information using our approach consistently outperforms multiple document embedding baselines, and analyses of the global modes and response trigger subvectors show that the model learns common communication strategies in discussion forums.

2 Model Description

To characterize different aspects of language use in a comment, the proposed model factorizes a comment embedding into two sub-vectors, *i.e.* a *local mode* vector and a *content* vector. The local mode vector, computed as a mixture of global mode vectors, exploits the global context of a comment. In Reddit discussions that we use, the global mode represents the topic and language idiosyncracies (style) of a particular subreddit. More specific information communicated in the comment is captured in the content vector. The generation process of a comment is modeled through a recurrent neural network (RNN) language model (LM) conditioned on local mode and content vectors, while the global mode vectors are jointly learned during the training. Moreover, a residual learning architecture (He et al., 2016b) is used to extend the RNN LM for separating the information flow of the mode and the content vectors.

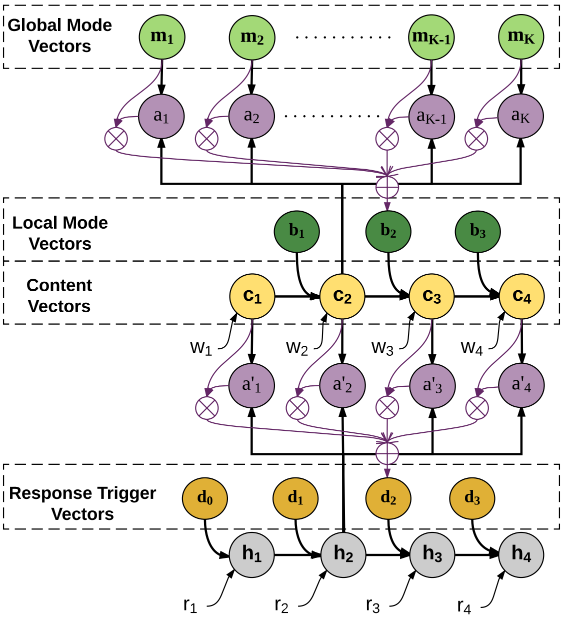

Figure 1: The structure of the full model omitting output layers, illustrating the computation of attention weights for $\mathbf{b}_2$ and $\mathbf{d}_3$ in a comment $w_{1:4}$ with its response $r_{1:4}$. Purple circles a_k and a'_j represent scalars computed in (1) and (6), respectively. $\otimes$ and $\oplus$ are scaling and element-wise addition operators, respectively. Black arrowed lines are connections carrying weight matrices.

In addition to the global context, the full model further exploits direct responses to the comment in order to learn better comment embeddings. This is achieved by modeling the generation of comment responses through another RNN LM conditioned on *response trigger* vectors. The response trigger vectors are computed as mixtures of content vectors, with the idea that they will characterize aspects of the comment that incent others to respond, whether that be information or framing.

The full model is illustrated in Fig. 1. While the end goal is a joint framework, the model is described in the following two sub-sections in terms of two components: i) mode vectors for capturing global context, and ii) response trigger vectors for exploiting comment responses.

2.1 Mode Vectors

Using an RNN LM shown in the upper part of Fig. 1, we model the generation process of a word sequence by predicting the next word conditioned on the global context as well as the local content. The global context is encoded in the local mode vector, computed as a mixture of global mode vectors with mixture weights inferred based on content vectors. The local mode vector indicates where the comment fits in terms of what people in this subreddit generally say. It changes dynamically with the content vector as the comment generation progresses, considering the possibility of topic shifts or different broad categories of discussion participants.

Suppose there is a set of K latent global modes with distributed representations $\mathbf{m}_{1:K} \in \mathbb{R}^n$. For the t-th word w_t in a sequence, a local mode vector $\mathbf{b}_t \in \mathbb{R}^n$ is computed as

$$\mathbf{b}_t = \textstyle\sum_{k=1}^{K} a(\mathbf{c}_t, \mathbf{m}_k) \otimes \mathbf{m}_k,$$

where $\mathbf{c}_t \in \mathbb{R}^n$ is the content vector for the current partial sequence $w_{1:t}$, $\otimes$ multiplies a vector by a scalar, and the function $a(\mathbf{c}_t, \mathbf{m}_k)$ outputs a scalar *association probability* for the current content vector $\mathbf{c}_t$ and a mode vector $\mathbf{m}_k$. The association function $a(\mathbf{c}, \mathbf{m}_k)$ is defined as

$$a(\mathbf{c}, \mathbf{m}_k) = \frac{\exp(\mathbf{v}^T \tanh(\mathbf{U}\,[\mathbf{c}; \mathbf{m}_k]))}{\sum_{i=1}^{K} \exp(\mathbf{v}^T \tanh(\mathbf{U}\,[\mathbf{c}; \mathbf{m}_i]))}, \quad (1)$$

where $\mathbf{U} \in \mathbb{R}^{n \times 2n}$ and $\mathbf{v} \in \mathbb{R}^n$ are parameters characterizing the similarity between $\mathbf{m}_k$ and $\mathbf{c}$.

The computation of the association probability is the well-known attention mechanism (Bahdanau et al., 2015). However, unlike the original attention RNN model where the attended vector is concatenated with the input vector to augment the input to the recurrent layer, we adopt a residual learning approach (He et al., 2016b) to learn content vectors. For the t-th word w_t in a sequence, the content vector $\mathbf{c}_t$ under the original attention RNN model is computed as

$$\mathbf{c}_t = f(\mathbf{W}\mathbf{x}_t + \mathbf{G}\mathbf{b}_{t-1}, \mathbf{c}_{t-1}), \quad (2)$$

where $\mathbf{x}_t \in \mathbb{R}^d$ is the word embedding for w_t, $\mathbf{b}_{t-1} \in \mathbb{R}^n$ and $\mathbf{c}_{t-1} \in \mathbb{R}^n$ are previous local mode and content vectors, respectively, $\mathbf{W} \in \mathbb{R}^{n \times d}$ and $\mathbf{G} \in \mathbb{R}^{n \times n}$ are weight matrices transforming the input to the recurrent layer, and $f(\cdot, \cdot)$ is the recurrent layer activation function. To address the vanishing gradient issue in RNNs, we use the gated recurrent unit (Cho et al., 2014) for the RNN layer, *i.e.*

$$f(\mathbf{p}, \mathbf{q}) = (\mathbf{1} - \mathbf{u}) \odot \tanh(\mathbf{p} + \mathbf{R}[\mathbf{r} \odot \mathbf{q}]) + \mathbf{u} \odot \mathbf{q},$$

where $\odot$ is the element-wise multiplication, $\mathbf{R}$ is the recurrent weight matrix, and $\mathbf{u}$ and $\mathbf{r}$ are the update and reset gates, respectively. In this paper, we compute the content vector $\mathbf{c}_t$ as follows:

$$\mathbf{c}_t = f(\mathbf{W}\mathbf{x}_t, \mathbf{G}\mathbf{b}_{t-1} + \mathbf{c}_{t-1}). \quad (3)$$

Comparing (2) and (3), it can be seen that we first aggregate the local mode vector $\mathbf{b}_{t-1}$ and the content vector $\mathbf{c}_{t-1}$ and treat the resulting vector $\mathbf{G}\mathbf{b}_{t-1} + \mathbf{c}_{t-1}$ as the memory of the recurrent layer. The resulting hidden state vectors from the recurrent layer are content vectors $\mathbf{c}_t$'s. The use of residual learning is motivated by the following considerations. The local mode vector $\mathbf{b}_{t-1}$ can be seen as a non-linear transformation of $\mathbf{c}_{t-1}$ into a global mode space parameterized by $\mathbf{m}_{1:K}$. If the global information carried in $\mathbf{b}_{t-1}$ is residual for generating the following word in the comment, the model only needs to exploit the information in local content $\mathbf{c}_{t-1}$ and learns to zero out the local mode vector $\mathbf{b}_{t-1}$, *i.e.* $\mathbf{G} = 0$. He et al. (2016b) show that the residual learning usually leads to a more well-conditioned model which promises better generalization ability.

Finally, the RNN LM estimates the probability of the $(t+1)$-th word w_{t+1} based on the current local mode vector $\mathbf{b}_t$ and content vector $\mathbf{c}_t$, *i.e.*

$$\Pr(w_{t+1}|w_{1:t}) = \mathrm{softmax}(\mathbf{Q}(\mathbf{G}\mathbf{b}_t + \mathbf{c}_t)), \quad (4)$$

where $\mathbf{Q} \in \mathbb{R}^{V \times n}$ is the weight matrix, and V is the vocabulary size. Note that the model jointly learns all parameters in the RNN together with the mode vectors $\mathbf{m}_{1:K}$. This differs our model from the context-dependent RNN LM (Mikolov and Zweig, 2012), which is conditioned on a context vector inferred from a pre-trained topic model.

2.2 Response Trigger Vectors

Another important aspect of comments in online discussions is how other participants react to the content. In order to exploit those characteristics, we use comment-reply pairs in online discussions and build this component upon the encoder-decoder framework with the attention mechanism (Bahdanau et al., 2015), which is illustrated in the lower part of Fig. 1. The decoder is essentially another RNN LM conditioned on response trigger vectors aiming at distilling relevant parts of the comment which other people are responding to.

Let r_j denote the j-th word in a reply to a comment $w_1, \cdots, w_T$. The decoder RNN LM computes a hidden vector $\mathbf{h}_j \in \mathbb{R}^n$ for r_j as follows,

$$\mathbf{h}_j = f(\mathbf{W}^\dagger \mathbf{x}_j + \mathbf{G}^\dagger \mathbf{d}_{j-1}, \mathbf{h}_{j-1}), \tag{5}$$

where $\mathbf{W}^\dagger \in \mathbb{R}^{n \times d}$ and $\mathbf{G}^\dagger \in \mathbb{R}^{n \times n}$ are weight matrices, $\mathbf{x}_j$ is r_j's word embeddings from a shared embedding dictionary as used by the encoder RNN LM in Subsection 2.1, and $\mathbf{d}_{j-1} \in \mathbb{R}^n$ and $\mathbf{h}_{j-1} \in \mathbb{R}^n$ are the response trigger vector and hidden vector at the previous time step, respectively. The initial hidden vector $\mathbf{h}_0$ is set to be the last content vector $\mathbf{c}_T$. With the comment's content vectors $\mathbf{c}_1, \cdots, \mathbf{c}_T$ obtained from the encoder RNN LM in Subsection 2.1, a response trigger vector $\mathbf{d}_j$ is computed as the mixture:

$$\mathbf{d}_j = \textstyle\sum_{t=1}^T a'(\mathbf{h}_j, \mathbf{c}_t) \cdot \mathbf{c}_t, \tag{6}$$

where $a'(\mathbf{h}_j, \mathbf{c}_t)$ is a similar function to $a(\mathbf{c}_t, \mathbf{m}_k)$ defined in (1) with different parameters. Similar to the encoder RNN LM, the decoder RNN LM estimates the probability of the $(j+1)$-th word r_{j+1} in the reply based on the hidden vector $\mathbf{h}_j$ and the response trigger vector $\mathbf{d}_j$, *i.e.*

$$\Pr(r_{j+1}|r_{1:j}) = \mathrm{softmax}(\mathbf{Q}^\dagger\, [\mathbf{h}_j; \mathbf{d}_j]),$$

where $\mathbf{Q}^\dagger \in \mathbb{R}^{V \times 2n}$ is the weight matrix.

Note the decoder RNN only aims at providing additional supervision signals in training the encoder RNN through a response generation task. At test time, we do not use the responses therefore do not need to run the decoder RNN LM.

3 Model Learning

The full model is trained by maximizing the log-likelihood of the data, *i.e.*

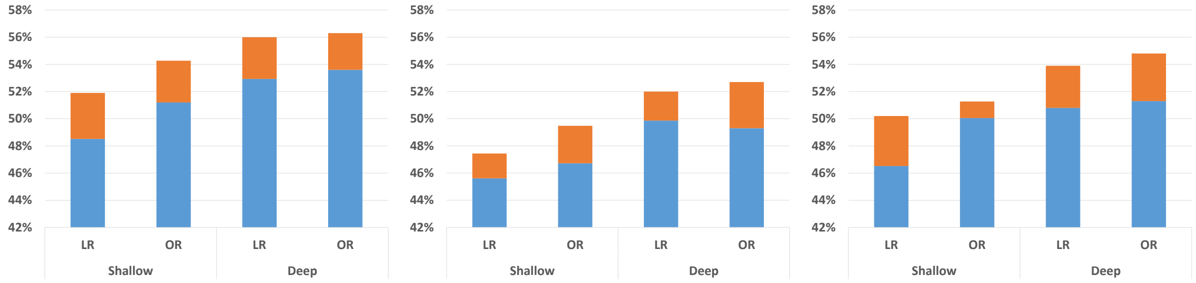
$$\textstyle\sum_i \log \Pr(w^{(i)}_{1:T^{(i)}}) + \alpha \log \Pr(r^{(i)}_{1:J^{(i)}} | w^{(i)}_{1:T^{(i)}}),$$

where the two terms correspond to the log-likelihood of the encoder RNN LM and the decoder RNN LM, respectively, and α is the hyper parameter which weights the importance of the second term. In our experiments, we let $\alpha = 0.1$. During the training, each comment-reply pair is used as a training sample. Considering that comments may receive a huge number of replies, we keep up to 5 replies for each comment. Due to memory limitations associated with the RNN, we use only the first 50 words of comments and the first 20 words of replies. If a comment has no reply, a special token is used. All weights are randomly initialized according to $\mathcal{N}(0, 0.01)$. The model is optimized using Adam (Kingma and Ba, 2015) with an initial learning rate 0.01. Once the validation log-likelihood decreases for the first time, we halve the learning rate at each epoch. The training process is terminated when the validation log-likelihood decreases for the second time. In our experiments, we learn word embeddings of dimension $d = 256$ from scratch. The number of modes K is set to 16. A single-layer RNN is used, with the dimension n of hidden layers set to 64.

4 Data and Task

In this paper, we work with Reddit discussion threads, taking advantage of their conversational and community-centric nature as well as the available karma scores. Each thread starts from a post and grows with comments to the post or other comments within the thread, presented as a tree structure. Posts and comments can be voted up or down by readers depending on whether they agree or disagree with the opinion, find it amusing vs. offensive, etc. A *karma* score is computed as the difference between up-votes and down-votes, which has been used as a proxy of community endorsement for a Reddit comment. Three popular subreddits with different topics and styles are studied[2] `AskWomen` (814K comments), `AskMen` (1,057K comments), and `Politics` (2,180K comments). For each subreddit, we randomly split comments by threads into training, validation, and test data, with a 3:1:1 ratio. The vocabulary of each subreddit is built on the training set. After removing singletons, the vocabulary sizes are 45K, 52K, and 60K for `AskWomen`, `AskMen`, and `Politics`, respectively.

[2] Comment IDs and labels used in this paper is at `https://github.com/hao-cheng/factored_neural`.



(a) `AskWomen` (b) `AskMen` (c) `Politics`

Figure 2: Averaged F1 scores of different classifiers. Blue bars show the performance using no comment embeddings. Orange bars show the absolute improvement by using factored comment embeddings.

Task: Considering the heavy-tailed Zipfian distribution of karma scores, regression with a mean squared error objective may not be informative because low-karma comments dominate the overall objective. Following (Fang et al., 2016), we quantize comment karma scores into 8 discrete levels and design a task consisting of 7 *binary* classification subtasks which individually predict whether a comment's karma is *at least* level-l for each level $l = 1, \cdots, 7$. This task is sensitive to the order of quantized karma scores, e.g., for the level-6 subtask, predicting a comment as level-5 or level-7 would lead to different evaluation results such as recall, which is not the case for a standard multi-class classification task. Additionally, compared to a standard multi-class classification task, these subtasks alleviate the unbalanced data issue, although higher levels are still more skewed.

Evaluation metric: For each level-l binary classification subtask, we compute the F1 score by treating comments at levels lower than l as negative samples and others as positive samples. Note that we only compute F1 scores for $l \in \{1, \ldots, 7\}$ since no comment is at a level lower than 0. The averaged F1 scores is used as an indicator of the overall prediction performance.

5 Experiments

In this section, we evaluate the effectiveness of the factored comment embeddings on the quantized karma prediction task. We use the concatenation of the local mode vector and the content vector at the last time step as the factored comment embedding. First, we study the overall prediction performance of four different classifiers under two settings, i.e., using factored comment embeddings or not. Then we compare the factored comment embeddings inferred from the full model and its two variants with other kinds of text features using the best type of classifiers. Finally, we carry out error analysis on prediction results of the best classifiers using the factored comment embeddings.

Range	Description
0/1	Whether the comment author is the user who initiated the thread.
$\mathbb{Z}_{\geq 0}$	Number of comments made by the author.
	Number of replies to the comment.
	Number of earlier comments.
	Number of later comments.
	Number of sibling comments.
	Number of comments in the subtree rooted from the comment.
	Height of the subtree rooted from the comment.
	Depth of the comment in the tree rooted from the original post.
$\mathbb{R}_{\geq 0}$	Relative comment time (in hours) with respect to the original post.
	Relative comment time (in hours) with respect to the parent comment.
	Normalized† number of replies to the comment.
	Normalized† number of comments in the subtree rooted from the comment.

Table 1: Content-agnostic features. † means two kinds of normalization are used: 1) zero-mean normalization; 2) divided by the squared-root-rank of the feature value in the thread.

	`AskWomen`	`AskMen`	`Politics`
Baseline	53.6%	49.3%	51.3%
BoW	53.1%	50.9%	51.8%
LDA	55.3%	51.1%	52.5%
Doc2Vec	55.2%	51.7%	53.0%
Factored$\backslash$M	54.2%	51.8%	52.9%
Factored$\backslash$R	55.1%	51.9%	53.4%
Factored	**56.3%**	**52.7%**	**54.8%**

Table 2: Averaged F1 scores of DeepOR classifiers using different text features. Baseline results do not use any text features.

5.1 Classifiers

The following four types of classifiers are studied:

- **ShallowLR**: A standard multi-class logistic regression model;
- **ShallowOR**: An ordinal regression model (Rennie and Srebro, 2005), which can exploit the or-

der information of the quantized karma labels;

- **DeepLR**: A feed-forward neural network using the logistic regression objective;
- **DeepOR**: A feed-forward neural network using the ordinal regression objective.

These classifiers have different objectives and model complexities, allowing us to study the robustness of the learned comment embeddings. The factored comment embeddings are inferred from the proposed models trained on the same training data but independently with these classifiers.

As baselines, we train the classifiers using only content-agnostic features, as shown in Table 1, which have strong correlations with community endorsement (Jaech et al., 2015; Fang et al., 2016). In our pilot work, we experimented with several groups of features from (Jaech et al., 2015) to find the content-agnostic features used in our paper. Since Jaech et al. (2015) work on a different task (ranking comments in a short time window), many of the useful content-agnostic features from (Jaech et al., 2015), including k-index, do not give additional improvement over the selected configuration for the karma prediction task.

All classifiers are trained on the training data for each subreddit independently, with hyperparameter tuned on the validation data. The penultimate weights are regularized using L_2 and the regularization parameters are selected in $\{0.0, 0.001, 0.01, 0.1, 1.0\}$. The number of hidden layers for deep classifiers are chosen from $\{1, 2, 3\}$, and the number of hidden neurons is selected from $\{32, 48, 64\}$.

We report the prediction performance on the test data, as shown in Fig. 2. We observe that using comment embeddings consistently improves the performance of these classifiers. While ShallowOR significantly outperforms ShallowLR, indicating the usefulness of exploiting the order information in quantized karma labels, the difference is much smaller for deep classifiers. Also, deep classifiers consistently outperforms their shallow counterparts.

5.2 Text Features

We compare the factored comment embeddings with the following text features:

- **BoW**: A sparse bag-of-word representation;
- **LDA**: A vector of topic probabilities inferred from the topic modeling (Blei et al., 2003);
- **Doc2Vec**: Embeddings inferred from the paragraph vector model (Le and Mikolov, 2014).

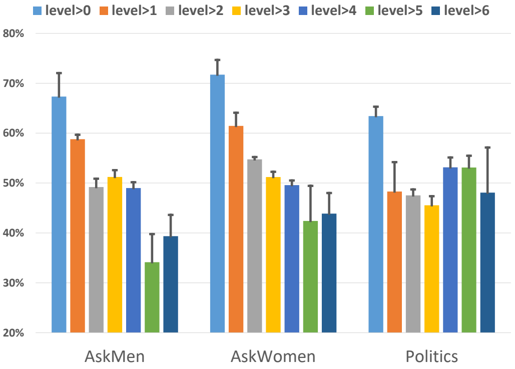


Figure 3: F1 scores of the DeepOR classifier for individual subtasks. Error bars indicate the improvement of using the factored comment embeddings over the classifier using no text features.

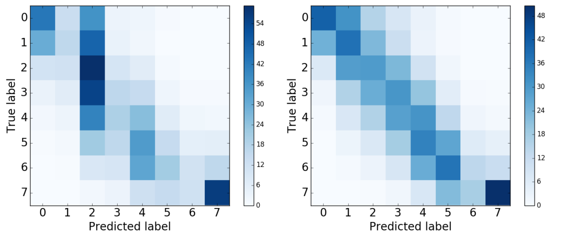
For these models, which do not use RNNs, all words in a comment are used. We use the gensim implementations (Řehůřek and Sojka, 2010) for both LDA and Doc2Vec. For LDA, the number of topic is selected in $\{16, 32, 64\}$, and 32 works the best on the validation set for all subreddits. For Doc2Vec, we select the embedding dimension from $\{32, 64, 128\}$, and 64 works the best on the validation set for all subreddits. We train the Doc2Vec for 20 epochs, and the learning rate is initialized as 0.025 and decreased by 0.001 at each epoch.

In addition to the factored comment embeddings obtained from our full model, we study two variants of the full model: 1) a model trained without the mode vector component (**Factored**\M), which is a normal sequence-to-sequence attention model (Bahdanau et al., 2015), and 2) a model trained without the response trigger vector component (**Factored**\R). All textual representations are used together with the baseline content-agnostic features described previously.

Since the DeepLR and the DeepOR perform best across all subreddits and they have similar trends, we report results of the DeepOR in Tabel 2. Among all text features, the BoW has the worst averaged F1 scores and even hurts the performance for AskWomen, probably due to the data sparsity problem. Both the LDA and the Doc2Vec outperform the BoW. The Doc2Vec performs slightly better on AskMen and Politics, which might be attributed to the relative larger training data size. The factored comment embeddings derived from the full model consistently achieve better averaged F1 scores. It can be observed that the



(a) w/o comment embeddings (b) w/ comment embeddings

Figure 4: The confusion matrices for the DeepOR classifier on `Politics`. The color of cell on the i-th row and the j-th column indicates the percentage of comments with quantized karma level i that are classified as j, and each row is normalized.

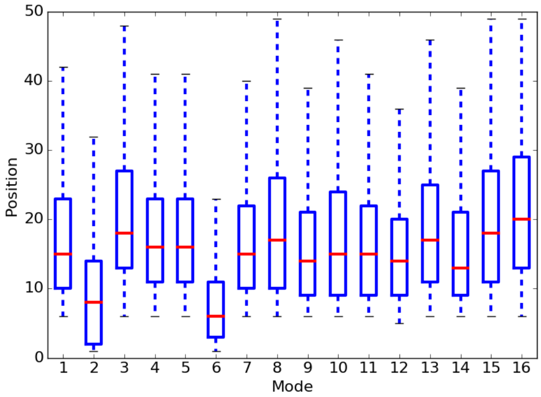


Figure 5: The box plot of strongest association positions for each global mode in `Politics`.

two variants of the full model mostly lead to similar performance as the Doc2Vec, though the Factored\R embeddings usually have higher averaged F1 scores than the Factored\M embeddings. These results suggest advantages of jointly modeling two components, which may drive the model to discover more latent factors and patterns in the data that could be useful for downstream tasks.

5.3 Error Analysis

In this subsection, we focus on analyzing how factored comment embeddings improve the prediction results of the DeepOR classifiers. The F1 scores for individual subtasks are shown in Fig. 3. Note that the higher the level is, the more skewed the task is, *i.e.* a lower positive ratio. As expected, comments with the lowest endorsement level are easier to classify. Adding comment embeddings primarily boosts the performance of the classifier on the high-endorsement tasks (level $> 5, 6$) and the low-endorsement tasks (level $> 0, 1$).

Confusion matrices for the DeepOR classifier with and without factored comment embeddings are shown in Fig. 4 for `Politics`. Using the additional comment embeddings leads to a higher concentration of cell weights near the diagonals, corresponding to errors that mainly confuse neighboring levels. Without any text features, the classifier seems to only distinguish four levels. We observe similar trends on `AskWomen` and `AskMen`.

6 Qualitative Analysis

In this section, we conduct analysis to better understand what the factored model is learning, again using the `Politics` subreddit. First, we analyze latent global modes learned from the full model. For each global mode, we extract comments with top association scores. Note that the model assumes a locally coherent mixture of global modes and updates the mixture for each observed word. Thus, each comment receives a sequence of association probabilities over the global modes. The association score β_k between a comment $w_{1:T}$ and `Mode-`k is then computed as $\beta_k = \max_{t\in\{1,\cdots,T\}} a(\mathbf{c}_t, \mathbf{m}_k)$ for $k \in \{1, \cdots, K\}$, where $a(\mathbf{c}_t, \mathbf{m}_k)$ is defined in (1). In Table 3, we show examples from the most coherent modes out of the 16 learned modes. Some modes seem to be capturing style (modes 2, 6, and 10), while others are related to topics (modes 7 and 16). `Mode-2` captures the style of starting with rhetorical question to express negative sentiment and disagreement. Many comments in `Mode-6` begin with words of drawing attention such as “bull” and “psst”. `Mode-10` tends to be associated with comments telling a story about a closely related person. Many comments in `Mode-7` discuss low salaries, whereas `Mode-16` comments discuss politicians or ideology of the Republican.

The characteristics of examples in modes 2 and 6 suggested that modes might have a location dependency, so we looked at word positions with the strongest association of each mode, *i.e.* $\mathrm{argmax}_{t\in\{1,\cdots,T\}} a(\mathbf{c}_t, \mathbf{m}_k)$. For each `Mode-`$k$, we only keep comments with association score higher than $\mathrm{mean}(\beta_k) + \mathrm{std}(\beta_k)$. Fig. 5 shows the box plot of locations where the strongest association happens. It can be seen that modes 2 and 6 usually have the strongest association at the beginning of a comment. For modes 3, 8, 15 and 16, the strongest associations occur over a wider span in comments. In addition to the interpretability of

Mode-2	• Oh come on! Really? One can't make that trip and spend maybe half and save the other for milk, bread and things that do spoil? … • Remind me. How many filibusters did Harry Reid conduct this year? … • Feckless tyrant? How did you do that with your brain? … • Seriously? You have to be registered to vote. … • Holy f*, seriously? This is some heavy duty shit. …
Mode-6	• Bull. Plenty of individuals influence policy by never missing a single chance to vote, no matter how minor the election. … • Bull. Conservatives hate Obamacare so much because if their constituents got mental health treatment, they'd stop voting Republican. • Utter bull s*. Where was the compromise from Obama and the Dems when they pushed through Obamacare without ONE Republican vote. … • psst…it's college • psst- he's "black" - meaning that one of his ancestors is black (as if it's pollutant of some sort).
Mode-7	• …, I used to work 55+ hours a week, salaried, lower quartile salary to boost. … • Or possibly that the standard of living between unemployment and the "jobs" that are out there is really insignificant. … • Where on earth is 7.25 a living wage? If by some miracle you get 40 hours a week that's only $1,160 before taxes. … • If you have to work 40 hours a week to pay your bills that means you are controlled in your fight for survival. … • …Working 15 hours a week for extra pocket money when you're a teen is easy. Working 50 hours a week at fast food to cover rent, food, …
Mode-10	• …Had a guy stalk a trans friend of mine for months trying to terrorize her because … • A co-worker of mine got audited by the IRS because … • …Some conservative friends of mind wanted to meet up at a coffee house with shittier coffee because the other one was too "liberal". … • …Friend of mine works with mentally unstable and aggressive people as part of some social service. … • …A student of mine asked our own AP about an atheist group and he just flat out said "You kidding me?" …
Mode-16	• …These same people will continue to listen to the bullshit that is the Republican Party. And when that happens, they have this twisted reality … • …After spending almost my entire life in Texas and as a Born gain evangelical conservative Republican, I learned my lessons about how completely dishonest and corrupted that entire culture is the hard way. …I will never gain ever vote for or support any kind of conservative. … • …has been our greatest embarrassment, but what makes matter even worse is the support he has for re-election. I would not be surprised … • Well, it is entirely possible that …the underlying cause of Limbaugh's attack was that this guy was playing the type of dirty politics … • …this was more of a referendum on the GOP leadership in Congress by Republican voters, because let's face it, they haven't done anything.…

Table 3: Examples of comments associated with the learned global modes for `Politics`.

the learned modes as one can get from LDA, these observations suggest that our model may further capture word location effects which may help predicting community endorsement.

Next, we analyze the response characteristics by examining the response trigger vectors associated with the onset of comment responses, which is a special start-of-reply token. These response trigger vectors are clustered into 8 classes via k-means and visualized in Fig. 6 using t-SNE (van der Maaten and Hinton, 2008). For each cluster, we study the karma distribution, as well as comments together with the first reply. Related data statistics and examples are shown in Fig. A-4 and Tables A-2&A-3 in the supplementary materials. The horizontal dimension seems to be associated with how many replies a comment elicits. The vertical dimension is less interpretable but most clusters have identifiable traits. The far left classes (Class-1&4) both have few replies and low karma, often two-party exchanges where Class-4 has more negative sentiment. Class-2 comments tend to involve complements, whereas comments in Class-3 usually trigger a reply with *but*-clause for a contrast and disagreement intent. Comments in Class-5 mostly receive responses expanding on the original comments. Class-6 has a lot of sarcastic and cynical comments and replies. Comments in Class-7 are mostly anomalous since their first responses were usually [deleted]. It seems there are multiple response trigger factors in the proposed embedding model, some may reflect dialog acts and others sentiment, any of which may be helpful in predicting community endorsement.

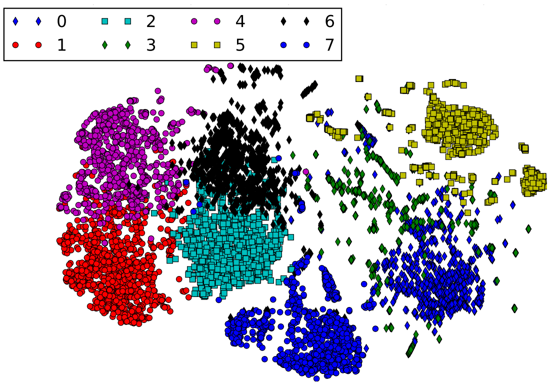

Figure 6: t-SNE visualization of response trigger vectors clustered using k-means.

7 Related Work

The skip-thought vector method (Kiros et al., 2015) is most closely related to our work in terms of utilizing context for unsupervised sequence modeling under the sequence-to-sequence framework (Sutskever et al., 2014). A key difference is the context being exploited. The skip-thought vector method uses surrounding sentences by abstracting the skip-gram structure (Mikolov et al., 2013a) from word to sequence. In our model, we exploit two types of context that are unique in online discussions: 1) the global context such as community topic and style which is learned in the *mode* vectors, and 2) the responses to a comment modeled as the *response trigger* vectors. Moreover, we augment our model with the attention mechanism (Bahdanau et al., 2015) to push the model to distill the relevant information from context.

The neural attention mechanism has been used for a variety of natural language processing tasks, e.g., machine translation (Bahdanau et al., 2015), question answering (Sukhbaatar et al., 2015), constituency parsing (Vinyals et al., 2015), social media opinion mining (Yang and Eisenstein, 2017). and dependency parsing (Cheng et al., 2016). The attention mechanism developed in this paper for exploiting global modes differs from previous work in that the global modes being attended over are *latent* rather than explicitly observed, and in that they are learned jointly with the full model.

Predicting the community endorsement has been studied by using either hand-crafted features (Jaech et al., 2015) or neural models (Fang et al., 2016; Zayats and Ostendorf, 2017), but all of them focus on supervised learning. Unsupervised learning strategies have been explored for characterizing different factors in language. A hierarchical Dirichlet process model was originally proposed for topic variations but has been extended to characterize multiple factors in (Huang and Renals, 2008). While much of the Dirichlet modeling work uses multinomial distributions, a loglinear version is introduced in (Eisenstein et al., 2011). Multi-dimensional structure latent factors in text are modeled by extending the sparsity-promoting topic model in (Paul and Dredze, 2012). Our model instead uses a neural network to characterize latent language factors, where the learned latent language factors could have a dependency on word positions.

8 Conclusion

This paper introduces a new factored neural model for unsupervised learning of comment embeddings leveraging two different types of context in online discussions. By extending the attention mechanism and using residual learning, our method is able to jointly model global context, comment content and response generation. Quantitative experiments on three different subreddits show that the factored embeddings achieve consistent improvement in predicting quantized karma scores over other standard document embedding methods. Analyses on the learned global modes show community-related style and topic characteristics are captured in our model. Also, we observe that response trigger vectors characterize certain aspects of comments that elicit different response patterns.

A potential future direction is to explore whether the comment embeddings derived from the unsupervised factored neural model can be useful across multiple tasks. Recently, a dataset with dialogue act annotations on Reddit discussions is published and can be used for a dialogue act prediction task (Zhang et al., 2017). Identifying or ranking persuasive arguments in the `ChangeMyView` subreddit (as studied in (Tan et al., 2016; Wei et al., 2016)) and asking for favors in the `RandomActsOfPizza` subreddit (used in (Althoff et al., 2014)) are also interesting for future work.

Abstract

This paper presents a corpus and experiments to determine dimensions of interpersonal relationships. We define a set of dimensions heavily inspired by work in social science. We create a corpus by retrieving pairs of people, and then annotating dimensions for their relationships. A corpus analysis shows that dimensions can be annotated reliably. Experimental results show that given a pair of people, values to dimensions can be assigned automatically.

1 Introduction

The task of information extraction (IE) consists in creating structured representations from unstructured text. These representations usually consist of relations explicitly stated in text, and involve two or more arguments. For example, IE systems would extract SPOUSE(*John*, *Mary*) or MARRIED(*John*, *Mary*, *1994*) from *John and Mary have been married since 1994*. IE systems have a long history, and became popular after evaluations such as MUC (Grishman and Sundheim, 1996) and ACE (Doddington et al., 2004).

Traditional IE systems are supervised and extract relations defined before training takes place (Peng and McCallum, 2004). More recently, open IE systems have been proposed to extract *all* relations explicitly stated in text in an unsupervised manner and without defining relations a priori (Mausam et al., 2012). Regarding interpersonal relations—relations that take as arguments two people—both IE approaches extract relations such as RELATIVE, FRIEND and COMMUNICATES_WITH. Open IE systems are domain independent and would extract, in principle, relations such as CLASSMATES and ADVISOR from students' diaries or biographies of scientists.

While useful for applications such as question answering (Yao and Van Durme, 2014), these dyadic relations only provide a generic understanding of the relationship between two people. For example, COMMUNICATES_WITH may relate people who have an *intense* or *superficial* relationship (e.g., engaged couples talking about wedding plans vs. home owners discussing remodels with contractors), *pleasure*- or *task-oriented* relationships (e.g., friends planning a backpacking trip vs. software developers discussing the next delivery), and may be *spatially near* or *distant* (e.g., inviduals having an in-person meeting vs. those exchanging emails or talking on the phone).

These elemental properties of interpersonal relationships are called *dimensions* in social science, and have been studied for decades (Wish et al., 1976). In those studies, the goal is to understand how relationships are *perceived* by people, not to extract them. Note that unlike interpersonal relationships, their dimensions are usually implicitly stated in text, thus extracting them is challenging. Also, extracting dimensions of interpersonal relationships requires text understanding beyond the event in which two people participate. As shown above, two people who communicate may have different dimension values depending on what they talk about or the communication device.

In this paper, we target dimensions of interpersonal relationships that characterize the nature of relationships beyond a name per relationship. The main contributions are: (a) set of dimensions of interpersonal relationships, including dimensions from previous work outside computational linguistics and novel ones; (b) corpus consisting of pairs of people and values for the dimensions of their relationships (Cohen's kappa: 0.68); (c) detailed corpus analysis; and (d) experimental results showing that the dimensions can be extracted automatically from text.

Dimension	Other descriptors and aliases	Ref.
Cooperative vs. Competitive	friendly vs. hostile, promotive vs. contrient	[1]
Equal vs. Hierarchical	autonomy vs. control, submission vs. dominance	[1]
Intense vs. Superficial	important vs. insignificant, influential vs. trivial	[1]
Pleasure vs. Task Oriented	personal vs. impersonal, emotionally involved vs. detached	[1]
Active vs. Passive	direct vs. indirect, unequivocal vs. equivocal	[2]
Intimate vs. Unintimate	emotionally close vs. distant, indifferent, random	[3]
Temporary vs. Enduring	momentary vs. lasting, provisional vs. permanent	[4]
Concurrent vs. Nonconcurrent	convergent vs. divergent, synchronous vs. asynchronous	New
Spatially Near vs. Distant	nearby vs. faraway, attached vs. detached	New

Table 1: Dimensions of interpersonal relationships targeted in this paper. [1] stands for (Wish et al., 1976), [2] for (Kelley, 2013), [3] for (Adamopoulos, 2012), and [4] for (Deutsch, 2011). *New* indicates a dimension discovered after analyzing several examples and pilot annotations.

2 Related Work

Extracting relations between entities such as people, organizations and locations is the core goal of the task of information extraction. A few competitions have served as evaluation benchmarks (Grishman and Sundheim, 1996; Doddington et al., 2004; Kulick et al., 2014; Surdeanu and Heng, 2014), and include interpersonal relationships such as BUSINESS, SPOUSE and CHILDREN. Aguilar et al. (2014) compare several evaluations, and automated approaches to relation extraction—also referred to as link prediction and knowledge base completion—include (Yu and Lam, 2010; Nguyen et al., 2016; West et al., 2014). Open information extraction (Wu and Weld, 2010; Angeli et al., 2015) has emerged as an unsupervised domain-independent approach to extract relations. Regardless of details, all these previous efforts extract explicit relations, and do not attempt to characterize instances of relations with dimensions.

Besides extracting relations per se, there have been efforts within computational linguistics involving interpersonal relationships. Voskarides et al. (2015) extract human-readable descriptions of relations in a knowledge graph by ranking sentences that justify the relations. Iyyer et al. (2016) propose an unsupervised algorithm to extract relationship trajectories of fictional characters, i.e., how interpersonal relationships evolve over time in fictional stories. Bracewell et al. (2012) introduce 9 social acts (e.g., agreement, undermining) designed to characterize relationships between individuals exhibiting adversarial and collegial behavior (similar to our cooperative vs. competitive dimension).

Researchers have studied from a computational perspective how people communicate with each other. For example, Danescu-Niculescu-Mizil et al. (2012) study how power differences affects language style in online communities, and Prabhakaran and Rambow (2014) present a classifier to detect power relationships in email threads. Similarly, Gilbert (2012) explores how people in hierarchical relationships communicate through email, and Bramsen et al. (2011) focus on identifying power relationships in social networks. Politeness in online forums has also been studied (Danescu-Niculescu-Mizil et al., 2013). While power (similar to our equal vs. hierarchical dimension, Section 3) and politeness could be considered dimensions, these works exploit structural and linguistic features derived from communications between two individuals. Unlike all of them, we extract 9 dimensions of interpersonal relationships from sentences describing an event involving two people, and without needing language samples from them.

3 Dimensions of Interpersonal Relationships

Dimensions of interpersonal relationships have been studied for decades outside of computational linguistics, mostly in psychology and social science in general (Wish et al., 1976). The set of dimensions is by no means agreed upon, and neither is the terminology to refer to what apparently is the same dimension. For example, the terms *dominance*, *submission*, *potency*, *autonomy* and *control* are used to describe the distribution of power in a relationship (Deutsch, 2011).

The dimensions we work with in this paper are primarily borrowed from previous works in social science, although we add two new dimensions. Interestingly, the previous works which define these dimensions do so from a theoretical point of view or after conducting experiments with subjects to reveal how they perceive interpersonal relationships. The latter was done using multidimensional scaling analysis after subjects compared 25 relationships, e.g., between a parent and child, between business partners (Wish et al., 1976).

Table 1 presents the nine dimensions targeted in this paper along with the original references and aliases found in the literature. Social scientists have proposed additional dimensions, e.g., voluntary vs. involuntary, public vs. private and licit vs. illicit (Deutsch, 2011), or self-benefiting vs. service-oriented (Adamopoulos, 2012). We discarded these additional dimensions because we discovered that they are not applicable to most pairs of people we work with (Section 4).

We provide below brief descriptions of the nine dimensions of interpersonal relationships we work with. Note that these dimensions are not completely independent, for example, *enduring* relationships are usually *intense* and *intimate*, and *intense* and *pleasure-oriented* relationship are almost always *intimate*. Section 4.3 presents examples, and Section 4.4 discusses inter-dimensional correlations and inter-annotator agreement. We point the reader to the references in Table 1 for additional details, rationales, and examples.

Cooperative vs. Competitive A relationship is *cooperative* if both people (a) have a common interest or goal, (b) like each other, (c) benefit from the relationship, or (d) think alike or have similar views. Otherwise, the relationship is *competitive*.

Equal vs. Hierarchical A relationship is *equal* if both people (a) have the same social status, (b) are at the same level in the power structure, (c) share similar responsibilities, or (d) have the same role. Otherwise, the relationship is *hierarchical*.

Intense vs. Superficial A relationship is *intense* if both people interact with each other frequently, i.e., they are involved repeatedly. Otherwise, the relationship is *superficial*.

Pleasure vs. Task Oriented A relationship is *pleasure oriented* if both people interact socially and their relationship is not bound by professional rules or regulations. Otherwise, the relationship is *task oriented*.

Active vs. Passive A relationship is *active* if both people are involved in a shared activity or event that grants the relationship. Otherwise, the relationship is *passive*. For example, individuals commuting to work in the same car have an *active* relationship, but those who happen to take the same subway line to work have a *passive* relationship.

Intimate vs. Unintimate A relationship is *intimate* if both people are emotionally close and warm to each other. Otherwise, the relationship in *unintimate*.

Temporary vs. Enduring A relationship is *temporary* if it lasts less than a day. A relationship is *enduring* if it lasts over a month. Otherwise (if it lasts more than a day and less than a month), this dimension is undefined.

Concurrent vs. Nonconcurrent A relationship is *concurrent* if both people are involved in an event or action at the same time. Otherwise, the relationship is *nonconcurrent*.

Spatially Near vs. Distant A relationship is *spatially near* (or *near* for short) if both people are at the same location during the event that grants the relationship. Otherwise, the relationship is *spatially distant* (or *distant*).

4 Building a Corpus of Dimensions of Interpersonal Relationships

Existing corpora annotating relations (Section 2) only consider selected interpersonal relationships and do not target dimensions. Our goal is to target dimensions of interpersonal relationships between any two individuals, from weak links (e.g., journalists interviewing celebrities) to strong ties (e.g., close friends). Thus, we create a corpus[1] by first retrieving pairs of people, and then annotating dimensions for their relationships.

We decided to add our annotations to OntoNotes (Hovy et al., 2006). Doing so has several advantages. First, OntoNotes contains texts from several domains and genres (e.g., conversational telephone speech, weblogs, broadcast), thus we not only work with newspaper articles. Second, OntoNotes includes part-of-speech tags, named entities and coreference chains, three annotation layers that allow us to streamline the corpus creation process.

4.1 Retrieving Pairs of People

We retrieve pairs of people within each sentence in OntoNotes following four steps:

[1] Available at `http://hilt.cse.unt.edu/`

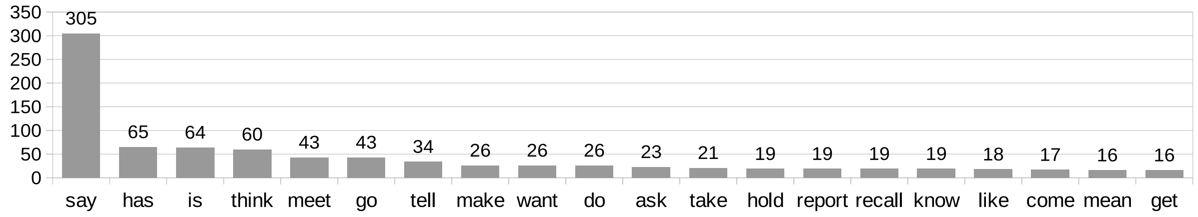

Figure 1: Frequencies of the top 20 most frequent verbs after retrieving pairs of people (Section 4.1). We discard verbs with frequency <4, and randomly select up to 26 pairs per verb for a total of 1,048 pairs.

1. Collect all instances of personal pronouns (part-of-speech tag PRP) *I*, *he* and *she*.
2. Collect all named entities PERSON.
3. Keep one mention per coreference chain, giving priority to named entities over pronouns.
4. Generate combinations of 2 elements from the union of the pronouns and named entities subject to the following constraints: at least
   (a) one is a PERSON named entity, and
   (b) one is the *nsubj* (nominal subject syntactic dependency) of a verb.

   The elements of the pair that satisfy restrictions (4a) and (4b) need not be the same.

Note that removing duplicate mentions (Step 3) does not reduce the number of relationships targeted, it simply avoids duplicate pairs. Also, the only syntactic constraint is that one person in the pair must be the nominal subject of a verb. Thus, we work with relationships between individuals from different clauses, and connected with a variety of syntactic paths (see Examples in Table 2).

The total number of pairs generated skipping Steps 3 and 4 would be 4,886. After removing duplicate mentions (Step 3), the number is reduced to 3,481; restrictions (4a) and (4b) further reduce the number to 3,143 and 2,696 respectively. Executing all steps yields 2,364 pairs.

Figure 1 presents verb frequencies for the top 20 most frequent verbs in the 2,364 pairs. In order to reduce the annotation effort and account for a variety of verbs, we set to annotate 1,000 pairs. After trying several thresholds, we retrieved 1,048 pairs by selecting pairs from verbs that occur at least 4 times, and randomly selecting up to 26 pairs per verb (most verbs occur less than 26 times).

4.2 Annotating Dimensions of Interpersonal Relationships

After generating pairs, annotators determine values for each dimension of interpersonal relationships. The annotation interface shows the sentence from which the pair was generated, and the previous and next sentence to provide some context. The pair of people of interest were highlighted, but no additional information was shown (e.g., the verb of which one person is the subject).

Annotators assign a value to each dimension based on the relationship between the two individuals at the time the verbal event of which one of the individuals is the subject takes place. They were trained to take into account context (previous and next sentences), and to interpret the text as they normally would. Therefore, they assign values using world knowledge that may not be explicitly stated in the text. For example, two people talking on the phone would have a *spatially distant* relationship because (most likely) they are not next to each other while talking. Annotating the changes over time of the dimensions is outside the scope of this paper.

During the first batch of annotations, we discovered that for a given pair of people, dimensions sometimes cannot be determined because (a) there is not enough evidence in the text provided (i.e., sentence from which the pair was generated, previous and next sentences) or (b) the pair is invalid and assigning dimensions is nonsensical. We use `0` label in the former case, and `inv` in the latter. For example, in the sentence *[He]*$_y$ *[criticized]*$_{verb}$ *[Ken Starr]*$_x$, the value for the dimension *spatially near* (vs. *distant*) was marked `0` as there is not enough information to determine whether *He* and *Ken Starr* are at the same location when *criticized* took place. The most frequent example of `inv` is when *God* is marked as a PERSON named entity in the gold annotations in OntoNotes.

In the rest of the paper, we refer to dimensions by the first descriptor in Table 1, and use `1` if the first descriptor of a dimension is true, and `-1` if the second descriptor is true. For example label `-1` applied to dimension *temporary* means that the realtionship is *enduring*.

	Sentence	Cooperative	Equal	Intense	Pleasure Oriented	Active	Intimate	Temporary	Concurrent	Spatially Near
1	[Cheney]$_x$ [got]$_{verb}$ a telephone call from his democratic counterpart [Joseph Lieberman]$_y$ wishing him a speedy recovery.	1	1	-1	-1	1	-1	1	1	-1
2	[...] [I]$_x$ [interviewed]$_{verb}$ one of the nation's top jockies [Shane Sellers]$_y$ about the battle he waged everyday to control his weight.	1	-1	-1	-1	1	-1	1	1	1
3	[I]$_x$ have always remembered the encouragement which Mr. [Yu Youren]$_y$ [gave]$_{verb}$ me as a young reporter. He said that to be a fearless champion of social justice, as is expected of a journalist, the [...]	1	-1	1	-1	1	1	-1	1	1
4	One day, Dingxiang took the opportunity to again urge him to change his ways [...]. After this, [Zhang Sheng]$_x$ [threw]$_{verb}$ out [Dingxiang]$_y$, sold off the family possessions, and spent his days living a life of dissipation.	-1	1	-1	1	1	-1	-1	1	1

Table 2: Annotation examples for pairs of people (x, y). We refer to dimensions by their first descriptor (Section 3); `1` (`-1`) indicates that the first (second) descriptor is true, and `0` that the value is unknown.

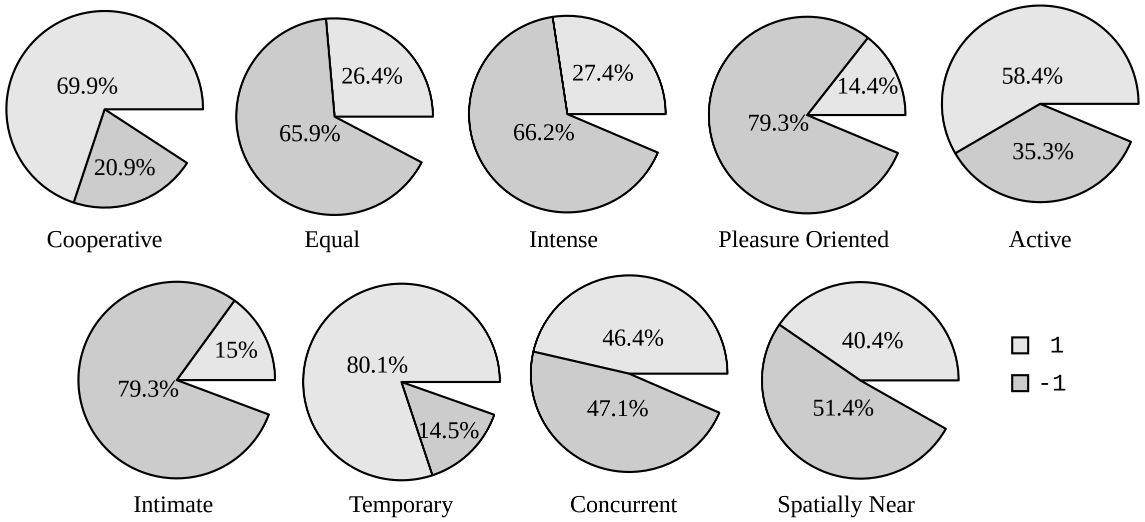

Figure 2: Label distribution per dimension of interpersonal relationships. The missing portion of each pie chart corresponds to labels `0` and `inv`, which always amount to less than 5% each.

4.3 Annotation Examples

We present annotation examples from our corpus in Table 2, including context if it is relevant. We acknowledge that some annotations are ambiguous, and discuss label distributions and inter-annotator agreement in Section 4.4.

Sentences (1) and (2) encode a COMMUNICATION relationships between two individuals, and both are *cooperative*, *superficial*, *work oriented*, *active*, *unintimate*, *temporary*, and *concurrent*. The values for two dimensions, however, are different. Two counterparts (Sentence 1) are at the same level in the power structure (*equal*), but interviewer and interviewee are not (Sentence 2). Similarly, talking on the phone entails that the individuals are *spatially distant* (Sentence 1), but interviewing (most likely) means that they were *spatially near* (Sentence 2). One could argue that `0` would be a better label for *spatially near* in Sentence (2), but annotators interpreted that *interviewed* refers to an in-person interview.

Sentence (3) in context describes one person (Yu Youren) encouraging another one (I). Annotators indicate that this relationship, unlike the ones in Sentences (1) and (2), is *intense* (frequent interaction), *intimate* (emotionally close), and *enduring* (lasting over a month). These values are not explicitly stated, but they are understood given the long-lasting impact *Yu Youren* had on *I*.

Finally, Sentence (4) exemplifies a *competitive* relationship. The context describes a struggling relationship between *Dingxiang* and *Zhang Sheng*. When the latter *threw* the former out, the rela-

	Cooperative	Equal	Intense	Pleasure Or.	Active	Intimate	Temporary	Concurrent
Cooperative	–							
Equal	-.06	–						
Intense	.24	.11	–					
Pleasure Or.	.14	.29	.39	–				
Active	.18	.22	.43	.25	–			
Intimate	.18	.17	.59	.62	.31	–		
Temporary	-.17	.10	-.56	-.43	-.27	-.61	–	
Concurrent	.17	.22	.31	.21	.74	.26	-.17	–
Spat. Near	.21	.18	.30	.25	.68	.28	.19	.89

Table 3: Pearson correlations between dimensions of interpersonal relationships in our corpus.

Dimension	Agreement	κ coefficient
Cooperative	86%	0.74
Equal	81%	0.63
Intense	84%	0.73
Pleasure Oriented	86%	0.70
Active	82%	0.59
Intimate	83%	0.68
Temporary	76%	0.61
Concurrent	84%	0.72
Spatially Near	80%	0.67
All	82%	0.68

Table 4: Inter-annotator agreement per dimension of interpersonal relationships. κ values in the 0.60–0.80 range are considered *substantial*, over 0.80 would be *perfect* (Landis and Koch, 1977).

tionship was *superficial* and *unintimate*, but (most likely) existed for longer than a month (*enduring*).

4.4 Corpus Analysis

Label Distribution. Figure 2 shows the percentage of label `1` (first descriptor) and `-1` (second descriptor) per dimension in our corpus. The percentage of Label `0` ranges from 0.86% (*temporary*) to 4.3% (cooperative) depending on the dimension, and the percentage of `inv` is 4.6% (not shown in Figure 2). Importantly, annotators assigned a useful value (either `1` or `-1`) to most pairs of people (>90%) for all dimensions.

The distributions of `1` and `-1` clearly show that most dimensions are biased towards one label. For example, few relationships are *pleasure oriented* (14.4%) or *enduring* (14.5%). The exceptions are *concurrent vs. nonconcurrent*, with roughly the same percentages (46.4% and 47.1%), *spatially near vs. distant* (40.4% and 51.4%) and *active vs. passive* (58.4% and 35.3%). These distributions are not a representative sample of all interpersonal relationships, we would expect many *pleasure oriented* and *intimate* relationship if we work with personal diaries instead of OntoNotes.

Inter-Dimension Correlations. While the dimensions we work with have a long tradition in social science (Section 2), to the best of our knowledge, they have not been extensively annotated in text before. Table 3 shows inter-dimensional correlations for all pairs of dimensions in our corpus. Not surprisingly, some dimensions correlate with each other. For example, *enduring* relationships tend to also be *intense* (0.56) and *intimate* (0.61), and *concurrent* relationships tend to be *active* (0.74). The highest correlation is between *concurrent* and *spatially near* (0.89), indicating that if two people participate in a common event at the same time, usually they are at the same location (see counterexample in Table 2, Sentence 1). Note, however, that most correlations are low, and some dimensions (e.g., *cooperative*, *equal*) have low correlations (<0.30) with all dimensions.

Inter-Annotator Agreement. The annotations were done by two graduate students. They started annotating small batches of pairs of people, and discussed disagreements with each other. After several iterations, they annotated independently 10% of all pairs of people generated. Table 4 depicts the inter-annotator agreements obtained. Overall Cohen's kappa coefficient is 0.68, and the coefficients range between 0.59 to 0.74 depending on the dimension. Note that kappa coefficients in the range 0.60–0.80 are considered *substantial*, and over 0.80 would be *perfect* (Landis and Koch, 1977). Given these high agreements, the rest of pairs were annotated once.

5 Experiments and Results

We conduct experiments using standard supervised machine learning. Each pair of people become an instance, and we split instances into training (80%) and test (20%). As a learning algorithm, we use SVM with RBF kernel as implemented in scikit-learn (Pedregosa et al., 2011).

We report results in the test set after tuning the SVM parameters (C and γ) using 10-fold cross-validation with the training set. More specifically, we train one classifier per dimension, and experiment with all instances but the ones annotated `inv`. Thus, each classifier predicts 3 labels: `1` (the first descriptor applies), `-1` (the second descriptor applies), and `0` (neither descriptor applies).

	Feature	Description
Verb	word, tag	Word form and part-of-speech tag of the verb
	dep_out	Outgoing syntactic dependency from verb
	deps_in	Flags indicating incoming syntactic dependencies to the verb
	lex_name	Name of the WordNet lexical file of the verb
	token_before	Word form and part-of-speech tag of the token before the verb
	token_after	Word form and part-of-speech tag of the token after the verb
Person	words, tags	Concatenation of word forms and part-of-speech tags
	type	Flag indicating whether the person is a pronoun or named entity
	dep_out	Outgoing syntactic dependency
	distance_verb	Number of tokens between the person and the verb
	first_token	Word form and part-of-speech tag of the first token in the person
	last_token	Word form and part-of-speech tag of the last token in the person
	token_before	Word form and part-of-speech tag of the token before the person
	token_after	Word form and part-of-speech tag of the token after the person
Person$_x$_Person$_y$	direction	Flag indicating whether *x* occurs before or after *y*
	type	Flag indicating whether *x* and *y* are PERSON NEs, or either one is a pronoun

Table 5: Feature set used to determine dimensions of interpersonal relationships between pairs of people (*x*, *y*). *Verb* features are extracted from the verb of which either *x* or *y* is the subject, *Person* features are extracted from *x* and *y* independently, and *Persons* features are extracted from *x* and *y*.

5.1 Feature Set

The features we work with are summarized in Table 5. Most features are standard and have been used before to extract relations from text (Section 2). Following the notation in Table 2, we refer to the pair of people as *x* and *y*.

Verb features capture information about the verb to which *x* or *y* attach. We include words and part-of-speech tags (verb, and tokens before and after), the name of the WordNet lexical file to which the verb belongs, and dependencies.

Person features are extracted from *x* and *y* independently, and consists mostly of words and part-of-speech tags. We also include a flag indicating whether the person is a pronoun or named entity (type feature), and the number of tokens between the person and the verb (distance_verb).

Person$_x$_Person$_y$ features capture information of both *x* and *y*. They capture (a) whether *x* occurs before or after *y* in the sentence, and (b) whether they are both named entities or one is a pronoun and the other one a named entity (type feature).

5.2 Results

We present overall results (averages of the classifiers for each dimension) using the majority baseline and with several feature combinations in Table 6. Then, we present detailed results per dimension with the best feature combination in Table 7. We only present results obtained in the test set.

Overall Results and Feature Ablation (Table 6). The majority baseline obtains 0.53 average F-measure. Recall that we build a classifier per dimension, thus the combination of the nine majority-baseline classifiers predict two labels: `1` (0.55 F-measure) and `-1` (0.64 F-measure).

Features	Label	P	R	F
Majority Baseline	`1`	0.43	0.76	0.55
	`0`	0.00	0.00	0.00
	`-1`	0.57	0.59	0.64
	Avg.	0.45	0.65	0.53
Verb	`1`	0.62	0.72	0.64
	`0`	0.00	0.00	0.00
	`-1`	0.71	0.78	0.65
	Avg.	0.62	0.71	0.65
Verb, Person$_x$	`1`	0.68	0.75	0.69
	`0`	0.00	0.00	0.00
	`-1`	0.78	0.79	0.78
	Avg.	0.70	0.74	0.71
Verb, Person$_y$	`1`	0.64	0.72	0.67
	`0`	0.00	0.00	0.00
	`-1`	0.74	0.76	0.74
	Avg.	0.66	0.70	0.67
Verb, Person$_x$, Person$_y$, Person$_x$_Person$_y$	`1`	0.69	0.74	0.70
	`0`	0.00	0.00	0.00
	`-1`	0.77	0.80	0.76
	Avg.	**0.71**	**0.76**	**0.72**

Table 6: Results obtained for all dimensions with several combinations of features.

Models trained with any combination of features outperform the majority baseline, but they never learn to predict label `0`. Since `0` occurs between 0.86% and 4.3% depending on the dimension (Section 4.4), this limitation does not affect overall performance substantially.

Dimension	`1` (1st descriptor)			`0` (unknown)			`-1` (2nd descriptor)			All		
	P	R	F	P	R	F	P	R	F	P	R	F
Cooperative	0.73	0.96	0.83	0.00	0.00	0.00	0.60	0.19	0.29	0.66	0.72	0.65
Equal	0.56	0.10	0.17	0.00	0.00	0.00	0.74	0.97	0.84	0.68	0.74	0.66
Intense	0.39	0.30	0.34	0.00	0.00	0.00	0.78	0.85	0.82	0.67	0.71	0.69
Pleasure	0.40	0.28	0.33	0.00	0.00	0.00	0.87	0.93	0.90	0.79	0.82	0.80
Active	0.69	0.85	0.76	0.00	0.00	0.00	0.68	0.51	0.58	0.67	0.69	0.67
Intimate	0.44	0.17	0.24	0.00	0.00	0.00	0.88	0.98	0.93	0.81	0.86	0.83
Temporary	0.85	0.96	0.91	0.00	0.00	0.00	0.33	0.10	0.16	0.77	0.83	0.79
Concurrent	0.72	0.80	0.76	0.00	0.00	0.00	0.77	0.75	0.76	0.71	0.74	0.73
Spat. Near	0.66	0.68	0.67	0.00	0.00	0.00	0.73	0.79	0.76	0.66	0.70	0.68
Average	0.69	0.74	0.70	0.00	0.00	0.00	0.77	0.80	0.76	0.71	0.76	0.72

Table 7: Results obtained for each dimension with the best combination of features for all dimensions (*Verb* + *Person*$_x$ + *Person*$_y$ + *Person*$_x$_*Person*$_y$, boldfaced in Table 6)

Verb features alone yield a 0.65 average F-measure (`1`: 0.64, `-1`: 0.65). Adding features derived from *x* (*Verb* + *Person*$_x$) improves performance (0.71 average F-measure), and adding features derived from *y* (*Verb* + *Person*$_y$) slightly improves performance (0.67 average F-measure). In both cases, `-1` is predicted more accurately than `1` (0.78 vs. 0.69 and 0.74 vs. 0.67).

Finally, adding all features (*Verb* + *Person*$_x$ + *Person*$_y$ + *Person*$_x$_*Person*$_y$) yields the best results (average F-measure: 0.72), although by a minimal margin with respect to *Verb* + *Person*$_x$.

Detailed Results per Dimension. Table 7 presents results per dimension with the best overall combination of features (*Verb* + *Person*$_x$ + *Person*$_y$ + *Person*$_x$_*Person*$_y$).

All dimensions obtain overall F-measures between 0.65 and 0.83 (last column). Results per label are heavily biased towards the most frequent label per dimension (Figure 2), although it is the case that the models we experiment with predict both `1` and `-1` for all dimensions. As stated above, none of them predict `0`, but this limitation does not substantially penalize overall performance because of the low frequency of this label.

The model obtains the same F-measures for `1` and `-1` with *concurrent* dimension (0.76), and the labels of this dimension are virtually distributed uniformly (46.4% vs. 47.1%, Figure 2). Similarly, F-measures for `1` and `-1` with *spatially near* and *active* dimensions are similar (0.67 vs. 0.76 and 0.76 vs. 0.58), and the labels are distributed relatively evenly in our corpus (40.4% vs 51.4% and. 58.4% vs. 35.3%).

Finally, F-measures per label with other dimension are biased towards the most frequent label. For example, only 15% of all pairs of people have an *enduring* relationship (Figure 2), and the F-measure for `1` with *temporary* dimension is much higher (0.91) that for `-1` (0.16).

6 Conclusions

We have presented a set of nine dimensions of interpersonal relationships, including dimensions with a long tradition in social science and new ones. These dimensions allow us to differentiate core characteristics of the relationship between two individuals. For example, people that communicate may be *spatially near* or *spatially distant* (asking questions in class vs. chatting online), and have a pleasure-oriented or work-oriented relationship (somebody wishing good luck to a friend vs. interviewer and interviewee).

Our annotations show that assigning values to dimensions can be done reliably (Cohen's kappa: 0.68), and that useful values (`1` and `-1` labels) are assigned to dimensions in most pairs of people (>90%). Experimental results following a standard supervised machine learning approach show that assigning values to dimensions can be automated (0.72 overall F-measure), and that results per label and dimensions are biased towards the most frequent label.

We believe that extracting dimensions of interpersonal relationships complements previous efforts that extract relationships. Our future plans include studying values of dimensions for selected relationships (e.g., COWORKER), and investigating changes on the dimensions of the relationship over time. The latter would allow us to, for example, analyze how the relationship between two individuals changes over time, and determine which events make a relationship go from *superficial* to *intense* and vice versa.

Argument Mining on Twitter: Arguments, Facts and Sources

Mihai Dusmanu and **Elena Cabrio** and **Serena Villata**
Université Côte dAzur, CNRS, Inria, I3S, France

Abstract

Social media collect and spread on the Web personal opinions, facts, fake news and all kind of information users may be interested in. Applying argument mining methods to such heterogeneous data sources is a challenging open research issue, in particular considering the peculiarities of the language used to write textual messages on social media. In addition, new issues emerge when dealing with arguments posted on such platforms, such as the need to make a distinction between personal opinions and actual facts, and to detect the source disseminating information about such facts to allow for provenance verification. In this paper, we apply supervised classification to identify arguments on Twitter, and we present two new tasks for argument mining, namely facts recognition and source identification. We study the feasibility of the approaches proposed to address these tasks on a set of tweets related to the Grexit and Brexit news topics.

1 Introduction

Argument mining aims at automatically extracting natural language arguments and their relations from a variety of textual corpora, with the final goal of providing machine-processable structured data for computational models of arguments and reasoning engines (Peldszus and Stede, 2013; Lippi and Torroni, 2016). Several approaches have been proposed so far to tackle the two main tasks identified in the field: *i) arguments extraction*, i.e., to detect arguments within the input natural language texts and the further detection of their boundaries, and *ii) relations prediction*, i.e., to predict what are the relations holding between the arguments identified in the first task[1]. Social media platforms like Twitter[2] and newspapers blogs allow users to post their own viewpoints on a certain topic, or to disseminate news read on newspapers. Being these texts short, without standard spelling and with specific conventions (e.g., hashtags, emoticons), they represent an open challenge for standard argument mining approaches (Snajder, 2017). The nature and peculiarity of social media data rise also the need of defining new tasks in the argument mining domain (Addawood and Bashir, 2016; Llewellyn et al., 2014).

In this paper, we tackle the first standard task in argument mining, addressing the research question: *how to mine arguments from Twitter?* Going a step further, we address also the following subquestions that arise in the context of social media: *i)* how to distinguish factual arguments from opinions? *ii)* how to automatically detect the source of factual arguments? To answer these questions, we extend and annotate a dataset of tweets extracted from the streams about the Grexit and the Brexit news. To address the first task of argument detection, we apply supervised classification to separate *argument-tweets* from non-argumentative ones. By considering only argument-tweets, in the second step we apply again a supervised classifier to recognize tweets reporting factual information from those containing opinions only. Finally, we detect, for all those arguments recognized as factual in the previous step, what is the source of such information (e.g., the CNN), relying on the type of the Named Entities recognized in the tweets. The last two steps represent new tasks in the argument

[1] We refer the reader interested in more details on argument mining to (Peldszus and Stede, 2013; Lippi and Torroni, 2016) as survey papers, and to the proceedings of the Argument Mining workshop series (`https://argmining2017.wordpress.com/`).

mining research field, of particular importance in social media applications.

2 Mining arguments on Twitter

In this section, we describe the approaches we have developed to address the following tasks: *i)* Argument detection, *ii)* Factual vs opinion classification, and *iii)* Source identification, on social media data. Our experimental setting - whose goal is to investigate the tasks' feasibility on such peculiar data - considers a dataset of tweets related to the political debates on whether or not Great Britain and Greece had to leave the European Union (i.e. #Brexit and #Grexit threads in Twitter).

2.1 Experimental setting

Dataset.[3] The only available resource of annotated tweets for argument mining is DART (Bosc et al., 2016a). From the highly heterogeneous topics contained in such resource (i.e. the letter to Iran written by 47 U.S. senators; the referendum for or against Greece leaving the EU; the release of Apple iWatch; the airing of the 4th episode of the 5th season of the TV series Game of Thrones), and considering the fact that tweets discussing a political topic generally have a more developed argumentative structure than tweets commenting on a product release, we decided to select for our experiments the subset of the DART dataset on the thread *#Grexit* (987 tweets). Then, following the same methodology described in (Bosc et al., 2016a), we have extended such dataset collecting 900 tweets from the thread on *#Brexit*. From the original thread, we filtered away retweets, accounts with a bot probability >0.5 (Davis et al., 2016), and almost identical tweets (Jaccard distance, empirically evaluated threshold). Given that tweets in DART are already annotated for task 1 (argument/non-argument, see Section 2.2), two annotators carried out the same task on the newly extracted data. Moreover, the same annotators annotated both datasets (Grexit/Brexit) for the other two tasks of our experiments, i.e. *i)* given the argument tweets, annotation of tweets as either containing factual information or opinions (see Section 2.3), and *ii)* given factual argument tweets, annotate their source when explicitly cited (see Section 2.4). Tables 1, 2 and 3 contain statistical information on the datasets.

Inter annotator agreement (IAA) (Carletta, 1996) between the two annotators has been calculated for the three annotation tasks, resulting in κ=0.767 on the first task (calculated on 100 tweets), κ=0.727 on the second task (on 80 tweets), and Dice=0.84 (Dice, 1945)[4] on the third task (on the whole dataset). More specifically, to compute IAA, we sampled the data applying the same strategy: for the first task, we randomly selected 10% of the tweets of the Grexit dataset (our training set); for task 2, again we randomly selected 10% of the tweets annotated as argument in the previous annotation step; for task 3, given the small size of the dataset, both annotators annotated the whole corpus.

dataset	# argument	# non-arg	total
Brexit	713	187	900
Grexit	746	241	987
total	1459	428	1887

Table 1: Dataset for task 1: argument detection

dataset	# factual arg.	# opinion	total
Brexit	138	575	713
Grexit	230	516	746
total	368	1091	1459

Table 2: Dataset for task 2: factual arguments vs opinions classification

dataset	# arg. with source cit.	# arg. without source cit.	total
Brexit	40	98	138
Grexit	79	151	230
total	119	249	368

Table 3: Dataset for task 3: source identification

Classification algorithms. We tested Logistic Regression (LR) and Random Forest (RF) classification algorithms, relying on the *scikit-learn* tool suite[5]. For the learning methods, we have used a Grid Search (exhaustive) through a set of predefined hyper-parameters to find the best performing ones (the goal of our work is not to optimize

[3] Annotated data are available upon request to the authors.

[4] Dice is used instead of κ to account for partial agreement on the set of sources detected in the tweets.

[5] http://scikit-learn.org/

the classification performance but to provide a preliminary investigation on new tasks in argument mining over Twitter data). We extract argument-level features from the dataset of tweets (following (Wang and Cardie, 2014)), that we group into the following categories:

- *Lexical (L):* unigram, bigram, WordNet verb synsets;
- *Twitter-specific (T):* punctuation, emoticons;
- *Syntactic/Semantic (S):* we have two versions of dependency relations as features, one being the original form, the other generalizing a word to its POS tag in turn. We also use the syntactic tree of the tweets as feature. We apply the Stanford parser (Manning et al., 2014) to obtain parse trees and dependency relations;
- *Sentiment (SE):* we extract the sentiment from the tweets with the Alchemy API[6], the sentiment analysis feature of IBM's Semantic Text Analysis API. It returns a polarity label (positive, negative or neutral) and a polarity score between -1 (totally negative) and 1 (totally positive).

As baselines we consider both LR and RF algorithms with a set of basic features (i.e., lexical).

2.2 Task 1: Argument detection

The task consists in classifying a tweet as being an argument or not. We consider as arguments all those text snippets providing a portion of a standard argument structure, i.e., opinions under the form of claims, facts mirroring the data in the Toulmin model of argument (Toulmin, 2003), or persuasive claims, following the definition of argument tweet provided in (Bosc et al., 2016a,b). Our dataset contains 746 argument tweets and 241 non-argument tweets for Grexit (that we use as training set), and 713 argument tweets and 187 non-argument tweets for Brexit (the test set). Below we report an example of argument tweet (a), and of a non-argument tweet (b).

(a) *Junker asks "who does he think I am". I suspect elected PM Tsipras thinks Junker is an unelected Eurocrat. #justsaying #democracy #grexit*

(b) *#USAvJPN #independenceday #JustinBieberBestIdol Macri #ConEsteFrioYo happy 4th of july #Grefenderum Wireless Festival*

We cast the argument detection task as a binary classification task, and we apply the supervised algorithms described in Section 2.1. Table 4 reports on the obtained results with the different configurations, while Table 5 reports on the results obtained by the best configuration, i.e., LR + All features, per each category.

Approach	Precision	Recall	F1
RF+L	0.76	0.69	0.71
LR+L	0.76	0.71	0.73
LR+all features	0.80	0.77	**0.78**

Table 4: Results obtained on the test set for the argument detection task (L=lexical features)

Category	P	R	F1	#arguments per category
non-arg	0.46	0.60	0.52	187
arg	0.89	0.82	0.85	713
avg/total	0.80	0.77	**0.78**	900

Table 5: Results obtained by the best model on each category of the test set for the argument detection task

Most of the miss-classified tweets are either ironical, e.g.:

If #Greece had a euro for every time someone mentioned #Grexit and #Greferendum they would probably have enough for a bailout. #GreekCrisis

that was wrongly classified as argument, or contain reported speech, e.g.:

Jeremy Warner: Unintentionally, the Greeks have done themselves a favour. Soon, they will be out of the euro `http://t.co/YmqXi361Gj` *#Grexit*

that was wrongly classified as non argument. Our results are comparable to those reported in (Bosc et al., 2016b) (they trained a supervised classifier on the tweets of all topics in the DART dataset but the iWatch, used as test set). Better performances obtained in our setting are most likely due to a better feature selection, and to the fact that in our case

[6] https://www.ibm.com/watson/alchemy-api.html

the topics in the training and test sets are more homogeneous.

2.3 Task 2: Factual vs opinion classification

This task consists in classifying argument-tweets as containing factual information or being opinion-based (Park et al., 2015). Our interest focuses in particular on factual argument-tweets, as we are interested then in the automated identification of their sources. This would allow then to rank factual tweet-arguments depending on the reliability or expertise of their source for subsequent tasks as fact checking. Given the huge amount of work in the literature devoted to opinion extraction, we do not address any further analysis on opinion-based arguments here, referring the interested reader to (Liu, 2012).

An argument is annotated as *factual* if it contains a piece of information which can be proved to be true (see example (a) below), or if it contains "reported speech" (see example (b) below). All the other argument tweets are considered as "opinion" (see example (c) below).

(a) *72% of people who identified as "English" supported #Brexit (while no majority among those identifying as "British")* https://t.co/MuUXqncUBe

(b) *#Hollande urges #UK to start #Brexit talks as soon as possible.* https://t.co/d12TV8JqYD.

(c) *Trump is going to sell us back to England. #Brexit #RNCinCLE*

Our dataset contains 230 factual argument tweets and 516 opinion argument tweets for Grexit (training set), and 138 factual argument tweets and 575 opinion argument tweets for Brexit (test set).

To address the task of factual vs opinion arguments classification, we apply the supervised classification algorithms described in Section 2.1. Tweets from Grexit dataset are used as training set, and those from Brexit dataset as test set. Table 6 reports on the obtained results, while Table 7 reports on the results obtained by the best configuration, i.e. LR + All features, per each category.

Most of the miss-classified tweets contain reported opinions/reported speech and are wrongly classified by the algorithm as opinion - such behaviour could be expected given that sentiment features play a major role in these cases, e.g.,

Approach	Precision	Recall	F1
RF+L	0.75	0.68	0.71
LR+L	0.75	0.75	0.75
LR+all features	0.81	0.79	**0.80**

Table 6: Results obtained on the test set for the factual vs opinion argument classification task (L=lexical features)

Category	P	R	F1	#arguments per category
fact	0.49	0.50	0.50	138
opinion	0.88	0.87	0.88	575
avg/total	0.81	0.79	**0.80**	713

Table 7: Results obtained by the best model on each category of the test set for the factual vs opinion argument classification task

Thomas Piketty accuses Germany of forgetting history as it lectures Greece http://t.co/B0UqPn0i6T *#grexit*

Again, the other main reason for miss-classification is sarcasm/irony contained in the tweets, e.g.,

So for Tsipras, no vote means back to the table, for Varoufakis, meant Grexit?

that was wrongly classified as fact.

2.4 Task 3: Source identification

Since factual arguments (as defined above) are generally reported by news agencies and individuals, the third task we address - and that can be of a value in the context of social media - is the recognition of the information source that disseminates the news reported in a tweet (when explicitly mentioned). For instance, in:

The Guardian: Greek crisis: European leaders scramble for response to referendum no vote. http://t.co/cUNiyLGfg3

the source of information is The Guardian newspaper. Such annotation is useful to rank factual tweet-arguments depending on the reliability or expertise of their source in news summarization or fact-checking applications, for example.

Our dataset contains 79 factual argument tweets where the source is explicitly cited for Grexit (training set), and 40 factual argument tweets where the source is explicitly cited for Brexit (test set). Given the small size of the available annotated dataset, to address this task we implemented a simple string matching algorithm that relies on a gazetteer containing a set of Twitter usernames and hashtags extracted from the training data, and a list of very common news agencies (e.g. BBC, CNN, CNBC). If no matches are found, the algorithm extracts the NEs from the tweets through (Nooralahzadeh et al., 2016)'s system, and applies the following two heuristics: *i)* if a NE is of type `dbo:Organisation` or `dbo:Person`, it considers such NE as the source; *ii)* it searches in the abstract of the DBpedia[7] page linked to that NE if the words "news", "newspaper" or "magazine" appear (if found, such entity is considered as the source). In the example above, the following NEs have been detected in the tweet: "The Guardian" (linked to the DBpedia resource `http://dbpedia.org/page/The_Guardian`) and "Greek crisis" (linked to `http://dbpedia.org/page/Greek_government-debt_crisis`). Applying the mentioned heuristics, the first NE is considered as the source. Table 8 reports on the obtained results. As baseline, we use a method that considers all the NEs detected in the tweet as sources.

Approach	Precision	Recall	F1
Baseline	0.26	0.48	0.33
Matching+heurist.	0.69	0.64	**0.67**

Table 8: Results obtained on the test set for the source identification task

Most of the errors of the algorithm are due to information sources not recognized as NEs (in particular, when the source is a Twitter user), or NEs that are linked to the wrong DBpedia page. However, in order to draw more interesting conclusions on the most suitable methods to address this task, we would need the increase the size of the dataset.

3 Discussion and Future work

This paper investigated argument mining tasks on Twitter data. The main contribution is twofold: first, we propose one of the very few approaches of argument mining on Twitter, and second, we propose and evaluate two new tasks for argument mining, i.e., facts recognition and source identification. These tasks are particularly relevant when applied to social media data, in line with the open popular challenges of fact-checking and source verification to which these results contribute.

The issue of argument detection on Twitter has already been addressed in the literature. Bosc et al. (2016a,b) address a binary classification task (argument-tweet vs. non argument), as first step of their pipeline. Goudas et al. (2015) experiments machine learning techniques over a dataset in Greek extracted from social media. They first detect argumentative sentences, and second identify premises and claims. However, none of them is neither interested in distinguishing facts from opinions nor to identify the arguments' sources. An argumentation-based approach is applied to Twitter data to extract opinions in (Grosse et al., 2015), with the aim of detecting conflicting elements in an opinion tree to avoid potentially inconsistent information. Both the goal and the adopted methodology are different from ours.

Being it a work in progress, several open issues have to be considered as future research. Among them, we are currently extending the dataset of annotated tweets both in terms of annotated tweets per topic, and in terms of addressed topics (e.g. Brexit after the referendum, Trump), in order to have more instances of facts and sources. On such extended dataset, we plan to run experiments using the three modules of the system as a pipeline.

Moreover, we plan to extend our pipeline by considering also the links provided in the tweets to verify their sources, i.e., if a tweet claims to report information from the CNN but the link actually redirects towards an advertisement website the source is not indubitably the CNN.

Distinguishing Japanese Non-standard Usages from Standard Ones

Abstract

We focus on non-standard usages of common words on social media. In the context of social media, words sometimes have other usages that are totally different from their original. In this study, we attempt to distinguish non-standard usages on social media from standard ones in an unsupervised manner. Our basic idea is that non-standardness can be measured by the inconsistency between the expected meaning of the target word and the given context. For this purpose, we use context embeddings derived from word embeddings. Our experimental results show that the model leveraging the context embedding outperforms other methods and provide us with findings, for example, on how to construct context embeddings and which corpus to use.

1 Introduction

On social media such as Twitter, we often find posts that are difficult to interpret without prior knowledge on non-standard usage of words. For example, consider the following Japanese sentence[1]:

鯖の	負担が	増える
mackerel-POSS	load-NOM	increase-PRS

"*The load on a mackerel increases*",

which does not make sense given the standard usages for the words in the sentence. But here, *mackerel* is a non-standard usage that means *computer server*. The entire sentence should be interpreted as *"The load on the computer server increases"*. The Japanese word "鯖 (*saba*)" (i.e., mackerel) is used to mean computer server by Japanese computer geeks because *saba* happens to have a pronunciation that is similar to *sābā* (i.e., computer server). When a word is used in a meaning that is different from its dictionary meaning, we call such a usage *non-standard*.[2]

Non-standard usages can be found in many languages (Sboev, 2016). For example, the word "catfish" means a ray-finned fish as in a standard dictionary, but on social media, it can mean a person who pretends to be someone else in order to create a fake identity. Such non-standard usages would be an obstacle to a variety of language processings including machine translation; Google Translate cannot correctly interpret examples such as this. Humans, however, would be able to notice non-standard usages from the inconsistency between the expected word meaning and the context.

The purpose of this work is to develop a method for distinguishing non-standard usages of Japanese words from standard ones. Since it is impractical to construct a large labeled data set for each word, we focus on unsupervised approaches. The main idea in our method is that the difference between the target word's embedding learned from a general corpus and the embedding predicted from the given context would be a good indicator of the degree of non-standardness.

2 Data

We created a dataset for evaluating our method. First, we selected 40 words that have non-standard usages, including computer terms, company/service names, and other Internet slang. Ten

[1] This is interlinear-gloss text representation. POSS, NOM, PRS respectively represent the possessive case, nominative case, and present tense. The third line is the standard translation of the Japanese sentence.

[2] Although some non-standard usages are metaphoric, such as *sunshine* in "*you are my sunshine*", our definition of non-standard usages covers a wider variety of usages, as in the example of "mackerel".

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2323–2328
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

Category	Usage	
	standard	non-standard
Computer terms	416	234
Company/Service names	440	252
Other Internet slang	817	814
Total	1,673	1,300

Table 1: Statistics of the dataset.

of the 40 words were computer terms, another 10 were company/service names, and the remaining 20 were other Internet slang. For each of the 40 target words, we found 100 tweets that contained the target word. Here, we used Twitter as the source for examples since there are many non-standard usages on it. To segment tweets into words, we used the Japanese morphological analyzer MeCab[3] with the standard IPA standard dictionary.[4]

Next, we asked two human annotators to judge whether the usage of the target word in each tweet is standard, non-standard, a named entity, or undecidable. We excluded tweets which at least one annotator judged as undecidable (96 tweets).[5] Cohen's kappa of the annotations for the remaining 3,904 tweets was 0.808. We further excluded tweets which at least one annotator judged as containing a named entity (772 tweets) in order to focus the dataset on our main purpose.[6]

Finally, to create a final dataset, we selected from the remaining 3,132 tweets the 2,973 tweets that are judged as standard by both annotators or as non-standard by them. The selected 2,973 tweets are equivalent to 94.9% of the entire set of tweets, which suggests that human can reliably distinguish non-standard usages from standard ones. The statistics of the final dataset are shown in Table 2.

3 Methodology

Our basic idea for distinguishing word usages is that if a word is used in a non-standard manner, the context words around it will tend to differ from standard context words. To implement this idea, we employed word embeddings. Below, we review the Skip-gram model used for obtaining the word embeddings in Section 3.1 and present our method in Section 3.2.

3.1 Skip-gram

Skip-gram (Mikolov et al., 2013) is widely used for obtaining word embeddings. Given a sequence of words w_1, w_2, ..., w_T as training data, Skip-gram maximizes the likelihood $\frac{1}{T}\sum_{t=1}^{T}\sum_{-m\leq i\leq m, i\neq 0}\log p(w_{t+i}|w_t)$, where m is the window size. w_{t+i} is a context word nearby w_t. $p(w_k|w_t)$ is given by

$$p(w_k|w_t) = \frac{\exp(v_{w_t}^{IN}\cdot v_{w_k}^{OUT})}{\sum_{w=1}^{W}\exp(v_{w_t}^{IN}\cdot v_{w}^{OUT})},$$

where W is the vocabulary size of the training data. Skip-gram learns a model predicting context words using word embeddings v^{IN} and v^{OUT}, which are called *input* embedding and *output* embedding respectively.

The embeddings are learned in such a way that $v_{w_t}^{IN}\cdot v_{w_k}^{OUT} - \log\sum_{w=1}^{W}\exp(v_{w_t}^{IN}\cdot v_{w}^{OUT})$ increases if word w_t occurs near w_k in the training corpus. As a result, $v_{w_t}^{IN}\cdot v_{w_k}^{OUT}$ tends to be large for such words and small for word pairs that do not co-occur in the training corpus. We exploited this tendency for recognizing non-standard usages; if the dot-product between the embeddings of the target word and the context words is small, it should indicate a non-standard usage, on the condition that the embeddings have been learned on a general balanced corpus where words correspond to their standard meanings in most cases.

v^{IN} is widely used as a *word embedding* in many studies, while v^{OUT} has not been in the limelight; only a few researchers have examined the effectiveness of v^{OUT} (Mitra et al., 2016; Press and Wolf, 2017). In recent studies, embeddings v^{IN} are usually used for measuring the similarity between words. However, given the characteristics described in the previous paragraph and SGNS's equivalence with shifted positive pointwise mutual information (Levy and Goldberg, 2014), if we want to measure to what extent word w_t tends to co-occur with w_k in the training data, then we should use the similarity of $v_{w_t}^{IN}\cdot v_{w_k}^{OUT}$, instead of $v_{w_t}^{IN}\cdot v_{w_k}^{IN}$.

In this study, we show the importance of using v^{OUT} in a task where we need to see if a word matches its context.

[3] http://taku910.github.io/mecab/

[4] https://ja.osdn.net/projects/ipadic/

[5] The undecidable tweets are meaningless expressions such as the emoticon "(*´茸｀*)", which includes the word "茸".

[6] Most of the discarded target words are in a named entity, such as the word "尻" in "利尻島". These expressions are different from our definition of non-standard usage.

Figure 1: Overview of our method. Our model exploits context embedding and weighting.

3.2 Distinguishing Non-standard Usages from Standard Ones

Following the idea described in Section 3.1, we propose a method for distinguishing non-standard usages from standard ones by leveraging word embeddings. An overview of our method is shown in Figure 1. We use Skip-gram with Negative Sampling (SGNS) (Mikolov et al., 2013) for obtaining the word embeddings.

Given a target word w_t and its context $\mathbf{w}_c$ as input, we calculate the following weighted average of scaled dot-products as a measure of standardness:

$$\frac{\sum_{w_j \in \mathbf{w}_c} \sigma(v^{IN}_{w_t} \cdot v^{OUT}_{w_j}) \times \alpha_{w_j}}{\sum_{w_j \in \mathbf{w}_c} \alpha_{w_j}}, \tag{1}$$

where $v^{IN}_{w_t}$ is the input embedding for the target word w_t and $v^{OUT}_{w_j}$ is the output embedding for the context word w_j. α_{w_j} is a non-negative weight for the word w_j, and σ is the sigmoid function used for scaling dot-products into a range from 0 to 1. Although the values of α_{w_j} are arbitrary, we will use the values given by the training algorithm used in `word2vec`[7] and `gensim` (Řehůřek and Sojka, 2010), popular tools for obtaining word embeddings. In their training of word embeddings, context words that are closer to the target word are weighted higher.[8] We therefore set α_{w_j} to be $m + 1 - d_{w_j}$, where m is the window size and d_{w_j} is an integer that represents the distance between w_j and the target word. Hence, this is a decaying weighting. In contrast, with uniform weights, we set α_{w_j} to be 1 for all w_j in the context. We call the score of Equation (1) *standardness*. If the standardness is low, our method regards the instance as non-standard; otherwise, our method regards it as standard. We should note again that, in our method, word embeddings should be learned on a general balanced corpus that is different from the domain of the target instances.

4 Experiment

4.1 Methods for Comparative Evaluation

Our model has three characteristics: (input and output) word embeddings, decaying weights, and a general balanced corpus. We evaluated each of these characteristics in a task distinguishing non-standard usages from standard ones.

First, we verified the effectiveness of the input and output embeddings. We tested a method in which only input embeddings are used to calculate the similarity: the cosine similarity between $v^{IN}_{w_t}$ and $v^{IN}_{w_j}$ instead of $\sigma(v^{IN}_{w_t} \cdot v^{OUT}_{w_j})$, which is a similar framework to that of previous work (Neelakantan et al., 2014; Gharbieh et al., 2016). We then tested a method based on the positive pointwise mutual information (PPMI) (Levy et al., 2015; Hamilton et al., 2016). Here, suppose that *M* is a matrix in which each element is a PPMI of words w_i and w_j. $v^{IN}_{w_t} \cdot v^{OUT}_{w_j}$ in Equation (1) is replaced with the (t, j)-element of the low-rank approximation of *M* obtained through singular value decomposition (SVD). We refer to this model as SVD.

Table 2: Description of corpora.

Next, we replaced the decaying weights α with uniform weights to examine the impact of decaying weights.

Finally, we conducted experiments with different training corpora to examine the impact of the balanced corpus. We used four corpora as training data for obtaining word embeddings. These corpora are described in Table 2.

4.2 Experimental Settings

In the training of the word embeddings, we set the window size to 5, and the dimensions of the word embeddings to 300. We regarded the words with frequency counts of 5 or less in the training data as unknown words and replaced those words with "<unk>". We used gensim (Řehůřek and Sojka, 2010) as an implementation of SGNS, where we set the number of negative samples to 10. We used the code provided by Levy et al. (2015) as the SVD implementation. For the evaluations, we ranked test instances in ascending order of standardness score and evaluated the ranking in terms of the area under the ROC curve (AUC) (Davis and Goadrich, 2006).

4.3 Results

Table 3 shows the AUC for each model.[13] First, we examined the impact of the choice of training corpus for obtaining word embeddings. The models with BCCWJ are constantly better than those with other corpora, although BCCWJ is smaller than the others (Table 2). This result suggests that use of a balanced corpus is crucial in our method for this task.

corpus	SGNS IN-OUT		SGNS IN-IN		SVD	
	decay	uni	decay	uni	decay	uni
BCCWJ	**.875**	**.870**	.846	.837	.821	.813
Web	.846	.842	.817	.807	.771	.765
Wikipedia	.827	.821	.824	.805	.739	.732
Newspaper	.844	.839	.825	.810	.770	.764

Table 3: Area under the ROC curve (AUC) in usage classification task for each model.

Next, we examined the impact of context embeddings. Table 3 shows that our model (SGNS IN-OUT) with BCCWJ achieved the best AUCs (.875 and .870), better than the AUCs of SGNS IN-IN with BCCWJ (.846 and .837). This result suggests that input embeddings should be used in combination with output embeddings for the task of judging whether a word matches its context or not. Table 3 also shows that SGNS-based models are better than SVD-based models.

As we discussed in Section 3.2, we used two weighting schemes for each model. Although the AUC of each decaying weight model is larger than that of the corresponding uniform weight model, the differences were not statistically significant.

5 Related Work

The previous studies focused on distinguishing non-standard usages that are multi-word expressions or idiomatic expressions (Kiela and Clark, 2013; Salehi et al., 2015; Li and Sporleder, 2010). The task of this research is similar to new sense detection (Cook et al., 2014). Our research target includes jargon, whose actual meaning is difficult to infer without specific knowledge about its usage (Huang and Riloff, 2010). Recent studies in computational linguistics have used word embeddings and other techniques to capture various semantic changes in words, such as diachronic changes, geographical variations, and sentiment changes (Mitra et al., 2014; Kulkarni et al., 2015; Fermann and Lapata, 2016; Eisenstein et al., 2010; Hamilton et al., 2016; Yang and Eisenstein, 2016).

A few researchers have exploited output embeddings for natural language applications such as document ranking (Mitra et al., 2016) and improving language models (Press and Wolf, 2017).

[9] The Balanced Corpus of Contemporary Written Japanese (Maekawa et al., 2010).

[10] Japanese sentences are collected using the method described in (Kawahara and Kurohashi, 2006).

[11] We downloaded Japanese Wikipedia articles in July 2016 from https://dumps.wikimedia.org/jawiki/.

[12] We used editions of the Mainichi Shimbun, Nihon Keizai Shimbun, and Yomiuri Shimbun published from 1994 to 2004.

[13] Although we also conducted experiments with a sigmoid function for the SGNS IN-IN model and with the cosine similarity for the SVD model, their accuracies were worse than those in Table 3.

6 Conclusion

We presented a model that uses context embeddings to distinguish Japanese non-standard usages from standard ones on social media. Our experimental results show that our model is better than the other models tested. They indicate the importance of context embeddings. To sum up, to distinguish non-standard usage, (1) using a balanced corpus as training data for obtaining word embeddings is crucial, (2) exploiting context embeddings derived from *input* and *output* word embeddings of SGNS achieves the best AUC, and (3) decaying weights have little impact on performance.

We are interested in expanding our method for detecting words that have non-standard usages. We are also interested in finding the meanings of the detected non-standard usages.

Connotation Frames of Power and Agency in Modern Films

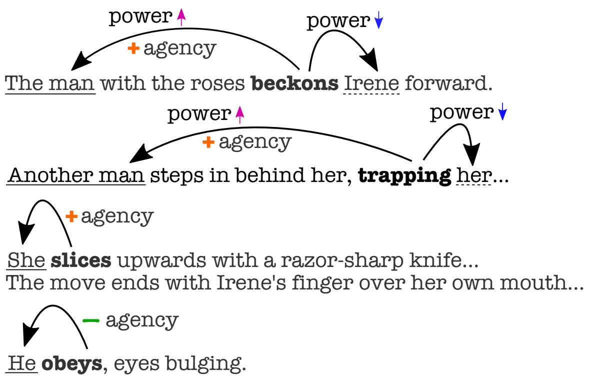
Abstract

The framing of an action influences how we perceive its actor. We introduce connotation frames of *power* and *agency*, a pragmatic formalism organized using frame semantic representations, to model how different levels of power and agency are implicitly projected on actors through their actions. We use the new power and agency frames to measure the subtle, but prevalent, gender bias in the portrayal of modern film characters and provide insights that deviate from the well-known Bechdel test. Our contributions include an extended lexicon of connotation frames along with a web interface that provides a comprehensive analysis through the lens of connotation frames.

1 Introduction

A viewer's impression of a movie character is influenced by how they are written and portrayed, which can in turn influence how people form stereotypes on gender norms (Behm-Morawitz and Mastro, 2008). A character's actions can be projected with varying levels of power and agency, depending on the specific verbs used. For instance, somebody who "accepts" things is implied to be a passive decision-maker (or of lower agency) than somebody who "assesses" things. While not explicitly stated, these connotative meanings projected by different verbs can influence the assumptions the audience makes about the people being described. These assumptions can have negative consequences if they reinforce negative stereotypes (Walton and Spencer, 2009).

To formalize this implicit information about people projected by actions, we introduce *power* and *agency* connotation frames, two new types of predicate-specific connotative relationships as an extension to Rashkin et al. (2016)'s connotation frame lexicon. For instance, in Figure 1, the verb "beckoning" implies that its theme (Irene) has less power than its agent (the man). In the third line, Irene displays strong agency when she "slices" in self-defense. In contrast, when the man "obeys", the man has low implied agency.



The man with the roses **beckons** Irene forward.
Another man steps in behind her, **trapping** her...
She **slices** upwards with a razor-sharp knife...
The move ends with Irene's finger over her own mouth...
He **obeys**, eyes bulging.

Figure 1: An excerpt from a box-office hit, *Sherlock Holmes* (2009). **Bolded** words are the predicates, solid underlined phrases are the agent of the verb, and dash underlined words are the theme. The full example with additional nuanced discussion is available in Figure 6 in the appendix.

Using the new connotation lexicon, we present a quantitative study to reveal the subtle, but prevalent gender[1] bias in modern films. Going beyond the surface level analysis such as screen time or number of female characters (Google, 2017), our study aims for a more focused and precise analysis of power differentials between fictional men and women.

In summary, our major contributions include the creation and release of a lexicon with two new connotative dimensions: *power* and *agency* and an

[1] We acknowledge that gender lies on a spectrum, and reducing it to a male-female binary is simplistic, however our data limits a more complex understanding of gender.

He **implored** the tribunal to show mercy.
AGENT
VERB
implore
THEME
power(AG < TH)
The princess **waited** for her prince.
AGENT
VERB
wait
THEME
agency(AG) = -

Figure 2: The formal notation of the connotation frames of power and agency. The first example shows the relative power differential implied by the verb **"implored"**, i.e., the agent ("he") is in a position of less power than the theme ("the tribunal"). In contrast, "He **demanded** the tribunal show mercy" implies that the agent has authority over the theme. The second example shows the low level of agency implied by the verb **"waited"**.

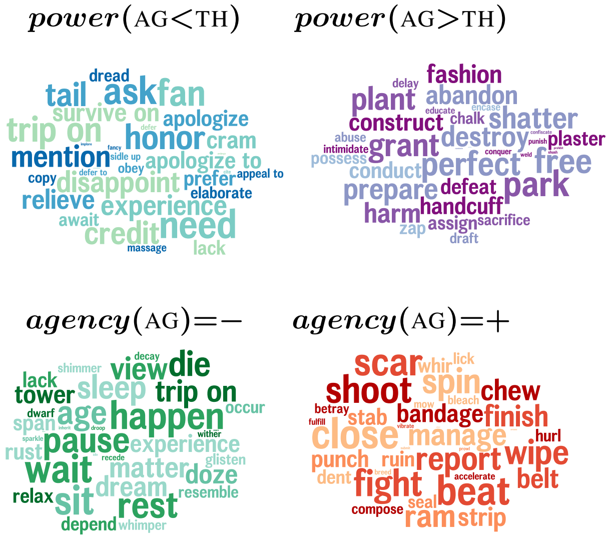

Figure 3: Sample verbs in the connotation frames with high annotator agreement. Size is indicative of verb frequency in our corpus (bigger = more frequent), color differences are only for legibility.

interactive demo website of our findings (see Figure 5 in the appendix for a screenshot).[2] Furthermore, as will be seen in Section 4.1, connotation frames offer new insights that complement and deviate from the well-known Bechdel test (Bechdel, 1986). In particular, we find that high-agency women through the lens of connotation frames are rare in modern films. It is, in part, because some movies (e.g., Snow White) accidentally pass the Bechdel test and also because even movies with strong female characters are not entirely free from the deeply ingrained biases in social norms.

2 Connotation Frames of Power and Agency

We create two new connotation relations, *power* and *agency* (examples in Figure 3), as an expansion of the existing connotation frame lexicons.[3] Three AMT crowdworkers annotated the verbs with placeholders to avoid gender bias in the context (e.g., `X` *rescued* `Y`; an example task is shown in the appendix in Figure 7). We define the annotated constructs as follows:

Power Differentials Many verbs imply the authority levels of the agent and theme relative to one another. For example, if the agent "dominates" the theme (denoted as $power$(AG>TH)), then the agent is implied to have a level of control over the theme. Alternatively, if the agent "honors" the theme (denoted as $power$(AG<TH)), the writer implies that the theme is more important or authoritative. We used AMT crowdsourcing to label 1700 transitive verbs for power differentials. With three annotators per verb, the inter-annotator agreement is 0.34 (Krippendorff's α).

Agency The agency attributed to the agent of the verb denotes whether the action being described implies that the agent is powerful, decisive, and capable of pushing forward their own storyline. For example, a person who is described as "experiencing" things does not seem as active and decisive as someone who is described as "determining" things. AMT workers labeled 2000 transitive verbs for implying high/moderate/low agency (inter-annotator agreement of 0.27). We denote high agency as $agency$(AG)=+, and low agency as $agency$(AG)=−.

Pairwise agreements on a hard constraint are 56% and 51% for power and agency, respectively. Despite this, agreements reach 96% and 94% when moderate labels are counted as agreeing with either high or low labels, showing that annotators rarely strongly disagree with one another. Some contributing factors in the lower KA scores include the subtlety of choosing between neutral

[3] The lexicons and a demo are available at `http://homes.cs.washington.edu/~msap/movie-bias/`.

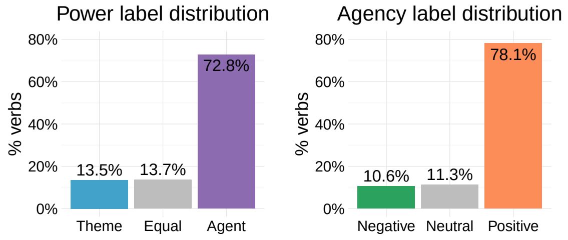

Figure 4: Label distributions for *power* and *agency* based on the crowdsourced annotations.

and positive/negative as well as the skews in the distributions of labels (i.e. more positive than negative labels, see Figure 4). Note that a similar difference between KA scores and soft percent agreement was found in our previous connotation frame work (Rashkin et al., 2016).

3 Bias in Movie Scripts

We use 772 movie scripts from (Gorinski and Lapata, 2015) as a test bed to validate our new connotation frames. Scripts have distinct structure, which allows us to easily parse narrations, dialogues and character names.

We automatically extract 21K male/female characters, using a name-gender list[4] along with gender specific lexicons (e.g., "actor"/"actresses", "duke"/"duchess") to automatically assign gender based on their first three narrations. To identify verbs with characters as their agent, we dependency parse the narratives using the SpaCy[5] parser. Power and agency label distributions in our corpus are consistent with the annotation distribution (Figure 4), and there is little variance across movies (see Figure 8 in the appendix).

In our dataset, there are nearly twice as many men as there are women (34.6% women), in line with previous findings by Smith et al. (2015) and Radford and Gallé (2015). Women are also less present on screen and speak less in movies (Google, 2017). We control for that disparity in all subsequent analyses by including the number of words for each character (standardized) as a covariate. Findings in all the following sections hold when controlling for movie genre (as retrieved from `IMDB.com`), as well as when controlling for effects from individual movies.

Frame	β	gender
$\textit{agency}(\text{AG})=+$	-0.951	**M****
$\textit{power}(\text{AG}>\text{TH})$	-0.468	**M****
$\textit{agency}(\text{AG})=-$	0.277	**F****
$\textit{power}(\text{AG}<\text{TH})$	*not sig.*	

Table 1: Power and agency connotation frames for male and female narratives, controlled for length of narrative text. β represents the change in log-odds of a character being male/female were the corresponding frame to change by one unit. Significant results (** : p<.001) are in bold. "Male" was coded as 0, "Female" as 1.

3.1 Bias in Narratives

Narratives describe what characters are *doing*. We investigate how they vary in terms of *power* and *agency*, using our connotation frames. We measure how each standardized frame metric is associated with the gender of the character through a logistic regression, controlling for the total number of words that the character said, and correcting for multiple comparisons using Holm's correction (Holm, 1979).

Listed in Table 1, our results show that male characters are portrayed with higher level of agency compared to women. Men are also portrayed to have more authority than women as they are more often the agent of powerful verbs.

This suggests that screenwriters tend to have female characters contribute more to the aesthetic of the movie through low-agency verbs, rather than the plot, which is reminiscent of existing gender bias tests for movies (Yehl, 2013).

3.2 Bias in Character Expression

To further our validation of the new connotative dimensions, we look at how characters *express* themselves in movies. Using our connotation frames and LIWC (Tausczik and Pennebaker, 2016), we compile metrics for every character's dialogue. As in subsection 3.1, metrics were standardized for better β interpretability. LIWC results that are not discussed below can be found in the appendix (Tables 4 and 5).

From Table 2, it seems male characters display more power and authority through their speech than their female counterparts do. Specifically, women are written to use more hedges (*# Hedges*) whereas men are written to use more imperative sentences (*# Imperative Sent.*), a finding that re-

inhib	-0.171	**M****

Table 2: Gender association with our connotation frames and a subset of LIWC metrics for characters' dialogue, controlled for number of words spoken. All results are significant (** : p<.001).

flects real-world dialogues (Prabhakaran et al., 2014). The usage of imperatives tends to convey power and dominance according to the findings of Bramsen et al. (2011). Along with the fact that female characters tend to agree (*assent*) more than male characters, this corroborates the finding in subsection 3.1 that male characters are generally given more power and agency. Furthermore, male characters use inhibitory language more (*inhib*), which contains words pertaining to blocking or allowing, suggesting that these characters are in positions of power.

Further evidence of power imbalances is found through function words. Women tend to use *I* and *you* pronouns more, whereas men use *we* and *they* pronouns more, echoing real life (Schwartz et al., 2013). Kacewicz et al. (2014) found an association between using "I" pronouns and being lower status, and conversely between "we" pronouns and being higher status. This corroborates the theory that women in movies are generally portrayed with a lower status than men.

Men in movies tend to mention more physical actions (*space* category) whereas women tend talk about what "could" be but isn't (*discrep*; e.g.,"should", "would"). This evokes more commanding connotations for male characters and subordinate connotations for female ones, reinforcing gender stereotypes.

These findings, rooted in previous research, confirm that our connotation frames capture existing bias in how male and female characters display different levels of power and agency in their dialogue.

Metric/Frame		β	P/F
F *dial.*	# Words	10.02	pass**
F *dial.*	$agency$(AG)$=+$	-9.65	fail**
F *dial.*	$power$(AG$>$TH)	2.05	pass*
F *narr.*	$power$(AG$>$TH)	-1.19	fail*

Table 3: Significant correlates of passing the Bechdel test. F: metric for female characters, computed on the dialogues (*dial.*) or on the narratives (*narr.*). * : p<.05; ** : p<.001.

4 Power, Agency and the Bechdel test

A movie passes the Bechdel test (Bechdel, 1986) if it (1) has two (named) female characters, (2) who talk to each other, (3) about something other than a man. While this is a low bar, a surprising number of movies fail at least one of the three criteria. In particular, as many as 42% of the movies in our dataset fail the test according to an online database of the Bechdel scores.[6]

4.1 Beyond the Bechdel Test

We provide comparative insights between the analysis based on connotation frames and the Bechdel test. First, we aggregate our connotation frames, both on dialogue and narration, into movie-level averages per gender. Then, we add features capturing presence of female/male characters (e.g., # F/M words, # F/M characters). Table 3 shows the correlation between passing the Bechdel test and our movie-level connotation frame features using a multivariate logistic regression.

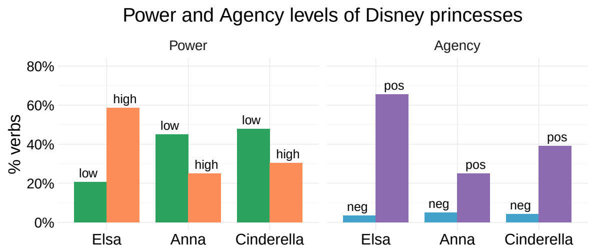
As expected, a movie with more female speaking time is more likely to pass the Bechdel test since it mostly captures female representation. We also find that female characters using agent-empowering verbs, which tend to be more assertive, slightly increases the odds of passing the Bechdel test. Female speakers who use empowering verbs, regardless of the verb's agent, tend to go against the gender-norms of hedging and being less assertive (as we showed in subsection 3.2).

Unexpectedly, movies where women talk with high agency are much less likely to pass the

[6] Available at http://bechdeltest.com. We use this site to obtain ratings for 324 of the movies in our corpus.

Bechdel test. Perhaps these movies typically only show scenes of women interacting in a male-dominated setting. Similarly, the use of more agent-empowering verbs in female narratives decrease the odds of passing the Bechdel test. Chances of two powerful women talking to each other might be lower because movies are less likely to have a lot of powerful women.[7]

Power and Agency of Princesses We further provide a qualitative analysis using Wikipedia plot summaries for movies that are not in our script dataset. Bechdel-passing movies with female protagonists, such as *Frozen* (2013) or *Cinderella* (1950), still perpetuate negative female stereotypes. In *Frozen*, Elsa is portrayed as the only high agency, high power woman, as seen below.[8] Anna and Cinderella, despite also being protagonists, display significantly less power and agency.



The Bechdel test is limited, either by being too inclusive of movies who portray women in non-authoritative, passive positions or by excluding movies that have strong women with agency, who just happen not to talk to each other about something besides men. Our extensions to the connotation frame lexicon provide finer grained information about how women are portrayed through their expression and their actions, which can act complementary to measures of their presence.

5 Related work

There is much prior research focus on bias in social media (Garcia et al., 2014; Prabhakaran et al., 2014; Ratkiewicz et al., 2011; Yano et al., 2010; Srivastava and Sahami, 2009), complementing our investigation on movies. Fast et al. (2016) examine the stereotypes present in fan-fiction using a lexicon-based strategy that focus on commonly gender-biased attributes (e.g., *emotional* for women) rather than the overall power dynamics of the story. In a similar vein, Ramakrishna et al. (2015) learn word-level “gender ladenness” features by looking at the neighbors of 925 manually annotated words.

There exist various sets of high-level criteria to assess gender bias of character portrayal in fiction (Yehl, 2013; Romano, 2013; Powers, 2016). Agarwal et al. (2015), in particular, automate the Bechdel test using social network features, finding that women are less central to the plot in movies that fail it. We compare our linguistic analysis of power and agency with the Bechdel test, demonstrating the need for more fine-grained analysis of how gender is depicted in movies.

Close in spirit to our investigation, Schofield and Mehr (2016) train a number of classifiers over movie scripts for determining the gender of individual (and pairs) of speakers as well as the expected length of their relationships. In contrast, we focus on understanding how the gender of a given character implicitly relates to features that track their control over their own path (agency) and the world around them (power).

6 Conclusion

We created and released new connotation frames of *power* and *agency*, allowing for more nuanced writing analysis than previously possible. We validate our new frames through a case study on movie scripts. Specifically, we analyze differences in power and agency for male and female characters, and compare these dimensions to the Bechdel test. Our connotation frames confirm evidence of imbalances in gender portrayal in movies.

Acknowledgments

We would like to thank Li Zilles for collecting the dataset, and Sydney Rubin and Laura Vianna for their input on the gender analyses. We would also like to thank anonymous reviewers for providing insightful feedback. Controlling Human Perception of Basic User Traits

{danielpr@sas,sharathg@sas,ungar@cis}.upenn.edu

Abstract

Much of our online communication is text-mediated and, lately, more common with automated agents. Unlike interacting with humans, these agents currently do not tailor their language to the type of person they are communicating to. In this pilot study, we measure the extent to which human perception of basic user trait information – gender and age – is controllable through text. Using automatic models of gender and age prediction, we estimate which tweets posted by a user are more likely to mis-characterize his traits. We perform multiple controlled crowdsourcing experiments in which we show that we can reduce the human prediction accuracy of gender to almost random – an over 20% drop in accuracy. Our experiments show that it is practically feasible for multiple applications such as text generation, text summarization or machine translation to be tailored to specific traits and perceived as such.

1 Introduction

Advances in Natural Language Processing are leading to a point when text generation methods are deployed at scale. However, in the quest to make these applications more likable, effective and hence more usable, these methods should consider a way to adapt themselves to the person or type of persons they are interacting with (Bates, 1994; Loyall and Bates, 1997) e.g., a student may learn better from a tutoring agent that expresses similar traits to himself (Baylor and Kim, 2004).

In this study, we explore the feasibility of controlling human perception of traits using automated methods. Flekova et al. (2016); Carpenter et al. (2016) are the first to study the difference between user traits and their perception by external raters using tweets from social media. Their focus was on quantifying differences between perception and reality and analyzing text features which lead to mis-perception. This study goes a step further, and using the same experimental design and crowdsourcing, aims to use automatic methods to control human perception of basic user traits – here age and gender – through tweets. To this end, we use gender and age prediction algorithms to select tweets posted by users with a known trait with the goal of increasing or decreasing human rater accuracy in guessing their traits.

Obfuscating gender as identified by an automatic classifier was attempted in (Reddy and Knight, 2016). This problem is related, but very different to ours as we study human perception which is both different (Flekova et al., 2016) and more complex. Reddy and Knight (2016) study a range of lexical substitutions that can be performed in order to decrease the prediction accuracy of a classifier, although acknowledging that these may affect lexical coherence. In this pilot study, we circumvent this problem by using tweets known to have been written by the same person, with the downside of possible topic confounds.

Our experiments show that, for gender, we can decrease the human accuracy in perceiving gender from text by more than 20% as compared to a random selection of their tweets, with accuracy in this case being only slightly higher than chance. Further, this accuracy is even lower when predicting males. For age perception, we show consistent results in altering perception as both younger or older, albeit for relatively smaller age differences.

Applications of our proposed line of research include conversational agents or automated e-mail generation. Personalization was motivated in the context of machine translation (Mirkin et al.,

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2335–2341
Copenhagen, Denmark, September 7–11, 2017.

2015) and recently attempted for gender (Rabinovich et al., 2017), even though the authors do not use humans to evaluate perception of gender. Automatic text personalization to user traits can also go beyond basic demographics to more salient ones such as social status (Preoţiuc-Pietro et al., 2015a,b), political ideology (Preoţiuc-Pietro et al., 2017a) or psychological traits such as personality (Schwartz et al., 2013; Guntuku et al., 2015a,b, 2016, 2017), narcissism (Preotiuc-Pietro et al., 2016), trust or empathy (Abdul-Mageed et al., 2017).

2 Data Set

We study two user traits through two Twitter data sets containing users with known gender and age information. First, for gender, we use a subset of 200 users (100 males, 100 females) of the data set collected by (Burger et al., 2011) and released by (Volkova et al., 2013) which mapped users to their gender by linking their Twitter account to their publicly self-declared gender on related blogs. The age data set consists of 200 users that self-reported their age in a survey and disclosed their public Twitter data that are part of a larger set used in (Flekova et al., 2016). The users are chosen to have an age in the 15–34 year old interval in the year 2015 and we only use tweets posted in 2015 in our analysis. We selected exactly 10 users of each age in this interval, as these are the most frequent ages present in our data set, most language variation happens in this interval and these are the age range which raters can most accurately predict (Nguyen et al., 2014).

We use the Twitter API to download up to 3200 tweets from these users. We pre-process tweets by filtering those not written in English as detected by an automated method (Lui and Baldwin, 2012), removing duplicate tweets (i.e., having the same first 6 tokens) and removing re-tweets as these are not authored by the user. All potentially sensitive or revealing information contained in tweets such as URL's, usernames, @-mentions, phone numbers were removed and replaced with placeholders before shown to annotators. Other than publicly available tweets, no other metadata or information was presented with the task, so raters were not able to map the tweets to actual user identities. The raters were also unaware of the conditions (Random, Opposite, Same, Youngest or Oldest) they were assigned to when performing the ratings. All our experiments received approval from Institutional Review Board (IRB) of the University of Pennsylvania.

We are aware that the proposed long-term applications we envision for this research can have personal impact on users. Hence, we propose following criteria which should be at the core of future research in controlling human perception, which we encourage to be completed over time:

- **Transparency**: data trained to build the personalized models should be transparent to any user. This would allow to observe any possible biases that may exist in the data.
- **Control**: the user interacting with a personalized system should be aware of the type of personalization employed by the agent (e.g. by gender, by which particular age group) and should be able to disable it when desired.

3 Experimental Setup

We use Amazon Mechanical Turk to create crowdsourcing tasks for predicting age and gender from tweets. Each HIT consists of 20 tweets authored by a single user and selected using different methods. The annotators were asked to predict gender (M/F) or age (integer value in 13–90) and rate their confidence of their guess from 1 (not at all confident) to 5 (very confident). We collected 3 annotations for each author and set of tweets.

Participants received a small compensation (.04$) for each rating and could repeat the task as many times as they wished, but never for the same authors and set of tweets. They were also presented with an initial bonus (.25$). For quality control, the participants underwent a short training and qualification questions, their location was limited to the US and they had to spend at least 10 seconds on each HIT before they were allowed to submit their guess.

In order to estimate which tweets are more likely to be written by females or a older user, we use the classifier introduced in (Sap et al., 2014). This is a regularized Linear SVM that obtains state-of-the-art prediction results on user gender (91.9% accuracy) and age ($r = .835$) prediction from social media text. We apply the model to all our tweets and select for each user 20 tweets based on the following criteria:

- **Random**: tweets chosen at random from a user's timeline;
- **Opposite**: for gender, tweets that are predicted

	Single Rating	Majority Vote
Baseline	50%	50%
Opposite	55.74%	61.57%
Random	76.67%	83.99%
Same	91.33%	95.49%

Table 1: Human accuracy in gender perception experiments in the three text selection conditions.

as more likely to be written by someone of the different gender;

- **Same**: for gender, tweets predicted to be written by someone of the same gender as the author.
- **Youngest**: for age, tweets from a user that are predicted as youngest age;
- **Oldest**: for age, tweets from a user that are predicted as oldest age;

The tweets selected based on the automatic prediction are presented in the order of prediction scores e.g. tweets for **Youngest** are sorted with the lowest predicted age being shown at the top of the list. Experiments with random ordering of tweets showed similar results.

4 Results

In this section we analyze the extent to which our experiments manage to alter trait perception, the errors and confidence of the annotations.

4.1 Gender

Overall accuracy results for our gender experiments are presented for both individual ratings and majority vote in Table 1. In all experimental setups, the raters were able to guess gender better than chance, with the majority vote of the three raters higher by a significant margin (5.77% on average) than the individual votes.

Our selection procedure has great impact on rater accuracy. Selecting tweets most likely to be written by the opposite gender – even if they are posted by the same user in reality – has an impact of decreasing the individual rater accuracy by 20.93% to only slightly above random guess (55.75%). For the majority vote ratings, the decrease is 22.42% (paired T-test, $t = 8.06$, $p < 10^{-14}$). On the other hand, selecting the tweets that are most likely to be posted by a user from the same gender as determined by our automatic model has the impact of increasing the individual rater accuracy by 14.66%. The majority vote prediction is increased by a relatively smaller amount (11.5% – paired T-test, $t = 7.09$, $p < 10^{-11}$), which we attribute to the accuracy being very close to oracle performance.

The confusion matrices from the three experiments are presented in Table 2. A couple of patterns stand out: females are easier to be accurately identified in all three experiments and males are more likely to be confused for females than vice-versa. This resulted in raters guessing more users to be females, despite our data set being balanced. Intriguingly, in the **Opposite** experiment, males were more often confused for females than correctly guessed, with females being guessed far more accurately, making the average accuracy better than chance. In the **Same** experiment, females are again easier to guess, with accuracy being very close to perfect. These results show that females are more distinctive in their language use on Twitter and thus are harder to be confused for males. On the other hand, as proven by the **Opposite** experiment, posts written by males can be selected such that they are perceived as written by females.

The inter-annotator agreement is presented in Table 4. Pairwise agreement at a user level is very high for the **Same** setup, decreasing significantly for the **Random** and **Opposite** setups.

The average self-rated confidence in assessments for the three experiments are presented in Table 3. Self-rated confidence mirrors almost perfectly the accuracy scores in all experiments and cases: confidence is higher on average in cases when accuracy is higher. Users are in general more confident when accurately guessing a female, and are least accurate when inaccurately guessing a female. Noteworthy, in the **Opposite** experiment, users who incorrectly guessed males were more confident than when correctly identifying males, which is not the case for females. This further shows that females are use more distinctive language on Twitter, while males could be more easily mistaken for females.

4.2 Age

Overall accuracy results for our age experiments are presented in Table 5. We only report results with a user age computed as the average three guesses. Results with individual ratings are very similar and we omit them for brevity.

The experiments show that our model's selection matches human perception: in the **Younger** experiment, the average predicted age is lower than in the **Random** experiment, which is in turn lower on average than the predicted age in the **Oldest** setup. Further, in the **Younger** experiment, many

(a) Random tweets (Acc. 76.66%).

		Predicted	
		Male	Female
Real	Male	35.99%	14%
	Female	9.33%	40.67%

(b) Opposite Tweets (Acc. 55.73%).

		Predicted	
		Male	Female
Real	Male	23.47%	26.35%
	Female	17.9%	32.26%

(c) Same Tweets (Accuracy 91.33%).

		Predicted

Opposite	.252	64.3%
Random	.354	68%
Same	.764	88.3%

(b) Age

	St. Dev.	Pearson r
Youngest	3.40	.368
Random	4.06	.170
Oldest	4.89	.341

Table 4: Inter-annotator agreement statistics.

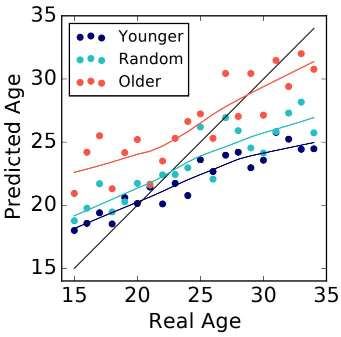

Figure 1: The average predicted ages compared to real age in the three experiments. The black line represents the ideal fit, the colored lines represent a LOESS fit to the data.

more users' age is under-estimated as compared to when predicting average age and in the **Older** experiment, more users' age is over-estimated. We also note that in the **Random** setup, raters tend to under-estimate age (53.5% younger vs. 39.3% older), with the mean being lower than in the data (23.3 vs. 24.5), which aligns with previous research (Nguyen et al., 2014).

Figure 1 plots the average prediction for users by age in the three experiments. Intriguingly, even in the **Younger** setup, users under 18 y.o. are predicted as older, while the groups of users over 20 y.o. are all under-predicted. Notably, the same near-linear pattern largely holds for the other two experiments, with the age cut-off being different (23 for **Random**, 27 for **Oldest**).

The accuracies of the three experiments are very similar regardless if comparing the number of correct guesses or guesses within 1, 3 of 5 years of the actual age. By examining Figure 1, we realize that the set of users accurately predicted shifts from one method to the other. This highlights that, even if controlling age perception is feasible, this is possible only for a difference of a few years.

The inter-annotator agreement is presented in Table 4. First, the average standard deviation across the three guesses for each author shows that **Youngest** setup generates the most similar guesses, which tend to be in the younger age range. In contrast, the **Oldest** setup generates the largest variance in guesses. Average Pearson correlation between the three guesses per author shows that both controlled setups result in higher agreement between raters than the **Random** setup, which shows that users are easier to rank by age based on their extreme language use (**Oldest** or **Youngest**) compared to a random tweet sample.

Finally, the average self-confidence of the ratings is highest in the **Youngest** experiment ($\mu = 3.35$), followed by the **Older** experiment ($\mu = 3.20$) with the **Random** experiment ($\mu = 2.97$) lowest. Further, we checked if there is a relationship between true or predicted age and self-rated confidence. In the **Youngest** experiment, both true age and predicted age are negatively correlated with self-rated confidence (true age: Pearson $r = -0.218$, p-value $< 10^{-8}$, predicted age: Pearson $r = -.246$, p-value $< 10^{-10}$), showing that raters believe their guess is easier when encountering younger users. In the **Random** experiment, a significant correlation exists between self-rated confi-

	Mean	σ	Median	Correct	Younger	Older	$\leq$1 Year	$\leq$3 Years	$\leq$5 Years
Baseline	24.0	0.0	24.0	5.0%	40.0%	45.0%	15.0%	35.0%	55.0%
Youngest	22.0	4.4	21.6	7.6%	62.2%	30.1%	20.7%	44.3%	59.0%
Random	23.3	4.8	22.8	7.1%	53.5%	39.3%	21.3%	42.8%	61.3%

Table 6: Most impactful features in tweet selection and representative tweet.

dence and predicted age only (Pearson $r = -.172$, p-value $< 10^{-5}$), while we found no relationship in the **Oldest** experiment. This indicates that language use at least apparently is more distinguishable for younger users, probably due to specific topics or interests.

5 Qualitative Analysis

Finally, we show in Table 6 the top features that impact selection of tweets in representative setups from this paper together with a representative tweet. The top features are computed by multiplying the regression/classification weight with the user-normalized average frequency of the feature in the displayed tweets. For gender, we use the **Opposite** setup to show words most indicative of females present in tweets selected and written by males and viceversa. Gender specific features are used with different senses than usual ('dress', 'wife', 'women's'), in reference to other persons rather than oneself ('herself', 'his'), or represent stylistic ('of') or topical ('haircut', 'burger') differences. For age, we select the feature most indicative of a younger user in the **Youngest** setup and the ones most indicative of older age in the **Oldest** setup. In this case, most of the top words are stylistic ('literally', 'so', 'though', 'excited, 'guys', 'ok', 'via') with features indicative of older age referencing the past ('years', 'ago') or generally specific of older age ('daughter').

6 Conclusions

We have presented the first study into automatically controlling human perception of written text. Our exploration used gender and age as basic human traits, which most have a good level of knowledge about, to measure the extent to which altering perception in text-mediated communication is feasible. Our results showed that this is possible to some extent, being especially accurate for males. Age experiments demonstrated consistent results across the three experiments, although alteration seems possible only for relatively small age deltas.

In this first experiments on this topic, we chose to perform tweet selection rather than generation, as these methods often generate text that is not semantically and syntactically correct or natural for a reader. In future work, we will experiment with automatically altering or generating text while keeping topic constant, as our current results are in part topically driven. Alterations can be performed through stylistic transformations such as normalization or by using paraphrasing as suggested in (Preoţiuc-Pietro et al., 2016, 2017b).

Text adaptation is especially important for conversational agents that interact only through text. As humans, we automatically perform this adaptation through multiple additional channels: speech tone, frequency, facial expression; which the agent can not alter. In addition to methodology, future work will also need to take into account ethical implications of this personalization.

Abstract

Highlighting the recurrence of topics usage in candidates speeches is a key feature to identify the main ideas of each candidate during a political campaign. In this paper, we present a method combining standard topic modeling with *signature mining* for analyzing topic recurrence in speeches of Clinton and Trump during the 2016 American presidential campaign. The results show that the method extracts automatically the main ideas of each candidate and, in addition, provides information about the evolution of these topics during the campaign.

1 Introduction

Political discourse analysis (Van Dijk, 1998) is a branch of discourse analysis that aims at expliciting from speeches or debates the salient features of political discourses. From that point of view, a presidential election provides interesting datasets to study. Indeed, it is a major political event in a country and gives rise to many political meetings where candidates discuss personally selected societal problems and detail their own solutions. In that context, the identification of the favourite topics of candidates as well as how they evolve throughout the campaign is a crucial task.

In (Savoy, 2010), the author presents an analysis of the evolution of topics in political speeches by comparing the words that are overused or underused by Obama and McCain during the 2008 US presidential campaign. The dynamics of these particular words usage is analyzed over monthly periods to identify the underlying dynamics of the campaign topics. A limitation of this approach is that the period is fixed (monthly) whereas predictable (vote, debates) or unpredictable (scandals) events usually give the rhythm to a political campaign. Other work used topic modeling methods, such as Latent Dirichlet Allocation (LDA) (Blei et al., 2003), Latent Semantic Anlayis (LSA) (Landauer et al., 1998) or Non-negative Matrix Factorization (NMF) (Lee and Seung, 1999), to study political texts (Prabhakaran et al., 2014; Quinn et al., 2010). For instance in (Quinn et al., 2010), a topic model for legislative speech is defined. However, those works study topics one at a time whereas a set of co-referenced topics is more relevant since it constitutes the core of a candidate's political program. There exist other works about political text analysis (Calvet and Véronis, 2008) but they focus on the use of predefined single words in speeches over time, whereas we aim at finding (without knowing in advance which topic are recurrent) the recurrent topics (multiple topics) usage over time.

In this paper, we propose to identify in political speeches the favourite topics considered by each candidate as well as how and when they evolve throughout the campaign. In our opinion, this gives critical clues to identify and to explain each candidate's main ideas and their evolution. Thus, we describe an approach to extract the *topic signature* of a candidate from her/his political speeches, i.e. the set of topics discussed by some candidate over time. The method associates NMF, a standard topic modeling technique (Lee and Seung, 1999), with *signature mining* (Gautrais et al., 2017) to analyze the speeches of Hillary Clinton and Donald Trump during the 2016 US presidential campaign. The advantages of this approach are twofold. First, the set of campaign speeches is modeled with *topic signatures*, i.e. recurrent topics occurring at a flexible periodicity during the campaign, instead of sets of specific words occurring at a fixed periodicity. The topic signature provides a more abstract view of each candidate's

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2342–2347
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

main ideas and propositions. Second, the *signature mining* technique automatically adapts the periodicity to the campaign rhythms, to provide a better insight of the *campaign dynamics*.

2 Topic Signature Model

To model recurrent topics in a political campaign, we use the signature model (Gautrais et al., 2017). This model was originally developed to capture the recurrent purchase behavior of retail customers. The analogy between politics and retail is that customers' purchases consist of regularly bought products, and, similarly, politicians' speeches contain recurrent topics.

We consider a set of topics ($\mathcal{W}$) and a sequence of speeches (α) such that $\alpha = \langle (t_1, S_1),\ (t_2, S_2) \dots (t_n, S_n) \rangle$ where $\forall i \in [1, n]$, $S_i \subseteq \mathcal{W}$ and t_i gives the timestamp of S_i. For instance, in Figure 1, $\mathcal{W} = \{a, b, c, d, e\}$ and α is a sequence of seven speeches displayed in chronological order. We see that during Speech S3, two topics were addressed: *b* and *d*.

A *k-segmentation* of a sequence of speeches α, $P(\alpha, k) = \langle E_1 \dots E_k \rangle$, is a sequence of k non-overlapping consecutive sub-sequences of α, E_i, called *episodes*, each consisting of consecutive speeches. An example of a 4-segmentation is given in Figure 1, the first episode $E1$ contains 3 speeches ($S1$, $S2$, $S3$), $E2$ contains 2 speeches ($S4$, $S5$), $E3$ contains speech $S6$ and $E4$ contains speech $S7$. This segmentation contains episodes of different sizes, in both number of speeches and time span. This flexibility of the model allows for adapting the episodes size to the sequence rhythm.

A *topic k-signature*, $Rec(\alpha, k)$, is defined as a *maximal* set of recurrent topics in a k-segmentation of α. Roughly, given $P(\alpha, k) = \langle E_1 \dots E_k \rangle$ a k-segmentation of α, we have $Rec(P(\alpha, k)) = \bigcap_{E_i \in P(\alpha,k)} (\bigcup_{S_j \in E_i} S_j)$. In other words, $Rec(P(\alpha, k))$ contains the set of all recurrent topics that are present in each episode of $P(\alpha, k)$. $Rec(\alpha, k)$ is *maximal* means that it is obtained from a k-segmentation of α that maximizes the size of the recurrent topics set: $Rec(\alpha, k) = Rec(P_{max}(\alpha, k))$ with $P_{max}(\alpha, k) = \text{argmax}_{\{P(\alpha,k)\}} |Rec(P(\alpha, k))|$. k gives the number of recurrences of the topic signature in sequence α. Thus, given a number of recurrences k, finding the *topic k-signature* relies on finding the k-segmentation that maximizes the size of the topic set that appears in each episode of that segmentation. For example, in Figure 1, $\{a, b\}$ is a topic 4-signature, indeed $Rec(\alpha, 4) = E1 \cap E2 \cap E3 \cap E4$ $= (S_1 \cup S_2 \cup S_3) \cap (S_4 \cup S_5) \cap (S_6) \cap (S_7) = \{a, b, c, d\} \cap \{a, b\} \cap \{a, b\} \cap \{a, b, c, e\} = \{a, b\}$. There is no largest set of topics that is repeated in each episode of a 4-segmentation of α. As one can see in this example, episodes can be of different sizes, and speeches are grouped into episodes such that the topic signature is the largest.

The signature model contains two types of information. First, the intersection of all E_j contains the topics that are recurrent. In our case, this reveals the topics that one candidate has been speaking about, throughout the campaign speeches. The second information is temporal, through the episode timestamps. These timestamps reveal the rhythm of the topics usage. The signature actually links both information, to give the recurrent topics and their dynamic.

By varying the value of k, one can explore the main topics (if k is large) or the secondary topics, that are still recurrent (when k is low). Therefore, recurrent topics and their dynamics can be analyzed on different time scales. The difference with some previous approaches (Savoy, 2010) is that the size of each episode E_j is not defined in advance. Instead, the signature adapts the segmentation and episode size to reveal the rhythm of the topics usage.

3 Case Study: 2016 US Presidential Campaign

In this section, the topic signatures of Clinton and Trump during the 2016 US presidential campaign are analyzed.

3.1 Dataset

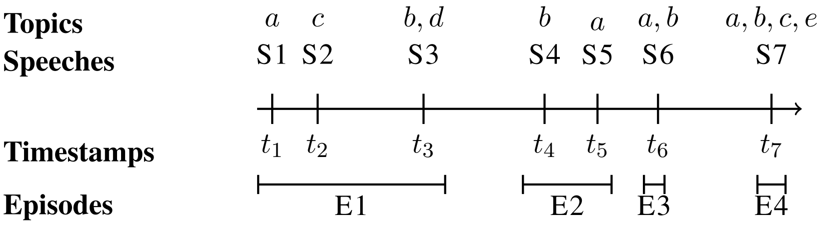
The dataset contains the transcripts of campaign speeches of both candidates Clinton and Trump, from April, 2015 to November, 2016. The speeches have been extracted from the American Presidency Project (APP)[1]. This yielded a total of 164 speeches: 93 for Clinton and 71 for Trump[2].

3.2 Preprocessing

The dataset was preprocessed as follows. First, the sentences that did not correspond to a candi-

[1] http://www.presidency.ucsb.edu/2016_election.php

[2] Including the 3 presidential debates. Speeches of Clinton prior to April 2015 were discarded



Topics
Speeches
Timestamps
Episodes
a c b,d b a a,b a,b,c,e
S1 S2 S3 S4 S5 S6 S7
t_1 t_2 t_3 t_4 t_5 t_6 t_7
E1 E2 E3 E4

Figure 1: A speech sequence and a 4-segmentation. The recurrent topics are $\{a, b\}$.

date utterance (journalists questions, introduction by another speaker . . .) were removed. Next, the sentences were tokenized and the tokens associated with some Part-of-Speech (POS) tags were kept. Precisely, nouns, adjectives and foreign words were kept while verbs and personal nouns were removed. While removing verbs can lead to a loss of semantic information, we found that it resulted in more interpretable topics. This choice of removing verbs has previously been made for topic modeling in political texts (Zirn and Stuckenschmidt, 2014). Personal nouns were discarded to remove all references to interviewers or other politicians. We considered keeping some proper nouns (the ones of both campaigners and of some other politicians) but it added noise in the topic modeling step, without providing additional relevant information. Finally, remaining tokens were lemmatized and stop words were removed. We used the WordNet lemmatizer (Miller and Fellbaum, 1998) and the list of stop words from the nltk library[3] (Bird et al., 2009). The final dataset contained 6240 different lemma.

3.3 Topic Modeling

Even though words could be analyzed directly (Savoy, 2010), we decided to analyze topics. This choice is mainly guided by the fact that we are looking for recurrent topics, and working directly on words gave uninteresting results, as recurrent words are not directly representative of each candidate ideas. Different topic modeling techniques were tested (Stevens et al., 2012) (LDA (Blei et al., 2003) and NMF (Lee and Seung, 1999)) with different parameters, number of topics and settings (with or without verbs for example). As a result, we concluded that using NMF on count vectors with 15 topics produced the most meaningful, diverse, yet non redundant topics. Some of these topics and their top lemma are shown in Table 1.

Table 1: Some topics found by NMF, and their main lemma.

Topic name	**Main topic lemma**
Economic policy	economy, growth, new, business, income, wage
Woman president and voters	woman, election, president, future, young
Illegal immigration	immigration, illegal, law, border, criminal, visa
Climate change	energy, climate, change, clean, future, important

However, it should be noted that other topic modeling techniques ((Greene and Cross, 2017) for example) could be used, and lead to meaningful results. Indeed, as our method is built on top of topics, any technique that provides good enough topics can be used. Any improvements in the topic model can help to draw more precise conclusions (if cleaner topics are available). This remark is also true regarding our choice of removing verbs and personal nouns.

Within NMF, a speech is represented as a numeric weight vector across all topics. However, the signature model works on symbolic data, which means that a set of representative topics for each speech has to be selected. As we want to discriminate the main topics of a speech from the remaining ones, we applied a clustering on the weight vectors of each speech. Two clusters were looked for, the first containing the highest weights i.e. the cluster of the main topics, and the second containing the secondary or absent topics, with lowest weights. We used the spectral clustering technique (Shi and Malik, 2000) from the scikit-learn library[4] (Pedregosa et al., 2011). We did not used techniques based on the Euclidean distance (such as k-means (MacQueen et al., 1967)) as it is not suited to separate main topics from minor ones. Three main topics emerged per speech on

[3] http://www.nltk.org/

[4] http://scikit-learn.org

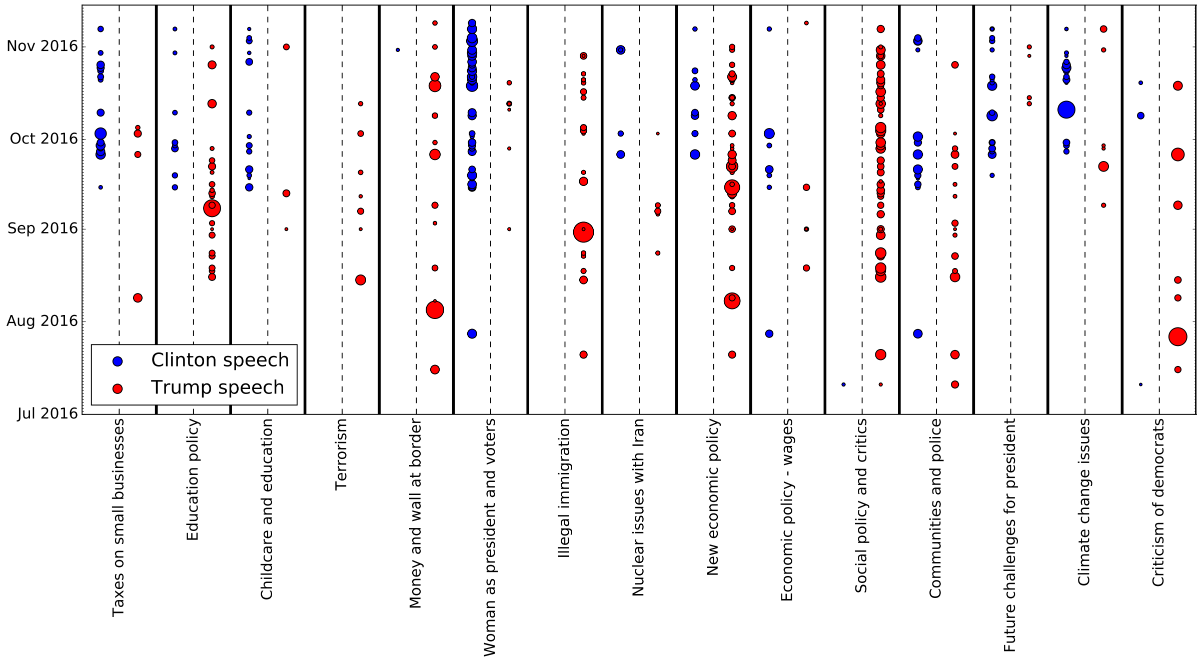


Figure 2: Campaign topics through time for each candidate. Each circle represents the presence of a topic in a speech. The larger the topic, the more present in a speech. Trump speeches are depicted in red, Clinton speeches in blue.

average.

3.4 Topic Signature Extraction

To study the main topics on different time scales, we computed signatures with different values of k. Table 2 displays the results.

3.5 Discussion

About Extracted Topics Figure 2 displays a visualization of all main topics. Only the last months of the campaign are plotted, since both candidates were particularly active during that period and speeches were sparse earlier. The visualization is especially suited to analyze single topics. First, we can see that most topics are discriminative, they appear often in one candidate's speech while being almost absent in the other's. Some topics, like *Communities and police*, are shared but not used on the same time line. Another example is the use of the *Climate change issues* topic. We can see that it is mainly used at the end of the presidential campaign by Clinton.[5]

About Topic Signatures While the previous section shows how individual topics can be analyzed, the signature allows for analyzing the main topics as a whole. Let us look at each candidate's recurring topics in Table 2. The main topics of each candidate are well separated, showing that each candidate has its own targeted voters. Clinton focused on topics related to communities, youth, issues for the next generations, and woman as president. Trump focused on topics such as new economical policies, illegal immigration, new social policies and criticism of the former government.

Table 2: Signature topics in speeches of Clinton (top) and Trump (bottom), for some values of k.

Clinton

No	Recurrences (k)	Signature topics
C1	57	Woman as President
C2	30	C1 + Future challenges for President
C3	16	C2 + Communities and police
C4	12	C3 + Childcare and education

Trump

No	Recurrences (k)	Signature topics
T1	48	Social policy and critics
T2	28	T1 + New economic policy
T3.1	15	T2 + Illegal immigration
T3.2	15	T2 + Education policy
T4.1	9	T3.2 + Illegal immigration (T3.1 + T3.2)
T4.2	9	T3.2 + Money and wall at border

The signature of Clinton is quite simple, as low-

[5] *Climate change issues* became a topic of interest when Clinton attacked Trump on him saying that climate change is a hoax in the first presidential debate (September 26, 2016).

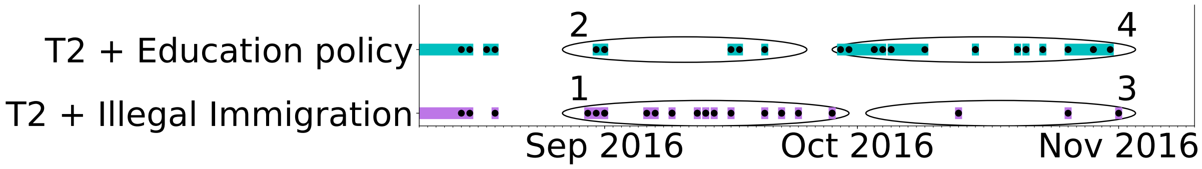

Figure 3: Episodes of two Trump signatures. T3.1: Social policy and critics + New economic policy + *Illegal immigration* ; T3.2: Social policy and critics + New economic policy + *Education policy*. Every rectangle in pink or blue represents an episode, and each black dot represents a speech belonging to an episode. Each numbered ellipse represents a group (annotated by hand) of episodes.

ering the minimal number of occurrences only adds new topics to the signature. This means that Clinton is very stable in her main topics. This observation is also partially true for Trump. Indeed, Trump has sometimes different signatures for a given number of occurrences. For example, with $k = 15$, Trump speeches main topics can include *Illegal immigration* or *Education policy*, but not both together. This is interesting because it shows that Trump is more diverse in his recurrent topics and that some of them rarely occur together.

To further deepen the analysis of the fact that Trump speeches include either *Education policy* or *Illegal Immigration* but rarely both, let us look at the episodes of the related signatures, represented in Figure 3. First, we note that the difference between both signatures episodes began to be apparent by September 2016. Indeed, the signature containing *Illegal immigration* only has three episodes (Group 2), whereas the one with *Education policy* has 11 episodes (Group 1). This large difference shows that, in September, Trump discussed his main topics a lot (*Criticism of former government*, *New social policies* and *New economic policy*) in association with *Education policies*. In October 2016, he switched to *Illegal immigration* while keeping his main topics, as there are 3 episodes for *Education policy* (Group 3) whereas there are 7 episodes for *Illegal immigration* (Group 4). While the fact that Trump stopped talking about *Education policy* at the end of September 2016 is visible in Figure 2, the segmentation performed by the signature brings additional information. Indeed, the signature is changing only one of its topics, so we know that Trump kept talking about his other main topics (*Social policy and critics* and *New economic policy*) while switching from *Education policy* to *Illegal immigration*.

Another important point is that by the beginning of October, when Trump switched from *Education policy* to *Illegal immigration*, the episodes are longer than the remaining ones (Group 4). This means that Trump's main topics are distributed among more speeches than before, which can reflect a change in his strategy. This information is not easily visible in Figure 2, but it is available from a simple analysis of Trump signature.

This case study, based on topic signatures, shows that our method is able to derive each candidate's recurrent topics. Analyzing episodes and related signature topics enables to spot changes in Trump speeches and to explain how some of his recurrent topics are related to each other. This kind of precise analysis is beyond the capabilities of naive regular segmentation techniques.

4 Conclusion

We have presented a new method for analyzing political discourse. It associates standard topic modeling with signature mining and enables the identification of the main topics of politicians during a campaign as well as their dynamics. The 2016 US presidential campaign analysis provides interesting results: though the discourse of H. Clinton was relatively stable, important changes could be identified in the discourse and communication strategy of D. Trump. These specific results on the campaign dynamics were obtained thanks to the temporal flexibility of the model.

In the future, we would like to apply the method to more challenging data, such as political tweets. Preliminary results on the 2016 US campaign tweets show that the topics used by both candidates were different from their speech: the tweets, being shorter than speeches, emphasize more oversimplified criticism of the opponent rather than justified political ideas.

Assessing Objective Recommendation Quality through Political Forecasting

H. Andrew Schwartz[†] Masoud Rouhizadeh[†,‡] Michael Bishop[‡]

Abstract

Recommendations are often rated for their subjective quality, but few researchers have studied quality in terms of objective utility. We explore quality assessment with respect to both subjective (i.e. users' ratings) and objective (i.e., did it influence? did it improve decisions?) metrics in a *massive online geopolitical forecasting system*, ultimately comparing linguistic characteristics of each quality metric. Using a variety of features, we predict all types of quality with better accuracy than the simple yet strong baseline of recommendation length. For example, more complex sentence constructions, as evidenced by subordinate conjunctions, are characteristic of recommendations leading to objective improvements in forecasting. Our analyses also reveal rater biases; for example, forecasters are subjectively biased in favor of recommendations mentioning business deals and material things, even though such recommendations do not indeed prove any more useful objectively.

1 Introduction

Finding good recommendations is an integral part of a modern information-seeking life – from purchasing products based on reviews to finding answers to baffling questions. Following the tradition of sentiment analysis, many have proposed methods to automatically assess the quality of recommendations or comments based on subjective ratings of their usefulness (Liu et al., 2007; Siersdorfer et al., 2010; Becker et al., 2012; Momeni et al., 2013) or of persuasiveness (Wei et al., 2016). However, information thought to be useful does not always prove so, and subjective ratings may be driven by biases. Reviews which convince you to watch a movie or buy a product do not guarantee that you will enjoy the product, and the most convincing or highest rated answers to questions on sites like Stack Overflow or Yahoo Answers are not always the most accurate.

We explore recommendations in a unique dataset, an online forecasting competition, which offers a rare glimpse into both subjective and objective quality. In this competition, the users (forecasters) had a measurable goal — to forecast the outcomes of geopolitical events — and a need to effectively gather information in order to reach this goal. They viewed recommendations (or "tips") from other forecasters, rated them, and potentially updated their own forecast. This data not only allows us to access what information the forecasters *thought* useful based on their ratings, but also what was objectively useful based on (a) the rate at which forecasters change their prediction after viewing tips and, (b) the average improvement (or decrease) in their prediction accuracy after this change.

We seek to tease out subjective biases by distinguishing the linguistic characteristics of recommendations with high subjective ratings from those of objective utility. Since objectively good recommendations tend to get higher subjective assessments, detecting such differences is nontrivial. Past literature has suggested that subjective quality is well predicted by comment length (Agichtein et al., 2008; Beygelzimer et al., 2015); We seek differences beyond this. We build quality predictive models from linguistic features of recommendations — 1 to 3 word sequences, parts-of-speech, and mentions of concepts from a taxonomy — comparing to surface-level features (length and readability). We then explore the language which distinguishes high quality comments from low quality, controlling for comment length,

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2348–2357
Copenhagen, Denmark, September 7–11, 2017.

and ultimately what distinguishes high subjective quality from objective quality in order to reveal subjective biases.

Contributions. We see the key contribution of this paper, perhaps non-conventional for NLP, as presenting an evidence-based suggestion for the field to consider metrics of objective quality beyond that of subjective ratings. To the best of our knowledge this represents the first study of objective comment quality using randomized experimental data. Specific novel contributions include (a) the development of automated assessments fit to objective outcomes, (b) the identification of linguistic features distinguishing high- from low-quality comments, (c) the use of a new, important, real-world domain for NLP – geopolitical information, and (d), most consequentially, the identification of subjective biases manifested in the comments' text itself.

2 Data Set

Data were collected from the **m**assive **o**nline ge**o**political **f**orecasting system (MOOF) described by Mellers et al. (Mellers et al., 2015; Atanasov et al., 2016). Forecasters completed *tasks* where they indicated the probability of discrete outcomes for specific future geopolitical events around the world. For example, forecasters might be asked to forecast the likelihood of a coup in Venezuela within the next 12 months. Respondents indicated a probability for the event and, after the event resolved, they received a score (Brier, 1950) based on how close their probability reflected the outcome of the event.[1]

Recommendations generated from a another *parallel* forecasting system were presented as "tips". In the parallel system, the recommendation writers were asked "Why did you answer the way you did?" when making forecasts, and were given the option to mark their response as potentially being useful to others. Comments marked useful from the *parallel* system were then presented as tips within the main *MOOF* system, where they were evaluated for their subjective and objective usefulness. Below is an example of one such comment:

> *Predicting the foreign ministers will meet and state something along the lines of "hoping for a summit at the appropriate time." ... Predict this because of the cautious language here and elsewhere: http://www.china.org.cn/wap/2015-03/13/... If wrong, will have time to redress the damage done before any possible summit.*

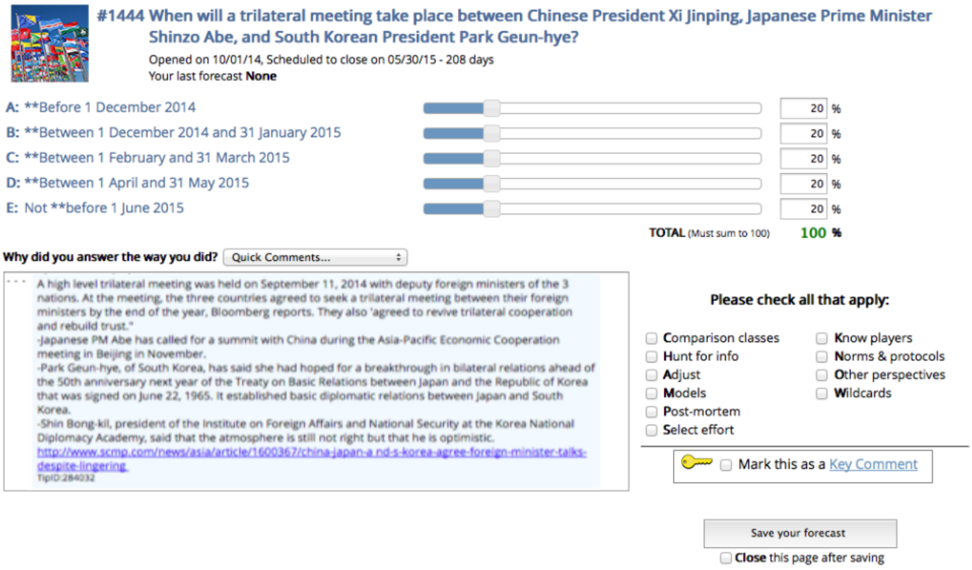
The above forecaster identifies a reason for their decision, a source of information (a Chinese news website), and even a contingency plan if their reasoning doesn't seem to be planning out. Figure 1 shows a representative screen shot from the *MOOF* system.

We focus on one subjective and two objective quality metrics for these recommendations:
rating: subjective ratings on a 5-point scale by the forecasters in the parallel system.
influence: the rate at which MOOF forecasters update their predictions after reading the comment.
benefit: the mean *change* in MOOF forecaster accuracy resulting from updating their predictions after rating the comment. Because there were numerous confounding factors regarding the magnitude of change (i.e. forecaster quality, time until task resolution), we simply encoded the *change* as a binary indicator of whether it was positive or negative.

For the purposes of this study, we consider both *influence* and *benefit* as assessments of objective utility, though they each capture different aspects of utility (behavioral *influence* of others in the case of influence; and specifically positive influence in the case of *benefit*). The *MOOF* forecasters did not know who wrote the tip or any other information about it; their actions were based on the comment's content and not reputation of the comment author. *MOOF forecasters* were also linked directly to the form to update their forecast from the comment to minimize outside influences between the reading of the comment and prediction update. However, as the forecasters were not in a laboratory, other Web browsing behavior in other tabs could not be controlled.

In order to balance quality score reliability with quantity of recommendation data, we restricted the dataset to recommendations with at least 10 words that received at least 3 ratings. This resulted in $8,498$ comments with *ratings* and *influence* scores. Out of those, $4,317$ comments had at

[1] Data, in the form of quality ratings, POS features, and aggregate concept features is released at `http://http://www3.cs.stonybrook.edu/~has/objective_quality/`. Due to IRB privacy considerations we are unable to release the full data set.



#1444 When will a trilateral meeting take place between Chinese President Xi Jinping, Japanese Prime Minister Shinzo Abe, and South Korean President Park Geun-hye?

Why did you answer the way you did? Quick Comments...

A high level trilateral meeting was held on September 11, 2014 with deputy foreign ministers of the 3 nations. At the meeting, the three countries agreed to seek a trilateral meeting between their foreign ministers by the end of the year, Bloomberg reports. They also 'agreed to revive trilateral cooperation and rebuild trust."
-Japanese PM Abe has called for a summit with China during the Asia-Pacific Economic Cooperation meeting in Beijing in November.
-Park Geun-hye, of South Korea, has said she had hoped for a breakthrough in bilateral relations ahead of the 50th anniversary next year of the Treaty on Basic Relations between Japan and the Republic of Korea that was signed on June 22, 1965. It established basic diplomatic relations between Japan and South Korea.
-Shin Bong-kil, president of the Institute on Foreign Affairs and National Security at the Korea National Diplomacy Academy, said that the atmosphere is still not right but that he is optimistic.

Figure 1: Screenshot of the forecasting system prompting users to justify their forecasts with recommendations. These recommendations are then passed on to the parallel *MOOF* system as "tips" which are rated and sometimes lead forecasters to change their predictions.

rating v influence	*rating v benefit*	*influence v benefit*
.45*	.01	.06*

Table 1: Correlation (Pearson product-moment coefficient) between all subjective and objective quality metrics: rating: forecaster subjective rating, influence: forecaster update rate, benefit: change in forecast accuracy due to update. *significant at $p < .01$.

least one associated change in forecast, and thus had a score for the final metric, *benefit*.

Table 1 shows correlations (Pearson product-moment coefficients) between all subjective and objective quality metrics. *Rating* and *influence* are fairly predictive of each other ($r = 0.45$, $p < 0.01$), and neither correlates particularly strongly with *benefit*. ($r = 0.01$, $p > .01$ for *rating* v *benefit*, and $r = 0.06$, $p < .01$ for *influence* v *benefit*). This implies that while comments rated for subjective utility are also more likely to influence users, they are not necessary influencing them in a positive way. Further, it is possible (and indeed the case) that the characteristics of comments deemed subjectively useful may differ from those that objectively provide benefit. In Section 4 we consider the content that leads to these differences in the metrics.

3 Regression

Our goal is to predict the quality score of a comment from its content over each of the three quality metrics: *rating*, *influence*, and *benefit*. These 3 types of features were chosen in order to account for qualitatively different types of linguistic attributes. To capture linguistic variance at varying resolutions, we use a combination of open-vocabulary and taxonomic linguistic features:

ngrams: *1 to 3 word sequences*. These ngrams were recorded as binary variables indicating whether each ngram appeared in each comment. We limited ngrams to those mentioned in at least 0.1% of all comments.

parts-of-speech: *POS frequences* The Stanford Part-of-Speech tagger was used to identify parts of speech in each comment. The relative frequency of each tag (i.e., the probability of the tag, given the comment) was recorded.

concepts: *Nominal concepts within a hierarchy.* The WordNet noun ontology (Fellbaum, 1998) was used. For each comment, we tracked all of the hypernyms of each noun within the comment. As features per comment, we use the presence of each hypernym concept, limited to those concepts that appeared in at least 0.1% of all comments.

To control for *task*-specific language, features (n-grams) were restricted to those mentioned in at least 50% of forecasting *tasks*. The *n-grams*, intended to capture fine-grained lexical information, were also restricted to those mentioned in at least 1% of comments, while the *parts-of-speech* and *concepts*, intended to capture more coarse-grained linguistic characteristics, were restricted to those appearing in 5% of comments. These thresholds were chosen such that total number of features was within the same order of magnitude as the number of recommendations with objective scores In the end, there were $1,202$ unique *n-grams*, 32 unique *parts-of-speech*, and 155 unique *concepts*.

3.1 Predictive Modeling

We built predictive models of all three quality metrics based on the linguistic features of the messages. To handle covariance and avoid over-fitting with so many features, we used a series of feature selection and dimensionality reduction techniques fed into a ridge regression to create the models. Specifically, we filtered the features (which were already restricted to those present in at least 50% of the forecasting tasks) to those with a small linear correlation with the outcome, defined as having a family-wise error rate < 60 (Toothaker, 1993). This feature selection was run independently on each type of feature (n-grams, parts-of-speech, and concepts). Similar to correcting for multiple hypothesis tests, family-wise error penalizes groups containing more features (i.e. n-grams) more stringently.

We then used randomized *singular value decomposition* (SVD) (Halko et al., 2011) to reduce the feature set to $^1/_5$ the number of original features. Randomized SVD uses stochastic sampling to more efficiently calculate the principal components (Martinsson et al., 2011).In this context, SVD functions as a type of regularization to reduce variance by removing lesser principal components (and thus helping to avoid overfit). Finally, the resulting dimensions were fit to the given quality metric using L2 penalized linear regression. All feature selection, dimensionality reduction, and L2 parameter tuning were done over a held-out portion of the training set.

3.2 Evaluation

To evaluate our models out-of-sample, we use 10-fold cross-validation over the subjective ratings (*rating*) and update rates (*influence*). In this process, a random selection of 1/10th of the comments are held-out as a test set, while the other 9/10ths are used to train (estimate) the model. This model is then used to predict the quality of the comments in the 1/10th sample and compared to the true quality for those comments (using Pearson correlation in this case). However, many of our scores for change in forecaster accuracy (*benefit*) are based simply on one change and thus quite unreliable. While it is best to include such noisy data when training, it does not provide a very accurate assessment. Therefore, we use dedicated training and test sets, where the test set is a random sample of 500 comments with more than 3 updates and thus a more reliable mean change in forecaster accuracy.

	rating	***influence***	***benefit***
baseline	.59	.24	.02
our model	.76*	.37	.21*

Table 2: Predictive accuracy (out-of-sample Pearson correlation coefficient) of our content-based models across the subjective and objective measures. *baseline*: square-root number of words; *our model*: based on *ngrams*, *parts-of-speech*, and *concepts*. *significant reduction in error over the baseline at $p < .001$.

As a baseline, we use the square-root of the number of words in the comment. This may seem like weak measure of quality, but the history of automatic quality assessment is saturated with findings that length is the best predictor of quality. This holds true for both answers to questions (Agichtein et al., 2008; Surdeanu et al., 2011; Beygelzimer et al., 2015); as well as e-commerce reviews (Cao et al., 2011; Racherla and Friske, 2012). Of course, length is not as shallow as it may seem at first; given no strong incentive for authors to leave long comments, length is likely a proxy for thoroughness of the comment. Still, because we would like to understand the content distinguishing various metrics of quality, we view length as a baseline to move beyond.

Table 2 compares the accuracy of models built on content (*ngrams*, *parts-of-speech*, and *concepts*) to the baseline of length. In all cases, *our models*, based on content, perform significantly better than those based only on length. Further in the case of *benefit* (change in forecaster accuracy), length has virtually no predictive power.

measure	*readability*	*length & readability*
rating	.23	.59
influence	.08	.24

Table 3: Predictive accuracy (out-of-sample Pearson correlation coefficient) of the baseline of length and the baseline of readability and their combination across the subjective and objective measures. *length*: square-root number of words; *readability*: Flesch-Kincaid Scale.

3.3 Relation to Readability

Some previous work used on *readability* measures to evaluate comment quality (e.g. (Agichtein et al., 2008; Hsu et al., 2009)). Readability often refers to the difficulty or complexity scale of a comment, determining the minimum age group able to perceive it. Various readability measures have been suggested in the past such as Flesch-Kincaid Formula (Kincaid et al., 1975), Gunning-Fog Index (Gunning, 1952), and SMOG Grading (Mc Laughlin, 1969). All methods are based on the combination of the count of syllables or words in the comment (as a representation of syntactic complexity), and the number of sentences in the comments (representing the semantic complexity). Such measures of readability are often considered naive and questionable, however, they are commonly used and present a coarse evaluation of the comment's complexity.

We used Flesch-Kincaid scale to measure readability. This scale measures readability by the average number of syllables per word as well as the average number of words per sentence (Doak et al., 1996). We combined the baseline of length and the baseline of readability in order to measure the quality of comments. Table 3 shows results for readability and length plus readability. We find no significant improvement in the baseline and that our model based on content still adds significantly more predictive accuracy.[2]

4 Differential Analysis

The prediction results show promise for automated quality assessment, and that linguistic content can predict quality above-and-beyond length (a proxy for comprehensiveness). Next, we explore what content exactly it is that is predictive of each quality metric, and what content suggests biases distinguishing subjective versus objective quality.

4.1 Method

To identify distinguishing features, we use a series of multivariate linear regressions to find the relationship between each individual linguistic feature and the given quality metric, controlling for comment length – a process known as differential language analysis (Schwartz et al., 2013). Specifically, the individual linguistic feature along with the comment length (logged) are standardized and used as independent variables, and then fit to the standardized form of the given quality metric. The coefficient given is then taken as the standardized effect size of the relationship between that feature and the quality metric, holding length constant (Fox, 1997). In other words, it tells us how much the feature can explain the quality score, beyond what is explainable simply from length.

Using regression to relate variables, although rarely done in Computer Science domains, is standard practice in social and political science (Fox, 1997), though typically not over thousands of potential independent variables as we do here. Therefore, we also correct for multiple hypotheses by using the Benjamini-Hochberg procedure (Benjamini and Hochberg, 1995) over our significance tests.

Differential language analysis allows us to observe and test the unique relationship between each feature and each metric, holding length constant. In addition, we use the difference between standardized metric scores to find the features that distinguish high quality comments in one metric versus another. All methods were implemented within the package, dlatk (Schwartz et al., 2017).

4.2 Quality Comment Features

Figure 2 shows the n-grams most highly correlated with each of our quality metrics. Size indicates correlation strength while color represents overall frequency. Across both subjective ratings and objective update rates, we see discussion of news plays an important role (e.g. "news", "article", and "www.reuters.com"). We do not see the same from comments resulting in positive changes of forecaster accuracy (benefit), which seemed to be distinguished by negation (e.g. "no", "unlikely"). For influence, we see other features indicating probabilistic reasoning (e.g. "%"); the individual

[2] Adding length and readability together to the full model had no benefit.

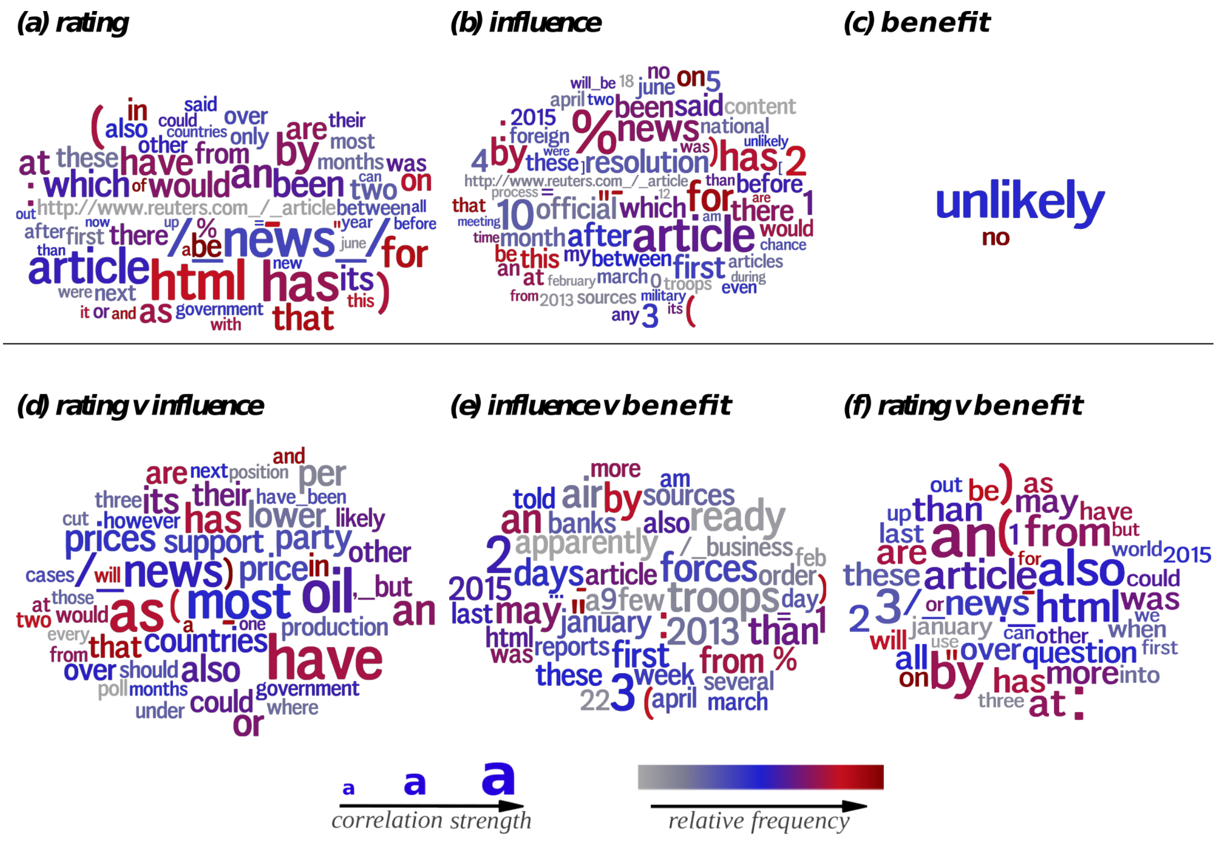

Figure 2: Top: *ngrams* (words and phrases) most distinguishing high quality comments based on (a) subjective ratings, (b) objective forecaster update rates, and (c) objective changes in forecaster accuracy. Bottom: *ngrams* (words and phrases) most distinguishing (d) subjective ratings from objective update rates and (e) objective update rates from objective changes in forecaster accuracy. All correlates are significant at $p < .05$ after a Benjamini-Hochberg false-discovery rate correction.

numbers in influence actually represent numbered lists of signal. These features are more indicative of a comment that convinces one to update their prediction rather than one that highly rated.

We can directly observe the differences in what the metrics capture by looking at the final two visualizations in Figure 2, *rating v influence* and *rating v benefit*. *Rating v influence* tells us which ngrams were predictive of high quality comments that were less likely to result in a forecast update. Discussion of energy topics (e.g. “oil”, “prices”, “cut”, “production”) are predictive of comments subjectively rated higher than their update rates would suggest. Further, discussion of dates (e.g. “january”, “may”, “days”, “2015”, “2013”) seems to predict comments that lead forecasters to update but which do not actually result in better predictions (*influence v benefit*). Discussion of news and articles (“article”, “news”, “html”, “question” appears to predict subjectively top-rated comments from those comments that actually result in better predictions (*influence v benefit*).

Table 4 shows differential language of quality based on part-of-speech. We observe that some patterns from the *ngram* results are generalized. Examples of these patterns include more numbers, parentheses, and quotes in highly rated and influential comments. Other results are somewhat novel, such as the use of more adverbs and subordinate conjunctions (e.g. “though”, “since”, “whereas”) in comments leading to better forecast accuracy, and that both ratings and influence favored quotes.

We notice that including explanation or afterthought (using more parentheses) can predict subjectively high rated comments from the comments leading to updated ratings. The use of quotes and numbers along with mentioning proper nouns can predict influential comments that do not help in better predictions. Including explanation, quotes, and numbers as well as reporting past events seems to predict comment that convinces

	Parts-of-speech				
rating	parentheses	number	line-break	quote	verb, past-tense
influence	line-break	number	parentheses	verb, past-tense	quote
benefit	adverb	sub-conjunction	-	-	-
rating v influence	parentheses	-	-	-	-
influence v benefit	quotes	proper noun	number	-	-
rating v benefit	parentheses	quotes	number	verb, past-tense	-

Table 4: Top: Most distinguishing parts-of-speech correlating with the three metrics of quality: subjective rating, forecaster updates (*influence*), and forecaster accuracy (*benefit*). Bottom: *parts-of-speech* most predictive of differences in quality metric scores (*rating v influence* and *rating v benefit*). All correlates are significant at $p < .05$ after a Benjamini-Hochberg false-discovery rate correction.

one to update their prediction as opposed to helping better forecasting accuracy.

Distinguishing *concepts*, in Table 5 offer a different perspective. Discussions of documents and written material characterize highly rated and influential comments, while changes in accuracy (*benefit*) were characterized by more discussion of abstract attributes or states of being. Highly rated comments were more likely to discuss concepts related to transactions and materials than influential comments, but they are more likely to discuss concepts about creation compared to comments resulting in better predictions.

5 Related Work

While no prior work has focused on recommendation quality in terms of how readers change or improve decisions (i.e. objective metrics), there is an extensive body of literature on the automated analysis of subjective comment quality from which we build. Such work typically uses subjective assessments specific to their application domain (e.g. thumbs up/ thumbs down over YouTube comments, answer ratings in Yahoo Answers, or helpfulness ratings of Amazon product reviews). Below we discuss such work organized into three main categories of subjective comment quality: *comment usefulness*, *the quality of answers in QA platform*, and *comment helpfulness*.

Comment usefulness concerns the acceptance (vs. non-acceptance) of comments by a community (Siersdorfer et al., 2010). Some previous work has focused on the usefulness of YouTube comments. For example, Siersdorfer et. al. (Siersdorfer et al., 2010) have used support vector machines to identify the acceptance of comments by the community in 6 million comments on 67,000 YouTube videos. They showed that community feedback and term weight features can be good predictors of comment acceptance. Other work such as (Momeni et al., 2013) predicted comment usefulness on YouTube and Flickr, and found that comments rated as useful usually include named entities and "insight"-related terms (think, know, consider, etc.), whereas non-useful comments contain emotional and affective expression, and "certainty"-related (always, never, etc.).

Others working on comment quality assessment focus on user-generated answers in social media and QA platforms. (Bian et al., 2008) present a general ranking approach for finding the answers from 1,250 TREC factoid questions containing at least one similar question from Yahoo! Answers. They found that various features including textual (e.g. word overlap, length ratio), and community (e.g. total points, total answers) are important in retrieving factual answers, whereas statistical features (e.g. length, lifetime, popularity) are not very effective. Exploring if additional features could outperform answer length in predicting the best answer, Beygelzimer et al. (2015) considered a wide variety of features including functional, linguistic, questioner and answerer personalization, and "superlative" features, but were unable to overcome the length baseline.

Helpfulness is mainly defined in the context of online reviews and represents the number of users indicating a particular review was helpful. Using structural features like sentence tokens, length,

	Concepts	
rating	*document, written document, papers* – writing that provides information (especially information of an official nature).	*gathering, assemblage* – a group of persons together in one place.
influence	*writing, written material, piece of writing* – the work of a writer; anything expressed in letters of the alphabet (especially when considered from the point of view of style and effect).	*auditory communication* – communication that relies on hearing.
benefit	*attribute* – an abstraction belonging to or characteristic of an entity.	*state* – the way something is with respect to its main attributes.
rating v influence	*transaction, dealing, dealings* – the act of transacting within or between groups (as carrying on commercial activities).	*material, stuff* – the tangible substance that goes into the makeup of a physical object.
rating v benefit	*creation* – an artifact that has been brought into existence by someone.	

Table 5: Top: Select concepts correlating with the three metrics of quality: subjective rating, forecaster updates (*influence*), and forecaster accuracy (*benefit*). Bottom: concepts most predictive of differences in qualtric metric scores (*rating* v *influence* and *rating* v *benefit*). All correlates are significant at $p < .05$ after a Benjamini-Hochberg false-discovery rate correction.

proportion of question sentences along with lexical and syntactic features, Kim et. al. (2006) could achieve rank correlations of up to 0.66 with helpfulness votes of Amazon reviews. Ghose and Ipeirotis (2011) analyzed length, readability, and subjective and objective information on Amazon.com reviews finding that reviews with objective, and highly subjective sentences are rated more helpful. Similar findings were reported by Mudambi and Schuff (2010), finding that review extremity, review depth, and product type affect the perceived helpfulness of the review.

Most studies listed thus far found length of comment to be the dominant predictor, with other features providing minimal benefit. However, a few studies (including our own) have found this baseline can be overcome. For example, Racherla and Friske (Racherla and Friske, 2012) investigated perceived usefulness of consumer reviews on Yelp and found that reputation and expertise were more important than total number of words on perceived usefulness.

All of these prior works focus on assessing subjective aspects of comments (usefulness, quality, and helpfulness); Perhaps the study coming closest in spirit to our own was Ghose et al. Ghose et al. (2007) who quantified quality of reviews by the economic change they produced. However, they still were not dealing with a randomized experiment and so conclusions were correlational and the objective was better sales of the product rather than benefit to the reader (i.e. leading to a better decision).

6 Conclusion

Our results suggest three key findings. First, what one writes in a comment is more important than simply how much one writes; this is true across both subjective and objective outcomes, though length had virtually no predictive ability for improving forecaster accuracy. Second, we found many linguistic features characteristic of quality, many of which seemingly align with attributes of strong forecasters (Mellers et al., 2015). For example, high quality comments contained signals of probabilistic reasoning (e.g. “%”, “unlikely”, numerical parts-of-speech), inductive reasoning (e.g. justifications with “news” and documents), and cognitive flexibility (e.g. subordinate conjunctions which signal more complex sentence constructions used to relate two independent clauses or ideas).

Most importantly, our results suggest a subjective bias: that what people believe to be useful does not always turn out to be truly useful. Subjective ratings were favorably biased towards comments containing energy-related content (e.g. “oil”, “production”, “prices”), news articles, and nouns of creation and materials (as opposed to abstractions or attributes).

The implications of identifying subjective biases in comment quality extend to many domains involving comment ratings. Consumers of comments, typically, desire information that ultimately leads to real utility benefits, and this domain is not the only one where objective quality can be obtained: For example, one could: (1) ask consumers of restaurant reviews to indicate if one convinces them to go to the restaurant and then follow up on their experience, (2) consider evaluating research paper quality – reviewer ratings versus citation count (influence), (3) determine whether the answer to the question about how to drive to conserve fuel lead to the reader actually using less gas? A review being convincing or being ”liked” may correlate with better outcomes, but it is not equivalent.

Never Abandon Minorities: Exhaustive Extraction of Bursty Phrases on Microblogs Using Set Cover Problem

Masumi Shirakawa[†‡] and **Takahiro Hara**[‡] and **Takuya Maekawa**[‡]
hapicom Inc., Japan[†]
Graduate School of Information Science and Technology, Osaka University, Japan[‡]

{hara, maekawa}@ist.osaka-u.ac.jp

Abstract

We propose a language-independent data-driven method to exhaustively extract bursty phrases of arbitrary forms (e.g., phrases other than simple noun phrases) from microblogs. The burst (i.e., the rapid increase of the occurrence) of a phrase causes the burst of overlapping N-grams including incomplete ones. In other words, bursty incomplete N-grams inevitably overlap bursty phrases. Thus, the proposed method performs the extraction of bursty phrases as the set cover problem in which all bursty N-grams are covered by a minimum set of bursty phrases. Experimental results using Japanese Twitter data showed that the proposed method outperformed word-based, noun phrase-based, and segmentation-based methods both in terms of accuracy and coverage.

1 Introduction

Background and motivation. Trends on microblogs reflect manifold real-world events including natural disaster, new product launch, television broadcasting, public speech, airplane accident, scandal and national holiday. To catch real-world events, not a few researchers and practitioners have sought ways to detect trends on microblogs. Trend detection often involves bursty phrase extraction, i.e., extracting phrases of which occurrence rate in microblog texts posted within a certain period of time (and from a certain location) is much higher than that of the normal state. Extracted bursty phrases are directly used as trends as Twitter[1] officially provides, or sent to higher-order processes such as clustering and event labeling.

Bursty phrases on microblogs are likely to be noun phrases, but sometimes deviate from such standards. The title of a movie, song, game or any creation can be an arbitrary form like a long and/or general phrase (e.g., Spielberg's movie "catch me if you can", the Beatles' song "let it be")[2]. A memorable phrase (e.g., Steve Jobs's phrase "stay hungry, stay foolish") can also be a bursty phrase on microblogs. Even numbers and symbols can be potentially bursty phrases (e.g., "1984" can be a novel, "!!!" can be an artist). Any filtering rule such as stop word removal, part-of-speech (POS) tag restrictions, or length limit can mistakenly filter out bursty phrases.

Extracting irregularly-formed bursty phrases as described in the previous paragraph is difficult since no restriction can be used anymore to filter out incomplete N-grams. However, they are rare and little influence the overall accuracy even if they are correctly extracted. Not only that, tackling such difficult and rare cases easily leads to extracting many incomplete N-grams and deteriorating the accuracy. Almost all existing work has therefore ignored difficult and rare cases, and concentrated on extracting simple phrases (e.g., unigrams, bi-grams, tri-grams, or noun phrases identified by POS taggers). By sacrificing minorities, most bursty phrases can be extracted with high accuracy. Thus, irregularly-formed phrases have been abandoned in bursty phrase extraction (and alike in many text analysis tasks).

Contributions. In this work, we aim to accurately and exhaustively extract bursty phrases of arbitrary forms from microblogs. The challenge here is: How do we avoid extracting bursty incomplete N-grams without introducing any filtering rule? To solve this challenging problem, we propose a set cover-based method. We found that the

(Aiello et al., 2013)-2	Uni-gram, bi-gram, tri-gram	DF-IDF
(Abdelhaq et al., 2013)	Uni-gram	Deviation from Gaussian distribution
(Schubert et al., 2014)	Uni-gram (pair)	Deviation from Gaussian distribution
(Feng et al., 2015)	Hashtag	Deviation from Gaussian distribution

burst (i.e., the rapid increase of occurrence) of a phrase causes the burst of overlapping incomplete N-grams. For example, if phrase "let it be" bursts, the occurrence of some overlapping N-grams such as "let it", "let it be is", and "it be is" inevitably increases, possibly generating bursty incomplete N-grams. Given that bursty incomplete N-grams always accompany overlapping bursty phrases, we can avoid extracting bursty incomplete N-grams using the set cover problem (Chvátal, 1979). The proposed set cover-based method finds a minimum set of bursty phrases that cover all bursty N-grams including incomplete ones. Because the set cover problem is NP-complete, the proposed method approximately solves it by iteratively choosing an N-gram that most covers remaining bursty N-grams.

The advantages of the proposed method are as follows. **1) Exhaustive.** The proposed method can extract bursty (contiguous) phrases of arbitrary forms. In our experiment, the coverage has been shown to be larger than that of word-based, noun phrase-based, and segmentation-based methods. **2) Accurate.** With adequate preprocessing of auto-generated texts, the proposed method achieved 99.3% of precision for top 10 bursty phrases and 97.3% for top 50 bursty phrases, which were even higher than the comparative methods. **3) Language-independent.** Because the proposed method processes texts as a sequence of characters (or words), it works in any languages including those without word boundary such as Japanese. **4) Purely data-driven.** The proposed method only requires raw microblog texts and does not need external resources.

2 Related Work

Much work has been focused on trend detection or event detection from microblogs. Majority of representative trend detection methods (summarized in Table 1) start with extracting bursty phrases, often followed by clustering bursty phrases in order to link them to real-world events. Others first build clusters of words (uni-grams) by using word co-occurrence (Pervin et al., 2013) or topic models (Aiello et al., 2013; Diao et al., 2012; Lau et al., 2012) and then apply burst detection for clusters. Also, there are different approaches such as the document-based approach (Aiello et al., 2013), sketch-based model (Xie et al., 2013) and bursty biterm topic model (Yan et al., 2015).

It is noteworthy that most methods in Table 1 only focus on uni-grams, short N-grams (up to tri-grams), or noun phrases (or rely on hashtags). This is because majority of bursty phrases conform to such simple forms. The rest of bursty phrases are rare but their forms are irregular and difficult to stereotype by using rules. Trying to extract such irregularly-formed phrases easily leads to the deterioration of the precision due to incorrect extraction. Also, the recall can hardly be increased since they are only a small portion of all bursty phrases. To balance the precision and recall of bursty phrase extraction, focusing on simple phrases and ignoring rare cases is a reasonable strategy. In the field of trend detection on microblogs, this ignoring-minority strategy has become a de facto standard. However, it always fails to extract irregularly-formed bursty phrases. In this work, we tackle the challenge of extracting bursty phrases without any restriction of forms.

Among methods in Table 1, Li et al. (Li et al., 2012) have only attempted to extract bursty phrases of arbitrary forms. Their method, Twevent, applies text segmentation (or chunking) before measuring the degree of the burst. Every microblog text is represented as a sequence of word N-grams called segments. N-gram length, Symmetric Conditional Probability (SCP) (da Silva and Lopes, 1999), and semantic resources extracted from Wikipedia are integrated to obtain the best segmentation results. Owing to a good segmentation algorithm, it can potentially detect bursty phrases other than noun phrases, uni-grams, bi-grams, and tri-grams with high accuracy. However, it is still possible to miss irregularly-formed bursty phrases because they are likely to be segmented incorrectly. Our set cover-based method guarantees that all bursty N-grams including irregularly-formed ones must be covered by extracted bursty phrases. Thus, it is unlikely to miss irregularly-formed bursty phrases.

One more thing to note in Table 1 is that how to measure the degree of the burst can be largely classified into a few groups: burstiness, TF-IDF-based measures, and distribution-based methods. The simplest approach is burstiness, which is the ratio of the occurrence rate in target and reference document sets. Reference document set is usually constructed from past microblog texts. TF-IDF-based measures compute term frequency (TF) or document frequency (DF) in the target document set and inverse document frequency (IDF) in the reference document set. Distribution-based methods generally measure how much the observed frequency deviates from the distribution of the normal state using standard scores (z-scores). The Poisson distribution is proper to represent the number of occurrence of phrases, but the Gaussian distribution is often used as its approximation due to computational reasons. We in this work primarily adopt a Gaussian distribution-based approach and use the z-score as the measure of the burst because it reasonably works well for the different magnitude of the number of occurrence.

3 Bursty Phrase Extraction

3.1 Problem Formulation

We formalize the problem of bursty phrase extraction from microblogs. Target document set D_T is a set of microblog messages posted within a certain period of time (e.g., one day, three hours). Reference document set D_R is a set of microblog messages posted before the target time. Both are usually limited to certain locations or languages. Each document is a sequence of characters (or words). The objective here is to extract bursty complete phrases from D_T as much as possible using D_R as the normal state. The output format is a list of bursty N-grams $L = [g_1, g_2, \cdots, g_{|L|}]$ (g_i is an N-gram or a sequence of characters) ranked by the degree of the burst. The accuracy and coverage of top K (K is a user-specified parameter) bursty phrases are important evaluation criteria.

The degree of the burst for N-grams in D_T is defined as the z-score when the Gaussian distribution is estimated from D_R. While most N-grams occur once in a single microblog message, a few N-grams are repeatedly used in it. We thus employ the document frequency-based z-score as the degree of the burst. The z-score of N-gram g is specifically computed as

$$zscore(g) = \frac{df(g) - \mu(g)}{\sigma(g)} \tag{1}$$

where $df(g)$ is the document frequency of g in D_T, and $\mu(g)$ and $\sigma(g)$ are respectively the mean and standard deviation for the document frequency of g estimated from D_R. Given that the Gaussian distribution used here is the approximation of the Poisson distribution, $\sigma(g)$ is approximated by $\sqrt{\mu(g)}$. To smooth $\mu(g)$ when g never occurs in D_R, we add $\delta = 1$ to $\mu(g)$.

3.2 Basic Idea

To exhaustively extract bursty phrases without any restriction of their forms, we have to refrain from using filtering rules such as stop word removal, POS tag restrictions, and length limit. Without filtering rules, there are far more bursty incomplete N-grams than bursty complete phrases. It is challenging to extract bursty phrases including irregularly-formed ones and at the same time to avoid extracting bursty incomplete N-grams. Is there any evident difference between bursty incomplete N-grams and bursty phrases of irregular forms?

We scrutinized Twitter data and found the following fact: Bursty incomplete N-grams always accompany overlapping bursty phrases provided that the definition of the burst is appropriate. We

Algorithm 1: Greedy Set Cover Algorithm for Bursty Phrase Extraction

```
   Input: Target document set $D_T$, reference document set $D_R$
   Output: Ranked list of bursty phrases $L$
1  Initialize $L$;
2  Get a set of valid N-grams $G_V = \{g_i\}$ satisfying $burstiness(g_i) \geq 1 + \epsilon$;
3  Get a set of bursty N-grams $G_B = \{g_i\} \subset G_V$ satisfying $zscore(g_i) \geq \theta$ and $zscore_{tf}(g_i) \geq \theta$;
4  Discard trivial N-grams from $G_V$;
5  while $G_B \neq \emptyset$ do
6      Select $g \in G_V$ that most cover the occurrence of bursty N-grams in $G_B$;
7      Get a set of longer N-grams $G_g \subset G_V$ containing $g$;
8      Determine a set of containment N-grams $G_C \subset G_g$ for $g$;
9      if $G_C = \emptyset$ then
10         Push $g$ into $L$;
11         Negate the occurrence of all N-grams in $G_B$ and $G_V$ where $g$ overlaps;
12         Delete $g_i \in G_B$ if it does not satisfy $zscore_{tf}(g_i) \geq \theta$;
13     else
14         Negate the occurrence of $g$ where containment N-grams $g_i \in G_C$ overlap;
15     end
16 end
17 Rerank $L$ based on the actual z-score;
```

explain this phenomenon in due order. When many microblog users intensively use a certain phrase, it becomes a bursty phrase. Here, the increment of the occurrence of the phrase contributes to the increment of the occurrence of overlapping N-grams. Consequently, (incomplete) N-grams that overlap the phrase can also burst. Thus, bursty incomplete N-grams always have their original bursty phrases that overlap each other.

Based on the phenomenon described in the previous paragraph, bursty incomplete N-grams cease bursting if their original bursty phrases disappear from microblog texts. In other words, all bursty N-grams including incomplete ones can be covered (overlapped) by bursty phrases. Given that bursty phrases cause bursty incomplete N-grams but the reverse was not true, we can formalize the extraction of bursty phrases as the set cover problem (Chvátal, 1979) where a minimum number of bursty phrases are selected to cover all bursty N-grams. When all selected bursty phrases are removed from microblog texts, it is guaranteed that there is no bursty N-gram.

3.3 Proposed Algorithm

Algorithm 1 is a pseudo-code of the greedy set cover algorithm for bursty phrase extraction. As formulated in Section 3.1, the input data is target D_T and reference document sets D_R of microblog messages. The output is a ranked list of bursty phrases $L = [g_1, g_2, \cdots, g_{|L|}]$. Basically, Algorithm 1 iteratively selects an N-gram that most covers the occurrence of bursty N-grams (Line 6) until all bursty N-grams are covered. In the following, we describe points of the Algorithm 1.

3.3.1 Bursty N-grams and Valid N-grams

A set of bursty N-grams G_B in Algorithm 1 (Line 3) corresponds to the universe of the set cover problem which should be all covered. Bursty N-grams satisfy z-score threshold θ both in document frequency-based (Eq. (1)) and term frequency-based z-scores (Eq. (2)).

$$zscore_{tf}(g) = \frac{tf(g) - \mu_{tf}(g)}{\sigma_{tf}(g)} \tag{2}$$

Here, $tf(g)$ is the term frequency of g in D_T, and $\mu_{tf}(g)$ and $\sigma_{tf}(g)$ are respectively the mean and standard deviation for the term frequency of g estimated from D_R. The term frequency-based z-score is used to judge whether a bursty N-gram in G_B still bursts when its occurrences are partly covered. This is required to handle N-grams repeatedly occurring in a single microblog message.

Valid N-grams in G_V (Line 2) are qualified to be bursty phrases to cover G_B. We differentiate bursty N-grams and valid N-grams (specifically, $G_B \subset G_V$) to handle threshold problems.

Namely, it is possible that bursty incomplete N-grams satisfy the z-score threshold but their original bursty phrases do not satisfy the threshold. The criterion of the valid N-gram is defined by using burstiness.

$$burstiness(g) = \frac{df(g)}{df_R(g)} \cdot \frac{|D_R|}{|D_T|} \qquad (3)$$

Here, $df_R(g)$ is the document frequency of N-gram g in D_R. To avoid division by zero, smoothing term $\delta = 1$ is added to $df_R(g)$. When $burstiness(g)$ satisfies threshold $1 + \epsilon$ (i.e., the occurrence of g actually increases), g becomes a valid N-gram. To reduce pointless processes, trivial N-grams that can never be phrases (e.g., starting or ending with spaces, occurring only as a part of a sole longer N-gram) are discarded (Line 4).

3.3.2 Occurrence-based Set Covering

Whereas the standard set cover problem assumes that each item is atomic, i.e., the state of an item is either *not covered* or *covered*, the proposed method manages the state of covering by using all occurrences of bursty N-grams. When a valid N-gram is selected (Line 10), the occurrence of all N-grams in G_B and G_V that the valid N-gram overlaps is negated (Line 11). Here, a bursty N-gram in G_B is completely covered if the term frequency-based z-score computed from remaining occurrences of the N-gram does not satisfy the threshold (Line 12).

Occurrence-based set covering can solve the case when a bursty N-gram is covered by multiple bursty phrases. That is, the bursty N-gram is not completely covered even if one of the bursty phrases is selected. For example, given two bursty phrases “let it be” and “let it go” (a song), incomplete N-gram “let it” ceases bursting only when the occurrence of both phrases is negated. Also, it can handle partially overlapping N-grams (e.g., “let it be” and “be is”) based on the number of overlaps.

3.3.3 Containment N-grams

N-grams that are contained in multiple phrases should be carefully treated in the set cover problem. Shorter N-grams are likely to be contained in more phrases and chosen in the set cover problem even if they are incomplete. For example, when phrases “let it be” and “let it go” burst, shared incomplete N-gram “let it” is likely to cover the occurrence of bursty N-grams more than the two phrases. To prevent selecting shared incomplete N-grams, we determine containment relations between an N-gram and longer N-grams containing it (Lines 7, 8). We define longer N-grams in containment relations as containment N-grams. Containment relations negate the occurrence of the shorter N-gram where containment N-grams overlap (Line 14). Containment relation is inspired by the idea of rectified frequency used in a segmentation-based quality phrase mining method (Liu et al., 2015), though how to rectify the frequency is different. Note that containment relations do not necessarily mean that shorter N-grams are incomplete because both shorter and longer N-grams can be phrases (e.g., “new york” and “new york times”).

How to determine containment relations is designed not to contradict the greedy set cover algorithm. Briefly, containment relations hold when only the containment N-grams among longer N-grams can cover the occurrence of bursty N-grams more than the shorter N-gram owing to the containment relations. That is, we find a stable state of containment relations. To find a stable state, we initially define temporal containment relations and then iteratively find a set of containment N-grams so that containment relations become stable.

Initial containment N-grams are determined using burst context variety, which is an extension of accessor variety (Feng et al., 2004). Accessor variety roughly measures how much an N-gram is likely to be a phrase. It specifically counts the number of distinct characters (or words) before or after the N-gram and employs the minimum one. The drawback of accessor variety is that it handles left and right contexts independently. We thus modify it as context variety in which both left and right contexts are simultaneously counted. Context variety can also be calculated using the set cover problem. In particular, a left or right character (or word) that most covers the occurrence of the N-gram is iteratively selected until all the occurrences are covered. Burst context variety is a further extension of context variety to count the number of contexts only for additional term frequencies given the mean of the term frequency. When the burst context variety of an N-gram is not greater than that of a longer N-gram, we extract the context (i.e., left or right character) and define all longer N-grams having the context as initial containment N-grams.

There are two minute settings for measuring burst context variety. One is that the start and end of every line are all unique and should be counted as distinct contexts. The other is that symbols[3] should be ignored when checking left and right contexts of the N-gram.

3.3.4 Reranking Bursty Phrases

The output L is finally reranked by using actual z-scores (Line 17), which are different from z-scores calculated from raw document frequency. The actual z-score is calculated from the number of occurrences of bursty N-grams that N-gram $g \in L$ actually covered during the set cover process. Since a single valid N-gram usually covers multiple bursty N-grams, the z-score for every covered bursty N-gram is recalculated and the maximum is used as the actual z-score. When the maximum z-score exceeds the original z-score, the original z-score is preserved. Without reranking, incomplete N-grams that covered very few occurrences of bursty N-grams may be overestimated.

4 Evaluation

We evaluated the proposed method using two weeks of Japanese Twitter data.

4.1 Setup

Dataset. We created a dataset using Twitter Streaming API statuses/sample. We chose Japanese as a language because it was one of popular languages used in Twitter and because it has no word boundary and finding phrases is difficult compared to space-delimited languages such as English. We specifically collected 15 days of tweets from September 30 to October 14, 2016[4]. For each day from October 1 to 14, we extracted bursty phrases in reference to the previous day.

To maximally alleviate the influence of auto-generated contents such as tweets posted by bots and spammers, we filtered out them. Detecting bots and spammers (Chu et al., 2010; Subrahmanian et al., 2016) is a nontrivial research task and out of the scope of this paper. In this experiment, we used simple but effective heuristics. First, we only used tweets posted by Twitter official clients[5] because they were mainly used by normal users. Second, we discarded tweets including URLs because most spammers tried to lure users to visit their websites. Third, retweets (actions to propagate someone's tweets) were discarded. The maximum and minimum numbers of remaining tweets per day were 326,002 (Oct. 2) and 253,044 (Oct. 13), respectively. Additionally, we deleted hashtags (starting by #) and mentions (starting by @) from tweets. Note that the degree of the burst for URLs, hashtags, and mentions can be independently measured. We concentrated on extracting bursty phrases from plain texts.

Ground truth. To create the ground truth, we mixed N-grams extracted with all methods and then manually annotated each N-gram by checking its real usage in tweets. While most N-grams were easily judged as complete phrase (i.e., *correct*) or incomplete N-grams (i.e., *incorrect*), a few N-grams were difficult to judge (e.g., a last name that was not frequently used to indicate the person in tweets). We annotated such N-grams as *maybe correct* and regarded as correct in the strict case and incorrect in the loose case when measuring evaluation metrics.

Evaluated methods. In the proposed method (**Proposed**), we processed Japanese texts as sequences of characters. Default threshold parameters θ and ϵ were set to 10 and 0.5, respectively. Comparative methods included the word-based method (**Word**), noun phrase-based method (**NP**), and segmentation-based method (**Segment**) (Li et al., 2012). Because these methods require word breaking, we used MeCab (Kudo et al., 2004) (version 0.996, ipadic as a dictionary), a Japanese morphological analyzer. The word-based method uses all self-sufficient words as candidate phrases. The noun phrase-based method regards concatenated successive nouns as a candidate phrase. In word-based and noun phrase-based methods, the dictionary or vocabulary significantly affects the performance. Thus, we also used neologd[6] (Sato et al., 2017) (version v0.0.5 updated at May 2, 2016), a neologism dictionary extracted from many language resources on the web, as an additional dictionary (**+Dic**). The segmentation-based method detects segments (chunks) from a sequence of words as candidate phrases. The segmentation model was constructed using three

[3] In our experiments, we used isalnum (or iswalnum for wide characters) in C++ standard library to distinguish words and symbols.

[4] We considered that a day changed at 4 am JST.

NP+Dic	0.971	0.979	0.974	0.971	0.973
Segment	0.957	0.954	0.952	0.955	0.953
Proposed	**0.993**	**0.996**	**0.998**	**0.995**	**0.991**

months of tweets (from July 1 to Sept. 30, 2016) and Japanese Wikipedia dump data (as of Oct. 1, 2016).

Evaluation metrics. We employed precision and min-z-score of top K bursty phrases (K was set to 10, 20, 30, 40, or 50) as evaluation metrics. We measured the precision both in strict and loose cases based on the ground truth labels. The min-z-score (the minimum of the z-score, computed from raw document frequency) was introduced to evaluate how much the top K output ranked by z-scores included highly bursty phrases. To increase the min-z-score, all the top K phrases should have high z-scores and hence highly bursty phrases should not be ignored. Thus the min-z-score can evaluate the coverage of extracted bursty phrases using a fixed size of the output. Higher precision and min-z-score indicate that the method can more accurately and exhaustively extract bursty phrases.

4.2 Performance Results: Precision

Tables 2, 3 show the precision of bursty phrase extraction. It was surprisingly that the proposed method achieved higher precision than noun-phrase based methods, which were supposed to be safety by sacrificing irregularly-formed phrases. The precision of the proposed method for top 50 bursty phrases was 97.3% (correct phrases were 681 out of 700) in the strict case and 99.1% (694 out of 700) in the loose case. The precision for top 10 bursty phrases was 99.3% (139 out of 140) even in the strict case. The results demonstrate that the burst information alone can accurately find the boundary of bursty phrases using the set cover problem. Error cases of the proposed method were largely classified into two: base sequences of diversified expressions and phrases with strongly-correlated attached characters.

In comparative methods, the accuracy tended to be high when noun phrases were used and the dictionary was well defined. Especially, the use of the neologism dictionary boosted the precision. The segmentation-based method also marked moderately high precision.

Table 4: Average min-z-score of top K bursty phrases.

Method	Top10	Top20	Top30	Top40	Top50
Word	41.5	25.7	20.4	17.2	15.3
Word+Dic	44.7	29.0	22.5	19.3	16.7
NP	42.6	26.4	20.4	16.7	14.6
NP+Dic	42.7	28.8	21.0	17.6	15.3
Segment	45.0	31.2	24.3	20.5	18.0
Proposed	**50.1**	**33.5**	**24.8**	**21.5**	**19.4**

4.3 Performance Results: Coverage

Table 4 shows the min-z-score of bursty phrase extraction. The proposed method achieved higher min-z-score than the comparative methods. This was because the proposed method extracted bursty phrases regardless of their forms. Noun phrase-based methods tended to miss highly bursty phrases of irregular forms. Therefore the min-z-score of extracted top K bursty phrases became small. Among comparative methods, the segmentation-based method best achieved the min-z-score since it did not restrict the form of phrases. However, it was still possible to miss very irregular phrases due to segmentation mistakes and the min-z-score was less than that of the proposed method. The use of the neologism dictionary increased the min-z-score as well as the precision, indicating that it had no negative effect.

To intuitively assess the coverage of the proposed method, we manually counted the number of bursty phrases that were extracted with the proposed method (when $K = 10$, i.e., 139 correct phrases) but completely missed with the comparative methods. Here, we regarded *completely missed* when neither of the bursty phrase, overlapping N-grams including incomplete ones nor orthographic variants were extracted in top

Table 5: Number of bursty phrases extracted with the proposed method ($K = 10$) but completely missed with comparative methods.

Word	Word+Dic	NP	NP+Dic	Segment
17/139	7/139	10/139	4/139	8/139

Table 6: Average precision of top K bursty phrases with different parameter settings in the proposed method (strict case).

Parameters	Top10	Top20	Top30	Top40	Top50
θ=5, ϵ=0.2	0.993	0.993	0.976	0.977	0.971
θ=5, ϵ=0.5	0.993	0.993	0.976	0.977	0.971
θ=5, ϵ=1.0	0.993	0.993	0.976	0.979	0.971

θ=15, ϵ=1.0	0.993	0.989	0.971	0.971	0.966

100 bursty N-grams. Table 5 shows the results. Although the percentages were small, any comparative method completely missed some highly bursty phrases that were extracted with the proposed method. Note that the proposed method did not completely miss top 10 bursty phrases of comparative methods at all since the set cover problem inevitably covered all bursty N-grams.

4.4 Influence of Parameter Settings

We changed threshold parameters θ and ϵ to evaluate their influence on performance. Tables 6, 7 show the performance results with different parameter settings. We confirmed that both parameters, especially ϵ, hardly affected the precision and min-z-score. The results indicate that the threshold parameters can be roughly set based on data.

4.5 Examples

Table 7: Average min-z-score of top K bursty phrases with different parameter settings in the proposed method.

Parameters	Top10	Top20	Top30	Top40	Top50
θ=5, ϵ=0.2	50.6	33.4	24.9	21.4	19.2
θ=5, ϵ=0.5	50.6	33.4	24.8	21.4	19.2
θ=5, ϵ=1.0	50.6	33.4	24.9	21.4	19.3
θ=10, ϵ=0.2	50.1	33.5	24.8	21.5	19.4
θ=10, ϵ=0.5	50.1	33.5	24.8	21.5	19.4
θ=10, ϵ=1.0	50.2	33.5	24.9	21.5	19.5
θ=15, ϵ=0.2	50.2	33.5	25.1	21.8	19.4

θ=15, ϵ=1.0	50.2	33.5	25.1	21.8	19.6

Table 8: Example of top 10 bursty phrases in Japanese (Oct. 1, 2016).

1.	三代目 (*Sandaime*, generally meaning "third", short name of a music group)
2.	坂口杏里 (*Sakaguchi Anri*, celebrity)
3.	**HE ★ VENS** (idol group)
4.	プリライ (*Pri-rai*, short name of a live concert)
5.	映っちゃった (*Utsucchatta*, generally meaning "it was reflected", short name of a TV program)
6.	単独 (*Tandoku*, generally meaning "singleness", implying a live concert without supporting acts)
7.	しやがれ (*Shiyagare*, generally a phrase used in an imperative sentence, short name of a TV program)
8.	うたプリ (*Utapri*, short name of an anime)
9.	**WORKING** (short name of an anime)
10.	うたぷり (*Utapri*, short name of an anime)

Table 8 shows top 10 bursty phrases (all of them are correct) on Oct. 1. This day contained many irregularly-formed phrases; phrases containing hiragana[7] characters (rank 5, 7, 8, 10), other than noun phrases (rank 5, 7), and containing symbols (rank 3). Especially, 映っちゃった (rank 5) and しやがれ (rank 7) were troublesome since they contain hiragana characters and at the same time they are other than noun phrases. Even with the neologism dictionary, the noun phrase-based method extracted しやがれ but missed 映っちゃった.

To demonstrate the language-independent nature of the proposed method, we also applied it to English with character-level processing[8]. Table 9 shows an example of bursty phrases extracted from English tweets. Whereas an incomplete phrase (rank 2) was extracted due to auto-generated contents that could not be eliminated from data, other top bursty phrases were correctly extracted. The proposed method also extracted a very long Internet meme (rank 5), which burst along with its counterpart "anyone that knows me knows i love _________." (rank 17).

5 Conclusions

We proposed a language-independent data-driven method to accurately and exhaustively extract bursty phrases of arbitrary forms from microblogs. We found that bursty incomplete N-grams always

[7] In Japanese, hiragana is mainly used for auxiliary words and thus difficult to break into words or phrases.

[8] Of course, we can process English in word level.

Table 9: Example of top 10 bursty phrases in English (Oct. 1, 2016, PST). Note that these bursty phrases were generated by processing English tweets in character level.

1.	**LizQuen InSydney Oct30** (maybe an auto-generated phrase used like a tag)
2.	**for The 100 most beautiful faces in 2016** (maybe an auto-generated sequence used to vote a celebrity for the ranking)
3.	**Lamar Jackson** (American football player)
4.	**Clemson** (American football team)
5.	**quote with what you think the answer is and copy this tweet to see what people say about you** (Internet meme)
6.	**Tennessee** (American football team)
7.	**Louisville** (American football team)
8.	**Milner** (American football player)
9.	**FSU** (American football team)
10.	**Louis Walsh** (talent manager)

accompany overlapping bursty phrases by ascertaining the mechanism why incomplete N-grams burst. Based on the findings, the proposed method solves the extraction of bursty phrases as the set cover problem where a minimum set of bursty phrases covers all bursty N-grams including incomplete ones. We confirmed from experimental results that the proposed method outperformed noun phrase-based and segmentation-based methods both in terms of the accuracy and coverage. The source code of the proposed method is publicly available[9].

The future work includes the reduction or estimation of the computation time and memory usage. They increase as the target document set grows or, specifically the number of occurrences of bursty N-grams increases. Also, handling auto-generated contents is an important issue. The proposed method should be used with effective methods of identifying auto-generated contents, bots, and spammers in microblogs.

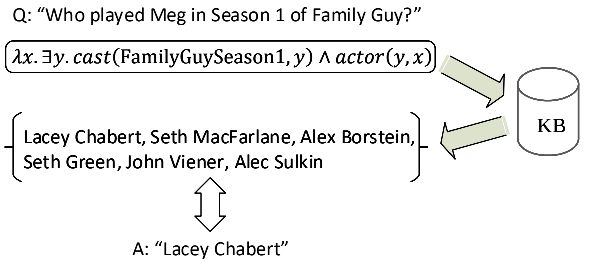
Abstract

Neural networks have achieved state-of-the-art performance on several structured-output prediction tasks, trained in a fully supervised fashion. However, annotated examples in structured domains are often costly to obtain, which thus limits the applications of neural networks. In this work, we propose Maximum Margin Reward Networks, a neural network-based framework that aims to learn from both explicit (full structures) and implicit supervision signals (delayed feedback on the correctness of the predicted structure). On named entity recognition and semantic parsing, our model outperforms previous systems on the benchmark datasets, CoNLL-2003 and WebQuestionsSP.

1 Introduction

Structured-output prediction problems, where the goal is to determine values of a set of interdependent variables, are ubiquitous in NLP. Structures of such problems can range from simple sequences like part-of-speech tagging (Ling et al., 2015) and named entity recognition (Lample et al., 2016), to complex syntactic or semantic analysis such as dependency parsing (Dyer et al., 2015) and semantic parsing (Dong and Lapata, 2016). State-of-the-art methods of these tasks are often neural network models trained using fully annotated structures, which can be costly or time-consuming to obtain. Weakly supervised learning settings, where the algorithm assumes only the existence of *implicit* signals on whether a prediction is correct, are thus more appealing in many scenarios.

For example, Figure 1 shows a weakly supervised setting of learning semantic parsers using only question–answer pairs. When the system generates a candidate semantic parse during training, the quality needs to be indirectly measured by comparing the derived answers from the knowledge base and the provided labeled answers.



Q: "Who played Meg in Season 1 of Family Guy?"
$\lambda x.\exists y.\,cast(\text{FamilyGuySeason1}, y) \wedge actor(y, x)$

Figure 1: Learning a semantic parser using *implicit* supervision signals (labeled answers). Since there are no gold parses, a model needs to explore different parses, where their quality can only be indirectly verified by comparing retrieved answers and the labeled answers.

This setting of implicit supervision increases the difficulty of learning a neural model, not only because the signals are vague and noisy, but also *delayed*. For instance, among different semantic parses that result in the same answers, typically only few of them correctly represent the meaning of the question. Moreover, the correctness of answers corresponding to a parse can only be evaluated through an external oracle (e.g., executing the query on the knowledge base) *after* the parse is fully constructed. Early model update before the search of a full semantic parse is complete is generally infeasible.[1] It is also not clear how to leverage implicit and explicit signals integrally during learning when both kinds of labels are present.

In this work, we propose Maximum Margin Reward Networks (MMRN), which is a general neural network-based framework that is able to learn from both implicit and explicit supervision signals. By casting structured-output learning as a search problem, the key insight in MMRN is the

[1] Existing weakly supervised methods (Clarke et al., 2010; Artzi and Zettlemoyer, 2013) often leverage domain-specific heuristics, which are not always available.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2368–2378

special mechanism of *rewards*. Rewards can be viewed as the training signals that drive the model to explore the search space and to find the correct structure. The explicit supervision signals can be viewed as a source of *immediate* rewards, as we can often instantly know the correctness of the current action. On the other hand, the implicit supervision can be viewed as a source of *delayed* rewards, where the reward of the actions can only be revealed later. We unify these two types of reward signals by using a maximum margin update, inspired by structured SVM (Joachims et al., 2009).

The effectiveness of `MMRN` is demonstrated on three NLP tasks: *named entity recognition*, *entity linking* and *semantic parsing*. `MMRN` outperforms the current best results on CoNLL-2003 named entity recognition dataset (Tjong Kim Sang and De Meulder, 2003), reaching 91.4% F_1, in the close setting where no gazetteer is allowed. It also performs comparably to the existing state-of-the-art systems on entity linking. Models for these two tasks are trained using explicit supervision. For semantic parsing, where only implicit supervision signals are provided, `MMRN` is able to learn from delayed rewards, improving the entity linking component and the overall semantic parsing framework jointly, and outperforms the best published system by 1.4% absolute on the WebQSP dataset (Yih et al., 2016).

In the rest of the paper, we survey the most related work in Sec. 2 and give an in-depth discussion on comparing `MMRN` and other learning frameworks in Sec. 7. We start the description of our method from the search formulation and the state–action spaces in our targeted tasks in Sec. 3, followed by the reward and learning algorithm in Sec. 4 and the detailed neural model design in Sec. 5. Sec. 6 reports the experimental results and Sec. 8 concludes the paper.

2 Related Work

Structured output prediction tasks have been studied extensively in the field of natural language processing (NLP). Many supervised structured learning algorithms has been proposed for capturing the relationships between output variables. These models include structured perceptron (Collins, 2002; Collins and Roark, 2004), conditional random fields (Lafferty et al., 2001), and structured SVM (Taskar et al., 2004; Joachims et al., 2009). Later, the *learning to search* framework is proposed (Daumé and Marcu, 2005; Daumé et al., 2009), which casts the structured prediction task as a general search problem. Most recently, recurrent neural networks such as LSTM models (Hochreiter and Schmidhuber, 1997) have been used as a general tool for structured output models (Vinyals et al., 2015).

Latent structured learning algorithms address the problem of learning from incomplete labeled data (Yu and Joachims, 2009; Quattoni et al., 2007). The main difference compared to our framework is the existence of the external environment when learning from implicit signals.

Upadhyay et al. (2016) first proposed the idea of learning from implicit supervision, and is the most related paper to our work. Compared to their linear algorithm, our framework is more principled and general as we integrate the concept of margin in our method. Furthermore, we also extend the framework using neural models.

3 Search-based Inference

In our framework, predicting the best structured output, *inference*, is formulated as a state/action search problem. Our search space can be described as follows. The initial state, s_0, is the starting point of the search process. We define $\gamma(s)$ as the set of all feasible actions that can be taken at s, and denote $s' = \tau(s,a)$ as the transition function, where s' is the new state after taking action a from s. A path $\mathbf{h}$ is a sequence of state–action pairs, starting with the initial state: $\mathbf{h} = \{(s_0, a_0), \ldots, (s_k, a_k)\}$, where $s_i = \tau(s_{i-1}, a_{i-1}), \forall i = 1, \ldots, k$. We denote $\mathbf{h} \rightsquigarrow \hat{s}$, if $\hat{s} = \tau(s_k, a_k)$, the final state which the path $\mathbf{h}$ leads to. A path essentially is a partial or complete structured prediction. For each input x, we define $\mathcal{H}(x)$ to be the set of all possible paths for the input. We also define $\mathcal{E}(x) = \{\mathbf{h} \mid \mathbf{h} \in \mathcal{H}(x), \mathbf{h} \rightsquigarrow \hat{s}, \gamma(\hat{s}) = \emptyset\}$, which is all possible paths that lead to terminal states.

Given a state s and an action a, the scoring function $f_\theta(s,a)$ measures the quality of an immediate action with respect to the current state, where θ is the model parameters. The score of a path $\mathbf{h}$ is defined as the sum of the scores for state-action pairs in $\mathbf{h}$: $f_\theta(\mathbf{h}) = \sum_{i=0}^{k} f_\theta(s_i, a_i)$. During test time, inference is to find the *best* path in $\mathcal{E}(x)$: $\arg\max_{\mathbf{h}\in\mathcal{E}(x)} f_\theta(\mathbf{h}; x)$. In practice, inference is often approximated by beam search when no efficient algorithm exists.

In the remaining of this section, we describe the states and actions in the targeted tasks in this work: *named entity recognition*, *entity linking* and *semantic parsing*. The the model and learning algorithm will be discussed in Sec. 4 and Sec. 5.

3.1 Named entity recognition

The task of named entity recognition (NER) is to identify entity mentions in a sentence, as well as to assign their types, such as Person or Location. Following the conventional setting, we treat it as a sequence labeling problem using the standard BIOES encoding. For instance, a "B-LOC" tag on a word means that the word is the beginning of a multi-word location entity.

Given a sentence as input, the states represent the tags assigned to the words. Starting from the initial state, s_0, where no tag has been assigned, the search process explores the sequence tagging from the left-to-right order. For each word, the actions are the legitimate tags that can be assigned to it, which depend on previous actions. For example, if the "S-PER" tag ("S" means a single word entity) has been assigned to the previous word, then an action of labeling the current word with either "I-PER" or "E-PER" cannot can be taken. The search reaches a terminal state when all words in the sentence have been tagged.

3.2 Entity linking

The problem of entity linking (EL) is similar to NER, but instead of tagging the mention using a small set of generic entity types, the goal here is to ground the mention to a specific entity, stored in a knowledge base or described by a Wikipedia page. For example, consider the sentence "*nfl news: draft results for giants*" and assume that the mention candidates "*nfl*" and "*giants*" are given. A state reflects how we have assigned the entity labels to these candidates. Following the same left-to-right order and starting from the empty assignment s_0, the first action to take is to assign the entity label to the first candidate "*nfl*". A legitimate action set can be all the entities that have been associated with this mention in the training set (e.g., "*National Football League*" or "*National Fertilizers Limited*"). Once the action is completed, the transition function will bring the focus to the next mention candidate (i.e., "*giants*"). The search reaches a terminal state when all the candidate mentions in the sentence have been linked.

$$\lambda x.\exists y.\, cast(\text{FamilyGuySeason1}, y) \wedge actor(y, x) \wedge character(y, \text{MegGriffin})$$

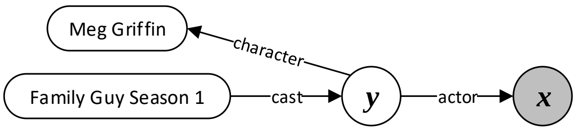

Figure 2: Semantic parses in λ-calculus (top) and query graph (bottom) of the question "*who played meg in season 1 of family guy?*"

3.3 Semantic parsing

Our third targeted task is semantic parsing (SP), which is a task of mapping a text utterance to a formal meaning representation. In this paper, we focus on a specific type of semantic parsing problem that maps a natural language question to a structured query, which is executed on a knowledge base to retrieve the answer to the original question.

Figure 2 shows the semantic parses of an example question "*who played meg in season 1 of family guy*", assuming the knowledge base is Freebase (Bollacker et al., 2008). An entity linking component plays an important role by mapping "*meg*" to `MegGriffin` and "*season 1 of family guy*" to `FamilyGuySeason1`. Predicates like `cast`, `actor` and `character` are also from the knowledge base that define the relationships between these entities and the answer. Together the semantic parse in λ-calculus is shown in the top of Figure 2. Equivalently, the semantic parse can be represented as a *query graph* (Figure 2 bottom), which is used in the STAGG system (Yih et al., 2015). The nodes are either grounded entities or variables, where x is the answer entity. The edges denote the relationship between two entities.

Regardless of the choice of the formal language, the process of constructing the semantic parse is typically formulated as a search problem. A state is essentially a partial or complete semantic parse, and an action is to extend the current semantic parse by adding a new relation or constraint.

Different from previous systems which treat entity linking as a static component, our search space consists of the search space of ***both*** entity linking and semantic parsing. That is, the search space is the union of the search space of entity linking described in Section 3.2 and the search space of the semantic parses, which we describe below. Integrating search spaces allows the model to use implicit signals to update both the semantic parsing and the entity linking systems. To the best of our knowledge, this is the first work that jointly learns the entity linking and semantic parsing systems.

Our search space is defined as follows. Starting from the initial state s_0, the model first explores the entity linking search space. Once the entity linking assignment are assigned (e.g. `FamilyGuySeason1` in Figure 2.) The second phase is then to determine the main relationship between the topic entity and the answer (e.g., the `cast-actor` chain between `FamilyGuySeason1` and x). Constraints (e.g., the `character` is `MegGriffin`) that describe the additional properties that the answer needs to have are added last. In this case, any state that is a legitimate semantic parse (consisting of one topic entity and one main relationship, as well as zero or more constraints) can lead to a terminal state.

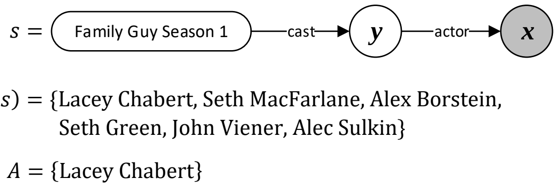
4 Maximum Margin Reward Networks

In this section, we introduce the learning framework of `MMRN`, which includes two main components: *reward* and *max-margin loss*. The former is a mechanism for using implicit and explicit supervision signals in a unified way; the latter formally defines the learning objective.

4.1 Reward

The key insight of `MMRN` is that different types of supervision signals can be represented using the appropriate design of the reward function. A reward function is defined over a state–action pair $R(s, a)$, representing the *true* quality of taking action a in the state s. The reward for a path can be formally defined as: $R(\mathbf{h}) = \sum_{i=0}^{k} R(s_i, a_i)$. Intuitively, when the annotated action sequences (explicit supervision signals) exist, the model only needs to learn to imitate the annotated sequence. For instance, when learning NER in the fully supervised setting, the equivalent way of using Hamming distance is to define the reward $R(s, a)$ to be 1 if a matches the annotated sequence at the current state, and 0 otherwise.

In the setting where only implicit supervision is available, the reward function can still be designed to capture the signals. For instance, when only the question–answer pairs exist for learning the semantic parser, the reward can be defined by comparing the answers derived from a candidate parse and the labeled answers. More formally, assume that $s = \tau(s', a)$ is the state after applying action a to state s'. Let $Y(s)$ be the set of predicted answers generated from state s, and $Y(s) = \{\}$ when s is not a legitimate semantic parse. The reward function $R(s', a)$ can be defined by comparing $Y(s)$ and the labeled answers, A, to the input question. While a set similarity function like the Jaccard coefficient can be used as the reward function, we chose the F_1 score in this work as it was used as the evaluation metric in previous work (Berant et al., 2013). Figure 3 shows an example of this reward function.



s =
Family Guy Season 1
cast
y
actor
x
Y(s) = {Lacey Chabert, Seth MacFarlane, Alex Borstein, Seth Green, John Viener, Alec Sulkin}
A = {Lacey Chabert}

Figure 3: For the question "*who played meg in season 1 of family guy?*", the candidate semantic parse s lists all the actors in "Family Guy Season 1" ($Y(s)$). By comparing $Y(s)$ to the answer set A, the precision is $\frac{1}{6}$ and the recall is 1. Therefore, the F_1 score used for the reward is $\frac{2}{7}$.

4.2 Max-Margin Loss & Learning Algorithm

The `MMRN` learning algorithm can be viewed as an extension of M^{3}N (Taskar et al., 2004) and Structured SVM (Joachims et al., 2009; Yu and Joachims, 2009). The learning algorithm takes three steps, where the first two involve two different search procedures. The final step is to update the models with respect to the inference results.

Finding the best path The first search step is to find the *best* path $\mathbf{h}^*$ by solving the following optimization problem:

$$\mathbf{h}^* = \arg\max_{\mathbf{h} \in \mathcal{E}(x)} R(\mathbf{h}; y) + \epsilon f_\theta(\mathbf{h}). \qquad (1)$$

The first term defines the path that has the highest reward. Because it is possible that several paths share the same reward, the second term leverages the current model and serves as the tie-breaker, where ϵ is a hyper-parameter that is set to a small positive number in our experiments.

When explicit supervision is available, solving Eq. (1) is trivial – the search simply returns the annotated sequence. In the case of implicit supervision, where true rewards are only revealed for complete action sequences, the search problem becomes difficult as the rewards of early state–action pairs are zeros. In this situation, the search algorithm uses the model score f_θ to guide the search. One possible design is to use beam search for the optimization problem, where the search procedure follows the current model in the early stage (given that $R(\mathbf{h}) = 0$). After generating several complete action sequences, the true reward function is then used to find $\mathbf{h}^*$. The tie-breaker also picks the best sequence when there are multiple sequences that lead to the same reward. Note that $\mathbf{h}^*$ can change between iterations because of the tie-breaker.

Finding the most violated path Once $\mathbf{h}^*$ is found, it is used as our reference path. We would like to update the model so that the scoring function f_θ will behave similarly to the reward R. More formally, we aim to update the model parameters θ to satisfy the following constraint.

$$f_\theta(\mathbf{h}^*) - f_\theta(\mathbf{h}) \geq R(\mathbf{h}^*) - R(\mathbf{h}), \forall \mathbf{h}.$$

The constraint implies that the "best" action sequence should rank higher than any other sequence by a margin computed from rewards as $R(\mathbf{h}^*) - R(\mathbf{h})$. The degree of violation of this constraint, with respect to $\mathbf{h}$, is thus $(R(\mathbf{h}^*) - R(\mathbf{h})) - (f_\theta(\mathbf{h}^*) - f_\theta(\mathbf{h})) = f_\theta(\mathbf{h}) - R(\mathbf{h}) - f_\theta(\mathbf{h}^*) + R(\mathbf{h}^*)$. The max-margin loss is defined accordingly:

$$\mathcal{L}(\mathbf{h}, \mathbf{h}^*) = \max(f_\theta(\mathbf{h}) - R(\mathbf{h}) - f_\theta(\mathbf{h}^*) + R(\mathbf{h}^*), 0)$$

$\mathcal{L}(\mathbf{h}, \mathbf{h}^*)$ is our optimization goal, where we want to update the model by fixing the biggest violation. Note that the associated constraint is only violated when $\mathcal{L}(\mathbf{h}, \mathbf{h}^*)$ is positive. To find the path $\mathbf{h}$ in this step that maximizes the violation is equivalent to maximizing $f_\theta(\mathbf{h}) - R(\mathbf{h})$, given that the rest of the terms are constant with respect to $\mathbf{h}$.

When there exist only explicit supervision signals, our objective function reduces to the one for optimizing structured SVM without regularization. For implicit signals, we find $\mathbf{h}^*$ approximately before we optimize the margin loss. In this case, the search is not exact as the reward signals are delayed. Nevertheless, we found the margin loss worked well empirically, as it kept decreasing in general until being stable.

Algorithm 1 summarizes the learning procedure of MMRN. Search is used in both Line 2 and 3. In Line 4, the algorithm performs a gradient update to modify all the model parameters.

Algorithm 1 Maximum Margin Reward Networks

```
1: for a random labeled data $(x, y)$ do
2:     $\mathbf{h}^* \leftarrow \arg\max_{\mathbf{h} \in \mathcal{E}(x)} R(\mathbf{h}; y) + \epsilon f_\theta(\mathbf{h})$
3:     $\hat{\mathbf{h}} \leftarrow \arg\max_{\mathbf{h} \in \mathcal{E}(x)} f_\theta(\mathbf{h}) - R(\mathbf{h}; y)$
4:     update $\theta$ by minimizing $\mathcal{L}(\hat{\mathbf{h}}, \mathbf{h}^*)$
5: end for
```

4.3 Practical Considerations

Although the learning algorithm of MMRN is simple and general, the quality of the learned model is dictated by the effectiveness of the search procedure. Increasing the beam size generally helps improve the model, but also slows down the training, and has a limited effect when dealing with a large search space. Domain-specific heuristics for pruning search space should thus be used when available. For instance, in the task of semantic parsing, when the reward of a legitimate semantic parse is 0, it implies that none of the derived answers is included in the labeled set of answers. When all the possible follow-up actions can only make the semantic parse stricter (e.g., adding constraints), and result in a subset of the current derived answers, it is clear that the rewards of all these new states are 0 as well. Paths from this state can thus be pruned.

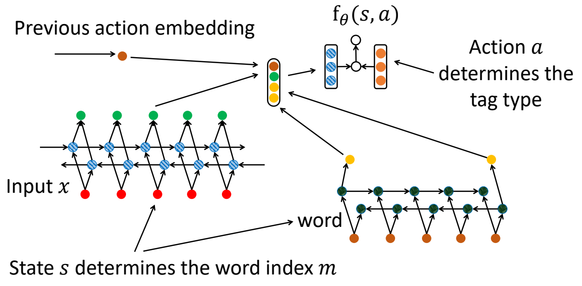
Another strategy for improving search quality is to use *approximated* reward in the early stage of search. Very often the true rewards at this stage are 0, and are not useful to guide the search to find the best path. The approximated reward function can be thought of as estimating whether there exists a high-reward state that is reachable from the current state. The effectiveness of this strategy has been demonstrated successfully by several recent efforts (Mnih et al., 2013; Krishnamurthy et al., 2015; Silver et al., 2016; Narasimhan et al., 2016).

5 Neural Architectures

While the learning algorithm of MMRN described in Sec. 4 is general, the exact model design is task-dependent. In this section, we describe in detail the neural network architectures of the three targeted tasks, *named entity recognition*, *entity linking* and *semantic parsing*.

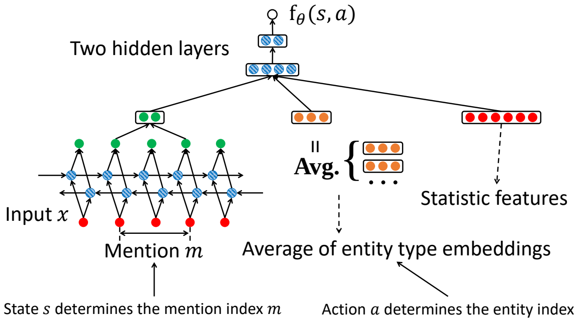
5.1 Named Entity Recognition

Recall that NER is formulated as a sequence labeling problem, and each action is to label a word with a tag using the BIOES encoding (cf. Sec. 3.1).



Previous action embedding
$f_\theta(s,a)$
Action a determines the tag type
Input x
word
State s determines the word index m

Figure 4: The action scoring model for NER.



$f_\theta(s,a)$
Two hidden layers

Avg.
Statistic features
Input x
Mention m
Average of entity type embeddings
State s determines the mention index m
Action a determines the entity index

Figure 5: The action scoring model for EL.

The model of the action scoring function $f_\theta(s,a)$ is depicted in Figure 4, which is basically the dot product of the *action embedding* and *state embedding*. The action embedding is initialized randomly for each action, but can be fine-tuned during training (i.e. back-propagate the error through the network and update the word/entity type embeddings). The state embedding is the concatenation of bi-LSTM word embeddings of the current word, the character-based word embeddings, and the embedding of the previous action. We also include the orthographic embeddings proposed by Limsopatham and Collier (2016).

5.2 Entity Linking

An action in entity linking is to determine whether a mention should be linked to a particular entity (cf. Sec. 3.2). As shown in Figure 5, we design the scoring function as a feed-forward neural network that takes as input three different input vectors: (1) surface features from hand-crafted mention-entity statistics that are similar to the ones used in (Yang and Chang, 2015); (2) mention context embeddings from a bidirectional LSTM module; (3) entity embeddings constructed from entity type embeddings. All these embeddings, except the feature vectors, are fine-tuned during training.

Some unique properties of our entity linking model are worth noticing. First, we add mention context embeddings from a bidirectional LSTM module as additional input. While using LSTMs is a common practice for sequence labeling, it is not usually used for short-text entity linking. For each mention, we only extract the output from the bi-LSTM module at the start and end tokens of the mention, and concatenate them as the mention context embeddings. Second, we construct entity embeddings using the average of its Freebase (Bollacker et al., 2008) type embeddings[2], initialized using pre-trained embeddings. Adding these two types of embeddings has shown to improve the performance in our experiments.

5.3 Semantic Parsing

Our semantic parsing model follows the STAGG system (Yih et al., 2015), which uses a stagewise search procedure to expand the candidate semantic parses gradually (cf. Sec. 3.3). Compared to the original system, we make two notable changes. First, we use a two-layer feed-forward neural network to replace the original linear ranker that scores the candidate semantic parses. Second, instead of using a separately trained entity linking system, we incorporate our entity linking networks described in Sec. 5.2 as part of the semantic parsing model. The training process will thus fine tune the entity linking component to improve the semantic parsing system.

6 Experiments

It is important to have a general machine learning model working for both implicit and explicit supervision signals. We valid our learning framework when the explicit supervision signals are presented, as well as demonstrate the support of the scenario where supervision signals are mixed.

Specifically, in this section, we report the experimental results of `MMRN` on named entity recognition and entity linking, both using explicit supervision, and on semantic parsing, using implicit supervision. In all our experiments, we tuned hyperparameters on the development set (each task respectively), and then re-trained the models on the combination of the training and development set.

6.1 Named entity recognition

We use the CoNLL-2003 shared task data for the NER experiments, where the standard evaluation

[2] We use only the 358 most frequent Freebase entity types.

System	F_1
Collobert et al. (2011)	89.59
Huang et al. (2015)	90.10
Chiu and Nichols (2015)	90.77
Ratinov and Roth (2009)	90.88
Lample et al. (2016)	90.94
Ma and Hovy (2016)	91.21
MMRN-NER Beam = 5	90.03
MMRN-NER Beam = 20	**91.39**

Table 1: **Explicit Supervision: Named Entity Recognition**. Our MMRN with beam size 20 outperforms current best systems, which are based on neural networks.

	NEEL-Test	TACL
	F_1	F_1
S-MART	77.7	63.6
NTEL	77.9	**68.1**
MMRN-EL	**78.5**	67.5
MMRN-EL - Entity	77.4	66.5
MMRN-EL - LSTM	76.6	66.0

Table 2: **Explicit Supervision: Entity Linking.** Our system trained with MMRN is comparable to the state-of-art NTEL system.

metric is the F_1 score. The pre-trained word embeddings are 100-dimension GloVe vectors trained on 6 billion tokens (Pennington et al., 2014)[3]. The search procedure is conducted using beam search, and the reward function is simply the number of correct tag assignments to the words.

The results are shown in Table 1, compared with recently proposed systems based on neural models. When the beam size is set to 20, MMRN achieves 91.4, which is the best published result so far (without using any gazetteers). Notice that when beam size is 5, the performance drops to 90.03. This demonstrates the importance of search quality when applying MMRN.

6.2 Entity linking

For entity linking, we adopt two publicly available datasets for tweet entity linking: NEEL (Cano et al., 2014)[4] and TACL (Guo et al., 2013; Fang and Chang, 2014; Yang and Chang, 2015; Yang et al., 2016). We follow prior works (Guo et al., 2013; Yang and Chang, 2015) and perform the standard evaluation for an end-to-end entity linking system by computing precision, recall, and F_1 scores, according to the entity references and the system output. An output entity is considered correct if it matches the gold entity and the mention boundary overlaps with the gold mention boundary. Interested readers can refer to (Carmel et al., 2014) for more detail.

We initialize the word embeddings from pre-trained GloVe vectors trained on the twitter corpus, and type embeddings from the pre-trained skip-gram model (Mikolov et al., 2013)[5]. Sizes of both word embeddings are set to 200. Inference is done using a dynamic programming algorithm.

Results of entity linking experiments are presented in Table 2, which are compared with those of S-MART (Yang and Chang, 2015)[6] and NTEL (Yang et al., 2016)[7], two state-of-the-art entity linking systems for short texts. Our MMRN-EL is comparable to the best system. We also conducted two ablation studies by removing the entity type vectors (MMRN-EL - Entity), and by removing the LSTM vectors (MMRN-EL - LSTM). Both show significant performance drops, which validates the importance of these two additional input vectors.

6.3 Semantic parsing

For semantic parsing, we use the dataset WebQSP[8] (Yih et al., 2016) in our experiments. This dataset is a clean and enhanced version of the widely used WebQuestions dataset (Berant et al., 2013), which consists of pairs of questions and answers found in Freebase. Compared to WebQuestions, WebQSP excludes questions with ambiguous intent, and provides verified answers and full semantic parses to the remaining 4,737 questions.

We follow the implicit supervision setting in (Yih et al., 2016), using $3,098$ question–answer pairs for training, and $1,639$ for testing. A subset of 620 pairs from the training set is used for hyper-parameter tuning. Because there can be multiple answers to a question, the quality of a semantic parser is measured using the averaged F_1 score of the predicted answers.

[3] Available at http://nlp.stanford.edu/projects/glove/

[4] NEEL dataset was originally created for an entity linking competition: `http://microposts2016.seas.upenn.edu/challenge.html`

[5] Available at https://code.google.com/archive/p/word2vec/

[6] The winning system of the NEEL challenge.

[7] To have a fair comparison, we compare to the results of NTEL which do not use pretrained user embedding.

[8] Available at http://aka.ms/WebQSP

We experiment with two configurations of incorporating the entity linking component. MMRN-Pipeline trains an MMRN-EL model using the entity linking labels in WebQSP separately. Given a question, the entities in it are first predicted, and used as input to the semantic parsing system. In contrast, MMRN-Joint incorporates the MMRN-EL model in the whole framework. During this joint training process, 15 entity link results are sampled according to the current MMRN-EL model, and passed to the downstream networks. In both cases, we use the previous entity linking model trained on the NEEL dataset to initialize the parameters. As discussed in Sec. 4.1, in this implicit supervision setting, we directly set the (delayed) reward function to be the F_1 score, which can be obtained by comparing the annotated answers with predicted answers.

Table 3 summarizes the results of the MMRN-based semantic parsing systems and other strong baselines. The SP column reports the averaged F_1 scores. Compared to the pipeline approach (MMRN-Pipeline), the joint learning framework (MMRN-Joint) improves significantly, reaching 68.1% F_1. To compare different learning methods, we also apply REINFORCE (Williams, 1992), a popular policy gradient algorithm, to train our joint model using the same setting and reward function.[9] MMRN-Joint outperforms REINFORCE and its variant, REINFORECE+, which re-normalizes the probabilities of the sampled candidate sequences. Its result is also better than the state-of-the-art STAGG system. Note that we use the same architectures and initialization procedures for MMRN-Pipeline/Joint and REINFORCE/REINFORCE+. Therefore, the superior performance of MMRN-Joint shows that the joint learning plays a crucial role in addition to the choices of architecture. Comparing to STAGG, note that Yih et al. (2016) did not jointly train the entity linker and semantic parser together, but they did improve the results by taking the top 10 predictions of their entity linking system for re-ranking parses. Our algorithm further allows to update the entity linker with the labels for semantic parsing and shows superior performance.

Our joint model also improves the entity linking prediction on the questions in WebQSP using the implicit signals (the EL columns in Table 3). The F_1 score of MMRN-Joint on entity linking is 2.4 points higher than the baseline MMRN-Pipeline. Note that the entity linking results of MMRN-Pipeline (line 1) are exactly the results of the entity linking component MMRN-EL. The result is also better than REINFORCE, and comparable to REINFORCE+.

	SP	EL		
	Avg. F_1	P	R	F_1
MMRN-Pipeline	62.5	85.6	77.5	81.3
MMRN-Joint	**68.1**	89.3	78.9	**83.7**
REINFORCE	62.9	87.5	76.6	81.7
REINFORCE+	66.7	91.1	76.9	83.4
STAGG	66.8	–	–	–

Table 3: **Implicit Supervision: Semantic Parsing**. By updating the entity linking and semantic parsing models jointly, MMRN-Joint improves over MMRN-Pipeline by 5 points in F_1 and outperforms REINFORCE+ (SP). It also improves the entity linking result on the WebQSP questions (EL).

Recently Liang et al. (2016) proposed Neural Symbolic Machine (NSM) and reported the best result of 69.0 F1 score on the WebQSP dataset using the weak supervision settings.[10] The NSM architecture for semantic parsing is significantly different from the architecture used in (Yih et al., 2016) and the one used in this paper. In contrast, MMRN is a general learning framework that allows joint training on existing models (i.e. entity linking and semantic parsing modules). This allows MMRN to use the labels of semantic parsing task as implicit supervision signals for the entity linking module. It would be interesting to apply MMRN on the newly proposed architectures as well.

7 Discussion

We discuss several issues that are highly related to MMRN in this section.

Learning to Search There are two main differences between MMRN and search-based algorithms, such as SEARN (Daumé et al., 2009) and DAGGER (Ross et al., 2011). First, both SEARN and DAGGER focus on imitation learning, assuming explicit supervision signals exist. They use a two-step model learning approach:

[9] The REINFORCE algorithm uses warm initialization—the entity linking parameters are initialized using the model trained on the NEEL dataset.

[10] The paper is published after the submission of this paper.

(1) create cost-sensitive examples by listing state–action pairs and their corresponding (estimated) losses; (2) apply cost-aware training algorithms. In contrast, MMRN directly updates the parameters using back-propagation based on search results of each example. Second, SEARN mixes the optimal and current policies during learning, while MMRN performs search twice and simply pushes the current policy towards the optimal one. Recently, Chang et al. (2015) extend this line of work and discuss different roll-in and roll-out strategies during training for structured contextual bandit settings. As MMRN uses two search procedures, there is no need to mix different search policies.

Reinforcement Learning In many reinforcement learning scenarios, the search space is not fully controllable by the agent. For example, a chess playing agent cannot control the move made by its opponent, and has to commit a single move and wait for the opponent. Note that the agent can still think ahead and build a search tree, but only one move can be made in the end. In contrast, in scenarios like semantic parsing, the whole search space is controlled by the agent itself. Therefore, from the initial state, we can explore several search paths and get their real rewards. This may explain why MMRN can be more efficient than REINFORCE, as MMRN can use the reward signals of multiple paths more effectively. In addition, MMRN is not a probabilistic model, so it does not need to handle normalization issues, which often causes large variance in estimating the gradient direction when optimizing the expected reward.

Semantic Parsing MMRN can be applied for many semantic parsing tasks. One key step is to design the right approximated reward for a given task to guide the beam search to nd the reference parses in MMRN, given that the actual reward is often very sparse. In our companion paper, (Iyyer et al., 2017), we used a simple form of approximated reward to get feedback as early as possible during search. In other words, the semantic parse will be executed as soon as the parse is executable (even if the parse is still not completed) *during search*. The execution results will be used to calculate the Jaccard coefficient with respect to the labeled answers as the approximated rewards. The use of approximated reward has been proven to be effective in (Iyyer et al., 2017).

An important research direction for semantic parsing is to reduce the supervision cost. In (Yih et al., 2016), the authors demonstrated that labeling semantic parses is possible and often more effective with a sophisticated labeling interface. However, collecting answers may still be easier or faster for certain problems or annotators. This suggests that we could allow the annotators to choose to label semantic parses or answers in order to minimize the supervision cost. MMRN would be an ideal learning algorithm for this scenario.

8 Conclusion

This paper proposes Maximum Margin Reward Networks, a structured learning framework that can learn from both explicit and implicit supervision signals. In the future, we plan to apply Maximum Margin Reward Networks on other structured learning tasks. Improving MMRN for dealing with large search space is an important future direction as well.

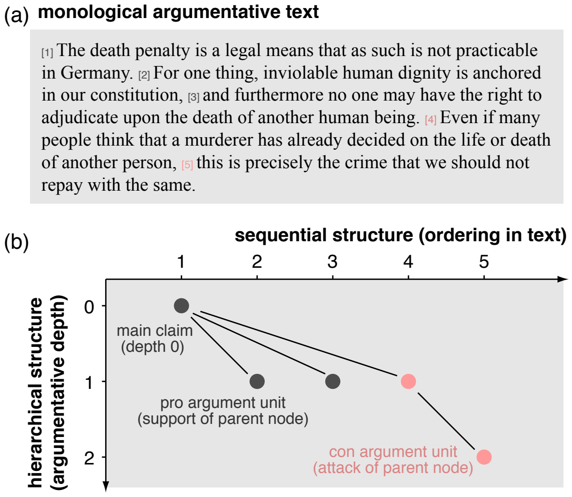
Abstract

Several approaches have been proposed to model either the explicit sequential structure of an argumentative text or its implicit hierarchical structure. So far, the adequacy of these models of overall argumentation remains unclear. This paper asks what type of structure is actually important to tackle downstream tasks in computational argumentation. We analyze patterns in the overall argumentation of texts from three corpora. Then, we adapt the idea of positional tree kernels in order to capture sequential and hierarchical argumentative structure together for the first time. In systematic experiments for three text classification tasks, we find strong evidence for the impact of both types of structure. Our results suggest that either of them is necessary while their combination may be beneficial.

1 Introduction

Argumentation theory has established a number of major argument models focusing on different aspects, such as the roles of an argument's units (Toulmin, 1958), the inference scheme of an argument (Walton et al., 2008), or the support and attack relations between arguments (Freeman, 2011). The common ground of these models is that they conceptualize an argument as a conclusion (in terms of a claim) inferred from a set of pro and con premises (reasons), which in turn may be the conclusions of other arguments. For the overall argumentation of a monological argumentative text such as the one in Figure 1(a), this results in an implicit hierarchical structure with the text's main claim at the lowest depth. In addition, the text has an explicit linguistic structure that can be seen as a regulated sequence of speech acts (van Eemeren and Grootendorst, 2004).



(a) **monological argumentative text**

[1] The death penalty is a legal means that as such is not practicable in Germany. [2] For one thing, inviolable human dignity is anchored in our constitution, [3] and furthermore no one may have the right to adjudicate upon the death of another human being. [4] Even if many people think that a murderer has already decided on the life or death of another person, [5] this is precisely the crime that we should not repay with the same.

Figure 1(b) illustrates the interplay of the two types of overall structure in form of a tree-like graph.

Natural language processing research has largely adopted the outlined hierarchical models for mining arguments from text (Stab and Gurevych, 2014; Habernal and Gurevych, 2015; Peldszus and Stede, 2016). However, the adequacy of the resulting overall structure for downstream analysis tasks of computational argumentation has rarely been evaluated (see Section 2 for details). In fact, a computational approach that can capture patterns in hierarchical overall argumentation is missing so far. Even more, our previous work indicates that a sequential model of overall structure is preferable for analysis tasks such as stance classification or quality assessment (Wachsmuth and Stein, 2017).

In this paper, we ask and investigate what model of (monological) overall argumentation is important to tackle argumentation-related analysis tasks. To this end, we consider three corpora with fully

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2379–2389
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

annotated argument structure (Section 3). Each corpus allows studying one text classification task, two of which we hypothesize to benefit from modeling argumentation (myside bias, stance), the third not (genre). An empirical analysis of the corpora reveals class-specific patterns of how people argue (Section 4). In order to combine the explicit sequential and the implicit hierarchical structure of an argumentative text for the first time, we then adapt the approach of *route kernels* (Aiolli et al., 2009), modeling overall argumentation in form of a positional tree (Section 5).

On this basis, we design an experiment to evaluate the impact of the different types of argumentative structure (Section 6). In particular, we decompose our approach into four complementary modeling steps, both for a general model of overall argumentation and for the specific models of the given corpora. Using the structure annotated in the corpora, we systematically compare the effectiveness of all eight resulting models and two standard baselines in the three classification tasks.

Our results provide strong evidence that both sequential and hierarchical structure are important. As indicated by related work, sequential structure nearly competes with hierarchical structure, at least based on the specific argument models. Even more impressively, modeling hierarchical structure practically solves the task of identifying argumentation with myside bias, achieving an outstanding accuracy of 97.1%. For stance classification, the combination captured by positional trees works best. In contrast, all types of structure fail in distinguishing genres, suggesting that they indeed capture properties of argumentation. We conclude that the impact of modeling overall structure on downstream analysis tasks is high, while the required type may vary.

Contributions To summarize, the main contributions of this paper are the following:

1. Empirical insights into how people structure argumentative texts in overall terms.
2. The first approach to model and analyze the sequential and hierarchical overall structure of argumentative texts in combination.
3. Evidence that modeling overall structure impacts argumentation-related analysis tasks.

2 Related Work

The study of overall argumentation traces back to Aristotle (2007) who outlined the impact of the sequential arrangement of the different parts of a speech. Conceptually, theory agrees that a monological argumentative text has an implicit tree-like hierarchical structure: Toulmin (1958) defines an argument as a claim supported by data that is reasoned by a warrant, which in turn may have a backing. In addition, a rebuttal may be given showing exceptions to the claim. The role of support and attack relations is investigated by Freeman (2011) who models dialectical arguments that discuss both a proponent's and an opponent's view on the main claim argued for. Walton et al. (2008) put the focus on the inference scheme that describes how an argument's conclusion follows from its premises, which may themselves be conclusions of arguments.

In natural language processing, argumentation research deals with the mining of argument units and their relations from text (Mochales and Moens, 2011). Several corpora with annotated argument structure have been published in the last years. Many of the corpora adapt the hierarchical models from theory (Reed and Rowe, 2004; Habernal and Gurevych, 2015; Peldszus and Stede, 2016) or propose comparable models (Stab and Gurevych, 2014). Since we target monological overall argumentation, we use those that capture the complete structure of texts, as detailed in Section 3. Corpora focusing on dialogical argumentation (Walker et al., 2012), topic-related arguments (Rinott et al., 2015), or sequential structure (Wachsmuth et al., 2014b; Al Khatib et al., 2016) are out of scope.

We do not mine the structure of argumentative texts, but we exploit the previously mined structure to tackle downstream tasks of computational argumentation, namely, to classify the myside bias and stance of texts. For myside bias, Stab and Gurevych (2016) use features derived from discourse structure, whereas Faulkner (2014) and Sobhani et al. (2015) model arguments to classify stance. Ong et al. (2014) and we ourselves (Wachsmuth et al., 2016) do similar to assess the quality of persuasive essays, and Beigman Klebanov et al. (2016) examine how an essay's content and structure influence quality. Other works predict the outcome of legal cases based on the applied types of reasoning (Brüninghaus and Ashley, 2003) or analyze inference schemes for given arguments (Feng and Hirst, 2011). In contrast to the local structure of single arguments employed by all these approaches, we study the impact of the global overall structure of complete monological argumentative texts.

In (Wachsmuth et al., 2017), we point out that the argumentation quality of a text is affected by interactions of its content at different levels of granularity, from single argument units over arguments to overall argumentation. Stede (2016) explores how different depths of overall argumentation can be identified, observing differences across genres. Unlike in our experiments, however, the genres considered there reflect diverging types of argumentation. Related to argumentation, Feng et al. (2014) build upon rhetorical structure theory (Mann and Thompson, 1988) to assess the coherence of texts, while Persing et al. (2010) score the organization of persuasive essays based on sequences of sentence and paragraph functions.

We introduced the first explicit computational model of overall argumentation in (Wachsmuth et al., 2014a). There, we compared the flow of local sentiment in a review to a set of learned flow patterns in order to classify global sentiment. Recently, we generalized the model in order to make flows applicable to any type of information relevant for argumentation-related analysis tasks (Wachsmuth and Stein, 2017). However, flows capture only *sequential* structure, whereas here we also model the *hierarchical* structure of overall argumentation. To this end, we make use of kernel methods.

Kernel methods are a popular approach for learning on structured data, with several applications in natural language processing (Moschitti, 2006b) including argument mining (Rooney et al., 2012). They employ a similarity function defined between any two input objects that are represented in a task-specific implicit feature space. The evaluation of such a kernel function relies on the common features of the input objects (Cristianini and Shawe-Taylor, 2000). The kernel function encodes knowledge of the task in the form of these features.

Several kernel functions have been defined for structured data. To assess the impact of sequential argumentation, we refer to the function of Mooney and Bunescu (2006), which computes common subsequences of two input sequences. For trees, most existing approaches count common subtrees of a certain type (Collins and Duffy, 2001; Moschitti, 2006a; Kimura and Kashima, 2012), but they do not take the ordering of the nodes in the subtrees into account. In contrast, Aiolli et al. (2009) developed a kernel that combines the content of substructures with the relative positions inside trees, called the *route kernel*. Similarly, the tree kernel of Daumé III and Marcu (2004) includes positional information for document compression. For overall argumentation, we decided to use the route kernel in Section 5, as it makes the modeling of the sequential positions of an argument unit in a text straightforward. This allows us to capture both the sequential and the hierarchical structure at the same time. To our knowledge, no work has done this before.[1]

Neural networks denote an alternative for learning on structured data. They become particularly effective when few prior knowledge about what is important to address a task at hand is available, because they can learn any feature representation in principle (Goodfellow et al., 2016). Due to this flexibility, however, large amounts of data are required for training an effective model, making neural networks inadequate for the small datasets that allow studying overall argumentation.

3 Tasks and Datasets

We seek to study the impact of modeling overall argumentation on downstream tasks without the noise from argument mining errors. To this end, we rely on three ground-truth argument corpora. Each corpus is suitable for evaluating one text classification task and comes with a specific model of overall argumentation, as detailed in the following.

Myside Bias on AAE-v2 The *Argument Annotated Essays* corpus was originally been presented by Stab and Gurevych (2014). We use version 2 of the corpus (available on the website of the authors), which consists of 402 persuasive student essays. In each essay, all *main claims*, *claims*, and *premises* are annotated as such. Each claim has a *pro* or *con* stance towards each instance of the main claim, whereas each premise *supports* or *attacks* a claim or another premise. Thereby, argumentation is modeled as one tree structure for each major claim.

Stab and Gurevych (2016) added a *myside bias* class to each essay, reflecting whether its argumentation is one-sided considering only arguments for the own stance (251 cases) or not (151 cases).

Stance on Arg-Microtexts The *Arg-Microtexts* corpus of Peldszus and Stede (2016) contains 112 short argumentative texts. They cover 18 different controversial topics and are annotated according to Freeman (2011): Each argument unit takes the role of the *proponent* or *opponent* of a main claim. What

[1] While extensions of the route kernel idea have been published later on (Aiolli et al., 2011, 2015), we resort to the original version in this paper for simplicity.

	AAE-v2	Arg-Microtexts	Web Discourse
Argument units	6089	576	1149
Avg. units/text	15.1	5.1	3.4
Min. units/text	7	3	0
Max. units/text	28	10	16
Arguments	5687	443	560
Avg. depth	2.8	2.0	0.6
Min. depth	2	1	0
Max. depth	5	4	1
Texts	402	112	340

Table 1: Statistics of the argument units and arguments in the three corpora analyzed in this paper.

the main claim is follows from a tree-like overall structure emerging from four types of relations: *normal* or *example* support from one unit to another, a *rebuttal* of units by other units, and *undercutters* where a relation is attacked by another unit.

For 88 texts, the *stance* towards a specified topic is labeled as *pro* (46) or *con* (42). We use these labels for classification, but we do not access the topic. This way, stance needs to be identified only based on a text itself — a very challenging task.[2]

Genre on Web Discourse Finally, we consider the *Argument Annotated User-Generated Web Discourse* corpus of Habernal and Gurevych (2015). There, 340 texts are annotated according to a modified version of the specific model of Toulmin (1958) where *claims* are supported by *premises* or attacked by *rebuttals*. *Rebuttals* in turn may be attacked by *refutations*. Besides, emotional units not participating in the actual arguments are marked as *pathos*. The support and attack relations build up the overall argumentation of a text.

The corpus composes argumentative texts of four *genres*, namely, 5 *articles*, 216 *comments* to articles, 46 *blog posts*, and 73 *forum posts*. The genre is specified in form of a label for each text. Due to the low number, we ignore the articles below.

To give an idea of the sequential and hierarchical overall structure in each corpus, Table 1 presents statistics of the argument units, the arguments (in terms of relations between two or more units), and the depth of the resulting argumentation.

While the size of the given corpora and the variety of tasks are limited, the only other available corpus with fully annotated argument structure that we are aware of is *AraucariaDB* (Reed and Rowe, 2004). No downstream task can be tackled on AraucariaDB besides inference scheme classification (Feng and Hirst, 2011). As all schemes compose a conclusion and a set of premises (without more specific roles), analyzing overall structure hardly makes sense, which is why we omit the corpus.

4 Insights into Overall Argumentation

Before we approach overall argumentation computationally, this section analyzes the three given corpora empirically to provide insights into how people argue in overall terms. For this, we unify the specific corpus models of overall argumentation outlined above in one general model.

4.1 A Unified View of Overall Argumentation

The texts in all corpora are segmented into argument units, partly with non-argumentative spans in between that we ignore here for lack of relevance. To capture the sequential ordering of the segmentation, we assign a global index to each unit.

As described in Section 3, the specific models of all three corpora in the end consider an argument as a composition of one unit serving as the conclusion with one or more units that support or attack the conclusion (the premises). This composition is defined through multiple relations from one premise to one conclusion each. There is one exception, namely, the undercutter relations in the Arg-Microtexts corpus have a relation as their target. To obtain a unified form in the general model, we modify the undercutters such that they target the premise of the undercutted relation.

In all corpora, a premise may be the conclusion of another argument, while no argument unit serves as a premise in multiple arguments. This leads to a tree structure for each main claim of the associated text. A main claim corresponds to a unit that is not a premise. In AAE-v2 and in Web Discourse, more than one such unit may exist per text.

Depending on the corpus, the distinction of support and attack is encoded through a specified relation type, a unit's stance, or both. We unify these alternatives by modeling the stance of each unit towards its parent in the associated tree. This stance can be derived in all corpora.[3] All other unit and relation types from the specific models are ignored, since there is no clear mapping between them.

[2] We do not include the topic, in order not to conflate the impact of modeling argumentation with the influence of the topic. The corpus is too small to analyze topic differences.

[3] Alternatively, the stance towards the main claim could be modeled. We decided against this alternative to avoid possibly wrong reinterpretations, e.g., it is unclear whether a unit that attacks its parent always supports a unit attacked by the parent.

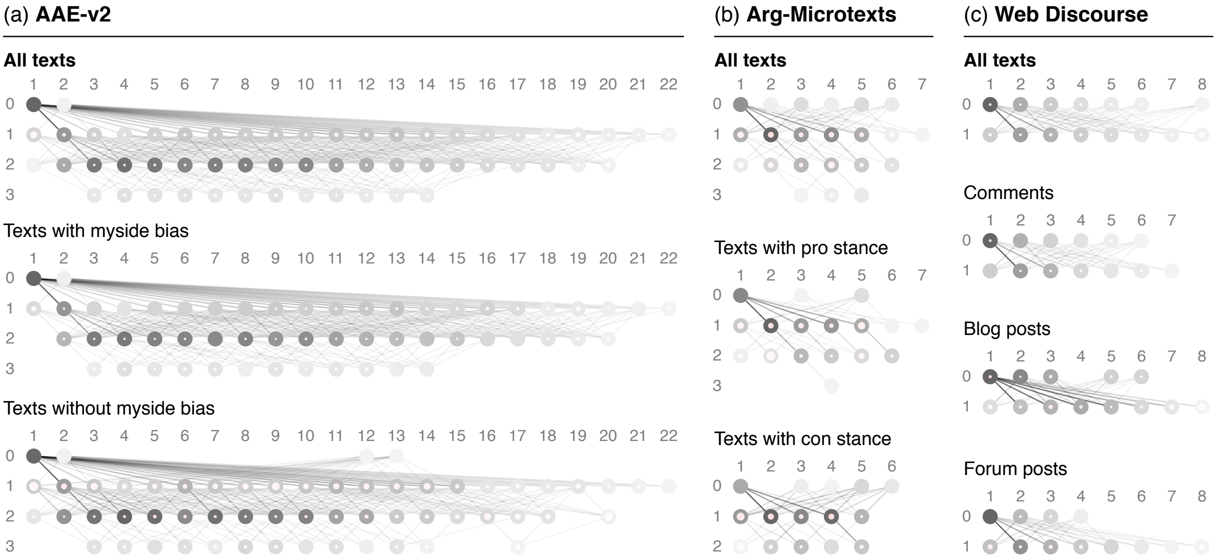

Figure 2: Visualization of the overall argumentation in the three considered corpora based on the introduced general model, averaged over all texts as well over all those texts that belong to a particular class. Left to right: Position in the text. Top to bottom: Depth in graph. Brightness: Inverse relative frequency of each position/depth combination in the corpus. Light red to gray: Proportion of argument units with con stance.

General Model As a result, we model the overall argumentation of an argumentative text as a forest of trees. Each node in a tree corresponds to an argument unit. It has an assigned stance (pro or con) as well as a global index that defines its position in the text. Each edge defines a relation from a premise (the child node) to a conclusion (the parent node). Each main claim defines the root of a tree.

Figure 1(b) has already illustrated an instance of the general model. The general model is slightly less expressive than the specific models. We evaluate in Section 6 to what extent this reduces its use for tackling argumentation-related analysis tasks. The advantage of the general model is that it allows a comparison of patterns of overall argumentation across corpora, as we do in the following.[4]

4.2 Visualization of Argumentation Patterns

Based on the general model, we empirically analyze class-specific patterns of overall argumentation on the three corpora. To this end, we compute one "average graph" for all texts in each complete corpus and one such graph for all texts with a particular class (e.g., for all "no myside bias" texts in case of AAE-v2). In an average graph, each node is labeled with the relative frequency of the associated combination of position and depth in all texts (edges accordingly). We align positions of different texts based on their start node, due to our observation that the first argument unit overproportionally often represents the main claim.[5] In addition the relative frequency, we determine the proportion of con to pro stance for each node.

As we aim to provide intuitive insights into how people argue in overall terms, we discuss the graphs in an informal visual way instead of listing exact numbers.[6] In the visualizations in Figure 2, brightness captures (inverse) frequency, so darker nodes represent more frequent argument units. The diameter of the inner light-red part of each node reflects its proportion of con stance. Nodes with a relative frequency below 0.3% and/or an absolute frequency below 3 are pruned, along with all their associated edges.

AAE-v2 Figure 2(a) stresses that most students state the main claim (depth 0, position 1) in a persuasive essay first. When the first argument unit is a premise of the main claim instead, it often attacks the main claim, as the large light-red proportion of the node at depth 1 and position 1 conveys. While, on average, texts with myside bias do not differ in length from those without, the latter show more con stance, especially at depth 1. Also, argumenta-

[4] Besides, although not in the focus here, we also assume stance to be easier to detect in practice than fine-grained roles.

[5] We also considered using the main claim as the fix point, but the resulting graphs would be much wider than the longest argumentation, which may be misleading.

[6] We provide files with the exact frequencies of all nodes and edges at: http://www.arguana.com/software.html

tion without myside bias shows more variance, as indicated, for instance, by the nodes at depth 0 and position 12 and 13 respectively. In contrast, clear patterns in the sequential ordering of pro and con stance are not recognizable in AAE-v2.

Arg-Microtexts According to the graphs in Figure 2(b), the position of the main claim varies in the microtexts. While the proportion of con stance seems rather similar between pro and con texts, our visualization reveals that their overall structure is "mirror-inverted" to a limited extent: Most pro texts start with the main claim (depth 0, position 1), discuss con stance later (red proportions increase to the right), and deepen the argumentation in a top-down fashion (most edges from top left to bottom right). Vice versa, con texts more often present the main claim later, attack it earlier, and seem to argue more bottom-up. This suggests that both sequential and hierarchical structure play a role here.

Web Discourse The web discourse texts, finally, comprise rather shallow argumentation across all genres. Slight structural differences can be seen, especially, the comments appear a little shorter and richer of pro stance on average. Besides, the blog posts have more con stance later. Still, the darker and thus more frequent nodes are at similar positions in all graphs. So, if at all, differences may be reflected in a sequential model of argumentation, which implicitly covers length. In terms of the hierarchical structure of the frequent nodes, the graphs of all genres are rather indistinguishable.

Altogether, the visualizations give first support for the impact of modeling overall argumentation. In particular, we hypothesize that hierarchical overall structure is decisive for myside bias, whereas a combination of sequential and hierarchical structure helps to distinguish pro-stance from con-stance texts. In contrast, we expect that the impact on classifying genres in the Web Discourse corpus is low.

5 Modeling Overall Argumentation

This section presents our kernel-based approaches for argumentation-related analysis tasks. They rely on a tree representation of overall argumentation.

5.1 Representation of Overall Argumentation

We model the overall structure of an argumentative text in form of a positional tree $T = (V, E)$ that, in principle, equals those exemplified in Figure 1 and analyzed above. Each node $v \in V$ represents an argument unit and each edge $e = (v_1, v_2) \in E$ a relation between two units. Technically, we therefor map the forest of trees representing a text (see Section 4) to a single tree by adding a "virtual" root node v_0 to V that is the parent of all tree roots.

In analysis tasks, we seek to compare sequential and hierarchical structures irrespective of the actual texts and the size of the associated trees. To this end, we represent labels and positions as follows:

Labels The tree kernel approaches in natural language processing discussed in Section 2 include text (usually words) in the leaf nodes. In contrast, we label each node $v \in V$ with the type of the associated argument unit only. Thereby, we almost fully abstract from the content of texts, which benefits the identification of common structures. In case of the general model, the only two labels are *pro* and *con*. In case of the specific models, we combine the role of a unit with the type of the relation the unit is the source of (if any). On Arg-Microtexts, for instance, this creates labels such as *opponent-support* or *opponent-undercutter*.

Positions As we adapt the route kernels of Aiolli et al. (2009) below, we follow their representation of sequential structure with one exception. In particular, the authors assigned an index to each edge that numbers the child nodes of each node ascending from 1. Thereby, they encoded the relative positions of sibling nodes *to each other*. To capture the ordering of argument units in a text from left to right, we also model positions as indices of the edges in E. Unlike Aiolli et al. (2009), however, we use indices decreasing from -1 in the left direction of the parent node and ascending from 1 to the right (derived from the nodes' global indices). While such a simple relabeling allows us to reuse their algorithm for computing kernels, it makes a decisive difference, namely, it encodes the relative positions of child nodes *to their parent*. This in turn implies the sequential structure of the whole tree.

Figure 3(a) exemplifies the tree representation for the argument unit types of the general model, omitting the virtual root v_0 for simplicity. Analogously, the types of the specific models of the three considered corpora could be used.

5.2 Kernel-based Modeling Approaches

Based on the tree representation, we now introduce four approaches for modeling overall argumentation. Figure 3(b) illustrates the kernel representations of each approach. As discussed in Section 2,

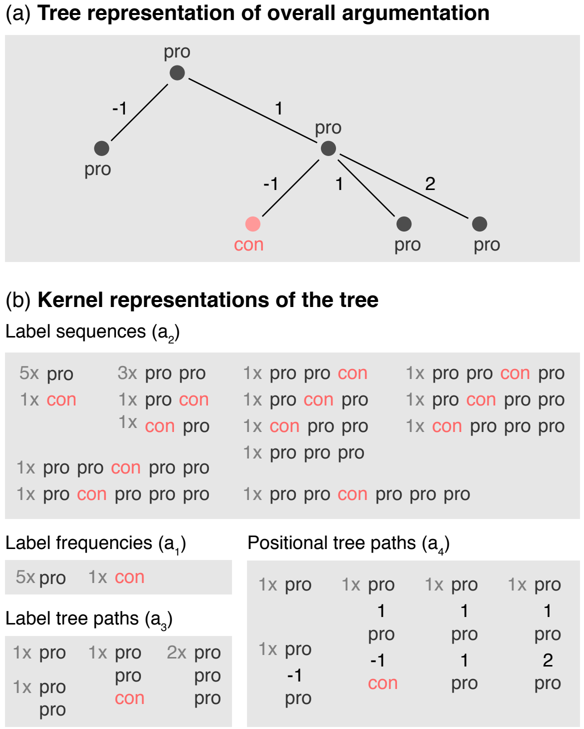

Figure 3: (a) Tree representation exemplified for the general model; node labels are unit types, edge indices relative positions of child nodes. (b) Kernel representations of the tree for all four approaches.

the associated kernel function compares the representations of the trees T, T' of any two texts.

Label Frequencies (a_1) Our simplest model of overall argumentation does not encode structure at all. Instead, it compares only the frequencies of each node label in T and T'. We represent the model with a linear kernel, which in the end corresponds to a standard feature representation.

Label Sequences (a_2) To encode sequential overall structure, we refer to the kernel of Mooney and Bunescu (2006), representing the sequential ordering of node labels in a tree by all contiguous subsequences. The similarity of two trees T and T' follows from the proportion of common subsequences, but longer subsequences are penalized by a decay factor. This approach can be seen as an imitation of our flow model (Wachsmuth and Stein, 2017).[7]

Label Tree Paths (a_3) We capture hierarchical overall structure adapting the non-positional part of the route kernel of Aiolli et al. (2009), *label paths*. A label path $\xi(v_i, v_j)$ denotes the sequence of labels of the nodes in the shortest path between v_i, v_j in a tree (including v_i, v_j). Following Aiolli et al. (2009), we consider only label paths starting at the root $v_i = v_0$, abbreviated here as $\xi(v_j)$. Implicitly, other paths may still be considered through the use of polynomial kernels with degree $d > 1$. As the authors, we compare any two paths with a function δ whose values is 1 when the paths are identical and 0 otherwise. Given two trees $T = (V, E)$ and $T' = (V', E')$, we then define a normalized polynomial kernel $K_\xi(T, T')$ over all label paths as:

$$\left(\sum_{v \in V} \sum_{v' \in V'} \frac{\delta(\xi(v), \xi(v'))}{|V| \cdot |V'|}\right)^d$$

Positional Tree Paths (a_4) In addition to label paths, Aiolli et al. (2009) define a *route* $\pi(v_i, v_j)$ as the sequence of edge indices on the shortest path between any two nodes v_i, v_j in a tree, i.e., the sequence of local positions. As above, they restrict their view to routes starting at the root, which we denote as $\pi(v_j)$, and compare them using δ. To combine positional information with label information, the authors build the product of a kernel based on the label paths and a kernel based on routes. As a result, sequential and hierarchical overall structure are compared at the same time. For overall argumentation, we define the resulting normalized polynomial product kernel $K_{\xi\pi}(T, T')$ as:

$$\left(\sum_{v \in V} \sum_{v' \in V'} \frac{\delta(\xi(v), \xi(v')) \cdot \delta(\pi(v), \pi(v'))}{(|V| \cdot |V'|)^2}\right)^d$$

Each approach, a_1–a_4, can be seen as representing one particular step of modeling overall argumentation; a_4 combines the complementary steps of a_2 and a_3, both of which implicitly include a_1.

6 Evaluation

Finally, we evaluate all four approaches to model overall argumentation from Section 5 on the three tasks associated to the corpora from Section 3.[8]

6.1 Experimental Set-up

Our goal is to assess the theoretical impact of each introduced step of modeling overall argumentation as far as possible. To this end, we conduct a systematic experiment where we use the ground-truth argument structure in each corpus for the associated downstream task based on the following set-up:

[7] We use a sequence kernel instead of flows in order to obtain a uniform setting. In Wachsmuth and Stein (2017), we also analyze flow abstractions (e.g., collapsing sequences of the same label). Here, we resort only to the original sequence.

[8] The Java source code for reproducing the experiment results is available at: http://www.arguana.com/software.html

#	Approach	Myside Bias on AAE-v2		Stance on Arg-Microtexts		Genre on Web Discourse	
		General model	*Specific model*	*General model*	*Specific model*	*General model*	*Specific model*
b_1	POS n-grams	63.3	63.3	58.8	58.8	74.0 (99.9% >a_2)	74.0 (99.9% >a_2)
b_2	Token n-grams	*70.5* (95% >b_1)	*70.5* (95% >b_1)	*65.2* (99% >a_2)	*65.2*	*75.6* (99.9% >a_2)	*75.6* (99.9% >a_2)
a_1	Label frequencies	83.4 (99.9% >b_2)	85.7 (99.9% >b_2)	49.7	54.4	62.6 (95% >a_4)	61.4
a_2	Label sequences	87.9 (99.9% >b_2)	94.7 (99.9% >a_1)	52.2	62.3	*64.5* (95% >a_3)	*64.5* (99.9% >a_3)
a_3	Label tree paths	***97.1*** (99.9% >a_2)	***97.1*** (95% >a_2)	59.8 (95% >a_1)	61.9	58.1	55.5
a_4	Positional tree paths	95.8 (99.9% >a_2)	95.6 (99.9% >a_1)	*66.7* (99% >a_2)	*67.8* (95% >a_1)	53.4	55.2
ba	**Best b_i + Best a_j**	**97.1** (99.9% >a_2)	**97.1** (95% >a_2)	69.8 (99.9% >a_2)	**71.0** (95% >a_1)	75.7 (99.9% >a_2)	**75.9** (99.9% >a_2)
	Majority baseline	62.4	62.4	52.3	52.3	64.5	64.5

Table 2: Accuracy in 10-fold cross-validation (10 repetitions, fairness in training) of all evaluated approaches on each of the three task/corpus combinations, both based on a *general model* of arguments and based on the *specific model* of the respective corpus. The highest value on each corpus is marked in bold; the best b_i and a_j in each column are italicized. In parenthesis: The confidence level in percent at which the respective approach is significantly better than the specified approach and all worse approaches.

Approaches The modeling steps are reflected by the approaches a_1–a_4 from Section 5. For each task, we measure the accuracy of all four approaches. We do this once for our *general model* of overall argumentation from Section 4 and once for the *specific model* annotated in the respective corpus, in order to assess the loss of resorting to our always applicable general model.

Baselines As a basic task-intrinsic measure, we compare a_1–a_4 to the *majority baseline* that always predicts the majority class in the given corpus. In addition, we employ two standard feature types and combine them with a_1–a_4, in order to roughly assess the need for modeling argumentation:

- b_1 *POS n-grams.* The frequency of each part-of-speech 1- to 3-gram found in $\geq$ 5% of all texts. This style feature has been effective in argumentation-related analysis tasks (Persing and Ng, 2015; Wachsmuth et al., 2016).
- b_2 *Token n-grams.* The frequency of each token 1- to 3-gram found in $\geq$ 5% of all texts. This content feature is strong in many text analysis tasks (Joachims, 1998; Pang et al., 2002).

From the tackled tasks, only myside bias has been approached on the given datasets in previous work. While we mention the respective results for completeness below, a comparison is in fact unfair due to our resort to ground-truth argument structure.

Experiments The evaluation of all approaches and baselines was done using the kernel-based machine learning platform *KeLP* (Filice et al., 2015), performing classification with the available implementation of *LibSVM* (Chang and Lin, 2011). As we target the theoretically possible impact of modeling overall argumentation, we tested a number of hyperparameter configurations.[9] We performed 10-fold cross-validation on the complete corpora and repeated each experiment 10 times, with instance shuffling in between. Then, we averaged the accuracy of each configuration over all folds and repetitions. To prevent the classifiers from using knowledge about the class distributions, we used fairness during training, i.e., each class was given an equal weight (Filice et al., 2014). Thus, the majority baseline is not a trivial competitor.

6.2 Results

Table 2 presents the best obtained results of each evaluated approach for each task/corpus combination. To clarify the reliability of the differences between the results, the table includes the confidence level (starting at 95%) at which each approach is significantly better than all weaker approaches according to a two-tailed paired student's t-test.[10]

Myside Bias on AAE-v2 The highest accuracy reported for classifying myside bias is 77.0 (Stab and Gurevych, 2016). While the comparability is limited (see above), we see that label frequencies (a_1) already achieve 83.4 and 85.7 for the general and specific model respectively, outperforming all baselines with 99.9% confidence. Matching the insights from Section 4, the sole proportion of attacks thus seems a good predictor of myside bias.

[9] SVM C parameter: 0.01, 0.1, 1, 10, 100; sequence kernel decay factor: 0, 0.5, 1; polynomial tree kernel degree: 1, 2, 3.

[10] While selecting the best result a posteriori gives an upper bound on the true effectiveness, we do this to assess to what extent each approach captures task-relevant information.

Label sequences (a_2) further improve over a_1, which underlines that also the sequential position of con stance and attack relations has an impact. a_2 is particular strong under the specific model (94.7). Unlike the general model, this model reflects some hierarchical information via the roles of argument units, such as *premise*. a_2 performs only slightly worse than the label tree paths (a_3), indicating that an adequate sequential model can compete with a hierarchical model, as we hypothesized in previous work (Wachsmuth and Stein, 2017).

Nevertheless, a_3 turns out best on AAE-v2, most likely due to its capability to capture the depth at which con stance occurs. Considering that no corpus annotation is perfect, the outstanding accuracy of 97.1 conveys an important finding: Modeling the tree structure of an argumentation basically *solves* the myside bias task without requiring other features. Neither the positional tree paths (a_4) nor the combination with token n-grams (**ba**) can add to that. Also, there is no difference between the general and the specific model, underlining that the unit roles in AAE-v2 are implicitly covered by the hierarchical structure in the general model.

Stance on Arg-Microtexts The accuracy results for the given challenging variant of stance classification (see Section 3) are much lower. Under the general model, the label frequencies (49.7) do not even compete with the majority baseline (52.3). Notable gains are achieved by the label sequences under the specific model (62.3), slightly beating the label tree paths (61.9). Putting them together in the positional tree paths (a_4) yields an accuracy of 66.7 and 67.8 respectively; more than the token n-grams (b_2, 65.2). Combining a_4 and b_2 in **ba** in turn results in the best observed accuracy value (71.0 on the specific model).

We conclude that both sequential and hierarchical overall structure are important for the distinction of pro from con argumentation, supporting our hypothesis from Section 4. They complement content-oriented approaches, such as b_2. Moreover, the fine-grained unit and relation types of the specific model annotated in Arg-Microtexts seem useful, consistently obtaining higher accuracy than the general model. Notice, though, that due to the small size of the corpus, only few reported gains are statistically significant, as shown in Table 2.

Genre on Web Discourse Although Section 4 has made minor structural differences in Web Discourse visible, Table 2 shows that a_1–a_4 all fail in genre classification: None of them beats the majority baseline (64.5), suggesting that no decisive discriminative patterns are learned. Both POS and token n-grams (b_1–b_2) significantly outperform a_1–a_4 at 99.9% confidence. While combining b_2 with a_2 (**ba**) minimally increases accuracy from 75.6 to 75.9, the results reveal that overall argumentation hardly impacts genre — as hypothesized.

7 Conclusion

This paper provides answers to the question of how the overall structure of a monological argumentative text should be modeled in order to tackle downstream tasks of computational argumentation. We have adopted the idea of including positional information in tree kernels in order to capture the explicit sequential and the implicit hierarchical overall structure of the text at the same time. In systematic experiments, we have demonstrated the strong impact of modeling overall argumentation. Most impressively, we have found that hierarchical structure decides about myside bias alone, while the combination of sequential and hierarchical structure has turned out beneficial for classifying stance. The missing impact on genre supports that the presented approaches actually capture argumentation-related properties of a text.

So far, however, we have restricted our view to ground-truth argument structure, leaving the integration of computational argument mining approaches to future work. While the noise from mining errors might qualify some of our findings, we also expect that larger corpora will allow us to discover more reliable and discriminative patterns. After all, our results underline the general importance of modeling overall argumentation.
