Abstract

Phrases play an important role in natural language understanding and machine translation (Sag et al., 2002; Villavicencio et al., 2005). However, it is difficult to integrate them into current neural machine translation (NMT) which reads and generates sentences word by word. In this work, we propose a method to translate phrases in NMT by integrating a phrase memory storing target phrases from a phrase-based statistical machine translation (SMT) system into the encoder-decoder architecture of NMT. At each decoding step, the phrase memory is first re-written by the SMT model, which dynamically generates relevant target phrases with contextual information provided by the NMT model. Then the proposed model reads the phrase memory to make probability estimations for all phrases in the phrase memory. If phrase generation is carried on, the NMT decoder selects an appropriate phrase from the memory to perform phrase translation and updates its decoding state by consuming the words in the selected phrase. Otherwise, the NMT decoder generates a word from the vocabulary as the general NMT decoder does. Experiment results on the Chinese→English translation show that the proposed model achieves significant improvements over the baseline on various test sets.

1 Introduction

Neural machine translation (NMT) has been receiving increasing attention due to its impressive translation performance (Kalchbrenner and Blunsom, 2013; Cho et al., 2014; Sutskever et al., 2014; Bahdanau et al., 2015; Wu et al., 2016). Significantly different from conventional statistical machine translation (SMT) (Brown et al., 1993; Koehn et al., 2003; Chiang, 2005), NMT adopts a big neural network to perform the entire translation process in one shot, for which an encoder-decoder architecture is widely used. Specifically, the encoder encodes a source sentence into a continuous vector representation, then the decoder uses the continuous vector representation to generate the corresponding target translation word by word.

The word-by-word generation philosophy in NMT makes it difficult to translate multi-word phrases. Phrases, especially multi-word expressions, are crucial for natural language understanding and machine translation (Sag et al., 2002; Villavicencio et al., 2005) as the meaning of a phrase cannot be always deducible from the meanings of its individual words or parts. Unfortunately current NMT is essentially a word-based or character-based (Chung et al., 2016; Costa-jussà and Fonollosa, 2016; Luong and Manning, 2016) translation system where phrases are not considered as translation units. In contrast, phrases are much better than words as translation units in SMT and have made a significant advance in translation quality. Therefore, a natural question arises: Can we translate phrases in NMT?

Recently, there have been some attempts on multi-word phrase generation in NMT (Stahlberg et al., 2016b; Zhang and Zong, 2016). However these efforts constrain NMT to generate either syntactic phrases or domain phrases in the word-by-word generation framework. To explore the phrase generation in NMT beyond the word-by-word generation framework, we propose a novel architecture that integrates a phrase-based SMT

Copenhagen, Denmark, September 7–11, 2017.

model into NMT. Specifically, we add an auxiliary phrase memory to store target phrases in symbolic form. At each decoding step, guided by the decoding information from the NMT decoder, the SMT model dynamically generates relevant target phrase translations and writes them to the memory. Then the NMT decoder scores phrases in the phrase memory and selects a proper phrase or word with the highest probability. If the phrase generation is carried out, the NMT decoder generates a multi-word phrase and updates its decoding state by consuming the words in the selected phrase.

Furthermore, in order to enhance the ability of the NMT decoder to effectively select appropriate target phrases, we modify the encoder of NMT to make it fit for exploring structural information of source sentences. Particularly, we integrate syntactic chunk information into the NMT encoder, to enrich the source-side representation. We validate our proposed model on the Chinese→English translation task. Experiment results show that the proposed model significantly outperforms the conventional attention-based NMT by 1.07 BLEU points on multiple NIST test sets.

The rest of this paper is organized as follows. Section 2 briefly introduces the attention-based NMT as background knowledge. Section 3 presents our proposed model which incorporates the phrase memory into the NMT encoder-decoder architecture, as well as the reading and writing procedures of the phrase memory. Section 4 presents our experiments on the Chinese→English translation task and reports the experiment results. Finally we discuss related work in Section 5 and conclude the paper in Section 6.

2 Background

Neural machine translation often adopts the encoder-decoder architecture with recurrent neural networks (RNN) to model the translation process. The bidirectional RNN encoder which consists of a forward RNN and a backward RNN reads a source sentence $\mathbf{x} = x_1, x_2, ..., x_{T_x}$ and transforms it into word annotations of the entire source sentence $\mathbf{h} = h_1, h_2, ..., h_{T_x}$. The decoder uses the annotations to emit a target sentence $\mathbf{y} = y_1, y_2, ..., y_{T_y}$ in a word-by-word manner.

In the training phase, given a parallel sentence $(\mathbf{x}, \mathbf{y})$, NMT models the conditional probability as follows,

$$P(\mathbf{y}|\mathbf{x}) = \prod_{i=1}^{T_y} P(y_i|\mathbf{y_{<i}}, \mathbf{x}) \tag{1}$$

where y_i is the target word emitted by the decoder at step i and $\mathbf{y_{<i}} = y_1, y_2, ..., y_{i-1}$. The conditional probability $P(y_i|\mathbf{y_{<i}}, \mathbf{x})$ is computed as

$$P(y_i|\mathbf{y_{<i}}, \mathbf{x}) = softmax(f(s_i, y_{i-1}, c_i)) \tag{2}$$

where $f(\cdot)$ is a non-linear function and s_i is the hidden state of the decoder at step i:

$$s_i = g(s_{i-1}, y_{i-1}, c_i) \tag{3}$$

where $g(\cdot)$ is a non-linear function. Here we adopt Gated Recurrent Unit (Cho et al., 2014) as the recurrent unit for the encoder and decoder. c_i is the context vector, computed as a weighted sum of the annotations $\mathbf{h}$:

$$c_i = \sum_{j=1}^{T_x} \alpha_{t,j} h_j \tag{4}$$

where h_j is the annotation of source word x_j and its weight $\alpha_{t,j}$ is computed by the attention model.

We train the attention-based NMT model by maximizing the log-likelihood:

$$C(\theta) = \sum_{n=1}^{N} \sum_{i=1}^{T_y} \log P(y_i^n|\mathbf{y}_{<i}^n, \mathbf{x}^n) \tag{5}$$

given the training data with N bilingual sentences (Cho, 2015).

In the testing phase, given a source sentence $\mathbf{x}$, we use beam search strategy to search a target sentence $\hat{\mathbf{y}}$ that approximately maximizes the conditional probability $P(\mathbf{y}|\mathbf{x})$

$$\hat{\mathbf{y}} = \operatorname*{argmax}_{\mathbf{y}} P(\mathbf{y}|\mathbf{x}) \tag{6}$$

3 Approach

In this section, we introduce the proposed model which incorporates a phrase memory into the encoder-decoder architecture of NMT. Inspired by the recent work on attaching an external structure to the encoder-decoder architecture (Gulcehre et al., 2016; Gu et al., 2016; Tang et al., 2016; Wang et al., 2017), we adopt a similar approach to incorporate the phrase memory into NMT.

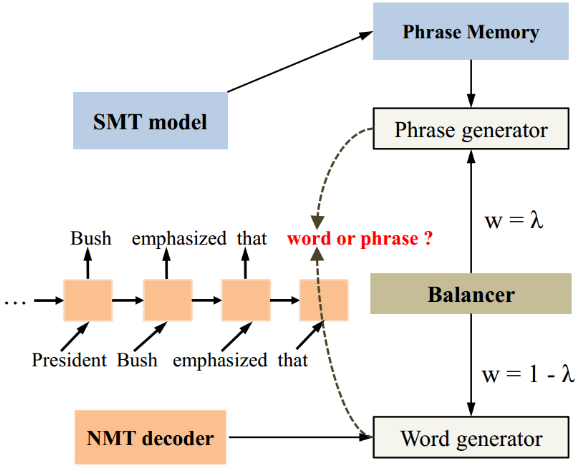

Figure 1: Architecture of the NMT decoder with the phrase memory. The NMT decoder performs phrase generation using the balancer and the phrase memory.

3.1 Framework

Figure 1 shows an example. Given the generated words "*President Bush emphasized that*", the model generates the next fragment either from a word generation mode or a phrase generation mode. If the model selects the word generation mode, it generates a word by the NMT decoder as in the standard NMT framework. Otherwise, it generates a multi-word phrase by enquiring a phrase memory, which is written by an SMT decoder based on the dynamic decoding information from the NMT model for each step. The trade-off between word generation mode and phrase generation mode is balanced by a weight λ, which is produced by a neural network based *balancer*.

Formally, a generated translation $\mathbf{y} = \{y_1, y_2, \ldots, y_{T_y}\}$ consists of two sets of fragments: words generated by NMT decoder $\mathbf{w} = \{w_1, w_2, \ldots, w_K\}$ and phrases generated from the phrase memory $\mathbf{p} = \{p_1, p_2, \ldots, p_L\}$. The probability of generating $\mathbf{y}$ is calculated by

$$P(\mathbf{y}|\mathbf{x}) = \prod_{w_k \in \mathbf{w}} (1 - \lambda_{t(w_k)}) P_{word}(w_k) \times \prod_{p_l \in \mathbf{p}} \lambda_{t(p_l)} P_{phrase}(p_l) \quad (7)$$

where $P_{word}(w_k)$ is the probability of generating the word w_k (see Equation 2), $P_{phrase}(p_l)$ is that of generating the phrase p_l which will be described in Section 3.2, and $t(\cdot)$ is the decoding step to generate the corresponding fragment.

The balancing weight λ is produced by the *balancer* – a multi-layer network. The balancer network takes as input the decoding information, including the context vector c_i, the previous decoding state s_{i-1} and the previous generated word y_{i-1}:

$$\lambda_i = \sigma(f_b(s_i, y_{i-1}, c_i)) \quad (8)$$

where $\sigma(\cdot)$ is a sigmoid function and $f_b(\cdot)$ is the activation function. Intuitively, the weight λ can be treated as the estimated importance of the phrase to be generated. We expect λ to be high if the phrase is appropriate at the current decoding step.

Well-Formed Phrases We employ a source-side chunker to chunk the source sentence, and only phrases that corresponds to a source chunk are used in our model. We restrict ourselves to the well-formed chunk phrases based on the following considerations: (1) In order to take advantage of dynamic programming, we restrict ourselves to non-overlap phrases.[1] (2) We explicitly utilize the boundary information of the source-side chunk phrases, to better guide the proposed model to adopt a target phrase at an appropriate decoding step. (3) We enable the model to exploit the syntactic categories of chunk phrases to enhance the proposed model with its selection preference for special target phrases. With these information, we enrich the context vector c_i to enable the proposed model to make better decisions, as described below.

Following the commonly-used strategy in sequence tagging tasks (Xue and Shen, 2003), we allow the words in a phrase to share the same chunk tag and introduce a special tag for the beginning word. For example, the phrase " 信息 安全 (information security)" is tagged as a noun phrase "NP", and the tag sequence should be "NP_B NP". Partially motivated by the work on integrating linguistic features into NMT (Sennrich and Haddow, 2016), we represent the encoder input as the combination of word embeddings and chunking tag embeddings, instead of word embeddings alone in the conventional NMT. The new input is formulated as follows:

$$[E^w x_i, E^t t_i] \quad (9)$$

[1] Overlapped phrases may result in a high dimensionality in translation hypothesis representation and make it hard to employ shared fragments for efficient dynamic programming.

where $E^w \in \mathbb{R}^{dw \times |V^{NMT}|}$ is a word embedding matrix and dw is the word embedding dimensionality, $E^t \in \mathbb{R}^{dt \times |V^{TAG}|}$ is a tag embedding matrix and dt is the tag embedding dimensionality. $[\cdot]$ is the vector concatenation operation.

3.2 Phrase Memory

The phrase memory stores relevant target phrases provided by an SMT model, which is trained on the same bilingual corpora. At each decoding step, the memory is firstly erased and re-written by the SMT model, the decoding of which is based on the translation information provided by the NMT model. Then, the proposed model enquires phrases along with their probabilities P_{phrase} from the memory.

Writing to Phrase Memory Given a partial translation $\mathbf{y}_{<i} = \{y_1, y_2, \dots, y_{t-1}\}$ generated from NMT, the SMT model picks potential phrases extracted from the translation table. The phrases are scored with multiple SMT features, including the language model score, the translation probabilities, the reordering score, and so on. Specially, the reordering score depends on alignment information between source and target words, which is derived from attention distribution produced by the NMT model (Wang et al., 2017). SMT coverage vector in (Wang et al., 2017) is also introduced to avoid repeat phrasal recommendations. In our work, the potential phrase is phrase with high SMT score which is defined as following:

$$SMT_{score}(p_l|\mathbf{y}_{<\mathbf{t}}, \mathbf{x}) = \sum_{m=1}^{M} w_m h_m(p_l, x(p_l)) \tag{10}$$

where p_l is a target phrase and $x(p_l)$ is its corresponding source span. $h_m(p_l, x(p_l))$ is a SMT feature function and w_m is its weight. The feature weights can be tuned by the minimum error rate training (MERT) algorithm (Och, 2003).

This leads to a better interaction between SMT and NMT models. It should be emphasized that our memory is dynamically updated at each decoding step based on the decoding history from both SMT and NMT models.

The proposed model is very flexible, where the phrase memory can be either fully dynamically generated by an SMT model or directly extracted from a bilingual dictionary, or any other bilingual resources storing idiomatic translations or bilingual multi-word expressions, which may lead to a further improvement. [2]

Reading Phrase Memory When phrases are read from the memory, they are rescored by a neural network based score function. The score function takes as input the phrase itself and decoding information from NMT ($i = t(p_l)$ denotes the current decoding step):

$$score_{phrase}(p_l) = g_s\big(e(p_l), s_i, y_{i-1}, c_i\big) \tag{11}$$

where $g_s(\cdot)$ is either an identity or a non-linear function. $e(p_l)$ is the representation of phrase p_l, which is modeled by a recurrent neural networks. Again, s_i is the decoder state, y_{i-1} is the lastly generated word, and c_i is the context vector. The scores are normalized for all phrases in the phrase memory, and the probability for phrase p_l is calculated as

$$P_{phrase}(p_l) = softmax(score_{phrase}(p_l)) \tag{12}$$

The probability calculation is controlled with parameters, which are trained together with the parameters from the NMT model.

3.3 Training

Formally, we train both the default parameters of standard NMT and the new parameters associated with phrase generation on a set of training examples $\{[\mathbf{x}^n, \mathbf{y}^n]\}_{n=1}^{N}$:

$$C(\theta) = \sum_{n=1}^{N} \log P(\mathbf{y}^n|\mathbf{x}^n) \tag{13}$$

where $P(\mathbf{y}^n|\mathbf{x}^n)$ is defined in Equation 7. Ideally, the trained model is expected to produce a higher balance weight λ and phrase probability P_{phrase} when a phrase is selected from the memory, and lower scores in other cases.

3.4 Decoding

During testing, the NMT decoder generates a target sentence which consists of a mixture of words and phrases. Due to the different granularities of words and phrases, we design a variant of beam search strategy: At decoding step i, we first compute P_{phrase} for all phrases in the phrase memory

[2] Bilingual resources can be utilized in two ways: First, we can store the bilingual resources in a static memory and keep all items available to NMT in the whole decoding period. Second, we can integrate the bilingual resources into SMT and then dynamically feed them into the phrase memory.

and P_{word} for all words in NMT vocabulary. Then the balancer outputs a balancing weight λ_i, which is used to scale the phrase and word probabilities : $\lambda_i \times P_{phrase}$ and $(1 - \lambda_i) \times P_{word}$. Now outputs are normalized probabilities on the concatenation of phrase memory and the general NMT vocabulary. At last, the NMT decoder generates a proper phrase or word of the highest probability.

If a target phrase in the phrase memory has the highest probability, the decoder generates the target phrase to complete the multi-word phrase generation process, and updates its decoding state by consuming the words in the selected phrase as described in Equation 3. All translation hypotheses are placed in the corresponding beams according to the number of generated target words.

4 Experiments

In this section, we evaluated the effectiveness of our model on the Chinese→English machine translation task. The training corpora consisted of about 1.25 million sentence pairs[3] with 27.9 million Chinese words and 34.5 million English words respectively. We used NIST 2006 (NIST06) dataset as development set, and NIST 2004 (NIST04), 2005 (NIST05) and 2008 (NIST08) datasets as test sets. We report experiment results with case-insensitive BLEU score[4].

We compared our proposed model with two state-of-the-art systems:

* **Moses**: a state-of-the-art phrase-based SMT system (Koehn et al., 2007) with its default settings, where feature function weights are tuned by the minimum error rate training (MERT) algorithm (Och, 2003).

* **RNNSearch**: an in-house implementation of the attention-based NMT system (Bahdanau et al., 2015) with its default settings.

For Moses, we used the full bilingual training data to train the phrase-based SMT model and the target portion of the bilingual training data to train a 4-gram language model using KenLM[5]. We ran Giza++ on the training data in both Chinese-to-English and English-to-Chinese directions and applied the "grow-diag-final" refinement rule (Koehn et al., 2003) to obtain word alignments. The maximum phrase length is set to 7.

For RNNSearch, we generally followed settings in the previous work (Bahdanau et al., 2015; Tu et al., 2017a,b). We only kept a shortlist of the most frequent 30,000 words in Chinese and English, covering approximately 97.7% and 99.3% of the data in the two languages respectively. We constrained our source and target sequences to have a maximum length of 50 words in the training data. The size of embedding layer of both sides was set to 620 and the size of hidden layer was set to 1000. We used a minibatch stochastic gradient descent (SGD) algorithm of size 80 together with Adadelta (Zeiler, 2012) to train the NMT models. The decay rates ρ and ϵ were set as 0.95 and 10^{-6}. We clipped the gradient norm to 1.0 (Pascanu et al., 2013). We also adopted the dropout technique. Dropout was applied only on the output layer and the dropout rate was set to 0.5. We used a simple beam search decoder with beam size 10 to find the most likely translation.

For the proposed model, we used a Chinese chunker[6] (Zhu et al., 2015) to chunk the source-side Chinese sentences. 13 chunking tags appeared in our chunked sentences and the size of chunking tag embedding was set to 10. We used the trained phrase-based SMT to translate the source-side chunks. The top 5 translations according to their translation scores (Equation 10) were kept and among them multi-word phrases were used as phrasal recommendations for each source chunk phrase. For a source-side chunk phrase, if there exists phrasal recommendations from SMT, the output chunk tag was used as its chunking tag feature as described in Section 3.1. Otherwise, the words in the chunk were treated as general words by being tagged with the default tag. In the phrase memory, we only keep the top 7 target translations with highest SMT scores at each decoding step. We used a forward neural network with two hidden layers for both the balancer (Equation 8) and the scoring function (Equation 11). The numbers of units in the hidden layers were set to 2000 and 500 respectively. We used a backward RNN encoder to learn the phrase representations of target phrases in the phrase memory.

[3] The corpus includes LDC2002E18, LDC2003E07, LDC2003E14, Hansards portion of LDC2004T07, LDC2004T08 and LDC2005T06.

SYSTEM	NIST04	NIST05	NIST08	Avg
Moses	34.74	31.99	23.69	30.14
RNNSearch	37.80	34.70	24.93	32.48
+memory	38.21	35.15	25.48†	32.95
+memory +chunking tag	38.83‡	35.72‡	26.09‡	33.55

Table 1: Main experiment results on the NIST Chinese-English translation task. BLEU scores in the table are case insensitive. Moses and RNNSearch are SMT and NMT baseline system respectively. "†": significantly better than RNNSearch ($p < 0.05$); "‡": significantly better than RNNSearch ($p < 0.01$).

	NIST04	NIST05	NIST08
+memory	34.3%	29.4%	22.2%
+chunking tag	66.4%	63.1%	58.4%

Table 2: Percentages of sentences that contain phrases generated by the proposed model.

Type	All		New	
	Total	Correct	Total	Correct
NP	81.0%	38.7%	46.0%	11.5%
VP	8.0%	1.7%	6.5%	0.8%
QP	10.8%	4.1%	6.2%	0.9%
Others	0.2%	0%	0.2%	0%
Sum	100%	44.5%	58.9%	13.2%

Table 3: Percentages of phrase categories to the total number of generated ones. "All" denotes all generated phrases, and "New" means new phrases that cannot be found in translations generated by the baseline system. "Total" is the total number of generated phrases and "Correct" denotes the fully correct ones.

4.1 Main Results

Table 1 reports main results of different models measured in terms of BLEU score. We observe that our implementation of RNNSearch outperforms Moses by 2.34 BLEU points. (*+memory*) which is the proposed model with the phrase memory obtains an improvement of 0.47 BLEU points over the baseline RNNSearch. With the source-side chunking tag feature, (*+memory+chunking tag*) outperforms the baseline RNNSearch by 1.07 BLEU points, showing the effectiveness of chunking syntactic categories on the selection of appropriate target phrases. From here on, we use "*+memory+chunking tag*" as the default setting in the following experiments if not otherwise stated.

Number of Sentences Affected by Generated Phrases We also check the number of translations that contain phrases generated by the proposed model, as shown in Table 2. As seen, a large portion of translations take the recommended phrases, and the number increases when the chunking tag feature is used.[7] Considering BLEU scores reported in Table 1, we believe that the chunking tag feature benefits the proposed model on its phrase generation.

4.2 Analysis on Generated Phrases

Syntactic Categories of Generated Phrases We first investigate which category of phrases is more likely to be selected by the proposed approach. There are some phrases, such as noun phrases (NPs, e.g., "national laboratory" and "vietnam airlines") and quantifier phrases (QPs, e.g., "15 seconds" and "two weeks") , that we expect to be favored by our approach. Statistics shown in Table 3 confirm our hypothesis. Let's first concern all generated phrases (i.e., column "All"): most selected phrases are noun phrases (81.0%) and quantifier phrases (10.8%). Among them, 44.5% percent of them are fully correct[8]. Specifically, NPs have relative higher generation accuracy (i.e., 47.8% = 38.7%/81.0%) while VPs have lower accuracy (i.e., 21.2% = 1.7%/8.0%). By looking into the wrong cases, we found most errors are related to verb tense, which is the drawback of SMT models.

Concerning the newly introduced phrases that cannot be found in baseline translations (i.e., column "New"), 13.2% of generated phrases are both new and fully correct, which contribute most to the performance improvement. We can also find that most newly introduced verb phrases and quantifier phrases are not correct, the patterns of which can be well learned by word-based NMT models.

[7] The numbers on NIST08 are relatively lower since part of the test set contains sentences from Web forums, which contain less multi-word expressions.

[8] Fully correct means that the generated phrases can be retrieved in corresponding references as a whole unit.

Words	All		New	
	Total	Correct	Total	Correct
2	66.2%	33.6%	34.9%	9.1%
3	20.7%	8.4%	13.4%	3.2%
4	7.4%	1.9%	5.4%	0.6%
$\geqslant$5	5.7%	0.6%	5.2%	0.3%

Table 4: Percentages of phrases with different word counts to the total number of generated ones.

Number of Words in Generated Phrases Table 4 lists the distribution of generated phrases based on the number of inside words. As seen, most generated phrases are short phrases (e.g., 2-gram and 3-gram phrases), which also contribute most to the new and fully correct phrases (i.e., $12.3\% = 9.1\% + 3.2\%$). Focusing on long phrases (e.g., order$\geqslant$ 4), most of them are newly introduced (10.6% out of 13.1%). Unfortunately, only a few portion of these phrases are fully correct, since long phrases have higher chance to contain one or two unmatched words.

SYSTEM	Test
+memory	32.95
+memory +NULL	31.63
+memory +chunking tag	33.55
+memory +chunking tag +NULL	30.81

Table 5: Additional experiment results on the translation task to directly measure the improvement obtained by the phrase generation. "+NULL" denotes that we replace the generated target phrases with a special symbol "NULL" in test sets. BLEU scores in the table are case insensitive.

Effect of Generated Phrases on Translation Performance Note that the proposed model benefits not only from fully matched phrases, but also from partially matched phrases. For example, the baseline system translates "国家 航空 暨 太空 总署" in a word-by-word manner and outputs "state aviation and space department". The generated phrase provided by SMT is "national aviation and space administration", but the only correct reference is "national aeronautics and space administration". The generated phrase is not fully correct but still useful.

To directly measure the improvement obtained by the phrase generation, we replace the generated target phrases with a special symbol "NULL" in test sets. As shown in Table 5, when deleting the generated target phrases, ("*+memory+chunking tag*") and ("*+memory*") translation performances decrease by 2.74 BLEU points and 1.32 BLEU points respectively. Moreover, translation performances on NIST08 decrease less than those on NIST04 and NIST05 in both settings. The reason is that NIST08 which contains sentences from web data has little influence on generating target phrases which are provided from a different domain [9]. The overall results demonstrate that neural machine translation benefits from phrase translation.

4.3 Effect of Balancer

Weight	Test
Dynamic	33.55
Constant ($\lambda = 0.1$)	31.35

Table 6: Translation performance with a variety of balancing weight strategies. "Dynamic" is the proposed approach and "Constant ($\lambda = 0.1$)" denotes fixing the balancing weight to 0.1. BLEU scores in the table are case insensitive.

The balancer which is used to coordinate the phrase generation and word generation is very crucial for the proposed model. We conducted an additional experiment to validate the effectiveness of the neural network based balancer. We use the setting "+memory +chunking tag" as baseline system to conduct the experiments. In this experiment, we fixed the balancing weight λ (Equation 8) to 0.1 during training and testing and report the results. As shown in Table 6, we find that using the fixed value for the balancing weight (*Constant ($\lambda = 0.1$)*) decreases the translation performance sharply. This demonstrates that the neural network based balancer is an essential component for the proposed model.

4.4 Comparison to Word-Level Recommendations and Discussions

Our approach is related to our previous work (Wang et al., 2017) which integrates the SMT word-level knowledge into NMT. To make a comparison, we conducted experiments followed settings in (Wang et al., 2017). The comparison results are reported in Table 7. We find that our approach is marginally better than the word-level

[9] The parallel training data are mainly from news domain.

SYSTEM	Test
+word level recommendation	33.27
+memory +chunking tag	33.55

Table 7: Experiment results on the translation task. "+word level recommendation" is the proposed model in (Wang et al., 2017). BLEU scores in the table are case insensitive.

model proposed in (Wang et al., 2017) by 0.28 BLEU points.

In our approach, the SMT model translates source-side chunk phrases using the NMT decoding information. Although we use high-quality target phrases as phrasal recommendations, our approach still suffers from the errors in segmentation and chunking. For example, the target phrase "laptop computers" cannot be recommended by the SMT model if the Chinese phrase "手提电脑" is not chunked as a phrase unit. This is the reason why some sentences do not have corresponding phrasal recommendations (Table 2). Therefore, our approach can be further enhanced if we can reduce the error propagations from the segmenter or chunker, for example, by using n-best chunk sequences instead of the single best chunk sequence.

Additionally, we also observe that some target phrasal recommendations have been also generated by the baseline system in a word-by-word manner. These phrases, even taken as parts of final translations by the proposed model, do not lead to improvements in terms of BLEU as they have already occurred in translations from the baseline system. For example, the proposed model successfully carries out the phrase generation mode to generate a target phrase "guangdong province" (the translation of Chinese phrase "广东省") which has appeared in the baseline system.

As external resources, e.g., bilingual dictionary, which are complementary to the SMT phrasal recommendations, are compatible with the proposed model, we believe that the proposed model will get further improvement by using external resources.

5 Related work

Our work is related to the following research topics on NMT:

Generating phrases for NMT In these studies, the generated NMT multi-word phrases are either from an SMT model or a bilingual dictionary. In syntactically guided neural machine translation (SGNMT), the NMT decoder uses phrase translations produced by the hierarchical phrase-based SMT system Hiero, as hard decoding constraints. In this way, syntactic phrases are generated by the NMT decoder (Stahlberg et al., 2016b). Zhang and Zong (2016) use an SMT translation system, which is integrated an additional bilingual dictionary, to synthesize pseudo-parallel sentences and feed the sentences into the training of NMT in order to translate low-frequency words or phrases. Tang et al. (2016) propose an external phrase memory that stores phrase pairs in symbolic forms for NMT. During decoding, the NMT decoder enquires the phrase memory and properly generates phrase translations. The significant differences between these efforts and ours are 1) that we dynamically generate phrase translations via an SMT model, and 2) that at the same time we modify the encoder to incorporate structural information to enhance the capability of NMT in phrase translation.

Incorporating linguistic information into NMT NMT is essentially a sequence to sequence mapping network that treats the input/output units, eg., words, subwords (Sennrich et al., 2016), characters (Chung et al., 2016; Costa-jussà and Fonollosa, 2016), as non-linguistic symbols. However, linguistic information can be viewed as the task-specific knowledge, which may be a useful supplementary to the sequence to sequence mapping network. To this end, various kinds of linguistic annotations have been introduced into NMT to improve its translation performance. Sennrich and Haddow (2016) enrich the input units of NMT with various linguistic features, including lemmas, part-of-speech tags, syntactic dependency labels and morphological features. García-Martínez et al. (2016) propose factored NMT using the morphological and grammatical decomposition of the words (factors) in output units. Eriguchi et al. (2016) explore the phrase structures of input sentences and propose a tree-to-sequence attention model for the vanilla NMT model. Li et al. (2017) propose to linearize source-side parse trees to obtain structural label sequences and explicitly incorporated the structural sequences into NMT, while Aharoni and Goldberg (2017) propose to incorporate target-side syntactic information into NMT by serializing the target sequences into linearized, lexicalized constituency trees. Zhang et al. (2016) integrate topic knowledge into NMT for domain/topic adaptation.

Combining NMT and SMT A variety of approaches have been explored for leveraging the advantages of both NMT and conventional SMT. He et al. (2016) integrate SMT features with the NMT model under the log-linear framework in order to help NMT alleviate the limited vocabulary problem (Luong et al., 2015; Jean et al., 2015) and coverage problem (Tu et al., 2016). Arthur et al. (2016) observe that NMT is prone to making mistakes in translating low-frequency content words and therefore attempt at incorporating discrete translation lexicons into the NMT model, to alliterate the imprecise translation problem (Wang et al., 2017). Motivated by the complementary strengths of syntactical SMT and NMT, different combination schemes of Hiero and NMT have been exploited to form SGNMT (Stahlberg et al., 2016a,b). Wang et al. (2017) propose an approach to incorporate the SMT model into attention-based NMT. They combine NMT posteriors with SMT word recommendations through linear interpolation implemented by a gating function which dynamically assigns the weights. Niehues et al. (2016) propose to use SMT to pre-translate the inputs into target translations and employ the target pre-translations as input sequences in NMT. Zhou et al. (2017) propose a neural system combination framework to directly combine NMT and SMT outputs. The combination of NMT and SMT has been also introduced in interactive machine translation to improve the system's suggestion quality (Wuebker et al., 2016). In addition, word alignments from the traditional SMT pipeline are also used to improve the attention mechanism in NMT (Cohn et al., 2016; Mi et al., 2016; Liu et al., 2016).

6 Conclusion

In this paper, we have presented a novel model to translate source phrases and generate target phrase translations in NMT by integrating the phrase memory into the encoder-decoder architecture. At decoding, the SMT model dynamically generates relevant target phrases with contextual information provided by the NMT model and writes them to the phrase memory. Then the proposed model reads the phrase memory and uses the balancer to make probability estimations for the phrases in the phrase memory. Finally the NMT decoder selects a phrase from the phrase memory or a word from the vocabulary of the highest probability to generate. Experiment results on Chinese→English translation have demonstrated that the proposed model can significantly improve the translation performance.

Abstract

This paper proposes a hierarchical attentional neural translation model which focuses on enhancing source-side hierarchical representations by covering both local and global semantic information using a bidirectional tree-based encoder. To maximize the predictive likelihood of target words, a weighted variant of an attention mechanism is used to balance the attentive information between lexical and phrase vectors. Using a tree-based rare word encoding, the proposed model is extended to sub-word level to alleviate the out-of-vocabulary (OOV) problem. Empirical results reveal that the proposed model significantly outperforms sequence-to-sequence attention-based and tree-based neural translation models in English-Chinese translation tasks.

1 Introduction

Neural machine translation (NMT) automatically learns the abstract features of and semantic relationship between the source and target sentences, and has recently given state-of-the-art results for various translation tasks (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2015). The most widely used model is the encoder-decoder framework (Sutskever et al., 2014), in which the source sentence is encoded into a dense representation, followed by a decoding process which generates the target translation. By exploiting the attention mechanism (Bahdanau et al., 2015), the generation of target words is conditional on the source hidden states, rather than on the context vector alone. From a model architecture perspective, prior studies of the attentive encoder-decoder translation model are mainly divided into two types.

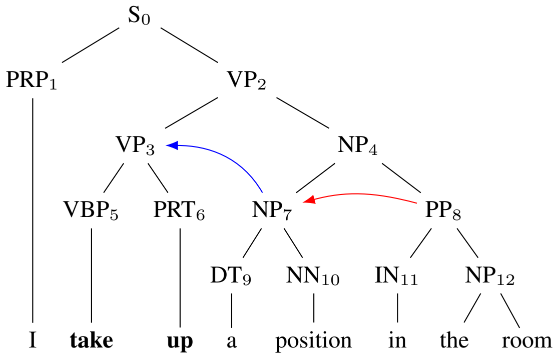

Figure 1: Induction of phrase and sentence representations over the syntactic structure of a sentence.

The **sequence-to-sequence model** treats a sentence as a sequence of tokens. The most fundamental approaches transform the source sentence sequentially into a fixed-length context vector, and the annotation vector of each word summarizes the preceding words (Sutskever et al., 2014; Cho et al., 2014b). Although Bahdanau et al. (2015) used a bidirectional recurrent neural network (RNN) (Schuster and Paliwal, 1997) to consider preceding and following words jointly, these sequential representations are insufficient to fully capture the semantics of a sentence, due to the fact that they do not account for the syntactic interpretations of sentence structure (Eriguchi et al., 2016; Tai et al., 2015). By incorporating additional features into a sequential model, Sennrich and Haddow (2016) and Stahlberg et al. (2016) suggest that a greater amount of linguistic information can improve the translation performance.

The **tree-to-sequence model** encodes a source sentence according to a given syntactic tree

over the sentence. The existing tree-based encoders (Tai et al., 2015; Eriguchi et al., 2016; Zhou et al., 2016) recursively generate phrase (sentence) representations in a bottom-up fashion, whereby the annotation vector of each phrase is derived from its constituent sub-phrases. As a result, the learned representations are limited to local information, while failing to capture the global meaning of a sentence. As illustrated in Figure 1, the phrases "take up"[1] and "a position"[2] have different meanings in different contexts. However, in composing the representations h_{VP_3} and h_{NP_7} for phrases VP$_3$ and NP$_7$, the current approaches do not account for the differences in meaning which arise as a result of ignoring the neighboring context as well as the remote context, i.e. $h_{\mathrm{NP}_7} \leftarrow h_{\mathrm{PP}_8}$ (sibling) and $h_{\mathrm{VP}_3} \leftarrow h_{\mathrm{NP}_7}$ (child of sibling). More specifically, at the encoding step t, the generated phrase is based on the results at the previous time steps h_{t-1} and h_{t-2}, but has no information about the parent phrases $h_{t'}$ for $t' > t$.

To address the above problems, we propose a novel architecture, a bidirectional hierarchical encoder, which extends the existing attentive tree-structured models (Eriguchi et al., 2016). In contrast to the model of Eriguchi et al. (2016), we first use a bidirectional RNN (Schuster and Paliwal, 1997) at lexical level to concatenate the forward and backward states as the hidden states of source words, to capture the preceding and following contexts (described in Section 3.1). Secondly, we propose a bidirectional tree-based encoder (described in Section 3.2), in which the original bottom-up encoding model is extended using an additional top-down encoding process. In the bidirectional hierarchical model, the vector representations of the sentence, phrases as well as words, are therefore based on the global context rather than local information.

To effectively leverage hierarchical representations in generating the target words, we adopt a variant weighted tree-based attention mechanism (described in Section 3.4) in which a time-dependent gating scalar is used to control the proportion of conditional information between the word and phrase vectors. To alleviate the out-of-vocabulary (OOV) problem, we further extend the proposed tree-based model to the sub-word level by integrating byte-pair encoding (BPE) (Sennrich et al., 2016) into the tree-based model (as described in Section 3.3). Experimental results for the NIST English-to-Chinese translation task reveal that the proposed model significantly outperforms the vanilla tree-based (Eriguchi et al., 2016) and sequential NMT models (Bahdanau et al., 2015) (Section 4.1).

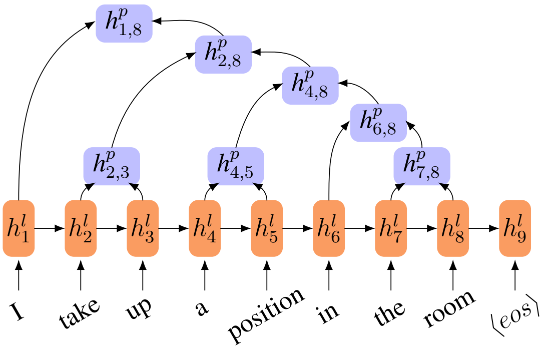

Figure 2: The tree-based model of Eriguchi et al. (2016) comprising a structured and sequential encoder.

2 Tree-Based Neural Machine Translation

A neural machine translation system (NMT) aims to use a single neural network to build a translation model, which is trained to maximize the conditional distribution of sentence pairs using a parallel training corpus (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Cho et al., 2014b,a). By incorporating syntactic information, the tree-based NMT exploits an additional syntactic structure of the source sentence to improve the translation. Since most existing NMTs generate one target word at a time, given a source sentence $\mathbf{x} = (x_1, ..., x_N)$ and its corresponding syntactic tree $\mathbf{tr}$, the conditional probability of a target sentence $\mathbf{y} = (y_1, ..., y_M)$ is formally expressed as:

$$p(\mathbf{y} \mid \mathbf{x}, \mathbf{tr}) = \prod_{1}^{M} p(y_j \mid y_1, ..., y_{j-1}, \mathbf{x}, \mathbf{tr}; \theta),$$

where θ represents the model parameters. A tree-based NMT consists of a tree-based encoder and a decoder.

2.1 Tree-Based Encoder

In a tree-based encoder, the source language $\mathbf{x}$ is encoded according to a given syntactic structure

[1] **Take up** has the meanings of *start doing something new*, *use space/time*, *accept an offer*, etc.

[2] **Position** has the meanings of *location*, *job offer*, *rank/status*, etc.

tr of the sentence. As shown in Figure 2, Eriguchi et al. (2016) employed a forward Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997; Gers et al., 2000) recurrent neural network (RNN) to encode the lexical nodes and a tree-LSTM (Tai et al., 2015) to generate the phrase representations in a bottom-up fashion. In the present study, we utilize the gated recurrent unit (GRU) (Cho et al., 2014b) instead of an LSTM, in view of its comparable performance (Chung et al., 2014) and since it yields even better results for certain tasks (Józefowicz et al., 2015). The lexical annotation vectors $(h^l_1, ..., h^l_N)$ are sequentially generated by using a GRU. The i-th leaf node vector is calculated as:

$$h^l_i = f^l_{GRU}(x_i, h^l_{i-1}), \qquad (1)$$

where x_i is the i-th source word embedding and h^l_{i-1} denotes the previous hidden state. The parent hidden state $h^{\uparrow}_{i,j}$ summarizes its left child $h^{\uparrow}_{i,k}$ and right child $h^{\uparrow}_{k+1,j}$ $(i < k < j)$ by applying the tree-GRU (Zhou et al., 2016) as follows:

$$\begin{aligned}
z^{\uparrow}_{i,j} &= \sigma(U^L_{(z)} h^{\uparrow}_{i,k} + U^R_{(z)} h^{\uparrow}_{k+1,j} + b^{\uparrow}_{(z)}) \\
r^{\uparrow}_{i,k} &= \sigma(U^L_{(rL)} h^{\uparrow}_{i,k} + U^R_{(rL)} h^{\uparrow}_{k+1,j} + b^{\uparrow}_{(rL)}) \\
r^{\uparrow}_{k+1,j} &= \sigma(U^L_{(rR)} h^{\uparrow}_{i,k} + U^R_{(rR)} h^{\uparrow}_{k+1,j} + b^{\uparrow}_{(rR)}) \\
\widetilde{h}^{\uparrow}_{i,j} &= \tanh(U^L_{(h)}(r^{\uparrow}_{i,k} \odot h^{\uparrow}_{i,k}) \\
&\quad + U^R_{(h)}(r^{\uparrow}_{k+1,j} \odot h^{\uparrow}_{k+1,j}) + b^{\uparrow}_{(h)}) \\
h^{\uparrow}_{i,j} &= z^{\uparrow}_{i,j} \widetilde{h}^{\uparrow}_{i,j} + (1 - z^{\uparrow}_{i,j})(h^{\uparrow}_{i,k} + h^{\uparrow}_{k+1,j}),
\end{aligned}$$

where $z^{\uparrow}_{i,j}$ is the update gate; $r^{\uparrow}_{i,k}$, $r^{\uparrow}_{k+1,j}$ are the reset gates for the left and right children; $\widetilde{h}^{\uparrow}_{i,j}$ denotes the candidate activation; $U^L_{(\cdot)}$ and $U^R_{(\cdot)}$ represent weight matrices; $b^{\uparrow}_{(\cdot)}$ denote bias vectors; σ is the logistic sigmoid function; and the operator $\odot$ denotes element-wise multiplication between vectors. The phrase representations are recursively built in an upward direction.

2.2 Decoding with a Tree-Based Attention Mechanism

In generating the target words, we employ a sequential decoder with an input-feeding method (Luong et al., 2015) and attention mechanism (Bahdanau et al., 2015). The conditional probability of the j-th target word y_j is calculated using a non-linear function $f_{softmax}$:

$$p(y_j \mid y_1, ..., y_{j-1}, \mathbf{x}, \mathbf{tr}; \theta) = f_{softmax}(c_j),$$

where c_j is the composite hidden state, which consists of a target hidden state s_j and a context vector d_j:

$$c_j = f_{\tanh}([s_j, d_j]).$$

Given the previous target word y_{j-1}, the concatenation of the previous hidden state s_{j-1} and the previous context vector c_{j-1} (input-feeding) (Luong et al., 2015), s_j, is calculated using a standard sequential GRU network:

$$s_j = f^{dec}_{gru}(y_{j-1}, [s_{j-1}, c_{j-1}]).$$

The context vector d_j is computed using an attention model which is used to softly summarize the attended part of the source-side representations. Eriguchi et al. (2016) adopted a tree-based attention mechanism to consider both the word and phrase vectors:

$$d_j = \sum_{i=1}^{N} \alpha_j(i) h^l_i + \sum_{k=1}^{N-1} \alpha_j(k) h^p_k, \qquad (2)$$

where h^l_i is the i-th hidden state of the source word at leaf level, and h^p_k is the k-th hidden state of the source phrase. The weight $\alpha_j(t)$ of node t is computed by:

$$\begin{aligned}
\alpha_j(t) &= \frac{\exp(e_t)}{\sum_{i=1}^{N} \exp(e^l_i) + \sum_{k=1}^{N-1} \exp(e^p_k)} \\
e_t &= (V_a)^T \tanh(U_a s_j + W_a h_t + b_a),
\end{aligned}$$

where h_t is the hidden state of the node. V_a, U_a, W_a and b_a are the model parameters.

3 The Bidirectional Hierarchical Model

Although the tree-based encoder of Eriguchi et al. (2016) has shown certain advantages in translation tasks involving distant language pairs, e.g. English-Japanese, the representation of a phrase relies solely on its child nodes, and the word representation at leaf level only takes into account the sequential information. We argue that the incorporation of more hierarchical information into the representations may contribute to an improvement in the translation. In particular, the use of global information can help in distinguishing the differences between word meanings. Based on this hypothesis, we propose an alternative architecture, the bidirectional hierarchical model, to enhance the source-side representations.

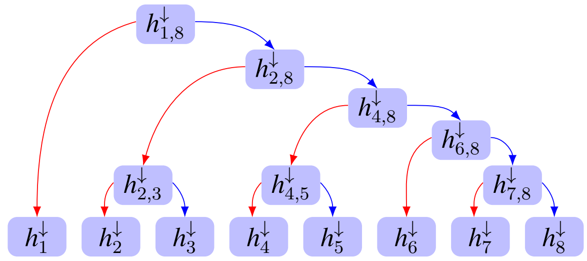

Figure 3: A top-down encoding process updates the hidden states recursively from root to leaf nodes. The red and blue lines denote the use of different learning parameters.

3.1 Bidirectional Leaf-Node Encoding

As discussed in Section 1, the unidirectional recurrent neural network reads an input sequence in order, from the first symbol to the last. In order to generate leaf node annotation vectors which jointly take into account both preceding and following annotations, we exploit a bidirectional RNN encoder (Bahdanau et al., 2015). The hidden state of the i-th leaf node h^l_i is the concatenation of the forward and backward vectors:

$$h^l_i = [\overrightarrow{h}^l_i, \overleftarrow{h}^l_i],$$

where $\overrightarrow{h}^l_i$ is obtained by a rightward GRU, as shown in Equation 1, and a leftward GRU calculates $\overleftarrow{h}^l_i$, as follows:

$$\overleftarrow{h}^l_i = f_{\overleftarrow{GRU}}(x_i, \overleftarrow{h}^l_{i-1}),$$

where $\overleftarrow{h}^l_{i-1}$ is the previous hidden state.

3.2 Bidirectional Tree-Node Encoding

Since the hidden states of leaf nodes are derived in a sequential, context-sensitive way, by generating phrase annotations in a bottom-up fashion, the sequential context can be propagated to tree nodes. However, the learned annotation vectors still fail to capture global information from the upper nodes. To enhance the representations with global semantic information, we propose to use a standard GRU recurrent network to update representations in a **top-down fashion**, as shown in Figure 3. The annotation vectors, which are learned by the previous encoding steps, are fed to the updating process.

First, we treat the bottom-up hidden state of root $h^{\uparrow}_{root}$, which covers the global meaning as well as the syntactic information of the source sentence, as the initial state of the top-down GRU network:

$$h^{\downarrow}_{root} = h^{\uparrow}_{root}.$$

Given an updated hidden state of the parent node $h^{\downarrow}_{i,j}$, the hidden states of left and right children $h^{\downarrow}_{i,k}$ and $h^{\downarrow}_{k+1,j}$ are calculated as:

$$\begin{aligned} h^{\downarrow}_{i,k} &= f^{ld}_{GRU}(h^{\uparrow}_{i,k}, h^{\downarrow}_{i,j}) \\ h^{\downarrow}_{k+1,j} &= f^{rd}_{GRU}(h^{\uparrow}_{k+1,j}, h^{\downarrow}_{i,j}), \end{aligned}$$

where $h^{\uparrow}_{i,k}$ and $h^{\uparrow}_{k+1,j}$ are the left and right child annotation vectors generated via the bottom-up tree-GRU network. Contrary to the similar top-down encoding for sentiment classification (Kokkinos and Potamianos, 2017), which uses same weighting parameters to handle both left and right child nodes, f^{ld}_{GRU} and f^{rd}_{GRU} with different parameters are applied in the proposed model to distinguish the left and right structural information. According to the definition of a GRU (Cho et al., 2014b), f^{ld}_{GRU} uses an update gate $z^{\downarrow}_{i,k}$, a reset gate $r^{\downarrow}_{i,k}$ and a candidate activation $\widetilde{h}^{\downarrow}_{i,k}$ to generate $h^{\downarrow}_{i,k}$, as follows:

$$\begin{aligned} z^{\downarrow}_{i,k} &= \sigma(W^{ld}_{(z)} h^{\uparrow}_{i,k} + U^{ld}_{(z)} h^{\downarrow}_{i,j} + b^{ld}_{(z)}) \\ r^{\downarrow}_{i,k} &= \sigma(W^{ld}_{(r)} h^{\uparrow}_{i,k} + U^{ld}_{(r)} h^{\downarrow}_{i,j} + b^{ld}_{(r)}) \\ \widetilde{h}^{\downarrow}_{i,k} &= \tanh(W^{ld}_{(h)} h^{\uparrow}_{i,k} + U^{ld}_{(h)} (r^{\downarrow}_{i,k} \odot h^{\downarrow}_{i,j}) + b^{ld}_{(h)}) \\ h^{\downarrow}_{i,k} &= (1 - z^{\downarrow}_{i,k}) h^{\downarrow}_{i,j} + z^{\downarrow}_{i,k} \widetilde{h}^{\downarrow}_{i,k}, \end{aligned} \quad (3)$$

where $W^{ld}_{(\cdot)}$ and $U^{ld}_{(\cdot)}$ represent weight matrices, and $b^{ld}_{(\cdot)}$ denote bias vectors. f^{rd}_{GRU} is defined in a similar way.

From a linguistic point of view, in the top-down GRU network, the reset gate is able to retain the useful global information and drop irrelevant information from the parent state $h^{\downarrow}_{i,j}$, while the proportions of the global context from the top-down state $h^{\downarrow}_{i,j}$, and the local context from the bottom-up state $h^{\uparrow}_{i,k}$ are controlled by the update gate. As it covers both the partial meaning of the phrase and the whole meaning of the sentence, $h^{\downarrow}_{i,k}$ is regarded as the final representation of $node_{i,k}$:

$$h^p_{i,k} = h^{\downarrow}_{i,k}.$$

With the propagation of information from root to leaf nodes, the i-th leaf node representation is updated as:

$$h^l_i = h^{\downarrow}_i.$$

As each source-side hidden state of the leaf nodes and tree nodes carries the hierarchical information of the sentence, we interpret such an encoded state as a **hierarchical representation**.

3.3 Handling Out-of-Vocabulary: Tree-Based Rare Word Encoding

In NMT, the translation of rare words and unknown words is an open problem, since the computational cost increases with the size of the vocabulary. Sennrich et al. (2016) proposed a simple and effective approach to handling out-of-vocabulary by representing rare words as a sequence of sub-word units, which are segmented using byte-pair encoding (BPE) (Gage, 1994).

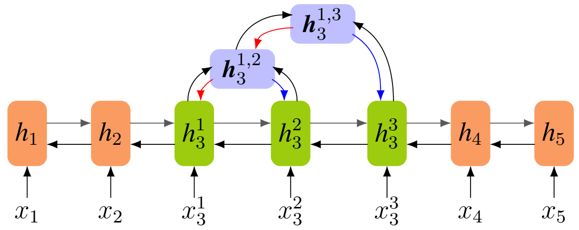

Figure 4: Encoding sub-word units with an additional binary lexical tree, where x_3^1, x_3^2, x_3^3 are the sub-units of word x_3.

We propose a variant tree-based rare word encoding approach which extends the tree-based model to the sub-word level. Sub-word units are encoded following an additional binary lexical tree. For a sentence $\mathbf{x} = (x_1, ..., x_i, ..., x_N)$, BPE segments the word x_i into a sequence of sub-word units $(x_i^1, ..., x_i^n)$. The binary lexical tree is simply built by composing two nodes in a rightwards fashion, $(((x_i^1, x_i^2), x_i^3)...), x_i^n)$, as shown in Figure 4. From the i-th leaf node, the original syntactic tree is extended downwards using the binary lexical tree, and the set of leaf nodes are replenished as $\mathbf{x} = (x_1, ..., x_i^1, x_i^2, ..., x_i^n, ..., x_N)$. Sub-word units can therefore be regarded as leaf nodes, and can be encoded using the proposed encoder, as illustrated in Figure 5. The experimental results in Section 4.1 demonstrate the effectiveness of this simple approach.

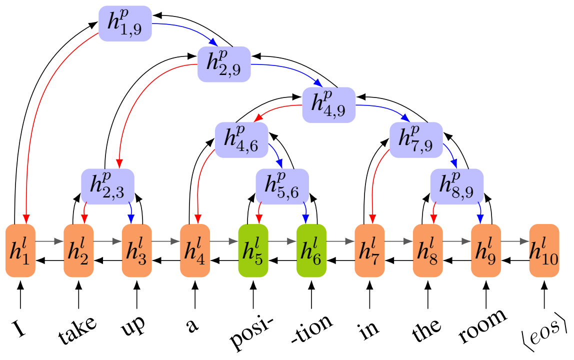

Figure 5: Illustration of the bidirectional hierarchical encoder: representations are enhanced by a bidirectional leaf-node encoding and a bidirectional tree-node encoding. The green nodes indicate the sub-word representations.

3.4 Decoder with Weighted Variant of Attention Mechanism

Since each representation carries both local and global information, in this case, attending fairly to the lexical and phrase representations in each decoding step may cause the problem of over-translation (repeatedly attending and translating the same constituent of a sentence). An alternative approach is to balance the attentive information between the lexical and phrase vectors in the context vector. To effectively leverage these hierarchical representations, we propose a weighted variant of the tree-based attention mechanism (the original is defined in Equation 2). Formally, the calculation of the context vector d_j at step j is modified as:

$$d_j = (1 - \beta_j) \sum_{i=1}^{n} \alpha_j(i) h_i^l + \beta_j \sum_{k=1}^{n-1} \alpha_j(k) h_k^p \quad (4)$$

where $\beta_j \in [0, 1]$ is used to weight the expected importance of the representations. Inspired by work on a multi-modal NMT (Calixto et al., 2017) which exploits a gating scalar (Xu et al., 2015) to weight the image context vector, we use such a scalar in our model in order to dynamically adapt the weighting scalar. The gating scalar β_j at step j is calculated by :

$$\beta_j = \sigma(W_\beta c_{j-1} + b_\beta),$$

where W_β and b_β represent the model parameters. In contrast with α, which denotes the correspondence between each source annotation and the current target hidden state, β is dominated by the target composite hidden state alone. In other words, β is a time-dependent scalar in relation to the current target word, and therefore enables the attention model to explicitly quantify how far the leaf and no-leaf states contribute to the word prediction at each time step. In the proposed model, the phrase and lexical context vectors are learned by a single attention model, meaning that they are dependent, and the gating scalar weights the phrase and lexical context vectors in complementary fashion, as shown in Equation 4. This distinguishes the model from that introduced by Calixto et al. (2017), in which the context vectors of the source sentence and image (bi-modal) are measured using two independent attention models and the gating scalar is merely used to weight the image context vector.

4 Experiments

4.1 Data

Training	Dev	Test		
LDC En-Zh	mt08	mt04	mt05	mt06
1,435,575	1,357	1,788	1,082	1,664

Table 1: Data used in the experiments.

We evaluate the proposed model on an English-to-Chinese translation task. For reasons of computational efficiency, we extracted 1.4M sentence pairs, in which the maximum length of the sentence was 40, from the LDC parallel corpus[3] as our training data. The models were developed using NIST mt08 data and were examined using NIST mt04, mt05, and mt06 data. The number of sentences in each dataset is shown in Table 1. On the English side, we used the *constituent parser* (Zeng et al., 2014, 2015) to produce a binary syntactic tree for each sentence, in constrast to the use of the *HPSG parser* by Eriguchi et al. (2016). On the Chinese side, the sentences are segmented using the Chinese word segmentation toolkit of *NiuTrans* (Xiao et al., 2012).

To avoid data sparsity, words referring to time, date and number, which are low in frequency, are generalized as '$time', '$date' and '$number'. In addition, as described in Section 3.3, the vocabularies are further compressed by segmenting the rare words into sub-word units using BPE.

4.2 Experimental Settings

Training Set	Original	Generalization	BPE
$\|V\|$ in En	159k	120k	40k
$\|V\|$ in Zh	198k	125k	40k

Table 2: The vocabulary size of the training set before and after applying the generalization and BPE segmentation.

As shown in Table 2, which gives the statistics of the token types, we limit the source and target vocabulary size to 40,000, in order to cover all the English and Chinese tokens. The dimensions of word embedding and hidden layer are respectively set as 620 and 1,000. Due to the concatenation in the bidirectional leaf-node encoding, the dimensions of the forward and backward vectors, which are half of those of the other hidden states, are set to 500. In order to prevent over-fitting, the training data is shuffled following each epoch. Moreover, the model parameters are optimized using AdaDelta (Zeiler, 2012), due to its capability for dynamically adapting the learning rate. We set the mini-batch size to 16 and the beam search size to 5. The accuracy of the translation relative to a reference is assessed using the BLEU metric (Papineni et al., 2002). In order to give an equitable comparison, all the NMT models used for comparison are implemented or re-implemented using GRU in our code, based on *dl4mt*[4].

4.3 Enhanced Hierarchical Representations

Firstly, the effectiveness of the enhanced hierarchical representations is evaluated through a set of experiments, the results of which are summarized in Table 3.

Compared with the original **tree-based encoder** (Eriguchi et al., 2016), the model with bidirectional leaf-node encoding (described in Section 3.1) shows better performance. This also reveals that the future context at leaf level can contribute to word prediction. Secondly, although the representations of leaf nodes are learned in a sequential, context-sensitive way, the translation quality is further improved by considering the global semantic information in the top-down encoding (Section 3.2).

By incorporating the above enhancements into the model, the proposed **hierarchical encoder** yields significant improvements over both the sequential and the tree-based models. The problem of OOV is alleviated by further extending the tree-

Table 3: Translation results for the various models. The first column shows the models; the second column indicates whether the corresponding experiment uses BPE data. The number of parameters (M = millions) in each model is given in the third column. The remaining columns are the translation accuracies for the test sets and development set, evaluated using BLEU scores (%). "↑ / ⇑": indicates that the hierarchical encoder is significantly better than the vanilla tree-based encoder ($p < 0.05/p < 0.01$).

based model to sub-word level (Section 3.3). In addition, we evaluate our tree-based rare word encoding method against the conventional rare word encoding (Sennrich et al., 2016) using the **sequential encoder** (Bahdanau et al., 2015). The empirical results confirm that our proposed tree-based BPE method achieves performance comparable to that of the standard BPE in the sequential model, but is applicable to the tree-based NMT model.

Overall, the proposed **hierarchical encoder** has demonstrated the ability to effectively model source-side representations from both the sequential and structural context. The NMT systems based on the proposed model significantly outperform those of conventional models using the **sequential encoder** and the **tree-based encoder**.

4.4 Weighted Attention Model

As discussed in Section 3.4, in order to effectively leverage hierarchical representations in generating the target word, we adopt a variant weighted tree-based attention mechanism which incorporates a scalar to control the proportion of conditional information between the word and phrase vectors. By manually or automatically varying the weight β, the utilization of the weighted attention model is assessed for four cases:

- $\beta = \mathbf{0.0}$: We manually set the weight of phrase vectors to 0.0; in other words, the decoder is forced to ignore the phrase vectors. The final translation is therefore generated by merely summarizing the leaf vectors.
- $\beta = \mathbf{0.5}$: The representations of non-leaf nodes and leaf nodes participate equally in the translation process. The decoder of this case therefore employs the same attention mechanism as that of the original model (Section 2.2).
- $\beta = \mathbf{1.0}$: In the reverse of the first case, the weight of the leaf nodes is manually set to 0.0. Thus, only the phrase vectors are used to predict the target words.
- Gating scalar (GS): A gating scalar is used for dynamically learning to control the proportion in which the lexical and phrase contexts contribute to the generation of the target words (Section 3.4).

Model	BLEU	Perplexity	Avg. Length
$\beta = 1.0$	17.16	98.65	21.13
$\beta = 0.5$	19.41	94.73	23.08
$\beta = 0.0$	19.83	94.68	23.33
GS	**20.10**	**94.18**	23.24

Table 4: Translation results for the development set. The last column indicates the average length of translation sentences, and the average length of reference sentences is 23.19.

The experimental results are shown in Table 4. The model which attends only to lexical annotation vectors ($\beta = 0.0$) gives slightly better performance than that which uses equal weights for

Figure 6: Translations of an English sentence output using the NMT models with bidirectional hierarchical model (**our**), sequential encoder (**seq-enc**) and original tree-based encoder (**tr-enc**). **Ref** indicates the reference Chinese sentence. The attention scores (α), which are noted over the source-side syntactic tree, are output by the bidirectional hierarchical model at the step where the fourth target word "在" is translated. The sequence of scores β denote the value of the gating scalar at each translation step.

lexical and phrase vectors ($\beta = 0.5$). The use of global information contributes to distinguishing the differences between word meanings, although the similar semantic information in the lexical and phrase representations aggravates the over-translation problem observed in the translation results. However, we found that the model which attends only to phrase representations tends to generate shorter translation of an average of 21.13 words in length, as shown in the last column of the first row of Table 4. Furthermore, the model that neglects the leaf representations ($\beta = 1.0$) is likely to underperform the others that are also conditioned on the leaf nodes. Even though the phrase representations are derived from the lexical level via a bottom-up encoding, we believe it is unable to fully capture the lexical information of the source sentence. Through the use of the gating scalar, the hierarchical model achieves progressive improvements, as shown in Tables 3 and 4, the problem of over-translation is also alleviated. The representations of non-leaf nodes can be regarded as supplements in the translation process.

5 Qualitative Analysis

Figure 6 shows an English sentence and its binary tree representation, together with the corresponding Chinese translations produced by the different NMT models. All the models successfully give the correct Chinese translation "该 组织 不会" for the first three words of the English sentence "the organization wouldn't". Differences appear in the translation of the fourth word, and these lead to markedly different meanings. The translation "使用 其 成员国 以外 的 武装力量" output by the sequential model, means "use the armed forces other than its member states" where "other than its member states" is incorrectly interpreted as a complement to "armed forces". This is caused by the intrinsic limitations of the sequential model, whereby it is unable to properly interpret the syntactic relationship of words. By explicitly incorporating the syntactic information, both the proposed hierarchical model and the tree-based model can accurately attend to the dashed section of Figure 6, and the translations can be correctly generated to reflect the meaning of the source sentence. The distinction between the translations produced by the original tree-based model and our hierarchical model is the interpretation of the words "areas outside". The tree-based model interprets it into "境外 (outside)", while our model correctly translates it into "以外 的 地区 (areas outside)". We believe that, with the help of global and local contextual information, our model is able to capture the short as well as long range dependencies.

We conducted an in-depth analysis of the BPE segmented units of rare words. It was observed that the sub-word units could be categorized into three groups. The first group of units involve the phonetic Romanization (Pinyin) of Chinese. In translation, these are simply transliterated into the corresponding Chinese characters. As shown in the second row of Table 5, "Liu/jing/min" is a person's name. The segmented units are the phonetic representations. Both models can successfully transliterate this into the Chinese equivalent, "刘/敬/民". The second group of sub-

Source	Reference	Hierarchical	Sequential
liu/jing/min	刘/敬/民 Liú/jìng/mín	刘/敬/民 Liú/jìng/mín	刘/敬/民 Liú/jìng/mín
adventur/er	探险家 Tàn xiǎn jiā	探险家 Tàn xiǎn jiā	探险者 Tàn xiǎn zhě
hi/k/ed	上调 Shàng tiáo	上升 Shàng shēng	发生 Fā shēng

Table 5: Translation examples of sub-words, where '/' indicates a separation between sub-word units. The first two columns show the segmented words and their Chinese references. The last two columns report the translations given by the hierarchical and sequential models respectively.

word units are likely to represent the word morphemes. The words are segmented into sub-word units, which are to some extent close to the linguistic word stems and suffixes. For example, the word "adventurer" is segmented into "adventur/er", which is correctly translated into the Chinese translations "探险/家" and "探险/者" respectively by the hierarchical and sequential models, while the third group of sub-word units offer no linguistic interpretation. It is easy to see, using the BPE algorithm, that the identification of sub-word units is merely based on their frequency in the training data, with the result that not all units are well-formed linguistic morphemes. However, an interesting finding arises regarding the translation of these segmented units. In the sequential model, the word is incorrectly translated; however, it can be correctly translated by the hierarchical model. Taking "hi/k/ed" as an example, the sequential model gives an incorrect translation "发生(happened)", while the hierarchical model translates it into "上升(rise)" which is a synonym of "hiked". This result indicates that in our hierarchical model, the parent node of hierarchical representation for sub-word units "hi/k/ed" is better able to capture the meaning of the word as a whole; this cannot be captured independently by the sequential model.

6 Conclusion

In this paper, we propose an improved NMT system with a novel bidirectional hierarchical encoder, which enhances the source-side representations of a sentence, that is, both phrases and words, with local and global context information. By introducing a tree-based rare word encoding, the hierarchical model is extended to sub-word level in order to alleviate the problem of OOVs. To effectively leverage the enhanced hierarchical representations, we also propose a weighted variant of the attention model which dynamically adjusts the proportion of conditional information between the lexical and phrase annotation vectors. Experimental results for NIST English-Chinese translation tasks demonstrate that the proposed model significantly outperforms the vanilla tree-based and sequential NMT models.

Abstract

Neural Machine Translation (NMT) has shown remarkable progress over the past few years, with production systems now being deployed to end-users. As the field is moving rapidly, it has become unclear which elements of NMT architectures have a significant impact on translation quality. In this work, we present a large-scale analysis of the sensitivity of NMT architectures to common hyperparameters. We report empirical results and variance numbers for several hundred experimental runs, corresponding to over 250,000 GPU hours on a WMT English to German translation task. Our experiments provide practical insights into the relative importance of factors such as embedding size, network depth, RNN cell type, residual connections, attention mechanism, and decoding heuristics. As part of this contribution, we also release an open-source NMT framework in TensorFlow to make it easy for others to reproduce our results and perform their own experiments.

1 Introduction

Neural Machine Translation (NMT) (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Cho et al., 2014) is an end-to-end approach to machine translation. NMT has shown impressive results (Jean et al., 2015; Luong et al., 2015b; Sennrich et al., 2016a; Wu et al., 2016) surpassing those of phrase-based systems while addressing shortcomings, such as the need for hand-engineered features. The most popular approaches to NMT are based on sequence-to-sequence models, an encoder-decoder architecture consisting of two recurrent neural networks (RNNs) and an attention mechanism that aligns target with source tokens (Bahdanau et al., 2015; Luong et al., 2015a).

One drawback of current NMT architectures is the huge amount of compute required to train them. Training on real-world datasets of several million examples typically requires dozens of GPUs and convergence time is on the order of days to weeks (Wu et al., 2016). While sweeping across large hyperparameter spaces is common in Computer Vision (Huang et al., 2016b), such exploration would be prohibitively expensive for NMT models, limiting researchers to well-established architecture and hyperparameter choices. Furthermore, there have been no large-scale studies of how these hyperparameters affect the performance of NMT systems. As a result, it remains unclear why these models perform as well as they do or how we might improve them.

In this work, we present an extensive analysis of architectural hyperparameters for NMT systems. Using a total of more than 250,000 GPU hours, we explore common variations of NMT architectures and provide insights into which architectural choices matter most. We report BLEU scores, perplexities, model sizes, and convergence time for all experiments, including variance numbers calculated across several runs of each experiment. In addition, we release the software framework that we wrote to facilitate this exploration.

In summary, the main contributions of this work are as follows:

- We provide immediately applicable insights into the optimization of NMT models, as well as promising directions for future research. For example, we found that deep encoders are

Copenhagen, Denmark, September 7–11, 2017.

more difficult to optimize than decoders, that dense residual connections yield better performance than regular residual connections, and that a well-tuned beam search is surprisingly critical to obtaining state-of-the-art results. By presenting practical advice for choosing baseline architectures, we help researchers avoid wasting time on unpromising model variations.

- We also establish the extent to which metrics such as BLEU are influenced by random initialization and slight hyperparameter variation, allowing researchers to better distinguish statistically significant results from noise.

- Finally, we release an open-source TensorFlow package, specifically designed to implement reproducible state-of-the-art sequence-to-sequence models. All experiments were run using this framework and we include all configuration files and processing scripts needed to reproduce the experiments in this paper. We hope to accelerate future research by releasing this framework to the public.

2 Background and Preliminaries

2.1 Neural Machine Translation

Our models are based on an encoder-decoder architecture with attention mechanism (Bahdanau et al., 2015; Luong et al., 2015a), as shown in figure 1. An encoder function f_{enc} takes as input a sequence of source tokens $\mathbf{x} = (x_1, ..., x_m)$ and produces a sequence of states $\mathbf{h} = (h_1, ..., h_m)$. In our base model, f_{enc} is a bi-directional RNN and the state h_i corresponds to the concatenation of the states produced by the backward and forward RNNs, $h_i = [\overrightarrow{h_i}; \overleftarrow{h_i}]$. The decoder f_{dec} is an RNN that predicts the probability of a target sequence $\mathbf{y} = (y_1, ..., y_k)$ based on $\mathbf{h}$. The probability of each target token $y_i \in 1, ...V$ is predicted based on the recurrent state in the decoder RNN s_i, the previous words, $y_{<i}$, and a context vector c_i. The context vector c_i is also called the attention vector and is calculated as a weighted average of the source states.

$$c_i = \sum_j a_{ij} h_j \tag{1}$$

$$a_{ij} = \frac{\hat{a}_{ij}}{\sum_j \hat{a}_{ij}} \tag{2}$$

$$\hat{a}_{ij} = att(s_i, h_j) \tag{3}$$

Here, $att(s_i, h_j)$ is an attention function that calculates an unnormalized alignment score between the encoder state h_j and the decoder state s_i. In our base model, we use a function of the form $att(s_i, h_j) = \langle W_h h_j, W_s s_i \rangle$, where the matrices W are used to transform the source and target states into a representation of the same size.

The decoder outputs a distribution over a vocabulary of fixed-size V:

$$\begin{aligned} &P(y_i | y_1, ..., y_{i-1}, \mathbf{x}) \\ &= \text{softmax}(W[s_i; c_i] + b) \end{aligned}$$

The whole model is trained end-to-end by minimizing the negative log likelihood of the target words using stochastic gradient descent.

3 Experimental Protocols

3.1 Datasets and Preprocessing

We run all experiments on the WMT'15 English→German task consisting of 4.5M sentence pairs, obtained by combining the Europarl v7, News Commentary v10, and Common Crawl corpora. We use newstest2013 as our validation set and newstest2014 and newstest2015 as our test sets. We focus on WMT English→German because it is a morphologically rich language therefore has been a standard benchmark in previous important work in Neural Machine Translation (Jean et al., 2015; Luong et al., 2015a; Sennrich et al., 2016b; Zhou et al., 2016; Wu et al., 2016)

To test for generality, we also ran a small number of experiments on English→French translation, and we found that the performance was highly correlated with that of English→German but that it took much longer to train models on the larger English→French dataset. Given that translation from the morphologically richer German is also considered a more challenging task, we felt justified in using the English→German translation task for this hyperparameter sweep.

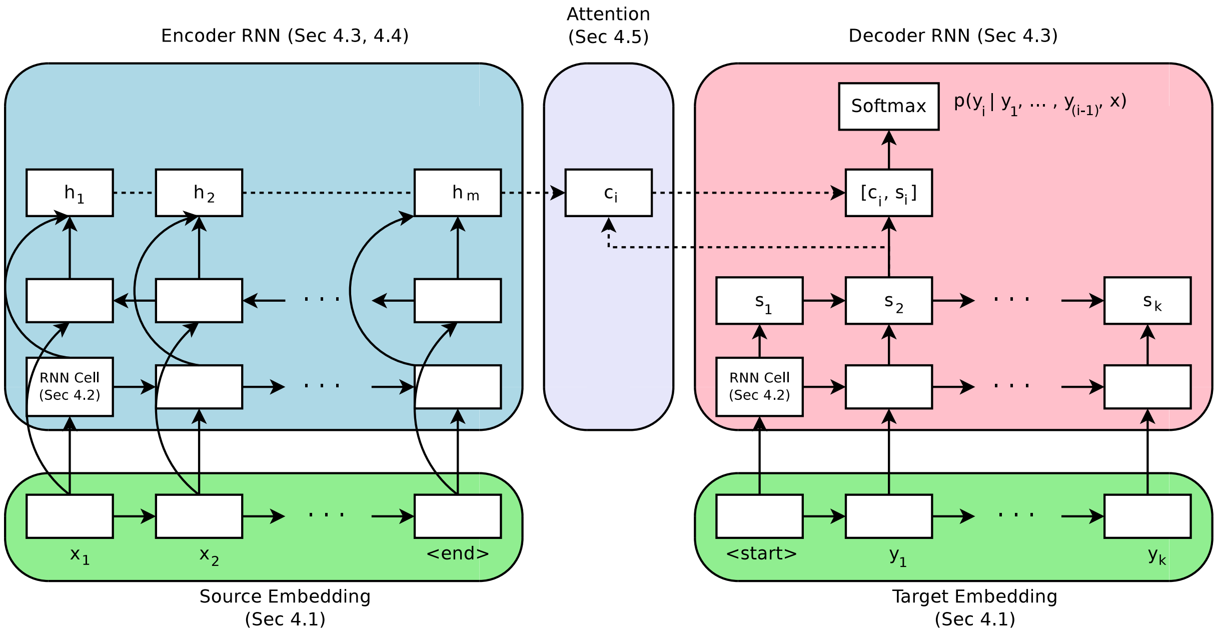

Figure 1: Encoder-Decoder architecture with attention module. Section numbers reference experiments corresponding to the components.

We tokenize and clean all datasets with the scripts in Moses[1] and learn shared subword units using Byte Pair Encoding (BPE) (Sennrich et al., 2016b) using 32,000 merge operations for a final vocabulary size of approximately 37k. We discovered that data preprocessing can have a large impact on final numbers, and since we wish to enable reproducibility, we release our data preprocessing scripts together with the NMT framework to the public. For more details on data preprocessing parameters, we refer the reader to the code release.

3.2 Training Setup and Software

All of the following experiments are carried out using our own implementation based on TensorFlow (Abadi et al., 2016). We built this framework to enable reproducible state-of-the-art implementations of Neural Machine Translation architectures. As part of our contribution, we are releasing the framework and all configuration files needed to reproduce our results. Training is performed on Nvidia Tesla K40m and Tesla K80 GPUs, distributed over 8 parallel workers and 6 parameter servers per experiment. We use a batch size of 128 and decode using beam search with a beam width of 10 and the length normalization penalty of 0.6 described in (Wu et al., 2016). BLEU scores are calculated on tokenized data using the *multi-bleu.perl* script in Moses.[2] Each experiment is run for a maximum of 2.5M steps and replicated 4 times with different initializations. We save model checkpoints every 30 minutes and choose the best checkpoint based on the validation set BLEU score. We report *mean and standard deviation* as well as *highest scores* (as per cross validation) for each experiment.

3.3 Baseline Model

Based on a review of recent literature, we chose a baseline model that we knew would perform reasonably well. Our goal was to keep the baseline model simple and standard, not to advance the start of the art. The model (described in 2.1) consists of a 2-layer bidirectional encoder (1 layer in each direction), and a 2 layer decoder with a multiplicative (Luong et al., 2015a) attention mechanism. We use 512-unit GRU (Cho et al., 2014) cells for both the encoder and decoder and apply Dropout of 0.2 at the input of each cell. We train using the Adam optimizer and a fixed learning rate of 0.0001 without decay. The embedding dimensionality is set to 512. A more detailed description of all model hyperparameters can be found in the supplementary material.

In each of the following experiments, the hy-

[1] https://github.com/moses-smt/mosesdecoder/

[2] https://github.com/moses-smt/mosesdecoder/blob/master/scripts/generic/multi-bleu.perl

perparameters of the baseline model are held constant, except for the one hyperparameter being studied. We hope that this allows us to isolate the effect of various hyperparameter changes. We recognize that this procedure does not account for interactions between hyperparameters, and we perform additional experiments when we believe such interactions are likely to occur (e.g., skip connections and number of layers).

4 Experiments and Results

For the sake of brevity, we only report mean BLEU, standard deviation, highest BLEU in parentheses, and model size in the following tables. Log perplexity, tokens/sec and convergence times can be found in the supplementary material tables. All reported p-values were calculated with a two-sample t-test that assumed equal variances.

4.1 Embedding Dimensionality

With a large vocabulary, the embedding layer may account for a significant fraction of the model parameters. Historically, researchers have used 620-dimensional (Bahdanau et al., 2015) or 1024-dimensional (Luong et al., 2015a) embeddings. We expected larger embeddings to result in better BLEU scores, or at least lower perplexities, but this wasn't always the case. While table 1 shows that 2048-dimensional embeddings yielded the overall best result, they only outperformed the smallest 128-dimensional embeddings by a narrow yet statistically significant margin (p = 0.01), but took nearly twice as long to converge. Gradient updates to both small and large embeddings did not differ significantly from each other and the norm of gradient updates to the embedding matrix stayed approximately constant throughout training, regardless of size. We did not observe overfitting with large embeddings and training log perplexity was almost equal across experiments, suggesting that the model does not make efficient use of the extra parameters and that there may be a need for better optimization techniques. Alternatively, it could be the case that models with large embeddings simply need far more than 2.5M steps to converge to the best solution.

Dim	newstest2013	Params
128	21.50 ± 0.16 (21.66)	36.13M
256	21.73 ± 0.09 (21.85)	46.20M
512	21.78 ± 0.05 (21.83)	66.32M
1024	21.36 ± 0.27 (21.67)	106.58M
2048	**21.86** ± 0.17 (22.08)	187.09M

Table 1: BLEU scores on newstest2013, varying the embedding dimensionality.

4.2 RNN Cell Variant

Both LSTM (Hochreiter and Schmidhuber, 1997) and GRU (Cho et al., 2014) cells are commonly used in NMT architectures. While there exist studies (Greff et al., 2016) that explore cell variants on small sequence tasks of a few thousand examples, we are not aware of any such studies in large-scale NMT settings.

The vanishing gradient problem is a motivation for gated cells, such as the GRU and LSTM. Using vanilla RNN cells, deep networks cannot efficiently propagate information and gradients through multiple layers and time steps. We initialize the decoder state to zero instead of passing the encoder state, and we experiment with using a vanilla RNN cell in the decoder only (Vanilla-Dec below). For the LSTM and GRU variants, we vary cell types in both the encoder and decoder. We use LSTM cells without peephole connections and initialize the forget bias of both LSTM and GRU cells to 1.

Cell	newstest2013	Params
LSTM	**22.22** ± 0.08 (22.33)	68.95M
GRU	21.78 ± 0.05 (21.83)	66.32M
Vanilla-Dec	15.38 ± 0.28 (15.73)	63.18M

Table 2: BLEU scores on newstest2013, varying the type of encoder and decoder cell.

In our experiments, *LSTM cells consistently outperformed GRU cells*, a result which was statistically significant ($p < 0.00001$). Since the computational bottleneck in our architecture is the softmax operation, we did not observe large differences in training speed between LSTM and GRU cells. Somewhat to our surprise, we found that the vanilla decoder is unable to learn nearly as well as the gated variant. This suggests that the decoder indeed passes information in its own state through multiple time steps instead of relying solely on the attention mechanism and current input (which includes the previous attention context). It could also be the case that the gating mechanism is necessary to mask out irrelevant parts of the input.

4.3 Encoder and Decoder Depth

We generally expect deeper networks to converge to better solutions than shallower ones (He et al., 2016). While some work (Luong et al., 2015b; Zhou et al., 2016; Luong and Manning, 2016; Wu et al., 2016) has achieved state-of-the-art results using deep networks, others (Jean et al., 2015; Chung et al., 2016; Sennrich et al., 2016b) have produced similar results with far shallower ones. Therefore, it is unclear how important depth is, and whether shallow networks are capable of producing results competitive with those of deep networks. Here, we explore the effect of both encoder and decoder depth up to 8 layers. For the bidirectional encoder, we separately stack the RNNs in both directions. For example, the Enc-8 model corresponds to one forward and one backward 4-layer RNN. For deeper networks, we also experiment with two variants of residual connections (He et al., 2016; Srivastava et al., 2015) to encourage gradient flow. In the standard variant, shown in equation (4), we insert residual connections between consecutive layers. If $h_t^{(l)}(x_t^{(l)}, h_{t-1}^{(l)})$ is the RNN output of layer l at time step t, then:

$$x_t^{(l+1)} = h_t^{(l)}(x_t^{(l)}, h_{t-1}^{(l)}) + x_t^{(l)} \tag{4}$$

where $x_t^{(0)}$ are the embedded input tokens. We also explore a dense (”ResD” below) variant of residual connections similar to those used by (Huang et al., 2016a) in Image Recognition. In this variant, we add skip connections from each layer to all other layers:

$$x_t^{(l+1)} = h_t^{(l)}(x_t^{(l)}, h_{t-1}^{(l)}) + \sum_{j=0}^{l} x_t^{(j)} \tag{5}$$

Our implementation differs from (Huang et al., 2016a) in that we use addition instead of concatenation in order to keep the state size constant.

Table 3 shows results of varying encoder and decoder depth with and without residual connection. We found no benefit to increasing encoder depth beyond two layers, as we observed no statistically significant improvement from going to four layers and even deeper models generally diverged during training. The best deep residual models achieved good results, but only one of four runs converged, as suggested by the large standard deviation.

Depth	newstest2013	Params
Enc-2	21.78 ± 0.05 (21.83)	66.32M
Enc-4	**21.85** ± 0.32 (22.23)	69.47M
Enc-8	21.32 ± 0.14 (21.51)	75.77M
Enc-8-Res	19.23 ± 1.96 (21.97)	75.77M
Enc-8-ResD	17.30 ± 2.64 (21.03)	75.77M
Dec-1	21.76 ± 0.12 (21.93)	64.75M
Dec-2	21.78 ± 0.05 (21.83)	66.32M
Dec-4	**22.37** ± 0.10 (22.51)	69.47M
Dec-4-Res	17.48 ± 0.25 (17.82)	68.69M
Dec-4-ResD	21.10 ± 0.24 (21.43)	68.69M
Dec-8	01.42 ± 0.23 (1.66)	75.77M
Dec-8-Res	16.99 ± 0.42 (17.47)	75.77M
Dec-8-ResD	20.97 ± 0.34 (21.42)	75.77M

Table 3: BLEU scores on newstest2013, varying the encoder and decoder depth and type of residual connections.

On the decoder side, deeper models outperformed shallower ones by a small but statistically significant margin ($p < 0.00001$), but without residual connections, we were unable to train decoders with 8 or more layers. Across the deep decoder experiments, dense residual connections consistently outperformed regular residual connections ($p < 0.00001$) and converged much faster in terms of step count, as shown in figure 2. We expected deep models to perform better (Sutskever et al., 2014; Zhou et al., 2016; Wu et al., 2016) across the board, and we believe that our experiments demonstrate the need for more robust techniques for optimizing deep sequential models. For example, we may need a better-tuned SGD optimizer or some form of batch normalization, in order to robustly train deep networks with residual connections.

4.4 Unidirectional vs. Bidirectional Encoder

In the literature, we see bidirectional encoders (Bahdanau et al., 2015), unidirectional encoders (Luong et al., 2015a), and a mix of both (Wu et al., 2016) being used. Bidirectional encoders are able to create representations that take into account both past and future inputs, while unidirectional encoders can only take past inputs into account. The benefit of unidirectional encoders is that their computation can be easily parallelized on GPUs, allowing them to run faster than their bidirectional counterparts. We are not aware of any studies that explore the necessity of bidirectional-

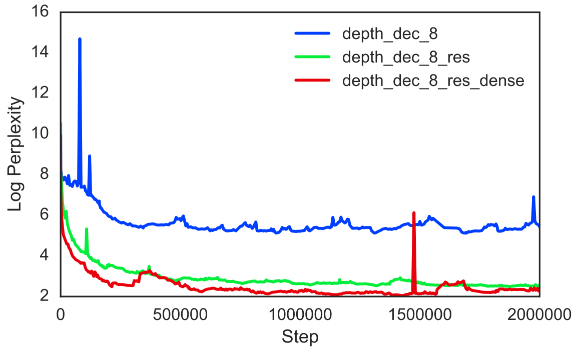

Figure 2: Training plots for deep decoder with and without residual connections, showing log perplexity on the eval set.

ity. In this set of experiments, we explore unidirectional encoders of varying depth with and without reversed source inputs, as this is a commonly used trick that allows the encoder to create richer representations for earlier words. Given that errors on the decoder side can easily cascade, the correctness of early words has disproportionate impact.

Cell	newstest2013	Params
Bidi-2	**21.78** ± 0.05 (21.83)	66.32M
Uni-1	20.54 ± 0.16 (20.73)	63.44M
Uni-1R	21.16 ± 0.35 (21.64)	63.44M
Uni-2	20.98 ± 0.10 (21.07)	65.01M
Uni-2R	21.76 ± 0.21 (21.93)	65.01M
Uni-4	21.47 ± 0.22 (21.70)	68.16M
Uni-4R	21.32 ± 0.42 (21.89)	68.16M

Table 4: BLEU scores on newstest2013, varying the type of encoder. The ”R” suffix indicates a reversed source sequence.

Table 4 shows that bidirectional encoders generally outperform unidirectional encoders, but not by a statistically significant margin. The encoders with reversed source consistently outperform their non-reversed counterparts (p = 0.009 for one layer models, p = 0.0003 for two layers, p = 0.2751 for four layers), but do not beat shallower bidirectional encoders.

4.5 Attention Mechanism

The two most commonly used attention mechanisms are the additive (Bahdanau et al., 2015) variant, equation (6) below, and the computationally less expensive multiplicative variant (Luong et al., 2015a), equation (7) below. Given an attention key h_j (an encoder state) and attention query s_i (a decoder state), the attention score for each pair is calculated as follows:

$$\text{score}(h_j, s_i) = \langle v, tanh(W_1 h_j + W_2 s_i)\rangle \quad (6)$$

$$\text{score}(h_j, s_i) = \langle W_1 h_j, W_2 s_i\rangle \quad (7)$$

We call the dimensionality of $W_1 h_j$ and $W_2 s_i$ the ”attention dimensionality” and vary it from 128 to 1024 by changing the layer size. We also experiment with using no attention mechanism by initializing the decoder state with the last encoder state (None-State), or concatenating the last encoder state to each decoder input (None-Input). The results are shown in table 5.

Attention	newstest2013	Params
Mul-128	22.03 ± 0.08 (22.14)	65.73M
Mul-256	22.33 ± 0.28 (22.64)	65.93M
Mul-512	21.78 ± 0.05 (21.83)	66.32M
Mul-1024	18.22 ± 0.03 (18.26)	67.11M
Add-128	22.23 ± 0.11 (22.38)	65.73M
Add-256	22.33 ± 0.04 (22.39)	65.93M
Add-512	**22.47** ± 0.27 (22.79)	66.33M
Add-1024	22.10 ± 0.18 (22.36)	67.11M
None-State	9.98 ± 0.28 (10.25)	64.23M
None-Input	11.57 ± 0.30 (11.85)	64.49M

Table 5: BLEU scores on newstest2013, varying the type of attention mechanism.

We found that the parameterized additive attention mechanism slightly but consistently outperformed the multiplicative one (p = 0.013 for 128 units, p = 0.5 for 256 units, p = 0.0012 for 512 units, and p < 0.00001 for 1024/8 units), with the attention dimensionality having little effect.

While we did expect the attention-based models to significantly outperform those without an attention mechanism, we were surprised by just how poorly the ”Non-Input” models fared, given that they had access to encoder information at each time step. Furthermore, we found that the attention-based models exhibited significantly larger gradient updates to decoder states throughout training. This suggests that the attention mechanism acts more like a ”weighted skip connection” that optimizes gradient flow than like a ”memory” that allows the encoder to access source states, as is commonly stated in the literature. We believe that further research in this direction is necessary to shed light on the role of the attention mechanism and whether it may be purely a vehicle for easier optimization.

4.6 Beam Search Strategies

Beam Search is a commonly used technique to find target sequences that maximize some scoring function $s(\mathbf{y}, \mathbf{x})$ through tree search. In the simplest case, the score to be maximized is the log probability of the target sequence given the source. Recently, extensions such as coverage penalties (Tu et al., 2016) and length normalizations (Wu et al., 2016) have been shown to improve decoding results. It has also been observed (Tu et al., 2017) that very large beam sizes, even with length penalty, perform worse than smaller ones. Thus, choosing the correct beam width can be crucial to achieving the best results.

Beam	**newstest2013**	**Params**
B1	20.66 ± 0.31 (21.08)	66.32M
B3	21.55 ± 0.26 (21.94)	66.32M
B5	21.60 ± 0.28 (22.03)	66.32M
B10	21.57 ± 0.26 (21.91)	66.32M
B25	21.47 ± 0.30 (21.77)	66.32M
B100	21.10 ± 0.31 (21.39)	66.32M
B10-LP-0.5	21.71 ± 0.25 (22.04)	66.32M
B10-LP-1.0	**21.80** ± 0.25 (22.16)	66.32M

Table 6: BLEU scores on newstest2013, varying the beam width and adding length penalties (LP).

Table 6 shows the effect of varying beam widths and adding length normalization penalties. A beam width of 1 corresponds to greedy search. We found that a well-tuned beam search is crucial to achieving good results, and that it leads to consistent gains of more than one BLEU point. Similar to (Tu et al., 2017) we found that very large beams yield worse results and that there is a ”sweet spot” of optimal beam width. We believe that further research into the robustness of hyperparameters in beam search is crucial to progress in NMT. We also experimented with a coverage penalty, but found no additional gain over a sufficiently large length penalty.

4.7 Final System Comparison

Finally, we compare our best performing model across all experiments, as chosen on the newstest2013 validation set, to historical results found in the literature in Table 8. Interestingly, the best performing model turned out to be nearly equivalent to the base model (described in Section 3.3), differing only in that it used 512-dimensional additive attention. While not the focus on this work, we were able to achieve further improvements by combining all of our insights into a single model described in Table 7.

Hyperparameter	**Value**
embedding dim	512
rnn cell variant	LSTMCell
encoder depth	4
decoder depth	4
attention dim	512
attention type	Bahdanau
encoder	bidirectional
beam size	10
length penalty	1.0

Table 7: Hyperparameter settings for our final combined model, consisting of all of the individually optimized values.

Model	**newstest14**	**newstest15**
Ours (best performing)	22.03	24.75
Ours (combined)	22.19	25.23
OpenNMT	19.34	-
Luong	20.9	-
BPE-Char	21.5	23.9
BPE	-	20.5
RNNSearch-LV	19.4	-
RNNSearch	-	16.5
Deep-Att*	20.6	-
GNMT*	24.61	-
Deep-Conv*	-	24.3

Table 8: Comparison to RNNSearch (Jean et al., 2015), RNNSearch-LV (Jean et al., 2015), BPE (Sennrich et al., 2016b), BPE-Char (Chung et al., 2016), Deep-Att (Zhou et al., 2016), Luong (Luong et al., 2015a), Deep-Conv (Gehring et al., 2016), GNMT (Wu et al., 2016), and OpenNMT (Klein et al., 2017). Systems with an * do not have a public implementation.

Although we do not offer architectural innovations, we do show that through careful hyperparameter tuning and good initialization, it is possible to achieve state-of-the-art performance on standard WMT benchmarks. Our model is outperformed only by (Wu et al., 2016), a model which is significantly more complex and lacks a public implementation.

To test whether our findings generalize to other languages, we also trained a model with the same hyperparameter configurations on the ASPEC Japanese to English translation task and achieved a BLEU score of 38.87, which is state-of-the-art.

5 Open-Source Release

We demonstrated empirically how small changes to hyperparameter values and different initialization can affect results, and how factors such as a well-tuned beam search are critical to high quality translation results. To move towards reproducible research, we believe it is important that researchers start building upon common frameworks and data processing pipelines. With this goal in mind, we built a modular software framework that allows researchers to explore novel architectures with minimal code changes, and define experimental parameters in a reproducible manner. While our initial experiments are in Machine Translation, our framework can easily be adapted to problems in Summarization (e.g., Nallapati et al. (2016)), Conversational Modeling (e.g., Vinyals and Le (2015); Shang et al. (2015); Sordoni et al. (2015); Li et al. (2015)) or Image-To-Text (e.g., Vinyals et al. (2015); Karpathy and Fei-Fei (2015); Xu et al. (2015)).

Although there exist open-source libraries such as OpenNMT (Klein et al., 2017) that share similar goals, they have not yet achieved state-of-the-art results (see table 8) and lack some important features, such as support for distributed training. We hope that by open sourcing our experimental toolkit, we can help to accelerate research in neural machine translation and sequence-to-sequence modeling.

6 Conclusion

We conducted a large-scale empirical analysis of architecture variations for Neural Machine Translation, teasing apart the key factors to achieving state-of-the-art results. We demonstrated a number of surprising insights, including the fact that beam search tuning is just as crucial as most architectural variations, and that with current optimization techniques deep models do not always outperform shallow ones. Here, we summarize our practical findings:

- Large embeddings with 2048 dimensions achieved the best results, but only by a small margin. Even small embeddings with 128 dimensions seem to have sufficient capacity to capture most of the necessary semantic information.

- LSTM Cells consistently outperformed GRU Cells.

- Bidirectional encoders with 2 to 4 layers performed best. Deeper encoders were significantly more likely to diverge, but show potential if they can be optimized well.

- Deep 4-layer decoders slightly outperformed shallower decoders. Residual connections were necessary to train decoders with 8 layers and dense residual connections offer additional robustness.

- Parameterized additive attention yielded the overall best results.

- A well-tuned beam search with length penalty is crucial. Beam widths of 5 to 10 along with a length penalty of 1.0 seemed to work well.

We highlighted several important research questions, including the efficient use of embedding parameters (4.1), the role of attention mechanisms as weighted skip connections (4.5) as opposed to memory units, the need for better optimization methods for deep recurrent networks (4.3), and the need for a better beam search (4.6) robust to hyperparameter variations.

Finally, given the recent surge in new applications for sequence-to-sequence models, we believe our new findings and state-of-the-art open-source package can significantly accelerate the pace of research in this domain.

Abstract

Bilingual Lexicon Induction is the task of learning word translations without bilingual parallel corpora. We model this task as a matrix completion problem, and present an effective and extendable framework for completing the matrix. This method harnesses diverse bilingual and monolingual signals, each of which may be incomplete or noisy. Our model achieves state-of-the-art performance for both high and low resource languages.

1 Introduction

Machine translation (MT) models typically require large, sentence-aligned bilingual texts to learn good translation models (Wu et al., 2016; Sennrich et al., 2016a; Koehn et al., 2003). However, for many language pairs, such parallel texts may only be available in limited quantities, which is problematic. Alignments at the word- or subword- levels (Sennrich et al., 2016b) can be inaccurate in the limited parallel texts, which can in turn lead to inaccurate translations. Due to the low quantity and thus coverage of the texts, there may still be "out-of-vocabulary" words encountered at run-time. The Bilingual Lexicon Induction (BLI) task (Rapp, 1995), which learns word translations from monolingual or comparable corpora, is an attempt to alleviate this problem. The goal is to use plentiful, more easily obtainable, monolingual or comparable data to infer word translations and reduce the need for parallel data to learn good translation models. The word translations obtained by BLI can, for example, be used to augment MT systems and improve alignment accuracy, coverage, and translation quality (Gulcehre et al., 2016; Callison-Burch et al., 2006; Daumé and Jagarlamudi, 2011).

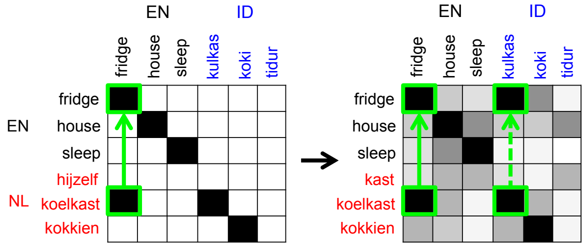

Figure 1: Our framework allows us to use a diverse range of signals to learn translations, including incomplete bilingual dictionaries, information from related languages (like Indonesian loan words from Dutch shown here), word embeddings, and even visual similarity cues.

Previous research has explored different sources for estimating translation equivalence from monolingual corpora (Schafer and Yarowsky, 2002; Klementiev and Roth, 2006; Irvine and Callison-Burch, 2013, 2017). These monolingual signals, when combined in a supervised model, can enhance end-to-end MT for low resource languages (Klementiev et al., 2012a; Irvine and Callison-Burch, 2016). More recently, similarities between words in different languages have been approximated by constructing a shared bilingual word embedding space with different forms of bilingual supervision (Upadhyay et al., 2016).

We present a framework for learning translations by combining diverse signals of translation that are each potentially sparse or noisy. We use matrix factorization (MF), which has been shown to be effective for harnessing incomplete or noisy distant supervision from multiple sources of information (Fan et al., 2014; Rocktäschel et al., 2015). MF is also shown to result in good cross-lingual representations for tasks such as alignment (Goutte et al., 2004), QA (Zhou et al., 2013), and cross-lingual word embeddings (Shi et al., 2015).

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1452–1463
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

Specifically, we represent translation as a matrix with source words in the columns and target words in the rows, and model the task of learning translations as a matrix completion problem. Starting from some observed translations (e.g., from existing bilingual dictionaries,) we infer missing translations in the matrix using MF with a Bayesian Personalized Ranking (BPR) objective (Rendle et al., 2009). We select BPR for a number of reasons: (1) BPR has been shown to outperform traditional supervised methods in the presence of positive-only data (Riedel et al., 2013), which is true in our case since we only observe positive translations. (2) BPR is easily extendable to incorporate additional signals for inferring missing values in the matrix (He and McAuley, 2016). Since observed translations may be sparse, i.e. the "cold start" problem in the matrix completion task, incorporating additional signals of translation equivalence estimated on monolingual corpora is useful. (3) BPR is also shown to be effective for multilingual transfer learning (Verga et al., 2016). For low resource source languages, there may be related, higher resource languages from which we can project available translations (e.g., translations of loan words) to the target language (Figure 1).

We conduct large scale experiments to learn translations from both low and high resource languages to English and achieve state-of-the-art performance on these languages. Our main contributions are as follows:

- We introduce a MF framework that learns translations by integrating diverse bilingual and monolingual signals of translation, each potentially noisy/incomplete.
- The framework is easily extendable to incorporate additional signals of translation equivalence. Since ours is a framework for integration, each signal can be improved separately to improve the overall system.
- Large scale experiments on both low and high resource languages show the effectiveness of our model, outperforming the current state-of-the-art.
- We make our code, datasets, and output translations publicly available.[1]

2 Related Work

Bilingual Lexicon Induction Previous research has used different sources for estimating translations from monolingual corpora. Signals such as contextual, temporal, topical, and ortographic similarities between words are used to measure their translation equivalence (Schafer and Yarowsky, 2002; Klementiev and Roth, 2006; Irvine and Callison-Burch, 2013, 2017).

With the increasing popularity of word embeddings, many recent works approximate similarities between words in different languages by constructing a shared bilingual embedding space (Klementiev et al., 2012b; Zou et al., 2013; Vulić and Moens, 2013; Mikolov et al., 2013a; Faruqui and Dyer, 2014; Chandar A P et al., 2014; Gouws et al., 2015; Luong et al., 2015; Lu et al., 2015; Upadhyay et al., 2016). In the shared space, words from different languages are represented in a language-independent manner such that similar words, regardless of language, have similar representations. Similarities between words can then be measured in the shared space. One approach to induce this shared space is to learn a mapping function between the languages' monolingual semantic spaces (Mikolov et al., 2013a; Dinu et al., 2014). The mapping relies on seed translations which can be from existing dictionaries or be reliably chosen from pseudo-bilingual corpora of comparable texts e.g., Wikipedia with interlanguage links. Vulić and Moens (2015) show that by learning a linear function with a reliably chosen seed lexicon, they outperform other models with more expensive bilingual signals for training on benchmark data.

Most prior work on BLI however, either makes use of only one monolingual signal or uses unsupervised methods (e.g., rank combination) to aggregate the signals. Irvine and Callison-Burch (2016) show that combining monolingual signals in a supervised logistic regression model produces higher accuracy word translations than unsupervised models. More recently, Vulić et al. (2016) show that their multi-modal model that employs a simple weighted-sum of word embeddings and visual similarities can improve translation accuracy. These works show that there is a need for combining diverse, multi-modal monolingual signals of translations. In this paper, we take this step further by combining the monolingual signals with bilingual signals of translations from existing bilingual dictionaries of related, "third" languages.

Bayesian Personalized Ranking (BPR) Our approach is based on extensions to the probabilis-

[1] http://www.cis.upenn.edu/%7Ederry/translations.html

tic model of MF in collaborative filtering (Koren et al., 2009; Rendle et al., 2009). We represent our translation task as a matrix with source words in the columns and target words in the rows (Figure 1). Based on some observed translations in the matrix found in a seed dictionary, our model learns low-dimensional feature vectors that encode the latent properties of the words in the row and the words in the column. The dot product of these vectors, which indicate how "aligned" the source and the target word properties are, captures how likely they are to be translations.

Since we do not observe false translations in the seed dictionary, the training data in the matrix consists only of positive translations. The absence of values in the matrix does not imply that the corresponding words are not translations. In fact, we seek to predict which of these missing values are true. The BPR approach to MF (Rendle et al., 2009) formulates the task of predicting missing values as a ranking task. With the assumption that observed true translations should be given higher values than unobserved translations, BPR learns to optimize the difference between values assigned to the observed translations and values assigned to the unobserved translations.

However, due to the sparsity of existing bilingual dictionaries (for some language pairs such dictionaries may not exist), the traditional formulation of MF with BPR suffers from the "cold start" issue (Gantner et al., 2010; He and McAuley, 2016; Verga et al., 2016). In our case, these are situations in which some source words have no translations to any word in the target or related languages. For these words, additional information, e.g., monolingual signals of translation equivalence or language-independent representations such as visual representations, must be used.

We use bilingual translations from the source to the target language, English, obtained from Wikipedia page titles with interlanguage links. Since Wikipedia pages in the source language may be linked to pages in languages other than English, we also use high accuracy, crowdsourced translations (Pavlick et al., 2014) from these *third* languages to English as additional bilingual translations. To alleviate the cold start issue, when a source word has no existing known translation to English or other third languages, our model backs-off to additional signals of translation equivalence estimated based on its word embedding and visual representations.

3 Method

In this section, we describe our framework for integrating bilingual and monolingual signals for learning translations. First we formulate the task of Bilingual Lexicon Induction, and introduce our model for learning translations given observed translations and additional monolingual/language-independent signals. Then we derive our learning procedure using the BPR objective function.

Problem Formulation Given a set of source words F, a set of target words E, the pair $\langle e, f\rangle$ where $e \in E$ and $f \in F$ is a candidate translation with an associated score $x_{e,f} \in [0,1]$ indicating the confidence of the translation. The input to our model is a set of observed translations $T := \{\langle e, f\rangle \mid x_{e,f} = 1\}$. These could come from an incomplete bilingual dictionary. We also add word identities to the matrix i.e., we define $T^{identity} := \{\langle e, e\rangle\}$, where $T^{identity} \subset T$. The task of Bilingual Lexicon Induction is then to generate *missing* translations: for a given source word f and a set of target words $\{e \mid \langle e, f\rangle \notin T\}$, predict the score $x_{e,f}$ of how likely it is for e to be a translation of f.

Bilingual Signals for Translation One way to predict $x_{e,f}$ is by using matrix factorization. The problem of predicting $x_{e,f}$ can be seen as a task of estimating a matrix $X : E \times F$. X is approximated by a matrix product of two low-rank matrices $P : |E| \times k$ and $Q : |F| \times k$:

$$\hat{X} := PQ^T$$

where k is the rank of the approximation. Each row p_e in P can be seen as a feature vector describing the latent properties of the target word e, and each row q_f of Q describes the latent properties of the source word f. Their dot product encodes how aligned the latent properties are and, since these vectors are trained on observed translations, it encodes how likely they are to be translation of each other. Thus, we can write this formulation of predicted scores $\hat{x}_{e,f}$ with MF as:

$$\hat{x}^{\mathrm{MF}}_{e,f} = p_e^T q_f = \sum_{i=1}^{k} p_{ei} \cdot q_{fi} \qquad (1)$$

Auxiliary Signals for Translation Because the observed bilingual translations may be sparse, the

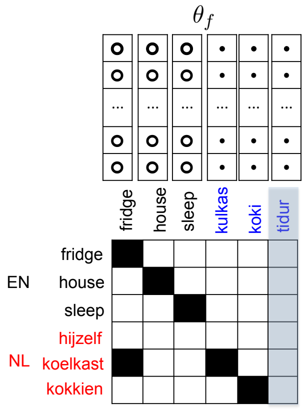

Figure 2: The word *tidur* (id) is a cold word with no associated translation in the matrix. Auxiliary features θ_f about the words can be used to predict translations for cold words.

MF approach can suffer from the existence of *cold* items: words that have none or too few associated observed translations to estimate their latent dimensions accurately (Figure 2). Additional signals for measuring translation equivalence can alleviate this problem. Hence, in the case of cold words, we use a formulation of $\hat{x}_{e,f}$ that involves auxiliary features about the words in the predicted $\hat{x}_{e,f}$:

$$\hat{x}^{\text{AUX}}_{e,f} = \theta_e^T \theta_f + \beta^T \theta_f \qquad (2)$$

θ_f represents an auxiliary information about the cold word f e.g., its word embedding or visual features. θ_e is a feature vector to be trained, whose dot product with θ_f models the extent to which the word e matches the auxiliary features of word f. In practice, learning θ_e amounts to learning a classifier, one for each target word e that learns weights θ_e given the feature vectors θ_f of its translations. β models the targets' overall bias toward a given word f.

Since each word can have multiple additional feature vectors, we can formulate $\hat{x}^{\text{AUX}}_{e,f}$ as a weighted sum of available auxiliary features[2]:

$$\hat{x}^{\text{AUX}}_{e,f} = \alpha_1\, \theta_e^T \theta_f + \alpha_2\, \gamma_e^T \gamma_f + ... + \alpha_n\, \delta_e^T \delta_f$$

where α_m are parameters assigned to control the contribution of each auxiliary feature.

In practice, we can combine the MF and auxiliary formulations by defining:

$$\hat{x}_{e,f} = \hat{x}^{\text{MF}}_{e,f} + \hat{x}^{\text{AUX}}_{e,f}$$

However, since bilingual signals that are input to $\hat{x}^{\text{MF}}_{e,f}$ are often precise but sparse, while monolingual signals that are input to $\hat{x}^{\text{AUX}}_{e,f}$ are often noisy and not sparse, in our model we only back-off to the less precise $\hat{x}^{\text{AUX}}_{e,f}$ for cold source words that have none or too few associated translations (more details are given in the experiments, Section 4). For other source words, we use $\hat{x}^{\text{MF}}_{e,f}$ to predict.

Learning with Bayesian Personalized Ranking Unlike traditional supervised models that try to maximize the scores assigned to positive instances (in our case, observed translations), the objective of Bayesian Personalized Ranking (BPR) is to maximize the *difference* in scores assigned to the observed translations compared to those assigned to the unobserved translations. Given a training set D consisting of triples of the form $\langle e, f, g\rangle$, where $\langle e, f\rangle \in T$ and $\langle e, g\rangle \notin T$, BPR wants to maximize $\hat{x}_{e,f,g}$, defined as:

$$\hat{x}_{e,f,g} = \hat{x}_{e,f} - \hat{x}_{e,g}$$

where $\hat{x}_{e,f}$ and $\hat{x}_{e,g}$ can be defined either by eq. 1 or eq. 2 (for cold words). Specifically, BPR optimizes (Rendle et al., 2009):

$$\sum_{\langle e,f,g\rangle \in D} \ln \sigma(\hat{x}_{e,f,g}) - \lambda_\Theta ||\Theta||^2$$

where σ is the logistic sigmoid function, Θ is the parameter vector of $\hat{x}_{e,f,g}$ to be trained, and λ_Θ is its hyperparameter vector. BPR can be trained using stochastic gradient ascent where a triple $\langle e, f, g\rangle$ is sampled from D and parameter updates are performed:

$$\Theta \leftarrow \Theta + \eta.(\sigma(-\hat{x}_{e,f,g})\frac{\partial \hat{x}_{e,f,g}}{\partial \Theta} - \lambda_\Theta \Theta)$$

η is the learning rate. Hence, for the MF formulation of $\hat{x}_{e,f,g}$, we can sample a triple $\langle e, f, g\rangle$ from D and update its parameters as:

$$p_e \leftarrow p_e + \eta.(\sigma(-\hat{x}^{\text{MF}}_{e,f,g})(q_f - q_g) - \lambda_P\, p_e)$$
$$q_f \leftarrow q_f + \eta.(\sigma(-\hat{x}^{\text{MF}}_{e,f,g})(p_e) - \lambda_{Q^+}\, q_f)$$
$$q_g \leftarrow q_g + \eta.(\sigma(-\hat{x}^{\text{MF}}_{e,f,g})(-p_e) - \lambda_{Q^-}\, q_g)$$

while for the auxiliary formulation of $\hat{x}_{e,f,g}$, we can sample a triple $\langle e, f, g\rangle$ from D and update its parameters as:

$$\theta_e \leftarrow \theta_e + \eta.(\sigma(-\hat{x}^{\text{AUX}}_{e,f,g})(\theta_f - \theta_g) - \lambda_\Theta\, \theta_e)$$
$$\beta \leftarrow \beta + \eta.(\sigma(-\hat{x}^{\text{AUX}}_{e,f,g})(\theta_f - \theta_g) - \lambda_\beta\, \beta)$$

[2] We omit bias terms for brevity.

4 Experiments

To implement our approach, we extend the implementation of BPR in LibRec[3] which is a publicly available Java library for recommender systems.

We evaluate our model for the task of Bilingual Lexicon Induction (BLI). Given a source word f, the task is to rank all candidate target words e by their predicted translation scores $\hat{x}_{e,f}$. We conduct large-scale experiments on 27 low- and high-resource source languages and evaluate their translations to English. We use the 100K most frequent words from English Wikipedia as candidate English target words (E).

At test time, for each source language, we evaluate the top-10 accuracy (Acc_{10}): the percent of source language words in the test set for which a correct English translation appears in the top-10 ranked English candidates.

4.1 Data

4.1.1 Test sets

We use benchmark test sets for the task of bilingual lexicon induction to evaluate the performance of our model. The **VULIC1000** dataset (Vulic and Moens, 2016) comprises 1000 nouns in Spanish, Italian, and Dutch, along with their one-to-one ground-truth word translations in English.

We construct a new test set (CrowdTest) for a larger set of 27 languages from crowdsourced dictionaries (Pavlick et al., 2014). For each language, we randomly pick up to 1000 words that have only one English word translation in the crowdsourced dictionary to be the test set for that language. On average, there are 967 test source words with a variety of POS per language. Since different language treats grammatical categories such as tense and number differently (for example, unlike English, tenses are not expressed by specific forms of words in Indonesian (`id`); rather, they are expressed through context), we make our evaluation on all languages in CrowdTest generic by treating a predicted English translation of a foreign word as correct as long as it has the same lemma as the gold English translation. To facilitate further research, we make CrowdTest publicly available in our website.

4.1.2 Bilingual Signals for Translation

We use Wikipedia to incorporate information from a *third* language into the matrix, with observed translations to both the source language and the target language, English. We first collect all interlingual links from English Wikipedia pages to pages in other languages. Using these links, we obtain translations of Wikipedia page titles in many languages to English e.g., `id.wikipedia.org/wiki/Kulkas` → *fridge* (en). The observed translations are projected to fill the missing translations in the matrix (Figure 3). We call these bilingual translations **`WIKI`**.

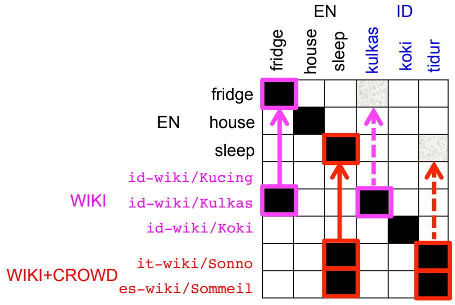

Figure 3: Wikipedia pages with observed translations to the source (id) and the target (en) languages act as a *third* language in the matrix.

From the links that we have collected, we can also infer links from Wikipedia pages in the source language to other pages in non-target languages e.g., `id.wikipedia.org/wiki/Kulkas` → `it.wikipedia.org/wiki/Frigorifero`. The titles of these pages can be translated to English if they exist as entries in the dictionaries. These non-source, non-target language pages can act as yet another third language whose observed translations can be projected to fill the missing translations in the matrix (Figure 3). We call these bilingual translations **`WIKI+CROWD`**.

4.1.3 Monolingual Signals for Translation

We define *cold* source words in our experiments as source words that have no associated **`WIKI`** translations and fewer than 2 associated **`WIKI+CROWD`** translations. For each cold source word f, we predict the score of its translation to each candidate English word e using the auxiliary formulation of $\hat{x}_{e,f}$ (Equation 2). There are two auxiliary signals about the words that we use in our experiments: (1) bilingually informed word embeddings and (2) visual representations.

Bilingually Informed Word Embeddings For each language, we learn monolingual embeddings for its words by training a standard monolingual `word2vec` skipgram model (Mikolov

[3] https://www.librec.net/index.html

et al., 2013b) on tokenized Wikipedia pages of that language using Gensim (Řehůřek and Sojka, 2010). We obtain 100-dimensional word embeddings with 15 epochs, 15 negatives, window size of 5, and cutoff value of 5.

Given two monolingual embedding spaces $\mathbb{R}^{d_F}$ and $\mathbb{R}^{d_E}$ of the source and target languages F and E, where d_f and d_e denote the dimensionality of the monolingual embedding spaces, we use the set of crowdsourced translations that are not in the test set as our seed bilingual translations[4] and learn a mapping function $\mathbf{W} \in \mathbb{R}^{d_E \times d_F}$ that maps the target language vectors in the seed translations to their corresponding source language vectors.[5]

We learn two types of mapping: linear and non-linear, and compare their performances. The linear mapping (Mikolov et al., 2013a; Dinu et al., 2014) minimizes: $||\mathbf{X_E W} - \mathbf{X_F}||_F^2$ where, following the notation in (Vulić and Korhonen, 2016), $\mathbf{X_E}$ and $\mathbf{X_F}$ are matrices obtained by respective concatenation of target language and source language vectors that are in the seed bilingual translations. We solve this optimization problem using stochastic gradient descent (SGD).

We also consider a non-linear mapping (Socher et al., 2013) using a simple four-layer neural network, $\mathbf{W}$ = ($\phi^{(1)}$, $\phi^{(2)}$, $\phi^{(3)}$, $\phi^{(4)}$) that is trained to minimize:

$$\sum_{\mathbf{x}_f \in \mathbf{X_F}} \sum_{\mathbf{x}_e \in \mathbf{X_E}} ||\mathbf{x}_f - \phi^{(4)} s(\phi^{(3)} s(\phi^{(2)} s(\phi^{(1)} \mathbf{x}_e)))||^2$$

where $\phi^{(1)} \in \mathbb{R}^{h_1 \times d_E}$, $\phi^{(2)} \in \mathbb{R}^{h_2 \times h_1}$, $\phi^{(3)} \in \mathbb{R}^{h_3 \times h_2}$, $\phi^{(4)} \in \mathbb{R}^{d_F \times h_3}$, h_n is the size of the hidden layer, and $s = \tanh$ is the chosen non-linear function.

Once the map $\mathbf{W}$ is learned, all candidate target word vectors $\mathbf{x}_e$ can be mapped into the source language embedding space $\mathbb{R}^{d_F}$ by computing $\mathbf{x}_e^T \mathbf{W}$. Instead of the raw monolingual word embeddings $\mathbf{x}_e$, we use these bilingually-informed mapped word vectors $\mathbf{x}_e^T \mathbf{W}$ as the auxiliary word features **WORD-AUX** to estimate $\hat{x}_{e,f}^{\mathrm{AUX}}$.

Visual Representations Pilot Study Recent work (Vulić et al., 2016) has shown that combining word embeddings and visual representations of words can help achieve more accurate bilingual translations. Since the visual representation of a word seems to be language-independent (e.g. the concept of *water* has similar images whether expressed in English or French (Figure 4), the visual representations of a word may be useful for inferring its translation and for complementing the information learned in text.

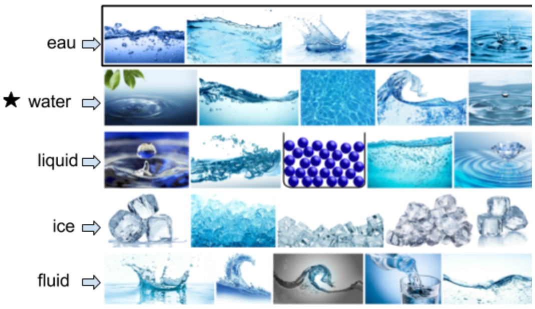

Figure 4: Five images for the French word *eau* and its top 4 translations ranked using visual similarities of images associated with English words (Bergsma and Van Durme, 2011)

We performed a pilot study to include visual features as auxiliary features in our framework. We use a large multilingual corpus of labeled images (Callahan, 2017) to obtain the visual representation of the words in our source and target languages. The corpus contains 100 images for up to 10k words in each of 100 foreign languages, plus images of each of their translations into English. For each of the images, a convolutional neural network (CNN) feature vector is also provided following the method of Kiela et al. (2015). For each word, we use 10 images provided by this corpus and use their CNN features as auxiliary visual features **VISUAL-AUX** to estimate $\hat{x}_{e,f}^{\mathrm{AUX}}$.

4.1.4 Combining Signals

During training, we trained the parameters of $\hat{x}_{e,f}^{\mathrm{MF}}$ and $\hat{x}_{e,f}^{\mathrm{AUX}}$ using a variety of signals:

- $\hat{x}_{e,f}^{\mathrm{MF-W}}$ is trained using **WIKI** translations as the set of observed translations T
- $\hat{x}_{e,f}^{\mathrm{MF-W+C}}$ is trained using **WIKI+CROWD** translations as the set of observed T
- $\hat{x}_{e,f}^{\mathrm{AUX-WE}}$ is trained using the set of word identities $T^{identity}$ and **WORD-AUX** as θ_f
- $\hat{x}_{e,f}^{\mathrm{AUX-VIS}}$ is trained using the set of word identities $T^{identity}$ and **VISUAL-AUX** as θ_f

During testing, we use the following back-off scheme to predict translation scores given a source word f and a candidate target word e:

[4] On average, there are 9846 crowdsourced translations per language that we can use as seed translations.

[5] We find that mapping from target to source vectors gives better performances across models in our experiments.

$$\hat{x}_{e,f} = \begin{cases} \hat{x}^{\mathrm{MF-W}}_{e,f} & \text{if } f \text{ has } \geq 1 \text{ associated } \texttt{WIKI}, \\ \hat{x}^{\mathrm{MF-W+C}}_{e,f} & \text{else if } f \text{ has } \geq 2 \\ & \quad \text{associated } \texttt{WIKI+CROWD}, \\ \hat{x}^{\mathrm{AUX}}_{e,f} & \text{otherwise} \end{cases}$$

where $\hat{x}^{\mathrm{AUX}}_{e,f} = \alpha_{\mathrm{we}}\, \hat{x}^{\mathrm{AUX-WE}}_{e,f} + \alpha_{\mathrm{vis}}\, \hat{x}^{\mathrm{AUX-VIS}}_{e,f}$

4.2 Results

We conduct experiments using the following variants of our model, each of which progressively incorporates more signals to rank candidate English target words. When a variant uses more than one formulation of $\hat{x}_{e,f}$, it applies them using the backoff scheme that we have described before.

- **BPR_W** uses *only* $\hat{x}^{\mathrm{MF-W}}_{e,f}$
- **BPR_W+C** uses $\hat{x}^{\mathrm{MF-W}}_{e,f}$ and $\hat{x}^{\mathrm{MF-W+C}}_{e,f}$
- **BPR_LN** uses *only* $\hat{x}^{\mathrm{AUX-WE}}_{e,f}$ with linear mapping
- **BPR_NN** uses *only* $\hat{x}^{\mathrm{AUX-WE}}_{e,f}$ with neural network (NN) mapping
- **BPR_WE** uses $\hat{x}^{\mathrm{MF-W}}_{e,f}$, $\hat{x}^{\mathrm{MF-W+C}}_{e,f}$, and $\hat{x}^{\mathrm{AUX-WE}}_{e,f}$ with NN mapping
- **BPR_VIS** adds $\hat{x}^{\mathrm{AUX-VIS}}_{e,f}$ to **BPR_WE**

Table 1: Acc_{10} performance on **VULIC1000**

	Baseline (MNN)	**BPR+MNN**	**BPR_LN**	**BPR_WE**
IT-EN	78.8%	79.4%	81.3%	86.0%
ES-EN	81.8%	82.1%	83.4%	87.1%
NL-EN	80.8%	81.6%	83.2%	87.2%

We evaluate the performance of **BPR_WE** against a baseline that is the state-of-the-art model of Vulić and Korhonen (2016), on benchmark **VULIC1000** (Table 1). The baseline (**MNN**) learns a linear mapping between monolingual embedding spaces and finds translations in an *unsupervised* manner: it ranks candidate target words based on their cosine similarities to the source word in the mapped space. As seed translation pairs, **MNN** uses mutual nearest neighbor pairs (MNN) obtained from *pseudo-bilingual* corpora constructed from unannotated monolingual data of the source and target languages (Vulic and Moens, 2016). We train **MNN** and our models using the same 100-dimensional `word2vec` monolingual word embeddings.

As seen in Table 1, we see the benefit of learning translations in a supervised manner. **BPR+MNN** uses the same MNN seed translations as **MNN**, obtained from unannotated monolingual data of English and the foreign language, to learn the linear mapping between their embedding spaces. However, unlike **MNN**, **BPR+MNN** uses the mapped word vectors to predict ranking in a *supervised* manner with BPR objective. This results in higher accuracies than **MNN**. Using seed translations from crowdsourced dictionaries to learn the linear mapping (**BPR_LN**) improves accuracies even further compared to using MNN seed translations obtained from unannotated data. Finally, **BPR_WE** that learns translations in a supervised manner and uses third language translations and non-linear mapping (trained with crowdsourced translations not in the test set) performs consistently and very significantly better than the state-of-the-art on all benchmark test sets. This shows that incorporating more and better signals of translation can improve performance significantly.

Evaluating on **CROWDTEST**, we observe a similar trend over all 27 languages (Figure 5). Particularly, we see that **BPR_W** and **BPR_W+C** suffer from the *cold* start issue where there are too few or no observed translations in the matrix to make accurate predictions. Incorporating auxiliary information in the form of bilingually-informed word embeddings improves the accuracy of the predictions dramatically. For many languages, learning these bilingually-informed word embeddings with non-linear mapping improves accuracy even more. The top accuracy scores achieved by the model vary across languages and seem to be influenced by the amount of data i.e., Wikipedia tokens and seed lexicons entries available for training. Somali (`so`) for example, has only 0.9 million tokens available in its Wikipedia for training the `word2vec` embeddings and only 3 thousand seed translations for learning the mapping between the word embedding spaces. In comparison, Spanish (`es`) has over 500 million tokens available in its Wikipedia and 11 thousand seed translations. We also believe that our choice of tokenization may not be suitable for some languages – we use a simple regular-expression based tokenizer for many languages that do not have a trained NLTK[6] tokenization model. This may influence performance on languages such as Vietnamese (`vi`) on which we have a low performance despite its large Wikipedia corpus.

Figure 5: Acc_{10} on **CROWDTEST** across all 27 languages show that adding more and better signals for translation improves translation accuracies. The top accuracies achieved by our model: **BPR_WE** vary across languages and appear to be influenced by the amount of data (Wikipedia tokens and seed translations) and tokenization available for the language.

Table 2: Top-5 translations of the Indonesian word *kesadaran* (*awareness*) using different model variants

BPR_W	**BPR_LN**	**BPR_NN**	**BPR_WE**
kesadaran	*kesadaran*	*kesadaran*	*kesadaran*
consciousness	consciousness	consciousness	conscience
goddess	*awareness*	empathy	*awareness*
friendship	empathy	*awareness*	understanding
night	perception	perceptions	consciousness
nation	mindedness	perception	acquaintance

Some example translations of an Indonesian word produced by different variants of our model are shown in Table 2. Adding third language translation signals on top of the bilingually-informed auxiliary signals improves accuracies even further.[7] The accuracies achieved by **BPR_WE** on these languages are significantly better than previously reported accuracies (Irvine and Callison-Burch, 2017) on test sets constructed from the same crowdsourced dictionaries (Pavlick et al., 2014)[8].

The accuracies across languages appear to improve consistently with the amount of signals being input to the model. In the following experiments, we investigate how sensitive these improvements are with varying training size.

In Figure 6, we show accuracies obtained by **BPR_WE** with varying sizes of seed translation lexicons used to train its mapping. The results show that a seed lexicon size of 5K is enough across languages to achieve optimum performance. This finding is consistent with the finding of Vulić and Korhonen (2016) that accuracies peak at about 5K seed translations across all their models and languages. For future work, it will be interesting to investigate further why this is the case: e.g., how optimal seed size is related to the quality of the seed translations and the size of the test set, and how the optimum seed size should be chosen. Lastly, we experiment with incorporating auxiliary visual signals for learning translations on the multilingual image corpus (Callahan, 2017). The corpus contains 100 images for up to 10K words in each of 100 foreign languages, plus images of each of their translations into English. We train and test our **BPR_VIS** model to learn translations of 5 low- and high-resource languages in this corpus. We use the translations of up to 10K words in each of these languages as test set and use up to

[7] Actual improvement per language depends on the coverage of the Wikipedia interlanguage links for that language

[8] The comparison however, cannot be made apples-to-apples since the way Irvine and Callison-Burch (2017) select test sets from the crowdsourced dictionaries maybe different and they do not release the test sets

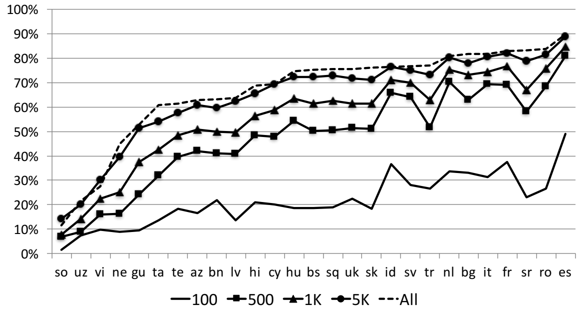

Figure 6: Acc_{10} across different seed lexicon sizes

Table 3: Acc_{10} performance on the multilingual image corpus test set (Callahan, 2017)

	Baseline (CNN-AvgMax)	BPR_VIS	# Seeds
IT-EN	31.4%	55.8%	581
ES-EN	33.0%	58.3%	488
NL-EN	35.5%	69.2%	1857
FR-EN	37.1%	65.9%	1697
ID-EN	36.9%	45.3%	462

10 images (CNN features) of the words in this set as auxiliary visual signals to predict their translations. In this experiment, we weigh auxiliary word embedding and visual features equally. To train the mapping of our word embedding features, we use as seeds crowdsourced translations not in test set.

We compare the quality of our translations with the baseline CNN-AvgMax (Bergsma and Van Durme, 2011), which considers cosine similarities between individual images from the source and target word languages and takes average of their maximum similarities as the final similarity between a source and a target word. For each source word, the candidate target words are ranked according to these final similarities. This baseline has been shown to be effective for inducing translations from images, both in the uni-modal (Bergsma and Van Durme, 2011; Kiela et al., 2015) and multi-modal models (Vulić et al., 2016).

As seen in Table 3, incorporating additional bilingual and textual signals to the visual signals improves translations. Accuracies on these image corpus' test sets are lower overall as they contain a lot of translations from our crowdsourced dictionaries; thus we have much less seeds to train our word embedding mapping. Furthermore, these test sets contain 10 times as many translations as our previous test sets. Using more images instead of just 10 per word may also improve performance.

5 Conclusion

In this paper, we propose a novel framework for combining diverse, sparse and potentially noisy multi-modal signals for translations. We view the problem of learning translations as a matrix completion task and use an effective and extendable matrix factorization approach with BPR to learn translations.

We show the effectiveness of our approach in large scale experiments. Starting from minimally-trained monolingual word embeddings, we consistently and very significantly outperform state-of-the-art approaches by combining these features with other features in a supervised manner using BPR. Since our framework is modular, each input to our prediction can be improved separately to improve the whole system e.g., by learning better word embeddings or a better mapping function to input into the auxiliary component. Our framework is also easily extendable to incorporate more bilingual and auxiliary signals of translation equivalence.

Abstract

Machine translation is a natural candidate problem for reinforcement learning from human feedback: users provide quick, dirty ratings on candidate translations to guide a system to improve. Yet, current neural machine translation training focuses on expensive human-generated reference translations. We describe a reinforcement learning algorithm that improves neural machine translation systems from simulated human feedback. Our algorithm combines the advantage actor-critic algorithm (Mnih et al., 2016) with the attention-based neural encoder-decoder architecture (Luong et al., 2015). This algorithm (a) is well-designed for problems with a large action space and delayed rewards, (b) effectively optimizes traditional corpus-level machine translation metrics, and (c) is robust to skewed, high-variance, granular feedback modeled after actual human behaviors.

1 Introduction

Bandit structured prediction is the task of learning to solve complex joint prediction problems (like parsing or machine translation) under a very limited feedback model: a system must produce a *single* structured output (e.g., translation) and then the world reveals a *score* that measures how good or bad that output is, but provides neither a "correct" output nor feedback on any other possible output (Chang et al., 2015; Sokolov et al., 2015). Because of the extreme sparsity of this feedback, a common experimental setup is that one pre-trains a good-but-not-great "reference" system based on whatever labeled data is available, and then seeks to improve it over time using this bandit feedback. A common motivation for this problem setting is cost. In the case of translation, bilingual "experts" can read a source sentence and a possible translation, and can much more quickly provide a rating of that translation than they can produce a full translation on their own. Furthermore, one can often collect even less expensive ratings from "non-experts" who may or may not be bilingual (Hu et al., 2014). Breaking this reliance on expensive data could unlock previously ignored languages and speed development of broad-coverage machine translation systems.

All work on bandit structured prediction we know makes an important simplifying assumption: the *score* provided by the world is *exactly* the score the system must optimize (§2). In the case of parsing, the score is attachment score; in the case of machine translation, the score is (sentence-level) BLEU. While this simplifying assumption has been incredibly useful in building algorithms, it is highly unrealistic. Any time we want to optimize a system by collecting user feedback, we must take into account:

1. The metric we care about (e.g., expert ratings) may not correlate perfectly with the measure that the reference system was trained on (e.g., BLEU or log likelihood);
2. Human judgments might be more granular than traditional continuous metrics (e.g., thumbs up vs. thumbs down);
3. Human feedback have high *variance* (e.g., different raters might give different responses given the same system output);
4. Human feedback might be substantially *skewed* (e.g., a rater may think all system outputs are poor).

Our first contribution is a strategy to simulate expert and non-expert ratings to evaluate the robustness of bandit structured prediction algorithms in general, in a more realistic environment (§4). We

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1464–1474
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

construct a family of perturbations to capture three attributes: *granularity*, *variance*, and *skew*. We apply these perturbations on automatically generated scores to simulate noisy human ratings. To make our simulated ratings as realistic as possible, we study recent human evaluation data (Graham et al., 2017) and fit models to match the noise profiles in actual human ratings (§4.2).

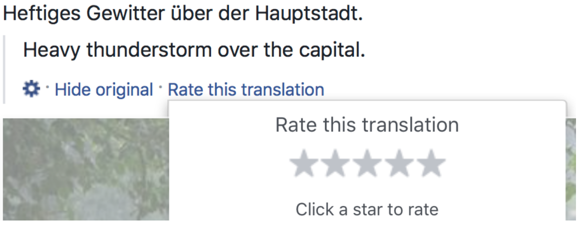
Our second contribution is a reinforcement learning solution to bandit structured prediction and a study of its robustness to these simulated human ratings (§ 3).[1] We combine an encoder-decoder architecture of machine translation (Luong et al., 2015) with the advantage actor-critic algorithm (Mnih et al., 2016), yielding an approach that is simple to implement but works on low-resource bandit machine translation. Even with substantially restricted granularity, with high variance feedback, or with skewed rewards, this combination improves pre-trained models (§6). In particular, under realistic settings of our noise parameters, the algorithm's online reward and final held-out accuracies do not significantly degrade from a noise-free setting.

2 Bandit Machine Translation

The bandit structured prediction problem (Chang et al., 2015; Sokolov et al., 2015) is an extension of the contextual bandits problem (Kakade et al., 2008; Langford and Zhang, 2008) to structured prediction. Bandit structured prediction operates over time $i = 1 \dots K$ as:

1. World reveals context $\boldsymbol{x}^{(i)}$
2. Algorithm predicts structured output $\hat{\boldsymbol{y}}^{(i)}$
3. World reveals reward $R\left(\hat{\boldsymbol{y}}^{(i)}, \boldsymbol{x}^{(i)}\right)$

We consider the problem of *learning to translate from human ratings* in a bandit structured prediction framework. In each round, a translation model receives a source sentence $\boldsymbol{x}^{(i)}$, produces a translation $\hat{\boldsymbol{y}}^{(i)}$, and receives a rating $R\left(\hat{\boldsymbol{y}}^{(i)}, \boldsymbol{x}^{(i)}\right)$ from a human that reflects the quality of the translation. We seek an algorithm that achieves high reward over K rounds (high cumulative reward). The challenge is that even though the model knows how good the translation is, it knows neither *where* its mistakes are nor *what* the "correct" translation looks like. It must balance exploration (finding new good predictions) with exploitation (producing predictions it already knows are good). This is especially difficult in a task like machine translation, where, for a twenty token sentence with a vocabulary size of $50k$, there are approximately 10^{94} possible outputs, of which the algorithm gets to test exactly one.



Heftiges Gewitter über der Hauptstadt.

Heavy thunderstorm over the capital.

Figure 1: A translation rating interface provided by Facebook. Users see a sentence followed by its machined-generated translation and can give ratings from one to five stars.

Despite these challenges, learning from non-expert ratings is desirable. In real-world scenarios, non-expert ratings are easy to collect but other stronger forms of feedback are prohibitively expensive. Platforms that offer translations can get quick feedback "for free" from their users to improve their systems (Figure 1). Even in a setting in which annotators are paid, it is much less expensive to ask a bilingual speaker to provide a rating of a proposed translation than it is to pay a professional translator to produce one from scratch.

3 Effective Algorithm for Bandit MT

This section describes the neural machine translation architecture of our system (§ 3.1). We formulate bandit neural machine translation as a reinforcement learning problem (§ 3.2) and discuss why standard actor-critic algorithms struggle with this problem (§ 3.3). Finally, we describe a more effective training approach based on the advantage actor-critic algorithm (§3.4).

3.1 Neural machine translation

Our neural machine translation (NMT) model is a neural encoder-decoder that directly computes the probability of translating a target sentence $\boldsymbol{y} = (y_1, \cdots, y_m)$ from source sentence $\boldsymbol{x}$:

$$P_{\boldsymbol{\theta}}(\boldsymbol{y} \mid \boldsymbol{x}) = \prod_{t=1}^{m} P_{\boldsymbol{\theta}}(y_t \mid \boldsymbol{y}_{<t}, \boldsymbol{x}) \qquad (1)$$

where $P_{\boldsymbol{\theta}}(y_t \mid \boldsymbol{y}_{<t}, \boldsymbol{x})$ is the probability of outputting the next word y_t at time step t given a translation prefix $\boldsymbol{y}_{<t}$ and a source sentence $\boldsymbol{x}$.

[1] Our code is at https://github.com/khanhptnk/bandit-nmt (in PyTorch).

We use an encoder-decoder NMT architecture with global attention (Luong et al., 2015), where both the encoder and decoder are recurrent neural networks (RNN) (see Appendix A for a more detailed description). These models are normally trained by supervised learning, but as reference translations are not available in our setting, we use reinforcement learning methods, which only require numerical feedback to function.

3.2 Bandit NMT as Reinforcement Learning

NMT generating process can be viewed as a Markov decision process on a continuous state space. The states are the hidden vectors $\boldsymbol{h}_t^{dec}$ generated by the decoder. The action space is the target language's vocabulary.

To generate a translation from a source sentence $\boldsymbol{x}$, an NMT model starts at an initial state $\boldsymbol{h}_0^{dec}$: a representation of $\boldsymbol{x}$ computed by the encoder. At time step t, the model decides the next action to take by defining a stochastic policy $P_{\boldsymbol{\theta}}(y_t \mid \boldsymbol{y}_{<t}, \boldsymbol{x})$, which is directly parametrized by the parameters $\boldsymbol{\theta}$ of the model. This policy takes the current state $\boldsymbol{h}_{t-1}^{dec}$ as input and produces a probability distribution over all actions (target vocabulary words). The next action $\hat{y}_t$ is chosen by taking $\arg\max$ or sampling from this distribution. The model computes the next state $\boldsymbol{h}_t^{dec}$ by updating the current state $\boldsymbol{h}_{t-1}^{dec}$ by the action taken $\hat{y}_t$.

The objective of bandit NMT is to find a policy that maximizes the expected reward of translations sampled from the model's policy:

$$\max_{\boldsymbol{\theta}} \mathcal{L}_{pg}(\boldsymbol{\theta}) = \max_{\boldsymbol{\theta}} \mathbb{E}_{\substack{\boldsymbol{x}\sim D_{\text{tr}} \\ \hat{\boldsymbol{y}}\sim P_{\boldsymbol{\theta}}(\cdot|\boldsymbol{x})}} \left[R(\hat{\boldsymbol{y}}, \boldsymbol{x}) \right] \tag{2}$$

where D_{tr} is the training set and R is the reward function (the rater).[2] We optimize this objective function with policy gradient methods. For a fixed $\boldsymbol{x}$, the gradient of the objective in Eq 2 is:

$$\nabla_{\boldsymbol{\theta}} \mathcal{L}_{pg}(\boldsymbol{\theta}) = \mathbb{E}_{\hat{\boldsymbol{y}}\sim P_{\boldsymbol{\theta}}(\cdot)} \left[R(\hat{\boldsymbol{y}}) \nabla_{\boldsymbol{\theta}} \log P_{\boldsymbol{\theta}}(\hat{\boldsymbol{y}}) \right] \tag{3}$$

$$= \sum_{t=1}^{m} \mathbb{E}_{\substack{\hat{y}_t\sim \\ P_{\boldsymbol{\theta}}(\cdot|\hat{\boldsymbol{y}}_{<t})}} \left[Q(\hat{\boldsymbol{y}}_{<t}, \hat{y}_t) \nabla_{\boldsymbol{\theta}} \log P_{\boldsymbol{\theta}}(\hat{y}_t \mid \hat{\boldsymbol{y}}_{<t}) \right]$$

where $Q(\hat{\boldsymbol{y}}_{<t}, \hat{y}_t)$ is the expected future reward of $\hat{y}_t$ given the current prefix $\hat{\boldsymbol{y}}_{<t}$, then continuing sampling from $P_{\boldsymbol{\theta}}$ to complete the translation:

$$Q(\hat{\boldsymbol{y}}_{<t}, \hat{y}_t) = \mathbb{E}_{\hat{\boldsymbol{y}}'\sim P_{\boldsymbol{\theta}}(\cdot|\boldsymbol{x})} \left[\tilde{R}(\hat{\boldsymbol{y}}', \boldsymbol{x}) \right] \tag{4}$$

with $\tilde{R}(\hat{\boldsymbol{y}}', \boldsymbol{x}) \equiv R(\hat{\boldsymbol{y}}', \boldsymbol{x}) \mathbb{1}\left\{ \hat{\boldsymbol{y}}'_{<t} = \hat{\boldsymbol{y}}_{<t}, \hat{y}'_t = \hat{y}_t \right\}$ $\mathbb{1}\{\cdot\}$ is the indicator function, which returns 1 if the logic inside the bracket is true and returns 0 otherwise.

The gradient in Eq 3 requires rating all possible translations, which is not feasible in bandit NMT. Naïve Monte Carlo reinforcement learning methods such as REINFORCE (Williams, 1992) estimates Q values by sample means but yields very high variance when the action space is large, leading to training instability.

3.3 Why are actor-critic algorithms not effective for bandit NMT?

Reinforcement learning methods that rely on function approximation are preferred when tackling bandit structured prediction with a large action space because they can capture similarities between structures and generalize to unseen regions of the structure space. The actor-critic algorithm (Konda and Tsitsiklis) uses function approximation to directly model the Q function, called the *critic* model. In our early attempts on bandit NMT, we adapted the actor-critic algorithm for NMT in Bahdanau et al. (2017), which employs the algorithm in a supervised learning setting. Specifically, while an encoder-decoder critic model $Q_{\boldsymbol{\omega}}$ as a substitute for the true Q function in Eq 3 enables taking the full expectation (because the critic model can be queried with any state-action pair), we are unable to obtain reasonable results with this approach.

Nevertheless, insights into why this approach fails on our problem explains the effectiveness of the approach discussed in the next section. There are two properties in Bahdanau et al. (2017) that our problem lacks but are key elements for a successful actor-critic. The first is access to reference translations: while the critic model is able to observe reference translations during training in their setting, bandit NMT assumes those are never available. The second is per-step rewards: while the reward function in their setting is known and can be exploited to compute immediate rewards after taking each action, in bandit NMT, the actor-critic algorithm struggles with credit assignment because it only receives reward when a translation is completed. Bahdanau et al. (2017) report that the algorithm degrades if rewards are delayed until the end, consistent with our observations.

With an enormous action space of bandit NMT, approximating gradients with the Q critic model

[2] Our raters are *stochastic*, but for simplicity we denote the reward as a function; it should be expected reward.

induces biases and potentially drives the model to wrong optima. Values of rarely taken actions are often overestimated without an explicit constraint between Q values of actions (e.g., a sum-to-one constraint). Bahdanau et al. (2017) add an ad-hoc regularization term to the loss function to mitigate this issue and further stablizes the algorithm with a delay update scheme, but at the same time introduces extra tuning hyper-parameters.

3.4 Advantage Actor-Critic for Bandit NMT

We follow the approach of advantage actor-critic (Mnih et al., 2016, A2C) and combine it with the neural encoder-decoder architecture. The resulting algorithm—which we call NED-A2C—approximates the gradient in Eq 3 by a single sample $\hat{\boldsymbol{y}} \sim P(\cdot \mid \hat{\boldsymbol{x}})$ and centers the reward $R(\hat{\boldsymbol{y}})$ using the state-specific expected future reward $V(\hat{\boldsymbol{y}}_{<t})$ to reduce variance:

$$\nabla_{\boldsymbol{\theta}} \mathcal{L}_{pg}(\boldsymbol{\theta}) \approx \sum_{t=1}^{m} \bar{R}_t(\hat{\boldsymbol{y}}) \nabla_{\boldsymbol{\theta}} \log P_{\boldsymbol{\theta}}(\hat{y}_t \mid \hat{\boldsymbol{y}}_{<t}) \tag{5}$$

$$\begin{aligned} \text{with } \bar{R}_t(\hat{\boldsymbol{y}}) &\equiv R(\hat{\boldsymbol{y}}) - V(\hat{\boldsymbol{y}}_{<t}) \\ V(\hat{\boldsymbol{y}}_{<t}) &\equiv \mathbb{E}_{\hat{y}'_t \sim P(\cdot \mid \hat{\boldsymbol{y}}_{<t})} \left[Q(\hat{\boldsymbol{y}}_{<t}, \hat{y}'_t) \right] \end{aligned}$$

We train a separate attention-based encoder-decoder model $V_{\boldsymbol{\omega}}$ to estimate V values. This model encodes a source sentence $\boldsymbol{x}$ and decodes a sampled translation $\hat{\boldsymbol{y}}$. At time step t, it computes $V_{\boldsymbol{\omega}}(\hat{\boldsymbol{y}}_{<t}, \boldsymbol{x}) = \boldsymbol{w}^\top \boldsymbol{h}_t^{crt}$, where $\boldsymbol{h}_t^{crt}$ is the current decoder's hidden vector and $\boldsymbol{w}$ is a learned weight vector. The critic model minimizes the MSE between its estimates and the true values:

$$\mathcal{L}_{crt}(\boldsymbol{\omega}) = \mathbb{E}_{\substack{\boldsymbol{x} \sim D_{\text{tr}} \\ \hat{\boldsymbol{y}} \sim P_{\boldsymbol{\theta}}(\cdot \mid \boldsymbol{x})}} \left[\sum_{t=1}^{m} L_t(\hat{\boldsymbol{y}}, \boldsymbol{x}) \right] \tag{6}$$

$$\text{with } L_t(\hat{\boldsymbol{y}}, \boldsymbol{x}) \equiv \left[V_{\boldsymbol{\omega}}(\hat{\boldsymbol{y}}_{<t}, \boldsymbol{x}) - R(\hat{\boldsymbol{y}}, \boldsymbol{x}) \right]^2 .$$

We use a gradient approximation to update $\boldsymbol{\omega}$ for a fixed $\boldsymbol{x}$ and $\hat{\boldsymbol{y}} \sim P(\cdot \mid \hat{\boldsymbol{x}})$:

$$\nabla_{\boldsymbol{\omega}} \mathcal{L}_{crt}(\boldsymbol{\omega}) \approx \sum_{t=1}^{m} \left[V_{\boldsymbol{\omega}}(\hat{\boldsymbol{y}}_{<t}) - R(\hat{\boldsymbol{y}}) \right] \nabla_{\boldsymbol{\omega}} V_{\boldsymbol{\omega}}(\hat{\boldsymbol{y}}_{<t}) \tag{7}$$

NED-A2C is better suited for problems with a large action space and has other advantages over actor-critic. For large action spaces, approximating gradients using the V critic model induces lower biases than using the Q critic model. As implied by its definition, the V model is robust to biases incurred by rarely taken actions since rewards of those actions are weighted by very small probabilities in the expectation. In addition, the V model has a much smaller number of parameters and thus is more sample-efficient and more stable to train than the Q model. These attractive properties were not studied in A2C's original paper (Mnih et al., 2016).

Algorithm 1 The NED-A2C algorithm for bandit NMT.

```
for $i = 1 \cdots K$ do
    receive a source sentence $\boldsymbol{x}^{(i)}$
    sample a translation: $\hat{\boldsymbol{y}}^{(i)} \sim P_{\boldsymbol{\theta}}(\cdot \mid \boldsymbol{x}^{(i)})$
    receive reward $R(\hat{\boldsymbol{y}}^{(i)}, \boldsymbol{x}^{(i)})$
    update the NMT model using Eq 5.
    update the critic model using Eq 7.
end for
```

Algorithm 1 summarizes NED-A2C for bandit NMT. For each $\boldsymbol{x}$, we draw a single sample $\hat{\boldsymbol{y}}$ from the NMT model, which is used for both estimating gradients of the NMT model and the critic model. We run this algorithm with mini-batches of $\boldsymbol{x}$ and aggregate gradients over all $\boldsymbol{x}$ in a mini-batch for each update. Although our focus is on bandit NMT, this algorithm naturally works with any bandit structured prediction problem.

4 Modeling Imperfect Ratings

Our goal is to establish the feasibility of using *real* human feedback to optimize a machine translation system, in a setting where one can collect *expert* feedback as well as a setting in which one only collects *non-expert* feedback. In all cases, we consider the expert feedback to be the "gold standard" that we wish to optimize. To establish the feasibility of driving learning from human feedback *without* doing a full, costly user study, we begin with a simulation study. The key aspects (Figure 2) of human feedback we capture are: (a) mismatch between training objective and feedback-maximizing objective, (b) human ratings typically are binned (§ 4.1), (c) individual human ratings have high variance (§4.2), and (d) non-expert ratings can be skewed with respect to expert ratings (§4.3).

In our simulated study, we begin by modeling gold standard human ratings using add-one-smoothed sentence-level BLEU (Chen and Cherry, 2014).[3] Our evaluation criteria, therefore, is average sentence-BLEU over the run of our algo-

[3] "Smoothing 2" in Chen and Cherry (2014).

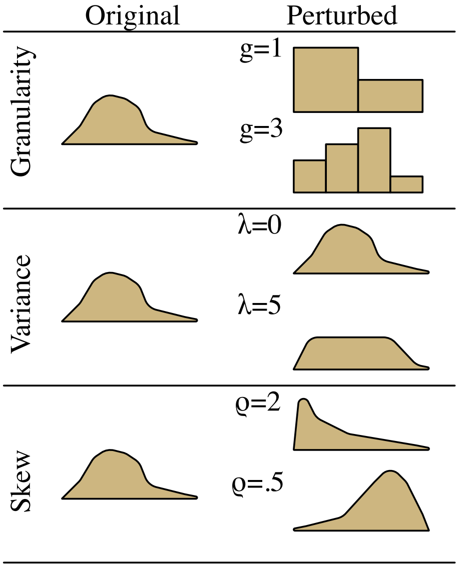


Figure 2: Examples of how our perturbation functions change the "true" feedback distribution (left) to ones that better capture features found in human feedback (right).

rithm. However, in any realistic scenario, human feedback will vary from its average, and so the reward that our algorithm receives will be a *perturbed* variant of sentence-BLEU. In particular, if the sentence-BLEU score is $s \in [0,1]$, the algorithm will only observe $s' \sim \text{pert}(s)$, where pert is a perturbation distribution. Because our reference machine translation system is pre-trained using log-likelihood, there is already an (a) mismatch between training objective and feedback, so we focus on (b-d) below.

4.1 Humans Provide Granular Feedback

When collecting human feedback, it is often more effective to collect discrete *binned* scores. A classic example is the Likert scale for human agreement (Likert, 1932) or star ratings for product reviews. Insisting that human judges provide continuous values (or feedback at too fine a granularity) can demotivate raters without improving rating quality (Preston and Colman, 2000).

To model granular feedback, we use a simple rounding procedure. Given an integer parameter g for degree of granularity, we define:

$$\text{pert}^{\text{gran}}(s; g) = \frac{1}{g}\text{round}(gs) \qquad (8)$$

This perturbation function divides the range of possible outputs into $g + 1$ bins. For example, for $g = 5$, we obtain bins $[0, 0.1)$, $[0.1, 0.3)$, $[0.3, 0.5)$, $[0.5, 0.7)$, $[0.7, 0.9)$ and $[0.9, 1.0]$. Since most sentence-BLEU scores are much closer to zero than to one, many of the larger bins are frequently vacant.

4.2 Experts Have High Variance

Human feedback has high variance around its expected value. A natural goal for a variance model of human annotators is to simulate—as closely as possible—how human raters actually perform. We use human evaluation data recently collected as part of the WMT shared task (Graham et al., 2017). The data consist of 7200 sentences multiply annotated by giving non-expert annotators on Amazon Mechanical Turk a reference sentence and a *single* system translation, and asking the raters to judge the adequacy of the translation.[4]

From these data, we treat the *average* human rating as the ground truth and consider how individual human ratings vary around that mean. To visualize these results with kernel density estimates (standard normal kernels) of the *standard deviation*. Figure 3 shows the mean rating (x-axis) and the deviation of the human ratings (y-axis) at each mean.[5] As expected, the standard deviation is small at the extremes and large in the middle (this is a bounded interval), with a fairly large range in the middle: a translation whose average score is 50 can get human evaluation scores anywhere between 20 and 80 with high probability. We use a linear approximation to define our variance-based perturbation function as a Gaussian distribution, which is parameterized by a scale λ that grows or shrinks the variances (when $\lambda = 1$ this exactly matches the variance in the plot).

$$\text{pert}^{\text{var}}(s; \lambda) = \text{Nor}\left(s, \lambda\sigma(s)^2\right) \qquad (9)$$

$$\sigma(s) = \begin{cases} 0.64s - 0.02 & \text{if } s < 50 \\ -0.67s + 67.0 & \text{otherwise} \end{cases}$$

4.3 Non-Experts are Skewed from Experts

The preceding two noise models assume that the reward closely models the value we want to optimize (has the same mean). This may not be the case with non-expert ratings. Non-expert

[4] Typical machine translation evaluations evaluate pairs and ask annotators to choose which is better.

[5] A current limitation of this model is that the simulated noise is i.i.d. conditioned on the rating (homoscedastic noise). While this is a stronger and more realistic model than assuming no noise, real noise is likely heteroscedastic: dependent on the input.

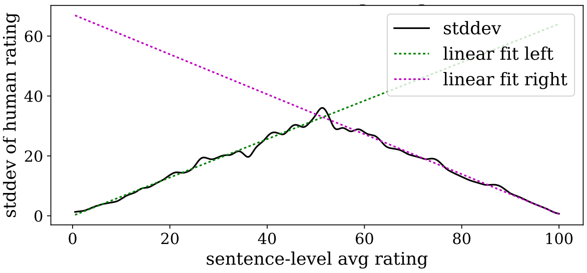

Figure 3: Average rating (x-axis) versus a kernel density estimate of the variance of human ratings around that mean, with linear fits. Human scores vary more around middling judgments than extreme judgments.

	De-En	Zh-En
Supervised training	186K	190K
Bandit training	167K	165K
Development	7.7K	7.9K
Test	9.1K	7.4K

Table 1: Sentence counts in data sets.

raters are skewed both for reinforcement learning (Thomaz et al., 2006; Thomaz and Breazeal, 2008; Loftin et al., 2014) and recommender systems (Herlocker et al., 2000; Adomavicius and Zhang, 2012), but are typically bimodal: some are harsh (typically provide very low scores, even for "okay" outputs) and some are motivational (providing high scores for "okay" outputs).

We can model both harsh and motivations raters with a simple deterministic skew perturbation function, parametrized by a scalar $\rho \in [0, \infty)$:

$$\text{pert}^{\text{skew}}(s; \rho) = s^{\rho} \tag{10}$$

For $\rho > 1$, the rater is harsh; for $\rho < 1$, the rater is motivational.

5 Experimental Setup

We choose two language pairs from different language families with different typological properties: German-to-English and (De-En) and Chinese-to-English (Zh-En). We use parallel transcriptions of TED talks for these pairs of languages from the machine translation track of the IWSLT 2014 and 2015 (Cettolo et al., 2014, 2015, 2012). For each language pair, we split its data into four sets for supervised training, bandit training, development and testing (Table 1). For English and German, we tokenize and clean sentences using Moses (Koehn et al., 2007). For Chinese, we use the Stanford Chinese word segmenter (Chang et al., 2008) to segment sentences and tokenize. We remove all sentences with length greater than 50, resulting in an average sentence length of 18. We use IWSLT 2015 data for supervised training and development, IWSLT 2014 data for bandit training and previous years' development and evaluation data for testing.

5.1 Evaluation Framework

For each task, we first use the supervised training set to pre-train a reference NMT model using supervised learning. On the same training set, we also pre-train the critic model with translations sampled from the pre-trained NMT model. Next, we enter a bandit learning mode where our models only observe the source sentences of the bandit training set. Unless specified differently, we train the NMT models with NED-A2C for one pass over the bandit training set. If a perturbation function is applied to Per-Sentence BLEU scores, it is only applied in this stage, not in the pre-training stage.

We measure the *improvement* ΔS of an evaluation metric S due to bandit training: $\Delta S = S_{A2C} - S_{ref}$, where S_{ref} is the metric computed on the reference models and S_{A2C} is the metric computed on models trained with NED-A2C. Our primary interest is *Per-Sentence* BLEU: average sentence-level BLEU of translations that are sampled and scored during the bandit learning pass. This metric represents average expert ratings, which we want to optimize for in real-world scenarios. We also measure *Heldout* BLEU: corpus-level BLEU on an unseen test set, where translations are greedily decoded by the NMT models. This shows how much our method improves translation quality, since corpus-level BLEU correlates better with human judgments than sentence-level BLEU.

Because of randomness due to both the random sampling in the model for "exploration" as well as the randomness in the reward function, we repeat each experiment five times and report the mean results with 95% confidence intervals.

5.2 Model configuration

Both the NMT model and the critic model are encoder-decoder models with global attention (Luong et al., 2015). The encoder and the decoder are unidirectional single-layer LSTMs. They have the same word embedding size and

LSTM hidden size of 500. The source and target vocabulary sizes are both 50K. We do not use dropout in our experiments. We train our models by the Adam optimizer (Kingma and Ba, 2015) with $\beta_1 = 0.9, \beta_2 = 0.999$ and a batch size of 64. For Adam's α hyperparameter, we use 10^{-3} during pre-training and 10^{-4} during bandit learning (for both the NMT model and the critic model). During pre-training, starting from the fifth pass, we decay α by a factor of 0.5 when perplexity on the development set increases. The NMT model reaches its highest corpus-level BLEU on the development set after ten passes through the supervised training data, while the critic model's training error stabilizes after five passes. The training speed is 18s/batch for supervised pre-training and 41s/batch for training with the NED-A2C algorithm.

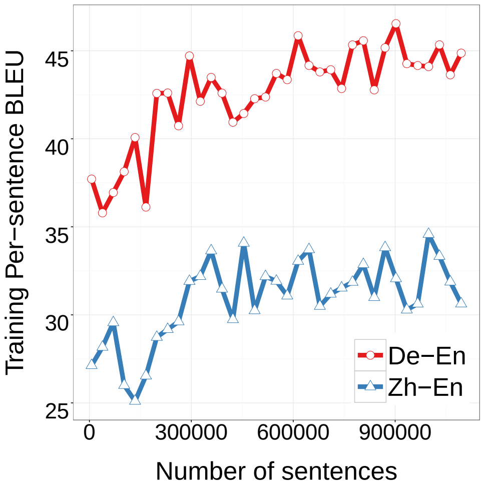

Figure 4: Learning curves of models trained with NED-A2C for five epochs.

6 Results and Analysis

In this section, we describe the results of our experiments, broken into the following questions: how NED-A2C improves reference models (§6.1); the effect the three perturbation functions have on the algorithm (§ 6.2); and whether the algorithm improves a corpus-level metric that corresponds well with human judgments (§6.3).

6.1 Effectiveness of NED-A2C under Un-perturbed Bandit Feedback

We evaluate our method in an ideal setting where *un-perturbed* Per-Sentence BLEU simulates ratings during both training and evaluation (Table 2).

Single round of feedback. In this setting, our models only observe each source sentence once and before producing its translation. On both De-En and Zh-En, NED-A2C improves Per-Sentence BLEU of reference models after only a single pass (+2.82 and +1.08 respectively).

Poor initialization. Policy gradient algorithms have difficulty improving from poor initializations, especially on problems with a large action space, because they use model-based exploration, which is ineffective when most actions have equal probabilities (Bahdanau et al., 2017; Ranzato et al., 2016). To see whether NED-A2C has this problem, we repeat the experiment with the same setup but with reference models pre-trained for only a single pass. Surprisingly, NED-A2C is highly effective at improving these poorly trained models (+7.07 on De-En and +3.60 on Zh-En in Per-Sentence BLEU).

Comparisons with supervised learning. To further demonstrate the effectiveness of NED-A2C, we compare it with training the reference models with supervised learning for a single pass on the bandit training set. Surprisingly, observing ground-truth translations barely improves the models in Per-Sentence BLEU when they are fully trained (less than +0.4 on both tasks). A possible explanation is that the models have already reached full capacity and do not benefit from more examples.[6] NED-A2C further enhances the models because it eliminates the mismatch between the supervised training objective and the evaluation objective. On weakly trained reference models, NED-A2C also significantly outperforms supervised learning (ΔPer-Sentence BLEU of NED-A2C is over three times as large as those of supervised learning).

Multiple rounds of feedback. We examine if NED-A2C can improve the models even further with multiple rounds of feedback.[7] With supervised learning, the models can memorize the reference translations but, in this case, the models have to be able to exploit and explore effectively. We train the models with NED-A2C for five

[6] This result may vary if the domains of the supervised learning set and the bandit training set are dissimilar. Our training data are all TED talks.

[7] The ability to receive feedback on the same example multiple times might not fit all use cases though.

	De-En			Zh-En		
	Reference	Δ_{sup}	Δ_{A2C}	Reference	Δ_{sup}	Δ_{A2C}

Table 2: Translation scores and improvements based on a single round of un-perturbed bandit feedback. Per-Sentence BLEU and Heldout BLEU are not comparable: the former is sentence-BLEU, the latter is corpus-BLEU.

passes and observe a much more significant ΔPer-Sentence BLEU than training for a single pass in both pairs of language (+6.73 on De-En and +4.56 on Zh-En) (Figure 4).

6.2 Effect of Perturbed Bandit Feedback

We apply perturbation functions defined in § 4.1 to Per-Sentence BLEU scores and use the perturbed scores as rewards during bandit training (Figure 5).

Granular Rewards. We discretize raw Per-Sentence BLEU scores using $\text{pert}^{gran}(s; g)$ (§4.1). We vary g from one to ten (number of bins varies from two to eleven). Compared to continuous rewards, for both pairs of languages, ΔPer-Sentence BLEU is not affected with g at least five (at least six bins). As granularity decreases, ΔPer-Sentence BLEU monotonically degrades. However, even when $g = 1$ (scores are either 0 or 1), the models still improve by at least a point.

High-variance Rewards. We simulate noisy rewards using the model of human rating variance $\text{pert}^{var}(s; \lambda)$ (§ 4.2) with $\lambda \in \{0.1, 0.2, 0.5, 1, 2, 5\}$. Our models can withstand an amount of about 20% the variance in our human eval data without dropping in ΔPer-Sentence BLEU. When the amount of variance attains 100%, matching the amount of variance in the human data, ΔPer-Sentence BLEU go down by about 30% for both pairs of languages. As more variance is injected, the models degrade quickly but still improve from the pre-trained models. Variance is the most detrimental type of perturbation to NED-A2C among the three aspects of human ratings we model.

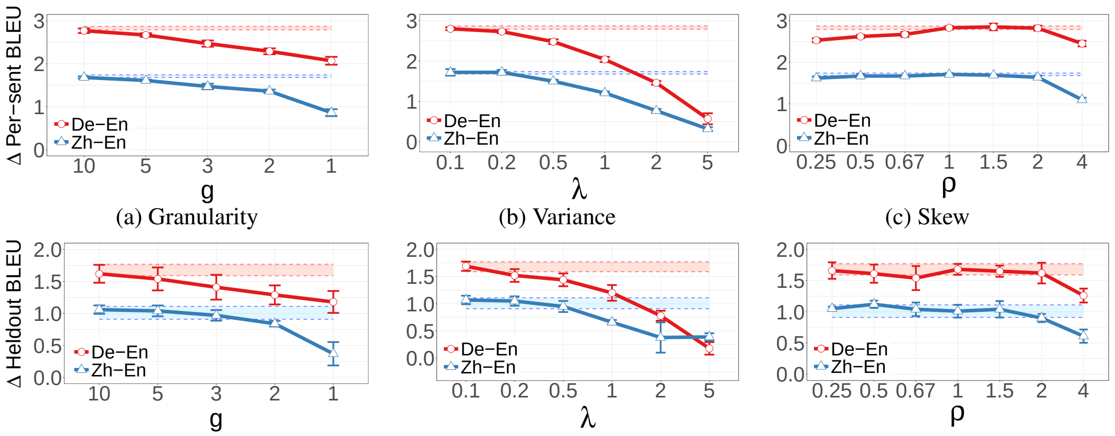
Skewed Rewards. We model skewed raters using $\text{pert}^{skew}(s; \rho)$ (§ 4.3) with $\rho \in \{0.25, 0.5, 0.67, 1, 1.5, 2, 4\}$. NED-A2C is robust to skewed scores. ΔPer-Sentence BLEU is at least 90% of unskewed scores for most skew values. Only when the scores are extremely harsh ($\rho = 4$) does ΔPer-Sentence BLEU degrade significantly (most dramatically by 35% on Zh-En). At that degree of skew, a score of 0.3 is suppressed to be less than 0.08, giving little signal for the models to learn from. On the other spectrum, the models are less sensitive to motivating scores as Per-Sentence BLEU is unaffected on Zh-En and only decreases by 7% on De-En.

6.3 Held-out Translation Quality

Our method also improves pre-trained models in Heldout BLEU, a metric that correlates with translation quality better than Per-Sentence BLEU (Table 2). When scores are perturbed by our rating model, we observe similar patterns as with Per-Sentence BLEU: the models are robust to most perturbations except when scores are very coarse, or very harsh, or have very high variance (Figure 5, second row). Supervised learning improves Heldout BLEU better, possibly because maximizing log-likelihood of reference translations correlates more strongly with maximizing Heldout BLEU of predicted translations than maximizing Per-Sentence BLEU of predicted translations.

7 Related Work and Discussion

Ratings provided by humans can be used as effective learning signals for machines. Reinforcement learning has become the *de facto* standard for incorporating this feedback across diverse tasks such as robot voice control (Tenorio-Gonzalez et al.,



(a) Granularity (b) Variance (c) Skew

(d) Granularity (e) Variance (f) Skew

Figure 5: Performance gains of NMT models trained with NED-A2C in Per-Sentence BLEU (top row) and in Heldout BLEU (bottom row) under various degrees of granularity, variance, and skew of scores. Performance gains of models trained with un-perturbed scores are within the shaded regions.

2010), myoelectric control (Pilarski et al., 2011), and virtual assistants (Isbell et al., 2001). Recently, this learning framework has been combined with recurrent neural networks to solve machine translation (Bahdanau et al., 2017), dialogue generation (Li et al., 2016), neural architecture search (Zoph and Le, 2017), and device placement (Mirhoseini et al., 2017). Other approaches to more general structured prediction under bandit feedback (Chang et al., 2015; Sokolov et al., 2016a,b) show the broader efficacy of this framework. Ranzato et al. (2016) describe MIXER for training neural encoder-decoder models, which is a reinforcement learning approach closely related to ours but requires a policy-mixing strategy and only uses a linear critic model. Among work on bandit MT, ours is closest to Kreutzer et al. (2017), which also tackle this problem using neural encoder-decoder models, but we (a) take advantage of a state-of-the-art reinforcement learning method; (b) devise a strategy to simulate noisy rewards; and (c) demonstrate the robustness of our method on noisy simulated rewards.

Our results show that bandit feedback can be an effective feedback mechanism for neural machine translation systems. This is *despite* that errors in human annotations hurt machine learning models in many NLP tasks (Snow et al., 2008). An obvious question is whether we could extend our framework to model individual annotator preferences (Passonneau and Carpenter, 2014) or learn personalized models (Mirkin et al., 2015; Rabinovich et al., 2017), and handle heteroscedastic noise (Park, 1966; Kersting et al., 2007; Antos et al., 2010). Another direction is to apply active learning techniques to reduce the sample complexity required to improve the systems or to extend to richer action spaces for problems like simultaneous translation, which requires prediction (Grissom II et al., 2014) and reordering (He et al., 2015) among other strategies to both minimize delay and effectively translate a sentence (He et al., 2016).

Abstract

Neural Machine Translation (NMT) lays intensive burden on computation and memory cost. It is a challenge to deploy NMT models on the devices with limited computation and memory budgets. This paper presents a four stage pipeline to compress model and speed up the decoding for NMT. Our method first introduces a compact architecture based on convolutional encoder and weight shared embeddings. Then weight pruning is applied to obtain a sparse model. Next, we propose a fast sequence interpolation approach which enables the greedy decoding to achieve performance on par with the beam search. Hence, the time-consuming beam search can be replaced by simple greedy decoding. Finally, vocabulary selection is used to reduce the computation of softmax layer. Our final model achieves 10× speedup, 17× parameters reduction, <35MB storage size and comparable performance compared to the baseline model.

1 Introduction

Neural Machine Translation (NMT) (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2015) has recently gained popularity in solving the machine translation problem. Although NMT has achieved state-of-the-art performance for several language pairs (Jean et al., 2015; Wu et al., 2016), like many other deep learning domains, it is both computationally intensive and memory intensive. This leads to a challenge of deploying NMT models on the devices with limited computation and memory budgets.

Numerous approaches have been proposed for compression and inference speedup of neural networks, including but not limited to low-rank approximation (Denton et al., 2014), hash function (Chen et al., 2015), knowledge distillation (Hinton et al., 2015), quantization (Courbariaux et al., 2015; Han et al., 2016; Zhou et al., 2017) and sparsification (Han et al., 2015; Wen et al., 2016).

Weight pruning and knowledge distillation have been proved to be able to compress NMT models (See et al., 2016; Kim and Rush, 2016; Freitag et al., 2017). The above methods reduce the parameters from a global perspective. However, embeddings dominate the parameters in a relatively compact NMT model even if subword (Sennrich et al., 2016) (typical about 30K) is used. Character-aware methods (Ling et al., 2015; Lee et al., 2016) have fewer embeddings while suffer from slower decoding speed (Wu et al., 2016). Recent work by Li et al. (2016) has shown that weight sharing can be adopted to compress embeddings in language model. We are interested in applying embeddings weight sharing to NMT.

As for decoding speedup, Gehring et al. (2016); Kalchbrenner et al. (2016) tried to improve the parallelism in NMT by substituting CNNs for RNNs . Kim and Rush (2016) proposed sequence-level knowledge distillation which allows us to replace beam search with greedy decoding. Gu et al. (2017) exploited trainable greedy decoding by the actor-critic algorithm (Konda and Tsitsiklis, 2002). Wu et al. (2016) evaluated the quantized inference of NMT. Vocabulary selection (Jean et al., 2015; Mi et al., 2016; L'Hostis et al., 2016) was commonly used to speed up the softmax layer. Search pruning was also applied to speed up beam search (Hu et al., 2015; Wu et al., 2016; Freitag and Al-Onaizan, 2017). Compared to search pruning, the speedup of greedy decoding is more attractive. Knowledge distillation improves the per-

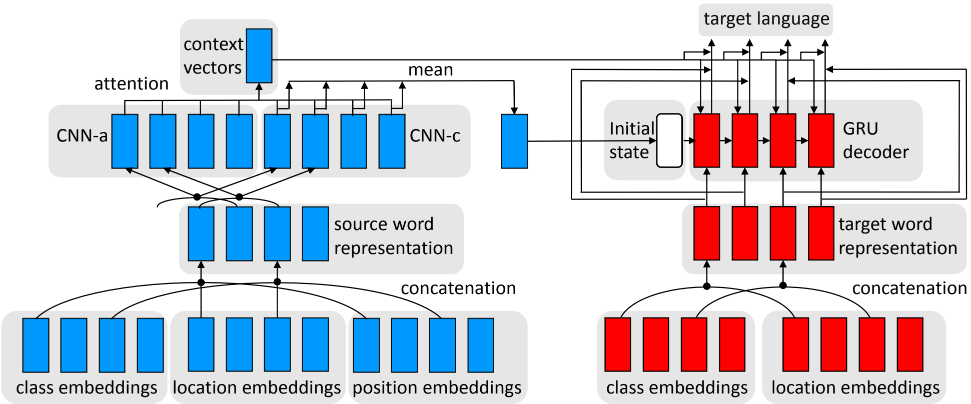

Figure 1: Our network architecture. The 2-component word representation contains class embeddings and location embeddings. Position embeddings are concatenated to convey the absolute positional information of each source word.

formance of greedy decoding while the method needs to run beam search over the training set, and therefore results in inefficiency for tens of millions of corpus. The trainable greedy decoding using a relatively sophisticated training procedure. We prefer a simple and fast approach that allows us to replace beam search with the greedy search.

In this work, a novel approach is proposed to improve the performance of greedy decoding directly and the embeddings weight sharing is introduced into NMT. We investigate the model compression and decoding speedup for NMT from the views of network architecture, sparsification, computation and search strategy, and test the performance of their combination. Specifically, we present a four stage pipeline for model compression and decoding speedup. Firstly, we train a compact NMT model based on convolutional encoder and weight sharing. The convolutional encoder works well with smaller model size and is robust for pruning. Weight sharing further reduces the number of embeddings by several folds. Then weight pruning is applied to get a sparse model. Next, we propose fast sequence interpolation to improve the performance of greedy decoding directly. This approach uses batched greedy decoding to obtain samples and therefore is more efficient than Kim and Rush (2016). Finally, we use vocabulary selection to reduce the computation of the softmax layer. Our final model achieves 10× speedup, 17× parameters reduction, <35MB storage size and comparable performance compared to the baseline model.

2 Method

2.1 Compact Network Architecture

Our network architecture is illustrated in Figure 1. This architecture works well with fewer parameters, which allows us to match the performance of the baseline model at lower capacity. The convolutional encoder is similar to Gehring et al. (2016), which consists of two convolutional neural networks: *CNN-a* for attention score computation and *CNN-c* for the conditional input to be fed to the decoder. The CNNs are constructed by blocks with residual connections (He et al., 2015). We use the *relu6*[1] non-linear activation function instead of *tanh* in Gehring et al. (2016) and achieve better training stability.

To compress the embeddings, the cluster based 2-component word representation is introduced: we cluster the words into C classes by *word2vector*[2] (Mikolov et al., 2013), and each class contains up to L words. Then the conventional embedding lookup table is replaced by $C + L$ unique vectors. For each word, we first do a lookup from C class embeddings according to which cluster the word belongs, next we do another lookup from L location embeddings according to the location of the word. We concatenate the results of the two embedding lookup as the 2-component word representation. As a result, the number of embeddings is reduced from about $C \times L$ to $C + L$. Referring to Gehring et al. (2016), position embeddings are concatenated to convey the absolute positional information of each source word within a sentence.

[1] Computes *relu6*: min(max(features, 0), 6).

Boundary words
Reference (Y): the official said the grenade blast did not cause any death or injury nor any damage .
Sample (S): the official said the grenade explosion did not cause any casualties or damage .
replace
Interpolated Sample: the official said the grenade blast did not cause any casualties or damage .

Figure 2: Editing operation. We search for subsequences with the same boundary words between S and Y. The words within the boundary words can be different. Then we replace the subsequence in S by the subsequence in Y.

2.2 Weight Pruning

Then the iterative pruning (Han et al., 2015) is applied to obtain a sparse network, which allows us to use sparse matrix storage. In order to further reduce the storage size, most sparse matrix index of our pruned model is stored using *uint8* and *uint16* depend on the matrix dimension.

2.3 Fast Sequence Interpolation

Let (X, Y) be a source-target sequence pair. Given X as input, S is the corresponding greedy decoding result using a well trained model. Then we make two assumptions:
(1) Let $\tilde{S}$ be a sequence close to S. If training with $(X, \tilde{S})$, $\tilde{S}$ will replace S to become the result of greedy decoding with a probability $P(\tilde{S}, S)$.
(2) The following relationship holds:

$$\begin{cases} P(\tilde{S}, S) \propto sim(\tilde{S}, S) \\ sim(\tilde{S}, S) > sim(Y, S) \end{cases}$$

where sim is a function measuring closeness such as edit-distance. If $\tilde{S}$ has higher evaluation metric[3] (we write as E) than S, according to (2) we have:

$$\begin{cases} P(\tilde{S}, S) > P(Y, S) \\ E(\tilde{S}, Y) > E(S, Y) \end{cases}$$

Algorithm 1 Editing algorithm of fast sequence interpolation.

Input: (X, Y, S, k): (X, Y) is a sequence pair in training data. S is the result of the greedy decoding using source sequence X. k is the maximum number of tokens in replaced subsequence of S or Y.
Output: $\tilde{S}$: the edited sample.

```
for $s_i$ in $S$, $y_j$ in $Y$ do
    if $(s_i == y_j)$ then
        for $1 \le p \le k+1, 1 \le q \le k+1$ do
            if $(s_{i+p} == y_{j+q})$ then
                $Ss = (s_i, ..., s_p)$
                $Ys = (y_j, ..., y_q)$
                Break
            end if
        end for
    end if
    Replace subsequence of $S$: $S_s \leftarrow Y_s$
    Break
end for
$\tilde{S} \leftarrow S$
```

We note that using $\tilde{S}$ as a label is more attractive than Y for improving the performance of greedy decoding. The reason is that S and Y are often quite different (Kim and Rush, 2016), resulting in a relatively low $P(Y, S)$. We bridge the gap between S and Y by interpolating inner sequence between them. Specifically, we *edit* S toward Y, which can be seen as interpolation. *Editing* is a heuristic operation as illustrated in Figure 2. Concretely, let S_s be a subsequence of S and let Y_s be a subsequence of Y. Given that:

$$\begin{cases} S = (s_0, ..., s_p, S_s, s_q, ..., s_n) \\ Y = (y_0, ..., s_p, Y_s, s_q, ..., y_m) \\ \text{length}(S_s) \leqslant k \\ \text{length}(Y_s) \leqslant k \end{cases}$$

where k is the length limit of S_s and Y_s. The interpolated sample $\tilde{S}$ has the following form:

$$\tilde{S} = (s_0, ..., s_p, Y_s, s_q, ..., s_n)$$

To obtain the target sequence $\tilde{Y}$ for training, we substitute $\tilde{S}$ for Y according to the following rule:

$$\tilde{Y} = \begin{cases} \tilde{S} & E(\tilde{S}, Y) - E(S, Y) > \varepsilon \\ Y & \text{otherwise} \end{cases}$$

where ε aims to ensure the quality of $\tilde{S}$. We define *substitution rate* as the ratio of $\tilde{S}$ substituting Y

[3] We use smoothed sentence-level BLEU (Chen and Cherry, 2014).

over the training set. In summary, the following procedure is done iteratively: (1) get a new batch of (X, Y), (2) run batched greedy decoding on X, (3) edit S to obtain $\tilde{S}$, (4) get $\tilde{Y}$ according to the substitution rule, (5) train on the batched $(X, \tilde{Y})$.

2.4 Vocabulary Selection

We use word alignment[4] (Dyer et al., 2013) to build a candidate dictionary. For each source word, we build a list of candidate target words. When decoding, top *n* candidates of each word are merged to form a short-list for softmax layer. We do not apply vocabulary selection in training.

3 Experiments

3.1 Setup

Datasets and Evaluation Metrics: We evaluate these approaches on two pairs of languages: English-German and Chinese-English. Our English-German data comes from WMT'14[5]. The training set consists of 4.5M sentence pairs with 116M English words and 110M German words. We choose *newstest2013* as the development set and *newstest2014* as the test set. The Chinese-English training data consists of 1.6M pairs with 34M Chinese words and 38M English words. We choose *NIST 2002* as the development set and *NIST 2005* as the test set.

For the two translation task, top 50K and 30k most frequent words are kept respectively. The rest words are replaced with UNK. We only use sentences of length up to 50 symbols. We do not use any UNK handling methods for fair comparison. The evaluation metric is case-insensitive BLEU (Papineni et al., 2002) as calculated by the *multi-bleu.perl* script.

Hyper-parameters: For the baseline model, we use a 2-layer bidirectional GRU encoder (1 layer in each direction) and a 1-layer GRU decoder. In *Baseline*$_L$, the embedding size is 512 and the hidden size is 1024. In *Baseline*$_S$, the embedding size is 256 and the hidden size is 512. Our baseline models are similar to the architecture in DL4MT[6]. For the convolutional encoder model, 512 hidden units are used for the 6-layer CNN-a, and 256 hidden units are used for the 8-layer CNN-c. The embedding size is 256. The hidden size of the decoder is 512. The kernel width in CNNs is 3. The number of clusters for both source and target vocabulary is 6. The editing rule for fast sequence interpolation is detailed in Algorithm 1. We use the top 50 candidates for each source word in vocabulary selection. The initial dropout rate is 0.3, and gradually decreases to 0 as the pruning rate increases. We use AdaDelta optimizer and clip the norm of the gradient to be no more than 1. Our methods are implemented with TensorFlow[7] (Abadi et al., 2015). We run one sentence decoding for all models under the same computing environment[8].

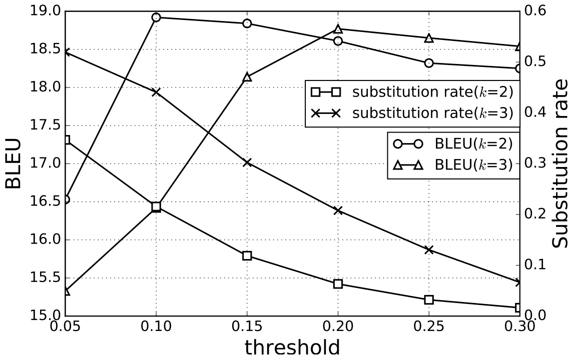

Figure 3: The performance and the *substitution rate* of *FSI* on English-German (newstest2013) development set with varying threshold ε and subsequence length limit k.

3.2 Results and Discussions

Our experimental results are summarized in Table 1. The convolutional encoder model matches the performance of the GRU encoder model with about 2× fewer parameters. Combining with embeddings weight sharing results in a compact model that has about 3.5× fewer parameters than the baseline model. After pruning 80% of the weights, we reduce the parameters by about 17× with only a decrease of 0.2 BLEU. The storage size of the final models is about 30MB, which is easily fit into the memory of a mobile device. We find that the pruning rate of embeddings is highest even if weight sharing is used. Furthermore, the pruning rate of CNN layers is higher than GRU layers. This reveals that the CNNs are more robust for pruning than RNNs. The pruning rate of each

[6] https://github.com/nyu-dl/dl4mt-tutorial

[7] https://github.com/zxw866/CFNMT

[8] We also test batched greedy decoding with a batch size 128. We find that batched greedy decoding is nearly ten times faster than one sentence greedy decoding. We conjecture that our current one sentence decoding implementation does not fully make use of available hardware optimized for parallel computations. We can obtain a higher speedup with well optimized one sentence decoding implementation.

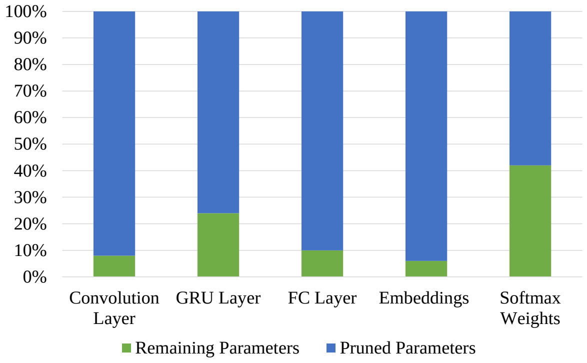

Figure 4: Pruning rate of different layers.

layer and the performance with increasing pruning rate are detailed in Figure 4. The compact architecture reduces the decoding time by only 20%. The reason is that the decoding time is dominated by the softmax layer. After applying fast sequence interpolation, we replace beam search with greedy decoding, which results in a speedup of over 5× with little loss in performance. We find that the details of the editing rules have little effect on *FSI*. Because we only accept $\tilde{S}$ that BLEU improved by more than the threshold ε, otherwise we choose the gold target sequence. Figure 3 shows that appropriate *substitution rate* is important for fast sequence interpolation. We conjecture that edited samples are still worse than gold target sequences, and therefore relatively high substitution rate may lead to instability in training. The speedup of vocabulary selection is only about 30%. It shows that the softmax layer no longer dominates the decoding time when using greedy search.

4 Conclusion and Future Work

We investigate the model compression and decoding speedup for NMT from the views of network architecture, sparsification, computation and search strategy, and verify the performance on their combination. A novel approach is proposed to improve the performance of greedy decoding and the embeddings weight sharing is introduced into NMT. In the future, we plan to integrate weight quantization into our method.

Abstract

Instance weighting has been widely applied to phrase-based machine translation domain adaptation. However, it is challenging to be applied to Neural Machine Translation (NMT) directly, because NMT is not a linear model. In this paper, two instance weighting technologies, i.e., sentence weighting and domain weighting with a dynamic weight learning strategy, are proposed for NMT domain adaptation. Empirical results on the IWSLT English-German/French tasks show that the proposed methods can substantially improve NMT performance by up to 2.7-6.7 BLEU points, outperforming the existing baselines by up to 1.6-3.6 BLEU points.

1 Introduction

In Statistical Machine Translation (SMT), unrelated additional corpora, known as out-of-domain corpora, have been shown not to benefit some domains and tasks, such as TED-talks and IWSLT tasks (Axelrod et al., 2011; Luong and Manning, 2015). Several Phrase-based SMT (PBSMT) domain adaptation methods have been proposed to overcome this problem of the lack of substantial data in some specific domains and languages:

i) Data selection. The main idea is to score the out-of-domain data using models trained from the in-domain and out-of-domain data, respectively. Then select training data by using these ranked scores (Moore and Lewis, 2010; Axelrod et al., 2011; Duh et al., 2013; Hoang and Sima'an, 2014a,b; Durrani et al., 2015; Chen et al., 2016).

ii) Model Linear Interpolation. Several PBSMT models, such as language models, translation models, and reordering models, individually corresponding to each corpus, are trained. These models are then combined to achieve the best performance (Sennrich, 2012; Sennrich et al., 2013; Durrani et al., 2015, 2016; Imamura and Sumita, 2016).

iii) Instance Weighting. Instance Weighting has been applied to several NLP domain adaptation tasks (Jiang and Zhai, 2007), such as POS tagging, entity type classification and especially PBSMT (Matsoukas et al., 2009; Shah et al., 2010; Foster et al., 2010; Rousseau et al., 2011; Zhou et al., 2015; Wang et al., 2016; Imamura and Sumita, 2016). They firstly score each instance/domain by using rules or statistical methods as a weight, and then train PBSMT models by giving each instance/domain the weight.

For Neural Machine Translation (NMT) domain adaptation, the sentence selection can also be used (Chen et al., 2016; Wang et al., 2017). Meanwhile, the model linear interpolation is not easily applied to NMT directly, because NMT is not a linear model. There are two methods for model combination of NMT: i) the in-domain model and out-of-domain model can be *ensembled* (Jean et al., 2015). ii) an NMT further training (fine-tuning) method (Luong and Manning, 2015). The training is performed in two steps: first, the NMT system is trained using out-of-domain data, and then further trained using in-domain data. Recently, Chu et al. (2017) make an empirical comparison of NMT further training (Luong and Manning, 2015) and domain control (Kobus et al., 2016), which applied word-level domain features to word embedding layer. This approach provides natural baselines for comparison.

To the best of our knowledge, there is no existing work concerning instance weighting in

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1482–1488
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

NMT. The main challenge is that NMT is not a liner model or combination of linear models, where the instance weight can be integrated into directly. To overcome this difficulty, we try to integrate the instance weight into NMT objective function. Two technologies, i.e., sentence weighting and domain weighting, are proposed to apply instance weighting to NMT. In addition, we also propose a dynamic weight learning strategy to tune the proposed domain weights.

2 NMT Background

An attention based NMT is a neural network that directly models the conditional probability $p(\mathbf{y}|\mathbf{x})$ of translating a source sentence, $\mathbf{x} = \{x_1, ..., x_n\}$, to a target sentence, $\mathbf{y} = \{y_1, ..., y_m\}$ (Luong et al., 2015):

$$p(\mathbf{y}|\mathbf{x}) = \prod_{j=1}^{m} softmax(g(y_j|y_{j-1}, s_j, c_j)), \quad (1)$$

with g being the transformation function that outputs a vocabulary-sized vector, s_j being the RNN hidden unit and c_j being the weighted sum of source annotations $\mathbf{H}_{\mathbf{x}}$. The NMT training objective (maximize) is formulated as,

$$J = \sum_{(\mathbf{x},\mathbf{y}) \in \mathcal{D}} \log p(\mathbf{y}|\mathbf{x}), \quad (2)$$

where $\mathcal{D}$ is the parallel training corpus.

3 Instance weighting for NMT

In this paper, we integrate the instance weight into the NMT objective function. Our main hypothesis is that the in-domain data should have a higher weight in the NMT objective function than the out-of-domain ones.

The training corpus $\mathcal{D}$ can be divided into in-domain one $\mathcal{D}_{in}$ and the out-of-domain one $\mathcal{D}_{out}$. So, the Eq. (2) can be rewritten as,

$$J = (\sum_{\langle \mathbf{x},\mathbf{y} \rangle \in \mathcal{D}_{in}} \log p(\mathbf{y}|\mathbf{x}) + \sum_{\langle \mathbf{x}',\mathbf{y}' \rangle \in \mathcal{D}_{out}} \log p(\mathbf{y}'|\mathbf{x}')), \quad (3)$$

where $\langle \mathbf{x}, \mathbf{y} \rangle$ is a parallel sentence pair.

3.1 Sentence Weighting

A general method is to give each sentence a weight. As Axelrod et al. (2011) mentioned, there are some pseudo in-domain data in out-of-domain data, which are close to in-domain data. We can apply their bilingual cross-entropy method to score each $\langle \mathbf{x}_i, \mathbf{y}_i \rangle$ as a weight λ_i, the higher the better,[1]

$$\begin{aligned} \lambda_i = \delta(&H_{out}(\mathbf{x}_i) - H_{in}(\mathbf{x}_i) \\ &+ H_{out}(\mathbf{y}_i) - H_{in}(\mathbf{y}_i)). \end{aligned} \quad (4)$$

Take $H_{in}(\mathbf{x}_i)$ as example, it indicates the cross-entropy between sentence $\mathbf{x}_i$ and in-domain language model (Axelrod et al., 2011). Min-max normalization δ (Priddy and Keller, 2005) is used to normalize each λ_i into range $[0, 1]$,

$$\delta(\lambda_i) = \frac{\lambda_i - \lambda_{min}}{\lambda_{max} - \lambda_{min}}. \quad (5)$$

The λ for in-domain data will set as one directly. The updated objective function by sentence weighting (J_{sw}) can be rewritten as,

$$J_{sw} = \sum_{\langle \mathbf{x}_i,\mathbf{y}_i \rangle \in \mathcal{D}} \lambda_i \log p(\mathbf{y}_i|\mathbf{x}_i). \quad (6)$$

3.2 Domain Weighting

An alternative way is to modify the weight of each domain in objective function. For we design a weight parameter λ_{in} for in-domain data. The updated objective function by domain weighting (J_{dw}) can be estimated as,

$$J_{dw} = \lambda_{in} \sum_{(\mathbf{x},\mathbf{y}) \in \mathcal{D}_{in}} logp(\mathbf{y}|\mathbf{x}) + \sum_{(\mathbf{x}',\mathbf{y}') \in \mathcal{D}_{out}} logp(\mathbf{y}'|\mathbf{x}'). \quad (7)$$

3.2.1 Batch weighting

A straightforward domain weighting implementation is to modify the ratio between in-domain and out-of-domain data in each NMT mini-batch. That is, we can increase the in-domain weight by increasing the number of in-domain sentences included in a mini-batch. The updated in-domain data ratio $\mathcal{R}_{in}$ in each NMT mini-batch can be calculated as,

$$\mathcal{R}_{in} = \frac{|\hat{\mathcal{D}}_{in}|}{|\hat{\mathcal{D}'}_{in}| + |\hat{\mathcal{D}'}_{out}|} = \frac{\lambda_{in}}{\lambda_{in} + 1}, \quad (8)$$

where $|\hat{\mathcal{D}}_{in}|$ and $|\hat{\mathcal{D}}_{out}|$ are the sentence number from in and out-of-domain data in each mini-batch, respectively.

[1] The original cross-entropy is the lower the better, and we swap the in and out order.

Take the IWSLT EN-DE corpus in Table 1 as example, the original ratio $\mathcal{R}_{in}$ between in-domain data and all of the data is around 1:20. That is, for a 80-sized mini-batch, it would include around four sentence from in-domain data and 76 from out-of-domain data on average. For batch weighting, we can set the ratio $\mathcal{R}_{in}$ as 1:2 manually. That is, we load 40 in-domain and 40 out-of-domain sentences into each mini-batch.

In practice, we create two data iterators, one for in-domain and one for out-of-domain. Both of the in and out-of-domain data will be randomly shuffled and then loaded into corresponding data iterators before each epoch. For each mini-batch, the data from these two data iterators are determined by the ratio $\mathcal{R}_{in}$. Because the size of out-of-domain data is much larger than the in-domain one, the in-domain data will be loaded and trained for several epochs, while the out-of-domain data is only trained for one epoch at the same time.

3.2.2 Dynamic Weight Tuning

For the batch weight tuning, one way is to fix the weights for several systems and select the best-performed system on the development data. Besides this, we also tried to learn the batch weighting dynamically. That is, the initial in-domain data ration in mini-batch is set as 0%. We increased 10% ratio of in-domain data in the mini-batch if the training cost does not decrease for ten-time evaluations (the training cost is evaluated on development data set every 1K batches training).

4 Experiments

4.1 Data Sets

The proposed methods were evaluated by adapting WMT corpora to IWSLT (mainly contains TED talks) corpora.[2] Statistics on data sets were shown in Table 1.

- IWSLT 2015 English (EN) to German (DE) training corpus (Cettolo et al., 2015) was used as in-domain training data. Out-of-domain corpora contained WMT 2014 English-German corpora. This adaptation corpora settings were the same as those used in (Luong and Manning, 2015).
- IWSLT 2014 English (EN) to French (FR) training corpus (Cettolo et al., 2014) was used as in-domain training data. Out-of-domain corpora contained WMT 2015 English-French corpora. This adaptation corpora settings were nearly the same as those used in (Wang et al., 2016).

IWSLT EN-DE	Sentences	Tokens
TED training (in-domain)	207.1K	3.2M
WMT training (out-of-domain)	4.5M	119.9M
TED tst2012 (development)	1.7K	29.2K
TED tst2013 (test)	0.9K	19.6K
TED tst2014 (test)	1.3K	23.8K
IWSLT EN-FR	**Sentences**	**Tokens**
TED training (in-domain)	178.1K	3.5M
WMT training (out-of-domain)	17.8M	450.0M
TED dev2010 (development)	0.9K	20.1K
TED tst2010 (test)	1.6K	31.9K
TED tst2011 (test)	0.8K	21.4K

Table 1: Statistics on data sets.

4.2 NMT Systems

We implemented the proposed method in Nematus[3] (Sennrich et al., 2017) and online available[4], which is one of the state-of-the-art NMT frameworks. The default settings of Nematus were applied to all NMT systems (both baselines and the proposed methods): the word embedding dimension was 620 and the size of a hidden layer was 1000, the batch size was 80, the maximum sequence length were 50, and the beam size for decoding was 10. The 30K-sized vocabulary, which was created by using both in and out-of-domain data, were applied to all of the systems. Default dropout was applied. Each NMT model was trained for 500K batches by using ADADELTA optimizer (Zeiler, 2012). Training was conducted on a single Tesla P100 GPU, taking 7-10 days. We observed that all of the systems converged before 500K batches training.

For the coding cost of duplicating data, we only add two data iterators as mentioned in 3.2.1. For the training cost, using batch weighting can a accelerate the model converge on development data in our experiments, because the development data are also in-domain data. Overall, the overhead cost is not too much.

[2] In practice, we also also evaluated on the Chinese-to-English NIST task. Due to limited time and space, we only showed the IWSLT task.

[3] https://github.com/EdinburghNLP/nematus

[4] https://github.com/wangruinlp/nmt_instance_weighting The batch weighting part was partially motivated by Nematus.

4.3 Results and Analysis

In Tables 2 and 3, SMT indicates standard PBSMT (Koehn et al., 2007) models were trained by corresponding corpora (*in*, *out*, and *in+out*). The *in*, *out* and *in + out* indicate that the in-domain, out-of-domain and their mixture were used as the NMT training corpora.

For related NMT domain adaptation baselines, “ensemble” indicates *in* and *out* models were ensembled in decoding and “sampler” indicates that we sampled duplicated in-domain data into training data, to make the ratio between *in*/*out* be 1:1 manually. Actually, if the mini-batch size was as large as the whole corpus, the sampling method, and batch weighting method would be the same. Batch weighting method makes the data more balanced in each single mini-batch. However, the mini-batch size is limited, so these two methods are different.

We also compared Axelrod et al. (2011)’s sentence selection and Kobus et al. (2016)’s domain control method, which added a word feature (in or out) to each word in the training corpora. For all of the baselines, we tried our best to re-implemented their methods. The translation performance was measured by the case-insensitive BLEU (Papineni et al., 2002), with the paired bootstrap re-sampling test (Koehn, 2004)[5].

batch weighting(bw)	29.81++	35.54++	39.48++
bw + dynamic tuning	**30.40++**	**36.50++**	**41.90++**

Table 3: IWSLT EN-FR results.

In Tables 2 and 3, we reached the following observations:

- Adding out-of-domain to in-domain data, or directly using out-of-domain data, degraded NMT performance.
- The proposed instance weighting methods substantially improved NMT performance (in) up to 2.7-6.7 BLEU points, and outperformed the best existing baselines up to 1.6-3.6 BLEU points.
- Among the proposed methods, batch weighting performed the best, although it was the simplest one. The reason may be: a) the batch weighting method directly balanced the in-domain data ratio in each mini-batch, to overcome the in-domain data sparse problem. b) The batch weight can be tuned on development data, in comparison with sentence weighting method, whose weights were learned and fixed before NMT training.
- The dynamic weight tuning strategy outperformed the fixed weight tuning strategy by 0.6-2.4 BLEU points.

5 Discussions

5.1 Weights Tuning

Figure 1 showed the batch weight tuning experiments on development data of IWSLT EN-DE, where the horizontal axis indicates the in-domain ratio $\mathcal{R}_{in}$ in Eq. (8). “Fix” indicates several systems were trained with fixed weights and the best-performed system would be selected. “Dynamic” indicates that only one system was trained and the domain weight was learned dynamically as mentioned in Section 3.2.2.

[5] http://www.ark.cs.cmu.edu/MT

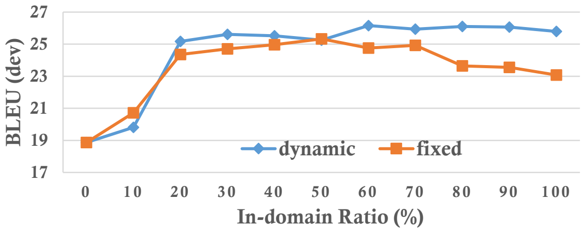

Figure 1: Batch weight tuning on IWSLT EN-DE.

As shown in Figure 1, the fixed weight learning reached the highest BLEU on dev at around 50% and dynamic learning at around 60%. If we keep training the dynamic learning after 100% in-domain data were used, the performance would trend to become similar to only using in-domain data from the beginning.

5.2 Further Training

Further training (Luong and Manning, 2015) can be viewed as a special case of the proposed batch weighting method. That is, it trained NMT model by using 0% in-domain data at first and then using 100% in-domain data. In comparison, our batch weighting kept some ratio of out-of-domain data during the whole training process. In addition, further training can work together with batch weighting. That is, NMT was trained with 0% in-domain data at first and then with batch weighing method for further training (Luong + bw in Table 4). . $\mathcal{R}_{in}$ was tuned on development data. As mentioned in Section 3.2.2, “bw + dynamic tuning” indicates that this batch weighting was learned dynamically.

IWSLT EN-DE	tst2012	tst2013	tst2014
Luong	25.68	28.14	24.31
Luong + bw	25.87	28.54+	**24.53**
bw + dynamic tuning	**26.03**	**28.58+**	24.12
IWSLT EN-FR	dev2010	tst2010	tst2011
Luong	29.33	35.36	40.62
Luong + bw	29.65	35.65	41.20+
bw + dynamic tuning	**30.40++**	**36.50++**	**41.90++**

Table 4: Further training (Luong and Manning, 2015) is the baseline for significance test.

Table 4 shows that batch weighting worked synergistically with Luong’s further training method, and slightly improved NMT performance. The “bw + dynamic tuning” method outperformed both of them. We observed that the original further training overfitted quickly after around one epoch training. Keeping some out-of-domain data would prevent further training from overfitting.

6 Conclusion and Future Work

In this paper, we proposed two straightforward instance weighting methods with a dynamic weight learning strategy for NMT domain adaptation. Empirical results on IWSLT EN-DE/FR tasks showed that the proposed methods can substantially improve NMT performances and outperform state-of-the-art NMT adaptation methods.

The current sentence weighting method is a simple implementation of the existing PBSMT adaptation methods. In the future, we will try to study a specific sentence weighting method for NMT domain adaptation.

Abstract

We investigate techniques for supervised domain adaptation for neural machine translation where an existing model trained on a large out-of-domain dataset is adapted to a small in-domain dataset.

In this scenario, overfitting is a major challenge. We investigate a number of techniques to reduce overfitting and improve transfer learning, including regularization techniques such as dropout and L2-regularization towards an out-of-domain prior. In addition, we introduce *tuneout*, a novel regularization technique inspired by dropout. We apply these techniques, alone and in combination, to neural machine translation, obtaining improvements on IWSLT datasets for English→German and English→Russian. We also investigate the amounts of in-domain training data needed for domain adaptation in NMT, and find a logarithmic relationship between the amount of training data and gain in BLEU score.

1 Introduction

Neural machine translation (Bahdanau et al., 2015; Sutskever et al., 2014) has established itself as the new state of the art at recent shared translation tasks (Bojar et al., 2016; Cettolo et al., 2016). In order to achieve good generalization accuracy, neural machine translation, like most other large machine learning systems, requires large amounts of training examples sampled from a distribution as close as possible to the distribution of the inputs seen during execution. However, in many applications, only a small amount of parallel text is available for the specific application domain, and it is therefore desirable to leverage larger out-domain datasets.

Owing to the incremental nature of stochastic gradient-based training algorithms, a simple yet effective approach to transfer learning for neural networks is *fine-tuning* (Hinton and Salakhutdinov, 2006; Mesnil et al., 2012; Yosinski et al., 2014): to continue training an existing model which was trained on out-of-domain data with in-domain training data. This strategy was also found to be very effective for neural machine translation (Luong and Manning, 2015; Sennrich et al., 2016b).

Since the amount of in-domain data is typically small, overfitting is a concern. A common solution is early stopping on a small held-out in-domain validation dataset, but this reduces the amount of in-domain data available for training.

In this paper, we show that we can make fine-tuning strategies for neural machine translation more robust by using several regularization techniques. We consider fine-tuning with varying amounts of in-domain training data, showing that improvements are logarithmic in the amount of in-domain data.

We investigate techniques where domain adaptation starts from a pre-trained out-domain model, and only needs to process the in-domain corpus. Since we do not need to process the large out-domain corpus during adaptation, this is suitable for scenarios where adaptation must be performed quickly or where the original out-domain corpus is not available. Other works consider techniques that jointly train on the out-domain and in-domain corpora, distinguishing them using specific input features (Daume III, 2007; Finkel and Manning, 2009; Wuebker et al., 2015). These techniques are largely orthogonal to

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1489–1494
Copenhagen, Denmark, September 7–11, 2017.

ours[1] and can be used in combination. In fact, Chu et al. (2017) successfully apply fine-tuning in combination with joint training.

2 Regularization Techniques for Transfer Learning

Overfitting to the small amount of in-domain training data that may be available is a major challenge in transfer learning for domain adaptation. We investigate the effect of different regularization techniques to reduce overfitting, and improve the quality of transfer learning.

2.1 Dropout

The first variant that we consider is fine-tuning with dropout. Dropout (Srivastava et al., 2014) is a stochastic regularization technique for neural networks. In particular, we consider "Bayesian" dropout for recurrent neural networks (Gal and Ghahramani, 2016).

In this technique, during training, the columns of the weight matrices of the neural network are randomly set to zero, independently for each example and each epoch, but with the caveat that when the same weight matrix appears multiple times in the unrolled computational graph of a given example, the same columns are zeroed.

For an arbitrary layer that takes an input vector h and computes the pre-activation vector v (ignoring the bias parameter),

$$v_{i,j} = W \cdot M_{W,i,j} \cdot h_{i,j} \tag{1}$$

where $M_{W,i,j} = \frac{1}{p}\mathrm{diag}(\mathrm{Bernoulli}^{\otimes n}(p))$ is the dropout mask for matrix W and training example i seen in epoch j. This mask is a diagonal matrix whose entries are drawn from independent Bernoulli random variables with probability p and then scaled by $1/p$. Gal and Ghahramani (2016) have shown that this corresponds to approximate variational Bayesian inference over the weight matrices considered as model-wise random variables, where the individual weights have a Gaussian prior with zero mean and small diagonal covariance. During execution we simply set the dropout masks to identity matrices, as in the standard approximation scheme.

Since dropout is not a specific transfer learning technique per se, we can apply it during fine-tuning, irrespective of whether or not the original out-of-domain model was also trained with dropout.

2.2 MAP-L2

L2-norm regularization is widely used for machine learning and statistical models. For linear models, it corresponds to imposing a diagonal Gaussian prior with zero mean on the weights. Chelba and Acero (2006) extended this technique to transfer learning by penalizing the weights of the in-domain model by their L2-distance from the weights of the previously trained out-of-domain model.

For each parameter matrix W, the penalty term is

$$L_W = \lambda \cdot \left\| W - \hat{W} \right\|_2^2 \tag{2}$$

where W is the in-domain parameter matrix to be learned and $\hat{W}$ is the corresponding fixed out-of-domain parameter matrix. Bias parameters may be regularized as well. For linear models, this corresponds to maximum a posteriori inference w.r.t. a diagonal Gaussian prior with mean equal to the out-of-domain parameters and $1/\lambda$ variance.

To our knowledge this method has not been applied to neural networks, except for a recent work by Kirkpatrick et al. (2017) which investigates a variant of it for *continual learning* (learning a new task while preserving performance on previously learned task) rather than domain adaptation. In this work we investigate L2-distance from out-of-domain penalization (MAP-L2) as a domain adaptation technique for neural machine translation.

2.3 Tuneout

We also propose a novel transfer learning technique which we call *tuneout*. Like Bayesian dropout, we randomly drop columns of the weight matrices during training, but instead of setting them to zero, we set them to the corresponding columns of the out-of-domain parameter matrices.

This can be alternatively seen as learning matrices of parameter differences between in-domain and out-of-domain models with standard dropout, starting from a zero initialization at the beginning of fine-tuning. Therefore, equation 2 becomes

$$v_{i,j} = (\hat{W} + \Delta W \cdot M_{\Delta W,i,j}) \cdot h_{i,j} \tag{3}$$

where $\hat{W}$ is the fixed out-of-domain parameter matrix and ΔW is the parameter difference matrix to be learned and $M_{\Delta W,i,j}$ is a Bayesian dropout mask.

[1] although in the special case of linear models, they are related to MAP-L2 fine-tuning.

3 Evaluation

We evaluate transfer learning on test sets from the IWSLT shared translation task (Cettolo et al., 2012).

3.1 Data and Methods

Test sets consist of transcripts of TED talks and their translations; small amounts of in-domain training data are also provided. For English-to-German we use IWSLT 2015 training data, while for English-to-Russian we use IWSLT 2014 training data. For the out-of-domain systems, we use training data from the WMT shared translation task,[2] which is considered permissible for IWSLT tasks, including back-translations of monolingual training data (Sennrich et al., 2016b), i.e., automatic translations of data available only in target language "back" into the source language[3].

We train out-of-domain systems following tools and hyperparameters reported by Sennrich et al. (2016a), using Nematus (Sennrich et al., 2017) as the neural machine translation toolkit. We differ from their setup only in that we use Adam (Kingma and Ba, 2015) for optimization. Our baseline fine-tuning models use the same hyperparameters, except that the learning rate is 4 times smaller and the validation frequency for early stopping 4 times higher. Early stopping serves an important function as the only form of regularization in the baseline fine-tuning model. We also use this configuration for the in-domain only baselines.

After some exploratory experiments for English-to-German, we set dropout retention probabilities to 0.9 for word-dropout and 0.8 for all the other parameter matrices. Tuneout retention probabilities are set to 0.6 (word-dropout) and 0.2 (other parameters). For MAP-L2 regularization, we found that a penalty of 10^{-3} per mini-batch performs best. For English-to-Russian, retention probabilities of 0.95 (word-dropout) 0.89 (other parameters) for both dropout and tuneout performed best.

The out-of-domain training data consists of about $7.92M$ sentence pairs for English-to-German and $4.06M$ sentence pairs for English-to-Russian. In-domain training data is about $206k$ sentence pairs for English-to-German and $181k$ sentence pairs for English-to-Russian. Training data is tokenized, truecased and segmented into subword units using byte-pair encoding (BPE) (Sennrich et al., 2016c).

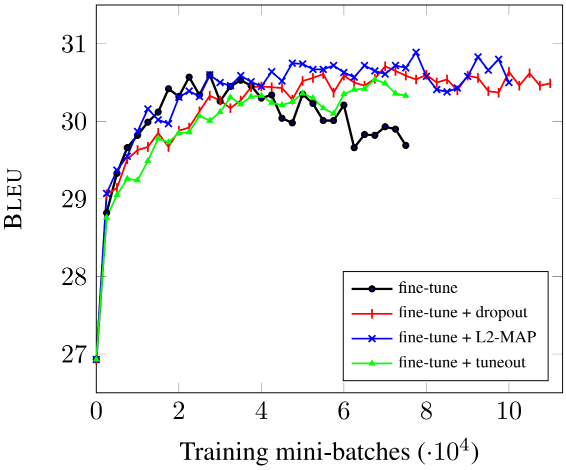

Figure 1: English→German validation BLEU over training mini-batches.

For replicability and ease of adoption, we include our implementation of dropout and MAP-L2 in the master branch of Nematus. Tuneout regularization is available in a separate code branch of Nematus.[4]

3.2 Results

We report the translation quality in terms of NIST-BLEU scores of our models in Table 1 for English-to-German and Table 2 for English-to-Russian. Statistical significance on the concatenated test sets scores is determined via bootstrap resampling (Koehn, 2004).

Dropout and MAP-L2 improve translation quality when fine-tuning both separately and in combination. When the two methods are used in combination, the improvements are significant at 5% for both language pairs, while in isolation dropout is non-significant and MAP-L2 is only significant for English-to-Russian. Tuneout does not yield improvements for English-to-German, in fact it is significantly worse, but yields a small, non-significant improvement for English-to-Russian.

In order to obtain a better picture of the training dynamics, we plot training curves[5] for several of our English-to-German models in Figure 1.

†: different from the fine-tuning baseline at 5% significance.

Baseline fine-tuning starts to noticeably overfit between the second and third epoch (1 epoch $\approx 10^4$ mini-batches), while dropout, MAP-L2 and tuneout seem to converge without displaying noticeable overfitting.

In our experiments, all forms of regularization, including early stopping, have shown to be successful at mitigating the effect of overfitting. Still, our results suggest that there is value in not relying only on early stopping:

- our results suggest that multiple regularizers outperform a single one.
- if the amount of in-domain data is very small, we may want to use all of it for fine-tuning, and not hold out any for early stopping.

To evaluate different fine-tuning streategies on varying amounts of in-domain data, we tested fine-tuning with random samples of in-domain data, ranging from 10 sentence pairs to the full data set of $206k$ sentence pairs. Fine-tuning with low amounts of training data is of special interest for online adaptation scenarios where a system is fed back post-edited translation.[6] Results are shown

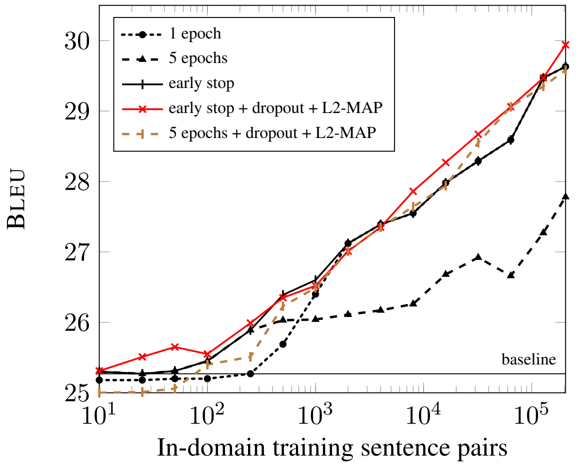

Figure 2: English→German test BLEU with fine-tuning on different in-domain data set size. Baseline trained on WMT data.

[6] We expect even bigger gains in that scenario because we would not train on a random sample, but on translations that are conceivably from the same document.

in Figure 2.

The results show an approximately logarithmic relation between the size of the in-domain training set and BLEU. We consider three baseline approaches: fine-tuning for a fixed number of epochs (1 or 5), or early stopping. All three baseline approaches have their disadvantages. Fine-tuning for 1 epoch shows underfitting on small amounts of data (less than 1,000 sentence pairs); fine-tuning for 5 epochs overfits on 500-200,000 sentence pairs. Early stopping is generally a good strategy, but it requires an in-domain held-out dataset.

On the same amount of data, regularization (dropout+MAP-L2) leads to performance that is better (or no worse) than the baseline with only early stopping. Fine-tuning with regularization is also more stable, and if we have no access to a in-domain valdiation set for early stopping, can be run for a fixed number of epochs with little or no accuracy loss.

4 Conclusion

We investigated fine-tuning for domain adaptation in neural machine translation with different amounts of in-domain training data, and strategies to avoid overfitting. We found that our baseline that relies only on early stopping has a strong performance, but fine-tuning with recurrent dropout and with MAP-L2 regularization yield additional small improvements of the order of 0.3 BLEU points for both English-to-German and English-to-Russian, while the improvements in terms of final translation accuracy of tuneout appear to be less consistent.

Furthermore, we found that regularization techniques that we considered make training more robust to overfitting, which is particularly helpful in scenarios where only small amounts of in-domain data is available, making early-stopping impractical as it relies on a sufficiently large in-domain validation set. Given the results of our experiments, we recommend using both dropout and MAP-L2 regularization for fine-tuning tasks, since they are easy to implement, efficient, and yield improvements while stabilizing training. We also present a learning curve that shows a logarithmic relationship between the amount of in-domain training data and the quality of the adapted system.

Our techniques are not specific to neural machine translation, and we propose that they could be also tried for other neural network architectures and other tasks.

Source-Side Left-to-Right or Target-Side Left-to-Right? An Empirical Comparison of Two Phrase-Based Decoding Algorithms

Yin-Wen Chang
Google Research, New York
yinwen@google.com

Michael Collins[*]
Google Research, New York
mjcollins@google.com

Abstract

This paper describes an empirical study of the phrase-based decoding algorithm proposed by Chang and Collins (2017). The algorithm produces a translation by processing the source-language sentence in strictly left-to-right order, differing from commonly used approaches that build the target-language sentence in left-to-right order. Our results show that the new algorithm is competitive with Moses (Koehn et al., 2007) in terms of both speed and BLEU scores.

1 Introduction

Phrase-based models (Koehn et al., 2003; Och and Ney, 2004) have until recently been a state-of-the-art method for statistical machine translation, and Moses (Koehn et al., 2007) is one of the most used phrase-based translation systems. Moses uses a beam search decoder based on a dynamic programming algorithm that constructs the target-language sentence from left to right (Koehn et al., 2003). Neural machine translation systems (Kalchbrenner and Blunsom, 2013; Cho et al., 2014; Sutskever et al., 2014), which have given impressive improvements over phrase-based systems, also typically use models and decoders that construct the target-language string in strictly left-to-right order.

Recently, Chang and Collins (2017) proposed a phrase-based decoding algorithm that processes the *source-language* string in strictly left-to-right order. Reordering is implemented by maintaining multiple sub-strings in the target-language, with phrases being used to extend these sub-strings by various operations (see Section 2 for a full description). With a fixed distortion limit on reordering, the time complexity of the algorithm is linear in terms of sentence length, and is polynomial time in other factors.

Chang and Collins (2017) present the algorithm and give a proof of its time complexity, but do not describe experiments, leaving an open question of whether the algorithm is useful in practice. This paper complements the original paper by studying the algorithm empirically. In addition to an exact dynamic programming implementation, we study the use of beam search with the algorithm, and another pruning method that restricts the maximum number of target-language strings maintained at any point. The experiments show that the algorithm is competitive with Moses in terms of both speed and translation quality (BLEU score).

The new decoding algorithm is of interest for a few reasons. While the experiments in this paper are with phrase-based translation systems, the method could potentially be extended to neural translation, for example with an attention-based model that is in some sense monotonic (left-to-right). The decoder may be relevant to work on simultaneous translation (He et al., 2016). The ideas may be applicable to string-to-string transduction problems other than machine translation.

2 A Sketch of the Decoding Algorithm of Chang and Collins (2017)

This section gives a sketch of the decoding algorithm of Chang and Collins (2017). We first define the phrase-based decoding problem, and then describe the algorithm.

2.1 The Phrase-based Decoding Problem

Throughout this paper we will consider the following decoding problem. Given a source sentence $x_1 \dots x_n$ for $n \geq 1$, a phrase $p = (s, t, e)$ specifies a possible translation from $x_s \dots x_t$ to a string

Figure 1: Illustrations of how the new algorithm produces the output translation. We note each phrase that is being added and the operation it takes to generate the next segments of phrase sequence.

of target-language words $e = e_1 \dots e_m$. We use $s(p)$, $t(p)$, and $e(p)$ to refer to the three elements of a phrase p. A *derivation* is a sequence of L phrases, $p_1 \dots p_L$. The derivation gives a translation by concatenating the target-language strings $e(p_1) \dots e(p_L)$.

We will always assume that $x_1 = \text{<s>}$, the start-of-sentence symbol, and $x_n = \text{</s>}$, the end-of-sentence symbol. The only phrases covering positions 1 and n are $(1, 1, \text{<s>})$ and $(n, n, \text{</s>})$.

A derivation $p_1 \dots p_L$ is *valid* if each word in the source sentence is translated exactly once, and if for $i = 2 \dots L$ we have $|t(p_{i-1})+1-s(p_i)| \leq d$, where d is the distortion limit.

The score for any derivation is

$$f(p_1 \dots p_L) = \lambda(e(p_1) \dots e(p_L)) + \sum_{i=1}^{L} \kappa(p_i) + \sum_{i=2}^{L} \eta \times |t(p_{i-1}) + 1 - s(p_i)|$$

where the parameter η is the distortion penalty, $\lambda(e)$ is a language model score for the word sequence e, and $\kappa(p)$ is the score for phrase p under the phrase-based model. For example under a bigram language model, we have $\lambda(e_1 \dots e_m) = \sum_{i=2}^{m} \lambda(e_i|e_{i-1})$. where $\lambda(v|u)$ is the score for bigram (u, v).

The phrase-based decoding problem is to find

$$\arg\max_{p_1 \dots p_L \in \mathcal{P}} f(p_1 \dots p_L)$$

where $\mathcal{P}$ is the set of all valid derivations for the input sentence.

2.2 The Decoding Algorithm

At a high level, the decoding algorithm of Chang and Collins (2017) differs from the commonly-used approach of Koehn et al. (2003) in two important respects:

1. The decoding algorithm proceeds in strictly left-to-right order in the *source* sentence.

2. Each sub-derivation (item) in the beam consists of *multiple* sequences of phrases, instead of a single sequence.

To be more precise, each sub-derivation in the decoding algorithm consists of:

1. An integer j specifying the length of the derivation (i.e., that words $x_1 \dots x_j$ have been translated).

2. A set of segments $\{\pi_1, \pi_2, \dots, \pi_r\}$ where $r \geq 1$. Each segment π is a sequence of phrases. The segment π_1 always has $(1, 1, \text{<s>})$ as its first element. Each word $x_1 \dots x_j$ is translated exactly once in these segments.

As one example, the sub-derivation $(1, \{\langle(1, 1, \text{<s>})\rangle\})$ is always the initial sub-derivation, with only the first word x_1 being translated, and with a single segment

$\pi_1 = \langle(1, 1, \texttt{<s>})\rangle$. A more complex sub-derivation is

$$(7, \{\langle(1, 1, \texttt{<s>})(2, 3, \text{we must})(4, 4, \text{also})\rangle,$$
$$\langle(5, 6, \text{these criticisms})(7, 7, \text{seriously})\rangle\}) \quad (1)$$

which translates words $x_1 \dots x_7$, and has two segments,

$$\pi_1 = \langle(1, 1, \texttt{<s>})(2, 3, \text{we must})(4, 4, \text{also})\rangle$$
$$\pi_2 = \langle(5, 6, \text{these criticisms})(7, 7, \text{seriously})\rangle$$

We now describe how sub-derivations can be built as the source sentence is processed in left-to-right order. A derivation $(j, \{\pi_1 \dots \pi_r\})$ can be extended as follows:

1. First select some phrase $p = (j + 1, t, e)$ where the phrase-based lexicon specifies that words $x_{j+1} \dots x_t$ can be translated as the English sequence $e = e_1 \dots e_m$.

2. Second, extend the derivation using one of the following operations (we use CONCAT to denote an operation that concatenates two or more phrase sequences):

   (a) Replace π_i for some $i \in 1 \dots r$ by $\text{CONCAT}(\pi_i, p)$.

   (b) Replace π_i for some $i \in 2 \dots r$ by $\text{CONCAT}(p, \pi_i)$.

   (c) Replace $\pi_i, \pi_{i'}$ for integers $i \neq i'$ by $\text{CONCAT}(\pi_i, p, \pi_{i'})$

   (d) Create a new segment $\pi_{r+1} = \langle p \rangle$.

Figure 1 shows the sequence of steps, and the resulting sequence of sub-derivations, in the translation of a German sentence.

A few remarks:

Remark 1. The score for each of the operations (a)-(d) described above is easily calculated using a combination of phrase, language model, and distortion scores.

Remark 2. The distortion limit can be used to rule out some of the operations (a)-(d) above, depending on the phrase p and the start/end points of each of the segments $\pi_1 \dots \pi_r$.

Remark 3. Dynamic programming can be used with this algorithm. Under a bigram language model, the dynamic programming state for a sub-derivation $(j, \{\pi_1 \dots \pi_r\})$ records the words and positions at the start and end of each segment $\pi_1 \dots \pi_r$. For example under a bigram language model the sub-derivation $(7, \dots)$ in Eq. 1 would be mapped to the dynamic-programming state $(7, \{(1, \texttt{<s>}, 4, \text{also}), (5, \text{these}, 7, \text{seriously})\})$. See Chang and Collins (2017) for more details.

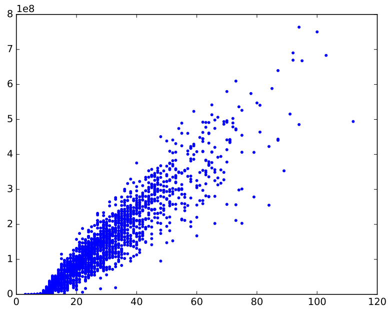

Figure 2: The total number of dynamic programming transitions and the sentence length.

Remark 4. It is simple to use beam search in conjunction with the algorithm. Different derivations of the same length j are compared in the beam. A heuristic—typically a lower-order language model—can be used to score the first $n - 1$ words in each segment $\pi_1 \cdots \pi_r$: this can be used as the "future score" for each item in the beam. This is arguably simpler than the future scores used in (Koehn et al., 2003), which have to take into account the fact that different items in the beam correspond to translations of different subsets of words in the source sentence. In our approach different derivations of the same length j have translated the same set of words $x_1 \cdots x_j$. For example in the sub-derivation $(7, \dots)$ given above (Eq. 1), and given a trigram language model, the initial bigram *these criticisms* in π_2 is scored as $p_u(\text{these}) \times p_b(\text{criticisms}|\text{these})$ where p_u and p_b are unigram and bigram language models.

3 Experiments

The original motivation for Chang and Collins (2017) was to develop a dynamic-programming algorithm for phrase-based decoding that for a fixed distortion limit d was polynomial time in other factors: the resulting dynamic programming algorithm is $O(nd!lh^{d+1})$ time, where d is the distortion limit, l is a bound on the number of phrases starting at any position, and h is related to the maximum number of different target translations for any source position. However an open question is whether the algorithm is useful in practice when used in conjunction with beam search. This

section describes experiments comparing beam search under the new algorithm to the method of Koehn et al. (2003). Throughout this section we refer to the algorithm of Chang and Collins (2017) as the "new" decoding algorithm.

Data. We use the Europarl parallel corpus (Version 7)[3] (Koehn, 2005) for all language pairs except for Vietnamese-English (vi-en). For Czech-English (cs-en), we use the Newstest2015 as the development set and Newstest2016 as the test set. For European languages other than Czech, we use the development and test set released for the Shared Task of WPT 2005[4]. For vi-en, we use the IWSLT'15 data.

3.1 Search Space with a Bigram Model

We first analyze the properties of the algorithm by running the exact decoding algorithm with a bigram language model and a fixed distortion limit of four, with no pruning. In Figure 2, we plot the number of transitions computed versus sentence length for translation of 2,000 German sentences to English. The figure confirms that the search space grows linearly with the number of words in the source sentence.

3.2 Beam Search under the New Algorithm

Even though the exact algorithm is linear time in the input sentence length, other factors (the dependence on d, l, and h, as described above) make the exact algorithm too costly to be useful in practice. We experiment with beam search under the new algorithm,[5] both with and without further pruning or restriction.

# segments	# sentences	percentage
1	636	34.93%
2	1,136	62.38%
3	49	2.69%

(a) The distribution of the number of segments required for the optimal solutions. Note that the distortion limit is four.

# segments	# sentences	percentage
1	119,428	15.97%
2	541,833	72.44%
3	82,869	11.08%
4	3,747	0.50%
5	128	0.02%
6	1	0.00%

(b) The distribution of the number of segments required for reordering the parsed German sentence.

Figure 4: The number of segments required for German-to-English translation.

We experimented with a *segment constraint* on the new algorithm: more specifically, we describe experiments with a hard limit $r \leq 2$ on the number of segments $\pi_1 \ldots \pi_r$ used in any translation.

Figure 3 shows results using a trigram language model for the new algorithm with beam search (SegmentD), the new algorithm with beam search and a hard limit $r \leq 2$ on the number of segments (Segment2), and Moses. A beam size of 100 is used with all the algorithms. For each language pair, we pick the distortion limit that maximizes the BLEU score for Moses. Moses was used to train all the translation models. It can be seen that the Segment2 algorithm gives very similar performance to Moses, while SegmentD has inferior performance for languges which require a larger distortion limit.

3.3 Experiments on the Number of Segments Required for German-to-English Translation

Finally, we investigate empirically how many segments (the maximum value of r) are required for translation from German to English. In a first experiment, we use the system of Chang and Collins (2011) to give exact search for German-to-English

[1] Unable to produce translations for 36 sentences.

[2] Unable to produce translations for one sentence.

[3] http://www.statmt.org/europarl/

[4] ACL 2005 Workshop on Building and Using Parallel Texts.

[5] See Section 5.1 in Chang and Collins (2017)

translation under a trigram language model with a distortion limit $d = 4$, and then look at the maximum value for r for each optimal translation. Out of 1,821 sentences, 34.9% have a maximum value of $r = 1$, 62.4% have $r = 2$, and 2.69% have $r = 3$ (Table 4a). No optimal translations require a value of r greater than 3. It can be seen that very few translations require more than 2 segments.

In a second experiment, we take the reordering system of Collins et al. (2005) and test the maximum value for r on each sentence to capture the reordering rules. Table 4b gives the results. It can be seen that over 99% of sentences require a value of $r = 3$ or less, again suggesting that for at least this language pair, a choice of $r = 3$ or $r = 4$ is large enough to capture the majority of reorderings (assuming that the rules of Collins et al. (2005) are comprehensive).

4 Conclusion

The goal of this paper was to understand the empirical performance of a newly proposed decoding algorithm that operates from left to right on the source side. We compare our implementation of the new algorithm with the Moses decoder. The experimental results demonstrate that the new algorithm combined with beam search and segment-based pruning is competitive with the Moses decoder. Future work should consider integration of the method with more recent models, in particular neural translation models.

Using Target-side Monolingual Data for Neural Machine Translation through Multi-task Learning

Tobias Domhan and **Felix Hieber**

{domhant,fhieber}@amazon.com

Abstract

The performance of Neural Machine Translation (NMT) models relies heavily on the availability of sufficient amounts of parallel data, and an efficient and effective way of leveraging the vastly available amounts of monolingual data has yet to be found. We propose to modify the decoder in a neural sequence-to-sequence model to enable multi-task learning for two strongly related tasks: target-side language modeling and translation. The decoder predicts the next target word through two channels, a target-side language model on the lowest layer, and an attentional recurrent model which is conditioned on the source representation. This architecture allows joint training on both large amounts of monolingual and moderate amounts of bilingual data to improve NMT performance. Initial results in the news domain for three language pairs show moderate but consistent improvements over a baseline trained on bilingual data only.

1 Introduction

In recent years, neural encoder-decoder models (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2014) have significantly advanced the state of the art in NMT, and now consistently outperform Statistical Machine Translation (SMT) (Bojar et al., 2016). However, their success hinges on the availability of sufficient amounts of parallel data, and contrary to the long line of research in SMT, there has only been a limited amount of work on how to effectively *and efficiently* make use of monolingual data which is typically amply available. We propose a modified neural sequence-to-sequence model with attention (Bahdanau et al., 2014; Luong et al., 2015b) that uses multi-task learning on the decoder side to jointly learn two strongly related tasks: target-side language modeling and translation. Our approach does not require any pre-translation or pre-training to learn from monolingual data and thus provides a principled way to integrate monolingual data resources into NMT training.

2 Related Work

Gülçehre et al. (2015) investigate two ways of integrating a pre-trained neural Language Model (LM) into a pre-trained NMT system: shallow fusion, where the LM is used at test time to rescore beam search hypothesis, requiring no additional fine-tuning and deep fusion, where hidden states of NMT decoder and LM are concatenated before making a prediction for the next word. Both components are pre-trained separately and fine-tuned together.

More recently, Sennrich et al. (2016) have shown significant improvements by *back-translating* target-side monolingual data and using such synthetic data as additional parallel training data. One downside of this approach is the significantly increased training time, due to training of a model in the reverse direction and translation of monolingual data. In contrast, we propose to train NMT models from scratch on both bilingual and target-side monolingual data in a multi-task setting.

Our approach aims to exploit the signals from target-side monolingual data to learn a strong language model that supports the decoder in making translation decisions for the next word. Our approach further relates to Zhang and Zong (2016), who investigate multi-task learning for sequence-to-sequence models by strengthening the encoder using source-side monolingual data. A shared encoder architecture is used to predict both, transla-

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1500–1505

tions of parallel source sentences and permutations of monolingual source sentences. In this paper we focus on target-side monolingual data and only update encoder parameters based on existing parallel data.

In a broader context, multi-task learning has shown to be effective in the context of sequence-to-sequence models (Luong et al., 2015a), where different parts of the network can be shared across multiple tasks.

3 Neural Machine Translation

We briefly recap the baseline NMT model (Bahdanau et al., 2014; Luong et al., 2015b) and highlight architectural differences of our implementation where necessary.

Given source sentence $\mathbf{x} = x_1, ..., x_n$ and target sentence $\mathbf{y} = y_1, ..., y_m$, NMT models $p(\mathbf{y}|\mathbf{x})$ as a target language sequence model, conditioning the probability of the target word y_t on the target history $\mathbf{y}_{1:t-1}$ and source sentence $\mathbf{x}$. Each x_i and y_t are integer ids given by source and target vocabulary mappings, $\mathbf{V}_{src}$, $\mathbf{V}_{trg}$, built from the training data tokens. The target sequence is factorized as:

$$p(\mathbf{y}|\mathbf{x};\boldsymbol{\theta}) = \prod_{t=1}^{m} p(y_t|\mathbf{y}_{1:t-1}, \mathbf{x}; \boldsymbol{\theta}). \quad (1)$$

The model, parameterized by $\boldsymbol{\theta}$, consists of an *encoder* and a *decoder* part (Sutskever et al., 2014).

For training set $\mathbb{P}$ consisting of parallel sentence pairs $(\mathbf{x}, \mathbf{y})$, we minimize the cross-entropy loss w.r.t $\boldsymbol{\theta}$:

$$\mathcal{L}_{\boldsymbol{\theta}} = \sum_{(\mathbf{x},\mathbf{y})\in\mathbb{P}} -\log p(\mathbf{y}|\mathbf{x};\boldsymbol{\theta}). \quad (2)$$

Encoder Given source sentence $\mathbf{x} = x_1, ..., x_n$, the encoder produces a sequence of hidden states $\mathbf{h}_1 \ldots \mathbf{h}_n$ through an Recurrent Neural Network (RNN), such that:

$$\overrightarrow{\mathbf{h}}_i = f_{enc}(\mathbf{E}_S\mathbf{x}_i, \overrightarrow{\mathbf{h}}_{i-1}), \quad (3)$$

where $\mathbf{h}_0 = \mathbf{0}$, $\mathbf{x}_i \in \{0,1\}^{|\mathbf{V}_{src}|}$ is the one-hot encoding of x_i, $\mathbf{E}_S \in \mathbb{R}^{e\times|\mathbf{V}_{src}|}$ is a source embedding matrix with embedding size e, and f_{enc} some non-linear function, such as the Gated Rectified Unit (GRU) (Cho et al., 2014) or a Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) network.

Attentional Decoder The decoder also consists of an RNN to predict one target word at a time through a *state vector* $\mathbf{s}$:

$$\mathbf{s}_t = f_{dec}([\mathbf{E}_T\mathbf{y}_{t-1}; \bar{\mathbf{s}}_{t-1}], \mathbf{s}_{t-1}), \quad (4)$$

where $\mathbf{y}_{t-1} \in \{0,1\}^{|\mathbf{V}_{trg}|}$ is the one-hot encoding of the previous target word, $\mathbf{E}_T \in \mathbb{R}^{e\times|\mathbf{V}_{trg}|}$ the target word embedding matrix, f_{dec} an RNN, $\mathbf{s}_{t-1}$ the previous state vector, and $\bar{\mathbf{s}}_{t-1}$ the source-dependent *attentional vector*. The initial decoder hidden state is a non-linear transformation of the last encoder hidden state: $\mathbf{s}_0 = \tanh(\mathbf{W}_{init}\mathbf{h}_n + \mathbf{b}_{init})$. The attentional vector $\bar{\mathbf{s}}_t$ combines the decoder state with a *context vector* $\mathbf{c}_t$:

$$\bar{\mathbf{s}}_t = \tanh(\mathbf{W}_{\bar{s}}[\mathbf{s}_t; \mathbf{c}_t]), \quad (5)$$

where $\mathbf{c}_t$ is a weighted sum of encoder hidden states: $\mathbf{c}_t = \sum_{i=1}^{n} \alpha_{ti}\mathbf{h}_i$ and brackets denote vector concatenation.

The attention vector $\boldsymbol{\alpha}_t$ is computed by an attention network (Bahdanau et al., 2014; Luong et al., 2015b):

$$\alpha_{ti} = softmax(score(\mathbf{s}_t, \mathbf{h}_i))$$
$$score(\mathbf{s}, \mathbf{h}) = \mathbf{v}_a^\top \tanh(\mathbf{W}_u\mathbf{s} + \mathbf{W}_v\mathbf{h}). \quad (6)$$

The next target word y_t is predicted through a softmax layer over the attentional vector $\bar{\mathbf{s}}_t$:

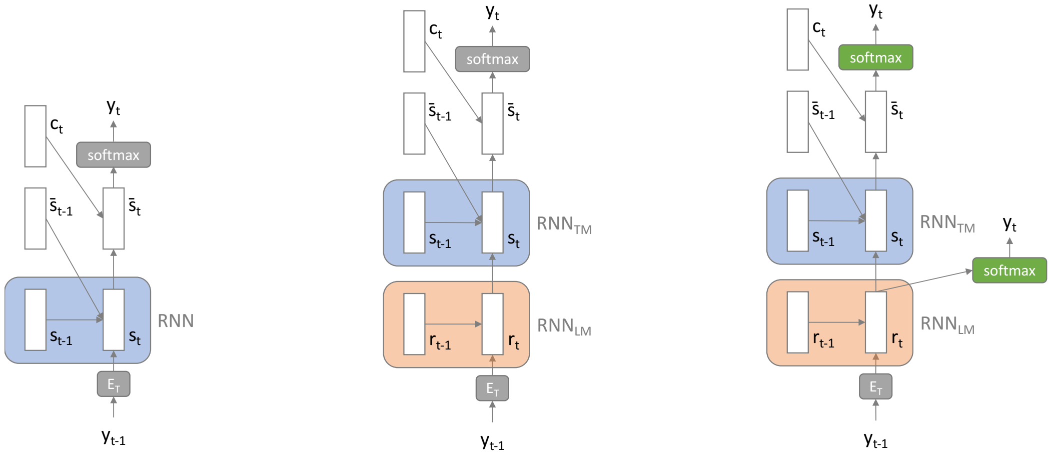
$$p(y_t|\mathbf{y}_{1:t-1}, \mathbf{x}; \boldsymbol{\theta}) = softmax(\mathbf{W}_o\bar{\mathbf{s}}_t + \mathbf{b}_o) \quad (7)$$

where $\mathbf{W}_o$ maps $\bar{\mathbf{s}}_t$ to the dimension of the target vocabulary. Figure 1a depicts this decoder architecture. Note that source information from $\mathbf{c}$ indirectly influences the states $\mathbf{s}$ of the decoder RNN as it takes $\bar{\mathbf{s}}$ as one of its inputs.

4 Incorporating Monolingual Data

4.1 Separate Decoder LM layer

The decoder RNN (Figure 1a) is essentially a target-side language model, additionally conditioned on source-side sequences. Such sequences are not available for monolingual corpora and previous work has tried to overcome this problem by either using synthetically generated source sequences or using a NULL token as the source sequence (Sennrich et al., 2016). As previously shown empirically, the model tends to "forget" source-side information if trained on much more monolingual than parallel data.



(a) baseline (b) +LML (c) +LML +MTL

Figure 1: Illustration of the proposed decoder architecture. (a) Baseline model with a single-layer decoder RNN and attention (b) Addition of a source-independent LM layer that feeds into the source-dependent decoder (c) Multi-task setting next-word prediction from both layers; green softmax layers are shared.

In our approach we explicitly define a source-independent network that only learns from target-side sequences (a language model), and a source-dependent network on top, that takes information from the source sequence into account (a translation model) through the attentional vector $\bar{\mathbf{s}}$. Formally, we modify the decoder RNN of Equation 4 to operate on the outputs an LM layer, which is independent of any source-side information:

$$\mathbf{s}_t = f_{dec}([\mathbf{r}_t; \bar{\mathbf{s}}_{t-1}], \mathbf{s}_{t-1}) \quad (8)$$

$$\mathbf{r}_t = f_{lm}(\mathbf{E}_T \mathbf{y}_{t-1}, \mathbf{r}_{t-1}) \quad (9)$$

Figure 1b illustrates this separation graphically.

4.2 Multi-task Learning

The separation from above allows us to train the target embeddings $\mathbf{E}_T$ and f_{lm} parameters from monolingual data, concurrent to training the rest of the network on bilingual data. Let us denote the source-independent parameters by $\boldsymbol{\sigma}$. We connect a second loss to f_{lm} to predict the next target word also conditioned only on target history information (Figure 1c). Parameters for softmax layers are shared such that predictions of the LM layer are given by:

$$p(y_t|\mathbf{y}_{1:t-1}, \boldsymbol{\sigma}) = softmax(\mathbf{W}_o \mathbf{r}_t + \mathbf{b}_o). \quad (10)$$

Formally, for a heterogeneous data set $\mathbb{Z} = \{\mathbb{P}, \mathbb{M}\}$, consisting of parallel and monolingual sentences $(\mathbf{x}, \mathbf{y}), (\mathbf{y})$, we optimize the following joint loss:

$$\mathcal{L}_{\boldsymbol{\theta},\boldsymbol{\sigma}} = \frac{1}{|\mathbb{P}|} \sum_{(\mathbf{x},\mathbf{y}) \in \mathbb{P}} -\log p(\mathbf{y}|\mathbf{x}; \boldsymbol{\theta}) + \gamma \frac{1}{|\mathbb{M}|} \sum_{\mathbf{y} \in \mathbb{M}} -\log p(\mathbf{y}; \boldsymbol{\sigma}), \quad (11)$$

where the source-independent parameters $\boldsymbol{\sigma} \subset \boldsymbol{\theta}$ are updated by gradients from both mono- and parallel data examples, and source-dependent parameters $\boldsymbol{\theta}$ are updated only through gradients from parallel data examples. $\gamma \geq 0$ is a scalar to influence the importance of the monolingual loss. In practice, we construct mini-batches of training examples, where 50% of the data is parallel, and 50% of the data is monolingual and set $\gamma = 1$.

Since parts of the decoder are shared among both tasks and we optimize both loss terms concurrently, we view this approach as an instance of multi-task learning rather than transfer learning, where optimization is typically carried out sequentially.

5 Experiments

We conduct experiments for three different language pairs in the news domain: FR→EN, EN→DE, and CS→EN.

5.1 Data

For EN→DE and CS→EN we use *news-commentary-v11* as bilingual training data, *NewsCrawl 2015* as monolingual data, and news development and test sets from

System	Data	EN→DE	FR→EN	CS→EN
baseline		20.3 39.9 63.0	21.7 27.5 59.1	17.0 24.4 65.2
+ LML		20.4 39.8 63.1	21.3 27.2 59.8	16.9 24.4 65.4
+ LML + MTL	+ mono	21.4 40.8 61.4	22.3 27.7 58.3	17.2 24.7 64.3
Sennrich et al. (2016)	+ synthetic	24.4 43.4 56.4	27.4 31.5 52.1	21.2 27.5 59.4
ensemble baseline		22.2 41.6 60.6	23.9 29.1 56.4	18.3 25.5 63.0
+ LML		22.4 41.8 60.9	23.5 28.7 57.2	18.3 25.6 63.4
+ LML + MTL	+ mono	23.6 42.8 58.9	24.2 29.2 55.9	18.8 25.9 62.2
ensemble Sennrich et al. (2016)	+ synthetic	25.7 44.6 55.0	29.1 32.6 50.3	22.5 28.4 57.8

Table 1: BLEU/METEOR/TER scores on test sets for different language pairs. For BLEU and METEOR higher is better. For TER lower is better.

WMT2016 (Bojar et al., 2016). For FR→EN we use *newscommentary-v9* as bilingual data, *NewsCrawl 2009-13* as monolingual data, and news development and test sets from WMT 2014 (Bojar et al., 2014). The number of sentences for these corpora is shown below:

Data Set	bilingual	monolingual
EN→DE	242,770	51,315,088
FR→EN	183,251	51,995,709
CS→EN	191,432	27,236,445

5.2 Experimental Setup

We tokenize all data and apply Byte Pair Encoding (BPE) (Sennrich et al., 2015) with 30k merge operations learned on the joined bilingual data. Models are evaluated in terms of BLEU (Papineni et al., 2002), METEOR (Lavie and Denkowski, 2009) and TER (Snover et al., 2006) on tokenized, cased test data. Decoding is performed using beam search with a beam of size 5. We implement all models using MXNet (Chen et al., 2015)[1].

Baselines Our baseline model consists of a 1-layer bi-directional LSTM encoder with an embedding size of 512 and a hidden size of 1024. The 1-layer LSTM decoder with 1024 hidden units uses an attention network with 256 hidden units. The model is optimized using Adam (Kingma and Ba, 2014) with a learning rate of 0.0003, no weight decay and gradient clipping if the norm exceeds 1.0. The batch size is set to 64 and the maximum sequence length to 100. Dropout (Srivastava et al., 2014) of 0.3 is applied to source word embeddings and outputs of RNN cells. We initialize all RNN parameters with orthogonal matrices (Saxe et al., 2013) and the remaining parameters with the Xavier (Glorot and Bengio, 2010) method. We use early stopping with respect to perplexity on the development set. We train each model configuration three times with different seeds and report average metrics across the three runs.

Further, we train models with synthetic parallel data generated through *back-translation* (Sennrich et al., 2016). For this, we first train a baseline model in the reverse direction and then translate a random sample of 200k sentences from the monolingual target data. On the combined parallel and synthetic training data we train a new model with the same training hyper-parameters as the baseline.

Language Model Layer The architecture with an additional source-independent LM layer (+LML) is trained with the same hyper-parameters and data as the baseline model. The LM RNN uses a hidden size of 1024. The multi-task system (+LML + MTL) is trained on both parallel and monolingual data. In practice, all +LML +MTL models converge before seeing the entire monolingual corpus and at about the same number of updates as the baseline.

6 Results

Table 1 shows results on the held-out test sets. We observe that a separate LM layer does not significantly impact performance across all metrics. Adding monolingual data in the described multi-task setting improves translation performance by a small but consistent margin across all metrics. Interestingly, the improvements from monolingual data are additive to the gains from ensembling of

[1] Baseline systems are equivalent to an earlier version of Sockeye: https://github.com/awslabs/sockeye

3 models with different random seeds. However, the use of synthetic parallel data still outperforms our approach both in single and ensemble systems.

While separating out a language model allowed us to carry out multi-task training on mixed data types, it constrains gradients from monolingual data examples to a subset of source-independent network parameters ($\boldsymbol{\sigma}$). In contrast, synthetic data always affects all network parameters ($\boldsymbol{\theta}$) and has a positive effect despite source sequences being noisy. We speculate that training from synthetic source data may also act as a model regularizer.

7 Conclusion

We proposed a way to directly integrate target-side monolingual data into NMT through multi-task learning. Our approach avoids costly pre-training processes and jointly trains on bilingual and monolingual data from scratch. While initial results show only moderate improvements over the baseline and fall short against using synthetic parallel data, we believe there is value in pursuing this line of research further to simplify training procedures.

Encoding Sentences with Graph Convolutional Networks for Semantic Role Labeling

Diego Marcheggiani[1] **Ivan Titov**[1,2]
[1]ILLC, University of Amsterdam

marcheggiani@uva.nl ititov@inf.ed.ac.uk

Abstract

Semantic role labeling (SRL) is the task of identifying the predicate-argument structure of a sentence. It is typically regarded as an important step in the standard NLP pipeline. As the semantic representations are closely related to syntactic ones, we exploit syntactic information in our model. We propose a version of graph convolutional networks (GCNs), a recent class of neural networks operating on graphs, suited to model syntactic dependency graphs. GCNs over syntactic dependency trees are used as sentence encoders, producing latent feature representations of words in a sentence. We observe that GCN layers are complementary to LSTM ones: when we stack both GCN and LSTM layers, we obtain a substantial improvement over an already state-of-the-art LSTM SRL model, resulting in the best reported scores on the standard benchmark (CoNLL-2009) both for Chinese and English.

1 Introduction

Semantic role labeling (SRL) (Gildea and Jurafsky, 2002) can be informally described as the task of discovering *who* did *what* to *whom*. For example, consider an SRL dependency graph shown above the sentence in Figure 1. Formally, the task includes (1) detection of predicates (e.g., *makes*); (2) labeling the predicates with a sense from a sense inventory (e.g., *make*.01); (3) identifying and assigning arguments to *semantic roles* (e.g., *Sequa* is A0, i.e., an agent / 'doer' for the corresponding predicate, and *engines* is A1, i.e., a patient / 'an affected entity'). SRL is often regarded as an important step in the standard NLP pipeline, providing information to downstream tasks such as information extraction and question answering.

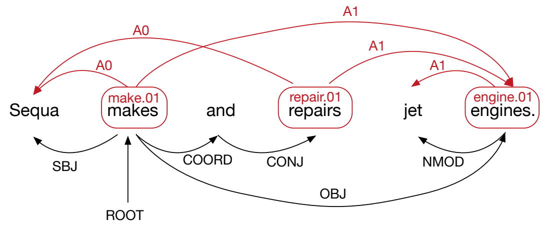

Figure 1: An example sentence annotated with semantic (top) and syntactic dependencies (bottom).

The semantic representations are closely related to syntactic ones, even though the syntax-semantics interface is far from trivial (Levin, 1993). For example, one can observe that many arcs in the syntactic dependency graph (shown in black below the sentence in Figure 1) are mirrored in the semantic dependency graph. Given these similarities and also because of availability of accurate syntactic parsers for many languages, it seems natural to exploit syntactic information when predicting semantics. Though historically most SRL approaches did rely on syntax (Thompson et al., 2003; Pradhan et al., 2005; Punyakanok et al., 2008; Johansson and Nugues, 2008), the last generation of SRL models put syntax aside in favor of neural sequence models, namely LSTMs (Zhou and Xu, 2015; Marcheggiani et al., 2017), and outperformed syntactically-driven methods on standard benchmarks. We believe that one of the reasons for this radical choice is the lack of simple and effective methods for incorporating syntactic information into sequential neural networks (namely, at the level of words). In this paper we

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1506–1515
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

propose one way how to address this limitation.

Specifically, we rely on graph convolutional networks (GCNs) (Duvenaud et al., 2015; Kipf and Welling, 2017; Kearnes et al., 2016), a recent class of multilayer neural networks operating on graphs. For every node in the graph (in our case a word in a sentence), GCN encodes relevant information about its neighborhood as a real-valued feature vector. GCNs have been studied largely in the context of undirected unlabeled graphs. We introduce a version of GCNs for modeling syntactic dependency structures and generally applicable to labeled directed graphs.

One layer GCN encodes only information about immediate neighbors and K layers are needed to encode K-order neighborhoods (i.e., information about nodes at most K hops aways). This contrasts with recurrent and recursive neural networks (Elman, 1990; Socher et al., 2013) which, at least in theory, can capture statistical dependencies across unbounded paths in a trees or in a sequence. However, as we will further discuss in Section 3.3, this is not a serious limitation when GCNs are used in combination with encoders based on recurrent networks (LSTMs). When we stack GCNs on top of LSTM layers, we obtain a substantial improvement over an already state-of-the-art LSTM SRL model, resulting in the best reported scores on the standard benchmark (CoNLL-2009), both for English and Chinese.[1]

Interestingly, again unlike recursive neural networks, GCNs do not constrain the graph to be a tree. We believe that there are many applications in NLP, where GCN-based encoders of sentences or even documents can be used to incorporate knowledge about linguistic structures (e.g., representations of syntax, semantics or discourse). For example, GCNs can take as input combined syntactic-semantic graphs (e.g., the entire graph from Figure 1) and be used within downstream tasks such as machine translation or question answering. However, we leave this for future work and here solely focus on SRL.

The contributions of this paper can be summarized as follows:

- we are the first to show that GCNs are effective for NLP;
- we propose a generalization of GCNs suited to encoding syntactic information at word level;
- we propose a GCN-based SRL model and obtain state-of-the-art results on English and Chinese portions of the CoNLL-2009 dataset;
- we show that bidirectional LSTMs and syntax-based GCNs have complementary modeling power.

2 Graph Convolutional Networks

In this section we describe GCNs of Kipf and Welling (2017). Please refer to Gilmer et al. (2017) for a comprehensive overview of GCN versions.

GCNs are neural networks operating on graphs and inducing features of nodes (i.e., real-valued vectors / embeddings) based on properties of their neighborhoods. In Kipf and Welling (2017), they were shown to be very effective for the node classification task: the classifier was estimated jointly with a GCN, so that the induced node features were informative for the node classification problem. Depending on how many layers of convolution are used, GCNs can capture information only about immediate neighbors (with one layer of convolution) or any nodes at most K hops aways (if K layers are stacked on top of each other).

More formally, consider an undirected graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, where $\mathcal{V}$ ($|V| = n$) and $\mathcal{E}$ are sets of nodes and edges, respectively. Kipf and Welling (2017) assume that edges contain all the self-loops, i.e., $(v, v) \in \mathcal{E}$ for any v. We can define a matrix $X \in \mathbb{R}^{m \times n}$ with each its column $x_v \in \mathbb{R}^m$ ($v \in \mathcal{V}$) encoding node features. The vectors can either encode genuine features (e.g., this vector can encode the title of a paper if citation graphs are considered) or be a one-hot vector. The node representation, encoding information about its immediate neighbors, is computed as

$$h_v = ReLU\left(\sum_{u \in \mathcal{N}(v)} (W x_u + b)\right), \qquad (1)$$

where $W \in \mathbb{R}^{m \times m}$ and $b \in \mathbb{R}^m$ are a weight matrix and a bias, respectively; $\mathcal{N}(v)$ are neighbors of v; $ReLU$ is the rectifier linear unit activation function.[2] Note that $v \in \mathcal{N}(v)$ (because of self-loops), so the input feature representation of v (i.e. x_v) affects its induced representation h_v.

[1] The code is available at `https://github.com/diegma/neural-dep-srl`.

[2] We dropped normalization factors used in Kipf and Welling (2017), as they are not used in our syntactic GCNs.

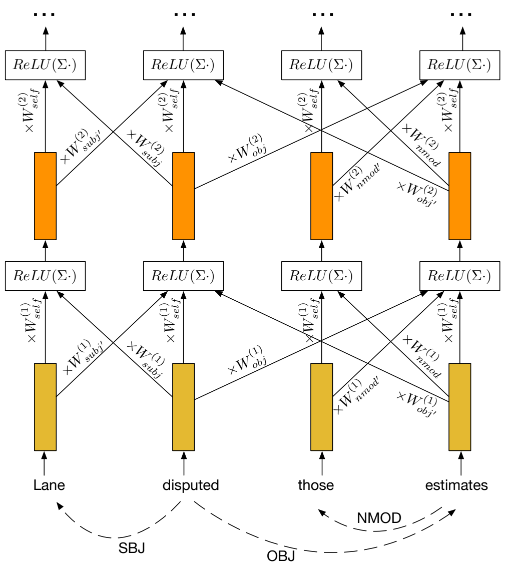

Figure 2: A simplified syntactic GCN (bias terms and gates are omitted); the syntactic graph of the sentence is shown with dashed lines at the bottom. Parameter matrices are sub-indexed with syntactic functions, and apostrophes (e.g., *subj'*) signify that information flows in the direction opposite of the dependency arcs (i.e., from dependents to heads).

As in standard convolutional networks (LeCun et al., 2001), by stacking GCN layers one can incorporate higher degree neighborhoods:

$$h_v^{(k+1)} = ReLU\left(\sum_{u\in\mathcal{N}(v)} W^{(k)} h_u^{(k)} + b^{(k)}\right)$$

where k denotes the layer number and $h_v^{(1)} = x_v$.

3 Syntactic GCNs

As syntactic dependency trees are directed and labeled (we refer to the dependency labels as *syntactic functions*), we first need to modify the computation in order to incorporate label information (Section 3.1). In the subsequent section, we incorporate gates in GCNs, so that the model can decide which edges are more relevant to the task in question. Having gates is also important as we rely on automatically predicted syntactic representations, and the gates can detect and downweight potentially erroneous edges.

3.1 Incorporating directions and labels

Now, we introduce a generalization of GCNs appropriate for syntactic dependency trees, and in general, for directed labeled graphs. First note that there is no reason to assume that information flows only along the syntactic dependency arcs (e.g., from *makes* to *Sequa*), so we allow it to flow in the opposite direction as well (i.e., from dependents to heads). We use a graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, where the edge set contains all pairs of nodes (i.e., words) adjacent in the dependency tree. In our example, both (*Sequa*, *makes*) and (*makes*, *Sequa*) belong to the edge set. The graph is labeled, and the label $L(u, v)$ for $(u, v) \in \mathcal{E}$ contains both information about the syntactic function and indicates whether the edge is in the same or opposite direction as the syntactic dependency arc. For example, the label for (*makes*, *Sequa*) is $subj$, whereas the label for (*Sequa*, *makes*) is $subj'$, with the apostrophe indicating that the edge is in the direction opposite to the corresponding syntactic arc. Similarly, self-loops will have label $self$. Consequently, we can simply assume that the GCN parameters are label-specific, resulting in the following computation, also illustrated in Figure 2:

$$h_v^{(k+1)} = ReLU\left(\sum_{u\in\mathcal{N}(v)} W^{(k)}_{L(u,v)} h_u^{(k)} + b^{(k)}_{L(u,v)}\right).$$

This model is over-parameterized,[3] especially given that SRL datasets are moderately sized, by deep learning standards. So instead of learning the GCN parameters directly, we define them as

$$W^{(k)}_{L(u,v)} = V^{(k)}_{dir(u,v)}, \quad (2)$$

where $dir(u, v)$ indicates whether the edge (u, v) is directed (1) along, (2) in the opposite direction to the syntactic dependency arc, or (3) is a self-loop; $V^{(k)}_{dir(u,v)} \in \mathbb{R}^{m\times m}$. Our simplification captures the intuition that information should be propagated differently along edges depending whether this is a head-to-dependent or dependent-to-head edge (i.e., along or opposite the corresponding syntactic arc) and whether it is a self-loop. So we do not share any parameters between these three very different edge types. Syntactic functions are important, but perhaps less crucial, so they are encoded only in the feature vectors $b_{L(u,v)}$.

3.2 Edge-wise gating

Uniformly accepting information from all neighboring nodes may not be appropriate for the SRL

[3] Chinese and English CoNLL-2009 datasets used 41 and 48 different syntactic functions, which would result in having 83 and 97 different matrices in every layer, respectively.

setting. For example, we see in Figure 1 that many semantic arcs just mirror their syntactic counterparts, so they may need to be up-weighted. Moreover, we rely on automatically predicted syntactic structures, and, even for English, syntactic parsers are far from being perfect, especially when used out-of-domain. It is risky for a downstream application to rely on a potentially wrong syntactic edge, so the corresponding message in the neural network may need to be down-weighted.

In order to address the above issues, inspired by recent literature (van den Oord et al., 2016; Dauphin et al., 2016), we calculate for each edge node pair a scalar gate of the form

$$g_{u,v}^{(k)} = \sigma\left(h_u^{(k)} \cdot \hat{v}_{dir(u,v)}^{(k)} + \hat{b}_{L(u,v)}^{(k)}\right), \quad (3)$$

where σ is the logistic sigmoid function, $\hat{v}_{dir(u,v)}^{(k)} \in \mathbb{R}^m$ and $\hat{b}_{L(u,v)}^{(k)} \in \mathbb{R}$ are weights and a bias for the gate. With this additional gating mechanism, the final syntactic GCN computation is formulated as

$$h_v^{(k+1)} = ReLU(\sum_{u \in \mathcal{N}(v)} g_{v,u}^{(k)} (V_{dir(u,v)}^{(k)} h_u^{(k)} + b_{L(u,v)}^{(k)})). \quad (4)$$

3.3 Complementarity of GCNs and LSTMs

The inability of GCNs to capture dependencies between nodes far away from each other in the graph may seem like a serious problem, especially in the context of SRL: paths between predicates and arguments often include many dependency arcs (Roth and Lapata, 2016). However, when graph convolution is performed on top of LSTM states (i.e., LSTM states serve as input $x_v = h_v^{(1)}$ to GCN) rather than static word embeddings, GCN may not need to capture more than a couple of hops.

To elaborate on this, let us speculate what role GCNs would play when used in combinations with LSTMs, given that LSTMs have already been shown very effective for SRL (Zhou and Xu, 2015; Marcheggiani et al., 2017). Though LSTMs are capable of capturing at least some degree of syntax (Linzen et al., 2016) without explicit syntactic supervision, SRL datasets are moderately sized, so LSTM models may still struggle with harder cases. Typically, harder cases for SRL involve arguments far away from their predicates. In fact, 20% and 30% of arguments are more than 5 tokens away from their predicate, in our English and Chinese collections, respectively. However, if we imagine that we can ‘teleport’ even over a single (longest) syntactic dependency edge, the ’distance’ would shrink: only 9% and 13% arguments will now be more than 5 LSTM steps away (again for English and Chinese, respectively). GCNs provide this ‘teleportation’ capability. These observations suggest that LSTMs and GCNs may be complementary, and we will see that empirical results support this intuition.

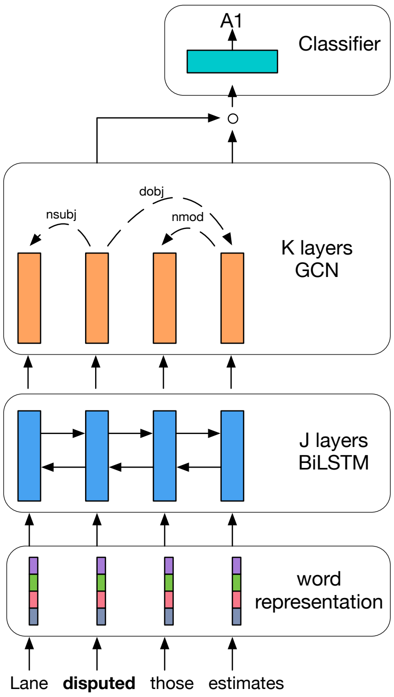

Figure 3: Predicting an argument and its label with an LSTM + GCN encoder.

4 Syntax-Aware Neural SRL Encoder

In this work, we build our semantic role labeler on top of the syntax-agnostic LSTM-based SRL model of Marcheggiani et al. (2017), which already achieves state-of-the-art results on the CoNLL-2009 English dataset. Following their approach we employ the same bidirectional (BiLSTM) encoder and enrich it with a syntactic GCN.

The CoNLL-2009 benchmark assumes that predicate positions are already marked in the test set (e.g., we would know that *makes*, *repairs* and *engines* in Figure 1 are predicates), so no predicate identification is needed. Also, as we focus here solely on identifying arguments and labeling them with semantic roles, for predicate disambiguation (i.e., marking *makes* as *make.01*) we use of an off-the-shelf disambiguation model (Roth and Lapata, 2016; Björkelund et al., 2009). As in Marcheggiani et al. (2017) and in most previous work, we process individual predicates in isolation, so for each predicate, our task reduces to a sequence labeling problem. That is, given a predicate (e.g., *disputed* in Figure 3) one needs to identify and label all its arguments (e.g., label *estimates* as A1 and label *those* as 'NULL', indicating that *those* is not an argument of *disputed*).

The semantic role labeler we propose is composed of four components (see Figure 3):

- look-ups of word embeddings;
- a BiLSTM encoder that takes as input the word representation of each word in a sentence;
- a syntax-based GCN encoder that re-encodes the BiLSTM representation based on the automatically predicted syntactic structure of the sentence;
- a role classifier that takes as input the GCN representation of the candidate argument and the representation of the predicate to predict the role associated with the candidate word.

4.1 Word representations

For each word w_i in the considered sentence, we create a sentence-specific word representation x_i. We represent each word w as the concatenation of four vectors:[4] a randomly initialized word embedding $x^{re} \in \mathbb{R}^{d_w}$, a pre-trained word embedding $x^{pe} \in \mathbb{R}^{d_w}$ estimated on an external text collection, a randomly initialized part-of-speech tag embedding $x^{pos} \in \mathbb{R}^{d_p}$ and a randomly initialized lemma embedding $x^{le} \in \mathbb{R}^{d_l}$ (active only if the word is a predicate). The randomly initialized embeddings x^{re}, x^{pos}, and x^{le} are fine-tuned during training, while the pre-trained ones are kept fixed. The final word representation is given by $x = x^{re} \circ x^{pe} \circ x^{pos} \circ x^{le}$, where $\circ$ represents the concatenation operator.

4.2 Bidirectional LSTM layer

One of the most popular and effective ways to represent sequences, such as sentences (Mikolov et al., 2010), is to use recurrent neural networks (RNN) (Elman, 1990). In particular their gated versions, Long Short-Term Memory (LSTM) networks (Hochreiter and Schmidhuber, 1997) and Gated Recurrent Units (GRU) (Cho et al., 2014), have proven effective in modeling long sequences (Chiu and Nichols, 2016; Sutskever et al., 2014).

Formally, an LSTM can be defined as a function $LSTM_\theta(x_{1:i})$ that takes as input the sequence $x_{1:i}$ and returns a hidden state $h_i \in \mathbb{R}^{d_h}$. This state can be regarded as a representation of the sentence from the start to the position i, or, in other words, it encodes the word at position i along with its left context. However, the right context is also important, so Bidirectional LSTMs (Graves, 2008) use two LSTMs: one for the forward pass, and another for the backward pass, $LSTM_F$ and $LSTM_B$, respectively. By concatenating the states of both LSTMs, we create a complete context-aware representation of a word $BiLSTM(x_{1:n}, i) = LSTM_F(x_{1:i}) \circ LSTM_B(x_{n:i})$. We follow Marcheggiani et al. (2017) and stack J layers of bidirectional LSTMs, where each layer takes the lower layer as its input.

4.3 Graph convolutional layer

The representation calculated with the BiLSTM encoder is fed as input to a GCN of the form defined in Equation (4). The neighboring nodes of a node v, namely $\mathcal{N}(v)$, and their relations to v are predicted by an external syntactic parser.

4.4 Semantic role classifier

The classifier predicts semantic roles of words given the predicate while relying on word representations provided by GCN; we concatenate hidden states of the candidate argument word and the predicate word and use them as input to a classifier (Figure 3, top). The softmax classifier computes the probability of the role (including special 'NULL' role):

$$p(r|t_i, t_p, l) \propto \exp(W_{l,r}(t_i \circ t_p)), \quad (5)$$

where t_i and t_p are representations produced by the graph convolutional encoder, l is the lemma of predicate p, and the symbol $\propto$ signifies proportionality.[5] As FitzGerald et al. (2015) and Marcheggiani et al. (2017), instead of using a fixed matrix $W_{l,r}$ or simply assuming that $W_{l,r} = W_r$,

[4] We drop the index i from the notation for the sake of brevity.

[5] We abuse the notation and refer as p both to the predicate word and to its position in the sentence.

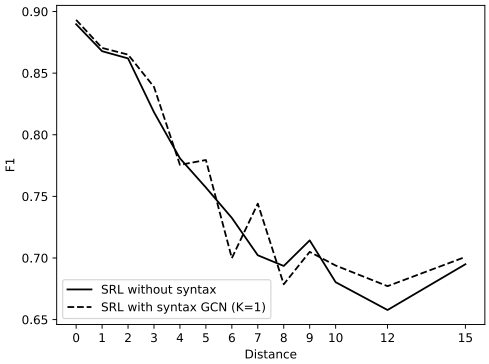

Figure 4: F_1 as function of word distance. The distance starts from zero, since nominal predicates can be arguments of themselves.

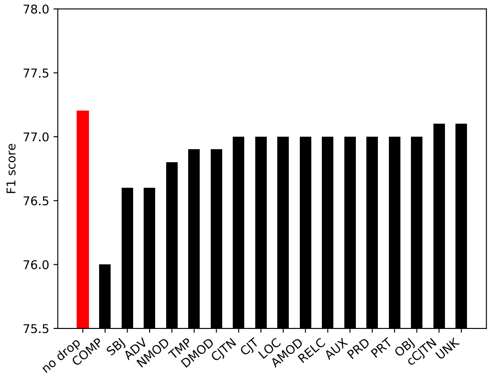

Figure 5: Performance with dependency arcs of given type dropped, on Chinese development set.

System (English)	P	R	F_1
LSTMs	84.3	81.1	82.7
LSTMs + GCNs (K=1)	85.2	81.6	83.3
LSTMs + GCNs (K=2)	84.1	81.4	82.7
LSTMs + GCNs (K=1), no gates	84.7	81.4	83.0
GCNs (no LSTMs), K=1	79.9	70.4	74.9
GCNs (no LSTMs), K=2	83.4	74.6	78.7
GCNs (no LSTMs), K=3	83.6	75.8	79.5
GCNs (no LSTMs), K=4	82.7	76.0	79.2

Table 1: SRL results without predicate disambiguation on the English development set.

we jointly embed the role r and predicate lemma l using a non-linear transformation:

$$W_{l,r} = ReLU(U(q_l \circ q_r)), \qquad (6)$$

where U is a parameter matrix, whereas $q_l \in \mathbb{R}^{d'_l}$ and $q_r \in \mathbb{R}^{d_r}$ are randomly initialized embeddings of predicate lemmas and roles. In this way each role prediction is predicate-specific, and, at the same time, we expect to learn a good representation for roles associated with infrequent predicates. As our training objective we use the categorical cross-entropy.

5 Experiments

5.1 Datasets and parameters

We tested the proposed SRL model on the English and Chinese CoNLL-2009 dataset with standard splits into training, test and development sets. The predicted POS tags for both languages were provided by the CoNLL-2009 shared-task organizers. For the predicate disambiguator we used the ones from Roth and Lapata (2016) for English and from Björkelund et al. (2009) for Chinese. We parsed English sentences with the BIST Parser (Kiperwasser and Goldberg, 2016), whereas for Chinese we used automatically predicted parses provided by the CoNLL-2009 shared-task organizers.

For English, we used external embeddings of Dyer et al. (2015), learned using the structured skip n-gram approach of Ling et al. (2015). For Chinese we used external embeddings produced with the neural language model of Bengio et al. (2003). We used *edge dropout* in GCN: when computing $h_v^{(k)}$, we ignore each node $v \in \mathcal{N}(v)$ with probability β. Adam (Kingma and Ba, 2015) was used as an optimizer. The hyperparameter tuning and all model selection were performed on the English development set; the chosen values are shown in Appendix.

5.2 Results and discussion

In order to show that GCN layers are effective, we first compare our model against its version which lacks GCN layers (i.e. essentially the model of Marcheggiani et al. (2017)). Importantly, to measure the genuine contribution of GCNs, we first tuned this syntax-agnostic model (e.g., the number of LSTM layers) to get best possible performance on the development set.[6]

We compare the syntax-agnostic model with 3 syntax-aware versions: one GCN layer over syntax ($K = 1$), one layer GCN without gates and two GCN layers ($K = 2$). As we rely on the same

[6] For example, if we would have used only one layer of LSTMs, gains from using GCNs would be even larger.

System (Chinese)	P	R	F_1
LSTMs	78.3	72.3	75.2
LSTMs + GCNs (K=1)	79.9	74.4	77.1
LSTMs + GCNs (K=2)	78.7	74.0	76.2
LSTMs + GCNs (K=1), no gates	78.2	74.8	76.5
GCNs (no LSTMs), K=1	78.7	58.5	67.1
GCNs (no LSTMs), K=2	79.7	62.7	70.1
GCNs (no LSTMs), K=3	76.8	66.8	71.4
GCNs (no LSTMs), K=4	79.1	63.5	70.4

Table 3: Results on the test set for English.

off-the-shelf disambiguator for all versions of the model, in Table 1 and 2 we report SRL-only scores (i.e., predicate disambiguation is not evaluated) on the English and Chinese development sets. For both datasets, the syntax-aware model with one GCN layers ($K = 1$) performs the best, outperforming the LSTM version by 1.9% and 0.6% for Chinese and English, respectively. The reasons why the improvements on Chinese are much larger are not entirely clear (e.g., both languages are relative fixed word order ones, and the syntactic parses for Chinese are considerably less accurate), this may be attributed to a higher proportion of long-distance dependencies between predicates and arguments in Chinese (see Section 3.3). Edge-wise gating (Section 3.2) also appears important: removing gates leads to a drop of 0.3% F_1 for English and 0.6% F_1 for Chinese.

Stacking two GCN layers does not give any benefit. When BiLSTM layers are dropped altogether, stacking two layers ($K = 2$) of GCNs greatly improves the performance, resulting in a 3.8% jump in F_1 for English and a 3.0% jump in F_1 for Chinese. Adding a 3rd layer of GCN ($K = 3$) further improves the performance.[7] This suggests that extra GCN layers are effective but largely redundant with respect to what LSTMs already capture.

Table 4: Results on the Chinese test set.

In Figure 4, we show the F_1 scores results on the English development set as a function of the distance, in terms of tokens, between a candidate argument and its predicate. As expected, GCNs appear to be more beneficial for long distance dependencies, as shorter ones are already accurately captured by the LSTM encoder.

We looked closer in contribution of specific dependency relations for Chinese. In order to assess this without retraining the model multiple times, we drop all dependencies of a given type at test time (one type at a time, only for types appearing over 300 times in the development set) and observe changes in performance. In Figure 5, we see that the most informative dependency is COMP (complement). Relative clauses in Chinese are very frequent and typically marked with particle 的 (de). The relative clause will syntactically depend on 的 as COMP, so COMP encodes important information about predicate-argument structure. These are often long-distance dependencies and may not be accurately captured by LSTMs. Although TMP (temporal) dependencies are not as frequent (∼2% of all dependencies), they are also important: temporal information is mirrored in semantic roles.

In order to compare to previous work, in Table 3 we report test results on the English in-domain (WSJ) evaluation data. Our model is *local*, as all the argument detection and labeling decisions are conditionally independent: their interaction is captured solely by the LSTM+GCN encoder. This makes our model fast and simple, though, as shown in previous work, *global* modeling of the structured output is beneficial.[8] We leave this extension for future work. Interestingly,

[7] Note that GCN layers are computationally cheaper than LSTM ones, even in our non-optimized implementation.

[8] As seen in Table 3, labelers of FitzGerald et al. (2015) and Roth and Lapata (2016) gained 0.6-1.0%.

System	P	R	F_1

Table 5: Results on the out-of-domain test set.

we outperform even the best global model and the best ensemble of global models, without using global modeling or ensembles. When we create an ensemble of 3 models with the product-of-expert combination rule, we improve by 1.2% over the best previous result, achieving 89.1% F_1.[9]

For Chinese (Table 4), our best model outperforms the state-of-the-art model of Roth and Lapata (2016) by even larger margin of 3.1%.

For English, in the CoNLL shared task, systems are also evaluated on the out-of-domain dataset. Statistical models are typically less accurate when they are applied to out-of-domain data. Consequently, the predicted syntax for the out-of-domain test set is of lower quality, which negatively affects the quality of GCN embeddings. However, our model works surprisingly well on out-of-domain data (Table 5), substantially outperforming all the previous syntax-aware models. This suggests that our model is fairly robust to mistakes in syntax. As expected though, our model does not outperform the syntax-agnostic model of Marcheggiani et al. (2017).

6 Related Work

Perhaps the earliest methods modeling syntax-semantics interface with RNNs are due to (Henderson et al., 2008; Titov et al., 2009; Gesmundo et al., 2009), they used shift-reduce parsers for joint SRL and syntactic parsing, and relied on RNNs to model statistical dependencies across syntactic and semantic parsing actions. A more modern (e.g., based on LSTMs) and effective reincarnation of this line of research has been proposed in Swayamdipta et al. (2016). Other recent work which considered incorporation of syntactic information in neural SRL models include: FitzGerald et al. (2015) who use standard syntactic features within an MLP calculating potentials of a CRF model; Roth and Lapata (2016) who enriched standard features for SRL with LSTM representations of syntactic paths between arguments and predicates; Lei et al. (2015) who relied on low-rank tensor factorizations for modeling syntax. Also Foland and Martin (2015) used (non-graph) convolutional networks and provided syntactic features as input. A very different line of research, but with similar goals to ours (i.e. integrating syntax with minimal feature engineering), used tree kernels (Moschitti et al., 2008).

Beyond SRL, there have been many proposals on how to incorporate syntactic information in RNN models, for example, in the context of neural machine translation (Eriguchi et al., 2017; Sennrich and Haddow, 2016). One of the most popular and attractive approaches is to use tree-structured recursive neural networks (Socher et al., 2013; Le and Zuidema, 2014; Dyer et al., 2015), including stacking them on top of a sequential BiLSTM (Miwa and Bansal, 2016). An approach of Mou et al. (2015) to sentiment analysis and question classification, introduced even before GCNs became popular in the machine learning community, is related to graph convolution. However, it is inherently single-layer and tree-specific, uses bottom-up computations, does not share parameters across syntactic functions and does not use gates. Gates have been previously used in GCNs (Li et al., 2016) but between GCN layers rather than for individual edges.

Previous approaches to integrating syntactic information in neural models are mainly designed to induce representations of sentences or syntactic constituents. In contrast, the approach we presented incorporates syntactic information at word level. This may be attractive from the engineering perspective, as it can be used, as we have shown, instead or along with RNN models.

7 Conclusions and Future Work

We demonstrated how GCNs can be used to incorporate syntactic information in neural models and specifically to construct a syntax-aware SRL

[9] To compare to previous work, we report combined scores which also include predicate disambiguation. As we use disambiguators from previous work (see Section 5.1), actual gains in argument identification and labeling are even larger.

model, resulting in state-of-the-art results for Chinese and English. There are relatively straightforward steps which can further improve the SRL results. For example, we relied on labeling arguments independently, whereas using a joint model is likely to significantly improve the performance. Also, in this paper we consider the dependency version of the SRL task, however the model can be generalized to the span-based version of the task (i.e. labeling argument spans with roles rather that syntactic heads of arguments) in a relatively straightforward fashion.

More generally, given simplicity of GCNs and their applicability to general graph structures (not necessarily trees), we believe that there are many NLP tasks where GCNs can be used to incorporate linguistic structures (e.g., syntactic and semantic representations of sentences and discourse parses or co-reference graphs for documents).

Abstract

We present a new semantic parsing model for answering compositional questions on semi-structured Wikipedia tables. Our parser is an encoder-decoder neural network with two key technical innovations: (1) a grammar for the decoder that only generates well-typed logical forms; and (2) an entity embedding and linking module that identifies entity mentions while generalizing across tables. We also introduce a novel method for training our neural model with question-answer supervision. On the WIKITABLEQUESTIONS data set, our parser achieves a state-of-the-art accuracy of 43.3% for a single model and 45.9% for a 5-model ensemble, improving on the best prior score of 38.7% set by a 15-model ensemble. These results suggest that type constraints and entity linking are valuable components to incorporate in neural semantic parsers.

1 Introduction

Semantic parsing is the problem of translating human language into computer language, and therefore is at the heart of natural language understanding. A typical semantic parsing task is question answering against a database, which is accomplished by translating questions into executable logical forms (i.e., programs) that output their answers. Recent work has shown that recurrent neural networks can be used for semantic parsing by encoding the question then predicting each token of the logical form in sequence (Jia and Liang, 2016; Dong and Lapata, 2016). These approaches, while effective, have two major limitations. First, they treat the logical form as an unstructured sequence, thereby ignoring type constraints on well-formed programs. Second, they do not address entity linking, which is a critical subproblem of semantic parsing (Yih et al., 2015).

This paper introduces a novel neural semantic parsing model that addresses these limitations of prior work. Our parser uses an encoder-decoder architecture with two key innovations. First, the decoder generates from a grammar that guarantees that generated logical forms are well-typed. This grammar is automatically induced from typed logical forms, and does not require any manual engineering to produce. Second, the encoder incorporates an entity linking and embedding module that enables it to learn to identify which question spans should be linked to entities. Finally, we also introduce a new approach for training neural semantic parsers from question-answer supervision.

We evaluate our parser on WIKITABLEQUESTIONS, a challenging data set for question answering against semi-structured Wikipedia tables (Pasupat and Liang, 2015). This data set has a broad variety of entities and relations across different tables, along with complex questions that necessitate long logical forms. On this data set, our parser achieves a question answering accuracy of 43.3% and an ensemble of 5 parsers achieves 45.9%, both of which outperform the previous state-of-the-art of 38.7% set by an ensemble of 15 models (Haug et al., 2017). We further perform several ablation studies that demonstrate the importance of both type constraints and entity linking to achieving high accuracy on this task.

2 Related Work

Semantic parsers vary along a few important dimensions:

Formalism Early work on semantic parsing used lexicalized grammar formalisms such as Combinatory Categorial Grammar (Zettlemoyer

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1516–1526
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

and Collins, 2005, 2007; Kwiatkowski et al., 2011, 2013; Krishnamurthy and Mitchell, 2012; Artzi and Zettlemoyer, 2013) and others (Liang et al., 2011; Berant et al., 2013; Zhao and Huang, 2015; Wong and Mooney, 2006, 2007). These formalisms have the advantage of only generating well-typed logical forms, but the disadvantage of introducing latent syntactic variables that make learning difficult. Another approach is to treat semantic parsing as a machine translation problem, where the logical form is linearized then predicted as an unstructured sequence of tokens (Andreas et al., 2013). This approach is taken by recent neural semantic parsers (Jia and Liang, 2016; Dong and Lapata, 2016; Locascio et al., 2016; Ling et al., 2016). This approach has the advantage of predicting the logical form directly from the question without latent variables, which simplifies learning, but the disadvantage of ignoring type constraints on logical forms. Our type-constrained neural semantic parser inherits the advantages of both approaches: it only generates well-typed logical forms and has no syntactic latent variables as every logical form has a unique derivation. Recent work has explored similar ideas to ours in the context of Python code generation (Yin and Neubig, 2017; Rabinovich et al., 2017).

Entity Linking Identifying the entities mentioned in a question is a critical subproblem of semantic parsing in broad domains and proper entity linking can lead to large accuracy improvements (Yih et al., 2015). However, semantic parsers have typically ignored this problem by assuming that entity linking is done beforehand (as the neural parsers above do) or using a simple parameterization for the entity linking portion (as the lexicalized parsers do). Our parser explicitly includes an entity linking module that enables it to model the highly ambiguous and implicit entity mentions in WIKITABLEQUESTIONS.

Supervision Semantic parsers can be trained from labeled logical forms (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005) or question-answer pairs (Liang et al., 2011; Berant et al., 2013). Question-answer pairs were considered easier to obtain than labeled logical forms, though recent work has demonstrated that logical forms can be collected efficiently and are more effective (Yih et al., 2016). However, a key advantage of question-answer pairs is that they are agnostic to the domain representation and logical form language (e.g., lambda calculus or λ-DCS). This property is important for problems such as semi-structured tables where the proper domain representation is unclear.

Data Sets We use WIKITABLEQUESTIONS to evaluate our parser as this data set exhibits both a broad domain and complex questions. Early data sets, such as GEOQUERY (Zelle and Mooney, 1996) and ATIS (Dahl et al., 1994), have small domains with only a handful of different predicates. More recent data sets for question answering against Freebase have a much broader domain, but simple questions (Berant et al., 2013; Cai and Yates, 2013).

3 Model

This section describes our semantic parsing model and training procedure. For clarity, we describe the model on WIKITABLEQUESTIONS, though it is also applicable to other problems. The input to our model is a natural language question and a context in which it is to be answered, which in our task is a table. The model predicts the answer to the question by semantically parsing it to a logical form then executing it against the table.

Our model follows an encoder-decoder architecture using recurrent neural networks with Long Short Term Memory (LSTM) cells (Hochreiter and Schmidhuber, 1997). The input question and table entities are first encoded as vectors that are then decoded into a logical form (Figure 1). We make two significant additions to the encoder-decoder architecture. First, the encoder includes a special entity embedding and linking module that produces a *link embedding* for each question token that represents the table entities it links to (Section 3.2). Second, the action space of the decoder is defined by a *type-constrained grammar* which guarantees that generated logical forms satisfy type constraints (Section 3.3).

We train the parser using question-answer pairs as supervision using an approximation of marginal loglikelihood based on enumerating logical forms via dynamic programming on denotations (Pasupat and Liang, 2016) (Section 3.4). This approximation makes it possible to train neural models with question-answer supervision, which is otherwise difficult for efficiency and gradient variance reasons.

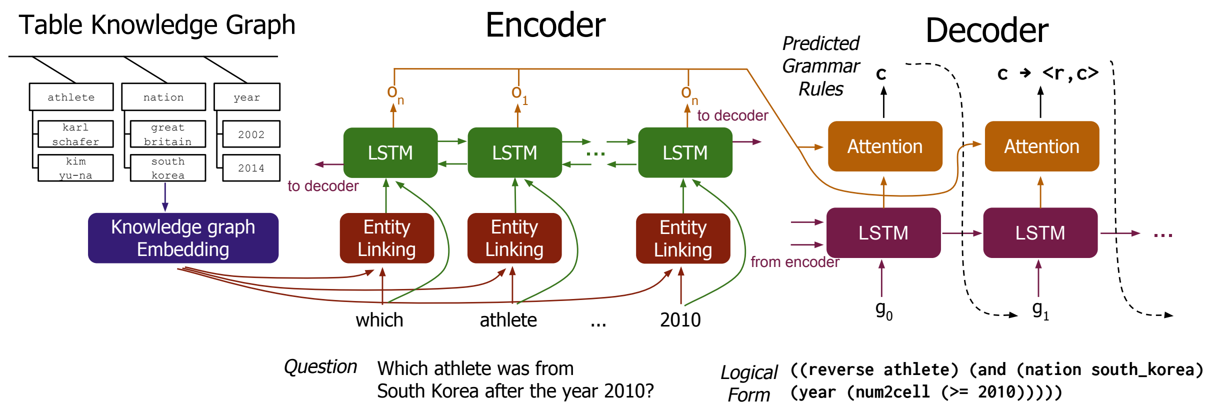

Figure 1: Overview of our semantic parsing model. The encoder performs entity embedding and linking before encoding the question with a bidirectional LSTM. The decoder predicts a sequence of grammar rules that generate a well-typed logical form.

3.1 Preliminaries

We follow (Pasupat and Liang, 2015) in using the same table structure representation and λ-DCS language for expressing logical forms. In this representation, tables are expressed as knowledge graphs over 6 types of entities: cells, cell parts, rows, columns, numbers and dates. Each entity also has a name, which is typically a string value in the table. Our parser uses both the entity names and the knowledge graph structure to construct embeddings for each entity.

The logical form language consists of a collection of named sets and entities, along with operators on them. The named sets are used to select table cells, e.g., `united_states` is the set of cells that contain the text “united states”. The operators include functions from sets to sets, e.g., the `next` operator maps a row to the next row. Columns are treated as functions from cells to their rows, e.g., `(country united_states)` generates the rows whose `country` column contains “united states”. Other operators include reversing relations (e.g., in order to map rows to cells in a certain column), relations that interpret cells as numbers and dates, and set and arithmetic operations. The language also includes aggregation and quantification operations such as `count` and `argmax`, along with λ abstractions that can be used to join binary relations.

Our parser also assigns a type to every λ-DCS expression, which is used to enforce type constraints on generated logical forms. The base types are cells `c`, parts `p`, rows `r`, numbers `i`, and dates `d`. Columns such as `country` have the functional type $\langle \mathtt{c}, \mathtt{r}\rangle$, representing functions from cells `c` to rows `r`. Other operations have more complex functional types, e.g., `reverse` has type $\langle\langle \mathtt{c}, \mathtt{r}\rangle, \langle \mathtt{r}, \mathtt{c}\rangle\rangle$, which enables us to write `(reverse country)`.[1] The parser assigns every λ-DCS constant a type, then applies standard programming language type inference algorithms (Pierce, 2002) to automatically assign types to larger expressions.

3.2 Encoder

The encoder is a bidirectional LSTM augmented with an entity embedding and linking module.

Notation. Throughout this section, we denote entities as e, and their corresponding types as $\tau(e)$. The set of all entities is denoted as E, and the entities with type τ as E_τ. E includes the cells, cell parts, and columns from the table in addition to numeric entities detected in the question by NER. The question is denoted as a sequence of tokens $[q_1, ..., q_n]$. We use v_w to denote a learned vector representation (embedding) of word w, e.g., v_{q_i} denotes the vector representation of the ith question token.

Entity Embedding. The encoder first constructs an embedding for each entity in the knowledge graph given its type and position in the graph. Let $W(e)$ denote the set of words in the name of en-

[1] Technically, `reverse` has the parametric polymorphic type $\langle\langle \alpha, \beta\rangle, \langle \beta, \alpha\rangle\rangle$, where α and β are *type variables* that can be any type. This type allows `reverse` to reverse any function. However, this is a detail that can largely be ignored. We only use parametric polymorphism when typing logical forms to generate the type-constrained grammar; the grammar itself does not have type variables, but rather a fixed number of concrete instances – such as $\langle\langle \mathtt{c}, \mathtt{r}\rangle, \langle \mathtt{r}, \mathtt{c}\rangle\rangle$ – of the above polymorphic type.

tity e and $N(e)$ the neighbors of entity e in the knowledge graph. Specifically, the neighbors of a column are the cells it contains, and the neighbors of a cell are the columns it belongs to. Each entity's embedding r_e is a nonlinear projection of a type vector $v_{\tau(e)}$ and a neighbor vector $v_{N(e)}$:

$$v_{N(e)} = \frac{1}{|N(e)|} \sum_{e' \in N(e)} \frac{1}{|W(e')|} \sum_{w \in W(e')} v_w$$

$$r_e = \tanh\left(P_\tau v_{\tau(e)} + P_N v_{N(e)}\right)$$

The type vector $v_{\tau(e)}$ is a one-hot vector for $\tau(e)$, with dimension equal to the number of entity types in the grammar. The neighbor vector $v_{N(e)}$ is simply an average of the word vectors in the names of e's neighbors. P_τ and P_N are learned parameter matrices for combining these two vectors.

Entity Linking. This module generates a *link embedding* l_i for each question token representing the entities it links to. The first part of this module generates an entity linking score $s(e, i)$ for each entity e and token index i:

$$s(e, i) = \max_{w \in W(e)} v_w^\intercal v_{q_i} + \psi^\intercal \phi(e, i)$$

This score has two terms. The first represents similarity in word embedding space between the token and entity name, computed as function of the embeddings of words in e's name, $W(e)$, and the word embedding of the ith token, v_{q_i}. The max-pooling architecture allows each question token to pick its best match in the entity's name. The second term represents a linear classifier with parameters ψ on features $\phi(e, i)$. The feature function ϕ includes only a few features: indicators for exact token and lemma match, edit distance, an NER tag indicator, and a bias feature. It also includes "related column" versions of the token and lemma features that are active when e is a column and the original feature matches a cell entity in column e. We found that features were an effective way to address sparsity in the entity name tokens, many of which appear too infrequently to learn embeddings for. We produce an independent score for each entity and token index even though we expect entities to link to multi-token spans in order to avoid the quadratic computational complexity of scoring each span.

Finally, the entity embeddings and linking scores are combined to produce a link embedding for each token. The scores $s(e, i)$ are then fed into a softmax layer over all entities e of the same type, and the link embedding l_i is an average of entity vectors r_e weighted by the resulting distribution, then summed over all types. We include a null entity, $\varnothing$, in each softmax layer to permit the model to identify tokens that do not refer to an entity. The null entity's embedding is the all-zero vector and its score $s(\varnothing, \cdot) = 0$. Note that the null entity may still be assigned high probability as the other entity scores of may be negative. The link embedding ℓ_i for the ith question token is computed as:

$$p(e|i, \tau) = \frac{\exp s(e, i)}{\sum_{e' \in E_\tau \cup \{\varnothing\}} \exp s(e', i)}$$

$$l_i = \sum_{\tau} \sum_{e \in E_\tau} r_e p(e|i, \tau)$$

For WikiTableQuestions, we ran the entity embedding and linking module over every entity. However, this approach may be prohibitively expensive in applications with a very large number of entities. In these cases, our method can be applied by adding a preliminary filtering step to identify a subset of entities that may be mentioned in the question. This filter need not have high precision, and therefore could rely on simple text overlap or similarity heuristics. This reduced set of entities can then be fed into the entity embedding and linking module, which will learn to further prune this set of candidates.

Bidirectional LSTM. We concatenate the link embedding l_i and the word embedding v_{q_i} of each token in the question, and feed them into a bidirectional LSTM:

$$x_i = \begin{bmatrix} l_i \\ v_{q_i} \end{bmatrix}$$

$$(o_i^f, f_i) = \text{LSTM}(f_{i-1}, x_i)$$

$$(o_i^b, b_i) = \text{LSTM}(b_{i+1}, x_i)$$

$$o_i = \begin{bmatrix} o_i^f \\ o_i^b \end{bmatrix}$$

This process produces an encoded vector representation of each token o_i. The final LSTM hidden states f_{n+1} and b_0 are concatenated and used to initialize the decoder.

3.3 Decoder

The decoder is an LSTM with attention that selects parsing actions from a grammar over well-typed logical forms.

Type-Constrained Grammar. The parser maintains a state at each step of decoding that consists of a logical form with nonterminals standing for portions that are yet to be generated. Each nonterminal is a tuple $[\tau, \Gamma]$ of a type τ and a *scope* Γ that contains typed variable bindings, $(x : \alpha) \in \Gamma$, where x is a variable name and α is a type. The scope is used to store and generate the arguments of lambda expressions. The grammar consists of a collection of four kinds of production rules on nonterminals:

1. **Application** $[\tau, \Gamma] \rightarrow ([\langle \beta, \tau \rangle, \Gamma] \quad [\beta, \Gamma])$ rewrites a nonterminal of type τ by applying a function from β to τ to an argument of type β. We also permit applications with more than one argument.

2. **Constant** $[\tau, \Gamma] \rightarrow$`const` where constant `const` has type τ. This rule generates both table-independent operations such as `argmax` and table-specific entities such as `united_states`.

3. **Lambda** $[\langle \alpha, \tau \rangle, \Gamma] \rightarrow \lambda x. \, [\tau, \Gamma \cup \{(x : \alpha)\}]$ generates a lambda expression where the argument has type α. x represents a fresh variable name. The right hand side of this rule extends the scope Γ with a binding for x then generates an expression of type τ.

4. **Variable** $[\tau, \Gamma] \rightarrow x$ where $(x : \tau) \in \Gamma$. This rule generates a variable bound in a previously-generated lambda expression that is currently in scope.

We instantiate each of the four rules above by replacing the type variables τ, α, β with concrete types, producing, e.g., $[\mathtt{c}, \Gamma] \rightarrow ([\langle \mathtt{r}, \mathtt{c} \rangle, \Gamma] \ [\mathtt{r}, \Gamma])$ from the application rule. The set of instantiated rules is automatically derived from a corpus of logical forms, which we in turn produce by running dynamic programming on denotations (see Section 3.4). Every logical form can be derived in exactly one way using the four kinds of rules above; this derivation is combined with the (automatically-assigned) type of each of the logical form's subexpressions to instantiate the type variables in each rule. Finally, as a postprocessing step, we filter out table-dependent rules, such as those that generate table cells, to produce a table-independent grammar. The table-dependent rules are handled specially by the decoder in order to guarantee that they are only generated when answering questions against the appropriate table. The table-independent grammar generates well-typed expressions that include functions such as `next` and quantifiers such as `argmax`; however, it cannot generate cells, columns, or other table entities.

The first action of the parser is to predict a root type for the logical form, and then decoding proceeds according to the production rules above. Each time step of decoding fills the leftmost nonterminal in the logical form, and decoding terminates when no nonterminals remain. Figure 2 shows the sequence of decoder actions used to generate an example logical form.

Network Architecture. The decoder is an LSTM that outputs a distribution over grammar actions using an attention mechanism over the encoded question tokens. The decoder also uses a copy-like mechanism on the entity linking scores to generate entities. Say that, during the jth time step, the current nonterminal has type τ. The decoder generates a score for each grammar action whose left-hand side is τ using the following equations:

$$(y_j, h_j) = \mathrm{LSTM}(h_{j-1}, \begin{bmatrix} g_{j-1} \\ o_{j-1} \end{bmatrix}) \tag{1}$$

$$a_j = \mathrm{softmax}(O W^a y_j) \tag{2}$$

$$o_j = (a_j)^T O \tag{3}$$

$$s_j = W_\tau^2 \, \mathrm{relu}(W^1 \begin{bmatrix} y_j \\ o_j \end{bmatrix} + b^1) + b_\tau^2 \tag{4}$$

$$s_j(e_k) = \sum_i s(e_k, i) a_{ji} \tag{5}$$

$$p_j = \mathrm{softmax}(\begin{bmatrix} s_j \\ s_j(e_1) \\ s_j(e_2) \\ \dots \end{bmatrix}) \tag{6}$$

The input to the LSTM g_{j-1} is a grammar action embedding for the action chosen in previous time step. g_0 is a learned parameter vector, and h_0 is the concatenated final hidden states of the encoder LSTMs. The matrix O contains the encoded token vectors $o_1, ..., , o_n$ from the encoder. The first three lines above perform a softmax attention over O using a learned parameter matrix W^a. The fourth line generates scores s_j for the table-independent grammar rules applicable to type τ using a multilayer perceptron with

Question: name the largest lake

weights W^1,b^1,W^2_τ,b^2_τ. The fifth line generates a score for each entity e with type τ by averaging the entity linking scores with the current attention a_j. Finally, the table-independent and -dependent scores are concatenated and softmaxed to produce a probability distribution p_j over grammar actions. If a table-independent action is chosen, g_j is a learned parameter vector for that action. Otherwise $g_j = g^\tau$, which is a learned parameter representing the selection of an entity with type τ.

3.4 DPD Training

Our parser is trained from question-answer pairs, treating logical forms as a latent variable. We use an approximate marginal loglikelihood objective function that first automatically enumerates a set of correct logical forms for each example, then trains on these logical forms. This objective simplifies the search problem during training and is well-suited to training our neural model.

The training data consists of a collection of n question-answer-table triples, $\{(q^i, a^i, T^i)\}_{i=1}^n$. We first run dynamic programming on denotations (Pasupat and Liang, 2016) on each table T^i and answer a^i to generate a set of logical forms $\ell \in \mathcal{L}^i$ that execute to the correct answer. Dynamic programming on denotations (DPD) is an automatic procedure for enumerating logical forms that execute to produce a particular value; it leverages the observation that there are fewer denotations than logical forms to enumerate this set relatively efficiently. However, many of these logical forms are *spurious*, in the sense that they do not represent the question's meaning. Therefore, the objective must marginalize over the many logical forms generated in this fashion:

$$\mathcal{O}(\theta) = \sum_{i=1}^{n} \log \sum_{\ell \in \mathcal{L}^i} P(\ell | q^i, T^i; \theta)$$

We optimize this objective function using stochastic gradient descent. If $|\mathcal{L}^i|$ is small, e.g., 5-10, the gradient of the ith example can be computed exactly by simply replicating the parser's network architecture $|\mathcal{L}^i|$ times, once per logical form. However, $|\mathcal{L}^i|$ often contains many thousands of logical forms, which makes the above computation infeasible. We address this problem by truncating $\mathcal{L}^i$ to the $m = 100$ shortest logical forms, then using a beam search with a beam of $k = 5$ to approximate the sum. Section 4.5 considers the effect of varying the number of logical forms m in this objective function.

We briefly contrast this approach with two other commonly-used approaches. The first is a similar marginal loglikelihood objective commonly used in prior semantic parsing work with loglinear models (Liang et al., 2011; Pasupat and Liang, 2015). However, this approach does not precompute correct logical forms. Therefore, computing its gradient requires running a wide beam search, generating, e.g., 300 logical forms, executing each one to identify which are correct, then backpropagating through a term for each. The wide beam is required to find correct logical forms; however, such a wide beam is prohibitively expensive with a neural model due to the cost of each backpropagation pass. Another approach is to train the network with REINFORCE (Williams, 1992), which essentially samples a logical form instead of using beam search. This approach is known to be difficult to apply when the space of outputs is large and the reward signal is sparse, and recent work has found that maximizing marginal loglikelihood is more effective in these circumstances (Guu et al., 2017). Our approach makes it tractable to maximize marginal loglikelihood with a neural model by using DPD to enumerate correct logical forms beforehand. This up-front enumeration, combined with the local normalization of the neural model, makes it possible to restrict the beam search to correct logical forms in the gradient computation, which enables training with a small beam size.

4 Evaluation

We evaluate our parser on the WIKITABLEQUESTIONS data set by comparing it to prior work and ablating several components to understand their contributions.

4.1 Experimental Setup

We used the standard train/test splits of WIKITABLEQUESTIONS. The training set consists of 14,152 examples and the test set consists of 4,344 examples. The training set comes divided into 5 cross-validation folds for development using an 80/20 split. All data sets are constructed so that the development and test tables are not present in the training set. We report question answering accuracy measured using the official evaluation script, which performs some simple normalization of numbers, dates, and strings before comparing predictions and answers. When generating answers from a model's predictions, we skip logical forms that do not execute (which may occur for some baseline models) or answer with the empty string (which is never correct). All reported accuracy numbers are an average of 5 parsers, each trained on one training fold, using the respective development set to perform early stopping.

We trained our parser with 20 epochs of stochastic gradient descent. We used 200-dimensional word embeddings for the question and entity tokens, mapping all tokens that occurred < 3 times in the training questions to UNK. (We tried using a larger vocabulary that included frequent tokens in tables, but this caused the parser to seriously overfit.) The hidden and output dimensions of the forward/backward encoder LSTMs were set to 100, such that the concatenated representations were also 200-dimensional. The decoder LSTM uses 100-dimensional action embeddings and has a 200-dimensional hidden state and output. The action selection MLP has a hidden layer dimension of 100. We used a dropout probability of 0.5 on the output of both the encoder and decoder LSTMs, as well as on the hidden layer of the action selection MLP. All parameters are initialized using Glorot initialization (Glorot and Bengio, 2010). The learning rate for SGD is initialized to 0.1 with a decay of 0.01. At test time, we decode with a beam size of 10.

Our model is implemented as a probabilistic neural program (Murray and Krishnamurthy, 2016). This Scala library combines ideas from dynamic neural network frameworks (Neubig et al., 2017) and probabilistic programming (Goodman and Stuhlmüller, 2014) to simplify the implementation of complex neural structured prediction models. This library enables a user to specify the structure of the model in terms of discrete nondeterministic choices – as in probabilistic programming – where a neural network is used to score each choice. We implement our parser by defining $P(\ell|q, T; \theta)$, from which the library automatically implements both inference and training. In particular, the beam search and the corresponding backpropagation bookkeeping to implement the objective in Section 3.4 are both automatically handled by the library. Code and supplementary material for this paper are available at:
`http://allenai.org/paper-appendix/emnlp2017-wt/`

4.2 Results

Table 1 compares the accuracy of our semantic parser to prior work on WIKITABLEQUESTIONS. We distinguish between single models and ensembles, as we expect ensembling to improve accuracy, but not all prior work has used it. Prior work on this data set includes a loglinear semantic parser (Pasupat and Liang, 2015), that same parser with a neural, paraphrase-based reranker (Haug et al., 2017), and a neural programmer that answers questions by predicting a sequence of table operations (Neelakantan et al., 2017). We find that our parser outperforms the best prior result on this data set by 4.6%, despite that prior result using a 15-model ensemble. An ensemble of 5 parsers improves accuracy by an additional 2.6% for a total improvement of 7.2%. This ensemble was constructed by averaging the logical form probabilities of parsers trained on each of the 5 cross-validation folds. Note that this ensemble is trained on the entire training set – the development data from one fold is training data for the others – so we therefore cannot report its development accuracy. We investigate the sources of this accuracy improvement in the remainder of this section via ablation experiments.

4.3 Type Constraints

Our second experiment measures the importance of type constraints on the decoder by comparing it to sequence-to-sequence (seq2seq) and sequence-to-tree (seq2tree) models. The seq2seq model generates the logical form a token at a time, e.g., [(, (,`reverse`, ...], and has been used in several

Model	Ensemble Size	Dev.	Test

Haug et al. (2017)	1	-	34.8
Pasupat and Liang (2015)	1	37.0	37.1
Neelakantan et al. (2017)	15	37.5	37.7
Haug et al. (2017)	15	-	38.7
Our Parser	1	42.7	43.3
Our Parser	5	-	**45.9**

Table 1: Development and test set accuracy of our semantic parser compared to prior work on WIKITABLEQUESTIONS.

recent neural semantic parsers (Jia and Liang, 2016; Dong and Lapata, 2016). The seq2tree model improves on the seq2seq model by including an action for generating matched parentheses, then recursively generating the subtree within (Dong and Lapata, 2016). These baseline models use the same network architecture (including entity embedding and linking) and training regime as our parser, but assign every constant the same type and have a different grammar in the decoder. These models were implemented by preprocessing logical forms and applying a different type system.

Table 2 compares the accuracy of our parser to both the seq2seq and seq2tree baselines. Both of these models perform considerably worse than our parser, demonstrating the importance of type constraints during decoding. Interestingly, we found that both baselines typically generate well-formed logical forms: only 7.4% of seq2seq and 6.6% of seq2tree's predicted logical forms failed to execute. Type constraints prevent these errors from occurring in our parser, though the relatively small number of such errors does not does not seem to fully explain the 9% accuracy improvement. We hypothesize that the additional improvement occurs because type constraints also increase the effective capacity of the model, as both the seq2seq and seq2tree models must use some of their capacity to learn the type constraints on logical forms.

4.4 Entity Embedding and Linking

Our next experiment measures the contribution of the entity embedding and linking module. We trained several ablated versions of our parser, removing both the embedding similarity and featurized classifier from the entity linking module. Table 3 shows the accuracy of the resulting models.

Model	Dev. Accuracy
seq2seq	31.3
seq2tree	31.6
Our Parser	42.7

Table 2: Development accuracy of our semantic parser compared to sequence-to-sequence and sequence-to-tree models.

Model	Dev. Accuracy
Full model	42.7
token features, no similarity	28.1
all features, no similarity	37.8
similarity only, no features	27.5

Table 3: Development accuracy of ablated parser variants trained without parts of the entity linking module.

The results demonstrate that the entity linking features are important, particularly the more complex features beyond simple token matching. In our experience, the "related column" features are especially important for this data set, as columns that appear in the logical form are often not mentioned in the text, but rather implied by a mention of a cell from the column. Embedding similarity alone is not very effective, but it does improve accuracy when combined with the featurized classifier. We found that word embeddings enabled the parser to overfit, which may be due to the relatively small size of the training set, or because we did not use pretrained embeddings. Incorporating pretrained embeddings is an area for future work.

We also examined the effect of the entity embeddings computed using each entity's knowledge graph context by replacing them with one-hot vectors for the entity's type. The accuracy of this parser dropped from 42.7% to 41.8%, demonstrating that the knowledge graph embeddings help.

4.5 DPD Training

Our final experiment examines the impact on accuracy of varying the number of logical forms m used when training with dynamic programming on denotations. Table 4 shows the development accuracy of several parsers trained with varying m. These results demonstrate that using more logical forms generally leads to higher accuracy.

# of logical forms	1	5	10	50	100
Dev. Accuracy	39.7	41.9	41.6	43.1	42.7

Table 4: Development accuracy of our semantic parser when trained with varying numbers of logical forms produced by dynamic programming on denotations.

4.6 Error Analysis

To better understand the mistakes made by our system, we analyzed a randomly selected set of 100 questions that were answered incorrectly. We identified three major classes of error:

Parser errors (41%): These are examples where a correct logical form is available, but the parser does not select it. A large number of these errors (15%) occur on questions that require selecting an answer from a given list of options, as in *Who had more silvers, Colombia or The Bahamas?* In such cases, the type of the predicted answer is often wrong. Another common subclass is entity linking errors due to missing background knowledge (13%), e.g., understanding that *largest* implicitly refers to the *Area* column.

Representation failures (25%): The knowledge graph representation makes certain assumptions about the table structure and cell values which are sometimes wrong. One common problem is that the graph lacks some cell parts necessary to answer the question (15%). For example, answering a question asking for a state may require splitting cell values in the *Location* column into city and state names. Another common problem is unusual table structures (10%), such as a table listing the number of Olympic medals won by each country that has a final row for the totals. These structures often cause quantifiers such as `argmax` to select the wrong row.

Unsupported operations (11%): These are examples where the logical form language lacks a necessary function. Examples of missing functions are finding consecutive sets of values, computing percentages and performing string operations on cell values.

5 Conclusion

We present a new semantic parsing model for answering compositional questions against semi-structured Wikipedia tables. Our semantic parser extends recent neural semantic parsers by enforcing type constraints during logical form generation, and by including an explicit entity embedding and linking module that enables it to identify entity mentions while generalizing across tables. An evaluation on WIKITABLEQUESTIONS demonstrates that our parser achieves state-of-the-art results, and furthermore that both type constraints and entity linking make significant contributions to accuracy. Analyzing the errors made by our parser suggests that improving entity linking and using the table structure are two directions for future work.

Joint Concept Learning and Semantic Parsing from Natural Language Explanations

Abstract

Natural language constitutes a predominant medium for much of human learning and pedagogy. We consider the problem of concept learning from natural language explanations, and a small number of labeled examples of the concept. For example, in learning the concept of a phishing email, one might say 'this is a phishing email because it asks for your bank account number'. Solving this problem involves both learning to interpret open-ended natural language statements, as well as learning the concept itself. We present a joint model for (1) language interpretation (semantic parsing) and (2) concept learning (classification) that does not require labeling statements with logical forms. Instead, the model prefers discriminative interpretations of statements in context of observable features of the data as a weak signal for parsing. On a dataset of email-related concepts, this approach yields across-the-board improvements in classification performance, with a 30% relative improvement in F1 score over competitive classification methods in the low data regime.

Figure 1: Examples of concepts explained using natural language statements.

1 Introduction

The ability to automatically learn concepts[1] from examples is a core cognitive ability, with applications across diverse domains. Examples of such concepts include the concept of a 'negative review' in product reviews, the concept of 'check' over the domain of game states in chess, the concept of 'fraud' in credit history analysis, etc. Concept learning is generally approached using classification methods that can automatically leverage regularities in large amounts of labeled training data. However, there are two shortcomings of this paradigm. First, labeling large amounts of data is unnatural compared to how a person might teach another person (e.g., a human secretary) in a similar situation. For example, for identifying emails about postdoc positions, a university professor might say 'These inquiries usually seek a postdoc opportunity and include a CV', rather than label scores of examples of such emails. Second, acquiring large quantities of labeled data may be infeasible because of a long tail of concepts that are highly domain or user specific. For our example of a busy professor, it might be relevant to teach concepts such as 'postdoc seeking emails', 'course related questions from students', etc. to an email assistant in order to better manage her/his inbox. However, these concepts might be irrelevant to a general user.

On the other hand, humans can efficiently learn about new concepts and phenomena through language. In fact, verbal and written language form the basis for much of human learning and pedagogy, as reflected in text-books, lectures and student-teacher dialogues. Natural language explanations can be a potent mode of supervision, and can alleviate issues of data sparsity by directly encoding relevant knowledge about concepts. Figure 1 shows

[1] where a concept is any Boolean function on some domain of instances.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1527–1536
Copenhagen, Denmark, September 7–11, 2017.

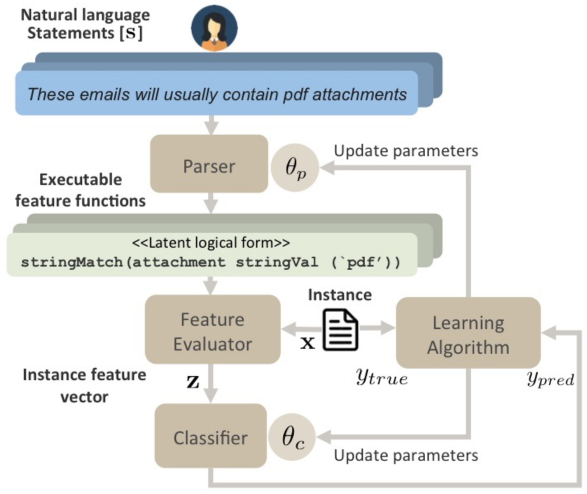

Figure 2: Schematic representation of approach

examples of concepts explained using natural language. In general, natural language can subsume several modes of supervision: instance labeling (e.g., 'This email is spam'), feature labeling (e.g., 'The word 'Viagra' indicates spam'), model expectations ('Spam emails *rarely* come from edu extensions'), etc. However, here we focus on the ability of natural language to express rich and compositional features for characterizing concepts.

In this paper, we address the task of learning concepts from natural language statements and a small number of labeled examples of the concept. Figure 2 summarizes the outline of our approach. We map statements to logical interpretations, which can be evaluated in context of new instances. In doing this, each statement s effectively acts as a binary feature function $\{z = f_s(x) \in \{0, 1\}\}$ that fires when the interpretation of a statement s is true for an instance x. The crux of our approach is that correct interpretations of natural language explanations are more likely to be useful in discriminating concepts, and this observation can be used to guide both semantic interpretation and concept learning[2].

In Section 3, we describe our probabilistic latent variable formulation that learns a semantic parser and a concept classifier from labeled examples of the concept. The latent variables correspond to evaluations of natural language statements for different instances, and training proceeds via a generalized EM procedure that iteratively (1) estimates evaluations of explanations (marginalizing over all interpretations), and (2) updates the classification and semantic parsing models. The inputs to the method consist of a small number of labeled examples and non-examples of a concept, natural language statements explaining the concept, and a domain specific lexicon. The method does not require labeling sentences with logical forms.

For our empirical evaluation, we focus on personal emails, a practical example of a domain where target concepts are often highly individualized and labeled data is scarce. The contributions of this work are:

- We introduce the problem of concept learning from natural language. We also collect a corpus of emails about common email concepts, along with statements from human users explaining these concepts.
- We provide a method for concept learning and language understanding that can be trained from a small number of labeled concept instances. Thus, we extend supervised semantic parsing by learning from a weaker form of supervision than has previously been explored.
- We demonstrate that for small labeled data, using natural language statements can achieve substantial gains in classification accuracy.

2 Related work

Concept learning from labeled examples has been a dominant focus of research in supervised learning (Caruana et al., 2008). Notable approaches such as Generalized Expectation (Mann and McCallum, 2010) and Posterior Regularization (Ganchev et al., 2010) have explored integration of manually provided 'side-information' (feature and label constraints) to guide machine learning models. Earlier work on Explanation-based learning (Mitchell et al., 1986; DeJong and Mooney, 1986) leverages structured knowledge to 'explain' why an example belongs to a concept. Recent work by Lake et al. (2015) explores visual concept learning from few examples, and presents encouraging results for one-shot learning by learning representations over Bayesian programs. However, none of these address the issue of learning from natural language.

Semantic interpretation of language has been explored in diverse domains. While semantic parsers have traditionally relied on labeled datasets of statements paired with labeled logical forms (Zettlemoyer and Collins, 2005), recent approaches have focused on training semantic parsers from

[2] e.g., a parser may associate multiple incorrect interpretations with the statement in Figure 2 (like `stringMatch(attachment stringVal ('usually'))`), which are unlikely to help in discriminating instances of the concept.

denotations of logical forms, rather than logical forms themselves (Krishnamurthy and Mitchell, 2012; Berant et al., 2013). Our work extends this paradigm by attempting to learn from still weaker signal, where denotations (evaluations) of logical forms too are not directly observed. Similar to our work, previous approaches have used different kinds of external-world signals to guide semantic interpretation (Liang et al., 2009; Branavan et al., 2009). Natural instructions have been studied in game playing frameworks (Branavan et al., 2012; Eisenstein et al., 2009). Our work is also closely related to work by Goldwasser and Roth (2014); Clarke et al. (2010), who also train semantic parsers in weakly supervised contexts, where language interpretation is integrated in real-world tasks. The general idea of learning through human interactions has previously been explored in settings such as behavioral programming (Harel et al., 2012), natural language programming (Biermann, 1983), learning by instruction (Azaria et al., 2016), etc. To the best of our knowledge, this work is the first to use semantic interpretation to guide concept learning.

3 Method

We consider concept learning problems in which the goal is to approximate an unknown classification function $f : X \to Y$ where $Y = \{0, 1\}$. The input to our learning algorithm consists of a set of labeled training examples $\mathcal{T} := \{(x_1, y_1), \ldots, (x_m, y_m)\}$, along with a set of natural language statements $\mathcal{S} := \{s_1 \ldots s_n\}$ about the concept. Our aim is to leverage statements in $\mathcal{S}$ to learn a better classifier for the concept. Our training data does not contain any other form of supervision (such as logical forms).

	s_1	s_2	s_j	s_m	Label
x_1	z_{11}	z_{12}	z_{1j}	z_{1m}	y_1
...					...
x_i	z_{i1}	z_{i2}	z_{ij}	z_{im}	y_i
...					...
x_n	z_{n1}	z_{n2}	z_{nj}	z_{nm}	y_n

Figure 3: Our data consist of instances x_i with binary labels y_i and statements $s_1 \ldots s_n$ about a concept. z_{ij} denotes whether the statement s_j applies to instance x_i, and is not observed in the data.

We assume that each statement s_j defines some Boolean property over the instances X; that is, statement s_j should be interpreted as defining a predicate $l_j : X \to \{0, 1\}$. We augment the representation of each instance, x_i, with a feature vector $\mathbf{z}_i$, that encodes the information contained in $\mathcal{S}$. The individual elements of this feature vector, $z_{ij} \in \{0, 1\}$, denote whether the statement s_j applies to instance x_i (see Figure 3). In the general case, the evaluation values $\mathbf{z}_i$'s are not directly observed. These are obtained by parsing each statement s_j into a logical expression $l_j : X \to \{0, 1\}$ which can be evaluated for an instance x_i to obtain $z_{ij} = [\![l_j]\!]_{x_i}$. Details of this evaluation are given in Section 3.4.

In this paper, we jointly learn a classifier and a semantic parser while treating z's as latent variables. For training, we maximize the conditional log likelihood of the observed data. Let us consider the log likelihood for a single data instance (ignoring the subscript i) for now. Since the evaluations $\mathbf{z}$ of natural statements for any context are latent, we marginalize over these. Using Jensen's inequality, any distribution q over the latent variables provides a lower-bound on the data log-likelihood:

$$\log p(y \mid x, \mathcal{S}) = \log \sum_{\mathbf{z}} p(y, \mathbf{z} \mid x, \mathcal{S})$$
$$\geq \sum_{\mathbf{z}} q(\mathbf{z}) \log \frac{p(y, \mathbf{z} \mid x, \mathcal{S})}{q(\mathbf{z})}$$
$$= \sum_{\mathbf{z}} q(\mathbf{z}) \big(\underbrace{\log p_{\theta_c}(y \mid \mathbf{z}, x)}_{\text{classification}} + \underbrace{\log p_{\theta_p}(\mathbf{z} \mid x, \mathcal{S})}_{\text{parsing}} \big)$$
$$+ \mathcal{H}_q \qquad (1)$$

Here, $\mathcal{H}_q$ is the entropy term for the distribution q.

3.1 Coupling parsing and classification:

In Equation 1, we observe that the data likelihood decouples into the log probability of observing the concept labels $p_{\theta_c}(y_i \mid \mathbf{z}, x)$ conditioned on the statement evaluations and the log probability of the latent statement evaluations $p_{\theta_p}(\mathbf{z} \mid x, \mathcal{S})$. In particular, the first term can be naturally parametrized by a discriminative classifier such as a loglinear model (with associated parameters θ_c). We provide more details in Section 3.3.

On the other hand, the probability of the latent statement evaluation values $\mathbf{z}$ can be parametrized using a probabilistic semantic parsing model (with associated parameters θ_p). The second term decouples over evaluations of individual statements ($\log p_{\theta_p}(\mathbf{z} \mid x, \mathcal{S}) = \sum_j \log p_{\theta_p}(z_j \mid x, s_j)$). In turn, since we never observe the correct interpretation l for any statement, but only model its evaluation z_j, we marginalize over all interpretations whose evaluations in a context x matches z_j (similar to Liang et al. (2011)).

$$\log p_{\theta_p}(z_j \mid x, s_j) = \log \sum_{l:[\![l]\!]_x = z_j} p_{\theta_p}(l \mid s_j) \quad (2)$$

Following recent work in semantic parsing (Liang and Potts, 2015; Krishnamurthy and Mitchell, 2012), we use a log-linear model over logical forms:

$$p_{\theta_p}(l \mid s) \propto \exp({\theta_p}^T \phi(s, l)) \qquad (3)$$

where $\phi(s, l) \in \mathbb{R}^d$ is a feature vector over statements s and logical interpretations l.

3.2 Learning:

In Equation 1, $q(\mathbf{z})$ denotes a distribution over evaluation values of statements; whereas θ_c and θ_p denote the model parameters for the classifier and semantic parser. The learning algorithm consists of an iterative generalized EM procedure, which can be interpreted as a block-coordinate ascent in the estimates of statement evaluations $q(\mathbf{z})$ and the model parameters θ_c and θ_p.

E-step: In the E-step, we update our estimates of evaluation variables ($\mathbf{z}$). We make a mean-field approximation by assuming that the joint distribution over evaluations decouples as $q(\mathbf{z}) = \prod q_j(z_j)$. Then maximizing the lower bound in Equation 1 in terms of q_j leads to the following update:

$$q_j(z_j) \propto \exp\left(\mathop{\mathbb{E}}_{j' \neq j} [\log p_{\theta_c}(\mathbf{z}|x)] + \log p_{\theta_p}(z_j|x, s_j)\right) \qquad (4)$$

The first term in the update prefers values of an evaluation variable that are more discriminative on average (when values of other statements are marginalized out). The second term favours values of the evaluation variable that conforms with the most likely interpretations of the corresponding statement (s_j) by the semantic parser. Thus, in the E-step, we upweight evaluations of statements that are both discriminative, as well as supported by interpretations from the semantic parser.

M-step: In the M-step, we update the model parameters to maximize the lower bound in Equation 1. This corresponds to independently optimizing the log likelihoods for the classification model and the semantic parser, based on current estimates of $q_j(z_j)$'s of the statement evaluations. The entropy term H_q is constant from the perspective of model parameters, and is not relevant for the optimization. In particular, the semantic parser is updated to agree with evaluations of natural language statements that are discriminative. At the same time, the classification model is updated to fit evaluations that are supported by interpretations from the semantic parser.

We now describe the M-step updates for the log-linear semantic parser with parameters, θ_p. The updates for the classifier parameters, θ_c, depend on the form of the classification model, and are described in Section 3.3. For clarity, we focus on updates corresponding to a particular statement s_j from the training dataset. From Equations 1, 2 and 3, the objective for the semantic parser is given by:

$$\ell_j(\theta_p) = \sum_i \sum_{z \in \{0,1\}} q(z_{ij}) \log \frac{\sum_{l:[\![l]\!]_{x_i} = z} \exp({\theta_p}^T \phi(s_j, l))}{\sum_l \exp({\theta_p}^T \phi(s_j, l))} \qquad (5)$$

Semantic parsers are usually optimized using gradient updates. Here, the gradient is:

$$\nabla \ell_j(\theta_p) = \sum_{i,z,l} q(z_{ij}) p_{\theta_p}(l \mid s) \frac{p_{\theta_p}(z_{ij} \neq z | x_i, s)}{p_{\theta_p}(z_{ij} = z | x_i, s)} \phi(s_j, l) \qquad (6)$$

3.3 Classification models

The model and learning procedure described in Sections 3.1 and 3.2 is agnostic to the choice of the classification model (with parameters θ_c). For this work, we experimented with a logistic classifier (LR) and a Naive Bayes model (NB). We briefly describe these here:

Logistic Regression (LR): The form of the logistic function $\log p(y|\mathbf{z}) = -\log(1 + \exp(-\theta_c^T \mathbf{z}\, y))$ means that the likelihood does not decouple for individual components in $\mathbf{z}$. Hence, in the E-step, the expectation in Equation 4 cannot be computed analytically. Instead, we estimate this by drawing Bernoulli samples for individual z_j's using previous estimates of $q_j(z_j)$. In the M-step, we update classification parameters θ_c using stochastic gradient updates, while again sampling individual z_j's.

Naive Bayes (NB): The likelihood for this model is $p(y, \mathbf{z}) = \prod_j \theta_{cy}^{z_j} (1 - \theta_{cy})^{1 - z_j}$. In this case, the individual components of $\mathbf{z}$ decouple in the log likelihood, leading to simple updates in both the E and M steps. While this is not a conditional likelihood

Predicate	Description and evaluation
`stringVal`	Returns string value corresponding to a text span in the statement
`getPhraseMention`	Looks for matching tokens or phrases in a target text, and return true if an exact match is found. e.g., *The subject contains the word postdoc* → `getPhraseMention(subject,stringVal('postdoc'))`
`getPhrasesLike`	Uses an alignment based Textual Entailment (RTE) model to find the closest semantic match for a phrase in a text. Uses distributional semantics to identify semantically similar words. Returns true if a match is found. e.g., *The emails often want me to buy something* → `getPhrasesLike(email,stringVal('buy something'))`
`getSemanticCategory`	Looks for occurrences of pre-specified semantic categories in a target text (identified with Stanford CoreNLP's expanded NER tagger), and returns true if a match is found. e.g., *these emails often have contain prices and quotes* → `getSemanticCategory(body, MONEY)`
`stringMatch`	Returns true if one string value contains another. e.g., *Spam emails are rarely from a yahoo or gmail address* → `not( or(stringMatch(sender, stringVal('yahoo')), stringMatch(sender, stringVal('gmail'))))`
`stringEquals`	Returns true if two string values are equal
`or/ and/ not`	Boolean predicates with usual interpretations
`beginWith/endWith`	Return true if a target text contains a phrase, a similar phrase, or a semantic category at its beginning/end. e.g., *The emails often mention a phone number at the end* → `endWith(body, NUMBER)`
`merge`	Combines multiple elements into a list. e.g., *These emails often refer to problems like baldness and aging.* → `getPhrasesLike(email, merge(stringVal('baldness'), stringVal('aging')))`
`before`	Returns true if there is an instance of one type preceding an instance of another type in a text
`length`	Lengths of lists or text fields (in number of words)
$\geq$, `equals`	Usual arithmetical comparators
`unknown`	Return false by default. Used to deal with statements that cannot be reasonably expressed using predicates in the language. e.g., *These emails are from weird addresses.* → `unknown`

Table 1: Predicates in logical language used by our semantic parser for learning of email based concepts.

(as expected in Section 3.1), in our experiments we found that the NB objective to be empirically effective with our approach.

3.4 Semantic Parsing details

Semantic parsing refers to mapping a sentence s like '*The subject contains the word postdoc*' to a logical form l like `getPhraseMention(subject, stringVal('postdoc'))`. Logical forms can be evaluated in a context x (here, an email) to yield some meaningful output $[\![l]\!]_x$ (whether the statement is true for an email). The predicates (such as `stringVal`) and constants (such as `subject`) come from a pre-specified logical language. Since our focus in this work is concepts about emails, we specify a logical language that is expressive enough to be useful for concept learning in this domain. Table 1 lists the predicates in our logical language along with descriptions of their evaluation, and some illustrative examples showing how they can represent the meaning of natural statements[3]. Note that this logical language can express compositional meanings. e.g., '*These inquiries will usually seek a postdoc opportunity and include a CV*' can be expressed as `and (getPhrasesLike(email, stringVal('seek postdoc opportunity')), (stringMatch attachment (stringVal'CV')))`. The evaluations of some predicates uses NLP tools that go beyond exact keyword matching. In Section 5, we show that it is language understanding (semantic parsing), rather than these resources, which enables learning from natural explanations.

Semantic parsers involve grammars containing mappings from words to symbols in the logical language, as well as coarse syntactic rules. The grammar specifies the possible set of logical interpretations that can be associated with a natural language sentence. For this work, we use CCG based semantic parsing, a popular semantic parsing approach (Zettlemoyer and Collins, 2005; Artzi et al., 2015) that couples syntax with semantics. For the CCG grammar, we manually compile a domain lexicon containing a list of trigger words mapped to their syntactic categories and associated logical predicates. e.g. {'subject', NP, `subject`}. We then use the PAL lexicon induction algorithm (Krishnamurthy, 2016) to expand the lexicon by adding automatically generated entries. For training the parser, we follow the feature set from (Zettlemoyer and Collins, 2007), consisting of indicator features for lexicon entries and rule applications that fire for a given parse of a logical form. We also include

[3] We include a special predicate (`unknown`) to label statements whose meanings go beyond our logical language (last row in Table 1), essentially ignoring them. Such statements compose about 25% of our data. An agent should ideally be able to ask a user about unfamiliar concepts such as 'weird email addresses' that occur in explanations. See Section 6.

string based features denoting the number of words in a string span, and whether a string spans occur at the beginning or end of the utterance. For retrieving the best parses for a statement, we use beam search with a beam size of 500.

While we have chosen a particular instantiation of a semantic parsing formalism, our learning approach is independent of the semantic parsing framework in principle, and only assumes a log-linear parametrization over logical interpretations of sentences. Thus, while we present results for a particular parsing framework and lexicon, the method may conceptually extend to other parsing formalisms such as DCS (Liang et al., 2011).

4 Data

We created a dataset of 1,030 emails paired with 235 natural language statements made by human users in the process of teaching a set of seven concepts. The dataset was collected using the Amazon Mechanical Turk crowdsourcing platform. We deployed two tasks: (i) a *Generation* task requiring workers to create original emails, and (ii) a *Teaching* task requiring workers to write statements that characterize a concept. Below, we describe the data and the two tasks in more detail.

We create an email corpus, rather than use an existing corpus such as Enron, since we wanted diverse examples representative of everyday concepts that most people would be able to understand as well as teach to a computer. Much of the Enron corpus is highly specific and contextualized, making it difficult to teach for an outsider.

The *Generation* task consisted of a web-page resembling a traditional email composition form (with fields: *recipient*, *subject*, *body*, *attachment*), requiring workers to compose emails in a grounded setting. For this task, we recruited 146 workers residing in the United States. The workers were presented with each of the seven concepts in a sequence, where each concept was represented by a short prompt encouraging workers to imagine a scenario (e.g., a boss writing a request to an employee) and write a hypothetical email. See Table 2 for details of email concepts and corresponding prompts. Workers were instructed to be realistic (e.g., to include an attachment if an email is likely to have an attachment in reality), but also creative (to encourage diversity) in composing their emails.

READ FIRST! (read carefully)

The category of emails that you want to teach now is:

☞ **"You are writing an email to yourself as a reminder to do something"**

In order to help you in teaching this category, we have identified some **examples** and **NON-examples** of this category on the left. **Examples** of this category are highlighted in yellow and marked with a "star" (★) and the **NON-examples** are in gray. You should study these emails to get a better understanding of the category to help you teach it effectively.

Your explanations should be based on the observations you make from the example emails!

DO NOT FORGET:

The examples shown are only to help you get an idea of how to explain this category. Your instructions should be **GENERAL** enough to help the assistant generalize to many future emails of this category!

Again, the category that you want to teach now is:

☞ **"You are writing an email to yourself as a reminder to do something"**

Each instruction should not exceed the length of the text field

All instructions must be filled out

1: how useful?
2: how useful?
3: how useful?
4: how useful?
5: how useful?

Figure 4: The *Teaching* task used to collect natural language statements characterizing a concept. Each worker is given a concept prompt, together with a set of emails. A turker can enter five statements characterizing the concept.

These emails usually closes with a name or title
Some reminders will have a date and time in the subject
The body of the email may say funny, picture, or internet
Messages to friends sometimes have jpg attachments
Emails from a public domain are not office requests

Table 3: Examples of natural language statements collected from the *Teaching* task

The *Teaching* task was then deployed to collect natural language statements that people would make to teach a particular concept to a machine. Workers were presented with five randomly selected concepts using the same prompts (Table 2) used in the *Generation* task. For each concept, a small sample of emails were shown in a style resembling a traditional email inbox (Figure 4) to illustrate the concept. Half of the emails were from the prompted concept (these emails were highlighted and "starred"), and half were sampled randomly from the other concepts. Workers were encouraged to peruse through the emails while creating up to five statements explaining the concept. A follow-up quiz assessed an understanding of the task, and contributions from workers with low scores were filtered. The final data contains between 30 and 35 statements describing each category.

5 Evaluation

In this section, we evaluate the performance of our approach from the perspectives of concept learn-

Concept	# of emails	Prompt
CONTACT	167	“You are writing an email to yourself to personally keep note of a person contact”
EMPLOYEE	149	“You are a boss writing an email to your employee requesting something to be done”
EVENT	138	“You are writing an email to a friend asking to meet up at some event”
HUMOR	134	“You are writing an email to a friend that includes something humorous from the Internet”
MEETING	142	“You are writing an email to a colleague trying to request a meeting about something”
POLICY	146	“You are writing an office email regarding announcement of some new policy”
REMINDER	154	“You are writing an email to yourself as a reminder to do something”

Table 2: Email concepts used in our experiment, together with the prompts used to describe the concept to workers. The same prompt was used in both the *Generation* and *Teaching* tasks.

	CONTACT	EMPLOYEE	EVENT	HUMOR	MEETING	POLICY	REMINDER	Average
BoW	0.510	0.354	0.381	0.484	0.455	0.588	0.415	0.455
BoW tf-Idf	0.431	0.379	0.402	0.513	0.392	0.576	0.399	0.441

LNI-NB + BoW	0.644	0.409	0.520	0.709	0.723	0.878	0.543	0.632
LNI-LR + BoW	0.634	0.398	0.604	0.704	0.747	0.891	0.567	0.649
LNL-Gold+BoW	0.667	0.449	0.659	0.798	0.771	0.927	0.595	0.695

Table 4: Concept learning performance (F1 scores) using $n = 10$ labeled examples. Columns indicate different concept learning tasks defined over emails. * for the rows corresponding to LNL-NB and LNL-LR denotes statistical significance over the best performing non-LNL model

ing as well as semantic parsing. We first compare our methods against traditional supervised learning methods on the task of learning email-based concepts described in the previous section.

Our baselines include the following models:

Text-only models:

- *BoW:* A logistic regression (LR) classifier over bag-of-words representation of emails
- *BoW tf-idf:* LR classifier over bag-of-words representation, with tf-idf weighting
- *Para2Vec:* LR classifier over a distributed representation of documents, using deep neural network approach by Le and Mikolov (2014).
- *Bigram:* LR model also incorporating bigram features, known to be competitive on several text classification tasks (Wang and Manning, 2012).
- *ESA:* LR model over ESA (Explicit Semantic Analysis) representations of emails (Gabrilovich and Markovitch, 2007), which describe a text in terms of its Wikipedia topics.

Models incorporating Statements:

- *RTE:* This uses a Textual Entailment model (based on features from Sachan et al. (2015)) that computes a score for aligning of each statement to the text of each email. A logistic regression is trained over this representation of the data.
- *Keyword filtering:* Filters based on keywords are common in email systems. We add this as a baseline by manually filtering statements referring to occurrences of specific keywords. Such statements compose nearly 30% of the data. We train a logistic regression over this representation.

Table 4 shows classification performance of our approaches for Learning from Natural Language (*LNL*) against baselines described above for $n = 10$ labeled examples. The reported numbers are average F1 scores over 10 data draws. We observe that *Bigram* and bag-of-word methods are the most competitive among the baselines. On the other hand, *Para2Vec* doesn’t perform well, probably due to the relatively small scale of the available training data, while *ESA* fails due to the lack of topical associations in concepts. However, most significantly, we observe that both *LNL-NB* (Naive Bayes) and *LNL-LR* (Logistic Regression) dramatically outperform all baselines for most concepts (except EMPLOYEE), and show a 30% relative improvement in average F1 over other methods ($p < 0.05$, Paired Permutation test). Interestingly, we note that *LNL-NB* and *LNL-LR* show similar performance for most concepts. For evaluating semantic parsing of natural language statements, we manually annotated the statements in our dataset using the logical language described in Section 3.4. In Table 4, *LNL-Gold* denotes the classification performance with using these annotated gold parses. This corresponds to the hypothetical case where the classifier knows the correct semantic interpretation of each natural language sentence from an oracle. While this provides a further 10% relative improvement over our proposed models, the results suggest that our weakly supervised method is quite effective in interpreting natural language statements for concept learning, without explicit supervision. We also observe that *LNL* models perform significantly better than *Keyword filtering* ($p < 0.05$), indicating that the model leverages the expressiveness of our logical language.

Finally, the last three rows show performance when the *LNL* methods also utilize BoW representations of the data. The further gains over the base *LNL* models suggest that original feature representations and natural language explanations contain complementary information for many concepts.

A significant motivation for this work is the promise of natural language explanations in facilitating concept learning with a relatively small number of examples. Figure 5 shows the dependence of concept learning performance of *LNL(-LR)* on the number of labeled training examples (size of training set). We observe that while our approach consistently outperforms the bag-of-words model (*BoW*), *LNL* also requires fewer examples to reach near optimal performance, before it plateaus. In particular, the generalization performance for *LNL* is more robust than *BoW* for $n < 10$. The performance trajectory for *LNL(-NB)* is similar, and omitted in the figure for clarity.

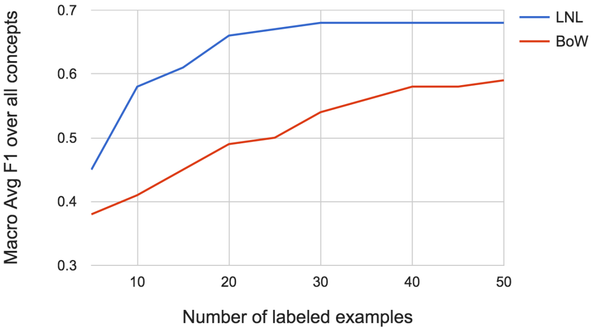

Figure 5: Figure showing Avg F1 accuracy over all concepts vs Number of labeled training examples

	Accuracy
Fully Supervised (ZC07)	0.63
LNL-LR	0.30
LNL-NB	0.28
No training	0.01

Table 5: Semantic parsing performance (exact match) for proposed weakly supervised methods vs full supervision (completely labeled logical forms)

Parsing performance: We next evaluate the parsing performance of our approach, which learns a semantic parser from only concept labels of examples. Table 5 evaluates parsing performance against the gold annotation logical forms for statements. For this task, we check for exact match of logical forms. In the table, full supervision refers to traditional training of a semantic parser using complete annotations of statements with their logical forms (Zettlemoyer and Collins, 2007). The results report average accuracy over 10-fold CV, and demonstrate that while not comparable to supervised parsing, our weakly supervised approach is relatively effective in learning semantic parsers.

Further, exact match to gold annotated logical forms is a restrictive measure. Qualitative analysis revealed that even when the predicted and gold annotation logical forms don't match, predicted logical forms are often strongly correlated in terms of evaluation to gold annotations. e.g., `getPhraseMention( email, stringVal(‘postdoc’))` vs `getPhraseMention( body, stringVal(‘postdoc’))`. In about 5% of cases, predicted and gold interpretations are different on the surface, but are semantically equivalent (e.g., `stringEquals( sender, recipient)` vs `stringEquals( recipient, sender)`).

Concept learning vs language interpretation: To delineate the relationship between parsing performance and concept learning more clearly, we plot concept classification performance for different levels of semantic parsing proficiency in Figure 6. For this, we choose the gold annotation logical form for a statement with a probability corresponding to the semantic parsing accuracy, or randomly select a candidate logical form with a uniform probability otherwise for all the statements in our data. The figure shows a (expectedly) strong association between parsing performance and concept learning, although gains from parsing taper after a certain level of proficiency. This is partially explained by the fact that natural statements in our

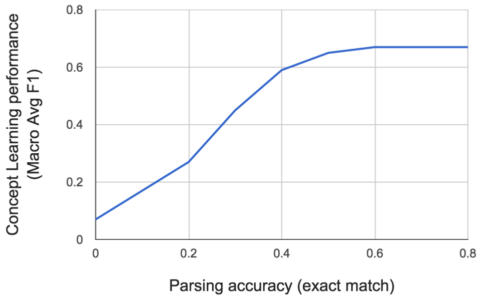

Figure 6: Figure showing concept classification performance vs parsing accuracy

data often contain overlapping information, and that the set of statements in our data set may not be sufficient to achieve perfect classification accuracy.

6 Conclusion and Future Work

We show that natural language explanations can be utilized by supervised learning methods to significantly improve generalization. This suggests a broader class of possible machine learning interfaces that use language to not only expedite learning, but make machine learning accessible to everyday users. Thus, we hope that the current work will inspire further explorations in learning from natural language explanations. In terms of scalability, learning from language would require specification of a logical language and a lexicon of trigger words for each new domain. However, this effort is one-time, and can find re-use across the long tail of concepts in a domain.

A consequence of the expressiveness of language is that in describing a concept, humans often invoke other concepts that may not correspond to existing predicates in the logical language. A natural solution could detect that a feature described in the statement is novel[4], and request the user to teach the unknown concept. The same principle can be applied recursively, resulting in a mixed-initiative dialog, much like between a student and a teacher. Future work can also incorporate other modes of supervision from language. For example, this work ignores modifiers such as ‘always’ and ‘usually’, which often carry valuable information that could be incorporated via model expectation constraints.

Abstract

The ubiquity of metaphor in our everyday communication makes it an important problem for natural language understanding. Yet, the majority of metaphor processing systems to date rely on hand-engineered features and there is still no consensus in the field as to which features are optimal for this task. In this paper, we present the first deep learning architecture designed to capture metaphorical composition. Our results demonstrate that it outperforms the existing approaches in the metaphor identification task.

1 Introduction

Metaphor is pervasive in our everyday communication, enriching it with sophisticated imagery and helping us to reconcile our experience in the world with our conceptual system (Lakoff and Johnson, 1980). In the most influential account of metaphor to date, Lakoff and Johnson explain the phenomenon through the presence of systematic metaphorical associations between two distinct concepts or domains. For instance, when we talk about "*curing* juvenile delinquency" or "corruption *transmitting* through the government ranks", we view the general concept of *crime* (the target concept) in terms of the properties of a *disease* (the source concept). Such metaphorical associations are broad generalisations that allow us to project knowledge and inferences across domains; and our metaphorical use of language is a reflection of this process.

Given its ubiquity, metaphorical language poses an important problem for natural language understanding (Cameron, 2003; Shutova and Teufel, 2010). A number of approaches to metaphor processing have thus been proposed, focusing predominantly on classifying linguistic expressions as literal or metaphorical. They experimented with a range of features, including lexical and syntactic information (Hovy et al., 2013; Beigman Klebanov et al., 2016) and higher-level features such as semantic roles (Gedigian et al., 2006), domain types (Dunn, 2013), concreteness (Turney et al., 2011), imageability (Strzalkowski et al., 2013) and WordNet supersenses (Tsvetkov et al., 2014). While reporting promising results, all of these approaches used hand-engineered features and relied on manually-annotated resources to extract them. In order to reduce the reliance on manual annotation, other researchers experimented with sparse distributional features (Shutova et al., 2010; Shutova and Sun, 2013) and dense neural word embeddings (Bracewell et al., 2014; Shutova et al., 2016). Their experiments have demonstrated that corpus-driven lexical representations already encode information about semantic domains needed to learn the patterns of metaphor usage from linguistic data.

We take this intuition a step further and present the first deep learning architecture designed to capture metaphorical composition. Deep learning methods have already been shown successful in many other semantic tasks (e.g. Hermann et al., 2015; Kumar et al., 2015; Zhao et al., 2015), which suggests that designing a specialised neural network architecture for metaphor detection will lead to improved performance. In this paper, we present a novel architecture which (1) models the interaction between the source and target domains in the metaphor via a gating function; (2) specialises word representations for the metaphor identification task via supervised training; (3) quantifies metaphoricity via a weighted similarity function that automatically selects the relevant dimensions of similarity. We experimented with two types of word representations

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1537–1546
Copenhagen, Denmark, September 7–11, 2017.

as inputs to the network: the standard skip-gram word embeddings (Mikolov et al., 2013a) and the cognitively-driven attribute-based vectors (Bulat et al., 2017), as well as a combination thereof.

We evaluate our method in the metaphor identification task, focusing on adjective–noun, verb–subject and verb–direct object constructions where the verbs and adjectives can be used metaphorically. Our results show that our architecture outperforms both a metaphor agnostic deep learning baseline (a basic feed forward network) and the previous corpus-based approaches to metaphor identification. We also investigate the effects of training data on this task, and demonstrate that with a sufficiently large training set our method also outperforms the best existing systems based on hand-coded lexical knowledge.

2 Related Work

The majority of approaches to metaphor processing cast the problem as classification of linguistic expressions as metaphorical or literal. Gedigian et al. (2006) classified verbs related to MOTION and CURE within the domain of financial discourse. They used the maximum entropy classifier and the verbs' nominal arguments and their FrameNet roles (Fillmore et al., 2003) as features, reporting encouraging results. Dunn (2013) used a logistic regression classifier and high-level properties of concepts extracted from SUMO ontology, including domain types (ABSTRACT, PHYSICAL, SOCIAL, MENTAL) and event status (PROCESS, STATE, OBJECT). Tsvetkov et al. (2014) used random forest classifier and coarse semantic features, such as concreteness, animateness, named entity types and WordNet supersenses. They have shown that the model learned with such coarse semantic features is portable across languages. The work of Hovy et al. (2013) is notable as they focused on compositional rather than categorical features. They trained an SVM with dependency-tree kernels to capture compositional information, using lexical, part-of-speech tag and WordNet supersense representations of sentence trees. Mohler et al. (2013) aimed at modelling conceptual information. They derived semantic signatures of texts as sets of highly-related and interlinked WordNet synsets. The semantic signatures served as features to train a set of classifiers (maximum entropy, decision trees, SVM, random forest) that mapped new metaphors to the semantic signatures of the known ones.

With the aim of reducing the dependence on manually-annotated lexical resources, other research focused on modelling metaphor using corpus-driven information alone. Shutova et al. (2010) pointed out that the metaphorical uses of words constitute a large portion of the dependency features extracted for abstract concepts from corpora. For example, the feature vector for *politics* would contain GAME or MECHANISM terms among the frequent features. As a result, distributional clustering of abstract nouns with such features identifies groups of diverse concepts metaphorically associated with the same source domain. Shutova et al. (2010) exploit this property of co-occurrence vectors to identify new metaphorical mappings starting from a set of examples. Shutova and Sun (2013) used hierarchical clustering to derive a network of concepts in which metaphorical associations are learned in an unsupervised way. Do Dinh and Gurevych (2016) investigated metaphors through the task of sequence labelling, detecting metaphor related words in context. Gutiérrez et al. (2016) investigated metaphorical composition in the compositional distributional semantics framework. Their method learns metaphors as linear transformations in a vector space and they demonstrated that it produces superior phrase representations for both metaphorical and literal language, as compared to the traditional "single-sense" compositional distributional model. They then used these representations in the metaphor identification task, achieving promising results.

The more recent approaches of Shutova et al. (2016) and Bulat et al. (2017) used dense skip-gram word embeddings (Mikolov et al., 2013a) instead of the sparse distributional features. Shutova et al. (2016) investigated a set of metaphor identification methods using linguistic and visual features. They learned linguistic and visual representations for both words and phrases, using skip-gram and convolutional neural networks (Kiela and Bottou, 2014) respectively. They then measured the difference between the phrase representation and those of its component words in terms of their cosine similarity, which served as a predictor of metaphoricity. They found basic cosine similarity between the component words in the phrase to be a powerful measure – the neural embeddings of the words were compared with cosine similar-

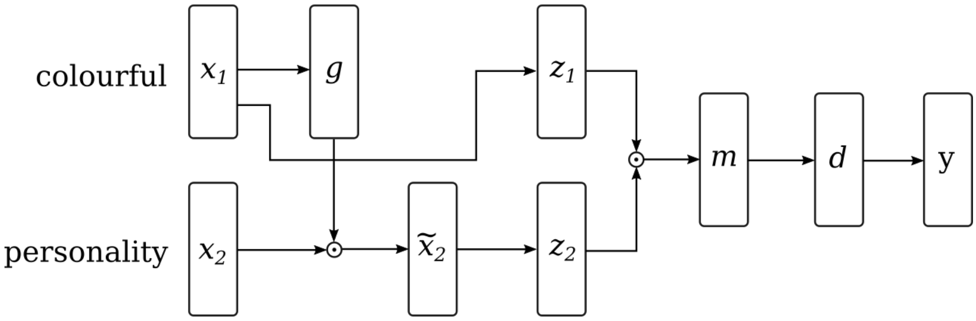

Figure 1: The network architecture for supervised metaphorical phrase classification. The $\odot$ symbol is used to indicate element-wise multiplication.

ity and a threshold was tuned on the development set to distinguish between literal and metaphorical phrases. This approach was their best performing linguistic model, outperformed only by a multi-modal system which included both linguistic and visual features.

Bulat et al. (2017) presented a metaphor identification method that uses representations constructed from human property norms (McRae et al., 2005). They first learn a mapping from the skip-gram embedding vector space to the property norm space using linear regression, which allows them to generate property norm representations for unseen words. The authors then train an SVM classifier to detect metaphors using these representations as input. Bulat et al. (2017) have shown that the cognitively-driven property norms outperform standard skip-gram representations in this task.

3 Supervised Similarity Network

Our method is inspired by the findings of Shutova et al. (2016), who showed that the cosine similarity between neural embeddings of the two words in a phrase is indicative of its metaphoricity. For example, the phrase *'colourful personality'* receives a score:

$$s = cos(x_c, x_p) \tag{1}$$

where x_c is the embedding for *colourful* and x_p is the embedding for *personality*. The combined phrase is classified as being metaphorical based on a threshold, which is optimised on a development dataset. In this paper, we propose several extensions to this general idea, creating a supervised version of the cosine similarity metric which can be optimised on training data to be more suitable for metaphor detection.

3.1 Word Representation Gating

Directly comparing the vector representations of both words treats each of the embeddings as an independent unit. In reality, however, word meanings vary and adapt based on the context. In case of metaphorical language (e.g. "*cure* crime"), the source domain properties of the verb (e.g. *cure*) are projected onto the target domain noun (e.g. *crime*), resulting in the interaction of the two domains in the interpretation of the metaphor.

In order to integrate this idea into the metaphor detection method, we can construct a gating function that modulates the representation of one word based on the other. Given embeddings x_1 and x_2, the gating values are predicted as a non-linear transformation of x_1 and applied to x_2 through element-wise multiplication:

$$g = \sigma(W_g x_1) \tag{2}$$

$$\widetilde{x}_2 = x_2 \odot g \tag{3}$$

where W_g is a weight matrix that is optimised during training, σ is the sigmoid activation function, and $\odot$ represents element-wise multiplication. In an adjective-noun phrase, this architecture allows the network to first look at the adjective, then use its meaning to change the representation of the noun. The sigmoid activation function makes it act as a filter, choosing which information from the original embedding gets through to the rest of the network. While learning a more complex gating function could be beneficial for very large training resources, the filtering approach is more suitable for the annotated metaphor datasets which are relatively small in size.

3.2 Vector Space Mapping

As the next step, we implement position-specific mappings for the word embeddings. The original method uses word embeddings that have been pre-trained using the distributional skip-gram objective (Mikolov et al., 2013a). While this tunes the vectors for predicting context words, there is no reason to believe that the same space is also optimal for the task of metaphor detection. In order to address this shortcoming, we allow the model to learn a mapping from the skip-gram vector space to a new metaphor-specific vector space:

$$z_1 = tanh(W_{z_1} x_1) \tag{4}$$

$$z_2 = tanh(W_{z_2} \widetilde{x}_2) \tag{5}$$

where W_{z_1} and W_{z_2} are weight matrices, z_1 and z_2 are the new position-specific word representations. While the original embeddings x_1 and x_2 are pre-trained on a large unannotated corpus, the transformation process is optimised using annotated metaphor examples, resulting in word representations that are more suitable for this task. Furthermore, the adjectives and nouns use separate mapping weights, which allows the model to better distinguish between the different functionalities of these words. In contrast, the original cosine similarity is not position-specific and would give the same result regardless of the word order.

3.3 Weighted Cosine

If the vectors x_1 and x_2 are normalised to unit length, the cosine similarity between them is equal to their dot product, which in turn is equal to their elementwise multiplication followed by a sum over all elements:

$$cos(x_1, x_2) \propto \sum_i x_{1,i} x_{2,i} \tag{6}$$

This calculation of cosine similarity can be formulated as a small neural network where the two unit-normalised input vectors are directly multiplied together. This is followed by a single output neuron, with all the intermediate weights set to value 1. Such a network would calculate the same sum over the element-wise multiplication, outputting the value of cosine similarity.

Since there is no reason to assume that all the embedding dimensions are equally important when detecting metaphors, we can explore other strategies for weighting the similarity calculation.

Metaphorical	Literal
absorb cost	accommodate guest
attack problem	attack village
attack cancer	blur vision
breathe life	breathe person
design excuse	deflate mattress
deflate economy	digest milk
leak news	land airplane
swallow anger	swim man

Table 1: Annotated verb-direct object and verb-subject pairs from MOH.

Rei and Briscoe (2014) used a fixed formula to calculate weights for different dimensions of cosine similarity and showed that it helped in recovering hyponym relations. We extend this even further and allow the network to use multiple different weighting strategies which are all optimised during training. This is done by first creating a vector m, which is an element-wise multiplication of the two word representations:

$$m_i = z_{1,i} z_{2,i} \tag{7}$$

where m_i is the i-th element of vector m and $z_{1,i}$ is the i-th element of vector z_1. After that, the resulting vector is used as input for a hidden neural layer:

$$d = \gamma(W_d m) \tag{8}$$

where W_d is a weight matrix and γ is an activation function. If the length of d is 1, all the weights in W_d have value 1, and γ is a linear activation, then this formula is equivalent to a regular cosine similarity. However, we use a larger length for d to capture more features, use $tanh$ as the activation function, and optimise the weights of W_d during training, giving the framework more flexibility to customise the model for the task of metaphor detection.

3.4 Prediction and Optimisation

Based on vector d we can output a prediction for the word pair, showing whether it is literal or metaphorical:

$$y = \sigma(W_y d) \tag{9}$$

where W_y is a weight matrix, σ is the logistic activation function, and y is a real-valued prediction with values between 0 and 1.

We optimise the model based on an annotated training dataset, while minimising the following hinge loss function:

$$E = \sum_{k} q_k \tag{10}$$

$$q_k = \begin{cases} (\widetilde{y} - y)^2 & \text{if } |\widetilde{y} - y| > 0.4 \\ 0, & \text{otherwise} \end{cases} \tag{11}$$

where y is the predicted value, $\widetilde{y}$ is the true label, and k iterates over all training examples. Equation 11 optimises the model to minimise the squared error between the predicted and true labels. However, this is only done for training examples where the predicted error is not already close enough to the desired result. The condition $|\widetilde{y} - y| > 0.4$ only updates training examples where the difference from the true label is greater than 0.4. The true labels $\widetilde{y}$ can only take values 0 (literal) or 1 (metaphorical), and the threshold 0.4 is chosen so that datapoints that are on the correct side of the decision boundary by more than 0.1 would be ignored, which helps reduce overfitting and allows the model to focus on the misclassified examples.

The diagram of the complete network can be seen in Figure 1.

4 Word Representations

Following Bulat et al. (2017) we experiment with two types of semantic vectors: skip-gram word embeddings and attribute-based representations.

The word embeddings are 100-dimensional and were trained using the standard log-linear skip-gram model with negative sampling of Mikolov et al. (2013b) on Wikipedia for 3 epochs, using a symmetric window of 5 and 10 negative samples per word-context pair.

We use the 2526-dimensional attribute-based vectors trained by Bulat et al. (2017), following Fagarasan et al. (2015). These representations were induced by using partial least squares regression to learn a cross-modal mapping function between the word embeddings described above and the McRae et al. (2005) property-norm semantic space.

5 Datasets

We evaluate our method using two datasets of phrases manually annotated for metaphoricity. Since these datasets include examples for different senses (both metaphorical and literal) of the same verbs or adjectives, they allow us to test the extent to which our model is able to discriminate between different word senses, as opposed to merely selecting the most frequent class for a given word.

Metaphorical	Literal
bloody stupidity	bloody nose
deep understanding	cold weather
empty promise	dry skin
green energy	empty can
healthy balance	frosty morning
hot topix	hot chocolate
muddy thinking	gold coin
ripe age	soft leather
sour mood	sour cherry
warm reception	steep hill

Table 2: Annotated adjective–noun pairs from TSV-TEST.

Mohammad et al. dataset (MOH) Mohammad et al. (2016) used WordNet to find verbs that had between three and ten senses and extracted the sentences exemplifying them in the corresponding glosses, yielding a total of 1639 verb uses in sentences. Each of these was annotated for metaphoricity by 10 annotators via the crowdsourcing platform CrowdFlower[1]. Mohammad et al. selected the verbs that were tagged by at least 70% of the annotators as metaphorical or literal to create their dataset. We extracted verb–direct object and verb–subject relations of the annotated verbs from this dataset, discarding the instances with pronominal or clausal subject or object. This resulted in a dataset of 647 verb–noun pairs (316 metaphorical and 331 literal). Some examples of annotated verb phrases from MOH are presented in Table 1.

Tsvetkov et al. dataset (TSV) Tsvetkov et al. (2014) construct a dataset of adjective–noun pairs annotated for metaphoricity. This is divided into a training set consisting of 884 literal and 884 metaphorical pairs (TSV-TRAIN) and a test set containing 100 literal and 100 metaphorical pairs (TSV-TEST). Table 2 shows a portion of annotated adjective-noun phrases from TSV-TEST. TSV-TRAIN was collected from publicly available metaphor collections on the web and manually

[1] www.crowdflower.com

curated by removing duplicates and metaphorical phrases that depend on wider context for their interpretation (e.g. *drowning students*). TSV-TEST was constructed by extracting nouns that co-occur with a list of 1000 frequent adjectives in the TenTen Web Corpus[2] using SketchEngine. The selected adjective-noun pairs were annotated for metaphoricity by 5 annotators with an inter-annotator agreement of $\kappa = 0.76$. Since TSV-TRAIN and TSV-TEST were constructed differently, we follow previous work (Tsvetkov et al., 2014; Shutova et al., 2016; Bulat et al., 2017) and report performance on TSV-TEST. We randomly separated 200 (out of the 1536) examples from the training set to use for development experiments.

6 Experiments and Results

The word representations in our model were initialised with either the 100-dimensional skip-gram embeddings or the 2,526-dimensional attribute vectors (Section 4). These were kept fixed and not updated, which reduces overfitting on the available training examples. For both word representations we use the same embeddings as Bulat et al. (2017), which makes the results directly comparable and shows that the improvements are coming from the novel architecture and are not due to a different embedding initialisation.

The network was optimised using AdaDelta (Zeiler, 2012) for controlling adaptive learning rates. The models were evaluated after each full pass over the training data and training was stopped if the F-score on the development set had not improved for 5 epochs. The transformed embeddings z_1 and z_2 were set to size 300, layer d was set to size 50. The values for these hyperparameters were chosen experimentally using the development dataset. In order to avoid drawing conclusions based on outlier results due to random initialisations, we ran each experiment 25 times with random seeds and present the averaged results in this paper. We implemented the framework using Theano (Al-Rfou et al., 2016) and are making the source code publicly available.[3]

Table 3 contains results of different system configurations on the TSV dataset. The original F-score by Tsvetkov et al. (2014) is still the highest, as they used a range of highly-engineered features that require manual annotation, such as the lexical abstractness, imageability scores and the relative number of supersenses for each word in the dataset. Our setup is more similar to the linguistic experiments by Shutova et al. (2016), where metaphor detection is performed using pretrained word embeddings. They also proposed combining the linguistic model with a system using visual word representations and achieved performance improvements. Recently, Bulat et al. (2017) compared different types of embeddings and showed that attribute-based representations can outperform regular skip-gram embeddings.

	Acc	P	R	F1
Tsvetkov et al. (2014)	-	-	-	**85**
Shutova et al. (2016)				
linguistic	-	73	80	76

SSN skip-gram	82.2	**91.1**	71.6	80.1
SSN attribute	81.9	86.6	**75.7**	80.6
SSN fusion	**82.9**	90.3	73.8	**81.1**

Table 3: System performance on the Tsvetkov et al. dataset (TSV) in terms of accuracy (Acc), precision (P), recall (R) and F-score (F1).

As an additional baseline, we report the performance on metaphor detection using a basic feed-forward network (FFN). In this configuration, the word embeddings x_1 and x_2 are directly connected to the hidden layer d, skipping all the intermediate network structure. The FFN achieves 74.4% F-score on TSV-TEST, showing that even such a simple model can perform relatively well in a supervised setting. Using attribute vectors instead of skip-gram embeddings gives a slight improvement, especially on the recall metric, which is consistent with the findings by Bulat et al. (2017).

The architecture described in Section 3, which we refer to as a supervised similarity network (SSN), outperforms the baseline and achieves 80.1% F-score using skip-gram embeddings and 80.6% with attribute-based representations. We also created a fusion of these two models where the predictions from both are combined as a weighted average. In this setting, the two networks are trained in tandem and a real-valued weight, which is also optimised during training, is

Table 4: System performance on the Mohammad et al. dataset (MOH) in terms of accuracy (Acc), precision (P), recall (R) and F-score (F1).

used to combine them together. This configuration achieves 81.1% F-score, indicating that the the skip-gram embeddings and attribute vectors capture somewhat complementary information. Excluding the system by Tsvetkov et al. (2014) which requires hand-annotated features, the proposed similarity network outperforms all the previous systems, even improving over the multimodal system by Shutova et al. (2016) without requiring any visual information. The attribute-based SSN also improves over Bulat et al. (2017) by 5.6% absolute, using the same word representations as input.

Table 4 contains results of different system architectures on the MOH dataset. Shutova et al. (2016) reported 75% F-score on this dataset with a multimodal system, after randomly separating a subset for testing. Since this corpus contains only 647 annotated examples, we instead evaluated the systems using 10-fold cross-validation. The feedforward baseline with skip-gram embeddings returns an F-score that is close to the linguistic configuration of Shutova et al, whereas the best results are achieved by the similarity network with skip-gram embeddings. In this setting, the attribute-based representations did not improve performance – this is expected, as the attribute norms by McRae et al. (2005) are designed for nouns, whereas the MOH dataset is centered on verbs.

Input phrase	Gold	Predicted	Score
sunny country	0	0	0.152
sweet treat	0	0	0.358
lost wallet	0	0	0.439
meaningless discussion	0	0	0.150
gentle soldier	0	0	0.175
unforgiving heights	1	1	0.867
easy money	1	1	0.503
blind hope	1	1	0.813
rolling hills	1	1	0.677

rich programmer	0	1	0.514
fishy offer	1	0	0.290
backward area	1	0	0.161
sweet person	1	0	0.332

Table 5: Examples from the Tsvetkov development set, together with the gold label, predicted label, and the predicted score from the best model.

Table 5 contains examples from the TSV development set, together with gold annotations and predicted scores. The system confidently detects literal phrases such as *sunny country* and *meaningless discussion*, along with metaphorical phrases such as *unforgiving heights* and *blind hope*. The predicted output disagrees with the annotation on cases such as *humane treatment* and *rich programmer* – some of these examples could also be argued as being metaphorical, depending on the specific sense of the words. While the system was relatively unsure about the false positives (the scores were close to 0.5), it tended to assign more decisive scores to the false negatives.

7 The Effects of Training Data

Results in Section 6 show that performance on the TSV dataset is higher than the MOH dataset, likely due to the former having more examples available for training. Therefore, we ran an additional experiment to investigate the effect of dataset size on the performance of metaphor detection. Gutiérrez et al. (2016) annotated a dataset of adjective-noun phrases as being literal or metaphorical, and we are able to use this as an additional training resource. While it contains only 23 unique adjectives, the total number of phrases reaches 8,592. We remove any phrases that occur in the development or test data of TSV, then incrementally add the remaining examples to the TSV training data and evaluate on the TSV-TEST.

Figure 2 shows a graph of the system performance, when increasing the training data at intervals of 500. There is a very rapid increase in performance until around 2,000 training points, whereas the existing TSV-TRAIN is limited to 1,336 examples. Providing even more data to the system gives an additional increase that is more gradual. The final performance of the system us-

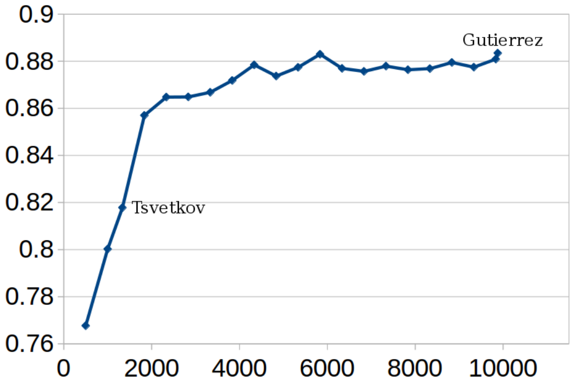

Figure 2: Performance as a function of training set size. The x-axis shows the number of training examples, the y-axis shows F-score on TSV-TEST.

Training data	Acc	P	R	F
Tsvetkov	83.0	88.3	76.3	81.8
Tsvetkov+Gutierrez	**88.7**	**91.6**	**85.4**	**88.3**

Table 6: System performance on the Tsvetkov et al. dataset (TSV), using additional training data.

ing both datasets is 88.3 F-score, which is the highest result reported on the TSV dataset and translates to 36% relative error reduction with respect to the same system trained only on the original dataset.

We report the exact values in Table 6 for the different training sets. The value on the Tsvetkov training data is different from the result in Table 3, which is due to the original attribute embeddings by Bulat et al. (2017) only containing representations for the vocabulary in the TSV dataset. In order to include the data from Gutiérrez et al. (2016), we recreated the attribute vectors for a larger vocabulary, which results in a slightly different baseline performance.

8 Qualitative analysis

The architecture in Section 3 also acts as a semantic composition model, extracting the meaning of the phrase by combining the meanings of its component words. Therefore, we performed a qualitative experiment to investigate: (1) how well do traditional compositional methods capture metaphors, without any fine-tuning; and (2) whether the supervised representations still retain their domain-specific semantic information. For this purpose, we construct three vector spaces and visualise some examples from the TSV training set, using t-SNE (Van Der Maaten and Hinton, 2008).

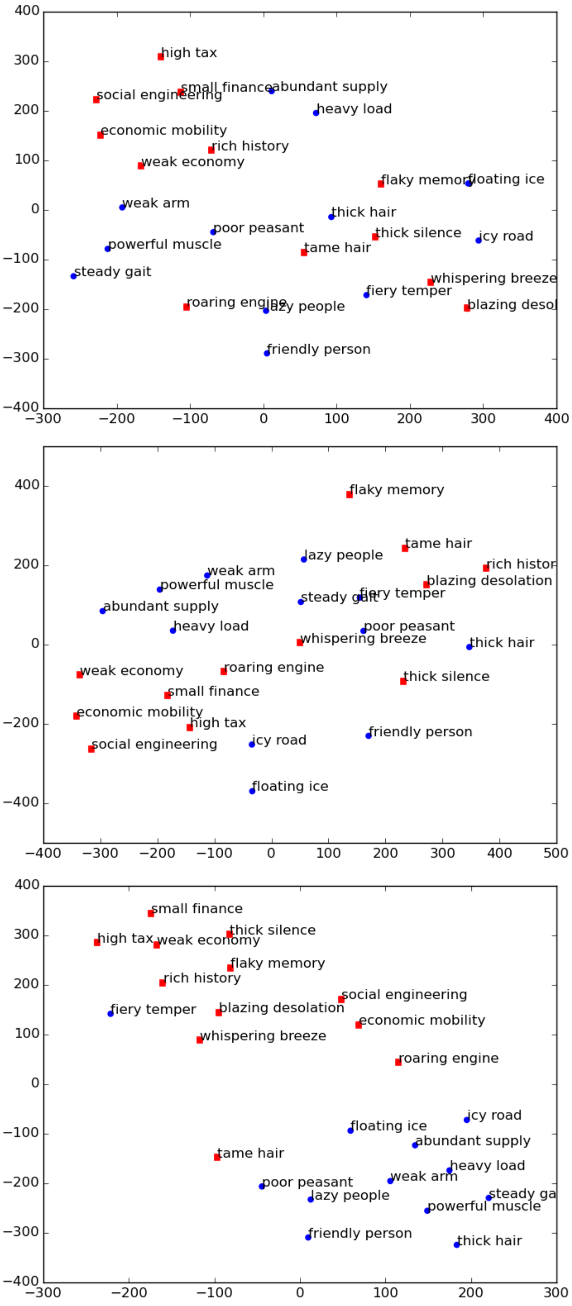

Figure 3: Comparison of metaphorical and literal phrases in different vector spaces. Blue circles indicate literal examples, red squares show metaphorical pairs. Top: additive vector space. Middle: multiplicative vector space. Bottom: vectors from layer m in the similarity network.

Figure 3 contains examples for three different composition methods: the additive method simply sums the skip-gram embeddings for both words (top); the multiplicative method multiplies the skip-gram embeddings (middle); the final system uses layer m from the SSN model to represent the phrases (bottom).

The visualisation shows that the additive and multiplicative models are both comparable when it comes to semantic clustering of the phrases, but metaphorical examples are mixed together with literal clusters. The SSN is optimised for metaphor classification and therefore it produces representations with a very clear boundary for metaphoricity. Interestingly, the graph also reveals a misannotated example in the dataset, since *'fiery temper'* should be labeled as a metaphor. At the same time, this space also retains the general semantic information, as similar phrases with the same label are still positioned close together. Future work could investigate models of multi-task training where metaphor detection is trained together with an unsupervised objective, allowing the system to take better advantage of unlabeled data while still learning to separate metaphors.

9 Conclusion

In this paper, we introduced the first deep learning architecture designed to capture metaphorical composition and evaluated it on a metaphor identification task.

Firstly, we demonstrated that the proposed framework outperforms both a metaphor-agnostic baseline (a feed-forward neural network) as well as previous corpus-driven approaches to metaphor identification. The results showed that it is beneficial to construct a specialised network architecture for metaphor detection, which includes a gating function for capturing the interaction between the source and target domains, word embeddings mapped to a metaphor-specific space, and optimisation using a hinge loss function.

Secondly, our qualitative analysis indicates that our supervised similarity network learns phrase representations with a very clear boundary for metaphoricity, in contrast to traditional compositional methods.

Finally, we show that with a sufficiently large training set our model can also outperform the state-of-the art metaphor identification systems based on hand-coded lexical knowledge.

Identifying civilians killed by police with distantly supervised entity-event extraction

Katherine A. Keith, Abram Handler, Michael Pinkham,

kkeith@cs.umass.edu, brenocon@cs.umass.edu
http://slanglab.cs.umass.edu/

Abstract

We propose a new, socially-impactful task for natural language processing: from a news corpus, extract names of persons who have been killed by police. We present a newly collected police fatality corpus, which we release publicly, and present a model to solve this problem that uses EM-based distant supervision with logistic regression and convolutional neural network classifiers. Our model outperforms two off-the-shelf event extractor systems, and it can suggest candidate victim names in some cases faster than one of the major manually-collected police fatality databases.

Appendix, software, and data are available online at: http://slanglab.cs.umass.edu/PoliceKillingsExtraction/

1 Introduction

The United States government does not keep systematic records of when police kill civilians, despite a clear need for this information to serve the public interest and support social scientific analysis. Federal records rely on incomplete cooperation from local police departments, and human rights statisticians assess that they fail to document thousands of fatalities (Lum and Ball, 2015).

News articles have emerged as a valuable alternative data source. Organizations including The Guardian, The Washington Post, Mapping Police Violence, and Fatal Encounters have started to build such databases of U.S. police killings by manually reading millions of news articles[1] and extracting victim names and event details. This approach was recently validated by a Bureau of Justice Statistics study (Banks et al., Dec. 2016) which augmented traditional police-maintained records with media reports, finding twice as many deaths compared to past government analyses. This suggests textual news data has enormous, real value, though *manual* news analysis remains extremely laborious.

Text	Person killed by police?
Alton Sterling was killed by police.	True
Officers shot and killed **Philando Castile**.	True
Officer **Andrew Hanson** was shot.	False
Police report **Megan Short** was fatally shot in apparent murder-suicide.	False

Table 1: Toy examples (with entities in bold) illustrating the problem of extracting from text names of persons who have been killed by police.

We propose to help automate this process by extracting the names of persons killed by police from event descriptions in news articles (Table 1). This can be formulated as either of two cross-document entity-event extraction tasks:

1. Populating an entity-event database: From a corpus of news articles $\mathcal{D}^{(test)}$ over timespan T, extract the names of persons killed by police during that same timespan ($\mathcal{E}^{(pred)}$).

2. Updating an entity-event database: In addition to $\mathcal{D}^{(test)}$, assume access to both a historical database of killings $\mathcal{E}^{(train)}$ and a historical news corpus $\mathcal{D}^{(train)}$ for events that occurred before T. This setting often occurs in practice, and is the focus of this paper; it allows for the use of distantly supervised learn-

[1] Fatal Encounters director D. Brian Burghart estimates he and colleagues have read 2 million news headlines and ledes to assemble its fatality records that date back to January, 2000 (pers. comm.); we find FE to be the most comprehensive publicly available database.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1547–1557
Copenhagen, Denmark, September 7–11, 2017.

ing methods.[2]

The task itself has important social value, but the NLP research community may be interested in a scientific justification as well. We propose that police fatalities are a useful test case for event extraction research. Fatalities are a well defined type of event with clear semantics for coreference, avoiding some of the more complex issues in this area (Hovy et al., 2013). The task also builds on a considerable information extraction literature on knowledge base population (e.g. Craven et al. (1998)). Finally, we posit that the field of natural language processing should, when possible, advance applications of important public interest. Previous work established the value of textual news for this problem, but computational methods could alleviate the scale of manual labor needed to use it.

To introduce this problem, we:

- Define the task of identifying persons killed by police, which is an instance of cross-document entity-event extraction (§3.1).
- Present a new dataset of web news articles collected throughout 2016 that describe possible fatal encounters with police officers (§3.2).
- Introduce, for the database update setting, a distant supervision model (§4) that incorporates feature-based logistic regression and convolutional neural network classifiers under a latent disjunction model.
- Demonstrate the approach's potential usefulness for practitioners: it outperforms two off-the-shelf event extractors (§5) and finds 39 persons not included in the Guardian's "The Counted" database of police fatalities as of January 1, 2017 (§6). This constitutes a promising first step, though performance needs to be improved for real-world usage.

2 Related Work

This task combines elements of information extraction, including: *event extraction* (a.k.a. *semantic parsing*), identifying descriptions of events and their arguments from text, and cross-document *relation extraction*, predicting semantic relations over entities. A fatality event indicates the killing of a particular person; we wish to specifically identify the names of fatality victims mentioned in text. Thus our task could be viewed as unary relation extraction: for a given person mentioned in a corpus, were they killed by a police officer?

Prior work in NLP has produced a number of event extraction systems, trained on text data hand-labeled with a pre-specified ontology, including ones that identify instances of killings (Li and Ji, 2014; Das et al., 2014). Unfortunately, they perform poorly on our task (§5), so we develop a new method.

Since we do not have access to text specifically annotated for police killing events, we instead turn to *distant supervision*—inducing labels by aligning relation-entity entries from a gold standard database to their mentions in a corpus (Craven and Kumlien, 1999; Mintz et al., 2009; Bunescu and Mooney, 2007; Riedel et al., 2010). Similar to this work, Reschke et al. (2014) apply distant supervision to multi-slot, template-based event extraction for airplane crashes; we focus on a simpler unary extraction setting with joint learning of a probabilistic model. Other related work in the cross-document setting has examined joint inference for relations, entities, and events (Yao et al., 2010; Lee et al., 2012; Yang et al., 2015).

Finally, other natural language processing efforts have sought to extract social behavioral event databases from news, such as instances of protests (Hanna, 2017), gun violence (Pavlick et al., 2016), and international relations (Schrodt and Gerner, 1994; Schrodt, 2012; Boschee et al., 2013; O'Connor et al., 2013; Gerrish, 2013). They can also be viewed as event database population tasks, with differing levels of semantic specificity in the definition of "event."

3 Task and Data

3.1 Cross-document entity-event extraction for police fatalties

From a corpus of documents $\mathcal{D}$, the task is to extract a list of candidate person names, $\mathcal{E}$, and for each $e \in \mathcal{E}$ find

$$P(y_e = 1 \mid x_{\mathcal{M}(e)}). \tag{1}$$

Here $y \in \{0, 1\}$ is the entity-level label where $y_e = 1$ means a person (entity) e was killed by police; $x_{\mathcal{M}(e)}$ are the sentences containing mentions $\mathcal{M}(e)$ of that person. A mention $i \in \mathcal{M}(e)$ is a token span in the corpus. Most entities have

[2] Konovalov et al. (2017) studies the database update task where edits to Wikipedia infoboxes constitute events.

Knowledge base	Historical	Test

multiple mentions; a single sentence can contain multiple mentions of different entities.

3.2 News documents

We download a collection of web news articles by continually querying Google News[3] throughout 2016 with lists of police keywords (i.e police, officer, cop etc.) and fatality-related keywords (i.e. kill, shot, murder etc.). The keyword lists were constructed semi-automatically from cosine similarity lookups from the *word2vec* pretrained word embeddings[4] in order to select a high-recall, broad set of keywords. The search is restricted to what Google News defines as a "regional edition" of "United States (English)" which seems to roughly restrict to U.S. news though we anecdotally observed instances of news about events in the U.K. and other countries. We apply a pipeline of text extraction, cleaning, and sentence de-duplication described in the appendix.

3.3 Entity and mention extraction

We process all documents with the open source *spaCy* NLP package[5] to segment sentences, and extract entity mentions. Mentions are token spans that (1) were identified as "persons" by spaCy's named entity recognizer, and (2) have a (firstname, lastname) pair as analyzed by the HAPNIS rule-based name parser,[6] which extracts, for example, (*John*, *Doe*) from the string *Mr. John A. Doe Jr.*.[7]

	x	z	y
"Hard" training	observed	fixed (distantly labeled)	observed
"Soft" (EM) training	observed	latent	observed
Testing	observed	latent	latent

Table 3: Training and testing settings for mention sentences x, mention labels z, and entity labels y.

To prepare sentence text for modeling, our preprocessor collapses the candidate mention span to a special TARGET symbol. To prevent overfitting, other person names are mapped to a different PERSON symbol; e.g. "TARGET was killed in an encounter with police officer PERSON."

There were initially 18,966,757 and 6,061,717 extracted mentions for the train and test periods respectively. To improve precision and computational efficiency, we filtered to sentences that contained at least one police keyword and one fatality keyword. This filter reduced positive entity recall a moderate amount (from 0.68 to 0.57), but removed 99% of the mentions, resulting in the $|\mathcal{M}|$ counts in Table 2.[8]

Other preprocessing steps included heuristics for extraction and name cleanups and are detailed in the appendix.

4 Models

Our goal is to classify entities as to whether they have been killed by police (§4.1). Since we do not have gold-standard labels to train our model, we turn to *distant supervision* (Craven and Kumlien, 1999; Mintz et al., 2009), which heuristically aligns facts in a knowledge base to text in a corpus to impute positive mention-level labels for supervised learning. Previous work typically examines distant supervision in the context of binary relation extraction (Bunescu and Mooney, 2007; Riedel et al., 2010; Hoffmann et al., 2011), but we are concerned with the unary predicate "person was killed by police." As our gold standard knowledge

[6] http://www.umiacs.umd.edu/~hal/HAPNIS/

[7] For both training and testing, we use a name matching assumption that a (firstname, lastname) match indicates coreference between mentions, and between a mention and a fatality database entity. This limitation does affect a small number of instances—the test set database contains the unique names of 453 persons but only 451 unique (firstname, lastname) tuples—but relaxing it raises complex issues for future work, such as how to evaluate whether a system correctly predicted two different fatality victims with the same name.

[8] In preliminary experiments, training and testing an n-gram classifier (§4.4) on the full mention dataset without keyword filtering resulted in a worse AUPRC than after the filter.

base ($\mathcal{G}$), we use Fatal Encounters' (FE) publicly available dataset: around 18,000 entries of victim's name, age, gender and race as well as location, cause and date of death. (We use a version of the FE database downloaded Feb. 27, 2017.) We compare two different distant supervision training paradigms (Table 3): "hard" label training (§4.2) and "soft" EM-based training (§4.3). This section also details mention-level models (§4.4,§4.5) and evaluation (§4.6).

4.1 Approach: Latent disjunction model

Our discriminative model is built on mention-level probabilistic classifiers. Recall a single entity will have one or more mentions (i.e. the same name occurs in multiple sentences in our corpus). For a given mention i in sentence x_i, our model predicts whether the person is described as having been killed by police, $z_i = 1$, with a binary logistic model,

$$P(z_i = 1 \mid x_i) = \sigma(\beta^{\mathsf{T}} f_\gamma(x_i)). \tag{2}$$

We experiment with both logistic regression (§4.4) and convolutional neural networks (§4.5) for this component, which use logistic regression weights β and feature extractor parameters γ. Then we must somehow aggregate mention-level decisions to determine entity labels y_e.[9] If a human reader were to observe at least one sentence that states a person was killed by police, they would infer that person was killed by police. Therefore we aggregate an entity's mention-level labels with a deterministic disjunction:

$$P(y_e = 1 \mid z_{\mathcal{M}(e)}) = 1\left\{\vee_{i\in\mathcal{M}(e)}\, z_i\right\}. \tag{3}$$

At test time, z_i is latent. Therefore the correct inference for an entity is to marginalize out the model's uncertainty over z_i:

$$\begin{aligned} P(y_e = 1|x_{\mathcal{M}(e)}) &= 1 - P(y_e = 0|x_{\mathcal{M}(e)}) && (4)\\ &= 1 - P(z_{\mathcal{M}(e)} = \vec{0} \mid x_{\mathcal{M}(e)}) && (5)\\ &= 1 - \prod_{i\in\mathcal{M}(e)} (1 - P(z_i = 1 \mid x_i)). && (6) \end{aligned}$$

Eq. 6 is the *noisyor* formula (Pearl, 1988; Craven and Kumlien, 1999). Procedurally, it counts strong probabilistic predictions as evidence, but can also incorporate a large number of weaker signals as positive evidence as well.[10]

In order to train these classifiers, we need mention-level labels (z_i) which we impute via two different distant supervision labeling methods: "hard" and "soft."

4.2 "Hard" distant label training

In "hard" distant labeling, labels for mentions in the training data are heuristically imputed and directly used for training. We use two labeling rules. First, **name-only:**

$$z_i = 1 \text{ if } \exists e \in \mathcal{G}^{(train)} : \text{name}(i) = \text{name}(e). \tag{7}$$

This is the direct unary predicate analogue of Mintz et al. (2009)'s *distant supervision assumption*, which assumes every mention of a gold-positive entity exhibits a description of a police killing.

This assumption is not correct. We manually analyze a sample of positive mentions and find 36 out of 100 name-only sentences did not express a police fatality event—for example, sentences contain commentary, or describe killings not by police. This is similar to the precision for distant supervision of binary relations found by Riedel et al. (2010), who reported 10–38% of sentences did not express the relation in question.

Our higher precision rule, **name-and-location**, leverages the fact that the location of the fatality is also in the Fatal Encounters database and requires both to be present:

$$\begin{aligned} &z_i = 1 \text{ if } \exists e \in \mathcal{G}^{(train)} :\\ &\text{name}(i) = \text{name}(e) \text{ and location}(e) \in x_i. \end{aligned} \tag{8}$$

We use this rule for training since precision is slightly better, although there is still a considerable level of noise.

4.3 "Soft" (EM) joint training

At training time, the *distant supervision assumption* used in "hard" label training is flawed: many positively-labeled mentions are in sentences that

[9] An alternative approach is to aggregate features across mentions into an entity-level feature vector (Mintz et al., 2009; Riedel et al., 2010); but here we opt to directly model at the mention level, which can use contextual information.

[10] In early experiments, we experimented with other, more ad-hoc aggregation rules with a "hard"-trained model. The maximum and arithmetic mean functions performed worse than *noisyor*, giving credence to the disjunction model. The sum rule ($\sum_i P(z_i = 1 \mid x_i)$) had similar ranking performance as *noisyor*—perhaps because it too can use weak signals, unlike mean or max—though it does not yield proper probabilities between 0 and 1.

do not assert the person was killed by a police officer. Alternatively, at training time we can treat z_i as a latent variable and assume, as our model states, that *at least one* of the mentions asserts the fatality event, but leave uncertainty over which mention (or multiple mentions) conveys this information. This corresponds to multiple instance learning (MIL; Dietterich et al. (1997)) which has been applied to distantly supervised relation extraction by enforcing the *at least one* constraint at training time (Bunescu and Mooney, 2007; Riedel et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012; Ritter et al., 2013). Our approach differs by using exact marginal posterior inference for the E-step.

With z_i as latent, the model can be trained with the EM algorithm (Dempster et al., 1977). We initialize the model by training on the "hard" distant labels (§4.2), and then learn improved parameters by alternating E- and M-steps.

The **E-step** requires calculating the marginal posterior probability for each z_i,

$$q(z_i) := P(z_i \mid x_{\mathcal{M}(e_i)}, y_{e_i}). \tag{9}$$

This corresponds to calculating the posterior probability of a disjunct, given knowledge of the output of the disjunction, and prior probabilities of all disjuncts (given by the mention-level classifier).

Since $P(z \mid x, y) = P(z, y \mid x)/P(y \mid x)$,

$$q(z_i = 1) = \frac{P(z_i = 1, y_{e_i} = 1 | x_{\mathcal{M}(e_i)})}{P(y_{e_i} = 1 | x_{\mathcal{M}(e_i)})}. \tag{10}$$

The numerator simplifies to the mention prediction $P(z_i = 1 \mid x_i)$ and the denominator is the entity-level *noisyor* probability (Eq. 6). This has the effect of taking the classifier's predicted probability and increasing it slightly (since Eq. 10's denominator is no greater than 1); thus the disjunction constraint implies a soft positive labeling. In the case of a negative entity with $y_e = 0$, the disjunction constraint implies all $z_{\mathcal{M}(e)}$ stay clamped to 0 as in the "hard" label training method.

The $q(z_i)$ posterior weights are then used for the **M-step**'s expected log-likelihood objective:

$$\max_\theta \sum_i \sum_{z \in \{0,1\}} q(z_i = z) \log P_\theta(z_i = z \mid x_i). \tag{11}$$

This objective (plus regularization) is maximized with gradient ascent as before.

This approach can be applied to any mention-level probabilistic model; we explore two in the next sections.

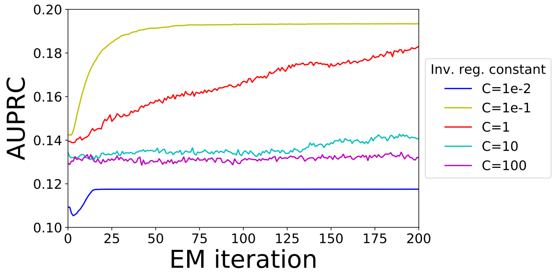

Figure 1: For soft-LR (EM), area under precision recall curve (AUPRC) results on the test set during training, for different inverse regularization values (C, the parameters' prior variance).

Table 4: Feature templates for logistic regression grouped into syntactic dependencies (D) and N-gram (N) features.

4.4 Feature-based logistic regression

We construct hand-crafted features for regularized logistic regression (LR) (Table 4), designed to be broadly similar to the n-gram and syntactic dependency features used in previous work on feature-based semantic parsing (e.g. Das et al. (2014); Thomson et al. (2014)). We use randomized feature hashing (Weinberger et al., 2009) to efficiently represent features in 450,000 dimensions, which achieved similar performance as an explicit feature representation. The logistic regression weights (β in Eq. 2) are learned with *scikit-learn* (Pedregosa et al., 2011).[11] For EM (soft-LR) training, the test set's area under the precision recall curve converges after 96 iterations (Fig. 1).

[11] With *FeatureHasher*, L2 regularization, 'lbfgs' solver, and inverse strength $C = 0.1$, tuned on a development dataset in "hard" training; for EM training the same regularization strength performs best.

4.5 Convolutional neural network

We also train a convolutional neural network (CNN) classifier, which uses word embeddings and their nonlinear compositions to potentially generalize better than sparse lexical and n-gram features. CNNs have been shown useful for sentence-level classification tasks (Kim, 2014; Zhang and Wallace, 2015), relation classification (Zeng et al., 2014) and, similar to this setting, event detection (Nguyen and Grishman, 2015). We use Kim (2014)'s open-source CNN implementation,[12] where a logistic function makes the final mention prediction based on max-pooled values from convolutional layers of three different filter sizes, whose parameters are learned (γ in Eq. 2). We use pretrained word embeddings for initialization,[13] and update them during training. We also add two special vectors for the TARGET and PERSON symbols, initialized randomly.[14]

For training, we perform stochastic gradient descent for the negative expected log-likelihood (Eq. 11) by sampling with replacement fifty mention-label pairs for each minibatch, choosing each $(i, k) \in \mathcal{M} \times \{0, 1\}$ with probability proportional to $q(z_i = k)$. This strategy attains the same expected gradient as the overall objective. We use "epoch" to refer to training on 265,700 examples (approx. twice the number of mentions). Unlike EM for logistic regression, we do not run gradient descent to convergence, instead applying an E-step every two epochs to update q; this approach is related to incremental and online variants of EM (Neal and Hinton, 1998; Liang and Klein, 2009), and is justified since both SGD and E-steps improve the evidence lower bound (ELBO). It is also similar to Salakhutdinov et al. (2003)'s expectation gradient method; their analysis implies the gradient calculated immediately after an E-step is in fact the gradient for the marginal log-likelihood. We are not aware of recent work that uses EM to train latent-variable neural network models, though this combination has been explored (e.g. Jordan and Jacobs (1994))

4.6 Evaluation

On documents from the test period (Sept–Dec 2016), our models predict entity-level labels $P(y_e = 1 \mid x_{\mathcal{M}(e)})$ (Eq. 6), and we wish to evaluate whether retrieved entities are listed in Fatal Encounters as being killed during Sept–Dec 2016. We rank entities by predicted probabilities to construct a precision-recall curve (Fig. 4, Table 5). Area under the precision-recall curve (AUPRC) is calculated with a trapezoidal rule; F1 scores are shown for convenient comparison to non-ranking approaches (§5).

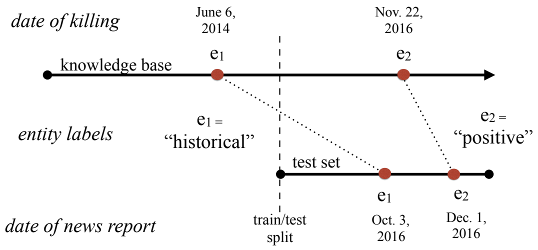

Figure 2: At test time, there are matches between the knowledge base and the news reports both for persons killed during the test period ("positive") and persons killed before it ("historical"). Historical cases are excluded from evaluation.

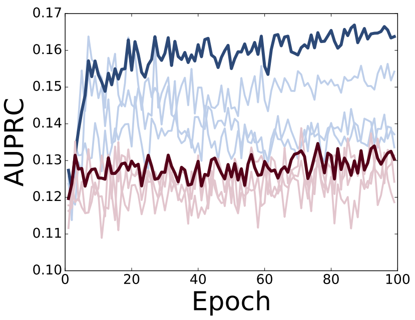

Figure 3: Test set AUPRC for three runs of soft-CNN (EM) (**blue**, higher in graph), and hard-CNN (**red**, lower in graph). Darker lines show performance of averaged predictions.

Excluding historical fatalities: Our model gives strong positive predictions for many people who were killed by police before the test period (i.e. before Sept 2016), when news articles contain discussion of historical police killings. We exclude these entities from evaluation, since we want to simulate an update to a fatality database (Fig 2). Our test dataset contains 1,148 such historical entities.

Data upper bound: Of the 452 gold entities in the FE database at test time, our news corpus only contained 258 (Table 2), hence the data up-

[12] https://github.com/yoonkim/CNN_sentence

[13] From the same *word2vec* embeddings used in §3.

[14] Training proceeds with ADADELTA (Zeiler, 2012). We tested several different settings of dropout and L2 regularization hyperparameters on a development set, but found mixed results, so used their default values.

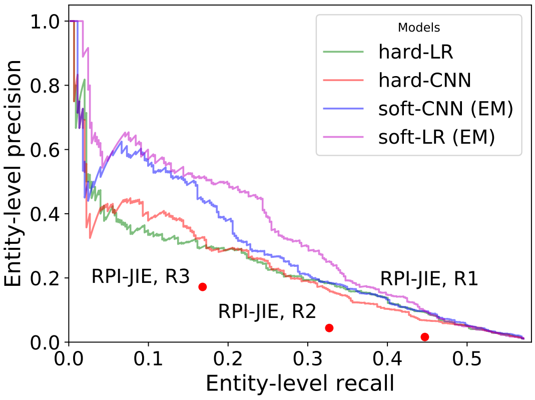

Figure 4: Precision-recall curves for the given models.

Model	AUPRC	F1
hard-LR, dep. feats.	0.117	0.229
hard-LR, n-gram feats.	0.134	0.257
hard-LR, all feats.	0.142	0.266
hard-CNN	0.130	0.252
soft-CNN (EM)	0.164	0.267
soft-LR (EM)	**0.193**	**0.316**
Data upper bound (§4.6)	0.57	0.73

Table 5: Area under precision-recall curve (AUPRC) and F1 (its maximum value from the PR curve) for entity prediction on the test set.

per bound of 0.57 recall, which also gives an upper bound of 0.57 on AUPRC. This is mostly a limitation of our news corpus; though we collect hundreds of thousands of news articles, it turns out Google News only accesses a subset of relevant web news, as opposed to more comprehensive data sources manually reviewed by Fatal Encounters' human experts. We still believe our dataset is large enough to be realistic for developing better methods, and expect the same approaches could be applied to a more comprehensive news corpus.

5 Off-the-shelf event extraction baselines

From a practitioner's perspective, a natural first approach to this task would be to run the corpus of police fatality documents through pre-trained, "off-the-shelf" event extractor systems that could identify killing events. In modern NLP research, a major paradigm for event extraction is to formulate a hand-crafted ontology of event classes, annotate a small corpus, and craft supervised learning systems to predict event parses of documents.

	Rule	Prec.	Recall	F1
SEMAFOR	R1	0.011	0.436	0.022
	R2	0.031	0.162	0.051
	R3	0.098	0.009	0.016
RPI-JIE	R1	0.016	0.447	0.030
	R2	0.044	0.327	0.078
	R3	0.172	0.168	**0.170**
Data upper bound (§4.6)		1.0	0.57	0.73

Table 6: Precision, recall, and F1 scores for test data using event extractors SEMAFOR and RPI-JIE and rules R1-R3 described below.

We evaluate two freely available, off-the-shelf event extractors that were developed under this paradigm: SEMAFOR (Das et al., 2014), and the RPI Joint Information Extraction System (RPI-JIE) (Li and Ji, 2014), which output semantic structures following the FrameNet (Fillmore et al., 2003) and ACE (Doddington et al., 2004) event ontologies, respectively.[15] Pavlick et al. (2016) use RPI-JIE to identify instances of gun violence.

For each mention $i \in \mathcal{M}$ we use SEMAFOR and RPI-JIE to extract event tuples of the form $t_i =$ (event type, agent, patient) from the sentence x_i. We want the system to detect (1) killing events, where (2) the killed person is the target mention i, and (3) the person who killed them is a police officer. We implement a small progression of these neo-Davidsonian (Parsons, 1990) conjuncts with rules to classify $z_i = 1$ if:[16]

- **(R1)** the event type is 'kill.'
- **(R2)** R1 holds and the patient token span contains e_i.

[15] Many other annotated datasets encode similar event structures in text, but with lighter ontologies where event classes directly correspond with lexical items—including PropBank, Prague Treebank, DELPHI-IN MRS, and Abstract Meaning Representation (Kingsbury and Palmer, 2002; Hajic et al., 2012; Oepen et al., 2014; Banarescu et al., 2013). We assume such systems are too narrow for our purposes, since we need an extraction system to handle different trigger constructions like "killed" versus "shot dead."

[16] For SEMAFOR, we use the FrameNet 'Killing' frame with frame elements 'Victim' and 'Killer'. For RPI-JIE, we use the ACE 'life/die' event type/subtype with roles 'victim' and 'agent'. SEMAFOR defines a token span for every argument; RPI-JIE/ACE defines two spans, both a head word and entity extent; we use the entity extent. SEMAFOR only predicts spans as event arguments, while RPI-JIE also predicts entities as event arguments, where each entity has a within-text coreference chain over one or more mentions; since we only use single sentences, these chains tend to be small, though they do sometimes resolve pronouns. For determining R2 and R3, we allow a match on any of an entity's extents from any of its mentions.

- **(R3)** R2 holds and the agent token span contains a police keyword.

As in §4.1 (Eq. 3), we aggregate mention-level z_i predictions to obtain entity-level predictions with a deterministic OR of $z_{\mathcal{M}(e)}$.

RPI-JIE under the full R3 system performs best, though all results are relatively poor (Table 6). Part of this is due to inherent difficulty of the task, though our task-specific model still outperforms (Table 5). We suspect a major issue is that these systems heavily rely on their annotated training sets and may have significant performance loss on new domains, or messy text extracted from web news, suggesting domain transfer for future work.

6 Results and discussion

Significance testing: We would like to test robustness of performance results to the finite datasets with bootstrap testing (Berg-Kirkpatrick et al., 2012), which can accomodate performence metrics like AUPRC. It is not clear what the appropriate unit of resampling should be—for example, parsing and machine translation research in NLP often resamples sentences, which is inappropriate for our setting. We elect to resample documents in the test set, simulating variability in the generation and retrieval of news articles. Standard errors for one model's AUPRC and F1 are in the range 0.004–0.008 and 0.008–0.010 respectively; we also note pairwise significance test results. See appendix for details.

Overall performance: Our results indicate our model is better than existing computational methods methods to extract names of people killed by police, by comparing to F1 scores of off-the-shelf extractors (Table 5 vs. Table 6; differences are statistically significant).

We also compare entities extracted from our test dataset to the Guardian's "The Counted" database of U.S. police killings during the span of the test period (Sept.–Dec., 2016),[17] and found 39 persons they did not include in the database, but who were in fact killed by police. This implies our approach could augment journalistic collection efforts. Additionally, our model could help practitioners by presenting them with sentence-level information in the form of Table 7; we hope this could decrease the amount of time and emotional toll required to maintain real-time updates of police fatality databases.

CNN: Model predictions were relatively unstable during the training process. Despite the fact that EM's evidence lower bound objective ($H(Q) + E_Q[\log P(Z, Y|X)]$) converged fairly well on the training set, test set AUPRC substantially fluctuated as much as 2% between epochs, and also between three different random initializations for training (Fig. 3). We conducted these multiple runs initially to check for variability, then used them to construct a basic ensemble: we averaged the three models' mention-level predictions before applying *noisyor* aggregation. This outperformed the individual models—especially for EM training—and showed less fluctuation in AUPRC, which made it easier to detect convergence. Reported performance numbers in Table 5 are with the average of all three runs from the final epoch of training.

LR vs. CNN: After feature ablation we found that hard-CNN and hard-LR with n-gram features (N1-N5) had comparable AUPRC values (Table 5). But adding dependency features (D1-D4) caused the logistic regression models to outperform the neural networks (albeit with bare significance: $p = 0.046$). We hypothesize these dependency features capture longer-distance semantic relationships between the entity, fatality trigger word, and police officer, which short n-grams cannot. Moving to sequence or graph LSTMs may better capture such dependencies.

Soft (EM) training: Using the EM algorithm gives substantially better performance: for the CNN, AUC improves from 0.130 to 0.164, and for LR, from 0.142 to 0.193. (Both improvements are statistically significant.) Logistic regression with EM training is the most accurate model. Examining the precision-recall curves (Fig. 4), many of the gains are in the higher confidence predictions (left side of figure). In fact, the soft EM model makes fewer strongly positive predictions: for example, hard-LR predicts $y_e = 1$ with more than 99% confidence for 170 out of 24,550 test set entities, but soft-LR does so for only 24. This makes sense given that the hard-LR model at training time assumes that many more positive entity mentions are evidence of a killing than they are in reality (§4.2).

Manual analysis: Manual analysis of false positives indicates misspellings or mismatches of names, police fatalities outside of the U.S., people who were shot by police but not killed, and names of police officers who were killed are com-

Keith Scott (true pos)	0.98	Charlotte protests Charlotte's Mayor Jennifer Roberts speaks to reporters the morning after protests against the police shooting of **Keith Scott**, in Charlotte, North Carolina .
Terence Crutcher (true pos)	0.96	Tulsa Police Department released video footage Monday, Sept. 19, 2016, showing white Tulsa police officer Betty Shelby fatally shooting **Terence Crutcher,** 40, a black man police later determined was unarmed.
Mark Duggan (false pos)	0.97	The fatal shooting of **Mark Duggan** by police led to some of the worst riots in England's recent history.
Logan Clarke (false pos)	0.92	**Logan Clarke** was shot by a campus police officer after waving kitchen knives at fellow students outside the cafeteria at Hug High School in Reno, Nevada, on December 7.

Table 7: Example of highly ranked entities, with selected mention predictions and text.

mon false positive errors (see detailed table in the appendix). This suggests many prediction errors are from ambiguous or challenging cases.[18]

Future work: While we have made progress on this application, more work is necessary for accuracy to be high enough to be useful for practitioners. Our model allows for the use of mention-level semantic parsing models; systems with explicit trigger/agent/patient representations, more like traditional event extraction systems, may be useful, as would more sophisticated neural network models, or attention models as an alternative to disjunction aggregation (Lin et al., 2016).

One goal is to use our model as part of a semi-automatic system, where people manually review a ranked list of entity suggestions. In this case, it is more important to focus on improving recall—specifically, improving precision at high-recall points on the precision-recall curve. Our best models, by contrast, tend to improve precision at lower-recall points on the curve. Higher recall may be possible through cost-sensitive training (e.g. Gimpel and Smith (2010)) and using features from beyond single sentences within the document.

Furthermore, our dataset could be used to contribute to communication studies, by exploring research questions about the dynamics of media attention (for example, the effect of race and geography on coverage of police killings), and discussions of historical killings in news—for example, many articles in 2016 discussed Michael Brown's 2014 death in Ferguson, Missouri. Improving NLP analysis of historical events would also be useful for the event extraction task itself, by delineating between recent events that require a database update, versus historical events that appear as "noise" from the perspective of the database update task. Finally, it may also be possible to adapt our model to extract other types of social behavior events.

Asking too much? The rhetorical role of questions in political discourse

Justine Zhang,[1] **Arthur Spirling,**[2] **Cristian Danescu-Niculescu-Mizil**[1]

Abstract

Questions play a prominent role in social interactions, performing rhetorical functions that go beyond that of simple informational exchange. The surface form of a question can signal the intention and background of the person asking it, as well as the nature of their relation with the interlocutor. While the informational nature of questions has been extensively examined in the context of question-answering applications, their rhetorical aspects have been largely understudied.

In this work we introduce an unsupervised methodology for extracting surface motifs that recur in questions, and for grouping them according to their latent rhetorical role. By applying this framework to the setting of question sessions in the UK parliament, we show that the resulting typology encodes key aspects of the political discourse—such as the bifurcation in questioning behavior between government and opposition parties—and reveals new insights into the effects of a legislator's tenure and political career ambitions.

1 Introduction

> "We'd now like to open the floor to shorter speeches disguised as questions..."
>
> – Steve Macone, New Yorker cartoon caption

Why do we ask questions? Perhaps we are seeking factual information that others hold, or maybe we are requesting a favor. Alternatively we could be simply making a rhetorical point, perhaps at the start of an academic paper.

Questions play a prominent role in social interactions (Goffman, 1976), performing a multitude of rhetorical functions that go beyond mere factual information gathering (Kearsley, 1976). While the informational component of questions has been well-studied in the context of question-answering applications, there is relatively little computational work addressing the rhetorical and social role of these basic dialogic units.

One domain where questions have a particularly salient rhetorical role is politics. The ability to question the actions and intentions of governments is a crucial part of democracy (Pitkin, 1967), particularly in parliamentary systems. Consequently, scholars have studied parliamentary questions in detail, in terms of their origins (Chester and Bowring, 1962), their institutionalization (Eggers and Spirling, 2014) and their importance for oversight (Proksch and Slapin, 2011). In particular, the United Kingdom's House of Commons, renowned for theatrical questions periods, has been studied in some depth. However, those accounts are largely qualitative in nature (Bull and Wells, 2012; Bates et al., 2014).

The present work: methodology. In order to approach these problems computationally, we introduce an unsupervised framework to structure the space of questions according to their rhetorical role. First, we identify common ways in which questions are phrased. To this end, we automatically extract these recurring surface forms, or *motifs*, based on the lexico-syntactic structure of the questions posed (Section 4). To capture rhetorical aspects we then group these motifs according to their role, relying on the intuition that this role is encoded in the type of *answer* a question receives. To operationalize this intuition we construct a latent question-answer space in which question motifs triggering similar answers are mapped to the same region (Section 5).

The present work: application. We apply this general framework to the political discourse that occurs during parliamentary question sessions in

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1558–1572
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

the British House of Commons, a new dataset which we make publicly available (Section 3). Our framework extracts intuitive question types ranging from narrow factual queries to pointed criticisms disguised as questions (Section 5, Table 1). We validate our framework by aligning these types with prior understandings of parliamentary proceedings from the political science literature (Section 6). In particular, previous work (Bates et al., 2014) has categorized questions asked in Parliament according to the intentions of the asker (e.g., to help the answerer, or to adversarially put them on the spot); we find a clear, predictive mapping between these expert-coded categories and the induced typology. We further show that the types of questions specific legislators tend to ask vary with whether they are part of the governing or opposition party, consistent with well-established accounts of partisan differences (Cowley, 2002; Spirling and McLean, 2007; Eggers and Spirling, 2014). Concretely, government legislators exhibit a preference for overtly friendly questions, while the opposition slants towards more aggressive question types.

We then apply our methodology to provide new insights into how a legislator's questioning behavior varies with their career trajectory. The pressures faced by legislators at various stages in their career are cross-cutting, and multiple possible hypotheses emerge. Younger, more enthusiastic legislators may be motivated to ask harder-hitting questions, but risk being passed over for future promotion if they are too combative (Cowley, 2002). Older legislators, whose opportunities for promotion are largely behind them and hence have "less to lose", may act more aggressively (Benedetto and Hix, 2007); or simply seek a quiet path to retirement. Viewing each group's behavior through the questions they ask brings evidence for the latter hypothesis that more tenured legislators are more aggressive, even when questioning their own leaders. In this way, their presence in the House of Commons, and their refusal to simply 'keep their heads down', facilitates a core component of democracy.

2 Related Work

Question-answering. Computationally, questions have received considerable attention in the context of question-answering (QA) systems—for a survey see Gupta and Gupta (2012)—with an emphasis on understanding their information need (Harabagiu, 2008). Techniques have been developed to categorize questions based on the nature of these information needs in the context of the TREC QA challenge (Harabagiu et al., 2000), and to identify questions asking for similar information (Shtok et al., 2012; Zhang et al., 2017; Jeon et al., 2005); questions have also been classified by topic (Cao et al., 2010) and quality (Treude et al., 2011; Ravi et al., 2014). In contrast, our work is not concerned with the information need central to QA applications, and instead focuses on the rhetorical aspect of questions.

Question types. To facilitate retrieval of frequently asked questions, Lytinen and Tomuro (2002) manually developed a typology of surface question forms (e.g., 'what'- and 'why'-questions) starting from Lehnerts' conceptual question categories (Lehnert, 1978). Question types were also hand annotated for dialog-act labeling, distinguishing between yes-no, wh-, open-ended and rhetorical questions (Dhillon et al., 2004). To complement this line of work, this paper introduces a completely unsupervised methodology to automatically build a domain-tailored question typology, bypassing the need for human annotation.

Pragmatic dimensions. One important pragmatic dimension of questions that has been previously studied computationally is their level of politeness (Danescu-Niculescu-Mizil et al., 2013; Aubakirova and Bansal, 2016); in the specific context of making requests, politeness was shown to correlate with the social status of the asker. Sachdeva and Kumaraguru (2017) studied another rhetorical aspect by examining linguistic attributes distinguishing serviceable requests addressed to police on social media from general conversation. Previous research has also been directed at identifying rhetorical questions (Bhattasali et al., 2015) and understanding the motivations of their "askers" (Ranganath et al., 2016). Using the relationship between questions and answers, our work examines the rhetorical and social aspect of questions without predefining a pragmatic dimension and without relying on labeled data. We also complement these efforts in analyzing a broader range of situations in which questions may be posed without an information-seeking intent.

Political discourse. Finally, our work contributes to a rapidly growing area of NLP applications to political domains (Monroe et al., 2008; Card et al., 2016; Gonzalez-Bailon et al., 2010; Niculae et al., 2015; Grimmer and Stewart, 2013; Grimmer et al., 2012; Iyyer et al., 2014b, inter alia). Particularly relevant are applications to discourse in congressional and parliamentary settings (Thomas et al., 2006; Boydstun et al., 2014; Rheault et al., 2016).

3 Data: Parliamentary Question Periods

The bulk of our analysis focuses on the questions asked, and responses given during parliamentary question periods in the British House of Commons. Below, we provide a brief overview of key features of this political system in general, as well as a description of the question period setting.

Parliamentary systems. Legislators in the House of Commons (*Members of Parliament*, henceforth *MPs* or *members*) belong to two main voting and debating *affiliations*: a *government* party which controls the executive and holds a majority of the seats in the chamber, and a set of *opposition* parties.[1] The executive is headed by the Prime Minister (PM) and run by a cabinet of *ministers*, high-ranking government MPs responsible for various departments such as finance and education.

Question periods. The House of Commons holds weekly, moderated *question periods*, in which MPs of all affiliations take turns to ask questions to (and theoretically receive answers from) government ministers for each department regarding their specific domains. Such events are a primary way in which legislators hold senior policy-makers responsible for their decisions. In practice, beyond narrow requests for information about specific policy points, MPs use their questions to critique or praise the government, or to self-promote; indeed, certain sessions, such as Questions to the Prime Minister, have gained renown for their partisan clashes, often fueled by the (mis)handling of a current crisis. The following question, asked to the Prime Minister by an opposition MP about contamination of the meat supply in 2013, encapsulates this odd mix of purposes:

> *"The Prime Minister is rightly shocked by the revelations that many food products contain 100% horse. Does he share my concern that, if tested, many of his answers may contain 100% bull?"*[2]

The moderated, relatively rigid format of questions periods, along with the multifaceted array of underlying incentives and interpersonal relationships, yields a structurally controlled setting with a rich variety of social interactions, taking place in the realm of important policy discussions. This complexity makes question periods a particularly fruitful and consequential setting in which to study questions as social signals, and expand our understanding of their role beyond factual queries.

Dataset description. Our dataset covers question periods from May 1979 to December 2016, encompassing six different Prime Ministers. For each question period, we extract all question-answer pairs, along with the identity of the asker and answerer. Because our focus here is on how questions are posed in a social setting, and not on the subsequent dialogue, we ignore questions which were tabled prior to the session, as well as any followup back-and-forth dialogue between the asker and answerer.

We augment this collection with metadata about each asker and answerer, including their political party, the time when they first took office, and whether they were serving as a minister at a given point in time. Such information is used to validate our methodology and interpret our results in light of the social context in which the questions were asked, described further in Sections 6 and 7.

In total there are 216,894 question-answer pairs in our data, occurring over 4,776 days and 6 prime-ministerships. The questions cover 1,975 different askers, 1,066 different answerers, and a variety of government departments with responsibilities ranging from defense to transport. We make this dataset publicly available, along with the code implementing our methodology, as part of the Cornell Conversational Analysis Toolkit.[3]

4 Question Motifs

The first component of our framework identifies lexico-syntactic phrasing patterns recurring in a collection of questions, which we call *motifs*. Intuitively, motifs constitute wordings commonly used to pose questions. To find motifs in a given collection, we first extract relevant *fragments* from each question. We then group sets of frequently co-occurring fragments into motifs.

[1] We use *affiliation* to refer broadly to the government and opposition roles, independent of the identity of the current government and opposition parties. In subsequent analysis we only consider the largest, "official" opposition party as the opposition.

[2] MPs almost always address each other in 3rd person.

[3] `https://github.com/CornellNLP/Cornell-Conversational-Analysis-Toolkit`

Question fragments. Our goal is to find motifs which reflect functional characteristics of questions. Hence, we start by extracting the key *fragments* within a question which encapsulate its functional nature. Following the intuition that the bulk of this functional information is contained in the root of a question's dependency parse along with its outgoing arcs (Iyyer et al., 2014a), we take the fragments of a question to be the root of its parse tree, along with each (root, child) pair. To capture cases when the operational word in the question is not connected to its root (such as "What..."), we also consider the initial unigram and bigram of a question as fragments. The following question has 5 fragments: what, what is, going→*, is←going and going→do.

(1) **What** **is** the minister **going** to **do** about ... ?

Because our goal is to capture topic-agnostic patterns, we ignore all fragments which contain a noun phrase (NP) or pronoun. NP subtrees are identified based on their outgoing dependencies to the root;[4] in the event that an NP starts with a WH-determiner (WDT), we consider (root, WDT) to be a fragment and drop the remainder of the NP.[5]

Finally, we note that some questions consist of multiple sub-questions ("What does the Minister think [...], *and* why [...]?"). For such questions, we recursively extract fragments from each child subtree in the same manner, starting from their roots.

From fragments to motifs. We define *motifs* as sets of question fragments that frequently co-occur (in at least n questions). We find motifs by applying the apriori algorithm (Agrawal and Srikant, 1994) to find these common itemsets. This results in a collection of motifs $\mathcal{M}$ which correspond to different question phrasings.[6] Examples of motifs are shown in Table 1.

Motifs can identify phrasings to varying degrees of specificity. For example, the singleton motif $\{$what is$\}$ corresponds to all questions starting with that bigram, while $\{$what is, going→do$\}$ narrows these down to questions also containing the fragment going→do. To model the specificity relation between motifs, we structure $\mathcal{M}$ as a directed acyclic graph where an edge points from a motif m_1 to another motif m_2 if the latter has exactly one more fragment in addition to those in m_1, corresponding to a narrower set of phrasings.

Motif-representation of a question. Finally, a question q contains a motif if it includes all of the fragments comprising that motif. We can hence capture the phrasing of a given question q using the subset of motifs it contains, structured as the subgraph $\mathcal{M}_q \subset \mathcal{M}$ induced by this subset. This directed subgraph represents the question at multiple levels of specificity simultaneously; in particular, the set of sinks (i.e., nodes with outdegree 0; henceforth *sink motifs*) of $\mathcal{M}_q$ is the most fine-grained way to specify the phrasing of q. For example $\{$what is, is←going, going→do$\}$ is the only sink motif of the question in example (1); its entire subgraph is shown in Figure 3 in the appendix.

5 Latent Question Types

The second component of our framework structures the space of questions according to their functional roles, thus going beyond the lexico-syntactic representation captured via motifs. The main intuition is that the nature of the answer that a question receives provides a good indication of its intention. Therefore, if two questions are phrased differently but answered in similar ways, the parallels exhibited by their answers should reflect commonalities in the askers' intentions.

To operationalize this intuition, we first construct a latent space based on answers, and then map question motifs (Section 4) to the same space. Using the resultant latent representations, we can then cluster questions with similar rhetorical functions, even if their surface forms are different.

Constructing a space of answers. In line with our focus on functional characterizations, we extract the fragments from each sentence of an *answer*, defined in the same way as question fragments. We then construct a term-document matrix, where terms correspond to answer fragments, and documents correspond to individual answers in the corpus. We filter out infrequent fragments occurring less than n_A times, reweight the rows of this matrix with tf-idf reweighting, and scale to unit norm, producing a fragment-answer matrix $\mathcal{A}$. We perform singular value decomposi-

[4] We take as NPs subtrees connected to the root with the following: nsubj, nsubjpass, dobj, iobj, pobj, attr.

[5] In the particular case of the Parliament dataset, removing NPs also removes conventional, partisan address terms (e.g. "my hon. Friend").

[6] In some cases, a pair of motifs almost always co-occurs in the same questions, making them redundant. We treat two motifs m_1 and m_2 as equivalent if, for some probability p, $\Pr(m_1|m_2) > p$ and $\Pr(m_2|m_1) > p$; we keep the smaller of the two as the representative motif, or pick one of them arbitrarily if they are of equal sizes.

tion on $\mathcal{A}$ and obtain a low-rank representation $\mathcal{A} \approx \hat{\mathcal{A}} = U_A S V_A^T$, for some rank d, where rows of U_A correspond to answer fragments and rows of V_A correspond to answers.[7]

Latent projection of question motifs. We can draw a natural correspondence between a question motif m and answer term t if m occurs in a question whose answer contains t. This enables us to compute representations of question motifs in the same space as $\hat{\mathcal{A}}$. Concretely, we construct a motif-question matrix $\mathcal{Q} = (q_{ij})$ where $q_{ij} = 1$ if motif i occurred in question j; we scale rows of $\mathcal{Q}$ to unit norm. To represent $\mathcal{Q}$ in the latent answer space, we solve for $\hat{\mathcal{Q}}$ in $\mathcal{Q} = \hat{\mathcal{Q}} S V_A^T$ as $\hat{\mathcal{Q}} = \mathcal{Q} V_A S^{-1}$, again scaling rows to unit norm. Row i of $\hat{\mathcal{Q}}$ then gives a d-dimensional representation of motif i, denoted $\hat{q}_i$.

Grouping similar questions. Finally, we identify *question types*—broad groups of similar motifs. Intuitively, if two motifs m_i and m_j have vectors q_i and q_j which are close together, they elicit answers that are close in the latent space, so are functionally similar in this sense. We use the K-Means algorithm (Pedregosa et al., 2011) to cluster motif vectors into k clusters; these clusters then constitute the desired set of question types.

To determine the type of a *particular* question q^*, we transform it to a binary vector (q_i^*) where $q_i^* = 1$ if motif i is a sink motif of q^*; using only sink motifs at this stage allows us to characterize a question according to the most specific representation of its phrasing, thus avoiding spurious associations resulting from more general motifs. We scale q^*, project it to the latent space as before, and assign the resultant projection $\hat{q}^*$ to a cluster t, hence determining its type.

Since question motifs and answer fragments have both been mapped to the same latent space (as rows of $\hat{\mathcal{Q}}$ and U_A respectively), we can also assign each answer fragment to a question type. This further facilitates interpretability through characterizing the answers commonly triggered by a particular type of question.

6 Validation

We now apply our general framework to the particular setting of parliamentary question periods, structuring the space of questions posed within these sessions according to their rhetorical function. To validate the induced typology, we quantitatively show that it recovers asker intentions in an expert-coded dataset, and qualitatively aligns with prior findings in the political science literature on parliamentary dynamics.

Question types in Parliament. We apply our motif extraction and question type induction pipeline to the questions in the parliamentary dataset.[8] Over 90% of the questions in the dataset contain at least one of the resulting 2,817 motifs; in subsequent analyses we discard questions without a matching motif. We apply our pipeline to the questions in the parliamentary dataset, and induce a typology of $k = 8$ question types to capture the rich array of questions represented in this space while preserving interpretability.

Table 1 displays extracted types, along with example questions, answers, and motifs.[9] The second author, a political scientist with domain expertise in the UK parliamentary setting, manually investigated each type and provided interpretable labels. For example, in questions of type 4, the asker is aware that his main premise is supported by the minister, and thus will be met with a positive statement backing the thrust of the question; we call this the **agreement** cluster. Types 6 and 7 are much more combative: in type 6 questions the asker explicitly attempts to force the minister to **concede/accept** a point that would undermine some government stance, while type 7 contains **condemnatory** questions that prompt the minister to justify a policy that is self-evidently bad in the eyes of the asker. In contrast, type 2 constitutes tamer **narrow** queries that require the minister to simply report on non-partisan matters of policy. (Extended interpretations in the appendix.)

Quantitative validation. We compare our output to a dataset of 1,256 questions asked to various Prime Ministers labeled by Bates et al. (2014)

[7] We experimented with grouping answer fragments into motifs as well, but found that most of the motifs produced were one fragment large. While future work could focus more on understanding consistent phrasings of answers, we note that at least in our chosen corpus, answers are longer and encompass a much greater variation of possible phrasings.

[8] We consider questions to be sentences ending in question marks. If an utterance consists of multiple questions, we extract fragments sets from each question separately, and take the motifs of the utterance to be the union of motifs of each component question. We set $n = 100$, $p = 0.9$, $n_A = 100$ and $d = 25$. The choice of parameters was done via manual inspection of the dataset.

[9] Each type contains a few hundred question motifs and answer fragments.

Type	Question motifs	Answer fragments	Example question-answer pairs
0: Issue update (16,693)	{what, are←taking}, {will←update}	continue→work, met→discuss	Q: **What** steps **are** the Department **taking** to create a system for asylum-seekers? A: We **continue** to **work** with the Department of Education to ensure an equitable [...]

1: Shared concerns (35,954)	{will←take},
	{may←urge}
		grateful←am,
		shall←consider
			Q: **Will** he **take** steps to support other MPs to employ apprentices?
			A: I **am grateful** for that suggestion [...]

2: Narrow factual (16,467)	{what←made},
	{what←happen, will←happen}
		is←considering,
		have←discussed
			Q: **What** representations has the Minister **made** on the future of rural policing [in] Dyfed-Powys?
			A:The Home Office **is considering** the matter [...]

3: Prompt for comment (16,588)	{what←say, say→to}, {will←tell}	must←say, said→was	Q: **What** has the Prime Minister to **say to** President Reagan for sending troops to Honduras? A: [...] I **must say** that we deplore the reported incursion by Nicaraguan forces [...]
4: Agreement (32,835)	{does←agree, agree→is}, {is→important}	agree→with, agree→completely	Q: **Does** [he] **agree** that one of the best ways to improve the trade balance **is** to continue the Government's strong economic policies? A: I **agree with** my hon. Friend [...]
5: Self promotion (26,351)	{is→aware}, {will←consider}	will←appreciate, am→certain	Q: **Is** my Friend **aware** that members of my parish church are pleased to have received a grant [...] ? A: [My Friend] **will appreciate** the significant performance of parishes up and down the country [...]

Table 1: Question types automatically extracted from the parliamentary question periods, along with representative motifs and question-answer pairs. The number of questions in our dataset assigned to each type is shown in parantheses. Interpretations and more examples in Tables 2 & 3 in the appendix.

(also included in our data distribution). Each question in this data is hand-coded by a domain expert with one of three labels indicating the rhetorical intention of the asker: compared to *standard* questions—denoting straightforward factual queries, *helpful* questions serve as prompts for the PM to talk favorably about their government, while *unanswerable* questions are effectively vehicles for delivering criticisms that the PM cannot respond to. Questions which are *unanswered* by the PM are also labeled. If our framework captures meaningful rhetorical dimensions, we expect a given label to be over-represented in some of our induced types, and under-represented in others.

Even though our clustering of questions is generated in an unsupervised fashion without any guidance from the coded rhetorical roles, we see that several of the types we discover closely align with these annotations. In particular, helpful questions are highly associated with the **agreement** type (constituting 28% of questions of that type compared to 14% over the entire dataset; binomial test $p < 0.01$), reinforcing our interpretation that this type captures MPs cheerleading their own government. Conversely, unanswerable questions are frequently of the **concede/accept** type (20% in-type vs. 11% overall), while **condemnatory** questions are often unanswered (43% vs. 24% overall), suggesting that questions of these types have an increased tendency to be posed as aggressive criticisms packaged as questions.

We also validate our framework in a prediction setting using these labels, in three binary classification tasks: distinguishing helpful vs. standard, unanswerable vs. standard, and unanswered vs. answered questions. (In each task, we balance the two classes.) To control for asker affiliation effects, we consider only questions asked by government MPs for the helpful task, and opposition questions in the unanswerable and unanswered tasks; we train on questions to Conservative PMs and evaluate on Labour PMs.[10] For each setting, we train logistic regression classifiers; as

[10] These choices are motivated by the number of questions from each affiliation and party in the dataset (see appendix for further details on this dataset).

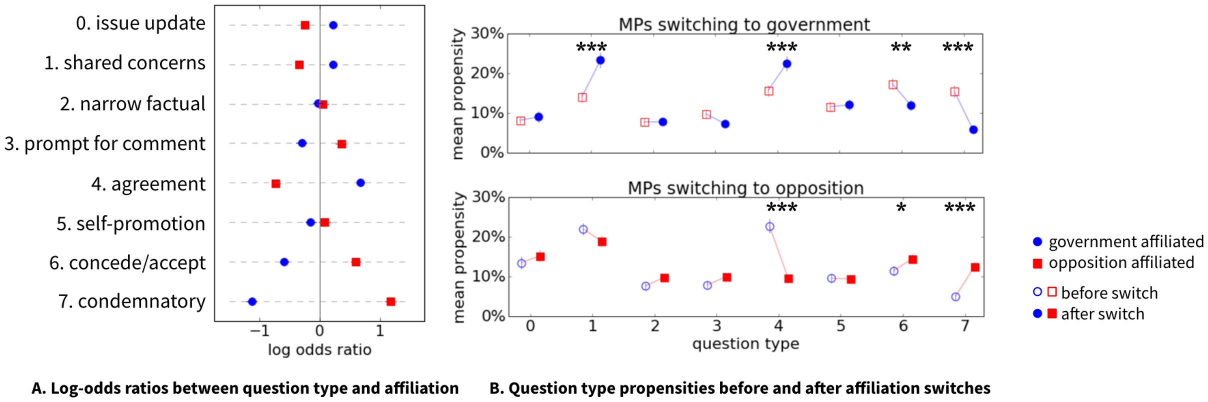

Figure 1: **A**: Log-odds ratios of questions of each type asked by government and opposition MPs, compared to MPs not of the respective affiliation; 95% confidence intervals (sometimes imperceptible) are depicted. **B**: Mean propensities for each question type, for MPs who switch from being in the opposition to being in the government (top) and vice-versa (bottom) after an election. Stars indicate statistically significant differences at the $p < 0.05$ (*), $p < 0.01$ (**) and $p < 0.001$ (***) levels (Wilcoxon test).

features we compare the latent representation of each question to a unigram BOW baseline.[11]

In the *unanswerable* and *unanswered* tasks, we find that the BOW features do not perform significantly better than a random (50%) baseline. However, the latent question features produced by our framework bring additional predictive signal and outperform the baseline when combined with BOW (binomial $p < 0.05$), achieving accuracies of 66% and 62% respectively (compared with 55% and 50% for BOW alone). This suggests that our representation captures useful rhetorical information that, given our train-test split, generalizes across parties. None of the models significantly outperform the random baseline on the *helpful* task, perhaps owing to the small data size.

Qualitative validation: question partisanship. We additionally provide a qualitative validation of our framework by comparing the question-asking activity of government and opposition-affiliated MPs—as viewed through the extracted question types—to well-established characterizations of these affiliations in the political science literature. In particular, prior work has examined the bifurcation in behavior between government and opposition members, in their differing focus on various issues (Louwerse, 2012), and in settings such as roll call votes (Cowley, 2002; Spirling and McLean, 2007; Eggers and Spirling, 2014). Since government MPs are elected on the same party ticket and manifesto, they primarily act to support the government's various policies and bolster the status of their cabinet, seldom airing disagreements publicly. In contrast, opposition members tend to offer trenchant partisan criticism of government policies, seeking to destabilize the government's relationship with its MPs and create negative press in the country at large. In characterizing the question-asking activity of government and opposition MPs, this friendly vs. adversarial behavior should also be reflected in a rhetorical typology of questions.[12]

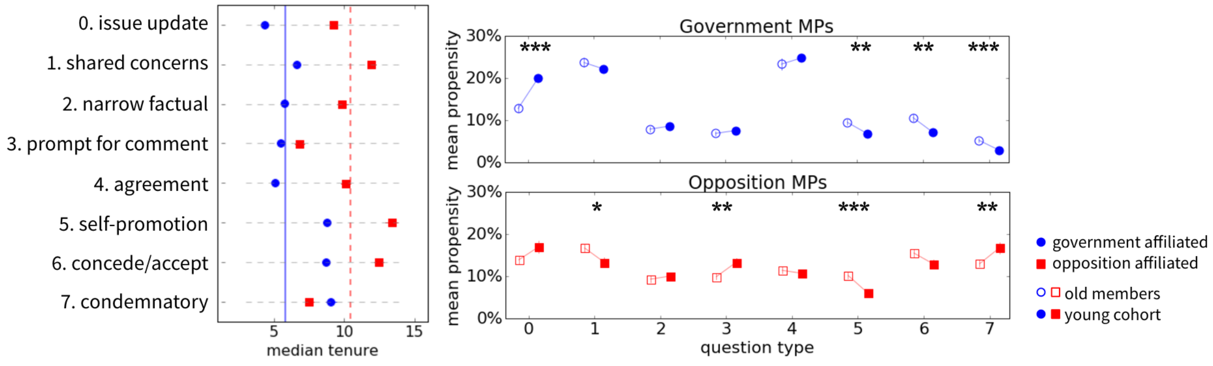
Concretely, to quantify the relationship between a particular question type t and asker affiliation $\mathcal{P}$, we compute the log-odds ratio of type t questions asked by MPs in $\mathcal{P}$, compared to MPs not in $\mathcal{P}$.[13]

Figure 1A shows the resultant log-odds ratios of each question type for government and opposition members. Notably, we see that **agreement**-type questions are significantly more likely to originate from government than from opposition MPs, while the opposite holds for **concede/accept** and **condemnatory** questions (binomial $p < 10^{-4}$ for each, comparing within-type to overall proportions of questions from an affiliation). No such

[11] We used tf-idf reweighting and excluded unigrams occurring less than 5 times.

[12] While we induce the typology over our entire dataset, we perform all subsequent analyses on a filtered subset of 50,152 questions. In particular, we omit utterances with multiple questions—i.e. multiple question marks—to ensure that we don't confound effects arising from different co-occurring question types. Our filtering decisions are also determined by the availability of information about the asker and answerers' roles in Parliament. Further information about these filtering choices can be found in the appendix.

[13] The log-odds values are not symmetric between government and opposition, because they includes questions asked by MPs not in the official opposition.



A. Median tenure of question askers

B. Question type propensities for old and young MPs

Figure 2: **A**: Median asker tenures over each question type, for government and opposition askers. Overall median tenures are also shown for reference (solid blue line for government, dashed red line for opposition). **B**: Mean propensities for newly elected MPs during the 1997 and 2010 elections, compared to re-elected MPs in the subsequent parliamentary sitting. Stars indicate statistically significant differences at the $p < 0.05$ (*), $p < 0.01$ (**) and $p < 0.001$ (***) levels (Mann Whitney U test).

slant is exhibited in the **narrow factual** type, further reinforcing the role of such questions as informational queries about relatively non-partisan issues. These results strongly cohere with the "textbook" accounts of parliamentary activity in the literature, as well as our interpretation of these types as bolstering or antagonistic.

Moreover, we find that the *same MP* shifts in her propensity for different question types as her affiliation changes. When a new political party is elected into office, MPs who were previously in the opposition now belong to the government party, and vice versa. Such a switch occurs within our data between the Major and Blair governments (Conservative to Labour, 1997), and between the Brown and Cameron governments (Labour to Conservative, 2010). For both switches, we consider all MPs who asked at least 5 questions both before and after the switch, resulting in 88 members who *became* government MPs and 102 who became opposition MPs. For an MP M we compute $P_{M,t}$, their *propensity* for a question type t, as the proportion of questions they ask which are from t. Comparing $P_{M,t}$ before and after a switch, we replicate the key differences observed above—for instance, we find that former opposition MPs who become government MPs decrease in their propensity for **condemnatory** questions, while newly opposition MPs move in the other direction (Wilcoxon $p < 0.001$, Figure 1B). This suggests that the general trends we observed before are driven by the shift in affiliation, and hence parliamentary role, of *individual* MPs.

7 Career Trajectory Effects

We now apply our framework to gain further insights into the nature of political discourse in Parliament, focusing on how questioning behavior varies with a member's tenure in the institution. As stated in the introduction, two alternative hypotheses arise: younger MPs may be more vigorously critical out of enthusiasm, but are potentially tempered by their stake in future promotion prospects compared to older members (Cowley, 2002, 2012). Alternatively, older MPs who have less at stake in terms of prospects of further promotion may ask more antagonistic questions. Throughout, *young* and *old* refer to tenure—i.e., how many years someone has served as an MP—rather than biological age.

In order to understand the extent to which young or old members contribute a specific type of question, for each question type t we compute the median tenure of askers of each question in t, and compare the median tenures of different question types, for each affiliation (Figure 2A).[14] We see that among both affiliations, more aggressive questions tend to originate more from older members, reflected in significantly higher median tenures (for types 6 in both affiliations, and 7 in government MPs; Mann Whitney U test $p < 0.001$ comparing within-type median tenure with outside-type median tenure); whereas standard **issue update** questions tend to come from younger

[14] Median tenures for opposition members are generally higher; winning an election tends to result in more newly-elected and therefore younger MPs (Webb and Farrell, 1999).

members ($p < 0.001$, both affiliations). Notably, the disproportionate aggressiveness of older members manifests even among *government* MPs who direct these questions towards their *own* government. This supports the "less to lose" intuition, offering a rhetorical parallel to previous findings about the increased tendency to vote contrary to party lines from MPs with little chance of ministerial promotion (Benedetto and Hix, 2007).

Interestingly, we find that these differential preferences across member tenure also manifest at a finer granularity than simply less to more aggressive. For instance, younger *opposition* members tend to contribute more **condemnatory** questions compared to older members (Mann Whitney U test $p < 0.01$), who disproportionately favor **concede/accept** questions. While further work is needed to fully explain these differences, we speculate that they are potentially reflective of strategic attempts by younger MPs to signal traits that could facilitate future promotion, such as partisan loyalty (Kam, 2009).

To discount the possibility of these effects being solely driven by a few very prolific young or old MPs, we also consider a setting where type propensities are macroaveraged over MPs. For each affiliation we compare the cohort of younger MPs who are newly voted in at the 1997 and 2010 elections, with older MPs who have been in office prior to the election.[15] We compute the type propensities of these two cohorts over the questions they asked during the *subsequent* parliamentary sitting, and replicate the tenure effects observed previously (Figure 2B). This suggests that these parliamentary career effects reflect behavioral changes at the level of individual MPs, whose incentives evolve over their tenure.

8 Conclusion and Future Work

In this work we introduced an unsupervised framework for structuring the space of questions according to their rhetorical role. We instantiated and validated our approach in the domain of parliamentary question periods, and revealed new interactions between questioning behavior and career trajectories.

We note that our methodology is not tied to a particular domain. It would be interesting to explore its potential in a variety of less structured domains where questions likewise play a crucial role. For example, examining how interviewers in high-profile media settings (e.g., Frost on Nixon) can use their questions to elicit substantive responses from influential people would aid us in the broader normative goal of holding elites to account, by gaining a better understanding of what and how to ask, and what (not) to accept as an answer.

From a technical standpoint, future work could also augment the representation of questions and answers presently used in our framework, beyond our heuristic of using root arcs without noun phrases. Richer linguistic representations, as well as more judicious ways of weighting different fragments and motifs, could enable us to capture a wider range of possible surface and rhetorical forms, especially in settings where phrasings are potentially less structured by institutional conventions. Additionally, as with most unsupervised methods, our approach is limited by the need to hand-select parameters such as the number of clusters, and manually interpret the typology's output. Having annotations of these corpora could better motivate the methodology and enable further evaluation and interpretation; we hope to encourage such annotation efforts by releasing the dataset.

Inevitably, drawing causal lessons from observational data is difficult. Moving forward, experimental tests of insights gathered through such explorations would enable us to establish causal effects of question-asking rhetoric, perhaps offering prescriptive insights into questioning strategies for objectives such as information-seeking (Dillman, 1978), request-making (Althoff et al., 2014; Mitra and Gilbert, 2014) and persuasion (Tan et al., 2016; Zhang et al., 2016; Wang et al., 2017).

Acknowledgements. The first author thanks John Bercow, the Speaker of the House, for suggesting she "calm [her]self down by taking up yoga" during the hectic deadline push (`https://youtu.be/AiAWdLAIj3c`). The authors thank the anonymous reviewers and Liye Fu for their comments and for their *helpful* questions. We are grateful to the organizers of the conference on New Directions in Text as Data for fostering the inter-disciplinary collaboration that led to this work, to Amber Boydstun and Philip Resnik for their insights on questions in the political domain, and to Stephen Bates, Peter Kerr and Christopher Byrne for sharing the labeled PMQ dataset. This research has been supported in part by a Discovery and Innovation Research Seed Award from the Office of the Vice Provost for Research at Cornell.

[15] This totals 272 new and 184 old government MPs, and 84 new and 179 old opposition MPs.

Appendix

A.1 Further examples of question types

Tables 2 and 3 provide further examples of representative questios and motifs from each of the eight question types we induce on our dataset of parliamentary question periods. Additionally, we include extended interpretations of each of these types, provided by the second author, a political scientist with domain expertise in the UK parliamentary setting.

A.2 Details about data filtering decisions

Here we provide further details about how we selected the subset of 50,152 questions which was used in the analyses described in Sections 6 & 7. First, we restrict our analysis to the questions which consist of only one question, as opposed to a series of questions (as delimited by multiple sentences ending in question marks; constituting 52% of the data). We omit these multi-question utterances in order to ensure that we don't confound effects arising from different co-occurring question types. Next, we only include questions for which information about the asker and answerers' party affiliations and ministership positions are available (such data is provided consistently from the Blair government onwards). Finally, we omit questions asked by opposition members who are specifically appointed by their party to *shadow* a government minister, and are hence obliged by their appointment to ask more critical questions. Our choice to omit such questions eliminates the possibility that our observed differences in question preference are driven by official appointment.

A.3 Details about the labeled PMQ dataset

Here we provide further details about the size of the labeled Questions to the Prime Minister (PMQ) dataset from Bates et al. (2014) used in the quantitative validation of our typology (Section 6). The dataset contains 931 standard, 186 helpful and 139 unanswerable questions. Additionally, 445 answers to questions are labeled as *answered*, while 305 are labeled as *not answered*; the rest are labeled as *deferred answer*, meaning the Prime Minister did not have the knowledge or capability to provide an answer.

We restrict all analysis done using the unanswered vs. answered labels to *standard* questions, i.e., questions for which the PM has an opportunity to provide a legitimate answer.

The *helpful vs. standard* classification task contains 264 train and 108 test examples; the *unanswerable vs. standard* classification task contains 190 train and 86 test examples; the *unanswered vs. answered* classification task contains 166 train and 84 test examples.

A.4 Example motif subgraph

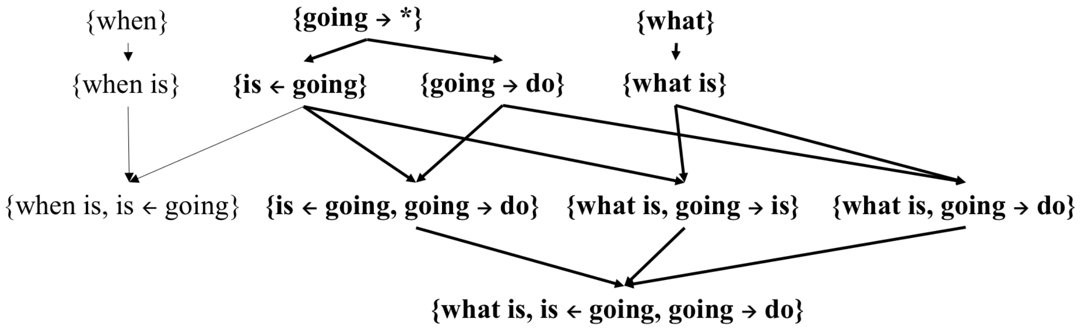
Figure 3 illustrates a section of the motif DAG $\mathcal{M}$ and highlights (in bold) the subgraph $\mathcal{M}_q$ corresponding to the phrasing of the question in example (1). Nodes that are higher in the graph serve as general representations, and capture similarities between broad sets of phrasings: e.g., {is←going going→do, is←going, what is} groups together example (1) with a question like "When is he going to get a grip on [the scandal]". By projecting such motifs into our latent question-answer space (Section 5) we capture characteristics shared between these phrasings and allow for generalizability. Nodes which are lower in the graph constitute more specific representations, disambiguating between phrasings. In particular, sink motifs serve as the most specific representation of a question, delineating the region of the latent space (and thus the question type) that best captures its phrasing. For instance, this additional specificity allows us to draw contrasts between "**What is** the minister **going** to **do** [about the policy]?" (sink motif: {what is, is←going, going→do}) and the more aggressive "**When is** he **going** to get a grip on [the scandal]?" (sink motif: {when is, is←going}).

Type	Interpretation and examples
0: Issue update	Requests for information or updates about a current event, issue, or policy. Typically the policy refers to a genuinely ‘national’ concern, rather than a partisan issue for which the major parties may have differing views. Q: **Will** the Minister also **update** the House on whether any decisions have been made on the post-2014 UK contribution to Afghanistan? Q: **What** more can the Government **do** to **ensure** that each pupil has a single point of contact [for mental health issues] throughout their education? Q: **What** further steps **can** we **take** to resolve [the] terrible situation [in Syria]? Question motifs: {what,are←taking}, {will←update}, {what←do, do→ensure}, {what←take, can←take}
1: Shared concerns	Straightforward factual question with no strong ideological underpinnings; answers are typically vague and involve explaining that the government takes it seriously, will continue to do so and will consult with the relevant stakeholders. Q: **May** I **urge** the Minister to concentrate on tough penalties for people who get involved in alcohol-induced antisocial behaviour? Q: **Will** the Secretary of State **look carefully at** reports that houses built to house the soldiers will block off the rising sun at the summer equinox [at] the Stonehenge? Q: **Will** [my hon. Friend] **raise** [the matter of] product placement **with** people in the film industry [when he meets them]? Question motifs: {will, take→*}, {may←urge}, {will←look, look→at, look→carefully}, {raise→will, raise→with}
2: Narrow factual	Narrow queries about relatively minor policy issues which are either extremely local in nature (perhaps referring to implications for a given constituency) or limited in scope (constituting a small issue within a much broader context of policy). Questions are precise if not especially penetrating. Answers typically explain the ministry response in narrow, non-ideological terms. Q: **What** funding will be **given to** the new postgraduate institute at the Edinburgh College of Dentistry? Q: **Will** the Minister **make** a statement **on** where we are with the website for the [National Health Service appraisals toolkit for general practitioners]? Q: **What will happen** to the French if they are found guilty of infringing the rules of the Commission? Question motifs: {what←made}, {what←happen, will←happen}, {what←given, given→to}, {will←make, make→on}
3: Prompt for comment	Requests for comments, or information, especially on a meeting that has taken place between a minister and constituents, colleagues, or opposite numbers, the contents of which would not normally be immediately accessible to MPs. The asker seeks that the minister clarifies policy where none might presently exist. Q: **Will** the Secretary of State **tell** us which Minister has been appointed to be responsible for green economic growth? Q: **Can** [the Secretary of State] **confirm** whether train platform capacity will **be** a part of the discussions between the city council and Network Rail? Q: **What would** the Prime Minister **say** to a borough council which is considering rejecting Government funding and instead [taxing] my constituents more? Question motifs: {what←say,say→to}, {will←tell}, {can←confirm, confirm→be}, {what←say, would←say}

Table 2: Interpretation for the first four types, with examples of representative questions and motifs.

Type	Interpretation and examples
4: Agreement	Airing a laudatory remark about a policy that the minister and MP clearly already agree on. Often these questions effectively serve as attempts to curry favor with the minister and bolster their (mutual) party. Q: **Is** it not **important** that the Department continues its excellent work [in] building flood defeneces? Q: **Does** [the Secretary of State] **agree with** me that part of protecting Britain's national interests is that Britain should develop relationships with emerging economies? Q: **Does** the Minister **agree** that UK taxpayers **need** to be considered at every single step of the way when it comes to our aid spending? Question motifs: {does←agree, agree→is}, {is→important}, {does←agree, agree→with}, {does←agree, agree→need}
5: Self-promotion	Here, "awareness" is entirely rhetorical: either the minister is aware and agrees or the minister is not aware and will investigate. These questions allow the question asker to be seen to be bringing local concerns to broader attention, but in a way that is more assertive than in type 2 (**narrow factual**). Q: **Has** the right hon. Gentleman **considered** compulsory postal voting , and moving polling day from a Thursday to the weekend? Q: In considering the role of local tribunals , **will** my hon Friend **take** account of the recommendation **in** the Oglesby report? Q: **Will** the Minister **reconsider** his reply to my [colleague], [in light of] the situation [on] school leavers applying for technical positions? Question motifs: {is→aware}, {considered←has}, {will←take, take→in}, {will←reconsider}
6: Concede, accept	Aggressive demand for minister to concede to, or accept, a fault. The premise of such questions is that the minister has been incompetent, or that the government has the wrong policy; these questions do not constitute a genuine attempt to obtain information. Q: **Is** it **not** now completely **true** that the Labour Government are out of touch with gut British instincts? Q: **Will** [the Secretary] **acknowledge** the importance of not completely abandoning the research on sustainable biofuels? Q: **Will** [the Deputy Prime Minister] now **concede** to the House that the Royal Mail was sold off too cheaply? Question motifs: {will←accept}, {is→not, is→true}, {will←acknowledge}, {will←concede}
7: Condemnatory	Similar to type 6 (**concede, accept**) but more aggressive and hectoring in tone, asking the minister to explain themselves and be contrite on the basis of very broad ideological premises that are difficult to answer without 'self-incrimination'. These questions often rely on rhetorical grandstanding and lacks any subtlety or policy detail on which minister can comment precisely. Q: When members of the armed forces are facing a pay freeze, **how can** the Secretary **justify** bonuses to senior offices in the civil service? Q: **Why does** the right hon Gentleman not have an industrial strategy to build that recovery? Q: **Will** the Government now **apologise** for their complacent decision to scrap the future jobs fund, [given that] long-term youth unemployment is rising? Question motifs: {can←explain}, {how←justify, can←justify}, {why does}, {will←apologise}

Table 3: Interpretation for the last four types, with examples of representative questions and motifs.



(1) What is the minister going to do about … ?

Figure 3: A section of the motif DAG $\mathcal{M}$ and the subgraph $\mathcal{M}_q$ (in bold) representing the phrasing of the question in example (1). For clarity, redundant and irrelevant nodes and edges are not shown.

Detecting Perspectives in Political Debates

Abstract

We explore how to detect people's perspectives that occupy a certain proposition. We propose a Bayesian modelling approach where topics (or propositions) and their associated perspectives (or viewpoints) are modeled as latent variables. Words associated with topics or perspectives follow different generative routes. Based on the extracted perspectives, we can extract the top associated sentences from text to generate a succinct summary which allows a quick glimpse of the main viewpoints in a document. The model is evaluated on debates from the House of Commons of the UK Parliament, revealing perspectives from the debates without the use of labelled data and obtaining better results than previous related solutions under a variety of evaluations.

1 Introduction

Stance classification is binary classification to detect whether people is supporting or against a topic. Existing approaches largely rely on labelled data collected under specific topics for learning supervised classifiers for stance classification (Mohammad et al., 2016a). At most time, apart from detecting one's stance, we are interested in finding out the arguments behind the person's position. Perspectives, that state people's ideas or the facts known to one, can be *contrastive*, i.e. to be in favour of or against something (e.g. Brexit vs Bremain), or *non-contrastive*, i.e. independent discussions that share a common topic (e.g. unemployment and migration in the context of economy).

Recent years have seen increasing interests in argumentation mining which involves the automatic identification of argumentative structures, e.g., the claims and premises, and detection of argumentative relations between claims and premises or evidences. However, learning models for argumentation mining often require text labelled with components within argumentative structures and detailed indication of argumentative relations among them. Such labelled data is expensive to obtain in practice and it is also difficult to port models trained on one domain to another.

We are particularly interested in detecting different perspectives in political debates. Essentially, we would like to achieve somewhere in between stance classification and argumentation mining. Given a text document, we want to identify a speaker's key arguments, without the use of any labelled data. For example, in debates about '*Education*', we want to automatically extract sentences summarising the key perspectives and their arguments, e.g. 'our education system needs to promote excellence in *stem subjects*', 'teenagers need to be taught with *sexual and health education*' or '*grammar schools* promote inequality'. Similarly, if '*Brexit*' is being discussed in terms of leaving or remaining, we want to cluster arguments into those two viewpoints.

To do this, we introduce a Latent Argument Model (LAM) which assumes that words can be separated as topic words and argument words and follow different generative routes. While topic words only involve a sampling of topics, argument words involve a joint sampling of both topics and arguments. The model does not rely on labelled data as opposed to most existing approaches to stance classification or argument recognition. It is also different from cross-perspective topic models which assume the perspectives are observed (Fang et al., 2012). Quantitative and qualitative evaluations on debates from the House of Commons of United Kingdom show the utility of the approach and provide a comparison against related models.

2 Related work

Our research is related to stance classification, argument recognition and topic modelling for sentiment/perspective detection.

2.1 Stance Classification

Stance detection aims to automatically detect from text whether the author is in favour of, against, or neutral towards a target. As previously reported in (Mohammad et al., 2016b), a person may express the same stance towards a target by using negative or positive language. Hence, stance detection is different from sentiment classification and sentiment features alone are not sufficient for stance detection. With the introduction of the shared task of stance detection in tweets in SemEval 2016 (Mohammad et al., 2016a), there have been increasing interests of developing various approaches for stance detection. But most of them focused on building supervised classifiers from labelled data. The best performing system (Zarrella and Marsh, 2016) made use of large unlabelled data by first learning sentence representations via a hashtag prediction auxiliary task and then fine tuning these sentence representations for stance detection on several hundred labelled examples. Nevertheless, labelled data are expensive to obtain and there is a lack of portability of classifiers trained on one domain to move to another domain.

2.2 Argument Recognition

Closely related to stance detection is argument recognition which can be considered as a more fine-grained task that it aims to identify text segments that contain premises that are against or in support of a claim. Cabrio and Villata (2012) combined textual entailment with argumentation theory to automatically extract the arguments from online debates. Boltuzic and Šnajder (2014) trained supervised classifiers for argument extraction from their manually annotated corpus by collecting comments from online discussions about two specific topics. Sardianos et al. (2015) proposed a supervised approach based on Conditional Random Fields for argument extraction from Greek news. Nguyen and Litman (2015) run an LDA model and post-processed the output, computing argument and domain weights for each of the topics, which were then used to extract argument and domain words. Their model outperformed traditional n-grams and lexical/syntactic rules on a collection of persuasive essays. Lippi and Torroni (2016a) hypothesized that vocal features of speech can improve argument mining and proposed to train supervised classifiers by combining features from both text and speech for claim detection from annotated political debates. Apart from claim/evidence detection, there has also been work focusing on identification of argument discourse structures such as the prediction of relations among arguments or argument components (Stab and Gurevych, 2014; Peldszus and Stede, 2015). A more recent survey of various machine learning approaches used for argumentation mining can be found in (Lippi and Torroni, 2016b). All these approaches have been largely domain-specific and rely on a small set of labelled data for supervised model learning.

2.3 Topic Modeling for Sentiment/Perspective Detection

Topic models can be modified to detect sentiments or perspectives. Lin and He (2009) introduced a joint sentiment topic (JST) model, which simultaneously extracts topics and topic-associated sentiments from text. Trabelsi and Zaıane (2014) proposed a joint topic viewpoint (JTV) model for the detection of latent viewpoints under a certain topic. This is essentially equivalent to the reparameterized version of the JST model called REVERSE-JST (Lin et al., 2012) in which sentiment label (or viewpoint) generation is dependent on topics, as opposed to JST where topic generation is conditioned on sentiment labels.

Fang et al. (2012) proposed a Cross-Perspective Topic Model (CPT) in which the generative processes for topic words (nouns) and opinion words (adjectives, adverbs and verbs) are different, as the opinion words are sampled independently from the topic. Also, CPT assumed perspectives are observed, which implies texts need to be annotated with the viewpoint they belong to. Awadallah et al. (2012) detected politically controversial topics by creating an opinion-base of opinion holders and their views. Das and Lavoie (2014) observed the editions and interactions of a user in Wikipedia pages to infer topics and points of view at the same time. Qiu et al. (2015) proposed a regression-based latent factor model which jointly models user arguments, interactions, and attributes for user stance prediction in online debates.

3 Latent Argument Model (LAM)

We assume that in a political debate, the speaker first decides on which topic she wants to comment on (e.g. *Education*). She then takes a stance (e.g. *remark the importance about stem subjects*) and elaborates her stance with arguments. It is worth noting that we do not consider the temporal dimension of documents here, i.e., our model is fed with a collection of unlabeled documents without temporal order.

We use a switch variable x to denote whether a word is a *background word* (shared across multiple topics), a *topic word* (relating to a certain topic) or an *argument word* (expressing arguments under a specific topic). Depending on the type of word, we follow a different generative process. For each word in a document, if it is a background word, we simply sample it from the background word distribution ϕ^b; if it is a topic word, we first sample a topic z from the document-specific topic distribution θ_d and then sample the word from the topic-word multinomial distribution ψ_z shared across all documents; if it is an argument word, we need to first jointly sample the topic-argument pair, (z, a), where z comes from the existing topics already sampled for the topic words in the document and a is sampled from the topic-specific argument distribution ω_z, and finally the word is sampled from the multinomial word distribution for the topic-specific argument $\psi_{z,a}$. The argument indicator here is a latent categorical variable. It can take a binary value to denote pro/con or positive/negative towards a certain topic. More generally, it could also take a value from multiple stance or perspective categories. We thus propose a Latent Argument Model (LAM) shown in Figure 1. Formally, the generative process is as follows:

- Draw a distribution over the word switch variable, $\phi \sim$ Dirichlet(γ), and background word distribution, $\psi^b \sim$ Dirichlet(β^b).
- For each topic $z \in \{1...T\}$, draw a multinomial topic-word distribution $\psi_z \sim$ Dirichlet(β^z).
  - For each argument $a \in \{1...A\}$ draw a multinomial topic-argument distribution $\omega_z \sim$ Dirichlet(δ) as well as a multinomial topic-argument-word distribution $\psi^v_{z,a} \sim$ Dirichlet(β^a).
- For each document $d \in \{1...D\}$:
  - Draw a multinomial topic distribution, $\theta_d \sim$ Dirichlet(α).
  - For each word $n \in \{1, .., N_d\}$ in d:
    - $*$ Choose $x_{d,n} \sim$ Multinomial(ϕ).
    - $*$ If $x_{d,n} = 0$, draw a background word $w_{d,n} \sim \psi^b$;
    - $*$ If $x_{d,n} = 1$, draw a topic $z \sim$ Multinomial(θ_d) and a word $w_{d,n} \sim$ Multinomial(ψ_z);
    - $*$ If $x_{d,n} = 2$, draw a topic $z \sim$ Multinomial(θ_d), an argument $a \sim$ Multinomial(ω_z) and a word $w_{d,n} \sim$ Multinomial$(\psi^a_{z,a})$.

Figure 1 shows its plate representation.

3.1 Inference and Parameter Estimation

We use Collapsed Gibbs Sampling (Casella and George, 1992) to infer the model parameters and the latent assignments of topics and arguments, given the observed data. Gibbs sampling is a Markov chain Monte Carlo method to iterative estimate latent parameters. In each iteration, a new sample of the hidden parameters is made based on the distribution of the previous epoch. Letting the index $t = (d, n)$ denote the nth word in document d and the subscript $-t$ denote a quantity that excludes data from the nth word position in document d, $\Lambda = \{\alpha, \beta^b, \beta^z, \beta^a, \gamma, \delta\}$, the conditional posterior for x_t is:

$$P(x_t = r|\boldsymbol{x}_{-t}, \boldsymbol{z}, \boldsymbol{a}, \boldsymbol{w}, \Lambda) \propto \frac{\{N^r_d\}_{-t} + \gamma}{\{N_d\}_{-t} + 3\gamma} \cdot \frac{\{N^r_{w_t}\}_{-t} + \beta^r}{\sum_{w'}\{N^r_{w'}\}_{-t} + W\beta^r}, \quad (1)$$

where r denotes different word types, either background word, topic word or argument word. N^r_d denotes the number of words in document d assigned to the word type r, N_d is the total number of words in the document d, $N^r_{w_t}$ is the number of times word w_t is sampled from the distribution for the word type r, W is the vocabulary size.

For topic words, the conditional posterior for z_t is:

$$P(z_t = k | \boldsymbol{z}_{-t}, \boldsymbol{w}, \Lambda) \propto \frac{N_{d,k}^{-t} + \alpha_k}{N_d^{-t} + \sum_k \alpha_k} \cdot \frac{N_{k,w_t}^{-t} + \beta^z}{N_k^{-t} + W\beta^z}, \quad (2)$$

where $N_{d,k}$ is the number of times topic k was assigned to some word tokens in document d, N_d is the total number of words in document d, N_{k,w_t} is the number of times word w_t appeared in topic k.

For argument words, the conditional posterior for z_t and a_t is:

$$P(z_t = k, a_t = j | \boldsymbol{z}_{-t}, \boldsymbol{a}_{-t}, \boldsymbol{w}, \Lambda) \propto \frac{N_{d,k}^{-t} + \alpha_k}{N_d^{-t} + \sum_k \alpha_k} \cdot \frac{N_{d,k,j}^{-t} + \delta_{k,j}}{N_{d,k}^{-t} + \sum_j \delta_{k,j}} \cdot \frac{N_{k,j,w_t}^{-t} + \beta^v}{N_{k,j}^{-t} + W\beta^v}, \quad (3)$$

where $N_{d,k,j}$ is the number of times a word from document d has been associated with topic k and argument j, N_{k,j,w_t} is the number of times word w_t appeared in topic k and with argument j, and $N_{k,j}$ is the number of words assigned to topic k and argument j.

Once the assignments for all the latent variables are known, we can easily estimate the model parameters $\{\boldsymbol{\theta}, \boldsymbol{\phi}, \boldsymbol{\rho}, \boldsymbol{\psi^b}, \boldsymbol{\psi^z}, \boldsymbol{\psi^a}, \boldsymbol{\omega}\}$. We set the symmetric prior $\gamma = 0.3$, $\epsilon = 0.01$, $\beta^b = \beta^z = 0.01$, $\delta = (0.05 \times L)/A$, where L is the average document length, A the is total number of arguments, and the value of 0.05 on average allocates 5% of probability mass for mixing. The asymmetric prior $\boldsymbol{\alpha}$ is learned directly from data using maximum-likelihood estimation (Minka, 2003) and updated every 40 iterations during the Gibbs sampling procedure. In this paper we only consider two possible stances, hence, $A = 2$. But the model can be easily extended to accommodate more than two stances or perspectives. We set the asymmetric prior β^a for the topic-argument-word distribution based on a subjectivity lexicon in hoping that contrastive perspectives can be identified based on the use of positive and negative words. We run Gibbs sampler for 1 000 iterations and stop the iteration once the log-likelihood of the training data converges.

3.2 Separating Topic and Perspective Words

Using the word type switch variable $\mathbf{x}$, we could separate topic and argument words in LAM based solely on the statistics gathered from data. We also explore another two methods to separate topic and argument words based on Part-of-Speech (POS) tags and with the incorporation of a subjectivity lexicon. For the first variant, we adopt the similary strategy as in (Fang et al., 2012) that nouns (NOUN) are topic words; adjectives (ADJ), adverbs (ADV) and verbs (VERB) are argument words; words with other POS tags are background words. Essentially, $\mathbf{x}$ is observed. We call this model LAM_POS.

For the second variant, instead of assuming $\mathbf{x}$ is observed, we incorporate the POS tags as prior information to modify the Dirichlet prior γ for the word type switch variable at the initialization step. In addition, we also consider a subjective lexicon[1], L, that if a word can be found in the lexicon, then it is very likely the word is used to convey an opinion or argument, although there is still a small probability that word could be either background or topic word. Assuming an asymmetric Dirichlet prior for $\mathbf{x}$ is parametrized by $\gamma^\intercal = [\gamma^b, \gamma^z, \gamma^a]$ for background, topic and argument words, it is modified by a transformation matrix λ, $\gamma^{\text{new}} = \lambda \times \gamma^\intercal$, where λ is defined by:

- If word $w \in L \wedge \text{POSTAG}(w) \neq \text{NOUN}$ then $\lambda^\intercal = [0.05, 0.05, 0.9]$
- else if $\text{POSTAG}(w) = \text{NOUN}$ then $\lambda^\intercal = [0.05, 0.9, 0.05]$
- else if $\text{POSTAG}(w) \in \{\text{ADJ,ADV,VERB}\}$ then $\lambda^\intercal = [0.05, 0.05, 0.9]$
- else $\lambda^\intercal = [0.9, 0.05, 0.05]$

The conditional probability for the switch variable x is modified by simultaneously considering the POS tag g for the word at position t:

$$P(x_t = r, y_t = g | \boldsymbol{x}_{-t}, \boldsymbol{z}, \boldsymbol{a}, \boldsymbol{w}, \Lambda) \propto \frac{\{N_d^r\}_{-t} + \gamma}{\{N_d\}_{-t} + 3\gamma} \cdot \frac{\{N_{w_t}^r\}_{-t} + \beta^r}{\sum_{w'} \{N_{w'}^r\}_{-t} + W\beta^r} \cdot \frac{\{N_g^r\} + \epsilon_g^r}{\{N_g\} + \sum_{g'} \epsilon_{g'}^r}, \quad (4)$$

where an additional term is added to the RHS of Equation 1. Here, N_g^r denotes the number of words with POS tag g assigned to the word type r, N_g is the total number of words assigned to the POS tag g, ϵ_g^r is the Dirichlet prior for the POS tag-word type distribution.

[1] In this work, we use the subjectivity lexicon presented at (Wiebe et al., 2005).

We call the second variant LAM_LEX. As both the POS tag information and the subjectivity lexicon are only incorporated in the initialisation step, LAM_LEX sits in-between LAM and LAM_POS that it performs soft clustering of topic words and argument words. That is, during the initialisation, nouns are more likely to be topic words, but there is still a small probability that they could be either argument or background words; and similarly for words tagged as adjectives, adverts and verbs.

4 House of Common Debates (HCD)

Debates from the UK parliament are archived and available for consulting.[2] A custom web-crawler was developed to obtain the records of every day that The House of Commons was in session between 2009 and 2016. Due to inconsistencies in the data format and volume of data, much of the analysis focuses on the recordings for the parliamentary year 2014-2015. The general structure of a single day of recording is as follows: a question will be put to the house (generally a Bill) and Members of Parliament (MPs) will discuss various aspects regarding the Bill or show stances about it. Each speech made by an MP is considered to be a single document. Multiple Bills will be discussed each day. The current item being discussed is clearly marked in the source data format, so linking documents to the current bill and MP is trivial. Each speech is labelled with a major (e.g. *education*) and a minor topic (e.g. *grammar schools*) and help us create a dataset with the desired needs.

The length that The House will be in session varies and the number of bills discussed also varies. In this paper, we considered debates occurred during March of 2015[3] and contains 1 992 speeches belonging to diverse domains: *justice*, *education*, *energy and climate change*, *treasury*, *transport*, *armed forces*, *foreign and commonwealth office*, *environment*, *transport*, *royal assent*, *work and pensions*, *northern Ireland*. This House of Commons Debates (HCD) dataset is made available for the research community.[4]

We followed a standard methodology to clean the texts: stopwords were removed, lemmatization was applied, and a naive negation treatment was considered for the particle 'not', by creating bigrams for words occurs in the subjectivity lexicon (e.g., 'not good' becomes 'not_good'). As topic models suffer from lack of robustness if large outliers are present, we also removed very frequent (above 99%) and rare words (below percentile 65%), assuming that word occurrences of the collection follow a Zip's law distribution.[5] Similar strategy was carried out for texts, in order to just consider texts of similar length. The preprocessed HCD contains a total of 1 598 speeches.

5 Experiments

This section evaluates LAM and its variants qualitatively and quantitatively (averaged over 5 runs).

The models for comparison are listed below:

- **LDA**. Latent Dirichlet Allocation (Blei et al., 2003).
- **CPT**. The Cross-perspective Topic Model (Fang et al., 2012) assumes perspectives are observed. To be able to run this model on the political speeches, we implemented a version that can manage latent perspectives and separately sample topics and viewpoints.
- **JTV**. Joint Topic-Viewpoint Model (Trabelsi and Zaıane, 2014) is essentially the reparameterized version of the Joint Sentiment-Topic (JST) model (Lin and He, 2009) called REVERSE-JST (Lin et al., 2012) in which sentiment label (or viewpoint) generation is dependent on topics. We implemented JTV as the reversed JST model.[6]
- **LAM**. Latent Argument Model from §3.
- **LAM_POS**. LAM with topic, argument or background words separated by POS tags.
- **LAM_LEX**. Both POS tags and a subjective lexicon are used to initialise the Dirichlet prior γ for the word type switch variable as described in §3.2.

5.1 Experimental Results

Results are evaluated in terms of both topic coherence and the quality of the extracted perspectives.

5.1.1 Topic Coherence

The CV metric[7] is used to measure the coherence of the topics generated by the models as it has been shown to give the results closest to human evaluation compared to other topic coherence metrics (Röder et al., 2015). In brief, given a set of words,

[2] https://hansard.parliament.uk

[3] Period of time what selected on a basis of existence of a large number of major topics.

[4] https://github.com/aghie/lam/blob/master/hcd.tsv

[5] Percentiles were selected on an empirical basis.

[6] We were not able to find a publicly available code of the JTV implementation.

[7] https://github.com/AKSW/Palmetto/

it gives an intuition of how likely those words co-occur compared to expected by chance.

Figure 2 plots the CV results[8] versus the number of topics on HCD for various models. For each topic z, we extract the top ten most representative words ranked by their respective normalised discriminative score defined by $\mathrm{DS}(w,z) = P(w|z)/[\max_{z' \neq z} P(w|z')]$. We chose this approach instead of simple $P(w|z)$ as it was observed to turn into higher quality topics. It is clear that LAM_LEX models outperform baselines and that all variants are learning well the topics from the data, showing that the three different mechanisms for the switch variable are effective to generate coherent topics. Also, our models work robustly under different number of topics. Moreover, LAM_LEX achieve better coherence scores than the original LAM and LAM_POS. This shows that it is more effective to use POS tags and a subjectivity lexicon to initialise the Dirichlet prior for the word type switch variable rather than simply relying on POS tags or subjectivity lexica to give hard discrimination between topic and argument words.

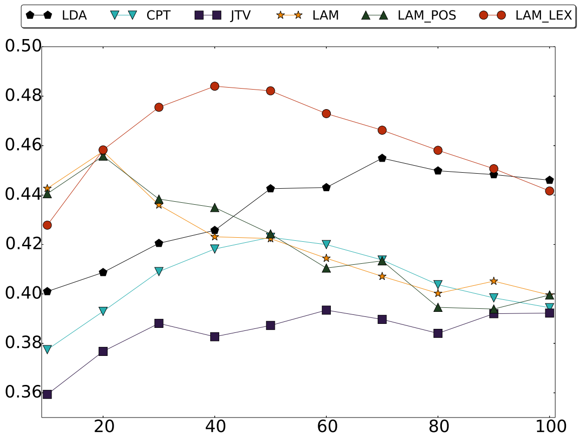

Figure 2: CV coherence vs the number of topics for different modeling approaches.

We also used the gold-standard major topic label assigned by Hansard to each speech to carry out an additional quantitative evaluation. For each topic z, we extract the top ten most representative sentences ranked by their respective normalised discriminative score defined by $\mathrm{DS}(s,z) = \sum_{w \in \boldsymbol{s}} \mathrm{DS}(w,z)/\mathrm{Length}(\boldsymbol{s})$.

If a particular model is clustering robustly, the top sentences it extracts should belong to speeches that discuss the same topic and share the same major and/or minor topic labels in the HCD corpus. Table 2 shows for the studied models the percentage of sentences where x out of top 10 topic sentences belong to the same major topic. The results reinforce the superior performance of the LAM_LEX approach in comparison with other models.

It is worth remarking that in cases where LAM_LEX cluster together sentences labelled with different major topics, some clustering results are actually quite sensible. Table 1 illustrates it with a representative case. These sentences were extracted from a cluster about *farmers* in which 9 out of 10 top topic sentences have "*environment, food and rural affairs*" as the gold major topic. The only discording sentence, belonging to *treasury* (major topic) and *infrastructure investment* (minor topic), is however closely related to *farmers* too and it makes sense to put it into the same cluster.

5.1.2 Perspectiven Summarisation

In this section we evaluate the quality of the relation of the arguments with respect to their topics.

In terms of a quantitative evaluation, we are interested in knowing how strongly the perspectives are related to their topic: it might be the case that the separate CV coherence for the topic and viewpoints is high, but there is no actual relation between them, which would be an undesirable behaviour. To determine whether this is happening or not in the studied models, for each perspective we compute a mixed topic-perspective CV value, by extracting the top 5 perspective words, concatenating them with the top 5 words of the corresponding topic and running Palmetto as in the previous section.[9] We then average the computed mixed topic-perspective CV values by $T \times A$. Following this methodology, a high average CV value means that the perspective words are likely to occur when discussing about that particular topic, and therefore a test of whether the model is learning perspectives that have to do with it. Figure 3 compares topic-perspective models evaluated following this methodology, showing that LAM_LEX gives the best overall coherence.

For a better understanding of what perspectives LAM_LEX is learning, we extract the top perspective sentences for a given topic based on normalised discriminative score of each sen-

[8] The CV results were calculated based on the top 10 words from each topic.

[9] Palmetto does not accept more than 10 words.

Sentence (extracted from a longer speech)	**Major topic**	**Minor topic**
I would add that HMRC can provide extra flexibility where there are particular impacts on particular farmers or other businesses	Treasury	Infrastructure Investment
I think milk prices will improve, but the banks need to support farmers in the meantime	Environment food and rural affairs	Topical questions

Table 1: Example sentences, belonging to speeches that were assigned in Hansard different major topics labels, were clustered together by LAM (and it is sensible to do so as they are both about "farmers").

Table 2: Ratio of topics where x or more than x out of top 10 topic sentences ($\geq x$) belong to the same major topic.

tence[10], similar to what have been done in selecting the top topic sentences. In specific, we first define the discriminative score of word w under topic z and argument a by: $\mathrm{DS}(w,a,z) = \frac{P(w|z,a)}{\max_{z' \neq z, a' \neq a} P(w|z',a')}$. Then the sentence-level discriminative score is calculated based on the aggregated discriminative scores over all the words normalised by the sentence length: $\mathrm{DS}(s,z,a) = \sum_{w \in \boldsymbol{s}} \mathrm{DS}(w,a,z)/\mathrm{Length}(\boldsymbol{s})$. In order to have better correspondence between topics and their respective arguments, we perform two-stage selection: first ranking sentences based on topic-level discriminative scores DS(s,z), and then further ranking sentences based on topic-argument-level discriminative scores $\mathrm{DS}(s,z,a)$.

We can use these extracted top representative sentences together with the gold major topics from HCD to measure if perspectives are connected to their topic. We define the label-based accuracy (LA) as follows: let p_i be the gold major topics associated to the top 10 perspective sentences of a perspective i and let t be the gold major topics corresponding to the top 10 topic sentences; LA(t,p_i) = $\frac{|t \cap p_i|}{|t \cup p_i|}$ measures how many gold major topic labels are shared between topic and perspective sentences. LA also penalises the major topics that are not in common. Table 3 shows for different number of topics the averaged LA measure across all perspectives for three models. It can be observed that LAM_LEX obtains the best performance, followed by CPT.

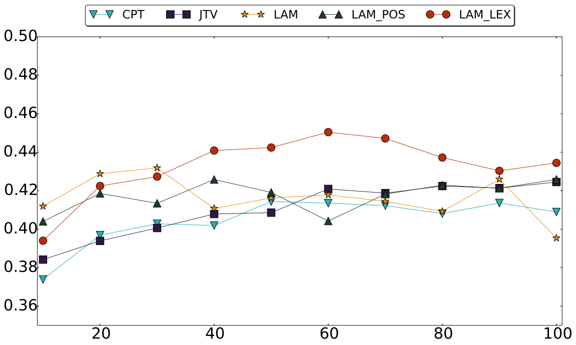

Figure 3: Average mixed topic-perspective CV coherence, across different number of topics.

Topics	**CPT**	**JTV**	**LAM_LEX**
10	0.254	0.308	**0.427**
20	0.369	0.366	**0.517**
30	0.401	0.389	**0.573**
40	0.426	0.394	**0.604**
50	0.431	0.408	**0.564**

Table 3: Averaged LA measure across all topic-perspectives for different models.

To compare the quality of perspectives inferred by LAM_LEX and CPT (over 30 topics) we also conducted human evaluation. To do this, topics and perspectives were represented as bag-of-words. Each perspective was also represented with its three most representative sentences. The outputs from the two models was first merged and shuffled. Two external annotators were then asked to answer ('yes' or 'no') for each topic if they could differentiate two perspectives. Co-

[10] We can also rank sentences for an argument a under a topic z based on the generative probability of sentences. But this consistently produce worse results.

hen's Kappa coefficient (Cohen, 1968) for inter-annotator agreement was 0.421. Table 4 shows the results of the evaluation and it is clear that LAM_LEX outperforms CPT.

Annotator	LAM_LEX	CPT
1	**0.63**	0.10
2	**0.67**	0.34
1&2	**0.53**	0.10

Table 4: Accuracy on detecting perspectives according to the human outputs. In 1&2 a 'yes' answer is only valid if marked by both annotators.

Table 5 shows the three most representative perspective sentences for some of the extracted topics by LAM_LEX and CPT, to illustrate how LAM_LEX obtains more coherent sentences.[11] The example involving the first topic shows a case where LAM_LEX learned non-contrastive perspectives: both deal with *Palestina*, but focusing in different aspects (*illegal settlements* vs. *Israel actions*). In contrast, CPT mixed perspectives about Israel/Palestina and other viewpoints about *GCSE* and *mortgages*. In the second topic, LAM_LEX ranks at the top sentences relating to *Sinn Fein & Northern Ireland*, that show two different stances (*positive* vs *negative)* meanwhile in CPT it is not possible to infer any clear perspective despite sentences contain semantically related terms.

Table 6 shows cases where LAM_LEX obtained a less-coherent output according to the annotators. The first topic deals with Shaker Aamer and the legality of its imprisonment in Guantanamo. Perspective 2 reflects this issue, but Perspective 1 includes other types of crimes. The second example discusses issues relating to transports. While Perspective 1 is all about the negotiation with the train company, First Great Western, on its franchise extension proposal, Perspective 2 contains sentences relating to a number of different issues under transports. To alleviate this problem, we hypothesise that additional levels of information (in addition to the topic and perspective levels), such as a Bill or a speaker, might be needed to better distinguish different topics and perspectives that share a significant proportion of vocabulary.

5.1.3 Discussion

LAM_LEX gave a glimpse of the perspectives that occupy a topic. However, in many cases those differ from the initial expectation given the priors used in our model. Despite of the use of the subjectivity lexicon to initialise the Dirichlet prior β^a for the topic-argument-word distribution, after a few iterations the initial distribution changes radically and turns instead into contrastive and non-contrastive perspectives, with the latter group being the most common one. We think this is due to factors that involve: (1) lack of contrastive speeches about very specific topics; and (2) jargon from the House of Commons that makes the task more challenging as stances are showed in subtle and polite way. This is also in line with what has been previously observed in (Mohammad et al., 2016b) that a person may express the same stance towards a target by using negative or positive language. This shows that LAM_LEX can infer perspectives from raw data, but we have little control on guiding the model on what perspectives to extract.

6 Conclusion and Future Work

We have presented LAM, a model able to provide a glimpse of what is going on in political debates, without relying on any labelled data and assuming the perspectives of a topic to be latent. It is implemented through a hierarchical Bayesian model considering that words can be separated as topic, argument or background words and follow different generative routes. Experiments show that our model obtains more coherent topics than related approaches and also extracts more interpretable perspectives. The code is made available at `https://github.com/aghie/lam`.

Although LAM can extract perspectives under a certain topic, there is little control in what kind of information to extract (e.g. we might want only contrastive or non-contrastive arguments). In future work, we plan to improve the model through complex priors or semantic similarity strategies. Also, adding a 'Bill' level could be beneficial as speeches about the same Bill should share the same high-level topic. But we need labels indicating to which Bill the text belongs to. Including a 'speaker' level to know which parliamentarians discuss which topics is another interesting path to follow.

Acknowledgments

We thank Charles Marshall for crawling the HCD data. DV was funded by MECD (FPU 13/01180), MINECO (FFI2014-51978-C2-2-R) and Inditex-UDC grants for research stays. YH is partly

[11] The examples were identified as two perspectives by at least one annotator. Its selection was made based on an existence of a similar topic both on LAM_LEX and CPT outputs.

	LAM_LEX	CPT
Topic 1	israel, iran, syria, settlement, relocation, counter-terrorism gaza, tpims, airline, metropolitan	israel, iran, middle, settlement, palestinian, israeli, gaza, negotiation, village, hamas
Perspective 1	a) It is contrary to international law in that sense, and any nation has obligations when dealing with occupied territories and their occupants. b) Again, I reiterate the difference between the two issues: one concerns the illegal settlements, and the other is a planning matter that we have raised concerns about. c) That is a slightly separate debate or concern if I can put it that way to the illegal settlements that have been put forward, but nevertheless we are concerned and are having a dialogue with Israel about that.	a) Does he agree that unless that happens it is difficult to envisage a unified and prosperous Palestinian state existing alongside Israel? b) Will the Minister discuss that issue with the Israeli Government, urge them to reconsider the upcoming evictions and demolitions due for next month, and instead consider villages co-existing side by side in the spirit of peace? c) That is caused partly by the security situation in Sinai and the Egyptian response to that, and partly by the situation between Israel and the Palestinians in Gaza.
Perspective 2	a) More to the point, the continual encroachment by the Israeli Government makes it impossible for East Jerusalem to become the capital of a Palestinian state. b) We know that 163 Palestinian children are being held in Israeli military detention, and that many are being held inside Israel in direct violation of the fourth Geneva c) We want to see the establishment of a sovereign and independent Palestinian state, living in peace and security alongside Israel.	a) I share the hon. Ladys desire that every school should offer three separate sciences at GCSE; that is very important. b) Everybody here will know, however, that a 1,000 monthly payment sustains a mortgage of 200,000. c) As I clarified, that is a different matter to the debate about the occupied Palestinian territories, but nevertheless we want a robust planning process that adequately.
Topic 2	stormont, sinn, fein, setback, scene, flag, belfast, backwards, surprise, feeling	northern, ireland, stormont, sinn, fein, fairly, poverty, corporation, molyneaux, monday
Perspective 1	a) Would that it was as simple as getting behind the democratic authority in Libyait is not clear that there is a democratic authority behind which we can get. b) It is very important for the Stormont House agreement to be implemented fully and fairly, including all the sections on welfare and budgets. c) The Stormont House agreement was a big step forward, and it is vital for all parties to work to ensure that it is implemented fully and fairly.	a) Following our two major reform programmes, spend has fallen to 1.7 billion in 2013-14 and is expected to fall to about 1.5 billion once the reforms have fully worked through the system. b) Universal credit is a major reform that will transform the welfare state in Britain for the better. c) We have put in place a five-year reform programme that will bring our courts into the 21st century.
Perspective 2	a) There is a clear disparity in political party funding in Northern Ireland, yet Sinn Fein Members continue to draw hundreds of thousands of pounds in allowances from this House, despite not taking their seats. b) In light of the reneging of Sinn Fein on the introduction of welfare reform, what implications does the Minister see in the devolution of corporation tax in Northern Ireland? c) There is no doubt that the announcement by Sinn Fein on Monday was a significant setback for the Stormont House agreement, but it is inevitable that there will be bumps in the road with agreements of this nature.	a) Will the National Crime Agency specifically target the organised criminal gangs that are engaging in subterfuge and in the organised criminal activity of fuel laundering along the border areas of Northern Ireland? b) This will ensure that the people of Northern Ireland are afforded the same protections from serious and organised crime as those in the rest of the United Kingdom. c) The Treasury has had meetings with the European Commission to discuss the reinstatement of the aggregate credit levy scheme for Northern Ireland, which could serve as a further tool of investment in infrastructure.

Table 5: Output sample for representative perspective sentences in non-contrastive and contrastive topics.

	LAM_LEX
Topic 1	aamer, shaker, bay, guantanamo, america, obama, american, timetable, embassy, harlington
Perspective 1	a) NSPCC research has shown that six in 10 teenagers have been asked for sexual images or videos online. b) Does my right hon. Friend agree that the report released last week that suggested that the punishments for online and offline crime should be equalised demonstrates that education is needed to show that the two sentences should be equal? c) I can confirm that the Government have announced that we are entering into a negotiation on a contract for difference for the Swansea bay lagoon to decide whether the project is affordable and represents value for money.
Perspective 2	a) This has been a helpful and constructive debate, and I join others in congratulating the hon. Member for Hayes and Harlington (John McDonnell) on securing it through the Backbench Business Committee. b) I thank the Backbench Business Committee for allocating time for this critical debate at an important time in the campaign to secure the release of Shaker Aamer. c) He has been one of the leading parliamentary campaigners for Mr Aamers release, and I acknowledge the presence of the hon. Member for Battersea (Jane Ellison) , who is the constituency MP for Mr Aamer and his familyindeed, this debate provides an important opportunity to follow up a Backbench Business Committee debate on the same subject that she initiated in April 2013.
Topic 2	passenger, franchise, fare, coast, connectivity, journey, gloucester, user, anglia, stagecoach
Perspective 1	a) Will my hon. Friend confirm when she expects the Departments negotiations with First Great Western on its franchise extension proposals, which include the improvements at Gloucester, to be completed? b) The hon. Gentleman will be pleased to learn that we expect to conclude negotiations with First Great Western and to finalise the second directly awarded franchise contract during this month, and expect the provision of services to start in September. c) My plans for the regeneration of the city of Gloucester include a new car park and entrance to Gloucester station, but they depend on a land sale agreement between the Ministry of Justice and the city council and the lands onward leasing to First Great Western.
Perspective 2	a) I do not want any young people to feel frightened of attending school or of their journey to and from school, and, sadly, that applies particularly to members of the Jewish community at present. b) Why, instead of real localism, have this Government presided over a failed record, with bus fares up 25% and 2,000 routes cut, and a broken bus market, which lets users down, but which Labour will fix in government? c) Last week we introduced the new invitation to tender for the Northern Rail and TransPennine Express services, and transferred East Coast back to the private sector.

Abstract

Social media users often make explicit predictions about upcoming events. Such statements vary in the degree of certainty the author expresses toward the outcome: “Leonardo DiCaprio will win Best Actor” vs. “Leonardo DiCaprio may win” or “No way Leonardo wins!”. Can popular beliefs on social media predict who will win? To answer this question, we build a corpus of tweets annotated for veridicality on which we train a log-linear classifier that detects positive veridicality with high precision.[1] We then forecast uncertain outcomes using the *wisdom of crowds*, by aggregating users’ explicit predictions. Our method for forecasting winners is fully automated, relying only on a set of contenders as input. It requires no training data of past outcomes and outperforms sentiment and tweet volume baselines on a broad range of contest prediction tasks. We further demonstrate how our approach can be used to measure the reliability of individual accounts’ predictions and retrospectively identify surprise outcomes.

(a)	*Natalie Portman is gonna beat out Meryl Streep for best actress*
(b)	*La La Land doesn’t have lead actress and actor guaranteed. Natalie Portman will probably (and should) get best actress*
(c)	*Adored #LALALAND but it’s #NataliePortman who deserves the best actress #oscar #OscarNoms > superb acting*

Table 1: Examples of tweets expressing varying degrees of veridicality toward Natalie Portman winning an Oscar.

1 Introduction

In the digital era we live in, millions of people broadcast their thoughts and opinions online. These include predictions about upcoming events of yet unknown outcomes, such as the Oscars or election results. Such statements vary in the extent to which their authors intend to convey the event will happen. For instance, (a) in Table 1 strongly asserts the win of Natalie Portman over Meryl Streep, whereas (b) imbues the claim with uncertainty. In contrast, (c) does not say anything about the likelihood of Natalie Portman winning (although it clearly indicates the author would like her to win).

Prior work has made predictions about contests such as NFL games (Sinha et al., 2013) and elections using tweet volumes (Tumasjan et al., 2010) or sentiment analysis (O’Connor et al., 2010; Shi et al., 2012). Many such indirect signals have been shown useful for prediction, however their utility varies across domains. In this paper we explore whether the “wisdom of crowds” (Surowiecki, 2005), as measured by users’ explicit predictions, can predict outcomes of future events. We show how it is possible to accurately forecast winners, by aggregating many individual predictions that assert an outcome. Our approach requires no historical data about outcomes for training and can directly be adapted to a broad range of contests.

To extract users’ predictions from text, we present TwiVer, a system that classifies veridicality toward future contests with uncertain outcomes. Given a list of contenders competing in a contest (e.g., Academy Award for Best Actor), we use TwiVer to count how many tweets explicitly assert the win of each contender. We find that aggregating veridicality in this way provides

[1] The code and data can be found at `https://github.com/SandeshS/Twitter-Veridicality`

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1583–1592
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

an accurate signal for predicting outcomes of future contests. Furthermore, TwiVer allows us to perform a number of novel qualitative analyses including retrospective detection of *surprise outcomes* that were not expected according to popular belief (Section 4.5). We also show how TwiVer can be used to measure the number of correct and incorrect predictions made by individual accounts. This provides an intuitive measurement of the reliability of an information source (Section 4.6).

2 Related Work

In this section we summarize related work on text-driven forecasting and computational models of veridicality.

Text-driven forecasting models (Smith, 2010) predict future response variables using text written in the present: e.g., forecasting films' box-office revenues using critics' reviews (Joshi et al., 2010), predicting citation counts of scientific articles (Yogatama et al., 2011) and success of literary works (Ashok et al., 2013), forecasting economic indicators using query logs (Choi and Varian, 2012), improving influenza forecasts using Twitter data (Paul et al., 2014), predicting betrayal in online strategy games (Niculae et al., 2015) and predicting changes to a knowledge-graph based on events mentioned in text (Konovalov et al., 2017). These methods typically require historical data for fitting model parameters, and may be sensitive to issues such as concept drift (Fung, 2014). In contrast, our approach does not rely on historical data for training; instead we forecast outcomes of future events by directly extracting users' explicit predictions from text.

Prior work has also demonstrated that user sentiment online directly correlates with various real-world time series, including polling data (O'Connor et al., 2010) and movie revenues (Mishne and Glance, 2006). In this paper, we empirically demonstrate that veridicality can often be more predictive than sentiment (Section 4.1).

Also related is prior work on *detecting veridicality* (de Marneffe et al., 2012; Søgaard et al., 2015) and sarcasm (González-Ibánez et al., 2011). Soni et al. (2014) investigate how journalists frame quoted content on Twitter using predicates such as *think*, *claim* or *admit*. In contrast, our system TwiVer, focuses on the author's belief toward a claim and direct predictions of future events as opposed to quoted content.

Our approach, which aggregates predictions extracted from user-generated text is related to prior work that leverages explicit, positive veridicality, statements to make inferences about users' demographics. For example, Coppersmith et al. (2014; 2015) exploit users' self-reported statements of diagnosis on Twitter.

3 Measuring the Veridicality of Users' Predictions

The first step of our approach is to extract statements that make explicit predictions about unknown outcomes of future events. We focus specifically on *contests* which we define as events planned to occur on a specific date, where a number of *contenders* compete and a single *winner* is chosen. For example, Table 2 shows the contenders for Best Actor in 2016, highlighting the winner.

Actor	Movie
Leonardo DiCaprio	**The Revenant**
Bryan Cranston	Trumbo
Matt Damon	The Martian
Michael Fassbender	Steve Jobs
Eddie Redmayne	The Danish Girl

Table 2: Oscar nominations for Best Actor 2016.

To explore the accuracy of user predictions in social media, we gathered a corpus of tweets that mention events belonging to one of the 10 types listed in Table 4. Relevant messages were collected by formulating queries to the Twitter search interface that include the name of a contender for a given contest in conjunction with the keyword *win*. We restricted the time range of the queries to retrieve only messages written before the time of the contest to ensure that outcomes were unknown when the tweets were written. We include 10 days of data before the event for the presidential primaries and the final presidential elections, 7 days for the Oscars, Ballon d'Or and Indian general elections, and the period between the semi-finals and the finals for the sporting events. Table 3 shows several example queries to the Twitter search interface which were used to gather data. We automatically generated queries, using templates, for events scraped from various websites: 483 queries were generated for the presidential primaries based on events scraped from ballotpe-

○ Strongly wants the event to happen
○ Probably wants the event to happen
● No desire about the event
○ Probably does not want the event to happen
○ Strongly against the event

Figure 1: Example of one item to be annotated, as displayed to the Turkers.

dia[2] , 176 queries were generated for the Oscars,[3] 18 for Ballon d'Or,[4] 162 for the Eurovision contest,[5] 52 for Tennis Grand Slams,[6] 6 for the Rugby World Cup,[7] 18 for the Cricket World Cup,[8] 12 for the Football World Cup,[9] 76 for the 2016 US presidential elections,[10] and 68 queries for the 2014 Indian general elections.[11]

We added an event prefix (e.g., "Oscars" or the state for presidential primaries), a keyword ("win"), and the relevant date range for the event. For example, "Oscars Leonardo DiCaprio win since:2016-2-22 until:2016-2-28" would be the query generated for the first entry in Table 2.

Minnesota Rubio win since:2016-2-18 until:2016-3-1
Vermont Sanders win since:2016-2-18 until:2016-3-1
Oscars Sandra Bullock win since:2010-3-1 until:2010-3-7
Oscars Spotlight win since:2016-2-22 until:2016-2-28

Table 3: Examples of queries to extract tweets.

We restricted the data to English tweets only, as tagged by *langid.py* (Lui and Baldwin, 2012). Jaccard similarity was computed between messages to identify and remove duplicates.[12] We removed URLs and preserved only tweets that mention contenders in the text. This automatic post-processing left us with 57,711 tweets for all winners and 55,558 tweets for losers (contenders who did not win) across all events. Table 4 gives the data distribution across event categories.

Event	Number of tweets Winners	 Losers
2016 US Presidential primaries	20,347	17,873
Oscars (2009 – 2016)	1,498	872
Tennis Grand Slams (2011 – 2016)	10,785	19,745
Ballon d'Or Award (2010 – 2016)	3,492	3,285
Eurovision (2010 – 2016)	261	1,421
2016 US Presidential elections	9,679	3,966
2014 Indian general elections	920	736
Rugby World Cup (2010 – 2016)	272	379
Football World Cup (2010 – 2016)	8,129	5,489
Cricket World Cup (2010 – 2016)	2,328	1,792

Table 4: Number of tweets for each event category.

3.1 Mechanical Turk Annotation

We obtained veridicality annotations on a sample of the data using Amazon Mechanical Turk. For each tweet, we asked Turkers to judge veridicality toward a candidate winning as expressed in the tweet as well as the author's desire toward the event. For veridicality, we asked Turkers to rate whether the author believes the event will happen on a 1-5 scale ("Definitely Yes", "Probably Yes", "Uncertain about the outcome", "Probably No",

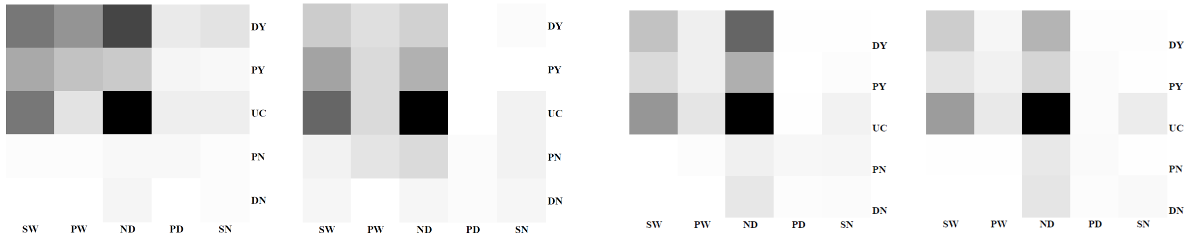
[12] A threshold of 0.7 was used.



(a) Oscar winners (b) Oscar losers (c) All events winners (d) All events losers

Figure 2: Heatmaps showing annotation distributions for one of the events - the Oscars and all event types, separating winners from losers. Vertical labels indicate veridicality (DY "Definitely Yes", PY "Probably Yes", UC "Uncertain about the outcome", PN "Probably No" and DN "Definitely No"). Horizontal labels indicate desire (SW "Strongly wants the event to happen", PW "Probably wants the event to happen", ND "No desire about the event outcome", PD "Probably does not want the event to happen", SN "Strongly against the event happening"). More data in the upper left hand corner indicates there are more tweets with positive veridicality and desire.

"Definitely No"). We also added a question about the author's desire toward the event to make clear the difference between veridicality and desire. For example, "I really want Leonardo to win at the Oscars!" asserts the author's desire toward Leonardo winning, but remains agnostic about the likelihood of this outcome, whereas "Leonardo DiCaprio will win the Oscars" is predicting with confidence that the event will happen.

Figure 1 shows the annotation interface presented to Turkers. Each HIT contained 10 tweets to be annotated. We gathered annotations for $1,841$ tweets for winners and $1,702$ tweets for losers, giving us a total of $3,543$ tweets. We paid $0.30 per HIT. The total cost for our dataset was $1,000. Each tweet was annotated by 7 Turkers. We used MACE (Hovy et al., 2013) to resolve differences between annotators and produce a single gold label for each tweet.

Figures 2a and 2c show heatmaps of the distribution of annotations for the winners for the Oscars in addition to all categories. In both instances, most of the data is annotated with "Definitely Yes" and "Probably Yes" labels for veridicality. Figures 2b and 2d show that the distribution is more diverse for the losers. Such distributions indicate that the veridicality of crowds' statements could indeed be predictive of outcomes. We provide additional evidence for this hypothesis using automatic veridicality classification on larger datasets in §4.

3.2 Veridicality Classifier

The goal of our system, TwiVer, is to automate the annotation process by predicting how veridical a tweet is toward a candidate winning a contest: is the candidate deemed to be winning, or is the author uncertain? For the purpose of our experiments, we collapsed the five labels for veridicality into three: positive veridicality ("Definitely Yes" and "Probably Yes"), neutral ("Uncertain about the outcome") and negative veridicality ("Definitely No" and "Probably No").

We model the conditional distribution over a tweet's veridicality toward a candidate c winning a contest against a set of opponents, O, using a log-linear model:

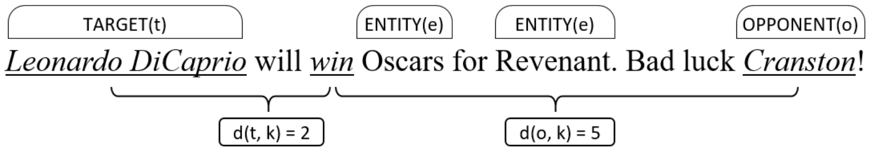
$$P(y = v|c, \text{tweet}) \propto \exp\left(\theta_v \cdot f(c, O, \text{tweet})\right)$$

where v is the veridicality (positive, negative or neutral).

To extract features $f(c, O, \text{tweet})$, we first preprocessed tweets retrieved for a specific event to identify named entities, using (Ritter et al., 2011)'s Twitter NER system. Candidate (c) and opponent entities were identified in the tweet as follows:

- TARGET (t). A target is a named entity that matches a contender name from our queries.
- OPPONENT (O). For every event, along with the current TARGET entity, we also keep track of other contenders for the same event. If a named entity in the tweet matches with one of other contenders, it is labeled as opponent.
- ENTITY (e): Any named entity which does not match the list of contenders.

Figure 3 illustrates the named entity labeling for a tweet obtained from the query "Oscars Leonardo DiCaprio win since:2016-2-22 until:2016-2-28". Leonardo DiCaprio is the TARGET, while the named entity tag for Bryan Cranston, one of the



TARGET(t)
ENTITY(e)
ENTITY(e)
OPPONENT(o)
Leonardo DiCaprio will win Oscars for Revenant. Bad luck Cranston!
d(t, k) = 2
d(o, k) = 5

Figure 3: Illustration of the three named entity tags and distance features between entities and keyword *win* for a tweet retrieved by the query "Oscars Leonardo DiCaprio win since:2016-2-22 until:2016-2-28".

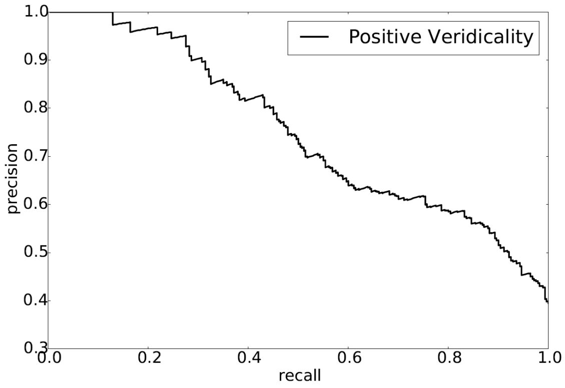


Figure 4: Precision/Recall curve showing TwiVer performance in identifying positive veridicality tweets in the test data.

	P	R	F1
− Context	47.7	**96.4**	63.8
− Distance	57.5	82.5	67.7
− Punctuation	53.4	88.2	66.6
− Dependency path	56.9	85.4	68.2
− Negated keyword	56.7	86.4	68.4
All features	**58.7**	83.1	**68.8**

Table 5: Feature ablation of the positive veridicality classifier by removing each group of features from the full set. The point of maximum F1 score is shown in each case.

losers for the Oscars, is re-tagged as OPPONENT. These tags provide information about the position of named entities relative to each other, which is used in the features.

3.3 Features

We use five feature templates: context words, distance between entities, presence of punctuation, dependency paths, and negated keyword.

Target and opponent contexts. For every TARGET (t) and OPPONENT ($o \in O$) entities in the tweet, we extract context words in a window of one to four words to the left and right of the TARGET ("Target context") and OPPONENT ("Opponent context"), e.g., *t will win*, *I'm going with* t, o *will win*.

Keyword context. For target and opponent entities, we also extract words between the entity and our specified keyword (k) (*win* in our case): t *predicted to* k, o *might* k.

Pair context. For the election type of events, in which two target entities are present (contender and state. e.g., *Clinton, Ohio*), we extract words between these two entities: e.g., t_1 *will win* t_2.

Distance to keyword. We also compute the distance of TARGET and OPPONENT entities to the keyword.

Punctuation. We introduce two binary features for the presence of exclamation marks and question marks in the tweet. We also have features which check whether a tweet ends with an exclamation mark, a question mark or a period. Punctuation, especially question marks, could indicate how certain authors are of their claims.

Dependency paths. We retrieve dependency paths between the two TARGET entities and between the TARGET and keyword (*win*) using the TweeboParser (Kong et al., 2014) after applying rules to normalize paths in the tree (e.g., "doesn't" → "does not").

Negated keyword. We check whether the keyword is negated (e.g., "not win", "never win"), using the normalized dependency paths.

We randomly divided the annotated tweets into a training set of 2,480 tweets, a development set of 354 tweets and a test set of 709 tweets. MAP parameters were fit using LBFGS-B (Zhu et al., 1997). Table 6 provides examples of high-weight features for positive and negative veridicality.

3.4 Evaluation

We evaluated TwiVer's precision and recall on our held-out test set of 709 tweets. Figure 4 shows the precision/recall curve for positive veridicality. By setting a threshold on the probability score to be greater than 0.64, we achieve a precision of

Positive Veridicality			Negative Veridicality		
Feature Type	Feature	Weight	Feature Type	Feature	Weight
Keyword context	TARGET *will* KEYWORD	0.41	Negated keyword	keyword is negated	0.47
Keyword dep. path	TARGET → *to* → KEYWORD	0.38	Keyword context	TARGET *won't* KEYWORD	0.41
Keyword dep. path	TARGET ← *is* → *going* → *to* → KEYWORD	0.29	Opponent context	OPPONENT *will win*	0.37
Target context	TARGET *is favored to win*	0.19	Keyword dep. path	TARGET ← *will* → *not* → KEYWORD	0.31
Keyword context	TARGET *are going to* KEYWORD	0.15	Distance to keyword	OPPONENT *closer to* KEYWORD	0.28
Target context	TARGET *predicted to win*	0.13	Target context	TARGET *may not win*	0.27
Pair context	TARGET1 *could win* TARGET2	0.13	Keyword dep. path	OPPONENT ← *will* → KEYWORD	0.23
Distance to keyword	TARGET *closer to* KEYWORD	0.11	Target context	TARGET *can't win*	0.18

Table 6: Some high-weight features for positive and negative veridicality.

Tweet	Gold	Predicted
The heart wants **Nadal** to win tomorrow but the mind points to a Djokovic win over 4 sets. Djokovic 7-5 4-6 7-5 6-4 **Nadal** for me.	negative	positive
Hopefully tomorrow Federer will win and beat that **Nadal** guy lol	neutral	negative
There is no doubt **India** have the tools required to win their second World Cup. Whether they do so will depend on ...	positive	neutral

Table 7: Some classification errors made by TwiVer. Contenders queried for are highlighted.

80.1% and a recall of 44.3% in identifying tweets expressing a positive veridicality toward a candidate winning a contest.

3.5 Performance on held-out event types

To assess the robustness of the veridicality classifier when applied to new types of events, we compared its performance when trained on all events vs. holding out one category for testing. Table 9 shows the comparison: the second and third columns give F1 score when training on all events vs. removing tweets related to the category we are testing on. In most cases we see a relatively modest drop in performance after holding out training data from the target event category, with the exception of elections. This suggests our approach can be applied to new event types without requiring in-domain training data for the veridicality classifier.

3.6 Error Analysis

Table 7 shows some examples which TwiVer incorrectly classifies. These errors indicate that even though shallow features and dependency paths do a decent job at predicting veridicality, deeper text understanding is needed for some cases. The opposition between "the heart ... the mind" in the first example is not trivial to capture. Paying attention to matrix clauses might be important too (as shown in the last tweet "There is no doubt ...").

4 Forecasting Contest Outcomes

We now have access to a classifier that can automatically detect positive veridicality predictions about a candidate winning a contest. This enables us to evaluate the accuracy of the crowd's wisdom by retrospectively comparing popular beliefs (as extracted and aggregated by TwiVer) against known outcomes of contests.

We will do this for each award category (Best Actor, Best Actress, Best Film and Best Director) in the Oscars from 2009 – 2016, for every state for both Republican and Democratic parties in the 2016 US primaries, for both the candidates in every state for the final 2016 US presidential elections, for every country in the finals of Eurovision song contest, for every contender for the Ballon d'Or award, for every party in every state for the 2014 Indian general elections, and for the contenders in the finals for all sporting events.

4.1 Prediction

A simple voting mechanism is used to predict contest outcomes: we collect tweets about each contender written before the date of the event,[13] and use TwiVer to measure the veridicality of users' predictions toward the events. Then, for each contender, we count the number of tweets that are labeled as positive with a confidence above 0.64, as well as the number of tweets with positive veridicality for all other contenders. Table 11 illustrates these counts for one contest, the Oscars Best Actress in 2014.

We then compute a simple prediction score, as follows:

$$\text{score} = (|T_c| + 1)/(|T_c| + |T_O| + 2) \qquad (1)$$

[13] These are a different set of tweets than those TwiVer was trained on.

Event	Veridicality			Sentiment			Frequency			#predictions
	P	R	F1	P	R	F1	P	R	F1	
Oscars	**80.6**	80.6	**80.6**	52.9	87.1	63.5	54.7	**93.5**	69.0	151
Ballon d'Or	**100.0**	100.0	**100.0**	85.7	100.0	92.2	85.7	100.0	92.2	18
Eurovision	**83.3**	71.4	**76.8**	38.5	71.4	50.0	50.0	57.1	53.3	87
Tennis Grand Slam	50.0	100.0	66.6	50.0	100.0	66.6	50.0	100.0	66.6	52
Rugby World Cup	**100.0**	100.0	**100.0**	50.0	100.0	66.6	50.0	100.0	66.6	4

2016 US presidential elections	60.9	**100.0**	**75.6**	63.3	73.8	68.1	**69.0**	69.0	69.0	84
2014 Indian general elections	**95.8**	100.0	**97.8**	65.6	91.3	76.3	56.1	100.0	71.8	52

Table 8: Performance of Veridicality, Sentiment baseline, and Frequency baseline on all event categories (%).

Event	Train on all	Train without held-out event	$\|T_t\|$
Oscars	69.5	63.8	64
Ballon d'Or	54.6	46.6	61
Eurovision	65.7	63.2	48
Tennis Grand Slams	52.1	45.5	44
Rugby World Cup	56.5	58.1	44
Cricket World Cup	61.9	66.8	49
Football World Cup	76.0	67.5	56
Presidential primaries	59.8	48.1	117
2016 US presidential elections	52.0	52.3	54
Indian elections	60.3	39.0	44

Table 9: F1 scores for each event when training on all events vs. holding out that event from training. $|T_t|$ is the number of tweets of that event category present in the test dataset.

where $|T_c|$ is the set of tweets mentioning positive veridicality predictions toward candidate c, and $|T_O|$ is the set of all tweets predicting any opponent will win. For each contest, we simply predict as winner the contender whose score is highest.

4.2 Sentiment Baseline

We compare the performance of our approach against a state-of-the-art sentiment baseline (Mohammad et al., 2013). Prior work on social media analysis used sentiment to make predictions about real-world outcomes. For instance, O'Connor et al. (2010) correlated sentiment with public opinion polls and Tumasjan et al. (2010) use political sentiment to make predictions about outcomes in German elections.

We use a re-implementation of (Mohammad et al., 2013)'s system[14] to estimate sentiment for tweets in our corpus. We run the tweets obtained for every contender through the sentiment analysis system to obtain a count of positive labels. Sentiment scores are computed analogously to veridicality using Equation (1). For each contest, the contender with the highest sentiment prediction score is predicted as the winner.

4.3 Frequency Baseline

We also compare our approach against a simple frequency (tweet volume) baseline. For every contender, we compute the number of tweets that has been retrieved. Frequency scores are computed in the same way as for veridicality and sentiment using Equation (1). For every contest, the contender with the highest frequency score is selected to be the winner.

4.4 Results

Table 8 gives the precision, recall and max-F1 scores for veridicality, sentiment and volume-based forecasts on all the contests. The veridicality-based approach outperforms sentiment and volume-based approaches on 9 of the 10 events considered. For the Tennis Grand Slam, the three approaches perform poorly. The difference in performance for the veridicality approach is quite lower for the Tennis events than for the other events. It is well known however that winners of tennis tournaments are very hard to predict. The performance of the players in the last minutes

Table 11: Positive veridicality tweet counts for the Best Actress category in 2014: $|T_c|$ is the count of positive veridicality tweets for the contender under consideration and $|T_O|$ is the count of positive veridicality tweets for the other contenders.

of the match are decisive, and even professionals have a difficult time predicting tennis winners.

Table 10 shows the 10 top predictions made by the veridicality and sentiment-based systems on two of the events we considered - the Oscars and the presidential primaries, highlighting correct predictions.

4.5 Surprise Outcomes

In addition to providing a general method for forecasting contest outcomes, our approach based on veridicality allows us to perform several novel analyses including retrospectively identifying surprise outcomes that were unexpected according to popular beliefs.

In Table 10, we see that the veridicality-based approach incorrectly predicts *The Revenant* as winning Best Film in 2016. This makes sense, because the film was widely expected to win at the time, according to popular belief. Numerous sources in the press,[15,16,17] qualify *The Revenant* not winning an Oscar as a big surprise.

Similarly, for the primaries, the two incorrect predictions made by the veridicality-based approach were surprise losses. News articles[18,19,20] indeed reported the loss of Maine for Trump and the loss of Indiana for Clinton as unexpected.

4.6 Assessing the Reliability of Accounts

Another nice feature of our approach based on veridicality is that it immediately provides an intuitive assessment on the reliability of individual Twitter accounts' predictions. For a given account, we can collect tweets about past contests, and extract those which exhibit positive veridicality toward the outcome, then simply count how often

breakingnewsnig	100 (out of 4)	User 4	77 (out of 13)

Table 12: List of users sorted by how accurate they were in their Ballon d'Or predictions.

the accounts were correct in their predictions.

As proof of concept, we retrieved within our dataset, the user names of accounts whose tweets about Ballon d'Or contests were classified as having positive veridicality. Table 12 gives accounts that made the largest number of correct predictions for Ballon d'Or awards between 2010 to 2016, sorted by users' prediction accuracy. Usernames of non-public figures are anonymized (as user 1, etc.) in the table. We did not extract more data for these users: we only look at the data we had already retrieved. Some users might not make predictions for all contests, which span 7 years.

Accounts like "goal_ghana", "breakingnewsnig" and "1Mrfutball", which are automatically identified by our analysis, are known to post tweets predominantly about soccer.

5 Conclusions

In this paper, we presented TwiVer, a veridicality classifier for tweets which is able to ascertain the degree of veridicality toward future contests. We showed that veridical statements on Twitter provide a strong predictive signal for winners on different types of events, and that our veridicality-based approach outperforms a sentiment and frequency baseline for predicting winners. Furthermore, our approach is able to retrospectively identify surprise outcomes. We also showed how our approach enables an intuitive yet novel method for evaluating the reliability of information sources.

Abstract

Emotion cause extraction aims to identify the reasons behind a certain emotion expressed in text. It is a much more difficult task compared to emotion classification. Inspired by recent advances in using deep memory networks for question answering (QA), we propose a new approach which considers emotion cause identification as a reading comprehension task in QA. Inspired by convolutional neural networks, we propose a new mechanism to store relevant context in different memory slots to model context information. Our proposed approach can extract both word level sequence features and lexical features. Performance evaluation shows that our method achieves the state-of-the-art performance on a recently released emotion cause dataset, outperforming a number of competitive baselines by at least 3.01% in F-measure.

1 Introduction

With the rapid growth of social network platforms, more and more people tend to share their experiences and emotions online. Emotion analysis of online text becomes a new challenge in Natural Language Processing (NLP). In recent years, studies in emotion analysis largely focus on emotion classification including detection of writers' emotions (Gao et al., 2013) as well as readers' emotions (Chang et al., 2015). There are also some information extraction tasks defined in emotion analysis (Chen et al., 2016; Balahur et al., 2011), such as extracting the feeler of an emotion (Das and Bandyopadhyay, 2010). These methods assume that emotion expressions are already observed. Sometimes, however, we care more about the stimuli, or the cause of an emotion. For instance, Samsung wants to know why people love or hate Note 7 rather than the distribution of different emotions.

Ex.1 我的手机昨天丢了，我现在很难过。

Ex.1 *Because I lost my phone yesterday, I feel sad now.*

In an example shown above, "sad" is an emotion word, and the cause of "sad" is "I lost my phone". The emotion cause extraction task aims to identify the reason behind an emotion expression. It is a more difficult task compared to emotion classification since it requires a deep understanding of the text that conveys an emotions.

Existing approaches to emotion cause extraction mostly rely on methods typically used in information extraction, such as rule based template matching, sequence labeling and classification based methods. Most of them use linguistic rules or lexicon features, but do not consider the semantic information and ignore the relation between the emotion word and emotion cause.

In this paper, we present a new method for emotion cause extraction. We consider emotion cause extraction as a question answering (QA) task. Given a text containing the description of an event which may or may not cause a certain emotion, we take an emotion word in context, such as "sad", as a query. The question to the QA system is: "Does the described event cause the emotion of sadness?". The expected answer is either "yes" or "no". (see Figure 1). We build our QA system based on a deep memory network. The memory network has two inputs: a piece of text, referred to as a story in QA systems, and a query. The story is represented using a sequence of word embeddings.

A recurrent structure is implemented to mine the deep relation between a query and a text. It

A story:
I lost my phone yesterday, I feel so sad now.
Reading
Will "I lost my phone yesterday" causes the emotion "sad" ?
Question
Yes!
Answering

Figure 1: An example of emotion cause extraction based on the QA framework.

measures the importance of each word in the text by an attention mechanism. Based on the learned attention result, the network maps the text into a low dimensional vector space. This vector is then used to generate an answer. Existing memory network based approaches to QA use weighted sum of attentions to jointly consider short text segments stored in memory. However, they do not explicitly model sequential information in the context. In this paper, we propose a new deep memory network architecture to model the context of each word simultaneously by multiple memory slots which capture sequential information using convolutional operations (Kim, 2014), and achieves the state-of-the-art performance compared to existing methods which use manual rules, common sense knowledge bases or other machine learning models.

The rest of the paper is organized as follows. Section 2 gives a review of related works on emotion analysis. Section 3 presents our proposed deep memory network based model for emotion cause extraction. Section 4 discusses evaluation results. Finally, Section 5 concludes the work and outlines the future directions.

2 Related Work

Identifying emotion categories in text is one of the key tasks in NLP (Liu, 2015). Going one step further, emotion cause extraction can reveal important information about what causes a certain emotion and why there is an emotion change. In this section, we introduce related work on emotion analysis including emotion cause extraction.

In emotion analysis, we first need to determine the taxonomy of emotions. Researchers have proposed a list of primary emotions (Plutchik, 1980; Ekman, 1984; Turner, 2000). In this study, we adopt Ekman's emotion classification scheme (Ekman, 1984), which identifies six primary emotions, namely *happiness, sadness, fear, anger, disgust* and *surprise*, known as the "Big6" scheme in the W3C Emotion Markup Language. This emotion classification scheme is agreed upon by most previous works in Chinese emotion analysis.

Existing work in emotion analysis mostly focuses on emotion classification (Li et al., 2013; Zhou et al., 2016) and emotion information extraction (Balahur et al., 2013). Xu et al. (2012) used a coarse to fine method to classify emotions in Chinese blogs. Gao et al. (2013) proposed a joint model to co-train a polarity classifier and an emotion classifier. Beck et al. (2014) proposed a Multi-task Gaussian-process based method for emotion classification. Chang et al. (2015) used linguistic templates to predict reader's emotions. Das and Bandyopadhyay (2010) used an unsupervised method to extract emotion feelers from Bengali blogs. There are other studies which focused on joint learning of sentiments (Luo et al., 2015; Mohtarami et al., 2013) or emotions in tweets or blogs (Quan and Ren, 2009; Liu et al., 2013; Hasegawa et al., 2013; Qadir and Riloff, 2014; Ou et al., 2014), and emotion lexicon construction (Mohammad and Turney, 2013; Yang et al., 2014; Staiano and Guerini, 2014). However, the aforementioned work all focused on analysis of emotion expressions rather than emotion causes.

Lee et al. (2010) first proposed a task on emotion cause extraction. They manually constructed a corpus from the Academia Sinica Balanced Chinese Corpus. Based on this corpus, Chen et al. (2010) proposed a rule based method to detect emotion causes based on manually define linguistic rules. Some studies (Gui et al., 2014; Li and Xu, 2014; Gao et al., 2015) extended the rule based method to informal text in Weibo text (Chinese tweets).

Other than rule based methods, Russo et al. (2011) proposed a crowdsourcing method to construct a common-sense knowledge base which is related to emotion causes. But it is challenging to extend the common-sense knowledge base automatically. Ghazi et al. (2015) used Conditional Random Fields (CRFs) to extract emotion causes. However, it requires emotion cause and emotion keywords to be in the same sentence. More recently, Gui et al. (2016) proposed a multi-kernel based method to extract emotion causes through learning from a manually annotated emotion cause dataset.

Most existing work does not consider the relation between an emotion word and the cause of such an emotion, or they simply use the emotion word as a feature in their model learning. Since emotion cause extraction requires an understanding of a given piece of text in order to correctly identify the relation between the description of an event which causes an emotion and the expression of that emotion, it can essentially be considered as a QA task. In our work, we choose the memory network, which is designed to model the relation between a story and a query for QA systems (Weston et al., 2014; Sukhbaatar et al., 2015). Apart from its application in QA, memory network has also achieved great successes in other NLP tasks, such as machine translation (Luong et al., 2015), sentiment analysis (Tang et al., 2016) or summarization (M. Rush et al., 2015). To the best of our knowledge, this is the first work which uses memory network for emotion cause extraction.

3 Our Approach

In this section, we will first define our task. Then, a brief introduction of memory network will be given, including its basic learning structure of memory network and deep architecture. Last, our modified deep memory network for emotion cause extraction will be presented.

3.1 Task Definition

The formal definition of emotion cause extraction is given in (Gui et al., 2016). In this task, a given document, which is a passage about an emotion event, contains an emotion word E and the cause of the event. The document is manually segmented in the clause level. For each clause $c = \{w_1, w_2, ...w_k\}$ consisting of k words, the goal is to identify which clause contains the emotion cause. For data representation, we can map each word into a low dimensional embedding space, a.k.a word vector (Mikolov et al., 2013). All the word vectors are stacked in a word embedding matrix $L \in \mathbb{R}^{d \times \|V\|}$, where d is the dimension of word vector and V is the vocabulary size.

For example, the sentence, "I lost my phone yesterday, I feel so sad now." shown in Figure 1, consists of two clauses. The first clause contains the emotion cause while the second clause expresses the emotion of sadness. Current methods to emotion cause extraction cannot handle complex sentence structures where the expression of an emotion and its cause are not adjacent. We envision that the memory network can better model the relation between a emotion word and its emotion causes in such complex sentence structures. In our approach, we only select the clause with the highest probability to be the emotion cause in each document.

3.2 Memory Network

We first present a basic memory network model for emotion cause extraction (shown in Figure 2). Given a clause $c = \{w_1, w_2, ..., w_k\}$, and an emotion word, we first obtain the emotion word's representation in an embedding space, denoted by E. For the clause, let the embedding representations of the words be denoted by $e_1, e_2, ..., e_k$. Here, both e_i and E are defined in $\mathbb{R}^d$. Then, we use the inner product to evaluate the correlation between each word i in a clause and the emotion word, denoted as m_i:

$$m_i = e_i \cdot E. \tag{1}$$

We then normalize the value of m_i to $[0, 1]$ using a softmax function, denoted by α_i as:

$$\alpha_i = \frac{\exp(m_i)}{\sum_{j=1}^{k} \exp(m_j)}, \tag{2}$$

where k is the length of the clause. k also serves as the size of the memory. Obviously, $\alpha_i \in [0, 1]$ and $\sum_{i=1}^{k} \alpha_i = 1$. α_i can serve as an attention weight to measure the importance of each word in our model.

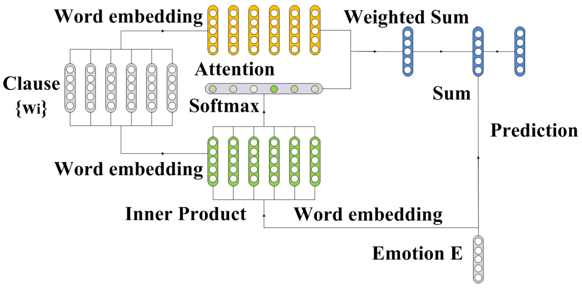

Figure 2: A single layer memory network.

Then, a sum over the word embedding e_i, weighted by the attention vector form the output of the memory network for the prediction of o:

$$o = \sum_{i=1}^{k} e_i \cdot \alpha_i + E. \tag{3}$$

The final prediction is an output from a softmax function, denoted as $\hat{o}$:

$$\hat{o} = \text{softmax}\left(W^T o\right). \quad (4)$$

Usually, W is a $d \times d$ weight matrix and T is the transposition. Since the answer in our task is a simple “yes” or “no”, we use a $d \times 1$ matrix for W. As the distance between a clause and an emotion words is a very important feature according to (Gui et al., 2016), we simply add this distance into the softmax function as an additional feature in our work.

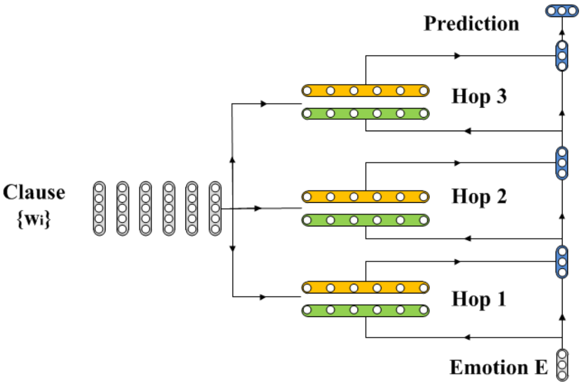

Figure 3: Deep memory network with three computational layers (hops).

The basic model can be extended to deep architecture consisting of multiple layers to handle L hop operations. The network is stacked as follows:

- For hop 1, the query is E and the prediction vector is o_1;
- For hop i, the query is the prediction vector of the previous hop and the prediction vector is o_i;
- The output vector is at the top of the network. It is a softmax function on the prediction vector from hop L: $\hat{o} = \text{softmax}\left(W^T o_L\right)$.

The illustration of a deep memory network with three layers is shown in Figure 3. Since a memory network models the emotion cause at a fine-grained level, each word has a corresponding weight to measure its importance in this task. Comparing to previous approaches in emotion cause extraction which are mostly based on manually defined rules or linguistic features, a memory network is a more principled way to identify the emotion cause from text. However, the basic memory network model does not capture the sequential information in context which is important in emotion cause extraction.

3.3 Convolutional Multiple-Slot Deep Memory Network

It is often the case that the meaning of a word is determined by its context, such as the previous word and the following word. Also, negations and emotion transitions are context sensitive. However, the memory network described in Section 3.2 has only one memory slot with size $d \times k$ to represent a clause, where d is the dimension of a word embedding and k is the length of a clause. It means that when the memory network models a clause, it only considers each word separately.

In order to capture context information for clauses, we propose a new architecture which contains more memory slot to model the context with a convolutional operation. The basic architecture of Convolutional Multiple-Slot Memory Network (in short: ConvMS-Memnet) is shown in Figure 4.

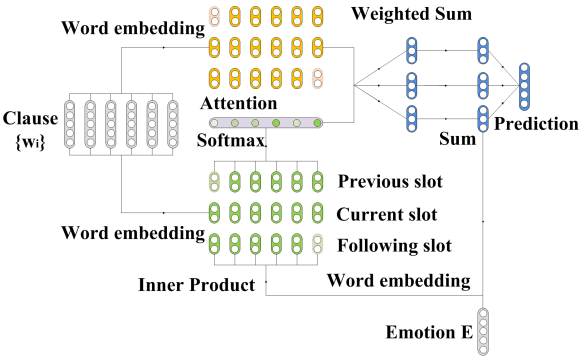

Figure 4: A single layer ConvMS-Memnet.

Considering the text length is usually short in the dataset used here for emotion cause extraction, we set the size of the convolutional kernel to 3. That is, the weight of word w_i in the i-th position considers both the previous word w_{i-1} and the following word w_{i+1} by a convolutional operation:

$$m'_i = \sum_{j=1}^{3} e_{i-2+j} \cdot E \quad (5)$$

For the first and the last word in a clause, we use zero padding, $w_0 = w_{k+1} = \vec{0}$, where k is the length of a clause. Then, the attention weight for each word position in the clause is now defined as:

$$\alpha_i' = \frac{\exp(m_i')}{\sum_{j=1}^{k} \exp\left(m_j'\right)} \tag{6}$$

Note that we obtain the attention for each position rather than each word. It means that the corresponding attention for the i-th word in the previous convolutional slot should be α_{i+1}. Hence, there are three prediction output vectors, namely, $o_{previous}$, $o_{current}$, $o_{following}$:

$$o_{previous} = \sum_{i=1}^{k} e_{i-1} \cdot \alpha_i' + E \tag{7}$$

$$o_{current} = \sum_{i=1}^{k} e_{i} \cdot \alpha_i' + E \tag{8}$$

$$o_{following} = \sum_{i=1}^{k} e_{i+1} \cdot \alpha_i' + E \tag{9}$$

At last, we concatenate the three vectors as $o = o_{previous} \bigoplus o_{current} \bigoplus o_{following}$ for the prediction by a softmax function:

$$\hat{o} = \text{softmax}\left(W_m^T o\right) \tag{10}$$

Here, the size of W_m is $(3 \cdot d) \times d$. Since the prediction vector is a concatenation of three outputs. We implement a concatenation operation rather than averaging or other operations because the parameters in different memory slots can be updated by back propagation. The concatenation of three output vectors forms a sequence-level feature which can be used in the training. Such a feature is important especially when the size of annotated training data is small.

For deep architecture with multiple layer training, the network is more complex (shown in Figure 5).

- For the first layer, the query is an embedding of the emotion word, E.

- In the next layer, there are three input queries since the previous layer has three outputs: $o^1_{previous}$, $o^1_{current}$, $o^1_{following}$. So, for the j-th layer ($j \neq 1$), we need to re-define the weight function (5) as:

$$m_i' = e_{i-1} \cdot o^{j-1}_{previous} + e_i \cdot o^{j-1}_{current} + e_{i+1} \cdot o^{j-1}_{following} \tag{11}$$

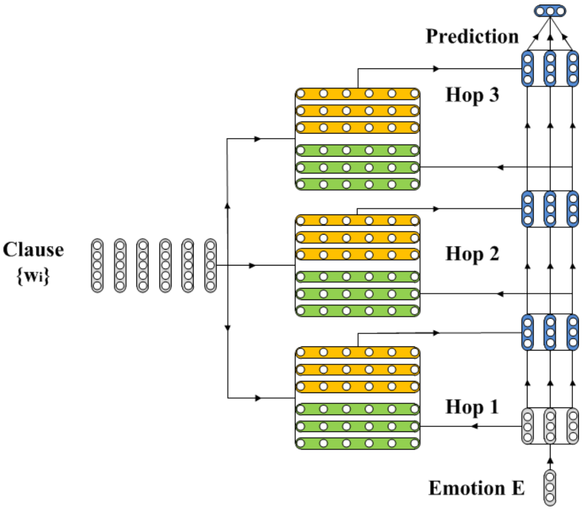

Figure 5: ConvMS-Memnet with three computational layers (hops).

- In the last layer, the concatenation of the three prediction vectors form the final prediction vector to generate the answer.

For model training, we use stochastic gradient descent and back propagation to optimize the loss function. Word embeddings are learned using a skip-gram model. The size of the word embedding is 20 since the vocabulary size in our dataset is small. The dropout is set to 0.4.

4 Experiments and Evaluation

We first presents the experimental settings and then report the results in this section.

4.1 Experimental Setup and Dataset

We conduct experiments on a simplified Chinese emotion cause corpus (Gui et al., 2016)[*], the only publicly available dataset on this task to the best of our knowledge. The corpus contains 2,105 documents from SINA city news[†]. Each document has only one emotion word and one or more emotion causes. The documents are segmented into clauses manually. The main task is to identify which clause contains the emotion cause.

Details of the corpus are shown in Table 1. The metrics we used in evaluation follows Lee et al. (2010). It is commonly accepted so that we can compare our results with others. If a proposed emotion cause clause covers the annotated answer, the word sequence is considered correct. The precision, recall, and F-measure are defined by

[*] Available at: http://hlt.hitsz.edu.cn/?page id=694

[†] http://news.sina.com.cn/society/

Item	Number
Documents	2,105
Clauses	11,799
Emotion Causes	2,167
Documents with 1 emotion	2,046
Documents with 2 emotions	56
Documents with 3 emotions	3

Table 1: Details of the dataset.

$$
\begin{aligned}
P &= \frac{\sum \text{correct causes } 1}{\sum \text{proposed causes } 1}, \\
R &= \frac{\sum \text{correct causes } 1}{\sum \text{annotated causes } 1}, \\
F &= \frac{2 \times P \times R}{P + R}.
\end{aligned}
$$

In the experiments, we randomly select 90% of the dataset as training data and 10% as testing data. In order to obtain statistically credible results, we evaluate our method and baseline methods 25 times with different train/test splits.

4.2 Evaluation and Comparison

We compare with the following baseline methods:

- **RB** (Rule based method): The rule based method proposed in (Lee et al., 2010).
- **CB** (Common-sense based method): This is the knowledge based method proposed by (Russo et al., 2011). We use the Chinese Emotion Cognition Lexicon (Xu et al., 2013) as the common-sense knowledge base. The lexicon contains more than 5,000 kinds of emotion stimulation and their corresponding reflection words.
- **RB+CB+ML** (Machine learning method trained from rule-based features and facts from a common-sense knowledge base): This methods was previously proposed for emotion cause classification in (Chen et al., 2010). It takes rules and facts in a knowledge base as features for classifier training. We train a SVM using features extracted from the rules defined in (Lee et al., 2010) and the Chinese Emotion Cognition Lexicon (Xu et al., 2013).
- **SVM**: This is a SVM classifier using the unigram, bigram and trigram features. It is a baseline previously used in (Li and Xu, 2014; Gui et al., 2016)

Method	P	R	F
RB	**0.6747**	0.4287	0.5243
CB	0.2672	**0.7130**	0.3887
RB+CB	0.5435	0.5307	0.5370
RB+CB+ML	0.5921	0.5307	0.5597
SVM	0.4200	0.4375	0.4285
Word2vec	0.4301	0.4233	0.4136
CNN	0.6215	0.5944	0.6076
Multi-kernel	0.6588	0.6927	**0.6752**
Memnet	0.5922	0.6354	0.6131
ConvMS-Memnet	**0.7076**	**0.6838**	**0.6955**

Table 2: Comparison with existing methods.

- **Word2vec**: This is a SVM classifier using word representations learned by Word2vec (Mikolov et al., 2013) as features.
- **Multi-kernel**: This is the state-of-the-art method using the multi-kernel method (Gui et al., 2016) to identify the emotion cause. We use the best performance reported in their paper.
- **CNN**: The convolutional neural network for sentence classification (Kim, 2014).
- **Memnet**: The deep memory network described in Section 3.2. Word embeddings are pre-trained by skip-grams. The number of hops is set to 3.
- **ConvMS-Memnet**: The convolutional multiple-slot deep memory network we proposed in Section 3.3. Word embeddings are pre-trained by skip-grams. The number of hops is 3 in our experiments.

Table 2 shows the evaluation results. The rule based RB gives fairly high precision but with low recall. CB, the common-sense based method, achieves the highest recall. Yet, its precision is the worst. RB+CB, the combination of RB and CB gives higher the F-measure But, the improvement of 1.27% is only marginal compared to RB.

For machine learning methods, RB+CB+ML uses both rules and common-sense knowledge as features to train a machine learning classifier. It achieves F-measure of 0.5597, outperforming RB+CB. Both SVM and word2vec are word feature based methods and they have similar performance. For word2vec, even though word representations are obtained from the SINA news raw corpus, it still performs worse than SVM trained using n-gram features only. The multi-kernel method (Gui et al., 2016) is the best performer

Word Embedding	P	R	F
Pre-trained	**0.7076**	**0.6838**	**0.6955**
Randomly initialized	0.6786	0.6608	0.6696

Table 3: Comparison of using pre-trained or randomly initialized word embedding.

Method	P	R	F
Hop 1	0.6597	0.6444	0.6520
Hop 2	0.6877	0.6718	0.6796
Hop 3	**0.7076**	**0.6838**	**0.6955**
Hop 4	0.6882	0.6722	0.6801
Hop 5	0.6763	0.6606	0.6683
Hop 6	0.6664	0.6509	0.6585
Hop 7	0.6483	0.6333	0.6407
Hop 8	0.6261	0.6116	0.6187
Hop 9	0.6161	0.6109	0.6089

Table 4: Performance with different number of hops in ConvMS-Memnet.

among the baselines because it considers context information in a structured way. It models text by its syntactic tree and also considers an emotion lexicon. Their work shows that the structure information is important for the emotion cause extraction task.

Naively applying the original deep memory network or convolutional network for emotion cause extraction outperforms all the baselines except the convolutional multi-kernel method. However, using our proposed ConvMS-Memnet architecture, we manage to boost the performance by 11.54% in precision, 4.84% in recall and 8.24% in F-measure respectively when compared to Memnet. The improvement is very significant with p-value less than 0.01 in t-test. The ConvMS-Memnet also outperforms the previous best-performing method, multi-kernel, by 3.01% in F-measure. It shows that by effectively capturing context information, ConvMS-Memnet is able to identify the emotion cause better compared to other methods.

4.3 More Insights into the ConvMS-Memnet

To gain better insights into our proposed ConvMS-Memnet, we conduct further experiments to understand the impact on performance by using: 1) pre-trained or randomly initialized word embedding; 2) multiple hops; 3) attention visualizations; 4) more training epochs.

4.3.1 Pre-trained Word Embeddings

In our ConvMS-Memnet, we use pre-trained word embedding as the input. The embedding maps each word into a lower dimensional real-value vector as its representation. Words sharing similar meanings should have similar representations. It enables our model to deal with synonyms more effectively.

The question is, "can we train the network without using pre-trained word embeddings?". We initialize word vectors randomly, and use an embedding matrix to update the word vectors in the training of the network simultaneously. Comparison results are shown in Table 3. It can be observed that pre-trained word embedding gives 2.59% higher F-measure compared to random initialization. This is partly due to the limited size of our training data. Hence using word embedding trained from other much larger corpus gives better results.

4.3.2 Multiple Hops

It is widely acknowledged that computational models using deep architecture with multiple layers have better ability to learn data representations with multiple levels of abstractions. In this section, we evaluate the power of multiple hops in this task. We set the number of hops from 1 to 9 with 1 standing for the simplest single layer network shown in Figure 4. The more hops are stacked, the more complicated the model is. Results are shown in Table 4. The single layer network has achieved a competitive performance. With the increasing number of hops, the performance improves. However, when the number of hops is larger than 3, the performance decreases due to overfitting. Since the dataset for this task is small, more parameters will lead to overfitting. As such, we choose 3 hops in our final model since it gives the best performance in our experiments.

4.3.3 Word-Level Attention Weights

Essentially, memory network aims to measure the weight of each word in the clause with respect to the emotion word. The question is, will the model really focus on the words which describe the emotion cause? We choose one example to show the attention results in Table 5:

Ex.2 家人/*family* 的/*'s* 坚持/*insistence* 更/*more* 让/*makes* 人/*people* 感动/*touched*

In this example, the cause of the emotion "touched" is "insistence". We show in Table 5 the distribution of word-level attention weights in different hops of memory network training. We can observe that in the first two hops, the highest attention weights centered on the word "more". However, from the third hop onwards, the highest atten-

previous slot	**current slot**	following slot	**Hop 1**	**Hop 2**	**Hop 3**	**Hop 4**	**Hop 5**

tion weight moves to the word sub-sequence centred on the word “insistence”. This shows that our model is effective in identifying the most important keyword relating to the emotion cause. Also, better results are obtained using deep memory network trained with at least 3 hops. This is consistent with what we observed in Section 4.3.2.

In order to evaluate the quality of keywords extracted by memory networks, we define a new metric on the keyword level of emotion cause extraction. The keyword is defined as the word which obtains the highest attention weight in the identified clause. If the keywords extracted by our algorithm is located within the boundary of annotation, it is treated as correct. Thus, we can obtain the precision, recall, and F-measure by comparing the proposed keywords with the correct keywords by:

$$P = \frac{\sum_{\text{correct keywords}} 1}{\sum_{\text{proposed keywords}} 1},$$

$$R = \frac{\sum_{\text{correct keywords}} 1}{\sum_{\text{annotated keywords}} 1},$$

$$F = \frac{2 \times P \times R}{P + R}.$$

Since the reference methods do not focus on the keywords level, we only compare the performance of Memnet and ConvMS-Memnet in Table 6. It can be observed that our proposed ConvMS-Memnet outperforms Memnet by 5.6% in F-measure. It shows that by capturing context features, ConvMS-Memnet is able to identify the word level emotion cause better compare to Memnet.

4.3.4 Training Epochs

In our model, the training epochs are set to 20. In this section, we examine the testing error using a case study. Due to the page length limit, we only choose one example from the corpus. The text below has four clauses:

Ex.3 *45*天，对于失去儿子的他们是多么的漫长，宝贝回家了，这个春节是多么幸福。

Ex.3 *45 days, it is long time for the parents who lost their baby. If the baby comes back home, they would become so happy in this Spring Festival.*

In this example, the cause of emotion “happy” is described in the third clause.

We show in Table 7 the probability of each clause containing an emotion cause in different training epochs. It is interesting to see that our model is able to detect the correct clause with only 5 epochs. With the increasing number of training epochs, the probability associated with the correct clause increases further while the probabilities of incorrect clauses decrease generally.

4.4 Limitations

We have shown in Section 4.3.4 a simple example consisting of only four clauses from which our model can identify the clause containing the emotion cause correctly. We notice that for some complex text passages which contain long distance dependency relations, negations or emotion transitions, our model may have a difficulty in detecting the correct clause containing the emotion causes. It is a challenging task to properly model the discourse relations among clauses. In the future, we will explore different network architecture with consideration of various discourse relations possibly through transfer learning of larger annotated data available for other tasks.

Another shortcoming of our model is that, the answer generated from our model is simply “yes” or “no”. The main reason is that the size of the annotated corpus is too small to train a model which can output natural language answers in full sentences. Ideally, we would like to develop a model which can directly give the cause of an emotion

Clause	5 Epochs	10 Epochs	15 Epochs	20 Epochs
45 Days	0.0018	0.0002	0.0000	0.0000
it is ... baby	0.3546	0.6778	0.5457	0.3254
If the ... back home	**0.7627**	**0.7946**	**0.8092**	**0.9626**
they ... Spring Festival	0.2060	0.0217	0.0004	0.0006

Table 7: The probability of a clause containing the emotion cause in different iterations in the multiple-slot memory network.

expressed in text. However, since the manual annotation of data is too expensive for this task, we need to explore feasible ways to automatically collect annotate data for emotion cause detection. We also need to study effective evaluation mechanisms for such QA systems.

5 Conclusions

In this work, we treat emotion cause extraction as a QA task and propose a new model based on deep memory networks for identifying the emotion causes for an emotion expressed in text. The key property of this approach is the use of context information in the learning process which is ignored in the original memory network. Our new memory network architecture is able to store context in different memory slots to capture context information in proper sequence by convolutional operation. Our model achieves the state-of-the-art performance on a dataset for emotion cause detection when compared to a number of competitive baselines. In the future, we will explore effective ways to model discourse relations among clauses and develop a QA system which can directly output the cause of emotions as answers.

Story Comprehension for Predicting What Happens Next

Snigdha Chaturvedi   Haoruo Peng   Dan Roth

Abstract

Automatic story comprehension is a fundamental challenge in Natural Language Understanding, and can enable computers to learn about social norms, human behavior and commonsense. In this paper, we present a story comprehension model that explores three distinct semantic aspects: (i) the sequence of events described in the story, (ii) its emotional trajectory, and (iii) its plot consistency. We judge the model's understanding of real-world stories by inquiring if, like humans, it can develop an expectation of what will happen next in a given story. Specifically, we use it to predict the correct ending of a given short story from possible alternatives. The model uses a hidden variable to weigh the semantic aspects in the context of the story. Our experiments demonstrate the potential of our approach to characterize these semantic aspects, and the strength of the hidden variable based approach. The model outperforms the state-of-the-art approaches and achieves best results on a publicly available dataset.

1 Introduction

Narratives are a fundamental part of human language and culture. They serve as vehicles to share experiences, information and goals. For these reasons, automatically understanding stories is an interesting but challenging task for Computational Linguists (Mani, 2012). Story comprehension involves not only an array of NLP capabilities, but also some common sense knowledge and an understanding of normative social behavior (Charniak, 1972). Past research has focused on various aspects of story understanding such as identifying character personas (Bamman et al., 2014; Valls-Vargas et al., 2015), interpersonal relationships (Chaturvedi, 2016), plot-patterns (Jockers, 2013), narrative structures (Finlayson, 2012). There has also been an interest in predicting what is expected to happen next in a piece of text (Chambers and Jurafsky, 2008). Human readers are good at *filling-in-the-gaps* or inferring information that is not explicitly stated in the text. However, computers are not yet able to match their performance on predicting what could be the likely next step in a given sequence of events described in a story.

Context: One day Wesley's auntie came over to visit. He was happy to see her, because he liked to play with her. When she started to give his little sister attention, he got jealous. He got angry at his auntie and bit her hand when she wasn't looking.

Incorrect Ending: She gave him a cookie for being so nice.
Correct Ending: He was scolded.

Figure 1: Example from the story-cloze task: predict the correct ending to a given short story out of provided options.

Recently, Mostafazadeh et al. (2016) introduced the story-cloze task for testing this ability, albeit without the aspect of language generation. This task requires choosing the correct ending to a given four sentences long story (also referred to as *context*) from two provided alternatives. Fig. 1 shows an example story consisting of a short context, and two ending options.

In this work we address this story-cloze task. While the short nature and third person narrative style of these stories help us circumvent the problem of speaker identification and processing long

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1603–1614
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

dialogues, the crowdsourced dataset ensures that they reflect real-world and commonsense stories. Our approach emphasizes the joint contribution of multiple aspects to story understanding, which future research can build upon.

In this paper we explore three semantic aspects of story understanding: (i) the sequence of events described in the story, (ii) the evolution of sentiment and emotional trajectories, and (iii) topical consistency. The first aspect is motivated from approaches in semantic script induction, and evaluates if events described in an ending-alternative *are likely* to occur within the sequence of events described in the preceding context. For example, in the story in Fig. 1, Wesley gets angry and bites his sister's hand. So, a next likely step might suggest that he would be scolded. However, there are multiple semantic aspects to story understanding beyond analyzing events and scripts. Stories often describe characters (e.g. Wesley) who need to be viewed as social and emotional agents. They not only describe events involving these characters, but also reflect their social lives and emotional states. Our model captures this by evaluating if the sentiment described in an ending option *makes sense* considering the context of the story. For example, in the story in Fig. 1, the general sentiment of being *scolded* is better aligned with the sentiment of Wesley being *angry* and *jealous*, compared to that of *being nice*. Also, stories generally revolve around coherent themes and topics. Our model accounts for that by analyzing if the topic of an ending option is consistent with the preceding context. We present a log-linear model that is used to weigh the various aspects of the story using a hidden variable. It then uses this hidden variable to predict the correct ending for the given story.

We demonstrate the strength of our approach by comparing it with the existing state-of-the-art methods for this task. We first validate the predictive potential of the features that correspond to the three semantic aspects through a simple classifier trained using these features. We then demonstrate the benefit of using our hidden variable approach by showing that it significantly outperforms the above mentioned classifier and other baselines, and achieves an accuracy of 77.60% on the task. Our key contributions are:

- We model story understanding as a joint model over multiple semantic aspects, and utilize the idea for predicting a story's end.
- We design linguistic features that incorporate world knowledge and narrative awareness.
- We present a hidden variable approach to weigh these aspects in a story's context.
- We empirically demonstrate that our approach significantly outperforms state-of-the-art methods.

2 Predicting Story Ending

Given an L sentences long context, $\mathbf{c} = \langle c_1, c_2, c_3 \ldots c_L \rangle$, and two ending-options, o_1 and o_2, we aim to predict which ending option forms an inconsistent story. This is a binary classification task. We assume that the inconsistency can arise from one (or more) of certain semantic aspects. In this section, we first describe the intuition behind using these aspects and the features that we designed to capture them (Sec. 2.1). We then describe our model which uses a latent variable to weigh these aspects in light of the story, and then predicts its ending (Sec. 2.2).

2.1 Measuring Consistency

Our approach analyzes the following aspects of story understanding: Event-sequence, Sentiment-trajectory, and Topical Consistency.

Event-sequence: For a story, or any piece of text, to be coherent, it needs to describe a meaningful or 'mutually entailing' sequence of events (Chatman, 1980). For instance, in Figure 1 *Wesley got angry* → *Wesley bit her hand* → *Wesley was scolded* describes a more coherent sequence of events, as compared to *Wesley got angry* → *Wesley bit her hand* → *Wesley got a cookie*

Prior work in script-learning attempts to model such *prototypical* sequence of events (usually captured through verbs). For this task, we wanted to model events at an abstraction level that would be generalizable and yet semantically meaningful. Peng and Roth (2016) recently proposed a neural SemLM approach, to model such sequence of events using a language model of FrameNet (Baker et al., 1998) frames that are evoked in the given text. It represents an event using the corresponding predicate frame and its sense, obtained using a Sematic Role Labeler (Punyakanok et al., 2004). It also extends the frame definition to include explicit discourse markers (such as *but*, *and*) since they model relationships between frames. For example, in Figure 1, the SemLM representation for the last sentence of the context is 'Get.01-and-bit.01'. Here, '01' indicates specific predicate senses for verbs 'get' and 'bit' with 'and' being a discourse marker. Also, it produces 'scold.01' and 'give.01' for the correct and incorrect endings respectively. We train this language model using a log bilinear language model (Mnih and Hinton, 2007) on a collection of unannotated short stories (see Sec. 3.1) and also 20 years of New York Times data[1].

Given a sequence of frames evoked in the context, such a trained language model can then be used to get the conditional probabilities of the frame(s) evoked in each of the two ending-options. The option with more probable frame(s) is likely to be the appropriate ending. With this intuition in mind, for each of the two ending-option, o_i, we design features whose values are probabilities of frames evoked in that option (f_{o_i}), given the sequence of frames, $\langle f_1, f_2, \ldots f_D \rangle$, evoked in the context, $\mathbf{c} = \langle c_1, c_2, c_3 \ldots c_L \rangle$. We consider increasingly longer frame-contexts for conditional probability computation, i.e. for each option, o_i, we extract the following features: $P(f_{o_i}|f_D)$, $P(f_{o_i}|f_D f_{D-1})$, $\ldots$ $P(f_{o_i}|f_D f_{D-1} \ldots f_1)$. For each of these features, we additionally also include a comparative binary feature whose value is 1 if the conditional probability of one of the options (o_2) is greater than the corresponding conditional probability of the other option (o_1) (E.g. $P(o_2|f_D) > P(o_1|f_D)$), and -1 otherwise. Our preliminary experiments indicated that these features were helpful for supervised classification.

Sentiment-trajectory: As mentioned before, stories are different from objective texts such as news articles, as they additionally describe sentiments or emotions. Some stories can be categorized as happy stories while others as sad. However, most stories depict evolving sentiments in their plots as they progress (Vonnegut, 1981).

With the goal of modeling such sentiment trajectories, we assumed that a story can be divided into the following narrative-segments: a *beginning*, a *body*, a *climax*, and an *ending*. While this narrative-segmentation process warrants deeper research, in this paper we adopt a simple methodology. We treat the first sentence of the L sentences long context as the *beginning*, the next $L-2$ sentences are treated as the *body*, the last sentence of the context forms the *climax*, and the two options form the (possible) *ending*[2]. We then assigned a positive, negative, or neutral sentiment to each segment, represented as $\mathbb{S}(segment) = \text{sign}($number of positive words - number of negative words$)$ in the segment. The sentiment polarity of a word was determined by a look-up from pre-trained sentiment lexica (Liu et al., 2005; Wilson et al., 2005)[3]. Thus, the L length context can now be viewed as a sequence of its segment's sentiments. Lastly, we learn sentiment trajectories in form of N-gram language models from an unannotated corpus of short stories (Sec. 3.1) that learn: (i) $P(\mathbb{S}(ending)|\mathbb{S}(climax), \mathbb{S}(body), \mathbb{S}(beginning))$; (ii) $P(\mathbb{S}(ending)|\mathbb{S}(climax), \mathbb{S}(body))$; and (iii) $P(\mathbb{S}(ending)|\mathbb{S}(climax))$.

The process described above learns typical sentiment trajectories over narrative-segments. However, it does not model a story's *overall* sentiment (i.e. whether it is a happy or a sad story, *in general*). To capture this notion, we train another language model to learn $P(\mathbb{S}(ending)|\mathbb{S}(context))$, where $\mathbb{S}(context)$ is the sentiment of the full context (without segmentation).

Finally, for each ending option, we extract features whose values are the four conditional probabilities described above. As before we also consider four comparative binary features.

Topical Consistency: This aspect is motivated by the idea that stories are topically cohesive (Bamberg, 2012), and in a typical story, new topics (concepts, entities or ideas) are not introduced towards the end because it does not allow the story-writer enough narrative space and time to develop and describe them (Jovchelovitch and Bauer, 2000). We capture the notion of topic of a sentence using *topic-words* (the nouns and verbs appearing in it (Lapata and Barzilay, 2005)). For each option, we first *align* each of its topic-words with the most similar topic-word in one of the context-sentences, while defining the alignment score as this similarity value. We measure similarity between two words using the cosine similarity of their vector space representations (using

[1] Owing to the large size of the training data and the fact that we abstract to the frame-semantic (and not verb) level, we cover most instances (76%) in our dataset.

[2] The reported segmentation process made sense from qualitative analysis on a random sample, and also led to superior performance compared to alternate strategies.

[3] Polarities of 'negated' word were reversed (determined from *neg* dependency relation in the corresponding sentence).

pretrained GloVe (Pennington et al., 2014) vectors). We then quantify the *topical-closeness* of an ending option with the context using averaged alignment score of its topic-words[4]. For each ending option, we extract one feature whose value is this *topical-closeness* with the context. As before, we also include a binary comparative feature.

2.2 Hidden Coherence Model

Sec. 2.1 described the three semantic consistency aspects and the corresponding features. We now describe our model which uses these features (represented as $\vec{f}_{co}$ in the rest of this paper) to identify the (in)coherent ending-option. The model is also dependent on another feature set, $\vec{\phi}_{co}$, which will be discussed later in this section.

Formally, our model addresses the following binary classification problem: given the multi-sentence context, $\mathbf{c}$, and two ending-options, o_1 and o_2, predict the answer, $a \in \{0, 1\}$. The correct ending for the story is o_1 when $a = 0$ and o_2 otherwise. Our training data consists of instances (context and ending options) labeled with corresponding answers a. It does not contain any other annotation (like semantic consistency aspects).

The model proceeds by assuming that there are K different semantic consistency aspects and that an ending-option can lead to an incoherent story by violating any of these aspects (our implementation uses $K = 3$ corresponding to the three aspects described in Sec. 2.1). The model achieves this by assuming that each instance belongs to a latent category, $z \in \{1, 2, 3 \ldots K\}$, which advises the model on the importance of these aspects for the given instance. Using these definitions and assumptions, the probability of an answer given the context and the ending-options can be modeled as:

$$P(a|\mathbf{c}, o_1, o_2) = \sum_{z}^{K} P(z|\mathbf{c}, o_1, o_2) P(a|z, \mathbf{c}, o_1, o_2)$$

We parameterize $P(z|\mathbf{c}, o_1, o_2)$ as:

$$P(z|\mathbf{c}, o_1, o_2) = \frac{e^{-\vec{\lambda}_z \vec{\phi}_{co}}}{\sum_k e^{-\vec{\lambda}_k \vec{\phi}_{co}}}$$

where, $\vec{\phi}_{co}$ is the feature vector used for assigning a value to the hidden variable for an instance, and $\vec{\lambda}_z$ is the weight vector of the log-linear model for the z^{th} aspect. There are K weight vectors, one corresponding to each of the K aspects.

For predicting the answer, a, we assume that each aspect has a separate logistic-regression based prediction model parameterized as:

$$P(a|z, \mathbf{c}, o_1, o_2) = \frac{(e^{-\vec{w}_z \vec{f}^z_{co}})^{1-a}}{1 + e^{-\vec{w}_z \vec{f}^z_{co}}}$$

where $\vec{f}^z_{co}$ is the feature vector constructed from the context and ending-options for the z^{th} aspect, and $\vec{w}_z$ are the corresponding weights.

Training: The model parameters, $\vec{w}_z$ and $\vec{\lambda}_z$, are learned during the training process by maximizing the log-likelihood of the data. We use Expectation-Maximization (Dempster et al., 1977) for training. During the E-step we compute the expectations for latent variable assignments using parameter values from the previous iteration as:

$$< z_n^k > \propto \frac{e^{-\vec{\lambda}_k \vec{\phi}_{co}}}{\sum_{k'}^{K} e^{-\vec{\lambda}_{k'} \vec{\phi}_{co}}} P(a_n | z_n^k, \mathbf{c}_n, o_{1n}, o_{2n})$$

where, a subscript of n represents the n^{th} training instance out of a total of N instances. z_n^k represents n^{th} instance getting assigned to the k^{th} aspect, and $<>$ denotes expected values.

In the M-step, given the expected assignments, we maximize the following expected log complete likelihood with respect to the model parameters using gradient ascent:

$$\begin{aligned} < L > \quad = \quad & \sum_{n}^{N} \sum_{k}^{K} < z_n^k > \Big(\log \frac{e^{-\vec{\lambda}_k \vec{\phi}_{co}}}{\sum_{k'}^{K} e^{-\vec{\lambda}_{k'} \vec{\phi}_{co}}} \\ & + \quad \log \frac{(e^{-\vec{w}_k \vec{f}^k_{co}})^{1-a_n}}{1 + e^{-\vec{w}_k \vec{f}^k_{co}}} \Big) \end{aligned}$$

Features: Our model uses two types of features: (i) for aspect-specific prediction model, $\vec{f}^k_{co}$, and (ii) for hidden aspect assignment, $\vec{\phi}_{co}$. The features extracted for each of the $K = 3$ aspects, $\vec{f}^k_{co}$, were described in Sec. 2.1. For the hidden aspect assignment, we needed features that could analyze the two options in light of the given context, and characterize the importance of various aspects for the given instance. One way to measure an aspect's importance is by quantifying how different the two options are with respect to that aspect. The underlying assumption is that the option that

[4] An alternative would be to compute similarity between averaged vector representations of the topic-words of the context and the ending-option(s). However, that assumes that a story is strictly about a single topic. Instead they reflect interplay of multiple related and 'narrow topics. E.g. a story describing a teacher walking in rain is about topics like 'teacher', 'walk', 'rain', etc. The correct ending option describes a passer-by helping the teacher. 'passer-by' was far from an average of all topics but close to the 'walk' topic.

leads to an inconsistent story, by compromising on one of the aspects, would differ significantly from the other option in that aspect. We quantify an aspect's importance using the normalized $L1$ distance between the corresponding features, $\vec{f_{co}^k}$, extracted for the two options in Sec. 2.1 (ignoring the comparative binary features, and normalizing by the number of features). Specifically, for an aspect k, lets represent the feature extracted for the two options by $\vec{f_1^k}$ and $\vec{f_2^k}$ (each of length n) then the corresponding 'importance feature' for this aspect $= |\vec{f_1^k} - \vec{f_2^k}|/n$. For example, for topical-consistency, for each option, we extracted 1 feature measuring its *topical-closeness* to the context. For $\vec{\phi}_{co}$ computation we consider the absolute difference between this value for the two options. To summarize, for each instance, we define $\vec{\phi}_{co}$ as a set of $K + 1$ features: K of these measure the importance of each of the aspects, while the last one is an additional always-one feature which captures the context-insensitive bias in the data.

3 Empirical Evaluation

In this section we describe our experiments.

3.1 Dataset

For our experiments, we have used a publicly available collection of commonsense short stories released by Mostafazadeh et al. (2016). It consists of about 100K unannotated five-sentences long stories. For collecting these stories, Amazon Mechanical Turk workers were asked to compose novel five-sentence long stories on everyday topics. They were prompted to write coherent stories with a specific beginning and ending, with *something* happening in between. This resulted in a wide variety in topics with causal and temporal links between the events described in the story. Also, the workers were asked to limit the length of individual sentences to 70 characters which yielded short and succinct sentences, and to not use informal language or quotations.

The dataset also contains an additional set of $3,742$ four-sentences long stories (context) with two ending options, only one of which is correct. Each instance is annotated with this correctness information. This set was collected by asking Amazon Mechanical Turk workers to write a coherent and an incoherent ending to a given short story. The workers were asked to ensure that both the options shared at least one character from the story, and that the options, in isolation, made sense. This resulted in non-trivial alternative endings, and was also validated by other human subjects for high quality. This set was divided by Mostafazadeh et al. (2016) into validation and test sets of 1871 instances each for the Story-Cloze Task, and were used for training and evaluating our model.

3.2 Baselines

We use the following baselines in our experiments:
DSSM: (Mostafazadeh et al., 2016) It trains two deep neural networks (Huang et al., 2013) to project the context and the ending-options into the same vector space. Based on these vector representations, it predicts the ending-option with the largest cosine similarity with the context.
Msap: The task addressed in this paper was also a shared task for an EACL'17 workshop and this baseline (Schwartz et al., 2017) represents the best performance reported on its leaderboard (Mostafazadeh et al., 2017). It trains a logistic regression based on stylistic and language-model based features.
LR: Our next baseline is a simple logistic regression model which is agnostic to the fact that there are multiple types of aspects. Given a context and ending-options, it predicts the answer using the same features (Sec. 2.1) as the Hidden Coherence model but clubs them all into one feature-vector.
Majority Vote: This ensemble method uses the features extracted for each of the $K = 3$ aspects, to train K separate logistic regression models. It then makes a prediction by taking a majority vote of these K classifiers.
Soft Voting: This baseline also learns K different aspect-specific classifiers. However, instead of taking a majority vote, it computes a score for each option, o_i, as $\Pi_k^K P_k(ending = o_i|\mathbf{c}, o_1, o_2)$. Here P_k represents the probability obtained from the k^{th} logistic regression. The final prediction corresponds to the option with greater score.
Aspect-aware Ensemble: Like the voting methods, this baseline also trains K different aspect-specific classifiers. However, it makes the final prediction by training another logistic regression over their predictions.

3.3 Quantitative Results

Table 1 shows accuracies of various models on the held-out test set. An always-one classifier would get 51.3% accuracy on the task and human performance is reported to be 100% (Mostafazadeh

Model	Accuracy
DSSM (Mostafazadeh et al., 2016)	58.5%
Msap (Schwartz et al., 2017)	75.2%
Majority Voting	69.5% *
Aspect aware ensemble	71.5% *
LR	74.4% *
Soft Voting	75.1%
Hidden Coherence Model	77.6% *

Table 1: Test-set accuracies of various models. Our Hidden Coherence Model outperforms competitive baselines and state-of-the-art system.

et al., 2016). A * indicates that the model's accuracy was significantly better than the previous best model in the table (using McNemar's test with $\alpha = 0.1$). We can see that the logistic regression, LR, outperforms the DSSM model indicating the strength of the features extracted for the various story-consistency aspects. Also, the Soft Voting approach gives us slight benefit over the LR model, possibly because of increased expressivity which includes better *organization* of features into groups or aspects. Majority Vote, in spite of sharing a similar classifier structure, does not perform as well. This might happen because it takes a *hard* vote of individual classifiers, which might be detrimental to model performance if one of the classifiers is weak. Our analysis in Sec. 3.4 shows that the topical-consistency features indeed result in a relatively weak classifier. The Aspect aware Ensemble performs better possibly because of its ability to weight the aspects (though not in context of the story).

Lastly, we can see that the proposed Hidden Coherence model, with an accuracy of 77.60%, outperforms all other models. The superior performance of our model indicates the benefit of the context-sensitive weighing of individual consistency aspects.

3.4 Ablation Study

We now investigate the predictive value of the various aspect-specific features. Table 2 shows the performance of a logistic regression model trained using all the features (All) and then using individual feature-groups. We can see that the features extracted from the aspect analyzing the event-sequence have the strongest predictive power, followed by those characterizing Sentiment-trajectory. The features measuring topical consistency result in lowest accuracy but they still perform better than random on the task.

Features	Accuracy
All	74.4%
Event-sequence	71.6%
Sentiment	64.5%
Topic	55.2%

Table 2: Performance comparison of various aspect features. Our event-sequence based features are most helpful followed by Sentiment-trajectory and then Topical Consistency based features.

3.5 Qualitative Results

Table 3 shows example stories, and weights given to the three aspects. An aspect's weight is its contribution towards the predicted output, and is shown as a bar of vertically stacked blocks in the last column. A block's height is proportional to its aspect's weight. Light grey block represents Event-sequence, and dark grey and black blocks represent Sentiment-trajectory and Topical consistency respectively.

The first row describes the story of a man hurting himself. A human reader can guess from commonsense knowledge that people usually recover (correct ending) after being hurt and do not repeat their mistake (incorrect ending). Accordingly, our model also primarily used the aspect analyzing events in this story, which is indicated by the long light grey block in its weight bar. Also, we can see that the topic of both the options is consistent with the story, and the model gave a very small weight to the Topical Consistency aspect indicated by the almost indiscernible black block in its weight bar. Similarly, the second row describes the story of Pam being proud of her yard work. There is a striking sentimental contrast between the two options (*upset* versus *satisfied*), and the model relies primarily on sentiments (dark grey). The last row, describes the story of Maria making candy apples. The incorrect ending introduces a new entity/idea, *apple pie*, resulting in topical incoherence of this option with the rest of the story. The model relies primarily on topic (black) and events (light grey). Reliance on events makes sense because it is likely for a person to *enjoy* what they fondly *cook*. The model gave a weight of 40% to the topical aspect, which is high as compared to its average weight across the dataset.

Context	Incorrect Ending	Correct Ending	Weights
He didn't know how the television worked. He tried to fix it, anyway. He climbed up on the roof and fiddled with the antenna. His foot **slipped** on the wet shingles and he went tumbling down.	He decided that was fun and to try tumbling again.	Thankfully, he **recovered**.	
Pam thought her front yard looked boring. So she decided to buy several plants. And she placed them in her front yard. She was **proud** of her work.	Pam was **upset** at herself.	Pam was **satisfied**.	Maria smelled the fresh Autumn air and decided to celebrate. She wanted to make candy apples. She picked up the ingredients at a local market and headed home. She cooked the candy and prepared the apples.	Maria's apple **pie** was delicious.	She enjoyed the candy apples.	
Table 3: Examples of stories, ending-options, and aspect weights learned by our model. Aspect weights are shown as bars of stacked blocks in the last column (light grey, dark grey and black represent Event-sequence, Sentiment-trajectory and Topical Consistency respectively). A block's height is proportional to its component's weight. Black blocks are sometimes not visible because there were too small.

3.6 Discussion

Error Analysis: Table 4 shows examples of stories for which our model could not predict the correct ending. We believe that many of these stories require a deeper understanding of language and commonsense. For example, in the story described in the first row, the protagonist accepted an invitation from his friends to go to a club but danced terribly, and so he was asked to stay home the next time. To make the correct prediction in this story, the model not only needs to understand that if one does not dance well at a club they are likely to be not invited in the future, but also that staying home is the same as not getting invited. Similarly, the second row shows a story in which Johnny asks Anita out, but she makes an excuse. He later sees her with another guy and decides not to ask her out again. This example requires identifying that Anita's excuse was a lie indicating her disinterest in Johnny, which makes it unlikely for Johnny to invite her again. It also needs an understanding of inter-personal relationships, i.e. seeing a potential lover with another person leads to estrangement.

Social Analysis: To further explore the significance of social relations in stories, we consider the special case of romantic stories. We use a deterministic heuristic to identify romantic stories using lexical matches with a handcrafted list containing words like *marry*, *proposal*, *girlfriend*, *ask out*, etc. We then applied the following two rules: (i) if a story contains two characters, then output the option whose sentiment matches that of the context, (ii) if a story contains three characters, then output the option with negative sentiment. Most stories in our dataset contained few characters. These rules are motivated by the intuition that a romantic story between two people can have a happy or sad ending depending on the context. However, a romantic story with three people is likely to describe a love triangle, and so not end well. Expectedly, these rules had low coverage (of about 60 stories), but a considerably high accuracy (70%) when active. Furthermore, a closer analysis revealed that most errors resulted from incorrect coreference resolutions (leading to incorrect count of characters). This indicates the utility of understanding semantics of social relationships for story comprehension and it could potentially be another aspect to consider while solving such tasks.

Sentiment Analysis: We now explore the insights obtained by modeling sentiments in stories. Mostafazadeh et al. (2016) presented two baselines for this task whose outputs were simply the *ending* whose sentiment agreed with (i) the complete story, or (ii) the *climax* (last sentence of the story). While their performances were close to random, our sentiment based features yield a much higher accuracy of 64.5% (see Table 2). This could possibly be attributed to our approach's ability to learn such rules from the data itself, rather

Context	Incorrect Ending	Correct Ending
My friends all love to go to the club to dance. They think it's a lot of fun and always invite. I finally decided to tag along last Saturday. I danced terribly and broke a friend's toe.	The next weekend, I was asked to please stay home.	My friends decided to keep inviting me as I am so much fun.
Johnny thought Anita was the girl for him, but he was wrong. He invited her out but she said she didn't feel well. Johnny decided to go to a club, just to drink and listen to music. At midnight, he looked back and saw Anita dancing with another guy.	Johnny did not ask Anita out again.	Johnny wanted to ask Anita out again.

Table 4: Examples of stories incorrectly predicted by our model.

than making hard assumptions. For instance, our language model of overall narrative sentiments indicates that while happy stories mostly have happy endings (with a conditional probability of 74%), the reverse is not true. In particular, sad stories (with overall negative sentiments) end with a negative sentiment in only 52% of the cases. We made similar observations regarding sentimental conformity between endings and climaxes.

Our features' superior performance can also be attributed to their deeper understanding of not just overall sentiments but also their trajectories. Our language models indicate that stories that exhibit a positive sentiment in all three narrative segments (beginning, body, and climax) have very high chance of happy endings (83%). Similarly, stories with negative sentiments in the three segments also have a fair chance of having sad endings (60%). This is different from stories with an overall negative sentiment, in which case the sentiment may be exhibited in only certain narrative segments. The language models also identify a pattern of *hopeful* stories, in which the sentiment begins as negative but moves towards positive in the body and climax, resulting in mostly happy endings ($\sim$ 70%). This was not true for the reverse case: *pessimistic* stories with positive beginning but negative body (and/or climax) were equally likely to have positive or negative endings (52%). Supplementary material contains sample stories for each of the above observations.

4 Related Work

We now review previous work done in this field. Our work touches upon several research areas.

4.1 Story understanding:

Our work is most closely related to the field of narrative understanding. Apart from event-centric understanding of narrative plots (Lehnert, 1981; McIntyre and Lapata, 2010; Goyal et al., 2010; Elsner, 2012; Finlayson, 2012), recent methods have focused on understanding narratives from the perspective of characters (Wilensky, 1978) mentioned in them. These methods study character personas (Bamman et al., 2013, 2014) or Proppian (Propp, 1968) roles (Valls-Vargas et al., 2014, 2015), inter-character relationships (Iyyer et al., 2016; Chaturvedi et al., 2016, 2017), and social networks of characters (Elson et al., 2010; Elson, 2012; Agarwal et al., 2013, 2014; Krishnan and Eisenstein, 2015; Srivastava et al., 2016).

4.2 Events-centered learning:

Our Entity-sequence component is closely related to semantic script learning. Script learning focuses on representing text using a prototypical sequences of events, their participants and causal relationships between them, called scripts (Schank and Abelson, 1977; Mooney and DeJong, 1985). Several statistical methods have been proposed to automatically learn scripts or scripts-like structures from unstructured text (Chambers and Jurafsky, 2008, 2009; Jans et al., 2012; Orr et al., 2014; Pichotta and Mooney, 2014). Such methods for script-learning also include Bayesian approaches (Bejan, 2008; Frermann et al., 2014), sequence alignment algorithms (Regneri et al., 2010) and neural networks (Modi and Titov, 2014; Granroth-Wilding and Clark, 2016; Pichotta and Mooney, 2016). There has also been work on representing events in a structured manner using schemas, which are learned probabilistically (Chambers, 2013; Cheung et al., 2013;

Nguyen et al., 2015), using graphs (Balasubramanian et al., 2013) or neural approaches (Titov and Khoddam, 2015). Recently, Ferraro and Durme (2016) presented a unified Bayesian model for scripts and frames.

4.3 Textual Coherence:

Our work is also related to the study of coherence in discourse. A significant amount of prior work is primarily based on the Centering Theory Framework (Grosz et al., 1995) and focus on entities and their syntactic roles (Karamanis, 2003; Karamanis et al., 2004; Lapata and Barzilay, 2005; Barzilay and Lapata, 2008; Elsner and Charniak, 2008). Other approaches measure coherence using topic drift within a domain (Barzilay and Lee, 2004; Fung and Ngai, 2006), co-occurrence of words (Lapata, 2003; Soricut and Marcu, 2006), syntactic patterns (Louis and Nenkova, 2012) and discourse relations (Pitler and Nenkova, 2008; Lin et al., 2011). The nature of the tasks addressed by these works (such as determining the correct arrangement order for a set of sentences) makes them focus on learning sequential order of the various discourse components (entities, ideas, etc.). Our goal, instead, is to choose between alternatives of discourse components themselves (and not just their order) to produce a consistent story.

5 Conclusion

Story comprehension is a complex Natural Language Understanding task involving linguistic intelligence as well as a semantic and social knowledge of the real world. This paper studies story comprehension from the perspective of learning what is likely to happen next in a story. We present a model that given a short story, predicts its correct ending. It incorporates three aspects of story-understanding, that are based on an analysis of the events, sentiments and topics described in the story. While this is the best-performing model till date on this task, our analysis indicates a need for even deeper analysis of human behavior and societal norms to further improve our understanding. This work emphasizes that there are multiple aspects to story understanding, which future research can build upon.

Abstract

NLP tasks are often limited by scarcity of manually annotated data. In social media sentiment analysis and related tasks, researchers have therefore used binarized emoticons and specific hashtags as forms of distant supervision. Our paper shows that by extending the distant supervision to a more diverse set of noisy labels, the models can learn richer representations. Through emoji prediction on a dataset of 1246 million tweets containing one of 64 common emojis we obtain state-of-the-art performance on 8 benchmark datasets within emotion, sentiment and sarcasm detection using a single pretrained model. Our analyses confirm that the diversity of our emotional labels yield a performance improvement over previous distant supervision approaches.

1 Introduction

A variety of NLP tasks are limited by scarcity of manually annotated data. Therefore, co-occurring emotional expressions have been used for distant supervision in social media sentiment analysis and related tasks to make the models learn useful text representations before modeling these tasks directly. For instance, the state-of-the-art approaches within sentiment analysis of social media data use positive/negative emoticons for training their models (Deriu et al., 2016; Tang et al., 2014). Similarly, hashtags such as #anger, #joy, #happytweet, #ugh, #yuck and #fml have in previous research been mapped into emotional categories for emotion analysis (Mohammad, 2012).

Distant supervision on noisy labels often enables a model to obtain better performance on the target task. In this paper, we show that extending the distant supervision to a more diverse set of noisy labels enables the models to learn richer representations of emotional content in text, thereby obtaining better performance on benchmarks for detecting sentiment, emotions and sarcasm. We show that the learned representation of a single pretrained model generalizes across 5 domains.

Table 1: Example sentences scored by our model. For each text the top five most likely emojis are shown with the model's probability estimates.

I love mom's cooking	😋 49.1%	😍 8.8%	❤ 3.1%	☺️ 3.0%	♡ 2.9%
I love how you never reply back..	😒 14.0%	😑 8.3%	😠 6.3%	😐 5.4%	💔 5.1%
I love cruising with my homies	😎 34.0%	👌 6.6%	✌ 5.7%	😌 4.1%	💯 3.8%

This is the shit	🎧 10.9%	🎶 9.7%	👌 6.5%	😎 5.7%	😏 4.8%

Emojis are not always a direct labeling of emotional content. For instance, a positive emoji may serve to disambiguate an ambiguous sentence or to complement an otherwise relatively negative text. Kunneman et al. (2014) discuss a similar duality in the use of emotional hashtags such as *#nice* and *#lame*. Nevertheless, our work shows that emojis can be used to classify the emotional content of texts accurately in many cases. For instance, our DeepMoji model captures varied usages of the word 'love' as well as slang such as 'this is the shit' being a positive statement (see Table 1). We provide an online demo at deepmoji.mit.edu to allow others to explore the predictions of our model.

Contributions We show how millions of readily available emoji occurrences on Twitter can be used to pretrain models to learn a richer emotional

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1615–1625
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

representation than traditionally obtained through distant supervision. We transfer this knowledge to the target tasks using a new layer-wise fine-tuning method, obtaining improvements over the state-of-the-art within a range of tasks: emotion, sarcasm and sentiment detection. We present multiple analyses on the effect of pretraining, including results that show that the diversity of our emoji set is important for the transfer learning potential of our model. Our pretrained DeepMoji model is released with the hope that other researchers can use it for various NLP tasks[1].

2 Related work

Using emotional expressions as noisy labels in text to counter scarcity of labels is not a new idea (Read, 2005; Go et al., 2009). Originally, binarized emoticons were used as noisy labels, but later also hashtags and emojis have been used. To our knowledge, previous research has always manually specified which emotional category each emotional expression belong to. Prior work has used theories of emotion such as Ekman's six basic emotions and Plutchik's eight basic emotions (Mohammad, 2012; Suttles and Ide, 2013).

Such manual categorization requires an understanding of the emotional content of each expression, which is difficult and time-consuming for sophisticated combinations of emotional content. Moreover, any manual selection and categorization is prone to misinterpretations and may omit important details regarding usage. In contrast, our approach requires no prior knowledge of the corpus and can capture diverse usage of 64 types of emojis (see Table 1 for examples and Figure 3 for how the model implicitly groups emojis).

Another way of automatically interpreting the emotional content of an emoji is to learn emoji embeddings from the words describing the emoji-semantics in official emoji tables (Eisner et al., 2016). This approach, in our context, suffers from two severe limitations: a) It requires emojis at test time while there are many domains with limited or no usage of emojis. b) The tables do not capture the dynamics of emoji usage, i.e., drift in an emoji's intended meaning over time.

Knowledge can be transferred from the emoji dataset to the target task in many different ways. In particular, multitask learning with simultaneous training on multiple datasets has shown promising results (Collobert and Weston, 2008). However, multitask learning requires access to the emoji dataset whenever the classifier needs to be tuned for a new target task. Requiring access to the dataset is problematic in terms of violating data access regulations. There are also issues from a data storage perspective as the dataset used for this research contains hundreds of millions of tweets (see Table 2). Instead we use transfer learning (Bengio et al., 2012) as described in §3.3, which does not require access to the original dataset, but only the pretrained classifier.

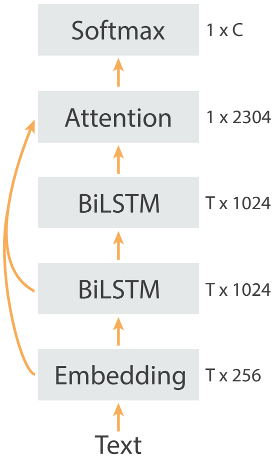

Figure 1: Illustration of the DeepMoji model with S being text length and C the number of classes.

3 Method

3.1 Pretraining

In many cases, emojis serve as a proxy for the emotional contents of a text. Therefore, pretraining on the classification task of predicting which emoji were initially part of a text can improve performance on the target task (see §5.3 for an analysis of why our pretraining helps). Social media contains large amounts of short texts with emojis that can be utilized as noisy labels for pretraining. Here, we use data from Twitter from January 1st 2013 to June 1st 2017, but any dataset with emoji occurrences could be used.

Only English tweets without URL's are used for the pretraining dataset. Our hypothesis is that the content obtained from the URL is likely to be important for understanding the emotional content of the text in the tweet. Therefore, we expect emojis associated with these tweets to be noiser labels

[1] Available with preprocessing code, examples of usage, benchmark datasets etc. at github.com/bfelbo/DeepMoji

than for tweets without URLs, and the tweets with URLs are thus removed.

Proper tokenization is important for generalization. All tweets are tokenized on a word-by-word basis. Words with 2 or more repeated characters are shortened to the same token (e.g. 'loool' and 'looooool' are tokenized such that they are treated the same). Similarly, we use a special token for all URLs (only relevant for benchmark datasets), user mentions (e.g. '@acl2017' and '@emnlp2017' are thus treated the same) and numbers. To be included in the training set the tweet must contain at least 1 token that is not a punctuation symbol, emoji or special token[2].

Many tweets contain multiple repetitions of the same emoji or multiple different emojis. In the training data, we address this in the following way. For each unique emoji type, we save a separate tweet for the pretraining with that emoji type as the label. We only save a single tweet for the pretraining per unique emoji type regardless of the number of emojis associated with the tweet. This data preprocessing allows the pretraining task to capture that multiple types of emotional content are associated with the tweet while making our pretraining task a single-label classification instead of a more complicated multi-label classification.

To ensure that the pretraining encourages the models to learn a rich understanding of emotional content in text rather than only emotional content associated with the most used emojis, we create a balanced pretraining dataset. The pretraining data is split into a training, validation and test set, where the validation and test set is randomly sampled in such a way that each emoji is equally represented. The remaining data is upsampled to create a balanced training dataset.

3.2 Model

With the millions of emoji occurrences available, we can train very expressive classifiers with limited risk of overfitting. We use a variant of the Long Short-Term Memory (LSTM) model that has been successful at many NLP tasks (Hochreiter and Schmidhuber, 1997; Sutskever et al., 2014). Our DeepMoji model uses an embedding layer of 256 dimensions to project each word into a vector space. A hyperbolic tangent activation function is used to enforce a constraint of each embedding dimension being within $[-1, 1]$. To capture the context of each word we use two bidirectional LSTM layers with 1024 hidden units in each (512 in each direction). Finally, an attention layer that take all of these layers as input using skip-connections is used (see Figure 1 for an illustration).

The attention mechanism lets the model decide the importance of each word for the prediction task by weighing them when constructing the representation of the text. For instance, a word such as 'amazing' is likely to be very informative of the emotional meaning of a text and it should thus be treated accordingly. We use a simple approach inspired by (Bahdanau et al., 2014; Yang et al., 2016) with a single parameter pr. input channel:

$$\begin{aligned} e_t &= h_t w_a \\ a_t &= \frac{exp(e_t)}{\sum_{i=1}^{T} exp(e_i)} \\ v &= \sum_{i=1}^{T} a_i h_i \end{aligned}$$

Here h_t is the representation of the word at time step t and w_a is the weight matrix for the attention layer. The attention importance scores for each time step, a_t, are obtained by multiplying the representations with the weight matrix and then normalizing to construct a probability distribution over the words. Lastly, the representation vector for the text, v, is found by a weighted summation over all the time steps using the attention importance scores as weights. This representation vector obtained from the attention layer is a high-level encoding of the entire text, which is used as input to the final Softmax layer for classification. We find that adding the attention mechanism and skip-connections improves the model's capabilities for transfer learning (see §5.2 for more details).

The only regularization used for the pretraining task is a L2 regularization of $1E{-}6$ on the embedding weights. For the finetuning additional regularization is applied (see §4.2). Our model is implemented using Theano (Theano Development Team, 2016) and we make an easy-to-use version available that uses Keras (Chollet et al., 2015).

3.3 Transfer learning

Our pretrained model can be fine-tuned to the target task in multiple ways with some approaches 'freezing' layers by disabling parameters updates to prevent overfitting. One common approach is

[2] Details available at github.com/bfelbo/deepmoji

to use the network as a feature extractor (Donahue et al., 2014), where all layers in the model are frozen when fine-tuning on the target task except the last layer (hereafter referred to as the *'last'* approach). Alternatively, another common approach is to use the pretrained model as an initialization (Erhan et al., 2010), where the full model is unfrozen (hereafter referred to as *'full'*).

We propose a new simple transfer learning approach, *'chain-thaw'*, that sequentially unfreezes and fine-tunes a single layer at a time. This approach increases accuracy on the target task at the expense of extra computational power needed for the fine-tuning. By training each layer separately the model is able to adjust the individual patterns across the network with a reduced risk of overfitting. The sequential fine-tuning seems to have a regularizing effect similar to what has been examined with layer-wise training in the context of unsupervised learning (Erhan et al., 2010).

More specifically, the chain-thaw approach first fine-tunes any new layers (often only a Softmax layer) to the target task until convergence on a validation set. Then the approach fine-tunes each layer individually starting from the first layer in the network. Lastly, the entire model is trained with all layers. Each time the model converges as measured on the validation set, the weights are reloaded to the best setting, thereby preventing overfitting in a similar manner to early stopping (Sjöberg and Ljung, 1995). This process is illustrated in Figure 2. Note how only performing step a) in the figure is identical to the 'last' approach, where the existing network is used as a feature extractor. Similarly, only doing step d) is identical to the 'full' approach, where the pretrained weights are used as an initialization for a fully trainable network. Although the chain-thaw procedure may seem extensive it is easily implemented with only a few lines of code. Similarly, the additional time spent on fine-tuning is limited when the target task uses GPUs on small datasets of manually annotated data as is often the case.

A benefit of the chain-thaw approach is the ability to expand the vocabulary to new domains with little risk of overfitting. For a given dataset up to 10000 new words from the training set are added to the vocabulary. §5.3 contains analysis on the added word coverage gained from this approach.

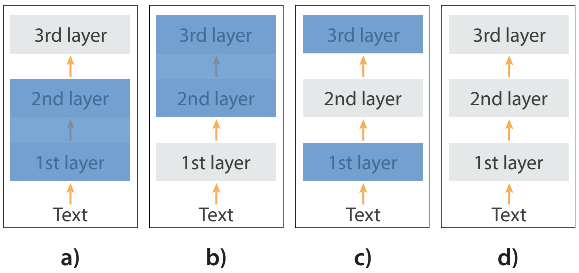

Figure 2: Illustration of the chain-thaw transfer learning approach, where each layer is fine-tuned separately. Layers covered with a blue rectangle are frozen. Step a) tunes any new layers, b) then tunes the 1st layer and c) the next layer until all layers have been fine-tuned individually. Lastly, in step d) all layers are fine-tuned together.

Table 2: The number of tweets in the pretraining dataset associated with each emoji in millions.

4 Experiments

4.1 Emoji prediction

We use a raw dataset of 56.6 billion tweets, which is then filtered to 1.2 billion relevant tweets (see details in §3.1). In the pretraining dataset a copy of a single tweet is stored once for each unique emoji, resulting in a dataset consisting of 1.6 billion tweets. Table 2 shows the distribution of tweets across different emoji types. To evaluate performance on the pretraining task a validation set and a test set both containing 640K tweets (10K of each emoji type) are used. The remaining tweets are used for the training set, which is balanced using upsampling.

The performance of the DeepMoji model is evaluated on the pretraining task with the results shown in Table 3. Both top 1 and top 5 accuracy is used for the evaluation as the emoji labels are noisy with multiple emojis being potentially correct for any given sentence. For comparison we also train a version of our DeepMoji model with smaller LSTM layers and a bag-of-words classifier, fastText, that has recently shown competitive results (Joulin et al., 2016). We use 256 dimen-

Table 3: Accuracy of classifiers on the emoji prediction task. d refers to the dimensionality of each LSTM layer. Parameters are in millions.

	Params	Top 1	Top 5
Random	–	1.6%	7.8%
fasttext	12.8	12.8%	36.2%
DeepMoji (d = 512)	15.5	16.7%	43.3%
DeepMoji (d = 1024)	22.4	17.0%	43.8%

sions for this fastText classifier, thereby making it almost identical to only using the embedding layer from the DeepMoji model. The difference in top 5 accuracy between the fastText classifier (36.2%) and the largest DeepMoji model (43.8%) underlines the difficulty of the emoji prediction task. As the two classifiers only differ in that the DeepMoji model has LSTM layers and an attention layer between the embedding and Softmax layer, this difference in accuracy demonstrates the importance of capturing the context of each word.

4.2 Benchmarking

We benchmark our method on 3 different NLP tasks using 8 datasets across 5 domains. To make for a fair comparison, we compare DeepMoji to other methods that also utilize external data sources in addition to the benchmark dataset. An averaged F1-measure across classes is used for evaluation in emotion analysis and sarcasm detection as these consist of unbalanced datasets while sentiment datasets are evaluated using accuracy.

An issue with many of the benchmark datasets is data scarcity, which is particularly problematic within emotion analysis. Many recent papers proposing new methods for emotion analysis such as (Staiano and Guerini, 2014) only evaluate performance on a single benchmark dataset, SemEval 2007 Task 14, that contains 1250 observations. Recently, criticism has been raised concerning the use of correlation with continuous ratings as a measure (Buechel and Hahn, 2016), making only the somewhat limited binary evaluation possible. We only evaluate the emotions {Fear, Joy, Sadness} as the remaining emotions occur in less than 5% of the observations.

To fully evaluate our method on emotion analysis against the current methods we thus make use of two other datasets: A dataset of emotions in tweets related to the Olympic Games created by Sintsova et al. that we convert to a single-label classification task and a dataset of self-reported emotional experiences created by a large group of psychologists (Wallbott and Scherer, 1986). See the supplementary material for details on the datasets and the preprocessing. As these two datasets do not have prior evaluations, we evaluate against a state-of-the-art approach, which is based on a valence-arousal-dominance framework (Buechel and Hahn, 2016). The scores extracted using this approach are mapped to the classes in the datasets using a logistic regression with parameter optimization using cross-validation. We release our preprocessing code and hope that these 2 two datasets will be used for future benchmarking within emotion analysis.

We evaluate sentiment analysis performance on three benchmark datasets. These small datasets are chosen to emphasize the importance of the transfer learning ability of the evaluated models. Two of the datasets are from SentiStrength (Thelwall et al., 2010), SS-Twitter and SS-Youtube, and follow the relabeling described in (Saif et al., 2013) to make the labels binary. The third dataset is from SemEval 2016 Task4A (Nakov et al., 2016). Due to tweets being deleted from Twitter, the SemEval dataset suffers from data decay, making it difficult to compare results across papers. At the time of writing, roughly 15% of the training dataset for SemEval 2016 Task 4A was impossible to obtain. We choose not to use review datasets for sentiment benchmarking as these datasets contain so many words pr. observation that even bag-of-words classifiers and unsupervised approaches can obtain a high accuracy (Joulin et al., 2016; Radford et al., 2017).

The current state of the art for sentiment analysis on social media (and winner of SemEval 2016 Task 4A) uses an ensemble of convolutional neural networks that are pretrained on a private dataset of tweets with emoticons, making it difficult to replicate (Deriu et al., 2016). Instead we pretrain a model with the hyperparameters of the largest model in their ensemble on the positive/negative emoticon dataset from Go et al. (2009). Using this pretraining as an initialization we finetune the model on the target tasks using early stopping on a validation set to determine the amount of training. We also implemented the Sentiment-Specific Word Embedding (SSWE) using the embeddings available on the authors' website (Tang et al., 2014), but found that it performed worse

Table 4: Description of benchmark datasets. Datasets without pre-existing training/test splits are split by us (with splits publicly available). Data used for hyperparameter tuning is taken from the training set.

Identifier	Study	Task	Domain	Classes	N_{train}	N_{test}

SCv2-GEN	F1	.72 [Joshi]	.71	.71	.74	**.75**

than the pretrained convolutional neural network. These results are therefore excluded.

For sarcasm detection we use the sarcasm dataset version 1 and 2 from the Internet Argument Corpus (Walker et al., 2012). Note that results presented on these benchmarks in e.g. Oraby et al. (2016) are not directly comparable as only a subset of the data is available online.[3] A state-of-the-art baseline is found by modeling the embedding-based features from Joshi et al. (2016) alongside unigrams, bigrams and trigrams with an SVM. GoogleNews word2vec embeddings (Mikolov et al., 2013) are used for computing the embedding-based features. A hyperparameter search for regularization parameters is carried out using cross-validation. Note that the sarcasm dataset version 2 contains both a quoted text and a sarcastic response, but to keep the models identical across the datasets only the response is used.

For training we use the Adam optimizer (Kingma and Ba, 2015) with gradient clipping of the norm to 1. Learning rate is set to 1E$-$3 for training of all new layers and 1E$-$4 for finetuning any pretrained layers. To prevent overfitting on the small datasets, 10% of the channels across all words in the embedding layer are dropped out during training. Unlike e.g. (Gal and Ghahramani, 2016) we do not drop out entire words in the input as some of our datasets contain observations with so few words that it could change the meaning of the text. In addition to the embedding dropout, L2 regularization for the embedding weights is used and 50% dropout is applied to the penultimate layer.

Table 5 shows that the DeepMoji model outperforms the state of the art across all benchmark datasets and that our new 'chain-thaw' approach consistently yields the highest performance for the transfer learning, albeit often only slightly better or equal to the 'last' approach. Results are averaged across 5 runs to reduce the variance. We test the statistical significance of our results by comparing the performance of DeepMoji (chain-thaw) vs. the state of the art. Bootstrap testing with 10000 samples is used. On all datasets are our results statistically significantly better than the state of the art with $p < 0.001$.

Our model is able to out-perform the state-of-

[3] We contacted the authors, but were unable to obtain the full dataset for neither version 1 or version 2.

the-art on datasets that originate from domains that differ substantially from the tweets on which it was pretrained. A key difference between the pretraining dataset and the benchmark datasets is the length of the observations. The average number of tokens pr. tweet in the pretraining dataset is 11, whereas e.g. the board posts from the Internet Argument Corpus version 1 (Oraby et al., 2016) has an average of 66 tokens with some observations being much longer.

5 Model Analysis

5.1 Importance of emoji diversity

One of the major differences between this work compared to previous papers using distant supervision is the diversity of the noisy labels used (see §2). For instance, both Deriu et al. (2016) and Tang et al. (2014) only used positive and negative emoticons as noisy labels. Other instances of previous work have used slightly more nuanced sets of noisy labels (see §2), but to our knowledge our set of noisy labels is the most diverse yet. To analyze the effect of using a diverse emoji set we create a subset of our pretraining data containing tweets with one of 8 emojis that are similar to the positive/negative emoticons used by Tang et al. (2014) and Hu et al. (2013) (the set of emoticons and corresponding emojis are available in the supplemental material). As the dataset based on this reduced set of emojis contains 433M tweets, any difference in performance on benchmark datasets is likely linked to the diversity of labels rather than differences in dataset sizes.

We train our DeepMoji model to predict whether the tweets contain a positive or negative emoji and evaluate this pretrained model across the benchmark datasets. We refer to the model trained on the subset of emojis as *DeepMoji-PosNeg* (as opposed to *DeepMoji*). To test the emotional representations learned by the two pretrained models the 'last' transfer learning approach is used for the comparison, thereby only allowing the models to map already learned features to classes in the target dataset. Table 6 shows that DeepMoji-PosNeg yields lower performance compared to DeepMoji across all 8 benchmarks, thereby showing that the diversity of our emoji types encourage the model to learn a richer representation of emotional content in text that is more useful for transfer learning.

Table 6: Benchmarks using a smaller emoji set (Pos/Neg emojis) or a classic architecture (standard LSTM). Results for DeepMoji from Table 5 are added for convenience. Evaluation metrics are as in Table 5. Reported values are the averages across five runs.

Dataset	Pos/Neg emojis	Standard LSTM	DeepMoji
SE0714	.32	.35	.36
Olympic	.55	.57	.61
PsychExp	.40	.49	.56
SS-Twitter	.86	.86	.87
SS-Youtube	.90	.91	.92
SE1604	.56	.57	.58
SCv1	.66	.66	.68
SCv2-GEN	.72	.73	.74

Many of the emojis carry similar emotional content, but have subtle differences in usage that our model is able to capture. Through hierarchical clustering on the correlation matrix of the DeepMoji model's predictions on the test set we can see that the model captures many similarities that one would intuitively expect (see Figure 3). For instance, the model groups emojis into overall categories associated with e.g. negativity, positivity or love. Similarly, the model learns to differentiate within these categories, mapping sad emojis in one subcategory of negativity, annoyed in another subcategory and angry in a third one.

5.2 Model architecture

Our DeepMoji model architecture as described in §3.2 use an attention mechanism and skip-connections to ease the transfer of the learned representation to new domains and tasks. Here we compare the DeepMoji model architecture to that of a standard 2-layer LSTM, both compared using the 'last' transfer learning approach. We use the same regularization and training parameters.

As seen in Table 6 the DeepMoji model performs better than a standard 2-layer LSTM across all benchmark datasets. The two architectures performed equally on the pretraining task, suggesting that while the DeepMoji model architecture is indeed better for transfer learning, it may not necessarily be better for single supervised classification task with ample available data.

A reasonable conjecture is that the improved transfer learning performance is due to two factors: a) the attention mechanism with skip-connections provide easy access to learned low-

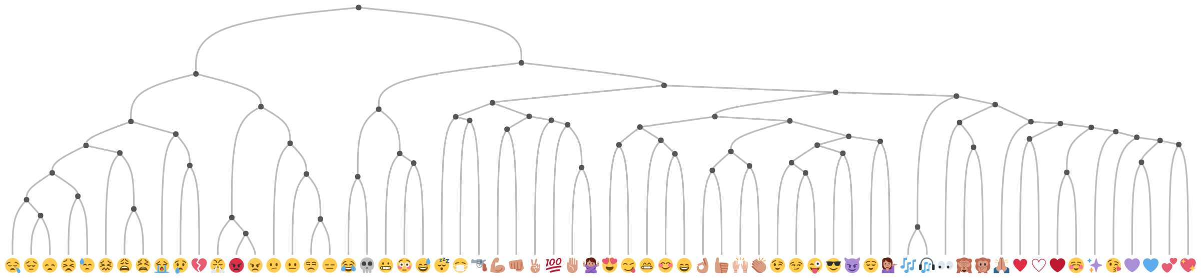

Figure 3: Hierarchical clustering of the DeepMoji model's predictions across categories on the test set. The dendrogram shows how the model learns to group emojis into overall categories and subcategories based on emotional content. The y-axis is the distance on the correlation matrix of the model's predictions measured using average linkage. More details are available in the supplementary material.

level features for any time step, making it easy to use this information if needed for a new task b) the improved gradient-flow from the output layer to the early layers in the network due to skip-connections (Graves, 2013) is important when adjusting parameters in early layers as part of transfer learning to small datasets. Detailed analysis of whether these factors actually explain why our architecture outperform a standard 2-layer LSTM is left for future work.

5.3 Analyzing the effect of pretraining

Performance on the target task benefits strongly from pretraining as shown in Table 5 by comparing DeepMoji (new) to DeepMoji (chain-thaw). In this section we experimentally decompose the benefit of pretraining into 2 effects: word coverage and phrase coverage. These two effects help regularize the model by preventing overfitting (see the supplementary details for an visualization of the effect of this regularization).

There are numerous ways to express a specific sentiment, emotion or sarcastic comment. Consequently, the test set may contain specific language use not present in the training set. The pretraining helps the target task models attend to low-support evidence by having previously observed similar usage in the pretraining dataset. We first examine this effect by measuring the improvement in word coverage on the test set when using the pretraining with word coverage being defined as the % of words in the test dataset seen in the training/pretraining dataset (see Table 7). An important reason why the 'chain-thaw' approach outperforms other transfer learning approaches is can be used to tune the embedding layer with limited risk of overfitting. Table 7 shows the increased word coverage from adding new words to the vocabulary as part of that tuning.

Note that word coverage can be a misleading metric in this context as for many of these small datasets a word will often occur only once in the training set. In contrast, all of the words in the pretraining vocabulary are present in thousands (if not millions) of observations in the emoji pretraining dataset thus making it possible for the model to learn a good representation of the emotional and semantic meaning. The added benefit of pretraining for learning word representations therefore likely extends beyond the differences seen in Table 7.

Table 7: Word coverage on benchmark test sets using only the vocabulary generated by finding words in the training data ('own'), the pretraining vocabulary ('last') or a combination of both vocabularies ('full / chain-thaw').

Dataset	Own	Last	Full / Chain-thaw
SE0714	41.9%	93.6%	94.0%
Olympic	73.9%	90.3%	96.0%
PsychExp	85.4%	98.5%	98.8%
SS-Twitter	80.1%	97.1%	97.2%
SS-Youtube	79.6%	97.2%	97.3%
SE1604	86.1%	96.6%	97.0%
SCv1	88.7%	97.3%	98.0%
SCv2-GEN	86.5%	97.2%	98.0%

To examine the importance of capturing phrases and the context of each word, we evaluate the accuracy on the SS-Youtube dataset using a fastText classifier pretrained on the same emoji dataset as our DeepMoji model. This fastText classifier is almost identical to only using the embedding layer from the DeepMoji model. We evaluate the representations learned by fine-tuning the models as feature extractors (i.e. using the 'last' transfer learning approach). The fastText model achieves an accuracy of 63% as compared to 93% for our DeepMoji model, thereby emphasizing the importance of phrase coverage. One concept that the LSTM layers likely learn is negation, which is known to be important for sentiment analysis (Wiegand et al., 2010).

5.4 Comparing with human-level agreement

To understand how well our DeepMoji classifier performs compared to humans, we created a new dataset of random tweets annotated for sentiment. Each tweet was annotated by a minimum of 10 English-speaking Amazon Mechanical Turkers (MTurk's) living in USA. Tweets were rated on a scale from 1 to 9 with a 'Do not know' option, and guidelines regarding how to rate the tweets were provided to the human raters. The tweets were selected to contain only English text, no mentions and no URL's to make it possible to rate them without any additional contextual information. Tweets where more than half of the evaluators chose 'Do not know' were removed (98 tweets).

For each tweet, we select a MTurk rating random to be the 'human evaluation', and average over the remaining nine MTurk ratings are averaged to form the ground truth. The 'sentiment label' for a given tweet is thus defined as the overall consensus among raters (excluding the randomly-selected 'human evaluation' rating). To ensure that the label categories are clearly separated, we removed neutral tweets in the interval $[4.5, 5.5]$ (roughly 29% of the tweets). The remaining dataset consists of 7 347 tweets. Of these tweets, 5000 are used for training/validation and the remaining are used as the test set. Our DeepMoji model is trained using the chain-thaw transfer learning approach.

Table 8 shows that the agreement of the random MTurk rater is 76.1%, meaning that the randomly selected rater will agree with the average of the nine other MTurk-ratings of the tweet's polarity 76.1% of the time. Our DeepMoji model achieves 82.4% agreement, which means it is better at capturing the average human sentiment-rating than a single MTurk rater.

Table 8: Comparison of agreement between classifiers and the aggregate opinion of Amazon Mechanical Turkers on sentiment prediction of tweets.

	Agreement
Random	50.1%
fastText	71.0%
MTurk	76.1%
DeepMoji	**82.4%**

6 Conclusion

We have shown how the millions of texts on social media with emojis can be used for pretraining models, thereby allowing them to learn representations of emotional content in texts. Through comparison with an identical model pretrained on a subset of emojis, we find that the diversity of our emoji set is important for the performance of our method. We release our pretrained DeepMoji model with the hope that other researchers will find good use of them for various emotion-related NLP tasks[4].

Acknowledgments

The authors would like to thank Janys Analytics for generously allowing us to use their dataset of human-rated tweets and the associated code to analyze it. Furthermore, we would like to thank Max Lever, who helped design the website, and Han Thi Nguyen, who helped code the software that is provided alongside the pretrained model.

Opinion Recommendation Using A Neural Model[*]

Zhongqing Wang[†,‡] and **Yue Zhang**[‡]

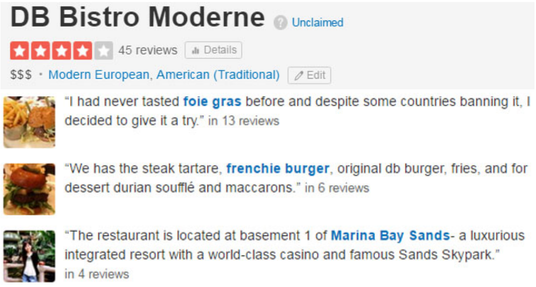
[‡]Singapore University of Technology and Design, Singapore
wangzq.antony@gmail.com, yue_zhang@sutd.edu.sg,

Abstract

We present opinion recommendation, a novel task of jointly generating a review with a rating score that a certain user would give to a certain product which is unreviewed by the user, given existing reviews to the product by other users, and the reviews that the user has given to other products. A characteristic of opinion recommendation is the reliance of multiple data sources for multi-task joint learning. We use a single neural network to model users and products, generating customised product representations using a deep memory network, from which customised ratings and reviews are constructed jointly. Results show that our opinion recommendation system gives ratings that are closer to real user ratings on Yelp.com data compared with Yelp's own ratings. our methods give better results compared to several pipelines baselines.

1 Introduction

Offering a channel for customers to share opinions and give scores to products and services, review websites have become a highly influential information source that customers refer to for making purchase decisions. Popular examples include IMDB.com on the movie domain, Epinions.com on the product domain, and Yelp.com on the service domain. Figure 1 shows a screenshot of a restaurant review page on Yelp.com, which offers two main types of information. First, an overall rating score is given under the restaurant name; second, detailed user reviews are listed below the rating.



DB Bistro Moderne

★★★★☆ 45 reviews

$$$ · Modern European, American (Traditional)

"I had never tasted **foie gras** before and despite some countries banning it, I decided to give it a try." in 13 reviews

"We has the steak tartare, **frenchie burger**, original db burger, fries, and for dessert durian soufflé and maccarons." in 6 reviews

"The restaurant is located at basement 1 of **Marina Bay Sands**- a luxurious integrated resort with a world-class casino and famous Sands Skypark." in 4 reviews

Figure 1: A restaurant review on Yelp.com.

Though offering useful overview and details about a product or service, such information has several limitations for a user who has *not* used the product or service. First, the overall rating is general and not necessarily agreeable to the taste of an individual customer. Being a simple reflection of all customer scores, it serves an average customer well, but can be rather inaccurate for individuals. For example, the authors themselves often find highly rated movies being tedious. Second, there can be hundreds of reviews for a product or service, which makes it infeasible for exhaustive reading. It would be useful to have a brief summary of all reviews, which ideally should be customized to the reader.

To address the limitations above, we propose a new task called **opinion recommendation**, which is to generate a *customized review score* of the product that the user is likely to give, as well as a *customized review* that the user would have written for the target product, if the user had reviewed the product. The proposed opinion recommendation task is closely related to several existing lines of work in NLP. The first is *sentiment analysis* (Hu and Liu, 2004; Pang and Lee, 2008) and *opinion summarization* (Nishikawa et al., 2010; Wang and Ling, 2016), which is to give a rating score or summary based on existing customer reviews. Our

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1626–1637
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

task is different in that we aim to generate user rating scores and review of a product unreviewed by the user. The second is *recommendation* (Su and Khoshgoftaar, 2009; Yang et al., 2014), which is to give a ranking score to a certain product or service based on the purchase history of the user and other customers who have purchased the target product. Our task is different in the source of input, which is *textual* customer reviews and ratings rather than *numerical* purchase history.

There are two types of inputs for our task, namely existing reviews of the target product, and the reviews of the user on other products, and two types of outputs, namely a customized rating score and a customized review. The ideal solution should consider the interaction between all given types of information, jointly predicting the two types of outputs. This poses significant challenges to statistical models, which require manually defined features to capture relevant patterns from training data. Deep learning is a relatively more feasible choice, offering viabilities of information fusion by fully connected hidden layers (Collobert et al., 2011; Henderson et al., 2013; Zhang and Weiss, 2016; Chen et al., 2016a). We leverage this advantage in building our model.

In particular, we use a sub RNN to model the semantic content of each review. A sub *product model* is used to consolidate existing reviews for the target product, and a *user model* is built by consolidating the reviews of the given user into a single vector form. To address potential sparsity of a user's history reviews, neighbor users are identified by collaborative filtering (Ding et al., 2006), and a vector representation is learned by using a neural *neighborhood model*. Finally, a deep memory network is utilized to find the association between the user and target product, jointly yielding the rating score and customised review. Experiments on a Yelp dataset show that the model outperforms several pipelined baselines. We make our source code publicly available under GPL at https://github.com/wangzq870305/opinion_recommend.

2 Related Work

Sentiment Analysis. Our task is related to document-level sentiment classification (Pang and Lee, 2008) for various neural network models have been used, including convolutional neural networks (Kim, 2014), recursive neural network (Socher et al., 2013) and recurrent neural network (Teng et al., 2016; Tai et al., 2015), Review rating prediction aims to predict the numeric rating of a given review. Pang and Lee (2005) pioneered this task by regarding it as a classification/regression problem. Most subsequent work focuses on designing effective textural features of reviews (Qu et al., 2010; Li et al., 2011; Wan, 2013).

User information has been widely investigated in sentiment analysis. Gao et al. (2013) developed user-specific features to capture user leniency, and Li et al. (2014) incorporated textual topic and user-word factors through topic modeling. For integrating user information into neural network models, Tang et al. (2015) predicted the rating score given a review by using both lexical semantic information and a user embedding model. Chen et al. (2016b) proposed a neural network to incorporate global user and product information for sentiment classification via an attention mechanism.

Different from the above research, which focuses on predicting the opinion on existing reviews, our task is to recommend the score that a user would give to a new product *without* knowing his review text. The difference originates from the objective. Previous research aims to predict opinions on reviewed products, while our task is to recommend opinion on new products, which the user has not reviewed.

Opinion Summarization. Our work also overlaps with to the area of opinion summarization, which constructs natural language summaries for multiple product reviews (Hu and Liu, 2004). Most previous work extracts opinion words and aspect terms. Typical approaches include association mining of frequent candidate aspects (Hu and Liu, 2004; Qiu et al., 2011), sequence labeling based methods (Jakob and Gurevych, 2010; Yang and Cardie, 2013), as well as topic modeling techniques (Lin and He, 2009). Recently, word embeddings and recurrent neural networks are also used to extract aspect terms (Irsoy and Cardie, 2014; Liu et al., 2015). While all the methods above are *extractive*, Ganesan et al. (2010) presented a graph-based summarization framework to generate concise abstractive summaries of highly redundant opinions, and Wang and Ling (2016) used an attention-based neural network model to absorb information from multiple text units and generate summaries of movie reviews. We also perform abstractive summarization. However, different from the above research, which summarize existing reviews, we generate *customized* reviews for a unreviewed product.

Recommendation. has been solved on mainly purchase history. There are two main approaches, which are content-based and collaborative-filtering (CF) based (Adomavicius and Tuzhilin, 2005; Yang et al., 2014), respectively. Most existing social recommendation systems are CF-based, and can be further grouped into model-based CF and neighborhood-based CF (Kantor et al., 2011; Su and Khoshgoftaar, 2009). Matrix Factorization (MF) is one of the most popular models for CF. In recent MF-based social recommendation works, user-user social trust information is integrated with user-item feedback history (e.g., ratings, clicks, purchases) to improve the accuracy of traditional recommendation systems, which only factorize user-item feedback data (Ding et al., 2006; Koren, 2008; He et al., 2016).

There has been work integrating sentiment analysis and recommendation systems, which use recommendation strategies such as matrix factorization to improve the performance of sentiment analysis (Leung et al., 2006; Singh et al., 2011). These methods typically use ensemble learning (Singh et al., 2011) or probabilistic graph models (Wu and Ester, 2015). For example, Zhang et al. (2014) proposed a factor graph model to recommend opinion rating scores by using explicit product features as hidden variables. Different from the above research, we recommend user opinions.

Neural Network Models. Multi-task learning has been recognised as a strength of neural network models for natural language processing (Collobert et al., 2011; Henderson et al., 2013; Zhang and Weiss, 2016; Chen et al., 2016a), where hidden feature layers are shared between different tasks that have common basis. Our work can be regarded as an instance of such multi-tasks learning via shared parameters, which has been widely used in the research community recently.

Dynamic memory network models have been applied for NLP tasks such as question answering (Sukhbaatar et al., 2015; Kumar et al., 2016), language modeling (Tran et al., 2016) and machine translation (Wang et al., 2016). There are typically used to find abstract semantic representations of texts towards certain tasks, which are consistent with our main need, namely abstracting the representation of a product that is biased towards the taste of a certain user. We use a variation of the memory network model for obtaining user-specific review representation.

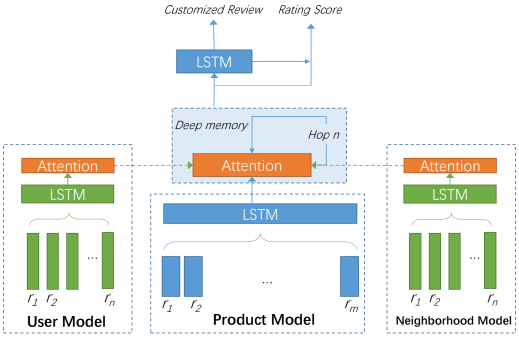

Figure 2: Overview of proposed model.

3 Model

Formally, the input to our model is a tuple $\langle R_T, R_U, R_N\rangle$, where $R_T = \{r_{T_1}, r_{T_2}, ..., r_{T_{n_t}}\}$ is the set of existing reviews of a target product, $R_U = \{r_{U_1}, r_{U_2}, ..., r_{U_{n_u}}\}$ is the set of user's history reviews, and $R_N = \{r_{N_1}, r_{N_2}, ..., r_{N_{n_n}}\}$ is the set of the user's neighborhood reviews. All the reviews are sorted with temporal order. The output is a pair $\langle Y_S, Y_R\rangle$, where Y_S is a real number between 0 and 5 representing the customized rating score of the target product, and Y_R is a customised review. A characteristic of our model is that Y_S and Y_R are generated on a product that the user has not reviewed.

For capturing both general and personalized information, we first build a *product model*, a *user model*, and a *neighborhood model*, respectively, and using a memory network model to integrate these three types of information, constructing a *customized product model*. Finally, we predict a customized rating score and a review collectively using neural stacking framework. The overall architecture of the model is shown in Figure 2.

3.1 Review Model

A review is the foundation of our model, based on which we derive representations of both a user and a target product. In particular, a user profile can be achieved by modeling all the reviews R_U of the user, and a target product profile can be obtained by using all existing reviews R_T of the product. We use the average of word embeddings to model a review. Formally, given a review $r = \{x_1, x_2, ..., x_m\}$, where m is the length of the review, each word x_k is represented with a K-dimensional embedding e_k^w (Mikolov et al., 2013). We use the $\sum_k(e_k^w)/m$ for the representation of the review $e^d(r)$.

3.2 User Model

A standard LSTM (Hochreiter and Schmidhuber, 1997) is used to learn the hidden states of an user's reviews to build the user model. Denoting the recurrent function at step t as $\text{LSTM}(x_t, h_{t-1})$, we obtain a sequence of hidden state vectors $\{h_{U_1}, h_{U_2}, ..., h_{U_{n_u}}\}$ recurrently by feeding $\{e^d(r_{U_1}), e^d(r_{U_2}), ..., e^d(r_{U_{n_u}})\}$ as inputs, where $h_{U_i} = \text{LSTM}(e^d(r_{U_i}), h_{U_{i-1}})$. The initial state and all standard LSTM parameters are randomly initialized and tuned during training.

Not all reviews contribute equally to the representation of a user. We use the attention mechanism (Bahdanau et al., 2014; Yang et al., 2016) to extract the reviews that are relatively more important, aggregating the representation of reviews to form a vector. Taking the hidden state $\{h_{U_1}, ...h_{U_2}, ..., h_{U_{n_u}}\}$ of user model as input, the attention model outputs, a continuous vector $v_U \in \mathbb{R}^{d\times 1}$, which is computed as a weighted sum of each hidden state h_{U_i}, namely

$$v_U = \sum_i^{n_u} \alpha_i h_{U_i} \tag{1}$$

where n_u is the hidden variable size, $\alpha_i \in [0, 1]$ is the weight of h_{U_i}, and $\sum_i \alpha_i = 1$.

For each piece of hidden state h_{U_i}, the scoring function is calculated by

$$u_i = \tanh(W_U h_{U_i} + b_U) \tag{2}$$

$$\alpha_i = \frac{\exp(u_i)}{\sum_j \exp(u_j)} \tag{3}$$

where W_U and b_U are model parameters. The attention vector v_U is used to represent the user for the *User Model*.

3.3 Neighborhood Model

We use neighborhood reviews to improve the user model, since a user may not have sufficient reviews to construct a reliable model. Here a neighbor refers to a user that has similar tastes to the target user (Koren, 2008; Desrosiers and Karypis, 2011). The same as the user model, we construct the *neighborhood model* v_N using the neighborhood reviews $R_N = \{r_{N_1}, r_{N_2}, ..., r_{N_{n_n}}\}$ with an attention recurrent network.

A key issue in building the neighborhood model is how to find neighbors of a certain user. In this study, we use matrix factorization (Koren, 2008) to detect neighbors, which is a standard approach for recommendation (Ding et al., 2006; Li et al., 2009; He et al., 2016). In particular, users' rating scores of products are used to build a product-users matrix $M \in \mathbb{R}^{n_t \times n_u}$ with n_t products and n_u users. We approximate it using three factors, specifying soft membership of products and users (Ding et al., 2006) by finding:

$$\begin{gathered}\min_{F,S,T} ||M - FST^T|| \\ s.t. S \geq 0, F \geq 0, T \geq 0\end{gathered} \tag{4}$$

where $F \in \mathbb{R}^{n_t \times K}$ represents the posterior probability of K topic clusters for each product; $S \in \mathbb{R}^{K\times K}$ encodes the distribution of each topic k; and $T \in \mathbb{R}^{K\times n_u}$ indicates the posterior probability of K topic clusters for each user.

As a result of matrix factorization, we directly obtain the probability of each user on each topic from the person-topic matrix T. To infer T, the optimization problem in Eq.4 can be solved using the following updating rule:

$$T_{jk} \leftarrow T_{jk} \frac{(M^T FS)_{jk}}{(TT^T M^T FS)_{jk}} \tag{5}$$

With the user-topic matrix T, we measure the implicit connection between two users using:

$$sim(i, j) = \sum_{k=1}^{k} T_{ik} T_{jk} \tag{6}$$

where $sim(i, j)$ measure the implicit connection degree between users i and j. If $sim(i, j)$ is higher than a threshold η, we consider user j as the neighbor of user i.

3.4 Product Model

Given the representations of existing reviews $\{e^d(r_{T_1}), e^d(r_{T_2}), ..., e^d(r_{T_{n_t}})\}$ of the product, we use LSTM to model their temporal orders, obtaining a sequence of hidden vectors $h_T = \{h_{T_1}, h_{T_2}, ..., h_{T_{n_t}}\}$ by recurrently feeding $\{e^d(r_{T_1}), e^d(r_{T_2}), ..., e^d(r_{T_{n_t}}\}$ as inputs. The hidden state vectors h_T are used to represent the product.

Customized Product Model. The product model represents salient information of existing reviews in their temporal order, yet do not reflect the taste of a particular user. We build the customised product model to integrate user information and product information (as reflected by the product model), resulting in a single vector that represents a customised product. From this vector we are able to synthesis both a customised review and a customised rating score. In particular, we use the user representation v_U and the neighbour representation v_N to transform the target product representation $h_T = \{h_{T_1}, h_{T_2}, ..., h_{T_{n_t}}\}$ into a customised product representation v_C, which is tailored to the taste of the user.

A naive model of yielding v_C could utilise the attention mechanism over h_t, deriving a weighted sum according to user information. On the other hand, dynamic memory networks have been shown highly useful for deriving abstract semantic information compared with simple attention, and hence we follow Sukhbaatar et al. (2015) and Xiong et al. (2016), building a variation of DMN to iteratively find increasingly abstract representations of h_t, by injecting v_U and v_N information.

The memory model consists of multiple dynamic computational layers (hops), each of which contains an attention layer and a linear layer. In the first computational layer (hop 1), we take the hidden variables h_{T_i} $(0 \leq i \leq n_t)$ of product model as input, adaptively selecting important evidences through one attention layer using v_U and v_N. The output of the attention layer gives a linear interpolation of h_T, and the result is considered as input to the next layer (hop 2). In the same way, we stack multiple hops and run the steps multiple times, so that more abstract representations of the target product can be derived.

The attention model outputs a continuous vector $v_C \in \mathbb{R}^{d\times 1}$, which is computed as a weighted sum of h_{T_i} $(0 \leq i \leq n_t)$, namely

$$v_C = \sum_{i}^{n_t} \beta_i h_{T_i} \tag{7}$$

where n_t is the hidden variable size, $\beta_i \in [0, 1]$ is the weight of h_{T_i}, and $\sum_i \beta_i = 1$. For each piece of hidden state h_{T_i}, we use a feed forward neural network to compute its semantic relatedness with the abstract representation v_C. The scoring function is calculated as follows at hop t:

$$\begin{aligned} u_i^t = \tanh(&W_T h_{T_i} + W_C v_C^{t-1} \\ &+ W_U v_U + W_N v_N + b) \end{aligned} \tag{8}$$

$$\beta_i^t = \frac{\exp(u_i^t)}{\sum_j \exp(u_j^t)} \tag{9}$$

The vector v_C is used to represent the customized product model. At the first hop, we define $V_C^0 = \sum_i h_{T_i}/n_t$.

The product model h_{T_i} $(0 \leq i \leq n_t)$ represents salient information of existing reviews in their temporal order, they do not reflect the taste of a particular user. We use the customised product model to integrate user information and product information (as reflected by the product model), resulting in a single vector that represents a customised product. From this vector we are able to synthesis both a customised review and a customised rating score.

3.5 Customized Review Generation

The goal of customized review generation is to generate a review Y_R from the customized product representation v_C, composed by a sequence of words $y_{R_1}, ..., y_{R_{n_r}}$. We use a standard LSTM decoder (Rush et al., 2015) to decompose the prediction of Y_R into a sequence of word-level predictions:

$$\begin{aligned} &\log P(Y_R|v_C) = \\ &\quad \sum_j P(y_{R_j}|y_{R_1}, ..., y_{R_{j-1}}, v_C) \end{aligned} \tag{10}$$

where each word y_{R_j} is predicted conditional on the previously generated $y_{R_1}, ..., y_{R_{j-1}}$ and the customized product vector v_C. The probability is estimated by using standard word softmax:

$$\begin{aligned} P(y_{R_j}|y_{R_1}, ..., y_{R_{j-1}}, v_C) = \\ \mathrm{softmax}(h_{R_j}) \end{aligned} \tag{11}$$

where h_{R_j} is the hidden state variable at timestamp j, which is modeled as $LSTM(u_{j-1}, h_{Rj})$. Here a LSTM is used to generate a new state h_{R_j} from the representation of the previous state $h_{R_{j-1}}$ and u_{j-1}. u_{j-1} is the concatenation of previously generated word $y_{R_{j-1}}$ and the input representation of customized model v_C.

3.6 Customized Rating Prediction

A straightforward approach to predicting the rating score of a product is to take the average of existing review scores. However, the drawback is that it cannot reflect the the variance in user tastes. In order to integrate user preferences into the rating, we instead take a user-based weighted average of existing rating scores, so that the scores of reviews that are closer to the user preference are given higher weights. However, existing ratings can be all different from a users personal rating, if the existing reviews do not come from the user's neighbours. We thus use the customized product vector v_c as a bias of the weighted average of existing rating scores.

Formally, given the rating scores $s_1, s_2, ..., s_n$ of existing reviews, and the the customized product representation v_C, we calculate:

$$Y_S = \sum_{i}^{n} \beta_i \cdot s_i + \mu \tanh(W_S v_C + b_S) \qquad (12)$$

In the left term $\sum_i^n \beta_i \cdot s_i$, we use attention weights β_i in Eq.9 to measure the important of each rating score s_i. The right term $\tanh(W_S v_C + b_S)$ is a review-based shift, weighted by μ.

Since the result of customized review generation can be helpful for rating score prediction, we use neural stacking additionally feeding the last hidden state h_{R_n} of review generation model as input for Y_S prediction, resulting in

$$\begin{aligned} Y_S = & \sum_{i}^{n} \alpha_i \cdot s_i + \\ & + \mu \tanh(W_S(v_C \oplus h_{R_n}) + b_S) \end{aligned} \qquad (13)$$

where $\oplus$ denotes vector concatenation.

3.7 Training

For our task, there are two joint training objectives, for review scoring and review summarisation, respectively. For review scoring, the loss function is defined as:

$$L(\Theta) = \sum_{i=1}^{N} (Y^*_{S_i} - Y_{S_i})^2 + \frac{\lambda}{2} ||\Theta||^2 \qquad (14)$$

where $Y^*_{S_i}$ is the predicted rating score, Y_{S_i} is the rating score in the training data, Θ is the set of model parameters and λ is a parameter for L2 regularization.

	Amount
Business	15,584
Review	334,997
User	303,032

Table 1: Statistics of the dataset.

For customized review generation, loss is defined by maximizing the log probability of Eq.10 (Sutskever et al., 2014; Rush et al., 2015). The two loss functions for score and review prediction share the representation vectors under v_C, hence forming multi-task learning.

Standard back propagation is performed to optimize parameters, where gradients also propagate from the scoring objective to the review generation objective due to neural stacking (Eq.13). We apply online training, where model parameters are optimized by using AdaGrad (Duchi et al., 2011). Word embeddings are trained using the *Skip-gram* algorithm (Mikolov et al., 2013)[1].

4 Experiments

4.1 Experimental Settings

Our data are collected from the yelp academic dataset[2], provided by Yelp.com, a popular restaurant review website. The data set contains three types of objects: *business*, *user*, and *review*, where business objects contain basic information about local businesses (i.e. restaurants), review objects contain review texts and star rating, and user objects contain aggregate information about a single user across all of Yelp. Table 1 illustrates the general statistics of the dataset.

For evaluating our model, we choose 4,755 user-product pairs from the dataset. The user-product pairs are extracted by following criterions: for each selected user-product pair, the user should have written 10 reviews at least, and the product should contain 100 reviews at least. In addition, the gold-standard review that the user write for the corresponding product should contain 10 helpful hits at least. We did not try alternative data selection rules. We will give the detail in our draft.

For each pair, the existing reviews of the target service (restaurant) are used for the product model. The rating score given by each user to the target service is considered as the gold customized rating score, and the review of the target service given by

[1] https://code.google.com/p/word2vec/

[2] https://www.yelp.com/academic_dataset

each user is used as the gold-standard customized review for the user. The remaining reviews of each user are used for training the user model. We use 3,000 user-product pairs to train the model, 1,000 pairs as testing data, and remaining data for development.

We use the ROUGE-1.5.5 (Lin, 2004) toolkit for evaluating the performance of customized review generation, and report unigram overlap (ROUGE-1) as a means of assessing informativeness. Mean Square Error (MSE) (Wan, 2013; Tang et al., 2015) is used as the evaluation metric for measuring the performance of customized rating score prediction. MSE penalizes more severe errors more heavily.

4.2 Hyper-parameters

There are several important hyper-parameters in our models, and we tune their values using the development dataset. We set the regularization weight $\lambda = 10^{-8}$ and the initial learning rate to 0.01. We set the size of word vectors to 128, the size of hidden vectors in LSTM to 128. In order to avoid over-fitting, dropout (Hinton et al., 2012) is used for word embedding with a ratio of 0.2. The neighbor similarity threshold η is set to 0.25.

4.3 Development Experiments

4.3.1 Ablation Test

Effects of various configurations of our model, are shown on Table 2, where *Joint* is the full model of this paper, *-user* ablates the user model, *-neighbor* ablates the neighbor model, *-rating* is a single-task model that generates a review without the rating score, and *-generation* yields only the rating.

By comparing "Joint" and "-user,-neighbor", we can find that customized information have significant influence on both the rating and review generation results ($p - value < 0.01$ using t-test). In addition, comparison between "-Joint" and "-user", and between "-user" and "-user, -neighbor" shows that both the user information and the neighbour user information of the user are effective for improving the results. A users neighbours can indeed alleviate scarcity of user reviews.

Finally, comparison between "Joint" and "-generation", and between "Joint" and "-rating" shows that multi-task learning by parameter sharing is highly useful.

	Rating	**Generation**
Joint	0.904	0.267
-user	1.254	0.220
-neighbor	1.162	0.245
-user,-neighbor	1.342	0.205
-rating	-	0.254
-generation	1.042	-

Table 2: Feature ablation tests.

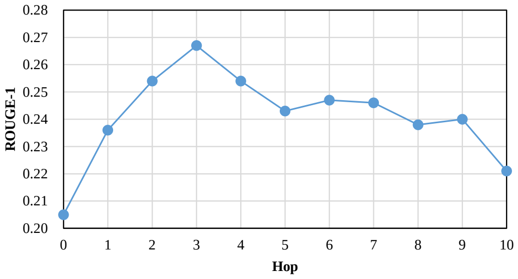

Figure 3: Influence of hops.

4.3.2 Influence of Hops

We show the influence of hops of memory network for customized review generation on Figure 3. When $hop = 0$, the model considers only the general product reviews ($-user, -neighbor$). When $hop \geq 1$, customized product information is leveraged. From the figure we can find that, when $hop = 3$, the performance is the best. It indicates that multiple hops can capture more abstract evidences from external memory to improve the performance. However, too many hops leads to over-fitting, thereby harms the performance. As a result, we choose 3 as the number of hops in our final test.

4.3.3 Influence of μ

We show the influence of the bias weight parameter μ for rating prediction in Figure 4. With μ being 0, the model uses the weighted sum of existing reviews to score the product. When μ is very large, the system tends to use only the customized product representation v_c to score the product, hence ignoring existing review scores, which are a useful source of information. Our results show that when μ is 1, the performance is optimal, thus indicating both existing review scores and review contents are equally useful.

4.4 Final Results

We show the final results for opinion recommendation, comparing our proposed model with the

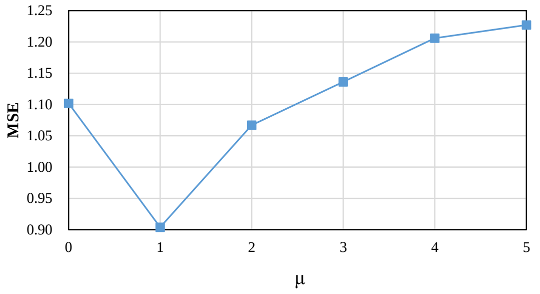

Figure 4: Influence of bias score.

	Rating	Generation
RS-Average-Yelp	1.280	-
RS-Linear	1.234	-
RS-Item	1.364	-
RS-MF	1.143	-
Sum-Opinosis	-	0.183
Sum-LSTM-Att	-	0.196
Joint	**1.023**	**0.250**

Table 3: Final results.

following state-of-the-art baseline systems:

- *RS-Average-Yelp* is the widely-adopted baseline (e.g., by Yelp.com), using the averaged review scores as the final score.
- *RS-Linear* estimates the rating score that a user would give by $s_{ui} = s_{all} + s_u + s_i$ (Ricci et al., 2011), where s_u and s_i are the the training deviations of rating score of the user u and the product i, respectively.
- *RS-Item* applies kNN to estimate the rating score (Sarwar et al., 2001). We choose the cosine similarity between v_c to measure the distance between product.
- *RS-MF* is a state-of-the-art recommendation model, which uses matrix factorisation to predict rating score (Ding et al., 2006; Li et al., 2009; He et al., 2016).
- *Sum-Opinosis* uses a graph-based framework to generate abstractive summarisation given redundant opinions (Ganesan et al., 2010).
- *Sum-LSTM-Att* is a state-of-the-art neural abstractive summariser, which uses an attentional neural model to consolidate information from multiple text sources, generating summaries using LSTM decoding (Rush et al., 2015; Wang and Ling, 2016).

Being non-opinion recommendation methods, all the baselines are single-task models, without considering rating and summarisation prediction jointly. The results are shown in Table 3. Our model (“ Joint”) significantly outperforms both “RS-Average-Yelp” and “RS-Linear” ($p - value < 0.01$ using t-test). Note that, our proposed rating recommendation for the user are significantly closer individual real user rating compared with Yelp’s rating.

Our proposed model also significantly outperforms state-of-the-art recommendation systems (RS-Item and RS-MF) ($p - value < 0.01$ using t-test), indicating that textual information are a useful addition to the rating scores themselves for recommending a product.

Finally, comparison between our proposed model and state-of-the-art summarisation techniques (Sum-Opinosis and Sum-LSTM-Att) shows the advantage of leveraging user information to enhance customised review generation, and also the strength of joint learning.

4.5 Example Output

Table 4 shows example outputs of rating scores and reviews. *Ref.* is the rating score and review written by user her/himself, and *Base* is the baseline model, that generates the rating score by RS-MF, and review by Sum-LSTM-Att. From these examples, we can find that, both rating score and review which generated by the proposed Joint model is closer to the real user. In particular, in the first example, the baseline system correctly identifies the main both price and quality information, which the target user wrote in the review, yet the baseline model did not yield comments about the price based on reviews of other users. Associating reviews and ratings closely, the joint model gives a rating score that is much closer to the real user score compared to the score given by the recommendation model MF. In addition, we can also find some habits of certain users from their customized reviews, for example, Mexican food, cheap and clean restaurant.

5 Conclusion

We proposed a novel task called opinion recommendation, which is to generate the review and rating score that a certain user would give to an unreviewed product or service. In particular, a

	Rating	Review
Ref.	5.0	Amazing beer selection, enough food choices, and a much smaller bill than I was expecting ...
Base	4.0	Boulders is JAM, favorite neighborhood bar, have amazing food ...
Joint	4.6	Bar is cheap, food is good enough ...
Ref.	4.0	This is one of my favorite Mexican fast food restaurants. It's clean and cool in the summer...
Base	5.0	The restaurant is great, This Chipotle is a great location, Their medium salsa good ...
Joint	4.2	Mexican food my favorite, place is clean ...

Table 4: Example outputs.

deep memory network was utilized to find the association between the user and the product, jointly yielding the rating score and customised review. Results show that our methods are better results compared to several pipelines baselines using state-of-the-art sentiment rating and summarisation systems. Review scores given by the opinion recordation system are closer to real user review scores compared to the review scores which Yelp assigns to target products.

Abstract

Unsupervised dependency parsing, which tries to discover linguistic dependency structures from unannotated data, is a very challenging task. Almost all previous work on this task focuses on learning generative models. In this paper, we develop an unsupervised dependency parsing model based on the CRF autoencoder. The encoder part of our model is discriminative and globally normalized which allows us to use rich features as well as universal linguistic priors. We propose an exact algorithm for parsing as well as a tractable learning algorithm. We evaluated the performance of our model on eight multilingual treebanks and found that our model achieved comparable performance with state-of-the-art approaches.

1 Introduction

Unsupervised dependency parsing, which aims to discover syntactic structures in sentences from unlabeled data, is a very challenging task in natural language processing. Most of the previous work on unsupervised dependency parsing is based on generative models such as the dependency model with valence (DMV) introduced by Klein and Manning (2004). Many approaches have been proposed to enhance these generative models, for example, by designing advanced Bayesian priors (Cohen et al., 2008), representing dependencies with features (Berg-Kirkpatrick et al., 2010), and representing discrete tokens with continuous vectors (Jiang et al., 2016).

Besides generative approaches, Grave and Elhadad (2015) proposed an unsupervised discriminative parser. They designed a convex quadratic objective function under the discriminative clustering framework. By utilizing global features and linguistic priors, their approach achieves state-of-the-art performance. However, their approach uses an approximate parsing algorithm, which has no theoretical guarantee. In addition, the performance of the approach depends on a set of manually specified linguistic priors.

Conditional random field autoencoder (Ammar et al., 2014) is a new framework for unsupervised structured prediction. There are two components of this model: an encoder and a decoder. The encoder is a globally normalized feature-rich CRF model predicting the conditional distribution of the latent structure given the observed structured input. The decoder of the model is a generative model generating a transformation of the structured input from the latent structure. Ammar et al. (2014) applied the model to two sequential structured prediction tasks, part-of-speech induction and word alignment and showed that by utilizing context information the model can achieve better performance than previous generative models and locally normalized models. However, to the best of our knowledge, there is no previous work applying the CRF autoencoder to tasks with more complicated outputs such as tree structures.

In this paper, we propose an unsupervised discriminative dependency parser based on the CRF autoencoder framework and provide tractable algorithms for learning and parsing. We performed experiments in eight languages and show that our approach achieves comparable results with previous state-of-the-art models.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1638–1643
Copenhagen, Denmark, September 7–11, 2017.

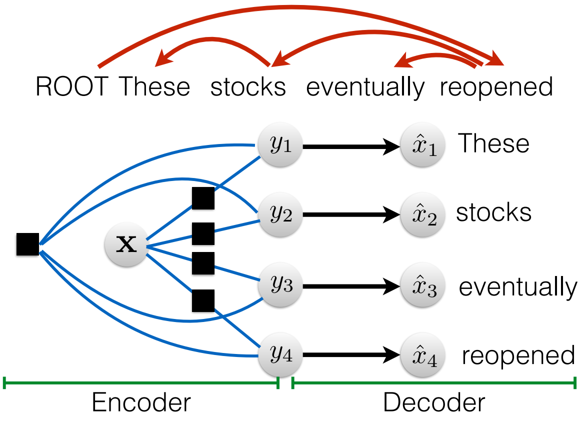

Figure 1: The CRF Autoencoder for the input sentence "These stocks eventually reopened" and its corresponding parse tree (shown at the top). $\mathbf{x}$ and $\hat{\mathbf{x}}$ are the original and reconstructed sentence. $\mathbf{y}$ is the dependency parse tree represented by a sequence where y_i contains the token and index of the parent of token x_i in the parse tree, e.g., $y_1 = \langle \text{stocks}, 2\rangle$ and $y_2 = \langle \text{reopened}, 4\rangle$. The encoder is represented by a factor graph (with a global factor specifying valid parse trees) and the decoder is represented by a Bayesian net.

2 Method

2.1 Model

Figure 1 shows our model with an example input sentence. Given an input sentence $\mathbf{x} = (x_1, x_2, \ldots, x_n)$, we regard its parse tree as the latent structure represented by a sequence $\mathbf{y} = (y_1, y_2, \ldots, y_n)$ where y_i is a pair $\langle t_i, h_i\rangle$, t_i is the head token of the dependency connecting to token x_i in the parse tree, and h_i is the index of this head token in the sentence. The model also contains a reconstruction output, which is a token sequence $\hat{\mathbf{x}} = (\hat{x}_1, \hat{x}_2, \ldots, \hat{x}_n)$. Throughout this paper, we set $\hat{\mathbf{x}} = \mathbf{x}$.

The encoder in our model is a log-linear model represented by a first-order dependency parser. The score of a dependency tree can be factorized as the sum of scores of its dependencies. For each dependency arc $(\mathbf{x}, i, j)$, where i and j are the indices of the head and child of the dependency, a feature vector $\mathbf{f}(\mathbf{x}, i, j)$ is specified. The score of a dependency is defined as the inner product of the feature vector and a weight vector $\mathbf{w}$,

$$\phi(\mathbf{x}, i, j) = \mathbf{w}^T \mathbf{f}(\mathbf{x}, i, j)$$

The score of a dependency tree $\mathbf{y}$ of sentence $\mathbf{x}$ is

$$\phi(\mathbf{x}, \mathbf{y}) = \sum_{i=1}^{n} \phi(\mathbf{x}, h_i, i)$$

We define the probability of parse tree $\mathbf{y}$ given sentence $\mathbf{x}$ as

$$P(\mathbf{y}|\mathbf{x}) = \frac{\exp(\phi(\mathbf{x}, \mathbf{y}))}{Z(\mathbf{x})}$$

$Z(\mathbf{x})$ is the partition function,

$$Z(\mathbf{x}) = \sum_{\mathbf{y}' \in \mathcal{Y}(\mathbf{x})} \exp(\phi(\mathbf{x}, \mathbf{y}'))$$

where $\mathcal{Y}(\mathbf{x})$ is the set of all valid parse trees of $\mathbf{x}$. The partition function can be efficiently computed in $O(n^3)$ time using a variant of the inside-outside algorithm (Paskin, 2001) for projective tree structures, or using the Matrix-Tree Theorem for non-projective tree structures (Koo et al., 2007).

The decoder of our model consists of a set of categorical conditional distributions $\theta_{x|t}$, which represents the probability of generating token x conditioned on token t. So the probability of the reconstruction output $\hat{\mathbf{x}}$ given the parse tree $\mathbf{y}$ is

$$P(\hat{\mathbf{x}}|\mathbf{y}) = \prod_{i=1}^{n} \theta_{\hat{x}_i|t_i}$$

The conditional distribution of $\hat{\mathbf{x}}, \mathbf{y}$ given $\mathbf{x}$ is

$$P(\mathbf{y}, \hat{\mathbf{x}}|\mathbf{x}) = P(\mathbf{y}|\mathbf{x})P(\hat{\mathbf{x}}|\mathbf{y})$$

2.1.1 Features

Following McDonald et al. (2005) and Grave et al. (2015), we define the feature vector of a dependency based on the part-of-speech tags (POS) of the head, child and context words, the direction, and the distance between the head and child of the dependency. The feature template used in our parser is shown in Table 1.

2.1.2 Parsing

Given parameters $\mathbf{w}$ and $\boldsymbol{\theta}$, we can parse a sentence $\mathbf{x}$ by searching for a dependency tree $\mathbf{y}$ which has the highest probability $P(\hat{\mathbf{x}}, \mathbf{y}|\mathbf{x})$.

$$\begin{aligned}\mathbf{y}^* &= \arg\max_{\mathbf{y} \in \mathcal{Y}(\mathbf{x})} \log P(\hat{\mathbf{x}}, \mathbf{y}|\mathbf{x}) \\ &= \arg\max_{\mathbf{y} \in \mathcal{Y}(\mathbf{x})} \sum_{i=1}^{n} \left(\phi(\mathbf{x}, h_i, i) + \log \theta_{\hat{x}_i|t_i}\right)\end{aligned}$$

$\text{POS}_i \times dis \times dir$
$\text{POS}_j \times dis \times dir$
$\text{POS}_i \times \text{POS}_j \times dis \times dir$
$\text{POS}_i \times \text{POS}_{i-1} \times \text{POS}_j \times dis \times dir$
$\text{POS}_i \times \text{POS}_{i+1} \times \text{POS}_j \times dis \times dir$
$\text{POS}_i \times \text{POS}_j \times \text{POS}_{j-1} \times dis \times dir$
$\text{POS}_i \times \text{POS}_j \times \text{POS}_{j+1} \times dis \times dir$

Table 1: Feature template of a dependency, where i is the index of the head, j is the index of the child, $dis = |i - j|$, and dir is the direction of the dependency.

For projective dependency parsing, we can use Eisners algorithm (1996) to find the best parse in $O(n^3)$ time. For non-projective dependency parsing, we can use the Chu-Liu/Edmond algorithm (Chu and Liu, 1965; Edmonds, 1967; Tarjan, 1977) to find the best parse in $O(n^2)$ time.

2.2 Parameter Learning

2.2.1 Objective Function

Spitkovsky et al. (2010) shows that Viterbi EM can improve the performance of unsupervised dependency parsing in comparison with EM. Therefore, instead of using negative conditional log likelihood as our objective function, we choose to use negative conditional Viterbi log likelihood,

$$-\sum_{i=1}^{N}\log\left(\max_{\mathbf{y}\in\mathcal{Y}(\mathbf{x}_i)} P(\hat{\mathbf{x}}_i,\mathbf{y}|\mathbf{x}_i)\right)+\lambda\Omega(\mathbf{w}) \tag{1}$$

where $\Omega(\mathbf{w})$ is a L1 regularization term of the encoder parameter $\mathbf{w}$ and λ is a hyper-parameter controlling the strength of regularization.

To encourage learning of dependency relations that satisfy universal linguistic knowledge, we add a soft constraint on the parse tree based on the universal syntactic rules following Naseem et al. (2010) and Grave et al. (2015). Hence our objective function becomes

$$-\sum_{i=1}^{N}\log\left(\max_{\mathbf{y}\in\mathcal{Y}(\mathbf{x}_i)} P(\hat{\mathbf{x}}_i,\mathbf{y}|\mathbf{x}_i)Q^{\alpha}(\mathbf{x}_i,\mathbf{y})\right)+\lambda\Omega(\mathbf{w})$$

where $Q(\mathbf{x},\mathbf{y})$ is a soft constraint factor over the parse tree, and α is a hyper-parameter controlling the strength of the constraint factor. The factor Q is also decomposable by edges in the same way as the encoder and the decoder, and therefore our parsing algorithm can still be used with this factor

VERB → VERB	NOUN → NOUN
VERB → NOUN	NOUN → ADJ
VERB → PRON	NOUN → DET
VERB → ADV	NOUN → NUM
VERB → ADP	NOUN → CONJ
ADJ → ADV	ADP → NOUN

Table 2: Universal linguistic rules

taken into account.

$$Q(\mathbf{x},\mathbf{y})=\exp\left(\sum_i \mathbb{1}[(t_i\rightarrow x_i)\in\mathcal{R}]\right)$$

where $\mathbb{1}[(t_i \rightarrow x_i)\in\mathcal{R}]$ is an indicator function of whether dependency $t_i \rightarrow x_i$ satisfies one of the universal linguistic rules in $\mathcal{R}$. The universal linguistic rules that we use are shown in Table 2 (Naseem et al., 2010).

2.2.2 Algorithm

We apply coordinate descent to minimize the objective function, which alternately updates $\mathbf{w}$ and $\boldsymbol{\theta}$. In each optimization step of $\mathbf{w}$, we run two epochs of stochastic gradient descent, and in each optimization step of $\boldsymbol{\theta}$, we run two iterations of the Viterbi EM algorithm.

To update $\mathbf{w}$ using stochastic gradient descent, for each sentence $\mathbf{x}$, we first run the parsing algorithm to find the best parse tree $\mathbf{y}^* = \arg\max_{\mathbf{y}\in\mathcal{Y}(\mathbf{x})}(P(\hat{\mathbf{x}},\mathbf{y}|\mathbf{x})Q^{\alpha}(\mathbf{x},\mathbf{y}))$; then we can calculate the gradient of the objective function based on the following derivation,

$$\begin{aligned}
&\frac{\partial \log P(\hat{\mathbf{x}},\mathbf{y}^*|\mathbf{x})}{\partial \mathbf{w}} \\
&= \frac{\partial \log P(\mathbf{y}^*|\mathbf{x})}{\partial \mathbf{w}} + \frac{\partial \log P(\hat{\mathbf{x}}|\mathbf{y}^*)}{\partial \mathbf{w}} \\
&= \frac{\partial \log P(\mathbf{y}^*|\mathbf{x})}{\partial \mathbf{w}} \\
&= \frac{\partial\left(\sum_{i=1}^{n}\mathbf{w}^T\mathbf{f}(\mathbf{x},h_i,i)-\log Z(\mathbf{x})\right)}{\partial \mathbf{w}} \\
&= \sum_{(i,j)\in\mathbf{D}(\mathbf{x})} f(\mathbf{x},i,j)\left(\mathbb{1}[y_j^*=\langle i,x_i\rangle]-\mu(\mathbf{x},i,j)\right)
\end{aligned}$$

where $\mathbf{D}(\mathbf{x})$ is the set of all possible dependency arcs of sentence $\mathbf{x}$, $\mathbb{1}[\cdot]$ is the indicator function, and $\mu(\mathbf{x},i,j)$ is the expected count defined as follows,

$$\mu(\mathbf{x},i,j)=\sum_{\mathbf{y}\in\mathcal{Y}(\mathbf{x})}\left(\mathbb{1}[y_j=\langle i,x_i\rangle]P(\mathbf{y}|\mathbf{x})\right)$$

CRFAE	71.7	55.7
Systems Using Extra Info		
LexTSG-DMV (Blunsom and Cohn, 2010)	67.7	55.7
CS (Spitkovsky et al., 2013)	72.0	64.4
MaxEnc (Le and Zuidema, 2015)	73.2	65.8

Table 3: Comparison of recent unsupervised dependency parsing systems on English. Basic setup is the same as our setup except that linguistic prior is not used. Extra info includes lexicalization, longer training sentences, etc.

The expected count can be efficiently computed using the Matrix-Tree Theorem (Koo et al., 2007) for non-projective tree structures or using a variant of the inside-outside algorithm for projective tree structures (Paskin, 2001).

To update $\boldsymbol{\theta}$ using Viterbi EM, in the E-step we again use the parsing algorithm to find the best parse tree $\mathbf{y}^*$ for each sentence $\mathbf{x}$; then in the M-step we update $\boldsymbol{\theta}$ by maximum likelihood estimation.

$$\theta_{c|t} = \frac{\sum_{\mathbf{x}} \sum_i \mathbb{1}[x_i = c, y_i^* = \langle \cdot, t \rangle]}{\sum_{c'} \sum_{\mathbf{x}} \sum_i \mathbb{1}[x_i = c', y_i^* = \langle \cdot, t \rangle]}$$

3 Experiments

3.1 Setup

We experimented with projective parsing and used the informed initialization method proposed by Klein and Manning (2004) to initialize our model before learning. We tested our model both with and without using the universal linguistic rules. We used AdaGrad to optimize $\mathbf{w}$. We used POS tags of the input sentence as the tokens in our model. We learned our model on training sentences of length $\leq$ 10 and reported the directed dependency accuracy on test sentences of length $\leq$ 10 and on all test sentences.

3.2 Results on English

We evaluated our model on the Wall Street Journal corpus. We trained our model on section 2-21, tuned the hyperparameters on section 22, and tested our model on section 23. Table 3 shows the directed dependency accuracy of our model (CRFAE) compared with recently published results. It can be seen that our method achieves a comparable performance with state-of-the-art systems.

We also compared the performances of CRF autoencoder using an objective function with negative log likelihood vs. using our Viterbi version of the objective function (Eq.1). We find that the Viterbi version leads to much better performance (55.7 vs. 41.8 in parsing accuracy of WSJ), which echoes Spitkovsky et al. 's findings on Viterbi EM (2010).

3.3 Multilingual Results

We evaluated our model on seven languages from the PASCAL Challenge on Grammar Induction (Gelling et al., 2012). We did not use the Arabic corpus because the number of training sentences with length ≤ 10 is less than 1000. The result is shown in Table 4. The accuracies of DMV and Neural DMV are from Jiang et.al (2016). Both our model (CRFAE) and Convex-MST were tuned on the validation set of each corpus. It can be seen that our method achieves the best results on average. Besides, our method outperforms Convex-MST both with and without linguistic prior. From the results we can also see that utilizing universal linguistic prior greatly improves the performance of Convex-MST and our model.

4 Conclusion

In this paper, we propose a new discriminative model for unsupervised dependency parsing based on CRF autoencoder. Both learning and inference of our model are tractable. We tested our method on eight languages and show that our model is competitive to the state-of-the-art systems.

Abstract

We present a new method for the joint task of tagging and non-projective dependency parsing. We demonstrate its usefulness with an application to discontinuous phrase-structure parsing where decoding lexicalized spines and syntactic derivations is performed jointly. The main contributions of this paper are (1) a reduction from joint tagging and non-projective dependency parsing to the Generalized Maximum Spanning Arborescence problem, and (2) a novel decoding algorithm for this problem through Lagrangian relaxation. We evaluate this model and obtain state-of-the-art results despite strong independence assumptions.

1 Introduction

Discontinuous phrase-structure parsing relies either on formal grammars such as LCFRS, which suffer from a high complexity, or on reductions to non-projective dependency parsing with complex labels to encode phrase combinations. We propose an alternative approach based on a variant of spinal TAGs, which allows parses with discontinuity while grounding this work on a lexicalized phrase-structure grammar. Contrarily to previous approaches, (Hall and Nivre, 2008; Versley, 2014; Fernández-González and Martins, 2015), we do not model supertagging nor spine interactions with a complex label scheme. We follow Carreras et al. (2008) but drop projectivity.

We first show that our discontinuous variant of spinal TAG reduces to the Generalized Maximum Spanning Arborescence (GMSA) problem (Myung et al., 1995). In a graph where vertices are partitioned into clusters, GMSA consists in finding the arborescence of maximum weight incident to exactly one vertex per cluster. This problem is NP-complete even for arc-factored models. In order to bypass complexity, we resort to Lagrangian relaxation and propose an efficient resolution based on dual decomposition which combines a simple non-projective dependency parser on a contracted graph and a local search on each cluster to find a global consensus.

We evaluated our model on the discontinuous PTB (Evang and Kallmeyer, 2011) and the Tiger (Brants et al., 2004) corpora. Moreover, we show that our algorithm is able to quickly parse the whole test sets.

Section 2 presents the parsing problem. Section 3 introduces GMSA from which we derive an effective resolution method in Section 4. In Section 5 we define a parameterization of the parser which uses neural networks to model local probabilities and present experimental results in Section 6. We discuss related work in Section 7.

2 Joint Supertagging and Spine Parsing

In this section we introduce our problem and set notation. The goal of phrase-structure parsing is to produce a derived tree by means of a sequence of operations called a derivation. For instance in context-free grammars the derived tree is built from a sequence of substitutions of a non-terminal symbol with a string of symbols, whereas in tree adjoining grammars (TAGs) a derivation is a sequence of substitutions and adjunctions over elementary trees. We are especially interested in building discontinuous phrase-structure trees which may contain constituents with gaps.[1]

We follow Shen (2006) and build derived trees from adjunctions performed on spines. Spines are lexicalized unary trees where each level represents

[1] Although we will borrow concepts from TAGs, we do not require derivations to be TAG compatible (i.e. well-nested dependencies with a bounded number of gaps).

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1644–1654
Copenhagen, Denmark, September 7–11, 2017.

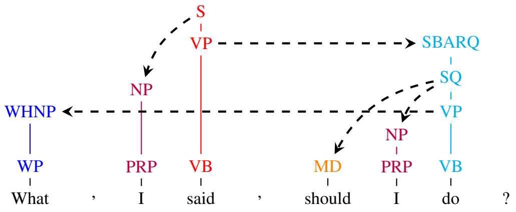

Figure 1: A derivation with spines and adjunctions (dashed arrows). The induced dependency tree is non-projective. Each color corresponds to a spine. We omit punctuation to simplify figures.

a lexical projection of the anchor. Carreras et al. (2008) showed how spine-based parsing could be reduced to dependency parsing: since spines are attached to words, equivalent derivations can be represented as a dependency tree where arcs are labeled by spine operations, an adjunction together with information about the adjunction site. However, we depart from previous approaches (Shen and Joshi, 2008; Carreras et al., 2008) by relaxing the projectivity constraint to represent all discontinuous phrase-structure trees (see Figure 1).

We assume a finite set of spines S. A spine s can be defined as a sequence of grammatical categories, beginning at root. For a sentence $\mathbf{w} = (w_0, w_1, \ldots, w_n)$ where w_k is the word at position k and w_0 is a dummy root symbol, a derivation is a triplet $(\mathbf{d}, \mathbf{s}, \mathbf{l})$ defined as follows. Adjunctions are described by a dependency tree rooted at 0 written as a sequence of arcs $\mathbf{d}$. If $(h, m) \in \mathbf{d}$ with $h \in \{0, \ldots, n\}$ and $m \in \{1, \ldots, n\}$, then the derivation contains an adjunction of the root of the spine at position m to a node from the spine at position h. Supertagging, the assignment of a spine to each word, is represented by a sequence $\mathbf{s} = (s_0, s_1, \ldots, s_n)$ of $n + 1$ spines, each spine s_k being assigned to word w_k. Finally, labeling $\mathbf{l} = (l_1, \ldots, l_n)$ is a sequence where l_k is the label of the k^{th} arc (h, m) of $\mathbf{d}$. The label consists of a couple (op, i) where op is the type of adjunction, here *sister* or *regular*[2], and i is the index of the adjunction node in s_h.

Each derivation is assigned an arc-factored score σ which is given by:

$$\sigma(\mathbf{d}, \mathbf{s}, \mathbf{l}; \mathbf{w}) = \sum_{(h,m) \in \mathbf{d}} \Omega(h, m, s_h, s_m, l_{hm}; \mathbf{w})$$

For instance, following score functions developed in (Carreras et al., 2008), this function could read $s_h[i]$, $s_h[i+1]$ and $s_m[0]$, where $s[i]$ denotes the i-th grammatical category of the spine s. The score of the derivation in Figure 1 could then reflect that the spine `WHNP-WP` associated with *What* is adjoined on the spine `SBARQ-SQ-VP-VB` associated with *do* on a site with the grammatical triple `[VP WHNP VB]`.

We assume that Ω accounts for the contribution of arcs, spines and labels to the score. The details of the contribution depend on the model. We choose the following:

$$\begin{aligned}\sigma(\mathbf{d}, \mathbf{s}, \mathbf{l}; \mathbf{w}) = \sum_{(h,m) \in \mathbf{d}} & (\alpha(h, m; \mathbf{w}) \\ & +\nu(s_m; h, m, \mathbf{w}) \\ & +\gamma(l_{hm}; h, m, s_h, \mathbf{w}))\end{aligned}$$

where α is the score related to the dependency tree, ν is the supertagging score and γ the labeling score. Note that functions α, ν and γ have access to the entire input string $\mathbf{w}$. Score function σ can be parameterized in many ways and we discuss our implementation in Section 5. In this setting, parsing a sentence $\mathbf{w}$ amounts to finding the highest-scoring derivation $(\mathbf{d}^*, \mathbf{s}^*, \mathbf{l}^*) = \arg\max_{(\mathbf{d},\mathbf{s},\mathbf{l})} \sigma(\mathbf{d}, \mathbf{s}, \mathbf{l}; \mathbf{w})$.

Recovering the derived tree from a derivation is performed by recursively mapping each spine and its dependencies to a possibly gappy constituent. Given a spine s_h and site index i, we look for the leftmost s_l and rightmost s_r dependents attached with regular adjunction. If any, we insert a new node between $s_h[i]$ and $s_h[i+1]$ with the same grammatical category as the first one. This new node fills the role of the foot node in TAGs. Every dependent of $s_h[i]$ with anchor in interval $[l+1, r-1]$ is moved to the newly created node. Remaining sister and regular adjunctions are simply attached to $s_h[i]$.

The complexity of the parsing problem depends on the type of dependency trees. In the case of projective trees, it has been shown (Eisner, 2000; Carreras et al., 2008; Li et al., 2011) that this could be performed in cubic worst-case time complexity with dynamic programming, whether supertags are fixed beforehand or not. However, the modification of the original Eisner algorithm requires that chart cells must be indexed not only by spans, or pairs of positions, but also by pairs of supertags. In practice the problem is intractable unless heavy

[2] The distinction is not crucial for the exposition. We refer readers to (Shen and Joshi, 2008; Carreras et al., 2008).

pruning is performed first in order to select a subset of spines at each position.

In the case of non-projective dependency trees, the problem has quadratic worst-case time complexity when supertags are fixed, since the problem then amounts to non-projective parsing and reduces to the Maximum Spanning Arborescence problem (MSA) as in (McDonald et al., 2005). Unfortunately, the efficient algorithm for MSA is greedy and does not *store* potential substructure candidates. Hence, when supertags are not fixed beforehand, a new arborescence must be recomputed for each choice of supertags. This problem can be seen as instance of the Generalized Maximum Spanning Arborescence problem, an NP-complete problem, which we review in the next section. Note that arc labels do not impact the asymptotic complexity of an arc-factored model. Indeed, only the labeled arc with maximum weight between two vertices is considered when parsing.

3 The Generalized Maximum Spanning Arborescence

In this section, we first define GMSA introduced by Myung et al. (1995). We formulate this problem as an integer linear program. We then explain the reduction from the joint supertagging and spine parsing task to this problem.[3]

3.1 Problem definition

Let $D = (V, A)$ be a directed graph. Given a subset $T \subseteq A$ of arcs, $V[T]$ denotes the set of vertices of V which are the tail or the head of at least one arc of T. These vertices are said to *be covered* by T. A subset $T \subseteq A$ of arcs is called an *arborescence* if the graph $(V[T], T)$ is connected, acyclic and each vertex has at most one entering arc. The vertex with no entering arc is called the *root* of T. An arborescence covering all vertices is called a *spanning arborescence*.

Let $\pi = \{V_0, \dots, V_n\}$, $n \in \mathbb{N}$ be a partition of V. Each element of π is called a *cluster*. An arborescence T of D covering exactly one vertex per cluster of π is called a *generalized spanning arborescence* (GSA). Figure 2 gives an example of a GSA. The partition of V is composed of a cluster having one vertex and six clusters having four vertices. Each cluster is depicted by a hatched area. The GSA is depicted by the dashed arcs.

Let W be a vertex subset of V. We denote $\delta^-(W)$ (resp. $\delta^+(W)$) the set of arcs entering (resp. leaving) W and $\delta(W) = \delta^-(W) \cup \delta^+(W)$.[4] Contracting W consists in replacing in D all vertices in W by a new vertex w, replacing each arc $uv \in \delta^-(W)$ by the arc uw and each arc $vu \in \delta^+(W)$ by wu. Let D^π be the graph obtained by contracting each cluster of π in D. Note that a GSA of D and π induces a spanning arborescence of D^π.[5] For instance, contracting each cluster in the graph given by Figure 2 leads to a graph D^π having 7 vertices and the set of dashed arcs corresponds to a spanning arborescence of D^π.

Given arc weights $\phi \in \mathbb{R}^A$, the weight of an arborescence T is $\sum_{a \in T} \phi_a$. Given (D, π, ϕ), the *Generalized Maximum Spanning Arborescence problem (GMSA)* consists in finding a GSA of D and π of maximum weight whose root is in V_0.

3.2 Integer linear program

Given a set S, $z \in \mathbb{R}^S$ is a vector indexed by elements in S. For $S' \subseteq S$, $z(S') = \sum_{s \in S'} z_s$.

A GSA $T \subseteq A$ is represented by variables $x \in \{0,1\}^V$ and $y \in \{0,1\}^A$ such that x_v (resp. y_a) is equal to 1 iff $v \in V[T]$ (resp. $a \in T$).

Since a GSA of D and π induces a spanning arborescence of D^π, the arc-incidence vector $y \in \{0,1\}^A$ of a GSA with root in V_0 satisfies the following, adapted from MSA (Schrijver, 2003):

$$y(\delta^-(V_0)) = 0 \tag{1}$$

$$y(\delta^-(V_k)) = 1 \qquad \forall 1 \leq k \leq n, \tag{2}$$

$$y(\delta^-(\bigcup_{V_k \in \pi'} V_k)) \geq 1 \quad \forall \pi' \subseteq \pi \setminus \{V_0\}. \tag{3}$$

Let $\mathcal{Y}$ denote all the arc-incidence vectors on D corresponding to a spanning arborescence in D^π whose root is the contraction of V_0. Then,

$$\mathcal{Y} = \{y \in \{0,1\}^A | y \text{ satisfies (1)-(3)}\}.$$

GMSA can be formulated with the following integer linear program:

$$\max_{x,y} \quad \phi \cdot y \tag{4}$$

$$\text{s.t.} \quad y \in \mathcal{Y} \tag{5}$$

$$x_v \geq y_a \qquad \forall v \in V, a \in \delta(v), \tag{6}$$

$$x_v(V_k) = 1 \qquad \forall 0 \leq k \leq n, \tag{7}$$

$$x_v \in \{0,1\} \qquad \forall v \in V. \tag{8}$$

[3] A similar reduction can be obtained in the reverse direction, thus proving the NP-completeness of our problem.

[4] By an abuse of notation, we identify any singleton $\{v\}$ with its element v.

[5] The converse does not hold: an arc subset of A corresponding to a spanning arborescence of D^π may not be a GSA of D and π since it may not induce a connected graph.

Let W and T be the vertex and arc sets given by $x_v = 1$ and $y_a = 1$ respectively. Since T is a spanning arborescence of D^π by (5), $(V[T], T)$ is an acyclic directed graph with n arcs such that V_0 has no entering arc and V_i, $i \in \{1, \dots, n\}$, has one entering arc. By constraints (7), W contains one vertex per cluster of π. Moreover, by inequalities (6), $V[T] \subseteq W$. Since $|W| = n + 1$ and $|T| = n$, $W = V[T]$ and $(V[T], T)$ is connected, so it is a GSA. Because its root is in V_0 by (5), it is an optimal solution for GMSA by (4).

3.3 Reduction from joint parsing to GMSA

Given an instance of the joint parsing problem, we construct an instance of GMSA as follows. With every spine s of every word w_k different from w_0, we associate a vertex v. For $k = 1, \dots, n$, we denote by V_k the set of vertices associated with the spines of w_k. We associate with w_0 a set V_0 containing only one vertex and V_0 will now refer both the cluster and the vertex it contains depending on the context. Let $\pi = \{V_0, \dots, V_n\}$ and $V = \cup_{k=0}^{n} V_k$. For every couple u, v of vertices such that $u \in V_h$ and $v \in V_m$, $h \neq m$ and $m \neq 0$, we associate an arc uv corresponding to the best adjunction of the root of spine s_m associated with v of V_m to spine s_h associated with vertex u of V_h. The weight of this arc is given by

$$\phi_{uv} = \alpha(h, m; \mathbf{w}) + \nu(s_m; h, m, \mathbf{w}) + \max_{l_{hm}} \gamma(l_{hm}; h, m, s_h, \mathbf{w})$$

which is the score of the best adjunction of s_m to s_h. This ends the construction of (D, π, ϕ).

There is a 1-to-1 correspondence between the solutions to GMSA and those to the joint supertagging and spine parsing task in which each adjunction is performed with the label maximizing the score of the adjunction. Indeed, the vertices covered by a GSA T with root V_0 correspond to the spines on which the derivation is performed. By definition of GSAs, one spine per word is chosen. Each arc of T corresponds to an adjunction. The score of the arborescence is the sum of the scores of the selected spines plus the sum of the scores of the best adjunctions with respect to T. Hence, one can solve GMSA to perform joint parsing.

As an illustration, the GSA depicted in Figure 2 represents the derivation tree of Figure 1: the vertices of $V \setminus V_0$ covered by the GSA are those associated with the spines of Figure 1 and the arcs represent the different adjunctions. For instance the arc from V_3 to V_2 represents the adjunction of spine `NP-PRP` to spine `S-VP-VB` at index 0.

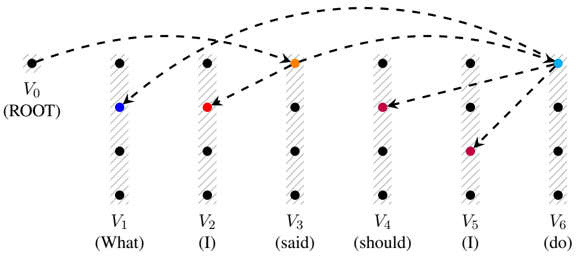

Figure 2: The generalized spanning arborescence inducing the derivation tree in Figure 1.

4 Efficient Decoding

Lagrangian relaxation has been successfully applied to various NLP tasks (Koo et al., 2010; Le Roux et al., 2013; Almeida and Martins, 2013; Das et al., 2012; Corro et al., 2016). Intuitively, given an integer linear program, it consists in relaxing some linear constraints which make the program difficult to solve and penalizing their violation in the objective function.

We propose a new decoding method for GMSA based on dual decomposition, a special flavor of Lagrangian relaxation where the problem is decomposed in several independent subproblems.

4.1 Dual decomposition

To perform the dual decomposition, we first reformulate the integer linear program (4)-(8) before relaxing linear constraints. For this purpose, we replace the variables y by three copies $\{y^i\} = \{y^0, y^1, y^2\}$, $y^i \in \{0,1\}^A$. We also consider variables $z \in \mathbb{R}^A$. Let ϕ^0, ϕ^1 and ϕ^2 be arc weight vectors such that $\sum_i \phi^i = \phi$.[6] GMSA can then be reformulated as:

$$\max_{x, \{y^i\}, z} \quad \sum_i \phi^i \cdot y^i \tag{9}$$

$$\text{s.t.} \quad y^0 \in \mathcal{Y} \tag{10}$$

$$x_v \geq y^1_a \qquad \forall v \in V, a \in \delta^-(v), \tag{11}$$

$$x_v \geq y^2_a \qquad \forall v \in V, a \in \delta^+(v), \tag{12}$$

$$x_v(V_k) = 1 \qquad \forall 0 \leq k \leq n, \tag{13}$$

$$x_v \in \{0,1\} \qquad \forall v \in V, \tag{14}$$

$$z = y^i \qquad \forall i. \tag{15}$$

[6] In our implementation, we choose $\phi^0 = \phi^1 = \phi^2 = \frac{1}{3}\phi$.

Note that variables z only appear in equations (15). Their goal is to ensure equality between copies y^0, y^1 and y^2. Variables z are usually called *witness variables* (Komodakis et al., 2007). Equality between y^0, y^1 and y^2 implies that (10)-(12) are equivalent to (5) and (6).

We now relax constraints (15) and build the dual objective (Lemaréchal, 2001) $\mathcal{L}^*(\{\lambda^i\})$:

$$\begin{aligned} \max_{x,\{y^i\},z} \quad & \sum_i \phi^i \cdot y^i + \sum_{i\in\{0,1,2\}} \lambda^i \cdot (z - y^i) \\ \text{s.t.} \quad & (10) - (14) \end{aligned}$$

where $\{\lambda^i\} = \{\lambda^0, \lambda^1, \lambda^2\}$, $\lambda^i \in \mathbb{R}^A$ for $i = 0, 1, 2$, is the set of Lagrangian multipliers. The dual problem is then:

$$\min_{\{\lambda^i\}} \mathcal{L}^*(\{\lambda^i\})$$

Note that, as there is no constraint on z, if $\sum_i \lambda^i \neq \mathbf{0}$ then $\mathcal{L}^*(\{\lambda^i\}) = +\infty$. Therefore, we can restrict the domain of $\{\lambda^i\}$ in the dual problem to the set $\Lambda = \{\{\lambda^i\} | \sum_i \lambda^i = \mathbf{0}\}$. This implies that z may be removed in the dual objective. This latter can be rewritten as:

$$\begin{aligned} \mathcal{L}^*(\{\lambda^i\}) = \max_{x,\{y^i\}} & \sum_i \bar{\phi}^i \cdot y^i \\ \text{s.t.} \quad & (10) - (14) \end{aligned}$$

where $\bar{\phi}^i = \phi^i - \lambda^i$ for $i = 0, 1, 2$.

4.2 Computing the dual objective

Given $\{\lambda^i\} \in \Lambda$, computing the dual objective $\mathcal{L}^*(\{\lambda^i\})$ can be done by solving the two following distinct subproblems:

$$\begin{aligned} P_1(\bar{\phi}^0) = & \max_{y^0} \bar{\phi}^0 \cdot y^0 \\ & \text{s.t.} \quad y^0 \in \mathcal{Y} \\ P_2(\bar{\phi}^1, \bar{\phi}^2) = & \max_{x,y^1,y^2} \bar{\phi}^1 \cdot y^1 + \bar{\phi}^2 \cdot y^2 \\ & \text{s.t.} \quad (11) - (14) \\ & \qquad y^i_a \in \{0, 1\} \qquad \forall a \in A, i = 1, 2. \end{aligned}$$

Subproblem P_1 can be solved by simply running the MSA algorithm on the contracted graph D^π.

Subproblem P_2 can be solved in a combinatorial way. Indeed, observe that each value of y^1 and y^2 is only constrained by a single value of x. The problem amounts to selecting for each cluster a vertex as well as all the arcs with positive weight covering it. More precisely, for each vertex $v \in V$, compute the *local weight* c_v defined by:

$$\sum_{a\in\delta^-(v)} \max\{0, \bar{\phi}^1\} + \sum_{a\in\delta^+(v)} \max\{0, \bar{\phi}^2\}.$$

Let $V^{\max}$ be the set of vertices defined as follows. For $k = 0, \ldots, n$, add in $V^{\max}$ the vertex $v \in V_k$ with the maximum weight c_v. Let A^1 and A^2 be the sets of arcs such that A^1 (resp. A^2) contains all the arcs with positive weights entering (resp. leaving) a vertex of $V^{\max}$. The vectors x, y^1 and y^2 corresponding respectively to the incidence vectors of $V^{\max}$, A^1 and A^2 form an optimal solution to P_2.

Hence, both supbroblems can be be solved with a $O(|\pi|^2)$ time complexity, that is quadratic w.r.t. the length of the input sentence.[7]

4.3 Decoding algorithm

Our algorithm seeks for a solution to GMSA by solving the dual problem since its solution is optimal to GMSA whenever it is a GSA. If not, a solution is constructed by returning the highest GSA on the spines computed during the resolution of the dual problem.

We solve the dual problem using a projected subgradient descent which consists in iteratively updating $\{\lambda^i\}$ in order to reduce the distance to the optimal assignment. Let $\{\lambda^{i,t}\}$ denotes the value of $\{\lambda^i\}$ at iteration t. $\{\lambda^{i,0}\}$ is initially set to $\mathbf{0}$. At each iteration, the value of $\{\lambda^{i,t+1}\}$ is computed from the value of $\{\lambda^{i,t}\}$ thanks to a subgradient of the dual objective. More precisely, we have

$$\{\lambda^{i,t+1}\} = \{\lambda^{i,t}\} - \eta^t \times \nabla\mathcal{L}^*(\{\lambda^{i,t}\})\}$$

where $\nabla\mathcal{L}^*(\{\lambda^{i,t}\})$ is a subgradient of $\mathcal{L}^*(\{\lambda^{i,t}\})$ and $\eta^t \in \mathbb{R}$ is the stepsize at iteration t. We use the projected subgradient from Komodakis et al. (2007). Hence, at iteration t, we must solve reparameterized subproblems P_1 and P_2 to obtain the current solution $(\bar{x}^t, \bar{y}^{0,t}, \bar{y}^{1,t}, \bar{y}^{2,t})$ of the dual objective. Then each multiplier is updated following

$$\lambda^{i,t+1} = \lambda^{i,t} - \eta^t \times \left(\bar{y}^{i,t} - \sum_{j=0}^{2} \frac{\bar{y}^{j,t}}{3} \right).$$

Note that for any value of $\{\lambda^i\}$, $\mathcal{L}^*(\{\lambda^i\})$ gives an upper bound for GMSA. So, whenever the

[7] In the general case, the time complexity is $O(|V|^2)$. But in our problem, the number of vertices per cluster is bounded by the grammar size: $O(|V|^2) = O(|S\pi|^2) = O(|\pi|^2)$.

optimal solution $\bar{x}^t, \{\bar{y}^{i,t}\}$ to the dual objective $\mathcal{L}^*(\{\lambda^{i,t}\})$ at iteration t is a primal feasible solution, that is $\bar{y}^{0,t} = \bar{y}^{1,t} = \bar{y}^{2,t}$, it is an optimal solution to GMSA and the algorithm ends. Otherwise, we construct a *pipeline solution* by performing a MSA on the vertices given by $\bar{x}^t$.

If after a fixed number of iterations we have not found an optimal solution to GMSA, we return the pipeline solution with maximum weight.

4.4 Lagrangian enhancement

The previsouly defined Lagrangian dual is valid but may lead to slow convergence. Thus, we propose three additional techniques which empirically improve the decoding time and the convergence rate: constraint tightening, arc reweighing and problem reduction.

Constraint tightening: In subproblem P_2, we consider a vertex and all of its adjacent arcs of positive weight. However, we know that our optimal solution must satisfy tree-shape constraints (5). Thus, every cluster except the root must have exactly one incoming arc and there is at most one arc between two clusters. Both constraints are added to P_2 without hurting its time complexity.

Reweighing: By modifying weights such that less incoming arcs have a positive weight, the solution of P_2 tends to be an arborescence. For each cluster $V_k \in \pi \setminus V_0$, let $\hat{A}_k$ be the set of incoming arcs with the highest weight $\hat{\phi}_k$. Then, let γ_k be a value such that $\phi_a - \gamma_k$ is positive only for arcs in $\hat{A}_k$. Subtracting γ_k from the weight ϕ_a of each arc of $\delta^-(V_k)$ and adding γ_k to the objective score does not modify the weight of the solution because only one entering arc per cluster is selected.

Problem reduction: We use the pipeline solutions computed at each iteration to set the value of some variables. Let $\bar{x}, \{\bar{y}^i\}$ be the optimal solution of $\mathcal{L}^*(\{\lambda^i\})$ computed at any iteration of the subgradient algorithm. For $k = 1, \dots, n$, let $\bar{v}$ be the vertex of V_k such that $\bar{x}_{\bar{v}} = 1$. Using the local weights (Section 4.2), for all $v \in V_k \setminus \{\bar{v}\}$, $\mathcal{L}^*(\{\lambda^i\}) + c_v - c_{\bar{v}}$ is an upper bound on the weight of any solution (x, y) to GMSA with $x_v = 1$. Hence, if it is lower than the weight of the best pipeline solution found so far, we can guarantee that $x_v = 0$ in any optimal solution. We can check the whole graph in linear time if we keep local weights c in memory.

5 Neural Parameterization

We present a probabilistic model for our framework. We implement our probability distributions with neural networks, more specifically we build a neural architecture on top of bidirectional recurrent networks that compute context sensitive representations of words. At each step, the recurrent architecture is given as input a concatenation of word and part-of-speech embeddings. We refer the reader to (Kiperwasser and Goldberg, 2016; Dozat and Manning) for further explanations about bidirectional LSTMs (Hochreiter and Schmidhuber, 1997). In the rest of this section, b_m denotes the context sensitive representation of word w_m.

We now describe the neural network models used to learn and assign weight functions α, ν and γ under a probabilistic model. Given a sentence $\mathbf{w}$ of length n, we assume a derivation $(\mathbf{d}, \mathbf{s}, \mathbf{l})$ is generated by three distinct tasks. By chain rule, $P(\mathbf{d}, \mathbf{s}, \mathbf{l}|\mathbf{w}) = P_\alpha(\mathbf{d}|\mathbf{w}) \times P_\nu(\mathbf{s}|\mathbf{d}, \mathbf{w}) \times P_\gamma(\mathbf{l}|\mathbf{d}, \mathbf{s}, \mathbf{w})$. We follow a common approach in dependency parsing and assign labels $\mathbf{l}$ in a post-processing step, although our model is able to incorporate label scores directly. Thus, we are left with jointly decoding a dependency structure and assigning a sequence of spines. We note s_i the i^{th} spine:[8]

$$\begin{aligned} & P_\alpha(\mathbf{d}|\mathbf{w}) \times P_\nu(\mathbf{s}|\mathbf{d}, \mathbf{w}) \\ &= \prod_{(h,m)\in\mathbf{d}} P_\alpha(h|m, \mathbf{w}) \times P_\nu(s_m|m, \mathbf{d}, \mathbf{w}) \\ &= \prod_{(h,m)\in\mathbf{d}} P_\alpha(h|m, \mathbf{w}) \times P_\nu(s_m|m, h, \mathbf{w}) \end{aligned}$$

We suppose that adjunctions are generated by an arc-factored model, and that a spine prediction depends on both current position and head position.

Then parsing amounts to finding the most probable derivation and can be realized in the log space, which gives following weight functions:

$$\begin{aligned} \alpha(h, m; \mathbf{w}) &= \log P_\alpha(h|m, \mathbf{w}) \\ \nu(s_m; h, m, \mathbf{w}) &= \log P_\nu(s_m|m, h, \mathbf{w}) \end{aligned}$$

where α represents the arc contribution and ν the spine contribution (cf. Section 2).

Word embeddings b_k are first passed through specific feed-forward networks depending on the

[8] We assume that the spine for the root w_0 is unique.

distribution and role. The result of the feed-forward transformation parameterized by set of parameters ρ of a word embedding b_s is a vector denoted $b_s^{(\rho)}$. We first define a biaffine attention networks weighting dependency relations (Dozat and Manning):

$$o^{(\alpha)}_{h,m} = b^{(\alpha_1)\top}_m W^{(\alpha)} b^{(\alpha_2)}_h + V^{(\alpha)} b^{(\alpha_2)}_h$$

where $W^{(\alpha)}$ and $V^{(\alpha)}$ are trainable parameters. Moreover, we define a biaffine attention classifier networks for class c as:

$$\begin{aligned} o^{(\tau)}_{c,h,m} &= b^{(\tau_1)\top}_m W^{(\tau_c)} b^{(\tau_2)}_h \\ &\quad + V^{(\tau_c)} \left(b^{(\tau_1)}_m \oplus b^{(\tau_2)}_h \right) \\ &\quad + u^{(\tau_c)} \end{aligned}$$

where $\oplus$ is the concatenation. $W^{(\tau_c)}$, $V^{(\tau_c)}$ and $u^{(\tau_c)}$ are trainable parameters. Then, we define the weight of assigning spine s to word at position m with head h as $o^{(\nu)}_{s,h,m}$.

Distributions P_α and P_ν are parameterized by these biaffine attention networks followed by a softmax layer:

$$P_\alpha(h|m,\mathbf{w}) = \frac{\exp o^{(\alpha)}_{h,m}}{\sum_{h'} \exp o^{(\alpha)}_{h',m}}$$

$$P_\nu(s|h,m,\mathbf{w}) = \frac{\exp o^{(\nu)}_{s,h,m}}{\sum_{s'} \exp o^{(\nu)}_{s',h,m}}$$

Now we move on to the post-processing step predicting arc labels. For each adjunction of spine s at position m to spine t at position h, instead of predicting a site index i, we predict the non-terminal nt at $t[i]$ with a biaffine attention classifier.[9] The probability of the adjunction of spine s at position m to a site labeled with nt on spine t at position h with type $a \in \{\text{regular}, \text{sister}\}$ is:

$$\begin{aligned} P_\gamma(nt, a|h,m) &= P_{\gamma'}(nt|h,m,\mathbf{w}) \\ &\quad \times P_{\gamma''}(a|h,m\mathbf{w}) \end{aligned}$$

P_γ and $P_{\gamma''}$ are again defined as distributions from the exponential family using biaffine attention classifiers:

$$P_{\gamma'}(nt|h,m,t) = \frac{\exp o^{(\gamma')}_{nt,h,m}}{\sum_{nt'} \exp o^{(\gamma')}_{nt,h,m}}$$

$$P_{\gamma''}(a|h,m,t) = \frac{\exp o^{(\gamma'')}_{t,h,m}}{\sum_{a'} \exp o^{(\gamma'')}_{a',h,m}}$$

We use embeddings of size 100 for words and size 50 for parts-of-speech tags. We stack two bidirectional LSTMs with a hidden layer of size 300, resulting in a context sensitive embedding of size 600. Embeddings are shared across distributions. All feed-forward networks have a unique elu-activated hidden layer of size 100 (Clevert et al., 2016). We regularize parameters with a dropout ratio of 0.5 on LSTM input. We estimate parameters by maximizing the likelihood of the training data through stochastic subgradient descent using Adam (Kingma and Ba, 2015). Our implementation uses the Dynet library (Neubig et al., 2017) with default parameters.

6 Experiments

We ran a series of experiments on two corpora annotated with discontinuous constituents.

English We used an updated version of the Wall Street Journal part of the Penn Treebank corpus (Marcus et al., 1994) which introduces discontinuity (Evang and Kallmeyer, 2011). Sections 2-21 are used for training, 22 for developpement and 23 for testing. We used gold and predicted POS tags by the Stanford tagger,[10] trained with 10-jackknifing. Dependencies are extracted following the head-percolation table of Collins (1997).

German We used the Tiger corpus (Brants et al., 2004) with the split defined for the SPMRL 2014 shared task (Maier, 2015; Seddah et al., 2013). Following Maier (2015) and Coavoux and Crabbé (2017), we removed sentences number 46234 and 50224 as they contain annotation errors. We only used the given gold POS tags. Dependencies are extracted following the head-percolation table distributed with Tulipa (Kallmeyer et al., 2008).

We emphasize that long sentences are not filtered out. Our derivation extraction algorithm is similar to the one proposed in Carreras et al. (2008). Regarding decoding, we use a beam of size 10 for spines w.r.t. $P_\nu(s_m|m,\mathbf{w}) = \sum_h P_\nu(s_m|h,m,\mathbf{w}) \times P_\alpha(h|m,\mathbf{w})$ but allow every possible adjunction. The maximum number of iterations of the subgradient descent is set to 500 and the stepsize η^t is fixed following the rule of Polyak (1987).

Parsing results and timing on short sentences only ($\leq$ 40 words) and full test set using the de-

[9] If a spine contains repeated non-terminal sequences, we select the lowest match.

[10] http://nlp.stanford.edu/software/tagger.shtml

fault discodop[11] eval script are reported on Table 1 and Table 2.[12] We report labeled recall (LR), precision (LP), F-measure (LF) and time measured in minutes. We also report results published by van Cranenburgh et al. (2016) for the discontinuous PTB and Coavoux and Crabbé (2017) for Tiger. Moreover, dependency unlabeled attachment scores (UAS) and tagging accuracies (Spine acc.) are given on Table 3. We achieve significantly better results on the discontinuous PTB, while being roughly 36 times faster together with a low memory footprint.[13] On the Tiger corpus, we achieve on par results. Note however that Coavoux and Crabbé (2017) rely on a greedy parser combined with beam search.

Fast and efficient parsing of discontinuous constituent is a challenging task. Our method can quickly parse the whole test set, without any parallelization or GPU, obtaining an optimality certificate for more than 99% of the sentences in less than 500 iterations of the subgradient descent. When using a non exact decoding algorithm, such as a greedy transition based method, we may not be able to deduce the best opportunity for improving scores on benchmarks, such as the parameterization method or the decoding algorithm. Here the behavior may be easier to interpret and directions for future improvement easier to see. We stress that our method is able to produce an optimality certificate on more than 99% of the test examples thanks to the enhancement presented in Section 4.4.

7 Related Work

Spine-based parsing has been investigated in (Shen and Joshi, 2005) for Lexicalized TAGs with a left-to-right shift-reduce parser which was subsequently extended to a bidirectional version in (Shen and Joshi, 2008). A graph-based algorithm was proposed in (Carreras et al., 2008) for second-order projective dependencies, and for a form of non-projectivity occurring in machine translation (i.e. projective parses of permutated input sentences) in (Carreras and Collins, 2009).

Discontinuous phrase-structure parsing through dependencies in contexts other that TAGs have been explored in (Hall and Nivre, 2008; Versley, 2014; Fernández-González and Martins, 2015). The first two encode spine information as arc labels while the third one relaxes spine information by keeping only the root and height of the adjunction, thus avoiding combinatorial explosion. Labeling is performed as a post-processing step in these approaches, since the number of labels can be very high. Our model also performs labeling after structure construction, but it could be performed jointly without major issue. This is one way our model could be improved.

GMSA has been studied mostly as a way to solve the non directed version (i.e. with symetric arc weights) (Myung et al., 1995), see (Pop, 2009; Feremans et al., 1999) for surveys on resolution methods. Myung et al. (1995) proposed an exact decoding algorithm through branch-and-bound using a dual ascent algorithm to compute bounds. Pop (2002) also used Lagrangian relaxation – in the non directed case – where a single subproblem is solved in polynomial time. However, the relaxed constraints are inequalities: if the dual objective returns a valid primal solution, it is not a sufficient condition in order to guarantee that

[11] https://github.com/andreasvc/disco-dop/

[12] C2017 processing time is 137.338 seconds plus approximatively 30 seconds for model and corpus loading (personnal communication).

[13] Execution times are not directly comparable because we report our experimental conditions and published results.

it is the optimal solution (Beasley, 1993), and thus the stopping criterion for the subgradient descent is usually slow to obtain. To our knowledge, our system is the first time that GMSA is used to solve a NLP problem.

Dual decomposition has been used to derive efficient practical resolution methods in NLP, mostly for machine translation and parsing, see (Rush et al., 2010) for an overview and (Koo et al., 2010) for an application to dependency parsing.

To accelerate the resolution, our method relies heavily on problem reduction (Beasley, 1993), which uses the primal/dual bounds to filter out suboptimal assignments. Exact pruning based on duality has already been studied in parsing, with branch and bound (Corro et al., 2016) or column generation (Riedel et al., 2012) and in machine translation with beam search (Rush et al., 2013).

8 Conclusion

We presented a novel framework for the joint task of supertagging and parsing by a reduction to GMSA. Within this framework we developed a model able to produce discontinuous constituents. The scoring model can be decomposed into tagging and dependency parsing and thus may rely on advances in those active fields.

This work could benefit from several extensions. Bigram scores on spines could be added at the expense of a third subproblem in the dual objective. High-order scores on arcs like grandparent or siblings can be handled in subproblem P_2 with the algorithms described in (Koo et al., 2010). In this work, the parameters are learned as separate models. Joint learning in the max-margin framework (Komodakis, 2011; Komodakis et al., 2015) may model interactions between vertex and arc weights better and lead to improved accuracy. Finally, we restricted our grammar to spinal trees but it could be possible to allow full lexicalized TAG-like trees, with substitution nodes and even obligatory adjunction sites. Derivations compatible with the TAG formalism (or more generally LCFRS) could be recovered by the use of a constrained version of MSA (Corro et al., 2016).

Acknowledgements

We thank the anonymous reviewers for their insightful comments. We thank Laura Kallmeyer and Kilian Evang for providing us with the script for the discontinuous PTB. Incremental Graph-based Neural Dependency Parsing

Abstract

Very recently, some studies on neural dependency parsers have shown advantage over the traditional ones on a wide variety of languages. However, for graph-based neural dependency parsing systems, they either count on the long-term memory and attention mechanism to implicitly capture the high-order features or give up the global exhaustive inference algorithms in order to harness the features over a rich history of parsing decisions. The former might miss out the important features for specific headword predictions without the help of the explicit structural information, and the latter may suffer from the error propagation as false early structural constraints are used to create features when making future predictions. We explore the feasibility of explicitly taking high-order features into account while remaining the main advantage of global inference and learning for graph-based parsing. The proposed parser first forms an initial parse tree by head-modifier predictions based on the first-order factorization. High-order features (such as grandparent, sibling, and uncle) then can be defined over the initial tree, and used to refine the parse tree in an iterative fashion. Experimental results showed that our model (called INDP) archived competitive performance to existing benchmark parsers on both English and Chinese datasets.

1 Introduction and Motivation

The rise of machine learning methods in natural language processing (NLP) coupled with the availability of treebanks (Buchholz and Marsi, 2006) for a wide variety of languages has led to a rapid increase in research on data-driven dependency parsing. Two predominant paradigms for the data-driven dependency parsing are often called graph-based and transition-based dependency parsing (McDonald and Nivre, 2007, 2011). The first category learns the parameters to score correct dependency subgraphs over incorrect ones, typically by factoring the graphs into their component directed arcs, and performs parsing by searching the highest-scoring graph for a given sentence. The second category of parsing systems instead learns to predict one transition from one parse state to the next given a parse history, and performs parsing by taking the predicted transitions at each parse state until a complete dependency graph is derived.

Empirical studies show that the graph-based and transition-based models exhibit no statistically significant difference in accuracy on a variety of languages, although they are very different theoretically (McDonald and Nivre, 2011). Graph-based models are usually trained by maximizing the difference in score between the entire correct dependency graph and all incorrect ones for every training sentence. However, exhaustive inference is generally NP-hard when the score is factored over any extended scope of the dependency subgraph beyond a single arc (McDonald and Satta, 2007), which is the primary shortcoming of the graph-based systems. In transition-based parsing, the feature representations are not restricted to a small number of arcs in the graph but can be derived from all the dependency subgraphs built so far, while the main disadvantage of these models is that the local greedy parsing strategy may lead to the error propagation because false early predictions can eliminate valid parse trees.

With a few exceptions (Zeman and Žabokrtskỳ, 2005; Zhang and Clark, 2008; Zhang et al., 2014), the graph-based parsers usually require global

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1655–1665
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

learning and inference, but define features over a limited scope of the dependency graph, while the transition-based ones typically use local, greedy training and inference, but introduce a rich feature space based on the history of parsing decisions.

Many approaches have been proposed to overcome the weaknesses of traditional graph-based or transition-based models. There are at least three ways for potential improvement: ensemble—weighting the predictions of multiple parsing systems (Sagae and Lavie, 2006; Hall et al., 2007), feature integration—combining the two models by allowing the output of one model to define features for the other (Martins et al., 2008; Nivre and McDonald, 2008; McDonald and Nivre, 2011), and novel approaches—changing the underlying model structure directly by constructing globally trained transition-based parsers (Zhang and Clark, 2008; Huang and Sagae, 2010) or graph-based parsers with rich features (Riedel and Clarke, 2006; Nakagawa, 2007; Smith and Eisner, 2008; Martins et al., 2009).

Very recently, some studies on the deep architectures have shown advantage over the shallow ones on a wide variety of dependency parsing benchmarks. Deep neural networks were used to replace the classifiers for predicting optimal transitions in transition-based parers (Chen and Manning, 2014) or the scoring functions for ranking the subgraphs in graph-based rivals (Kiperwasser and Goldberg, 2016a,b). There are several recent developments in neural dependency parsing (Weiss et al., 2015; Zhou et al., 2015; Dyer et al., 2015), which can be viewed as targeting the weaknesses of locally greedy algorithms in transition-based models by using the beam search and conditional random field loss objective, although using the beam search instead of strictly deterministic parsing can to some extent alleviate the error propagation problem but does not eliminate it.

For graph-based neural dependency parsing systems, they either count on the long-term memory and neural attention to implicitly capture the high-order features (Kiperwasser and Goldberg, 2016b; Cheng et al., 2016; Dozat and Manning, 2017) or give up the global inference algorithms in order to introduce features over a rich history of parsing decisions by a greedy, bottom-up method (Kiperwasser and Goldberg, 2016a). The former might miss out the important information for specific headword predictions without the help of the structural features derived from the entire parse tree, while the latter may suffer from the error propagation as false structural constraints are used to create features when making future predictions. In this study, we explore the feasibility of explicitly taking advantage of high-order features while remaining the strength of global exhaustive inference and learning as a graph-based parser.

The proposed parser first encodes each word in a sentence by distributed embeddings using a convolutional neural network and constructs an initial parse graph by head-modifier predictions with a maximum directed spanning tree algorithm based on the first-order features (i.e. the score is factored over the arcs in a graph). Once an initial parse graph is built, the high-order features (such as grandparent, sibling, and uncle) can be defined, and used to refine the structure of the parse tree in an iterative way. Theoretically, the refinement will continue until no change is made in the iteration. But experimental results demonstrated that pretty good performance can be achieved with no more than twice updates because many dependencies are determined by independent arc prediction and a few head-modifier pairs need to be re-estimated after one update (i.e. only a few changes above and beyond the dominant first-order scores). We call this proposed model an incremental neural dependency parsing (INDP)[1].

2 Incremental Neural Dependency Parser

Given an input sentence x, we denote the set of all valid dependency parse trees that can be constructed from x as $\mathcal{Y}(x)$. Assuming there exists a graph scoring function s, the dependency parsing problem can be formulated as finding the highest scoring directed spanning tree for the sentence x.

$$y^*(x) = \operatorname*{argmax}_{\hat{y} \in \mathcal{Y}(x)} s(x, \hat{y}; \theta) \tag{1}$$

where $y^*(x)$ is the parse tree with the highest score, and θ is a set of the parameters used to compute the scores. To make the search tractable, the score of a graph is usually factorized into the sum of its arc (head-modifier) scores (McDonald et al., 2005a).

$$s(x, \hat{y}; \theta) = \sum_{(h,m) \in A(\hat{y})} s(h, m; \theta) \tag{2}$$

[1] The source code is available at http://homepage.fudan.edu.cn/zhengxq/deeplearning/

where $A(\hat{y})$ represents a set of directed arcs in the parse tree $\hat{y}$. The score of an arc (h, m) represents the likelihood of creating a dependency from head h to modifier (or dependent) m in a dependency tree. If each arc score is estimated independently, we call it a first-order factorization. When the scoring is based on two or more arcs, second- or high-order factorizations are applied.

In traditional approaches, this score is commonly defined to be the product of a high dimensional feature representation of the arc and a learned weighting parameter vector. The performance of those systems is heavily dependent on the choice of features. For that reason, much effort in designing such systems goes into the feature engineering, which is important but labor-intensive, mainly first based on human ingenuity and linguistic intuition, and then confirmed or refined by empirical analyses. In this study, a neural network is designed instead to estimate the arc scores using the high-order features. In the following, we first describe how the word representations are produced. Then, the key components of the INDP, direction-specific scoring with special normalization and incremental refinement with high-order features, are discussed in detail. Finally, we present the entire parsing algorithm of the INDP.

2.1 Word Feature Representations

In graph-based neural dependency parsing work, such as (Kiperwasser and Goldberg, 2016a,b; Dozat and Manning, 2017), recurrent neural network (RNN) is a popular statistical learner used to produce the continuous vector representations for each word in a sentence due to its ability to bridge long time lags between relevant inputs. We chose to use one-dimensional convolution instead as a building block because it is good enough to capture the interactions of word feature representations in a context window with less computational cost. Such a design makes the parameters of our first-order parser to be optimized efficiently, which will be augmented with the high-order features (i.e. long distance dependencies) at incremental refinement stages.

The words are fed into the network as indices that are used by a lookup operation to transform words into their feature vectors. We consider a fixed-sized word dictionary $\mathcal{D}$[2]. The vector representations are stored in a word embedding matrix $E^{word} \in \mathbb{R}^{d \times |\mathcal{D}|}$, where d is the dimensionality of the vector space (a hyper-parameter to be chosen) and $|\mathcal{D}|$ is the size of the dictionary. Like (Chen and Manning, 2014; Dyer et al., 2015; Weiss et al., 2015; Cheng et al., 2016), we also map part-of-speech (POS) tags to another q-dimensional vector space, and provide POS type features for words. Formally, assume we are given a sentence $x_{[1:n]}$ that is a sequence of n words $x_i, 1 \leq i \leq n$. For each word $x_i \in \mathcal{D}$ that has an associated index k_i into the column of the matrix E^{word}, and is labeled as a POS tag of type l_i, its feature representation is obtained by concatenating both word and POS tag embeddings as:

$$E(x_i) = E^{word} e_{k_i} \oplus E^{pos} e_{l_i} \tag{3}$$

where $E^{pos} \in \mathbb{R}^{q \times |\mathcal{P}|}$ is a POS tag embedding matrix and $|\mathcal{P}|$ is the size of POS tag set $\mathcal{P}$ (fine-grained POS tags are used if available). Binary e_{k_i} and e_{l_i} are one-hot encoding vectors for the ith word in the sentence.

The lookup table layer extracts features for each single word, but the meaning of a word is strongly related to its surrounding words. Given a word, we consider a fixed size window w (another hyper-parameter) of words around it. More precisely, given an input sentence $x_{[1:n]}$, the feature window produced by the first lookup table layer at position x_i can be written as:

$$f^{win}_{x_i} = (E(x_{i-w/2}) \cdots E(x_i) \cdots E(x_{i+w/2})) \tag{4}$$

where the word feature window is a matrix $f^{win} \in \mathbb{R}^{(d+q) \times w}$, and each column of the matrix is the word feature vector in the context window. A one-dimensional convolution is used to yield another feature vector by taking the dot product of filter vectors with the rows of the matrix f^{win} at the same dimension. After each row of f^{win} is convolved with the corresponding column of a filter matrix W^1, some non-linear function $\phi(\cdot)$ will be applied as:

$$f^{con} = \phi(f^{win} \odot W^1) \tag{5}$$

where the weights in the matrix $W^1 \in \mathbb{R}^{w \times (d+q)}$ are the parameters to be trained, and the output $f^{con} \in \mathbb{R}^{(d+q)}$ is a vector. We choose a hyperbolic tangent as the non-linear function ϕ. The word feature vectors from a window of text can be computed efficiently thanks to the speed advantage of the one-dimensional convolution (Kalchbrenner et al., 2014).

[2] Unless otherwise specified, the word dictionary is extracted from the training set. Unknown words are mapped to a special symbol that is not used elsewhere.

2.2 Direction-Specific Scoring

For the same head-modifier arc (h, m), the head word h may occur on the left size of m (i.e. left-arc) in some sentences while it also can appear on the right size of m (i.e. right-arc) in other ones. Considering two English sentences excerpted from the Penn Treebank (Buchholz and Marsi, 2006): “A group of workers exposed to it.”, and “Mr. Vinken is chairman of Elsevier, the Dutch publishing group.”, they have the same (group, of) head-modifier arc, but those two words occur in different orders. This would not be problem in the traditional models, such as (McDonald et al., 2005a; Nivre and McDonald, 2008), in which the arc directions are directly used as features by their structured learning algorithms. However, it is hard to train a single neural network that gives a higher score to the left-arc case than the right-arc one in some situations while reverses in others because of the symmetries in weight space (Note that we cannot tell which case is correct in advance, and both cases need to be scored). It would be more serious when the first-order factorization is applied due to the lack of context information.

Based on the above observations, we use a multi-layer perceptron (MLP) to score the left-arc cases, and another MLP to score the right-arc ones. Those two MLPs share the word and POS tag embeddings, and can update them when necessary during the training process. Formally, if a MLP with one hidden layer is used, the score of each possible head-modifier arc is computed as:

$$s(h, m; \theta) = W^3(\phi(W^2(f_h^{con} \oplus f_m^{con} \oplus f_{h,m}^{dis}) + b^2)) \quad (6)$$

where the convolutional outputs of the head and dependent words are concatenated with a bucketed distance between the head and modifier, denoted by $f_{h,m}^{dis}$, in buckets of 0 (root), 1, 2, 3-5, and 6+, and feed into the MLP for scoring. The weights in the hidden and output layers are denoted by W^2 and W^3 respectively, and the corresponding bias by b^2. Once every possible arc is scored, we obtain a matrix like Figure 1, in which the element at the row i and column j is the score for (x_i, x_j) arc, denoted by $s(i, j)$. An artificial word, x_0, has been inserted at the beginning of a sentence that will always serve as the single root of the graph and is primarily a means to simplify computation. The scores at the lower (or upper) triangular are computed by the left-arc (or right-arc) MLP, and the shaded elements do not need to be calculated. We can treat $s(i, j)$ as a score of the corresponding arc and then search for the highest scoring directed spanning tree to form a dependency parse tree as proposed in (McDonald et al., 2005b). This problem can be solved using the Chu-Liu-Edmonds algorithm (Chu and Liu, 1965; Edmonds, 1967), which can be implemented in $O(n^2)$.

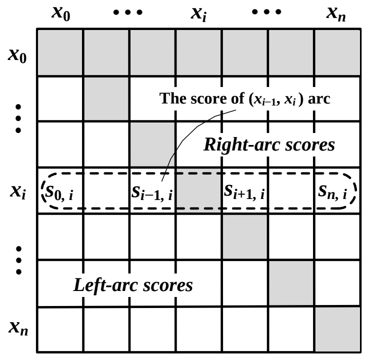

Figure 1: Scoring matrix for possible head and modifier arcs, in which the element at the row i and column j is the score for (x_i, x_j) arc, denoted by $s(i, j)$. A dependency tree can be formed by finding the highest scoring directed spanning tree over the scoring matrix.

The left-arc and right-arc MLPs should carefully collaborate with each other; otherwise, one MLP would be overwhelmed by another (i.e. the maximum score produced by one MLP is less than the minimum by another). To overcome this bias problem, we use the partition function by summing over the elements in each row of the scoring matrix, namely the scores/probabilities are normalized across the two MLPs. The conditional probability of arc (x_i, x_j) given a sentence $x_{[1:n]}$ is defined as:

$$\begin{gathered} p((x_i, x_j)|x_{[1:n]}; \theta) = \frac{\exp s(x_i, x_j; \theta)}{Z_i(x_{[1:n]}; \theta)} \\ \text{where } Z_i(x_{[1:n]}; \theta) = \sum_{i \in \{0 \ldots n\}, i \neq j} \exp s(x_i, x_j; \theta) \end{gathered} \quad (7)$$

Each $Z_i(x_{[1:n]}; \theta)$ is a normalization term used to predict x_i’s head word.

2.3 Incremental Refinement with High-order Features

Given an input sentence, once the initial dependency tree is built using the first-order factorization, we can define the high-order features over the resulting tree. For each head-modifier arc, the modifier’s left sibling, right sibling, leftmost child, and rightmost child vector representations are concatenated with the inputs of Equation (6), which are then feed into two new left-arc and right-arc

MLPs to update the scoring matrix. Like the head and modifier, those additional feature representations are added as the results produced by the convolution layer. As shown in Figure 2, commonly-used high-order features have been take into account, such as consecutive sibling (H, B, S), tri-siblings (B, M, S), and grandparent (H, M, R). The missing feature vectors are replaced by one of four special vectors, namely “left-sibling”, “right-sibling”, “leftmost-child”, and “rightmost-child” according to their relations to the modifier word.

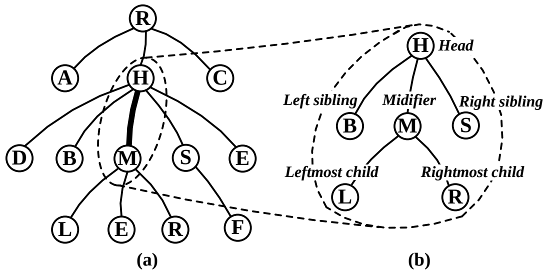

Figure 2: High-order features. (a) An example dependency parse tree. (b) The subgraph used to define high-order features for the head-modifier arc (H, M).

Although high-order features are used, the highest scoring parse tree still can be founded efficiently in $O(n^2)$ by the Chu-Liu-Edmonds algorithm (Chu and Liu, 1965; Edmonds, 1967). The main rationale is that, even in the presence of high-order features, the resulting scores remain based on single head-modifier arcs. The higher-order features are derived from the parse tree obtained with first-order inference, and because that tree is already pretty good, these higher-order features end up being a good approximation, and such approximation can be further improved by incremental refinements upon the parse tree. Thus, the high-order features used by the scoring MLPs can offer deliberate refinement above and beyond the first-order results. Theoretically, the refinement can be made until there is no update in the scoring matrix. However, experimental results show that comparable performance can be achieved with no more than twice high-order refinements (see Section 3).

We add a softmax layer to the network (after removing the last scoring layer) to predict syntactic labels for each arc. Labeling is trained by minimizing the cross-entropy error of the softmax layer using backpropagation. The network performs the structure prediction and labeling jointly. The two tasks shared the several layers (from the input to convolutional layers) of the network. When minimizing the cross-entropy error of the softmax layer, the error will also backpropagate and influence both the network parameters and the embeddings. We list our incremental neural dependency parsing algorithm in Figure 3. Staring with an initial tree formed using the first-order features, the algorithm makes changes to the parse tree with the high-order refinements in an attempt to climb the objective function.

```
Inputs:
 $\theta$: neural network parameters.
 $x$: an input sentence.
 $T$: maximum number of iterations.
Output: optimal dependency tree $y^*$.
Algorithm:
form an initial tree using the first-order features;
$t = 0$;
repeat
  update the scoring matrix using the high-order features;
  find the highest scoring tree $y$ by Chu-Liu-Edmonds
  algorithm;
  $t = t + 1$;
until no change in this iteration or $t \geq T$;
predict syntactic labels based on the parse tree $y$;
return $y^* = y$;
```

Figure 3: Incremental neural dependency parsing (INDP) algorithm.

2.4 Training

Given a training example (x, y), we defined a structured margin $\Delta(x, y, \hat{y})$ loss for proposing a parse $\hat{y}$ for sentence x when y is the true parse. This penalty is proportional to the number of unlabeled arcs on which the two parse trees do not agree. In general, $\Delta(x, y, \hat{y})$ is equal to 0 if $y = \hat{y}$. The loss function is defined as a penalization of incorrect arcs:

$$\Delta(x, y, \hat{y}) = \sum_{(h,m) \in A(\hat{y})} \kappa \mathbf{1}\{(h, m) \notin A(y)\} \qquad (8)$$

where κ is a penalization term to each incorrect arc, and $A(y)$ is a set of arcs in the true parse y.

For a training set, we seek a function with small expected loss on unseen sentences. The function we consider take the following form as Equation (1). The score of a tree $\hat{y}$ is higher if the algorithm is more confident that the structure of the tree is correct. In the max-margin estimation framework, we want to ensure that the highest scoring tree is the true parse for all training instances (x^i, y^i), $i = 1, \cdots, h$, and it’s score to be larger up to a margin defined by the loss. For all i in the training data:

$$s(\theta, x^i, y^i) \geq s(\theta, x^i, \hat{y}) + \Delta(x^i, y^i, \hat{y}) \qquad (9)$$

These lead us to minimize the following regularized objective for h training instances:

$$\begin{aligned} J(\theta) &= \frac{1}{h}\sum_{i=1}^{h} E^{i}(\theta) + \frac{\lambda}{2}||\theta||^{2}, \text{where} \\ E_i(\theta) &= \max_{\hat{y}\in\mathcal{Y}(x^i)} (0, (s(\theta, x^i, \hat{y}) + \Delta(x^i, y^i, \hat{y})) \\ &\quad - s(\theta, x^i, y^i)) \end{aligned} \tag{10}$$

where the coefficient λ governs the relative importance of the regularization term compared with the error. The trees are penalized more by the loss when they deviate from the correct one. Minimizing this objective maximizes the score of the correct tree, and minimizes that of the highest scoring but incorrect parse tree. The objective is not differentiable due to the hinge loss. We use the subgradient method to compute a gradient-like direction for minimizing the objective function.

3 Experiments

We conducted three sets of experiments. The first one is to test several variants of the INDP on the development set, to gain some understanding of how the choice of hyper-parameters impacts upon the performance. The goal of the second one is to see how well the incremental approach enhanced with the high-order features to improve the first-order results by analysing parsing errors relative to sentence length. In the third set, we compared the performance of the INDP with existing state-of-the-art models on both English and Chinese datasets. We report unlabeled attachment scores (UAS) and labeled attachment scores (LAS) with punctuations being omitted from evaluation.

3.1 Datasets

We show test results for the proposed model on the English Penn Treebank (PTB), converted into Stanford dependencies using version 3.3.0 of the Stanford dependency converter, and the Chinese Penn Treebank (CTB). We follow the standard splits of PTB, using section 2-21 for training, section 22 as development set and 23 as test set. We use POS tags generated from the Stanford POS tagger (Toutanova et al., 2003); for the Chinese PTB dataset, we use gold word segmentation and POS tags.

3.2 Training Strategy

Previous work demonstrated that the performance can be improved by using word embeddings learned from large-scale unlabeled data in many NLP tasks both in English (Collobert et al., 2011; Socher et al., 2011) and Chinese (Zheng et al., 2013). Unsupervised pretraining guides the learning towards basins of attraction of minima that support better generalization (Erhan et al., 2010). We leveraged large unlabeled corpus to learn word embeddings, and then used these improved embeddings to initialize the word embedding matrices of the neural networks. English and Chinese Wikipedia documents were used to train the word embeddings by Word2Vec tool[3] proposed in (Mikolov et al., 2013).

Previous studies show that a joint solution (i.e., performing several tasks at the same time) usually leads to the improvement in accuracy over pipelined systems because the error propagation is avoided and the various information normally used in the different steps of pipelined systems can be integrated. The INDP networks are also trained in a joint way, but adopting three-step strategy. The parameters of the parsing neural network using the first-order factorization are first learned, and when its unlabeled parsing accuracy exceeds a given threshold (e.g. 85%), we start to train the high-order parsing network. The weights already trained in the first step will remain unchanged for the first several epochs, and they are in fact used to generate the high-order features. After the parsing accuracy reaches another threshold (e.g. 90%), all the parameters for the first-order, and high-order predictions as well as labeling are trained jointly.

3.3 Hyper-parameter Choices

Hyper-parameters was tuned with the PTB 3.3.0 development set by trying only a few different networks. Generally, the dimensionality of the embeddings, and the numbers of hidden units, provided they are large enough, have a limited impact on the generalization performance. In the following experiments, the window size was set to 5, the learning rate to 0.02, and the number of hidden layer to 300. The embedding size of words was set to 50, and that of tags to 30, which achieved a good trade-off between speed and performance. All experiments were run on a computer equipped with an Intel Xeon processor working at 2.2GHz, with 16GB RAM and a NVIDIA Titan GPU. The parsing speed of the INDP is around 250-300 sents/sec in average on the PTB dataset.

[3] Available at http://code.google.com/p/word2vec/

3.4 Sentence Length Factors

It is well known that dependency parsers tend to have lower accuracies for longer sentences because the increased presence of complex syntactic structures. In order to get a better understanding of how well the incremental strategy and high-order features benefit the models, Figure 4 shows the accuracy of our neural dependency parser using the first-order features only (indicated with "NDP + First-order") and INDP with at most twice high-order refinements (indicated with "INDP + High-order + M2") on the English PTB develop set. For simplicity, the experiments report unlabeled parsing accuracy, and identical experiments using labeled parsing accuracy did not reveal any additional information.

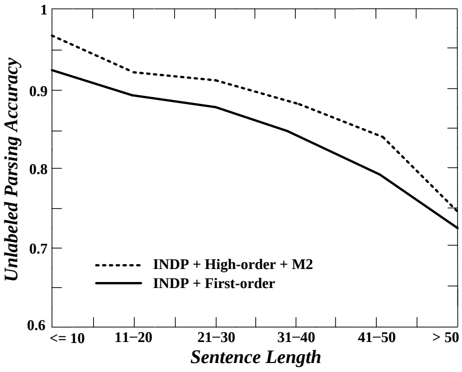

Figure 4: Accuracy relative to sentence length.

The INDP with the high-order refinements is more precise than the parser using only the first-order features. Due to the fact that longer dependencies are typically harder to parse, there is still a degradation in performance for our INDP. However, the accuracy curve for INDP is slightly flatter than its reduced version in which the high-order features and incremental recipe are not applied when the sentence length is within 11-50. This behavior can be explained by the reasons that the feature representations are not restricted to a limited number of graph arcs, but can take into account with the (almost) entire dependency graph built so far at the refinement stages of the INDP, and it do offer substantial refinements.

3.5 Results

We report the experimental results on the English PTB and Chinese CTB datasets in Table 1 and 2 respectively, in which our networks are denoted by "INDP". The "M1" indicates that the results are obtained by the INDP with just one refinement over the parse graphs built using the first-order features, and similarly, the "M2" indicates the results are achieved by the INDP with at most twice high-order refinements, while the "UNC" in the last row indicates that the refinements will continue until no change is made in the structure predictions (see the algorithm listed in Figure 3). All compared transition-based parsing systems are indicated by a "‡", and graph-based ones by "§".

Table 1: Results on the English PTB dataset.

Model	UAS	LAS
Zhou et al (2015)‡	93.28	92.35
Weiss et al (2015)‡	94.26	92.41
Ballesteros et al (2016)‡	93.56	91.42
Kiperwasser and Goldberg (2016b)‡	93.90	91.90
Andor et al (2016)‡	94.61	92.79
Kuncoro et al (2016)‡	**95.80**	**94.60**
Kiperwasser and Goldberg (2016a)§	93.00	90.90
Cheng et al (2016)§	94.10	91.49
Hashimoto et al (2016)§	94.67	92.90
Dozat and Manning (2017)§	95.74	94.08
NDP + First-order	90.88	88.93
INDP + High-order + M1	93.31	91.51
INDP + High-order + M2	94.76	93.12
INDP + High-order + UNC	95.53	93.94

From these numbers, a handful of trends are readily apparent. Firstly, we note that the "full-fledged" INDP (indicated with "UNC") is superior to that without the high-order refinements by a fairly significant margin (5.01% for English and 6.55% for Chinese in LAS). Another striking result of these experiments is that comparable performance can be obtained by no more than twice refinements with high-order features, and "INDP + High-order + M2" achieves a good trade-off between the performance and parsing complexity.

Table 2: Results on the Chinese CTB dataset.

Model	UAS	LAS
Ballesteros et al (2016)‡	87.65	86.21
Kiperwasser and Goldberg (2016b)‡	87.60	86.10
Kiperwasser and Goldberg (2016a)§	87.10	85.50
Cheng et al (2016)§	88.10	85.70
Dozat and Manning (2017)§	89.30	**88.23**
NDP + First-order	82.97	81.39
INDP + High-order + M1	87.35	85.82
INDP + High-order + M2	88.78	87.28
INDP + High-order + UNC	**89.42**	87.94

Our INDP gets nearly the same performance on the English PTB as the current models of (Kuncoro et al., 2016) and (Dozat and Manning, 2017) in spite of its simpler architectures, and gets state-of-the-art UAS accuracy on the Chinese CTB. The INDP lags behind in LAS, indicating one of a few possibilities. Firstly, we tried only a few different network configurations, and there are many ways (such as using deeper architectures, and recruiting bi-directional recurrent neural networks to produce word feature representations) that we could improve it further. Secondly, the model of (Kuncoro et al., 2016) is particularly designed to capture phrase compositionality, and thus, another possible improvement is to capture such compositionality by optimizing the network architectures, which may also lead to a better label score.

4 Related Work

Dependency-based syntactic representations of sentences have been found to be useful for various NLP tasks, especially for those involving natural language understanding in some way. We briefly review prior work both on graph-based and transition-based neural dependency parsers.

In transition-based parsing, we learn a model for scoring transitions from one state to the next, conditioned on the parse history, and parse a sentence by taking the highest-scoring transition out of every state until a complete dependency graph has been derived. Chen and Manning (2014) made the first successful attempt at introducing deep learning into a transition-based dependency parser. At each step, the feed-forward neural network assigns a probability to every action the parse can take from certain state (words on the stack and buffer). Some researchers have attempted to address the limitations of (Chen and Manning, 2014) by augmenting it with additional complexity.

A beam search and a conditional random field loss function were incorporated into the transition-based neural network models (Weiss et al., 2015; Zhou et al., 2015; Andor et al., 2016), which allow the parsers to keep the top-k partial parse trees and revoke previous actions once it finds evidence that they may have been incorrect by locally greedy choices. Dyer et al (2015) used three LSTMs to represent the buffer, stack, and parsing history, getting state-of-the-art results on Chinese and English dependency parsing tasks.

Graph-based parsers use machine learning for scoring each possible edge for a given sentence, typically by factoring the graphs into their component arcs, and constructing the parse tree with the highest score from these weighted edges. Kiperwasser and Goldberg (2016b) presented a neural graph-based parser in which the bi-directional L-STM's recurrent output vector for each word is concatenated with each possible head's vector (also produced by the same biLSTM), and the result is used as input to a multi-layer perceptron (MLP) for scoring this modifier-head pair. Given the scores of the arcs, the highest scoring tree is constructed using Eisner's decoding algorithm (Eisner, 1996). Labels are predicted similarly, with each word's recurrent output vector and its head's vector being used in a multi-class MLP.

Kiperwasser and Goldberg (2016a) also proposed a hierarchical tree LSTM to model the dependency tree structures in which each word is represented by the concatenation of its left and right modifier (child) vectors, and the modifier vectors are generated by two (leftward or rightward) recurrent neural networks. The tree representations were produced in a bottom-up recursive way with the (greedy) easy-first parsing algorithm (Goldberg and Elhadad, 2010). Similarly, Cheng et al (2016) proposed a graph-based neural dependency parser that is able to predict the scores for the next arc, conditioning on previous parsing decisions. In addition to using one bi-directional recurrent network that produces a recurrent vector for each word, they also have uni-directional recurrent neural networks (left-to-right and right-to-left) that keep track of the probabilities of each previous parsing actions.

In their many-task neural model, Hashimoto et al (2016) included a graph-based dependency parse in which the traditional MLP-based method that Kiperwasser and Goldberg (2016b) used was replaced with a bilinear one. Dozat and Manning (2017) modified the neural graph-based approach of (Kiperwasser and Goldberg, 2016b) in a few ways to improve the performance. In addition to building a network that is larger and uses more regularization, they replace the traditional MLP-based attention mechanism and affine label classifier with biaffine ones.

This work is most closely related to the graph-based parsing approaches with multiple high-order refinements (Rush and Petrov, 2012; Zhang et al., 2014), although the neural networks were not used in their parsers. Rush and Petrov (2012) proposed a multi-pass coarse-to-fine approach in which a coarse model was used to prune the search space in order to make the inference with up to third-order features practical. They start with a linear-time vine pruning pass and build up to high-order models. Zhang et al (2014) introduced a randomized greedy algorithm for dependency parsing in which they begin with a tree drawn from the uniform distribution and use hill-climbing strategy to find the optimal parse tree. Although they reported that drawing the initial tree randomly results in the same performance as when initialized from a trained first-order distribution, but multiple random restarts are required to avoid getting stuck in a locally optimal solution. Their greedy algorithm breaks the parsing into a sequence of local steps, which correspond to choosing the head for each modifier word (one arc at a time) in the bottom-up order relative to the current tree. In contrast, we employed the global inference algorithm to change the entire tree (all at a time) in each refinement step, which makes the improvement more efficient.

5 Conclusion

Graph-based parsers cannot easily condition on any extended scope of the dependency parse tree beyond a single arc, which is their primary shortcoming relative to transition-based competitors. We have shown that a simple, generally applicable incremental neural dependency parsing algorithm can deliver close to state-of-the-art parsing performance, which allows the high-order features to be taken into account without hurting the advantage of global exhaustive inference and learning as a member of graph-based parsing systems. Future work will involve exploring ways of augmenting the parser with a more innovative architecture than the relatively simple one used in current neural graph-based parsers.

Abstract

One of the most pressing issues in discontinuous constituency transition-based parsing is that the relevant information for parsing decisions could be located in any part of the stack or the buffer. In this paper, we propose a solution to this problem by replacing the structured perceptron model with a recursive neural model that computes a global representation of the configuration, therefore allowing even the most remote parts of the configuration to influence the parsing decisions. We also provide a detailed analysis of how this representation should be built out of sub-representations of its core elements (words, trees and stack). Additionally, we investigate how different types of swap oracles influence the results. Our model is the first neural discontinuous constituency parser, and it outperforms all the previously published models on three out of four datasets while on the fourth it obtains second place by a tiny difference.

1 Introduction

Research on constituency parsing has been mostly concentrated on projective trees, which can be modeled with Context-Free Grammars (CFGs). One of the main reasons for this is that modeling non-projective trees often requires richer grammar formalisms, which in practice implies slower runtime. For instance, the parsing algorithms for binary LCFRS—the most prominent grammar-based approach to parsing non-projective constituency trees—have computational complexity $O(n^{3k})$, where k is the *fan-out* of the grammar. For this reason, researchers turned to faster approximate methods. Approximations can be done in two ways: either on the types of structures that are predicted or on the parsing algorithm.

The first approach approximates discontinuous constituency structures with simpler structures for which more efficient algorithms exist. This method works as a pipeline: it converts the input to a simpler formalism, parses with it, and then converts it back. Relevant examples are the parsers by Hall and Nivre (2008) and Fernández-González and Martins (2015), who convert discontinuous constituents to dependencies, and Versley (2016), who also applied a conversion but in this case to the projective constituency trees.

The second approach—approximation on the parsing algorithm—consists of an approximate search for the most probable parse. This is analogous to the search done by transition-based parsers, which greedily search through the space of all possible parses, resulting in very fast models. The first transition-based discontinuous constituency parser of this sort was presented in Versley (2014), and it consists of a shift-reduce parser that handles discontinuities with swap transitions. This parser was very similar to dependency parsers with swap transitions (Nivre, 2009; Nivre et al., 2009), but unlike its dependency equivalents, it did not exhibit higher accuracy. Later work on discontinuous transition-based parsing was largely focused on finding alternative transitioning systems to handle discontinuity. Maier (2015) and Maier and Lichte (2016) proposed new types of swap operations (*CompoundSwap* and *SkipShift*) to make the transition sequences shorter—and therefore easier to learn. Coavoux and Crabbé (2017) went even further by modifying not only the transitions but the whole configuration structure by introducing an additional stack.

Over the years the transitioning system has seen some progress, but the learning model has remained the same : a sparse linear model trained

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1666–1676
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

with structured perceptron and early update strategy (Collins, 2002; Collins and Roark, 2004; Huang et al., 2012). This model requires heavy feature engineering and has a limited capacity in modeling interaction between the features.

Maier and Lichte (2016) argue that one of the biggest problems of transition based systems is precisely their greedy search, because they cannot recover from the bad decisions made in earlier parsing steps. Some researchers try to account for this problem by increasing the beam size, but there is a limit on how much the beam can be increased while remaining efficient for practical use (Coavoux and Crabbé, 2017).

The solution we propose is to use a probabilistic model that exploits the information from the whole configuration structure when making the decision for the next action. This can be achieved by using recurrent neural models that allow information to flow all the way from the individual characters, up trough the words, POS tags, subtrees, stack and buffer until the final configuration representation. Thanks to using a neural network model, which removes the need for feature engineering, we can concentrate on the question of which representations are more relevant for the model at each step of the flow. Thus, we reflect on how alternative representations should impact the task, and we report their relative contribution in an ablation study.

In our work, we also reduce the number of swap transitions by trying to postpone them as much as possible, in a style similar to the lazy-swap used in Nivre et al. (2009) —albeit with an even lower number of swaps. This change influences the model indirectly by introducing a helpful inductive bias.

Our model gets state-of-the-art results on Negra, Negra-30 and TigerSPMRL datasets, and on the TigerHN achieves the second best published result. To the best of our knowledge this is the first work that uses neural networks in the context of discontinuous constituency parsing.

2 Transition System

We base our transitioning system on the shift-promote-adjoin transitions proposed in Cross and Huang (2016), because they remove the need for explicit binarization. Transition-based parsers consist of two components: a configuration that represents a parsing state and a set of transitions between configurations.

The configuration consists of two data structures: a stack S that contains all the constituents built so far, and a buffer B of words that remain to be processed. The initial configuration consists of a buffer filled with words and an empty stack—presented as the *axiom* in Figure 1. The objective is to find a sequence of transitions that lead to a *goal* state in which the buffer is empty and the stack contains only one constituent with the ROOT label. The *shift* transition moves the first element from the buffer to the top of the stack. The *pro(X)* transition "promotes" the topmost element of the stack: it replaces it with a tree that has nonterminal X and the topmost element of the stack as its only child, which also becomes its head constituent. The *adj*$\curvearrowleft$ transition adjoins the second topmost element of the stack as a leftmost child of the topmost element of the stack. The *adj*$\curvearrowright$ transition is a mirror transition of the *adj*$\curvearrowleft$.

The transitions described so far are enough to handle projective constituency structures, and have been used with success for this task in Cross and Huang (2016). To make the parser able to process discontinuous constituents we need an additional transition that allows for constituents that are far apart on the stack to become close, so that they can be adjoined into a new constituent. For this we use the *swap* transition from Nivre (2009). This transition takes the second topmost element from the stack and puts it back to the buffer. To prevent infinite loops of *shift-swap* transitions, we put a constraint that *swap* can be applied only to constituents that have not been swapped before. To do this we use the linear ordering of constituents $<_{ind}$ based on the position of the leftmost word in their yield (Maier and Lichte, 2016).

2.1 Oracle

In the case of non-projective parsing, the extraction of the oracle is not trivial because there can be many possible oracles that would derive the same tree. Therefore it is common practice to use some heuristic to extract only one of the possible oracles.

To construct the oracle, we start with the initial configuration and apply the first transition whose conditions are satisfied. We keep applying transitions to the resulting configurations until the goal is reached. The transitions are determined as follows: first, we apply *adj*$\curvearrowleft$, *adj*$\curvearrowright$ or *pro(X)* if

$$\begin{array}{rl}
\textit{axiom} & \langle\ [],\ [w_1, w_2, ..., w_n]\ \rangle \\[1ex]
\textit{shift} & \dfrac{\langle\ S,\ x|B\ \rangle}{\langle\ S|x,\ B\ \rangle} \\[2ex]
\textit{pro(X)} & \dfrac{\langle\ S|t,\ B\ \rangle}{\langle\ S|X(t),\ B\ \rangle} \\[2ex]
\textit{adj}\curvearrowleft & \dfrac{\langle\ S|t|X(t_1 \dots t_k),\ B\ \rangle}{\langle\ S|X(t, t_1 \dots t_k),\ B\ \rangle} \\[2ex]
\textit{adj}\curvearrowright & \dfrac{\langle\ S|X(t_1 \dots t_k)|t,\ B\ \rangle}{\langle\ S|X(t_1 \dots t_k, t),\ B\ \rangle} \\[2ex]
\textit{swap} & \dfrac{\langle\ S|t_1|t_2,\ B\ \rangle}{\langle\ S|t_2,\ t_1|B\ \rangle}\ t_1 <_{ind} t_2 \\[2ex]
\textit{goal} & \langle\ ROOT,\ \epsilon\ \rangle
\end{array}$$

Figure 1: Transition System

one of those produces a constituent that is found in the tree; in case of failure, we check the condition for applying *swap*, which varies depending on the type of oracle, as we define next. If all these checks fail then a *shift* transition is performed.

2.1.1 Eager Oracle

Nivre (2009) introduced *swap* transitions with a very simple oracle. We can define the swapping condition for the extraction of the Eager oracle transition sequence as:

$$s_1 <_G s_0 \qquad (1)$$

where s_0 and s_1 are the topmost and second topmost elements of the stack respectively, and $<_G$ is the *projective ordering* of the nodes in the tree. That ordering can be computed by visiting the nodes in the tree in the postorder traversal.

This is the technique that has been used in most previous proposals on discontinuous constituency parsing (Maier, 2015; Maier and Lichte, 2016).

2.1.2 Lazy Oracle

Eager swapping strategy produces a large number of *swap* transitions which makes them difficult to predict. For this reason, Nivre et al. (2009) introduced a *lazy-swap* operation that postpones swapping by having an additional condition during the construction of an oracle. This technique was used successfully in Versley (2014) to improve over the eager swapping baseline. As an example, in Figure 2a word $w1$ should shift and swap many times to get to word $w5$ in order to construct constituent C. In contrast, a Lazy oracle would postpone swapping until constituent B is built so that only one swap operation over node B would be enough for word $w1$ to get to word $w5$.

In order to define that condition in the context of discontinuous constituency parsing, we need to define a few other terms. First of all, we call a *projective constituent* any constituent that yields a continuous span of words (marked with blue color in Figure 2). Note that a projective constituent might contain non-projective constituents as its descendants. A *fully projective constituent* is a constituent that is projective and whose descendants are all projective (marked with red in Figure 2). Finally, a *maximal fully projective constituent* is a fully projective constituent whose parent is not a fully projective constituent (marked green in Figure 2). Finally, we define a function $MPC(x)$ that returns the closest maximally projective constituent that is ascendant of a constituent x if there is one; otherwise, it returns x.

The condition for the lazy swap can now be expressed as:

$$s_1 <_G s_0 \quad \wedge \quad MPC(s_0) \neq MPC(b_0) \qquad (2)$$

where s_0 and b_0 are the topmost elements of the stack and buffer, respectively. This means that we do not allow *swap* to penetrate into maximally projective constituents, so swapping can be delayed until the maximally projective constituent has been built.

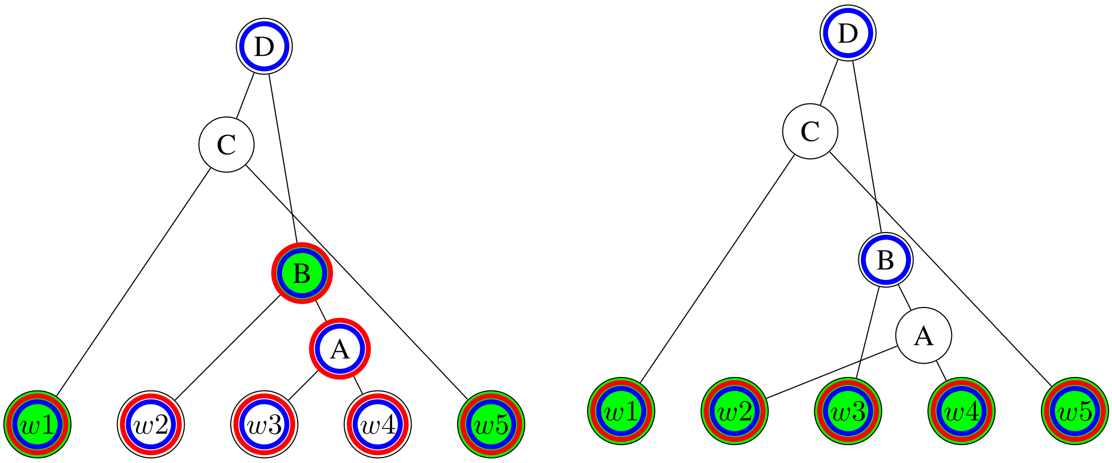
2.1.3 Lazier Oracle

The standard Lazy swap strategy helps in cases where MPC constituents exist, like in Figure 2a. But in cases like Figure 2b there are no MPC constituents (except for words), so Lazy would not show any improvement over Eager. Still, even in this case it is visible that swapping $w1$ should be postponed until B is built. We introduce an oracle strategy called Lazier that implements the heuristic of postponing swapping over projective constituents.[1]

Let a function $CPC(x)$ return the closest projective constituent ascendant of a constituent x. The condition for swap operation can now be expressed with:

$$s_1 <_G s_0 \quad \wedge \quad CPC(s_0) = CPC(s_1) \qquad (3)$$

[1] The same intuition is followed in the Barriers strategy of Versley (2014).



(a) Tree with Maximal Fully Projective Node B

(b) Tree without any Maximal Fully Projective Nodes (other than words themselves)

Figure 2: Example tree structures

This constraint prevents *swap* from allowing constituents to escape their closest projective ancestor. If we know that the *swap* operation can be performed, i.e. if $s_1 <_G s_0$, it is easy to show that in that case $CPC(s_0) = CPC(s_1) \implies MPC(s_0) \neq MPC(b_0)$ or in other words that Lazy is a special case of Lazier. There are are only two cases to consider about $CPC(s_0)$: case a) s_0 and $CPC(s_0)$ are separated by a non-empty sequence of non-projective constituents and case b) s_0 is the immediate child of $CPC(s_0)$. In case a) from definition of maximal projective constituents follows that $MPC(s_0) = s_0$ and therefore $MPC(s_0) \neq MPC(b_0)$ since s_0 and b_0 are non-overlapping. In case b) we need to consider two possible options: b1) $CPC(s_0)$ is fully projective and b2) $CPC(s_0)$ is not fully projective. Case b1) is not possible because it leads to contradiction with original condition $s_1 <_G s_0$. Case b2) leads again to $MPC(s_0) = s_0$ and by that $MPC(s_0) \neq MPC(b_0)$.

3 Model

As mentioned before, our goal is to have a model that can have a global representation of the parsing state. In order to define this global representation of the configuration, we first need to analyze what are the proper representations of its subparts.

3.1 How to Represent Terminal Nodes?

The representations induced by neural networks are continuous vectors that encode the information that is relevant for the loss function. The initial nodes in the computation graph are often embeddings that represent the atomic inputs in the model. In our model, the embedding of a terminal node is computed by concatenating the following four embeddings and then applying the affine transformation to compress the result into a smaller vector:

- a trained word embedding
- a trained POS tag embedding
- a pre-trained word embedding
- a trained character embedding of the word

Trained embeddings (both word and POS tag embedding) are automatically trained by our model to better suit the task that we are solving. The usage of pre-trained embeddings has become standard in neural parsing models: these presentations are helpful because they bring additional contextual information from a bigger non-annotated corpora. The embeddings that we use in this work are the ones distributed with the Polyglot package (Al-Rfou et al., 2013).

The character embedding representation of a word is computed by composing the representations of each character in the word form. This can be useful to recover some of the morphological features present in the word, such as suffixes or prefixes. We compose character embeddings by running a bi-directional LSTM (Bi-LSTM) over the characters (Ling et al., 2015; Ballesteros et al., 2015).

The embeddings composed in this way express the properties of a word, but they ignore the context in which the word appears in the actual sentence. To address this we compute the final representation of the word by running a separate Bi-LSTM model over the initial vectors of the terminals in the same way as done by Kiperwasser and Goldberg (2016) and Cross and Huang (2016).

3.2 How to Represent Non-Terminal Nodes?

During the parsing process we need to produce the representations of the full subtrees that are going to be placed on the stack. In the dependency parsing literature, many approaches for representing dependency subtrees use the representation of the head word. If the representation of the head word is computed using a model that takes context into account, such as Bi-LSTM models, then this simple architecture can give good results (Kiperwasser and Goldberg, 2016; Cross and Huang, 2016). However, we believe that this is not the right approach for discontinuous constituency parsing. The reason is that, for the parser to know to which constituents it should attach the current constituent, it needs to know which arguments have already been attached and which ones are missing. In other words, even if the head of two different constituents is the same, their representation should be different because they have different requirements.

To address this we use a "composition function" approach where we recursively compute the representation of the constituent. Recursive neural networks (RecNN) (Goller and Küchler, 1996) are one way of accomplishing this. Dyer et al. (2015) use RecNN to compute the representation of the subtrees in the dependency structure. We adapt this model to our case in the following way. For binary constituents (i.e. outputs of *adj*$\curvearrowleft$ and *adj*$\curvearrowright$) the composition function takes the representation of the head constituent h_{head}, the representation of the complement h_{comp} and one single bit that represents the directionality of the $e_{\curvearrowleft}$ in the adjoining operation (0 for *adj*$\curvearrowleft$ and 1 for *adj*$\curvearrowright$). The resulting h_{new} representation is computed as follows:

$$h_{new} = tanh(W_{adj}[h_{head}; h_{comp}; e_{\curvearrowleft}] + b_{adj})$$

Here, semi-colon (;) represents vector concatenation, and W_{adj} and b_{adj} are the weight matrix and the bias vector that are trained together with the rest of the model, to optimize the desired loss function.

The transition *pro(X)* also creates new trees and its composition function can be seen as a function of a Simple RNN model:

$$h_{new} = tanh(W_{pro}[h_{head}; e_{nt}] + b_{pro})$$

Here e_{nt} is the embedding for the non-terminal to which constituent gets promoted. W_{pro} and b_{pro} are again the weight matrix and the bias vector whose values are estimated during training.

Simple RNN models have been shown to suffer from vanishing gradient problem, and for that reason they have been largely replaced with LSTM models (Hochreiter and Schmidhuber, 1997). The same holds for recursive neural network models. Le and Zuidema (2016) have shown that, for deep and complex hierarchical structures, the models that have a memory akin to the memory in LSTM are much more robust towards the vanishing gradient problem. Thus, in our work we use the Tree-LSTM neural architecture from Tai et al. (2015), but the alternative recursive version of LSTM by Le and Zuidema (2015) could be used as well.

In the Tree-LSTM model each constituent is represented by the hidden state h and the *memory cell* c. The composition function for the binary constituents with representations h_{head}, c_{head}, h_{comp} and c_{comp} computes the new representations h_{new} and c_{new} in the following way:

$$\begin{aligned}
f_{head} &= \sigma(W_{11}^{(f)} h_{head} + W_{12}^{(f)} h_{comp} + b_{\curvearrowleft}^{(f)}) \\
f_{comp} &= \sigma(W_{21}^{(f)} h_{head} + W_{22}^{(f)} h_{comp} + b_{\curvearrowleft}^{(f)}) \\
i &= \sigma(W_{1}^{(i)} h_{head} + W_{2}^{(i)} h_{comp} + b_{\curvearrowleft}^{(i)}) \\
o &= \sigma(W_{1}^{(o)} h_{head} + W_{2}^{(o)} h_{comp} + b_{\curvearrowleft}^{(o)}) \\
u &= tanh(W_{1}^{(u)} h_{head} + W_{2}^{(u)} h_{comp} + b_{\curvearrowleft}^{(u)}) \\
c_{new} &= i \odot u + f_{head} \odot c_{head} + f_{comp} \odot c_{comp} \\
h_{new} &= o \odot tanh(c_{new})
\end{aligned}$$

All the W matrices and the bias vectors b are trained parameters of the composition function. For each equation above there is an alternative equation that instead of bias $b_{\curvearrowleft}$ uses bias $b_{\curvearrowright}$. Which equation/bias will be used depends on the directionality of the adjoining operation.

For the promote transition, since it creates only one unary node, we can use almost the same computation as in the standard LSTM:

$$
\begin{aligned}
f &= \sigma(W^{(f)} h_{head} + W_{nt}^{(f)} e_{nt} + b^{(f)}) \\
i &= \sigma(W^{(i)} h_{head} + W_{nt}^{(i)} e_{nt} + b^{(i)}) \\
o &= \sigma(W^{(o)} h_{head} + W_{nt}^{(o)} e_{nt} + b^{(o)}) \\
u &= tanh(W^{(u)} h_{head} + W_{nt}^{(u)} e_{nt} + b^{(u)}) \\
c_{new} &= i \odot u + f \odot c_{head} \\
h_{new} &= o \odot tanh(c_{new})
\end{aligned}
$$

The main difference from the standard LSTM is that here we additionally use the information from the non-terminal embedding e_{nt} to which the constituent is promoted.

3.3 How to Represent a Configuration?

We have covered how to represent syntactic objects (terminal and non-terminal nodes) that are stored in the stack and the buffer, but we still need to decide how to combine these representations to make a final decision about the next transition.

One possibility is to first find a suitable representation for the stack and the buffer individually, concatenate these representations and then apply a multi-layer perceptron (MLP) to produce the probabilities for the next action.

The stack and the buffer can be seen as the same type of data structure: the buffer can be interpreted as a stack that is filled by pushing the words in a sentence from the last to the first. Therefore, we can use same approach for modeling stack and buffer.

The most common approach for representing a stack structure in transition based parsers (both in perceptron and neural models) is to take the representations of the first few top constituents on the top of the stack. Thus, this approach assumes that only the top of the stack and buffer are relevant for deciding the next action. Even though this assumption seems reasonable in the context of continuous constituency parsing, for discontinuous parsing it can be very harmful because the constituents that we want to merge might be very far from each other in the stack, as argued in (Maier and Lichte, 2016).

In our work, we explore an alternative model that could address this problem; namely, the Stack-LSTM model proposed in (Dyer et al., 2015). This model consists of an LSTM that processes the whole stack as a sequence, to obtain in this way a representation of the stack that includes *all* of its elements. This approach gave good results on continuous dependency parsing, but its properties should be even more important for discontinuous parsing, since it allows to keep in the stack a representation of all the constituents.

Given the stack h_{stack} and buffer h_{buffer} representations computed by Stack-LSTMs, we compute the configuration representation h_{conf} by concatenating these vectors and then applying an affine transformation followed by a $ReLU(\cdot)$ nonlinearity:

$$h_{conf} = ReLU(W_{conf}[h_{stack}; h_{buffer}] + b_{conf})$$

This vector representation encodes the whole configuration: the information flow passes trough every character, every POS tag, every constituent in the stack and in the buffer. From this vector representation we can compute the probability of the transition z from the set of possible transitions Z by applying one final softmax layer:

$$p(z|h_{conf}) = \frac{exp(w_z^T h_{conf} + b_{z_i})}{\sum_{z_i \in Z} exp(w_{z_i}^T h_{conf} + b_{z_i})}$$

The probability of the whole sequence of transitions is defined as the product of the probabilities of its transitions:

$$p(\mathbf{z}|\mathbf{w}) = \prod_{i=1}^{|z|} p(z_i|h_{conf\_i})$$

The parameters are optimized for maximum likelihood of the oracle sequence of transitions.

4 Experiments

We empirically test the performance of our parser on two German constituency treebanks: Negra and Tiger. The preprocessing applied to these treebanks follows the same methods used in other discontinuous constituency parsing literature, as described in Maier (2015) and implemented in the *tree-tools* software[2].

We use two different versions of the Negra treebank. The first version is filtered for the sentences up to 30 words, in order to remain comparable to previous grammar-based models; the second version includes sentences of all lengths. As for the Tiger treebank, we use two different splits: TigerHN (Hall and Nivre, 2008) and TigerSPMRL

Table 2: Average number of swaps and jump sizes per sentence

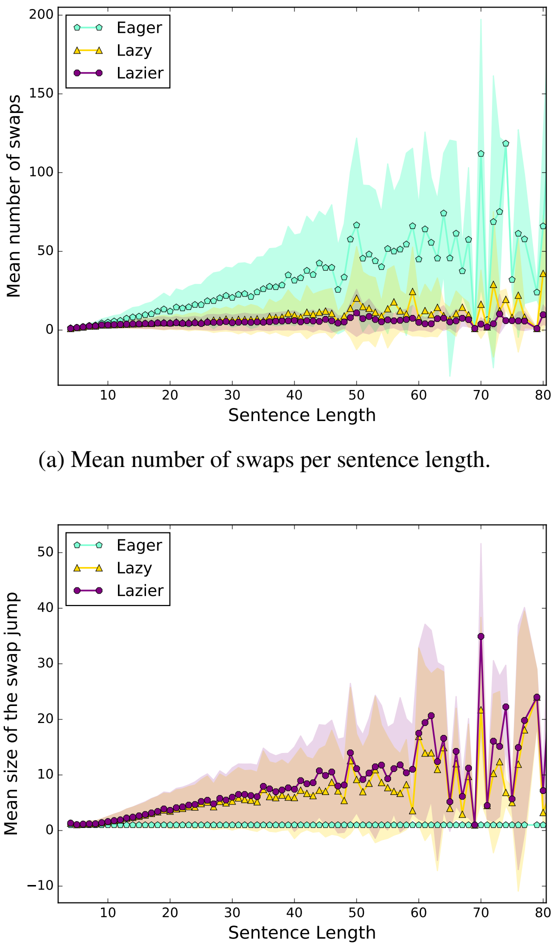
(Maier, 2015). We evaluated the model with the evaluation module of *discodop*[3] parser.

Our model is implemented with DyNet (Neubig et al., 2017) and the code is available at `https://github.com/stanojevic/BadParser`. The concrete hyper-parameters of our model are shown in Table 1. We optimize the parameters with Adam optimizer on the training set, for 10 iterations with 100 random restarts, and we do model selection on the validation set for the F-score. During test time we use beam search with beam of size 16.

We conducted the development of our model on the TigerHN train and development sets. First we will analyze the effect of different model design decisions and then we show the results over the test set. The development set scores on TigerHN are shown in Table 3.

4.1 Which oracle is better?

The results in Table 3 show that the Eager oracle works better than Lazy for discontinuous constituents, but for continuous constituents (and over all constituents on average) Lazy works better. This can be explained by Lazy being very conservative about swaps: since their number is significantly reduced, the transition becomes difficult to predict, and thus the model gives up on predicting swaps and concentrates on the statistics for the projective operations. In other words, Lazy predicts swaps only if the statistical evidence for swaps is high. This can be seen by the contrast between high precision but very low recall on discontinuous constituents.



(a) Mean number of swaps per sentence length.

(b) Mean size of the swap jumps per sentence length.

Figure 3: The effect of different swap strategies of sentences with up to 80 words

Eager works in the opposite direction: since it has observed many swaps it has a strong bias to predict them, which leads to a high recall but low precision. Lazier strikes a good balance between precision and recall on the discontinuous constituents, and because of that it outperforms both Eager and Lazy on F-score for both all constituents and discontinuous constituents.

The good result of Lazier cannot be subscribed only to the shorter transition sequences being easier to predict, because if it was up to the transition

sequences length alone then Lazy would work better than Eager on the discontinuous constituents. The more likely explanation is that Lazier introduces an inductive bias in the model that is useful for generalization, and that allows the model to generalize better than Eager and Lazy.

We also quantified how many swaps are made by Eager, Lazy and Lazier. Figure 3 shows the statistics over the TigerHN training set for different sentence lengths; the aggregated statistics over all sentence lengths can be read in Table 2. We can observe in Figure 3(a) that, in the case of short sentences, all the swapping strategies give similar results, but as sentences get longer the number of swaps in Eager gets much higher and more unstable than lazier alternatives. We found that for some sentences Lazy and Lazier do with 2 swaps what Eager does with 126 swaps. Compared to Lazy, Lazier is much more stable in terms of the number of swaps, which can be seen by the standard deviation in Table 2. In Figure 3(b) shows a similar trend for the size of the jump of swap transitions. All the swaps of Eager make a jump of size 1, while the jumps of Lazier can go up to 91 words.

4.2 What is the best word representation?

We have tested whether the representation of a word based solely on its embeddings is enough to get good results or, instead, this representation should be refined by the bi-directional LSTM. Table 3 shows that adding layers to the bi-directional LSTM consistently improves the scores. The difference between not using a bi-directional LSTM and using 2 layers of bi-directional LSTM is 3.63

F-score, which is a big margin. Adding a third layer did not improve scores significantly.

4.3 What is the best composition function?

We have tried three options for composition functions: Head (use only the head word embedding instead of a composition function), RecNN and TreeLSTM – all presented in Section 3.2. As we expected, the head representation alone did not perform well, which shows that some type of composition function is needed. We find that using a recursive model with a memory cell improves results by 1.12 F-score, and thus we settle for the TreeLSTM composition function.

4.4 What is the best configuration representation?

We tested two configuration representations: the first one – top3 – takes the 3 topmost elements from the stack and the buffer as the representatives, while the second one – Stack-LSTM – models the whole content of the configuration via recurrent neural models. In line with our intuitions, the Stack-LSTM, thanks to considering the whole stack and buffer structure instead of only a few elements, outperforms top3 by a margin of 2.65 F-score points.

4.5 Comparison with other models

We took the version of our model that performed the best on the TigerHN development set and compared it on the four different datasets (two treebanks with two different splits) with other parsers.

In Table 4 we show the results compared to the other works published on these datasets. Our parser outperforms all the previously published models on all datasets except TigerHN, where it ends up second best after Fernández-González and Martins (2015). As shown in our previous analysis, exploring alternative representations of the different components has allowed us to construct a better model. We must also notice that, when comparing to other models, one influential cause of the good performance may be the capacity of our model, provided by the neural architectures. Neural networks allow modeling relations from input to output that are much more complex than those captured by the approaches we compare to, most of which use linear models based on perceptron or simple PCFG type of generative models.

We have also tested our model on the predicted POS tags from TigerSPMRL split, as provided in the shared task (Seddah et al., 2013). The results are shown in Table 5. The biggest strength of our model—its capacity— is in this case its biggest weakness: it causes the model parameters to overfit the noisy predicted tags during training, because we have not used any form of regularization. Model combinations like the one in Versley (2016) do not suffer from this because they implicitly do strong regularization. Our model could probably achieve better results on this dataset with stronger regularization, which we leave for future research.

5 Conclusion

We have presented the first neural model for discontinuous constituency parsing that achieves state-of-the-art results in three out of four standard datasets for discontinuous parsing with gold POS tags. Our findings suggest that i) bidirectional LSTM should be used for refining the representations of terminals even in the cases when they are going to be combined by a recursive model, ii) the performance of the composition function depends to a big extent on the availability of the memory cells, to prevent the vanishing gradient, iii) it is crucial to use all the elements in the stack and buffer in the decision process instead of just few elements on the top and iv) Lazier oracle gives better and more stable results than Eager and Lazy oracles on both continuous and discontinuous constituents.

Acknowledgments

We are thankful to Andreas van Cranenburgh and Wolfgang Maier for sharing the data and preprocessing scripts, and to the anonymous reviewers for suggestions that improved the paper. We are grateful to the ILLC for providing us with traveling funds to attend the conference.

Abstract

Although sequence-to-sequence (seq2seq) network has achieved significant success in many NLP tasks such as machine translation and text summarization, simply applying this approach to transition-based dependency parsing cannot yield a comparable performance gain as in other state-of-the-art methods, such as stack-LSTM and head selection. In this paper, we propose a stack-based multi-layer attention model for seq2seq learning to better leverage structural linguistics information. In our method, two binary vectors are used to track the decoding stack in transition-based parsing, and multi-layer attention is introduced to capture multiple word dependencies in partial trees. We conduct experiments on PTB and CTB datasets, and the results show that our proposed model achieves state-of-the-art accuracy and significant improvement in labeled precision with respect to the baseline seq2seq model.

1 Introduction

Deep learning models have been proven very effective in solving various NLP problems such as language modeling, machine translation and syntactic parsing. For dependency parsing, one line of research aims to incrementally integrate distributed word representations into classic dependency parsing (Chen and Manning, 2014; Weiss et al., 2015; Andor et al., 2016; Cross and Huang, 2016; Kiperwasser and Goldberg, 2016; Dozat and Manning, 2016). Another line of research attempts to leverage end-to-end neural network to perform dependency parsing, such as stack-LSTM and sequence-to-sequence (seq2seq) model (Dyer et al., 2015; Zhang et al., 2017; Wiseman and Rush, 2016). Recently seq2seq model has made significant success in many NLP tasks, such as machine translation and text summarization (Cho et al., 2014; Sutskever et al., 2014; Rush et al., 2015). Unfortunately, to our best knowledge, simply applying seq2seq model to transition-based dependency parsing cannot achieve comparable results as in other state-of-the-art methods like stack-LSTM and head selection (Dyer et al., 2015; Zhang et al., 2017).

One issue with the simple seq2seq neural network for dependency parsing is that structural linguistic information, which plays a key role in classic transition-based or graph-based dependency parsing models, cannot be explicitly employed. For example, classic transition-based parsing algorithm utilizes a stack to manage the heads of partial sub-trees and leverages these evidents for action selection, while such information is missing from current seq2seq models. Another problem is related to the limit of the conventional attention network being used in seq2seq network, which is unable to capture dependencies between words in the input. As a matter of fact, various types of features (word unigram, bigram, trigram, ...) traditionally adopted by transition-based parsing algorithm are usually ignored by the current attention mechanism, but they are very important to capture word dependencies in generated partial trees.

In this paper, we propose a stack-based multi-layer attention mechanism to solve the above problems. To simulate the stack used in the transition-based dependency parsing, we introduce two binary vectors, one indicates whether a word is pushed into the stack, and another indicates whether a word is popped out from it. To model the complex structural information, we propose a multi-layer attention based on the stack information, previous action and input sentence.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1677–1682
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

The multi-layer attention aims to capture multiple word dependencies in partial trees for action prediction.

We evaluate our model on English and Chinese datasets. Experimental results show that our proposed model can significantly outperform the basic seq2seq model with 1.87 UAS (English) and 1.61 UAS (Chinese), matching the state-of-the-art parsing performance. With 4 models ensembled, we obtain further improvements with accuracies of 94.16 UAS (English) and 87.97 UAS (Chinese).

2 Neural Model for Sequence-to-Sequence Learning

In this work, we follow the encoder-decoder architecture proposed by Bahdanau et al. (2015). The whole architecture can be divided into three components: encoder, decoder and attention.

Encoder: The encoder reads in the source sentence $X = (x_1, x_2, \ldots, x_T)$ and transforms it into a sequence of hidden states $h = (h_1, h_2, \ldots, h_T)$, using a bi-directional recurrent neural network that is usually implemented as Gated Recurrent Unit (GRU) (Cho et al., 2014) or Long Short-Term Memory (LSTM) networks (Hochreiter and Schmidhuber, 1997).

Attention Mechanism: The context vector c_i is a weighted sum of the hidden states $(h_1, h_2, \ldots, h_T)$ with the coefficients $\alpha_{i,1}, \alpha_{i,2}, \ldots, \alpha_{i,T}$ computed by

$$\alpha_{i,t} = \frac{\exp(e_{i,t})}{\sum_k \exp(e_{i,k})} \qquad (1)$$

$$e_{i,t} = v_a^\top \tanh(W_a z_{i-1} + U_a h_t) \qquad (2)$$

where v_a,W_a, U_a are the weight matrices.

Decoder: The decoder uses another recurrent neural network to generate a corresponding target sequence $Y = (y_1, y_2, \ldots, y_{T'})$ based on the encoded sequence of hidden state h. At each time i, the conditional probability of target symbol y_i is computed by

$$z_i = \mathrm{RNN}([y_{i-1}; c_i], z_{i-1}) \qquad (3)$$

$$p(y_i | y_{<i}, h) = \mathrm{softmax}(g(y_{i-1}, z_i, c_i)) \qquad (4)$$

where g is a non-linear function, z_i is the i_{th} hidden state of the decoder, and it is calculated conditional on the previous hidden state z_{i-1}, previous target symbol y_{i-1} and source context vector c_i.

3 Sequence-to-Sequence Parsing Model

Transition-based dependency parsing conceptualizes the process of transforming a sentence into a dependency tree as a sequence of actions. It can be formulated as a sequence-to-sequence problem, and seq2seq framework can be applied. Compared with other tasks, such as machine translation, dependency parsing not only considers the previous action and input sentence, but also requires many structure information, such as the subtree structure during the parsing. Such information plays an important role in transition-based dependency parsing, so traditional methods adopt a stack to save structure information and design different type of features (word unigram, bigram, trigram, ...) to model them. However, vanilla seq2seq models have no explicit structure to model these necessary structure information. To better leverage the structure information, we extend the basic seq2seq architecture with a simulated stack and multi-layer attention, as illustrated in Figure 1. The main structure (encoder, decoder and attention part in Figure 1) of our parsing model is detailed below.

Encoder: As shown in the encoder part of Figure 1, to utilize POS tag information, each word w_i is additionally represented by x_i, the concatenation of two vectors corresponding to w_i's lexical and POS tag t_i embedding: $x_i = [W_e * e(w_i); W_t * e(t_i)]$, where $e(w_i)$ and $e(t_i)$ are one-hot vector representations of token w_i and its POS tag t_i, W_e and W_t are embedding matrices. The rest part of the encoder is the same with the basic seq2seq model.

Attention Mechanism: We improve the attention part in two aspects: introduction of stack information and multi-layer attention structure.

Stack information, which plays an essential role in the conventional algorithm, is simulated with two binary vectors $s = (s_1, \dots, s_T)$ and $r = (r_1, \dots, r_T)$ to record the state of each word w_i and initialized to zero. When parser pushes word w_i into stack, s_i is assigned to 1, while r_i is assigned to 1 only if word w_i is removed from stack. Intuitively, at each time step i in the decoding phase, stack information serves as an additional input to the attention model, which provides complementary information of that the source words is in the stack or not. We expect the stack information would guide the attention model to focus more on words in the stack. More formally, the coefficients $\alpha_1, \alpha_2, \dots, \alpha_T$ used in attention mechanism can be rewritten as

$$\alpha_{i,t} = \frac{\exp(e_{i,t}) * (1 - r_t)}{\sum_k \exp(e_{i,k}) * (1 - r_k)} \tag{5}$$

$$e_{i,t} = v_a^\top \tanh(W_a z_{i-1} + U_a h_t + S_a s_t) \tag{6}$$

where S_a is the weight matrix.

To extract complex structure information to help action prediction, we apply a l-layers network structure for attention mechanism as shown in the attention part of Figure 1. To further enhance connection between adjacent layers, we replace the state z_{i-1} in Equation 6 by the concatenation of z_{i-1} and context vector c_i^{m-1} at each layer $m(m > 1)$. The Equation 6 can be rewritten as:

$$e_{i,t}^m = v_a^\top \tanh(W_a^m [z_{i-1}; c_i^{m-1}] + U_a h_t + S_a s_t) \tag{7}$$

where W^m is the weight matrix. With this network structure, we obtain different context vectors $(c_i^1, c_i^2, \dots, c_i^l)$, and the final context vector c_i, which is considered as complex context information, is replaced by the concatenation of those vectors: $c_i = [c_i^1; c_i^2; \dots; c_i^l]$.

Decoder: Unlike machine translation and text summarization in which seq2seq model is widely applied, a sequence of action in dependency parsing must satisfy some constraints so that they can generate a dependency tree. Following the arc-standard algorithm (Nivre, 2004), the precondition can be categorized as 1) SHIFT(SH): There exists at least one word that is not pushed into the stack; 2) LEFT-ARC(LR(d)) and RIGHT-ARC(RR(d)): There are at least two words in the stack. These two constraints can be defined as indicator functions

$$I(y_i) = \begin{cases} 0 & y_i = \text{SH}, W_c \le 0 \\ 0 & y_i = \text{LR(d) or RR(d)}, S_c < 2 \\ 1 & \text{otherwise} \end{cases} \tag{8}$$

where S_c represents the number of words in the stack and W_c is the number of source words that are not pushed into the stack. To introduce these constraints, the conditional probability of each target symbol y_i can be rewritten as

$$p(y_i | y_{<i}, h) = \frac{\exp(g_i) * I(y_i)}{\sum_k \exp(g_k) * I(y_k)} \tag{9}$$

where g_i is the ith element of $g(y_{i-1}, z_i, c_i)$.

4 Experiments

In this section, we evaluate our parsing model on the English and Chinese datasets. Following Dyer et al. (2015), Stanford Dependencies (de Marneffe and Manning, 2008) conversion of the Penn Treebank (PTB) (Marcus et al., 1993) and Chinese Treebank 5.1 (CTB) are adopted. We leverage the arc-standard algorithm for our dependency parsing. In addition, we limit the vocabulary to contain up to 20k most frequent words and convert remaining words into the <unk> token.

4.1 Setup

For our model, 3-layers GRU is used for encoder and decoder. The dimension of word embedding is 300, the dimension of POS-tag/action embedding is 32, and the size of hidden units in GRU is 500. 3-layers attention structure is adopted in our model. Following Chen and Manning (2014); Dyer et al. (2015), we used 300-dimensional pretrained GloVe vectors (Pennington et al., 2014) to initialize our word embedding matrix. Other model parameters are initialized using a normal distribution with a mean of 0 and a variance of

Table 1: Results of various state-of-the-art parsing systems on English dataset (PTB with Stanford Dependencies) and Chinese dataset (CTB). The numbers reported from different systems are taken from: Z&N11 (Zhang and Nivre, 2011); C&M14 (Chen and Manning, 2014); ConBSO (Wiseman and Rush, 2016); Dyer15 (Dyer et al., 2015); Weiss15 (Weiss et al., 2015); K&G16 (Kiperwasser and Goldberg, 2016); DENSE (Zhang et al., 2017).

$\sqrt{6/(d_{row}+d_{col})}$, where d_{row} and d_{col} are the number of rows and columns (Glorot and Bengio, 2010). Our models are trained on a Tesla K40m GPU and optimized with vanilla SGD algorithm with mini-batch size 64 for English dataset and 32 for Chinese dataset. The initial learning rate is set to 2 and will be halved when unlabeled attachment scores (UAS) on the development set do not increase for 900 batches. To alleviate the gradient exploding problem, we rescale the gradient when its norm exceeds 1. Dropout (Srivastava et al., 2014) is applied to our model with the strategy recommended in Zaremba et al. (2014) and the dropout rate is 0.2. For testing, beam search is employed to find the best action sequence with beam size 8. For evaluation, we report unlabeled (UAS) and labeled attachment scores (LAS) on the development and test sets. Following Chen and Manning (2014), the punctuation is excluded from the evaluation.

4.2 Main Results

Table 1 lists the accuracies of our parsing models, compared to other state-of-the-art parsers. For the baseline, seq2seq model employs the same encoder and decoder network structure with our model. We can see that our proposed model can significantly outperform the basic seq2seq model with 1.87 UAS (English) and 1.61 UAS (Chinese) improvements on the test set. This demonstrates the effectiveness of our proposed multi-layer attention mechanism. Besides, our model achieves better UAS accuracy than Z&N11, C&M14, ConBSO and Dyer15 on development and test set, while slightly lower than Weiss15, K&G16 and DENSE. Weiss15 adopts a structured training procedure which can be easily applied to our model as well, and it will further improve the performance of our model. K&G16 uses 11 bidirectional LSTM vectors as features, which will be fed to a transition-based parser. It suggests a new direction that combines our model with feature engineering of the traditional transition-based parser to gain better performance. DENSE formalizes dependency parsing as head selection and applies MST algorithms to correct non-tree outputs, while our model doesn't require any post-processing at test time. Dozat and Manning (2016) use deep biaffine attention instead of traditional attention in the graph-based architectures of K&G16, achieving 95.74 UAS and 89.30 UAS on PTB-SD and CTB datasets respectively. For ensemble, we train 4 models using the same network with different random initialization. When we ensemble these 4 models, we simply average the output probabilities from different models and obtain the better result with accuracies of 94.16 UAS (English) and 87.97 UAS (Chinese) as shown in the Table 1.

4.3 Impact of l

The hyper-parameter l represents the number of layers in our proposed multi-layer attention mech-

Table 3: Impact of the different components on English PTB dataset.

anism. Larger l would bring more capacity, but lead to more computational complexity and aggravate the risk of over-fitting.

We conduct a group of experiments to investigate the impact of l. The results are shown in Table 2. Seq2seq model can be viewed as a special case of our model without any stack information. With $l = 1$, we can see that the introduction of stack information can strongly improve the parsing performance, especially for LAS. When l is small ($l < 4$), the general trend is that larger l leads to better result. However, further increasing l bring slightly damages to the parsing performance due to the over-fitting problem.

Although larger l would bring more capacity, multiple layers structure will double the training time compared with the vanilla seq2seq. In our implementation, our model costs about 500 seconds for a round of training data on English PTB dataset, while the vanilla costs about 260 seconds.

4.4 Additional Results

We perform some ablation experiments in order to quantify the effect of the different components on our models. As shown in Table 3, the POS-tag information plays the most important role in our model. We note that, different from Dyer et al. (2015), we don't utilize an external word embedding to tackle OOV problem, and it may cause our model to be more dependent on the POS-tag information. For s and r vectors, same as discussion in last section, we find that the introduction of stack information can strongly improve the parsing performance.

5 Conclusion

In order to leverage structure information for seq2seq based dependency parsing, in this paper, we propose a stack based multi-layer attention method, in which, stack is simulated with two binary vectors, and multi-layer attention is introduced to capture multiple word dependencies in partial trees. Experimental results demonstrate that our proposed model significantly outperforms the basic seq2seq model, and achieves a state-of-the-art parsing performance.

In the future, we plan to apply our approach in more languages and other transition-based system, such as arc-eager or arc-hybrid. Another direction we are interested in is to train our model with complex training approaches proposed in Weiss et al. (2015) and Andor et al. (2016).

Acknowledgments

We appreciate Dongdong Zhang, Nan Yang, Shuangzhi Wu and Qingyu Zhou for the fruitful discussions. We also thank the anonymous reviewers for their careful reading of our paper and insightful comments.

Dependency Grammar Induction with Neural Lexicalization and Big Training Data[*]

Wenjuan Han, Yong Jiang and **Kewei Tu**

School of Information Science and Technology
ShanghaiTech University, Shanghai, China

Abstract

We study the impact of big models (in terms of the degree of lexicalization) and big data (in terms of the training corpus size) on dependency grammar induction. We experimented with L-DMV, a lexicalized version of Dependency Model with Valence (Klein and Manning, 2004) and L-NDMV, our lexicalized extension of the Neural Dependency Model with Valence (Jiang et al., 2016). We find that L-DMV only benefits from very small degrees of lexicalization and moderate sizes of training corpora. L-NDMV can benefit from big training data and lexicalization of greater degrees, especially when enhanced with good model initialization, and it achieves a result that is competitive with the current state-of-the-art.

1 Introduction

Grammar induction is the task of learning a grammar from a set of unannotated sentences. In the most common setting, the grammar is unlexicalized with POS tags being the tokens, and the training data is the WSJ10 corpus (the Wall Street Journal corpus with sentences no longer than 10 words) containing no more than 6,000 training sentences (Cohen et al., 2008; Berg-Kirkpatrick et al., 2010; Tu and Honavar, 2012).

Lexicalized grammar induction aims to incorporate lexical information into the learned grammar to increase its representational power and improve the learning accuracy. The most straightforward approach to encoding lexical information is full lexicalization (Pate and Johnson, 2016; Spitkovsky et al., 2013). A major problem with full lexicalization is that the grammar becomes much larger and thus learning is more data demanding. To mitigate this problem, Headden et al. (2009) and Blunsom and Cohn (2010) used partial lexicalization in which infrequent words are replaced by special symbols or their POS tags. Another straightforward way to mitigate the data scarcity problem of lexicalization is to use training corpora larger than the standard WSJ corpus. For example, Pate and Johnson (2016) used two large corpora containing more than 700k sentences; Marecek and Straka (2013) utilized a very large corpus based on Wikipedia in learning an unlexicalized dependency grammar. Finally, smoothing techniques can be used to reduce the negative impact of data scarcity. One example is Neural DMV (NDMV) (Jiang et al., 2016) which incorporates neural networks into DMV and can automatically smooth correlated grammar rule probabilities.

Inspired by this background, we conduct a systematic study regarding the impact of the degree of lexicalization and the training data size on the accuracy of grammar induction approaches. We experimented with a lexicalized version of Dependency Model with Valence (L-DMV) (Klein and Manning, 2004) and our lexicalized extension of NDMV (L-NDMV). We find that L-DMV only benefits from very small degrees of lexicalization and moderate sizes of training corpora. In comparison, L-NDMV can benefit from big training data and lexicalization of greater degrees, especially when it is enhanced with good model initialization. The performance of L-NDMV is competitive with the current state-of-the-art.

2 Methods

2.1 Lexicalized DMV

We choose to lexicalize an extended version of DMV (Gillenwater et al., 2010). We adopt a sim-

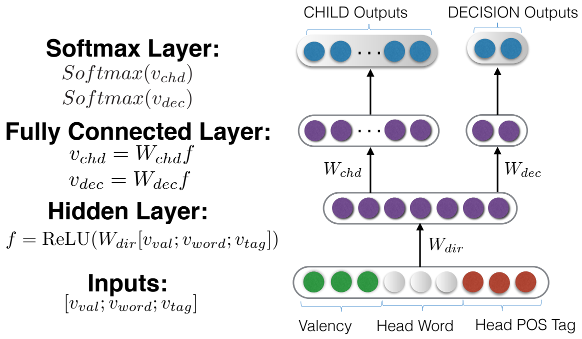

Figure 1: The structure of the neural networks in the L-NDMV model. It predicts the probabilities of the CHILD rules and DECISION rules.

ilar approach to that of Spitkovsky et al. (2013) and Blunsom and Cohn (2010) and represent each token as a word/POS pair. If a pair appears infrequently in the corpus, we simply ignore the word and represent it only with the POS tag. We control the degree of lexicalization by replacing words that appear less than a cutoff number in the WSJ10 corpus with their POS tags. With a very large cutoff number, the grammar is virtually unlexicalized; but when the cutoff number becomes smaller, the grammar becomes closer to be fully lexicalized. Note that our method is different from previous practice that simply replaces rare words with a special "unknown" symbol (Headden III et al., 2009). Using POS tags instead of the "unknown" symbol to represent rare words can be helpful in the neural approach introduced below in that the learned word vectors are more informative.

2.2 Lexicalized NDMV

With a larger degree of lexicalization, the grammar contains more tokens and hence more parameters (i.e., grammar rule probabilities), which require more data for accurate learning. Smoothing is a useful technique to reduce the demand for data in this case. Here we employ a neural approach to smoothing. Specifically, we propose a lexicalized extension of neural DMV (Jiang et al., 2016) and we call the resulting approach L-NDMV.

Extended Model: The model structure of L-NDMV is similar to that of NDMV except for the representations of the head and the child of the CHILD and DECISION rules. The network structure for predicting the probabilities of CHILD rules $[p_{c_1}, p_{c_2}, ..., p_{c_m}]$ (m is the vocabulary size; c_i is the i-th token) and DECISION rules $[p_{stop}, p_{continue}]$ given the head word, head POS tag, direction and valence is shown in Figure 1. We denote the input continuous representations of the head word, head POS tag and valence by v_{word}, v_{tag} and v_{val} respectively. By concatenating these vectors we get the input representation to the neural network: $[v_{val}; v_{word}; v_{tag}]$. We map the input representation to the hidden layer f using the direction-specific weight matrix W_{dir} and the ReLU activation function. We represent all the child tokens with matrix $W_{chd} = [W_{word}, W_{tag}]$ which contains two parts: child word matrix $W_{word} \in \mathbb{R}^{m \times k}$ and child POS tag matrix $W_{tag} \in \mathbb{R}^{m \times k'}$, where k and k' are the pre-specified dimensions of output word vectors and tag vectors respectively. The i-th rows of W_{word} and W_{tag} represent the output continuous representations of the i-th word and its POS tag respectively. Note that for two words with the same POS tag, the corresponding POS tag representations are the same. We take the product of f and the child matrix W_{chd} and apply a softmax function to obtain the CHILD rule probabilities. For DECISION rules, we replace W_{chd} with the decision weight matrix W_{dec} and follow the same procedure.

Extended Learning Algorithm: The original NDMV learning method is based on hard-EM and is very time-consuming when applied to L-NDMV with a large training corpus. We propose two improvements to achieve significant speedup. First, at each EM iteration we collect grammar rule counts from a different batch of sentences instead of from the whole training corpus and train the neural network using only these counts. Second, we train the same neural network across EM iterations without resetting. More details can be found in the supplementary material. Our algorithm can be seen as an extension of online EM (Liang and Klein, 2009) to accommodate neural network training.

2.3 Model Initialization

It was previously shown that the heuristic KM initialization method by Klein and Manning (2004) does not work well for lexicalized grammar induction (Headden III et al., 2009; Pate and Johnson, 2016) and it is very helpful to initialize learning with a model learned by a different grammar induction method (Le and Zuidema, 2015; Jiang et al., 2016). We tested both KM initialization and the following initialization method: we first learn an unlexicalized DMV using the grammar induction method of Naseem et al. (2010) and use it to parse the training corpus; then, from the parse trees we run maximum likelihood estimation to produce the initial lexicalized model.

3 Experimental Setup

For English, we used the BLLIP corpus[1] in addition to the regular WSJ corpus in our experiments. Note that the BLLIP corpus is collected from the same news article source as the WSJ corpus, so it is in-domain and is ideal for training grammars to be evaluated on the WSJ test set. In order to solve the compatibility issue as well as improve the POS tagging accuracy, we used the Stanford tagger (Toutanova et al., 2003) to retag the BLLIP corpus and selected the sentences for which the new tags are consistent with the original tags, which resulted in 182244 sentences with length less than or equal to 10 after removing punctuations. We used this subset of BLLIP and section 2-21 of WSJ10 for training, section 22 of WSJ for validation and section 23 of WSJ for testing. We used training sets of four different sizes: WSJ10 only (5779 sentences) and 20k, 50k, and all sentences from the BLLIP subset. For Chinese, we obtained 4762 sentences for training from Chinese Treebank 6.0 (CTB) after converting data to dependency structures via Penn2Malt (Nivre, 2006) and then stripping off punctuations. We used the recommended validation and test data split described in the documentation.

We trained the models with different degrees of lexicalization. We control the degree of lexicalization by replacing words that appear less than a cutoff number in the WSJ10 or CTB corpus with their POS tags. For each degree of lexicalization, we tuned the dimension of the hidden layer of the neural network on the validation dataset. For English, we tested nine word cutoff numbers: 100000, 500, 200, 100, 80, 70, 60, 50, and 40, which resulted in vocabulary sizes of 35, 63, 98, 166, 203, 226, 267, 306, and 390 respectively; for Chinese, the word cutoff numbers are 100000, 100, 70, 50, 40, 30, 20, 12, and 10. Ideally, with higher degrees of lexicalization, the hidden layer dimension should be larger in order to accommodate the increased number of tokens. For the neural network of L-NDMV, we initialized the word and tag vectors in the neural network by learning a CBOW model using the Gensim package (Řehůřek and Sojka, 2010). We set the dimension of input and output word vectors to 100 and the dimension of input and output tag vectors to 20. We trained the neural network with learning rate 0.03, mini-batch size 200 and momentum 0.9. Because some of the neural network weights are randomly initialized, the model converges to a different local minimum in each run of the learning algorithm. Therefore, for each setup we ran our learning algorithm for three times and reported the average accuracy. More detail of the experimental setup can be found in the supplementary material.

4 Experimental Results

4.1 Results on English

Figure 2(a) shows the directed dependency accuracy (DDA) of the learned lexicalized DMV with KM initialization. It can be seen that on the smallest WSJ10 training corpus, lexicalization improves learning only when the degree of lexicalization is small; with further lexicalization, the learning accuracy significantly degrades. On the three larger training corpora, the impact of lexicalization on the learning accuracy is still negative but is less severe. Overall, lexicalization seems to be very data demanding and even our largest training corpora could not bring about the benefit of lexicalization. Increasing the training corpus size is helpful regardless of the degree of lexicalization, but the learning accuracies with the 50K dataset are almost identical to those with the full dataset, suggesting diminishing return of more data.

Figure 2(b) shows the results of L-NDMV with KM initialization. The parsing accuracy is improved under all the settings, showing the advantage of NDMV. The range of lexicalization degrees that improve learning becomes larger, and the degradation in accuracy with large degrees of lexicalization becomes much less severe. Diminishing return of big data as seen in the first figure can still be observed.

Figure 2(c) shows the results of L-NDMV with the initialization method described in section 2.3. It can be seen that lexicalization becomes less data demanding and the learning accuracy does not decrease until the highest degrees of lexicalization. Larger training corpora now lead to significantly better learning accuracy and support lexicalization

(d) L-DMV and L-NDMV on Chinese

Figure 2: The impact of the training corpus size and the degree of lexicalization on L-DMV and L-NDMV with different initialization methods on English and Chinese.

of greater degrees than smaller corpora. Diminishing return of big data is no longer observed, which implies further increase in accuracy with even more data.

Table 1 compares the result of L-NDMV (with the largest corpus and the vocabulary size of 203 which was selected on the validation set) with previous approaches to dependency grammar induction. It can be seen that L-NDMV is competitive with previous state-of-the-art approaches. We did some further analysis of the learned word vectors in L-NDMV in the supplementary material.

4.2 Results on Chinese

Figure 2(d) shows the results of the three approaches on the Chinese treebank. Because the corpus is relatively small, we did not study the impact of the corpus size. Similar to the case of English, the accuracy of lexicalized DMV degrades with more lexicalization. However, the accuracy with L-NDMV increases significantly with more lexicalization even without good model initialization. Adding good initialization further boosts the performance of L-NDMV, but the benefit of lexicalization is less significant (from 0.55 to 0.58).

5 Effect of Grammar Rule Probability Initialization

We compare four initialization methods to L-NDMV: uniform initialization, random initialization, KM initialization (Klein and Manning, 2004), and good initialization as described in section 2.3 in Figure 3. Here we trained the L-NDMV model on the WSJ10 corpus with the same experimental setup as in section 3.

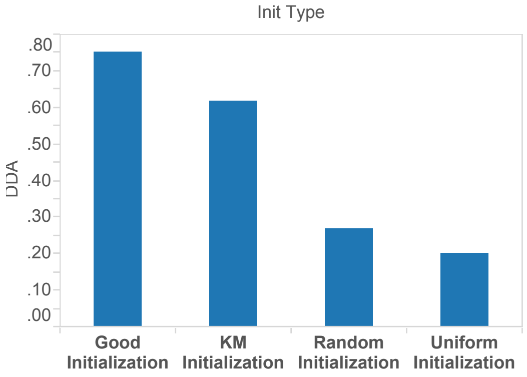

Figure 3: Comparison of four initialization methods to L-NDMV: uniform initialization, random initialization, KM initialization and good initialization.

Again, we find that good initialization leads to better performance than KM initialization, and both good initialization and KM initialization are significantly better than random and uniform initialization. Note that our results are different from those by Pate and Johnson (2016), who found that uniform initialization leads to similar performance to KM initialization. We speculate that it is because of the difference in the learning approaches (we use neural networks which may be more sensitive to initialization) and the training and test corpora (we use news articles while they use telephone scripts).

6 Conclusion and Future Work

We study the impact of the degree of lexicalization and the training data size on the accuracy of dependency grammar induction. We experimented with lexicalized DMV (L-DMV) and our lexicalized extension of Neural DMV (L-NDMV). We find that L-DMV only benefits from very small degrees of lexicalization and moderate sizes of training corpora. In contrast, L-NDMV can benefit from big training data and lexicalization of greater degrees, especially when enhanced with good model initialization, and it achieves a result that is competitive with the state-of-the-art.

In the future, we plan to study higher degrees of lexicalization or full lexicalization, as well as even larger training corpora (such as the Wikipedia corpus). We would also like to experiment with other grammar induction approaches with lexicalization and big training data.

Abstract

Unsupervised dependency parsing aims to learn a dependency parser from unannotated sentences. Existing work focuses on either learning generative models using the expectation-maximization algorithm and its variants, or learning discriminative models using the discriminative clustering algorithm. In this paper, we propose a new learning strategy that learns a generative model and a discriminative model jointly based on the dual decomposition method. Our method is simple and general, yet effective to capture the advantages of both models and improve their learning results. We tested our method on the UD treebank and achieved a state-of-the-art performance on thirty languages.

1 Introduction

Dependency parsing is an important task in natural language processing. It identifies dependencies between words in a sentence, which have been shown to benefit other tasks such as semantic role labeling (Lei et al., 2015) and sentence classification (Ma et al., 2015). Supervised learning of a dependency parser requires annotation of a training corpus by linguistic experts, which can be time and resource consuming. Unsupervised dependency parsing eliminates the need for dependency annotation by directly learning from unparsed text.

Previous work on unsupervised dependency parsing mainly focuses on learning generative models, such as the dependency model with valence (DMV) (Klein and Manning, 2004) and combinatory categorial grammars (CCG) (Bisk and Hockenmaier, 2012). Generative models have many advantages. For example, the learning objective function can be defined as the marginal likelihood of the training data, which is typically easy to compute in a generative model. In addition, many types of inductive bias, such as those favoring short dependency arcs (Smith and Eisner, 2006), encouraging correlations between POS tags (Cohen et al., 2008; Cohen and Smith, 2009; Berg-Kirkpatrick et al., 2010; Jiang et al., 2016), and limiting center embedding (Noji et al., 2016), can be incorporated into generative models to achieve better parsing accuracy. However, due to the strong independence assumption in most generative models, it is difficult for these models to utilize context information that has been shown to benefit supervised parsing.

Recently, a feature-rich discriminative model for unsupervised parsing is proposed that captures the global context information of sentences (Grave and Elhadad, 2015). Inspired by discriminative clustering, learning of the model is formulated as convex optimization of both the model parameters and the parses of training sentences. By utilizing language-independent rules between pairs of POS tags to guide learning, the model achieves state-of-the-art performance on the UD treebank dataset.

In this paper we propose to jointly train two state-of-the-art models of unsupervised dependency parsing: a generative model called LC-DMV (Noji et al., 2016) and a discriminative model called Convex-MST (Grave and Elhadad, 2015). We employ a learning algorithm based on the dual decomposition (Dantzig and Wolfe, 1960) inference algorithm, which encourages the two models to influence each other during training.

We evaluated our method on thirty languages and found that the jointly trained models surpass their separately trained counterparts in parsing accuracy. Further analysis shows that the two models positively influence each other during joint train-

ing by implicitly sharing the inductive bias.

2 Preliminaries

2.1 DMV

The dependency model with valence (DMV) (Klein and Manning, 2004) is the first generative model that outperforms the left-branching baseline in unsupervised dependency parsing. In DMV, a sentence is generated by recursively applying three types of grammar rules to construct a parse tree from the top down. The probability of the generated sentence and parse tree is the probability product of all the rules used in the generation process. To learn the parameters (rule probabilities) of DMV, the expectation maximization algorithm is often used. Noji et al. (2016) exploited two universal syntactic biases in learning DMV: restricting the center-embedding depth and encouraging short dependencies. They achieved a comparable performance with state-of-the-art approaches.

2.2 Convex-MST

Convex-MST (Grave and Elhadad, 2015) is a discriminative model for unsupervised dependency parsing based on the first-order maximum spanning tree dependency parser (McDonald et al., 2005). Given a sentence, whether each possible dependency exists or not is predicted based on a set of handcrafted features and a valid parse tree closest to the prediction is identified by the minimum spanning tree algorithm.

For each sentence $\mathbf{x}$, a first-order dependency graph is built over the words of the sentence. The weight of each edge is calculated by $\mathbf{w}^T\mathbf{f}(\mathbf{x}, i, j)$, where $\mathbf{w}$ is the parameters and $\mathbf{f}(\mathbf{x}, i, j)$ is the handcrafted feature vector of the dependency from the i-th word to the j-th word in sentence $\mathbf{x}$. For sentence $\mathbf{x}$ of length n, we can represent it as matrix $\mathbf{X}$ where each raw is a feature vector. The parse tree $\mathbf{y}$ is a spanning tree of the graph and can be represented as a binary vector with length $n \times n$ where each element is 1 if the corresponding arc is in the tree and 0 otherwise.

Learning is based on discriminative clustering with the following objective function:

$$\frac{1}{N}\sum_{\alpha=1}^{N}\left(\frac{1}{2n_\alpha}||\mathbf{y}_\alpha - \mathbf{X}_\alpha\mathbf{w}||_2^2 - \mu\mathbf{v}^T\mathbf{y}_\alpha\right)+\frac{\lambda}{2}||\mathbf{w}||_2^2$$

where $\mathbf{X}_\alpha$ is a matrix where each row is a feature representation $\mathbf{f}(\mathbf{x}_\alpha, i, j)$ of an edge in the dependency graph of sentence $\mathbf{x}_\alpha$, $\mathbf{v}$ represents whether each dependency arc in $\mathbf{y}_\alpha$ satisfies a set of prespecified linguistic rules, and λ and μ are hyperparameters. The Frank-Wolfe algorithm is employed to optimize the objective function.

2.3 Dual Decomposition

Dual decomposition (Dantzig and Wolfe, 1960), a special case of Lagrangian relaxation, is an optimization method that decomposes a hard problem into several small sub-problems. It has been widely used in machine learning (Komodakis et al., 2007) and natural language processing (Koo et al., 2010; Rush and Collins, 2012).

Komodakis et al. (2007) proposed using dual decomposition to do MAP inference for Markov random fields. Koo et al. (2010) proposed a new dependency parser based on dual decomposition by combining a graph based dependency model and a non-projective head automata. In the work of Rush et al. (2010), they showed that dual decomposition can effectively integrate two lexicalized parsing models or two correlated tasks.

2.4 Agreement based Learning

Liang et al. (2008) proposed agreement based learning that trains several tractable generative models jointly and encourages them to agree on certain latent variables. To effectively train the system, a product EM algorithm was used. They showed that the joint model can perform better than each independent model on the accuracy or convergence speed. They also showed that the objective function of the work of Klein and Manning (2004) is a special case of the product EM algorithm for grammar induction. Our approach has a similar motivation to agreement based learning but has two important advantages. First, while their approach only combines generative models, our approach can make use of both generative and discriminative models. Second, while their approach requires the sub-models to share the same dynamic programming structure when performing decoding, our approach does not have such restriction.

3 Joint Training

We minimize the following objective function that combines two different models of unsupervised dependency parsing:

$$J(\mathbf{M_F}, \mathbf{M_G}) = \sum_{\alpha=1}^{N} \min_{\mathbf{y}_\alpha \in \mathcal{Y}_\alpha} \left(F(\mathbf{x}_\alpha, \mathbf{y}_\alpha; \mathbf{M_F}) + G(\mathbf{x}_\alpha, \mathbf{y}_\alpha; \mathbf{M_G})\right)$$

where N is the size of training data, $\mathbf{M_F}$ and $\mathbf{M_G}$ are the parameters of the first and second model respectively, F and G are their respective learning objectives, and $\mathcal{Y}_\alpha$ is the set of valid dependency parses of sentence $\mathbf{x}_\alpha$. While in principle this objective can be used to combine many different types of models, here we consider two state-of-the-art models of unsupervised dependency parsing, a generative model LC-DMV (Noji et al., 2016) and a discriminative model Convex-MST (Grave and Elhadad, 2015). We denote the parameters of LC-DMV by Θ and the parameters of Convex-MST by $\mathbf{w}$. Their respective objective functions are,

$$F(\mathbf{x}_\alpha, \mathbf{y}_\alpha; \Theta) = -\log\left(P_\Theta(\mathbf{x}_\alpha, \mathbf{y}_\alpha) f(\mathbf{x}_\alpha, \mathbf{y}_\alpha)\right)$$

$$G(\mathbf{x}_\alpha, \mathbf{y}_\alpha; \mathbf{w}) = \frac{1}{2n_\alpha}||\mathbf{y}_\alpha - \mathbf{X}_\alpha \mathbf{w}||_2^2 + \frac{\lambda}{2N}||\mathbf{w}||_2^2 - \mu \mathbf{v}^T \mathbf{y}$$

where $P_\Theta(\mathbf{x}_\alpha, \mathbf{y}_\alpha)$ is the joint probability of sentence $\mathbf{x}_\alpha$ and parse $\mathbf{y}_\alpha$, f is a constraint factor, and the notations in the second objective function are explained in section 2.2.

3.1 Learning

We use coordinate descent to optimize the parameters of the two models. In each iteration, we first fix the parameters and find the best dependency parses of the training sentences (see section 3.2); we then fix the parses and optimize the parameters. The detailed algorithm is shown in Algorithm 1.

Pretraining of the two models is done by running their original learning algorithms separately. When the parses of the training sentences are fixed, it is easy to show that the parameters of the two models can be optimized separately. Updating the parameters Θ of LC-DMV can be done by simply counting the number of times each rule is used in the parse trees and then normalizing the counts to get the maximum-likelihood probabilities. The parameters $\mathbf{w}$ of Convex-MST can be updated by stochastic gradient descent. After updating Θ and $\mathbf{w}$ at each iteration, we additionally train each model separately for three iterations, which we find further improves learning.

Algorithm 1 Parameter Learning

```
Input: Training sentence $\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_N$
Pre-train $\Theta$ and $\mathbf{w}$
repeat
    Fix $\Theta$ and $\mathbf{w}$ and solve the decoding problem
        to get $\mathbf{y}_\alpha, \alpha = 1, 2, \ldots, N$
    Fix the parses and update $\Theta$ and $\mathbf{w}$
until Convergence
```

Algorithm 2 Decoding via Dual Decomposition

```
Input: Sentence $\mathbf{x}$, fixed parameters $\mathbf{w}$ and $\Theta$
Initialize vector $\mathbf{u}$ of size $n \times n$ to $\mathbf{0}$
repeat
    $\hat{\mathbf{y}} = \arg\min_{\mathbf{y} \in \mathcal{Y}} F(\mathbf{x}, \mathbf{y}; \Theta) + \mathbf{u}^T \mathbf{y}$
    $\hat{\mathbf{z}} = \arg\min_{\mathbf{z} \in \mathcal{Y}} G(\mathbf{x}, \mathbf{z}; \mathbf{w}) - \mathbf{u}^T \mathbf{z}$
    if $\hat{\mathbf{y}} = \hat{\mathbf{z}}$ then
        return $\hat{\mathbf{y}}$
    else
        $\mathbf{u} = \mathbf{u} - \tau(\hat{\mathbf{y}} - \hat{\mathbf{z}})$
    end if
until Convergence
```

3.2 Joint Decoding

Given a training sample $\mathbf{x}$ and parameters $\mathbf{w}, \Theta$, the goal of decoding is to find the best parse tree:

$$\hat{\mathbf{y}} = \arg\min_{\mathbf{y} \in \mathcal{Y}} \frac{1}{2n}||\mathbf{y} - \mathbf{X}\mathbf{w}||_2^2 - \mu \mathbf{v}^T \mathbf{y} - \log P_\Theta(\mathbf{x}, \mathbf{y})$$

We employ the dual decomposition algorithm to solve this problem (shown in Algorithm 2), where τ represents the step size.

The most important part of the algorithm is solving the two separate decoding problems:

$$\hat{\mathbf{y}} = \arg\min_{\mathbf{y} \in \mathcal{Y}} -\log(P_\Theta(\mathbf{x}, \mathbf{y}) f(\mathbf{x}, \mathbf{y})) + \mathbf{u}^T \mathbf{y}$$

$$\hat{\mathbf{z}} = \arg\min_{\mathbf{z} \in \mathcal{Y}} \frac{1}{2n}||\mathbf{z} - \mathbf{X}\mathbf{w}||_2^2 - \mu \mathbf{v}^T \mathbf{z} - \mathbf{u}^T \mathbf{z}$$

The first decoding problem can be solved by a modified CYK parsing algorithm that takes into account the information in vector $\mathbf{u}$. The second decoding problem can be solved using the same algorithm of Grave and Elhadad (2015) (we use the projective version in our approach).

4 Experiments

4.1 Setup

We use UD Treebank 1.4 as our datasets. We sorted the datasets in the treebank by the number of training sentences of length $\leq$ 15 and selected the top thirty datasets, which is similar to the setup of Noji et al. (2016). For each dataset, we trained our method on the training data with length $\leq$ 15 and tested our method on the testing data with length $\leq$ 40. We tuned the hyper-parameters of our method on the dataset of the English language and reported the results on the thirty datasets without any further parameter tuning. We compared our method with four baselines. The first two baselines are Convex-MST and LC-DMV that are independently trained. To construct the third baseline, we used the independently trained Convex-MST baseline to parse all the training sentences and then used the parses to initialize the training of LC-DMV. This can be seen as a simple method to combine two different approaches. On the other hand, we did not use the LC-DMV baseline to initialize Convex-MST training because the objective function of Convex-MST is convex and therefore the initialization does not matter.

4.2 Results

In Table 1, we compare our jointly trained models with the four baselines. We can see that with joint training and independent decoding, LC-DMV and Convex-MST can achieve superior overall performance than when they are separately trained with or without mutual initialization. Joint decoding with our jointly trained models performs worse than independent decoding. We made the same observation when applying joint decoding to the separately trained models (not shown in the table). We believe this is because unsupervised parsers have relatively low accuracy and forcing them to reconcile would not lead to better parses. On the other hand, joint decoding during training helps propagate useful inductive biases between models and thus leads to better trained models.

4.3 Analysis of Parsing Results

We analyze the parsing results from the two models to see how they benefit each other with joint training. Note that LC-DMV limits the depth of center embedding and encourages shorter dependency length, while Convex-MST encourages dependencies satisfying pre-specified linguistic rules. Therefore, we would like to see whether the jointly-trained LC-DMV produces more dependencies satisfying the linguistic priors than its separately-trained counterpart, and whether the jointly-trained Convex-MST produces parse trees with less center embedding and shorter dependencies than its separately-trained counterpart.

Table 1: Directed dependency accuracy on thirty datasets with test sentences of length $\leq$ 40. The last row indicates the average directed accuracy on sentences of length $\leq$ 15. M (Convex-MST) and D (LC-DMV) are the independently trained baselines. D-I is the third baseline in which the LC-DMV training is initialized by the parses produced from the trained Convex-MST model. With our jointly trained models, M-J and D-J denote separate decoding and DD denotes joint decoding.

Figure 1 shows the percentages of dependencies satisfying linguistic rules when using the separately and jointly trained LC-DMV to parse the test sentences in the English dataset. As we can see, with joint training, LC-DMV is indeed influenced by Convex-MST and produces more dependencies satisfying linguistic rules.

Table 2 shows the average dependency length when using the separately and jointly trained Convex-MST to parse the English test dataset. The dependency length can be seen to decrease with joint training, showing the influence from LC-DMV. As to center embedding depth, we find that separately trained Convext-MST already produces very few center embeddings of depth 2 or more,

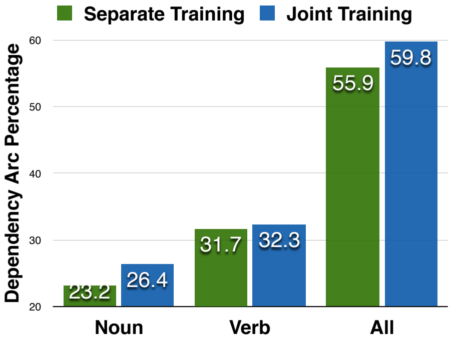

Figure 1: Percentages of dependencies satisfying linguistic rules in the LC-DMV parses of the English test dataset. Noun and Verb denote dependencies headed by nouns and verbs.

Methods	Average Dependency Length
Separate Training	1.673
Joint Training	**1.627**

so the influence from the center embedding constraint of LC-DMV during joint training is not obvious. We note that the influence on Convex-MST from LC-DMV during joint training is relatively small, which may contribute to the much smaller accuracy improvement (1.5%) of Convex-MST with joint training in comparison with the 9.3% improvement of LC-DMV. We conducted an additional experiment that scaled down the Convex-MST objective in joint training in order to increase the influence of LC-DMV. The results show that LC-DMV indeed influences Convex-MST to a greater degree, but the parsing accuracies of the two models decrease.

5 Conclusion

In this paper, we proposed a new learning strategy for unsupervised dependency parsing that learns a generative model and a discriminative model jointly based on dual decomposition. We show that with joint training, two state-of-the-art models can positively influence each other and achieve better performance than their separately trained counterparts.

Effective Inference for Generative Neural Parsing

Mitchell Stern **Daniel Fried** **Dan Klein**
Computer Science Division
University of California, Berkeley
{mitchell,dfried,klein}@cs.berkeley.edu

Abstract

Generative neural models have recently achieved state-of-the-art results for constituency parsing. However, without a feasible search procedure, their use has so far been limited to reranking the output of external parsers in which decoding is more tractable. We describe an alternative to the conventional action-level beam search used for discriminative neural models that enables us to decode directly in these generative models. We then show that by improving our basic candidate selection strategy and using a coarse pruning function, we can improve accuracy while exploring significantly less of the search space. Applied to the model of Choe and Charniak (2016), our inference procedure obtains 92.56 F1 on section 23 of the Penn Treebank, surpassing prior state-of-the-art results for single-model systems.

1 Introduction

A recent line of work has demonstrated the success of generative neural models for constituency parsing (Dyer et al., 2016; Choe and Charniak, 2016). As with discriminative neural parsers, these models lack a dynamic program for exact inference due to their modeling of unbounded dependencies. However, while discriminative neural parsers are able to obtain strong results using greedy search (Dyer et al., 2016) or beam search with a small beam (Vinyals et al., 2015), we find that a simple action-level approach fails outright in the generative setting. Perhaps because of this, the application of generative neural models has so far been restricted to reranking the output of external parsers.

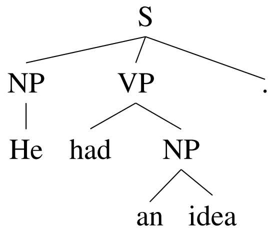
Intuitively, because a generative parser defines a joint distribution over sentences and parse trees, probability mass will be allocated unevenly between a small number of common structural actions and a large vocabulary of lexical items. This imbalance is a primary cause of failure for search procedures in which these two types of actions compete directly. A notion of equal competition among hypotheses is then desirable, an idea that has previously been explored in generative models for constituency parsing (Henderson, 2003) and dependency parsing (Titov and Henderson, 2010; Buys and Blunsom, 2015), among other tasks. We describe a related state-augmented beam search for neural generative constituency parsers in which lexical actions compete only with each other rather than with structural actions. Applying this inference procedure to the generative model of Choe and Charniak (2016), we find that it yields a self-contained generative parser that achieves high performance.

Beyond this, we propose an enhanced candidate selection strategy that yields significant improvements for all beam sizes. Additionally, motivated by the look-ahead heuristic used in the top-down parsers of Roark (2001) and Charniak (2010), we also experiment with a simple coarse pruning function that allows us to reduce the number of states expanded per candidate by several times without compromising accuracy. Using our final search procedure, we surpass prior state-of-the-art results among single-model parsers on the Penn Treebank, obtaining an F1 score of 92.56.

2 Common Framework

The generative neural parsers of Dyer et al. (2016) and Choe and Charniak (2016) can be unified under a common shift-reduce framework. Both systems build parse trees in left-to-right depth-first order by executing a sequence of actions, as illustrated in Figure 1. These actions can be grouped

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1695–1700
Copenhagen, Denmark, September 7–11, 2017.



(S (NP He NP) (VP had (NP an idea NP) VP) . S)

Figure 1: A parse tree and the action sequence that produced it, corresponding to the sentence "He had an idea." The tree is constructed in left-to-right depth-first order. The tree contains only nonterminals and words; part-of-speech tags are not included. OPEN(X) and CLOSE(X) are rendered as "(X" and "X)" for brevity.

into three major types: OPEN(X) and CLOSE(X), which open and close a constituent with nonterminal X,[1] respectively, and SHIFT(x), which adds the word x to the current constituent. The probability of an action sequence $(a_1, \ldots, a_T)$ is

$$\begin{aligned} P(a_1, \ldots, a_T) &= \prod_{t=1}^{T} P(a_t \mid a_1, \ldots, a_{t-1}) \\ &= \prod_{t=1}^{T} [\text{softmax}(\mathbf{W}\mathbf{u}_t + \mathbf{b})]_{a_t}, \end{aligned}$$

where $\mathbf{u}_t$ is a continuous representation of the parser's state at time t, and $[\mathbf{v}]_j$ denotes the jth component of a vector $\mathbf{v}$. We refer readers to the respective authors' papers for the parameterization of $\mathbf{u}_t$ in each model.

In both cases, the decoding process reduces to a search for the most probable action sequence that represents a valid tree over the input sentence. For a given hypothesis, this requirement implies several constraints on the successor set (Dyer et al., 2016); e.g., SHIFT(x) can only be executed if the next word in the sentence is x, and CLOSE(X) cannot be executed directly after OPEN(X).

3 Model and Training Setup

We reimplemented the generative model described in Choe and Charniak (2016) and trained it on the Penn Treebank (Marcus et al., 1993) using their published hyperparameters and preprocessing. However, rather than selecting the final model based on reranking performance, we instead perform early stopping based on development set perplexity. We use sections 2-21 of the Penn Treebank for training, section 22 for development, and section 23 for testing. The model's action space consists of 26 matching pairs of OPEN and CLOSE actions, one for each nonterminal, and 6,870 SHIFT actions, one for each preprocessed word type. While we use this particular model for our experiments, we note that our subsequent discussion of inference techniques is equally applicable to any generative parser that adheres to the framework described above in Section 2.

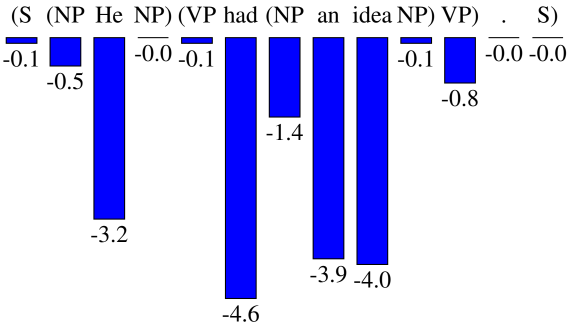


Figure 2: A plot of the action log probabilities $\log P(a_t \mid a_1, \ldots, a_{t-1})$ for the example in Figure 1 under our main model. We observe that OPEN and CLOSE actions have much higher probability than SHIFT actions. This imbalance is responsible for the failure of standard action-level beam search.

4 Action-Level Search

Given that ordinary action-level search has been applied successfully to discriminative neural parsers (Vinyals et al., 2015; Dyer et al., 2016), it offers a sensible starting point for decoding in generative models. However, even for large beam sizes, the following pathological behavior is encountered for generative decoding, preventing reasonable parses from being found. Regardless of the sequence of actions taken so far, the generative model tends to assign much higher probabilities to structural OPEN and CLOSE actions than it does lexical SHIFT actions, as shown in Figure 2. The model therefore prefers to continually open new constituents until a hard limit is reached, as the alternative at each step is to take the low-probability action of shifting the next word. The resulting

[1] The model described in Dyer et al. (2016) has only a single CLOSE action, whereas the model described in Choe and Charniak (2016) annotates CLOSE(X) actions with their nonterminals. We present the more general version here.

Beam Size k	200	400	600	800	1000	2000
$k_w = k$	87.47	89.86	90.98	91.62	91.97	92.74
$k_w = k/10$	89.25	91.16	91.83	92.12	92.38	92.93

Table 1: Development F1 scores using word-level search with various beam sizes k and two choices of word beam size k_w.

sequence typically has much lower overall probability than a plausible parse, but the model's myopic comparison between structural and lexical actions prevents reasonable candidates from staying on the beam. Action-level beam search with beam size 1000 obtains an F1 score of just 52.97 on the development set.

5 Word-Level Search

The imbalance between the probabilities of structural and lexical actions suggests that the two kinds of actions should not compete against each other within a beam. This leads us to consider an augmented state space in which they are kept separate by design, as was done by Fried et al. (2017). In conventional action-level beam search, hypotheses are grouped by the length of their action history $|A|$. Letting A_i denote the set of actions taken since the ith shift action, we instead group hypotheses by the pair $(i, |A_i|)$, where i ranges between 0 and the length of the sentence.

Let k denote the target beam size. The search process begins with the empty hypothesis in the $(0, 0)$ bucket. Word-level steps are then taken according to the following procedure for $i = 0, 1, \ldots,$ up to the length of the sentence (inclusive). Beginning with the $(i, 0)$ bucket, the successors of each hypothesis are pooled together, sorted by score, and filtered down to the top k. Of those that remain, successors obtained by taking an OPEN or CLOSE action advance to the $(i, 1)$ bucket, whereas successors obtained from a SHIFT action are placed in the $(i + 1, 0)$ bucket if i is less than the sentence length, or the completed list if i is equal to the sentence length. This process is repeated for the $(i, 1)$ bucket, the $(i, 2)$ bucket, and so forth, until the $(i+1, 0)$ bucket contains at least k hypotheses. If desired, a separate word beam size $k_w < k$ can be used at word boundaries, in which case each word-level step terminates when the $(i + 1, 0)$ bucket has k_w candidates instead of k. This introduces a bottleneck that can help to promote beam diversity.

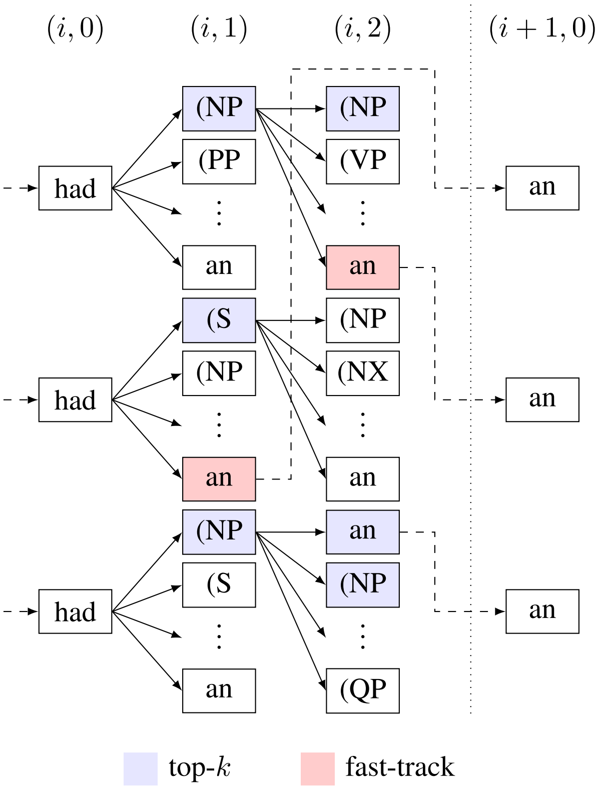

Figure 3: One step of word-level search with fast-track candidate selection (Sections 5 and 6) for the example in Figure 1. Grouping candidates by the current word i ensures that low-probability lexical actions are kept separate from high-probability structural actions at the beam level. Fast-track selection mitigates competition between the two types of actions within a single pool of successors.

Development set results for word-level search with a variety of beam sizes and with $k_w = k$ or $k_w = k/10$ are given in Table 1. We observe that performance in both cases increases steadily with beam size. Word-level search with $k_w = k/10$ consistently outperforms search without a bottleneck at all beam sizes, indicating the utility of this simple diversity-inducing modification. The top result of 92.93 F1 is already quite strong compared to other single-model systems.

6 Fast-Track Candidate Selection

The word-level beam search described in Section 5 goes one step toward ameliorating the issue that causes action-level beam search to fail, namely the direct competition between common structural actions with high probabilities and low-frequency shift actions with low probabilities. However, the issue is still present to some extent, in that successors of both types from a given bucket are pooled

Beam Size k	200	400	600	800	1000	2000
$k_w = k$	91.33	92.17	92.51	92.73	92.89	93.05
$k_w = k/10$	91.41	92.34	92.70	92.94	93.09	93.18

Table 2: Development F1 scores using the settings from Table 1, together with the fast-track selection strategy from Section 6 with $k_s = k/100$.

together and filtered down as a single collection before being routed to their respective destinations. We therefore propose a more direct solution to the problem, in which a small number $k_s \ll k$ of SHIFT successors are fast-tracked to the next word-level bucket *before* any filtering takes place. These fast-tracked candidates completely bypass competition with potentially high-scoring OPEN or CLOSE successors, allowing for higher-quality results in practice with minimal overhead. See Figure 3 for an illustration.

We repeat the experiments from Section 5 with $k_s = k/100$ and report the results in Table 2. Note that the use of fast-tracked candidates offers significant gains under all settings. The top result improves from 92.93 to 93.18 with the use of fast-tracked candidates, surpassing prior single-model systems on the development set.

7 OPEN Action Pruning

At any point during the trajectory of a hypothesis, either 0 or all 26 of the OPEN actions will be available, compared with at most 1 CLOSE action and at most 1 SHIFT action. Hence, when available, OPEN actions comprise most or all of a candidate's successor actions. To help cut down on this portion of the search space, it is natural to consider whether some of these actions could be ruled out using a coarse model for pruning.

7.1 Coarse Model

We consider a class of simple pruning models that condition on the $c \geq 0$ most recent actions and the next word in the sentence, and predict a probability distribution over the next action. In the interest of efficiency, we collapse all SHIFT actions into a single unlexicalized SHIFT action, significantly reducing the size of the output vocabulary.

The input $\mathbf{v}_t$ to the pruning model at time t is the concatenation of a vector embedding for each action in the context $(a_{t-c}, a_{t-c+1}, \ldots, a_{t-1})$ and a vector embedding for the next word w:

$$\mathbf{v}_t = [\mathbf{e}_{a_{t-c}}; \mathbf{e}_{a_{t-c+1}}; \ldots; \mathbf{e}_{a_{t-1}}; \mathbf{e}_w],$$

where each $\mathbf{e}_j$ is a learned vector embedding. The pruning model itself is implemented by feeding the input vector through a one-layer feedforward network with a ReLU non-linearity, then applying a softmax layer on top:

$$\begin{aligned}
&P(a_t = a \mid a_1, \ldots, a_{t-1}, \text{next-word} = w) \\
&= P(a_t = a \mid a_{t-c}, \ldots, a_{t-1}, \text{next-word} = w) \\
&= [\operatorname{softmax}(\mathbf{W}_2 \max(\mathbf{W}_1 \mathbf{v}_t + \mathbf{b}_1, 0) + \mathbf{b}_2)]_a.
\end{aligned}$$

The pruning model is trained separately from the main parsing model on gold action sequences derived from the training corpus, with log-likelihood as the objective function and a cross entropy loss.

7.2 Strategy and Empirical Lower Bound

Once equipped with a coarse model, we use it for search reduction in the following manner. As mentioned above, when a hypothesis is eligible to open a new constituent, most of its successors will be obtained through OPEN actions. Accordingly, we use the coarse model to restrict the set of OPEN actions to be explored. When evaluating the pool of successors for a given collection of hypotheses during beam search, we run the coarse model on each hypothesis to obtain a distribution over its next possible actions, and gather together all the coarse scores of the would-be OPEN successors. We then discard the OPEN successors whose coarse scores lie below the top $1-p$ quantile for a fixed $0 < p < 1$, guaranteeing that no more than a p-fraction of OPEN successors are considered for evaluation. Taking $p = 1$ corresponds to the unpruned setting.

This strategy gives us a tunable hyperparameter p that allows us to trade off between the amount of search we perform and the quality of our results. Before testing our procedure, however, we would first like to investigate whether there is a principled bound on how low we can expect to set p without a large drop in performance. A simple estimate arises from noting that the pruning fraction p should be set to a value for which most or all of the outputs encountered in the training set are retained. Otherwise, the pruning model would prevent the main model from even recreating the training data, let alone producing good parses for new sentences.

To this end, we collect training corpus statistics on the occurrences of inputs to the pruning function and their corresponding outputs. We then

c	1	2	3	4	5	6	7	8	9	10
0	20.0	58.4	82.4	91.0	94.9	96.8	97.9	98.6	98.9	99.2
1	54.9	80.5	91.1	95.9	97.7	98.8	99.5	99.8	99.9	100.0
2	61.2	85.0	93.8	97.4	98.6	99.5	99.8	99.9	100.0	100.0

Table 3: Cumulative distributions of the number of unique OPEN outputs per input for an order-c pruning function, computed over pruning inputs with at least one OPEN output.

p	6/26	7/26	8/26	9/26	10/26	11/26	1
Dev F1	92.78	93.00	93.08	93.13	93.19	93.19	93.18

Table 4: Results when the best setting from Section 6 is rerun with OPEN action pruning with context size $c = 2$ and various pruning fractions p. Lower values of p indicate more aggressive pruning, while $p = 1$ means no pruning is performed.

compute the number of unique OPEN actions associated with inputs occurring at least 20 times, and restrict our attention to inputs with at least one OPEN output. The resulting cumulative distributions for context sizes $c = 0, 1, 2$ are given in Table 3. If we require that our pruning fraction p be large enough to recreate at least 99% of the training data, then since there are 26 total nonterminals, approximate[2] lower bounds for p are $10/26 \approx 0.385$ for $c = 0$, $7/26 \approx 0.269$ for $c = 1$, and $6/26 \approx 0.231$ for $c = 2$.

7.3 Pruning Results

We reran our best experiment from Section 6 with an order-2 pruning function and pruning fractions $p = 6/26, \dots, 11/26$. The results are given in Table 4. We observe that performance is on par with the unpruned setup (at most 0.1 absolute difference in F1 score) for p as low as $8/26 \approx 0.308$. Setting p to $7/26 \approx 0.269$ results in a drop of 0.18, and setting p to $6/26 \approx 0.231$ results in a drop of 0.40. Hence, degradation begins to occur right around the empirically-motivated threshold of $6/26$ given above, but we can prune $1 - 8/26 \approx 69.2\%$ of OPEN successors with minimal changes in performance.

8 Final Results and Conclusion

We find that the best overall settings are a beam size of $k = 2000$, a word beam size of $k_w = 200$, and $k_s = 20$ fast-track candidates per step, as this setup achieves both the highest probabilities under the model and the highest development F1. We report our test results on section 23 of the Penn Treebank under these settings in Table 5 both with and without pruning, as well as a number of other recent results. We achieve F1 scores of 92.56 on the test set without pruning and 92.53 when $1 - 8/26 \approx 69.2\%$ of OPEN successors are pruned, obtaining performance well above the previous state-of-the-art scores for single-model parsers. This demonstrates that the model of Choe and Charniak (2016) works well as an accurate, self-contained system. The fact that we match the performance of their reranking parser using the same generative model confirms the efficacy of our approach. We believe that further refinements of our search procedure can continue to push the bar higher, such as the use of a learned heuristic function for forward score estimation, or a more sophisticated approximate decoding scheme making use of specific properties of the model. We look forward to exploring these directions in future work.

Abstract

In this paper we propose an end-to-end neural CRF autoencoder (NCRF-AE) model for semi-supervised learning of sequential structured prediction problems. Our NCRF-AE consists of two parts: an encoder which is a CRF model enhanced by deep neural networks, and a decoder which is a generative model trying to reconstruct the input. Our model has a unified structure with different loss functions for labeled and unlabeled data with shared parameters. We developed a variation of the EM algorithm for optimizing both the encoder and the decoder simultaneously by decoupling their parameters. Our experimental results over the Part-of-Speech (POS) tagging task on eight different languages, show that the NCRF-AE model can outperform competitive systems in both supervised and semi-supervised scenarios.

1 Introduction

The recent renaissance of deep learning has led to significant strides forward in several AI fields. In Natural Language Processing (NLP), characterized by highly structured tasks, promising results were obtained by models that combine deep learning methods with traditional structured learning algorithms (Chen and Manning, 2014; Durrett and Klein, 2015; Andor et al., 2016; Wiseman and Rush, 2016). These models combine the strengths of neural models, that can score local decisions using a rich non-linear representation, with efficient inference procedures used to combine the local decisions into a coherent global decision. Among these models, neural variants of the Conditional Random Fields (CRF) model (Lafferty et al., 2001) are especially popular. By replacing the linear potentials with non-linear potential using neural networks these models were able to improve performance in several structured prediction tasks (Andor et al., 2016; Peng and Dredze, 2016; Lample et al., 2016; Ma and Hovy, 2016; Durrett and Klein, 2015).

Despite their promise, wider adoption of these algorithms for new structured prediction tasks can be difficult. Neural networks are notoriously susceptible to over-fitting unless large amounts of training data are available. This problem is exacerbated in the structured settings, as accounting for the dependencies between decisions requires even more data. Providing it through manual annotation is often a difficult labor-intensive task.

In this paper we tackle this problem, and propose an end-to-end neural CRF autoencoder (NCRF-AE) model for semi-supervised learning on sequence labeling problems.

An autoencoder is a special type of neural net, modeling the conditional probability $P(\hat{X}|X)$, where X is the original input to the model and $\hat{X}$ is the reconstructed input (Hinton and Zemel, 1994). Autoencoders consist of two parts, an *encoder* projecting the input to a hidden space, and a *decoder* reconstructing the input from it.

Traditionally, autoencoders are used for generating a compressed representation of the input by projecting it into a dense low dimensional space. In our setting the hidden space consists of discrete variables that comprise the output structure. These generalized settings are described in Figure 1a. By definition, it is easy to see that the encoder (lower half in Figure 1a) can be modeled by a discriminative model describing $P(Y|X)$ directly, while the decoder (upper half in Figure 1a) naturally fits as a generative model, describing $P(\hat{X}|Y)$, where Y is the label. In our model, illustrated in Figure 1b, the encoder is a CRF model with neural networks

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1701–1711
Copenhagen, Denmark, September 7–11, 2017.

as its potential extractors, while the decoder is a generative model, trying to reconstruct the input.

Our model carries the merit of autoencoders, which can exploit valuable information from unlabeled data. Recent works (Ammar et al., 2014; Lin et al., 2015) suggested using an autoencoder with a CRF model as an encoder in an unsupervised setting. We significantly expand on these works and suggest the following contributions:

1. We propose a unified model seamlessly accommodating both unlabeled and labeled data. While past work focused on unsupervised structured prediction, neglecting the discriminative power of such models, our model easily supports learning in both fully supervised and semi-supervised settings. We developed a variation of the Expectation-Maximization (EM) algorithm, used for optimizing the encoder and the decoder of our model simultaneously.

2. We increase the expressivity of the traditional CRF autoencoder model using neural networks as the potential extractors, thus avoiding the heavy feature engineering necessary in previous works.

Interestingly, our model's predictions, which unify the discriminative neural CRF encoder and the generative decoder, have led to an improved performance over the highly optimized neural CRF (NCRF) model alone, even when trained in the supervised settings over the same data.

3. We demonstrate the advantages of our model empirically, focusing on the well-known Part-of-Speech (POS) tagging problem over 8 different languages, including low resource languages. In the supervised setting, our NCRF-AE outperformed the highly optimized NCRF. In the semi-supervised setting, our model was able to successfully utilize unlabeled data, improving on the performance obtained when only using the labeled data, and outperforming competing semi-supervised learning algorithms.

Furthermore, our newly proposed algorithm is directly applicable to other sequential learning tasks in NLP, and can be easily adapted to other structured tasks such as dependency parsing or constituent parsing by replacing the forward-backward algorithm with the inside-outside algorithm. All of these tasks can benefit from semi-supervised learning algorithms.[1]

2 Related Work

Neural networks were successfully applied to many NLP tasks, including tagging (Ma and Hovy, 2016; Mesnil et al., 2015; Lample et al., 2016), parsing (Chen and Manning, 2014), text generation (Sutskever et al., 2011), machine translation (Bahdanau et al., 2015), sentiment analysis (Kim, 2014) and question answering (Andreas et al., 2016). Most relevant to this work are structured prediction models capturing dependencies between decisions, either by modeling the dependencies between the hidden representations of connected decisions using RNN/LSTM (Vaswani et al., 2016; Katiyar and Cardie, 2016), by explicitly modeling the structural dependencies between output predictions (Durrett and Klein, 2015; Lample et al., 2016; Andor et al., 2016), or by combining the two approaches (Socher et al., 2013; Wiseman and Rush, 2016).

In contrast to supervised latent variable models, such as the Hidden Conditional Random Fields in (Quattoni et al., 2007), which utilize additional latent variables to infer for supervised structure prediction, we do not presume any additional latent variables in our NCRF-AE model in both supervised and semi-supervised setting.

The difficulty of providing sufficient supervision has motivated work on semi-supervised and unsupervised learning for many of these tasks (McClosky et al., 2006; Spitkovsky et al., 2010; Subramanya et al., 2010; Stratos and Collins, 2015; Marinho et al., 2016; Tran et al., 2016), including several that also used autoencoders (Ammar et al., 2014; Lin et al., 2015; Miao and Blunsom, 2016; Kociský et al., 2016; Cheng et al., 2017). In this paper we expand on these works, and suggest a neural CRF autoencoder, that can leverage both labeled and unlabeled data.

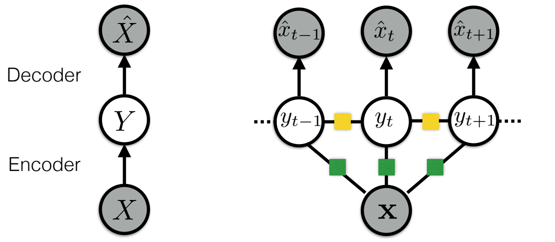
3 Neural CRF Autoencoder

In semi-supervised learning the algorithm needs to utilize both labeled and unlabeled data. Autoencoders offer a convenient way of dealing with both types of data in a unified fashion.

A generalized autoencoder (Figure 1a) tries to reconstruct the input $\hat{X}$ given the original input X, aiming to maximize the log probability $P(\hat{X}|X)$ without knowing the latent variable Y explicitly. Since we focus on sequential structured prediction problems, the encoding and decoding processes are no longer for a single data point (x, y) (x if

[1] Our code and experimental set up will be available at https://github.com/cosmozhang/NCRF-AE

unlabeled), but for the whole input instance and output sequence $(\boldsymbol{x}, \boldsymbol{y})$ ($\boldsymbol{x}$ if unlabeled). Additionally, as our main purpose in this study is to reconstruct the input with precision, $\hat{\boldsymbol{x}}$ is just a copy of $\boldsymbol{x}$.



(a) A generalized autoencoder.

(b) The neural CRF autoencoder model in this work.

Figure 1: On the left is a generalized autoencoder, of which the lower half is the encoder and the upper half is the decoder. On the right is an illustration of the graphical model of our NCRF-AE model. The yellow squares are interactive potentials among labels, and the green squares represent the unary potentials generated by the neural networks.

As shown in Figure 1b, our NCRF-AE model consists of two parts: the encoder (the lower half) is a discriminative CRF model enhanced by deep neural networks as its potential extractors with encoding parameters $\boldsymbol{\Lambda}$, describing the probability of a predicted sequence of labels given the input; the decoder (the upper half) is a generative model with reconstruction parameters $\boldsymbol{\Theta}$, modeling the probability of reconstructing the input given a sequence of labels. Accordingly, we present our model mathematically as follows:

$$\begin{aligned}P_{\boldsymbol{\Theta},\boldsymbol{\Lambda}}(\hat{\boldsymbol{x}}|\boldsymbol{x}) &= \sum_{\boldsymbol{y}} P_{\boldsymbol{\Theta},\boldsymbol{\Lambda}}(\hat{\boldsymbol{x}}, \boldsymbol{y}|\boldsymbol{x}) \\ &= \sum_{\boldsymbol{y}} P_{\boldsymbol{\Theta}}(\hat{\boldsymbol{x}}|\boldsymbol{y}) P_{\boldsymbol{\Lambda}}(\boldsymbol{y}|\boldsymbol{x}),\end{aligned}$$

where $P_{\boldsymbol{\Lambda}}(\boldsymbol{y}|\boldsymbol{x})$ is the probability given by the neural CRF encoder, and $P_{\boldsymbol{\Theta}}(\hat{\boldsymbol{x}}|\boldsymbol{y})$ is the probability produced by the generative decoder.

When making a prediction, the model tries to find the most probable output sequence by performing the following inference procedure using the Viterbi algorithm:

$$\boldsymbol{y}^* = \arg\max_{\boldsymbol{y}} P_{\boldsymbol{\Theta},\boldsymbol{\Lambda}}(\hat{\boldsymbol{x}}, \boldsymbol{y}|\boldsymbol{x}).$$

To clarify, as we focus on POS tagging problems in this study, in the unsupervised setting where the true POS tags are unknown, the labels used for reconstruction are actually the POS tags being induced. The labels induced here are corresponding to the hidden nodes in a generalized autoencoder model.

3.1 Neural CRF Encoder

In a CRF model, the probability of predicted labels $\boldsymbol{y}$, given sequence $\boldsymbol{x}$ as input is modeled as

$$P_{\boldsymbol{\Lambda}}(\boldsymbol{y}|\boldsymbol{x}) = \frac{e^{\Phi(\boldsymbol{x},\boldsymbol{y})}}{Z},$$

where $Z = \sum_{\tilde{\boldsymbol{y}}} e^{\Phi(\boldsymbol{x},\tilde{\boldsymbol{y}})}$ is the partition function that marginalize over all possible assignments to the predicted labels of the sequence, and $\Phi(\boldsymbol{x}, \boldsymbol{y})$ is the scoring function, which is defined as:

$$\Phi(\boldsymbol{x}, \boldsymbol{y}) = \sum_t \phi(\boldsymbol{x}, y_t) + \psi(y_{t-1}, y_t).$$

The partition function Z can be computed efficiently via the forward-backward algorithm. The term $\phi(\boldsymbol{x}, y_t)$ corresponds to the score of a particular tag y_t at position t in the sequence, and $\psi(y_{t-1}, y_t)$ represents the score of transition from the tag at position $t-1$ to the tag at position t. In our NCRF-AE model, $\phi(\boldsymbol{x}, y_t)$ is described by deep neural networks while $\psi(y_{t-1}, y_t)$ by a transition matrix. Such a structure allows for the use of distributed representations of the input, for instance, the word embeddings on a continuous vector space (Mikolov et al., 2013).

Typically in our work, $\phi(\boldsymbol{x}, y_t)$ is modeled jointly by a multi-layer perceptron (MLP) that utilizes the word-level information, and a bi-directional long-short term memory (LSTM) neural network (Hochreiter and Urgen Schmidhuber, 1997) that captures the character level information within each word. A bi-directional structure can extract character level information from both directions, with which we expect to catch the prefix and suffix information of words in an end-to-end system, rather than using hand-engineered features. The bi-directional LSTM neural network consumes character embeddings $\boldsymbol{e}_c \in \mathbb{R}^{k_1}$ as input, where k_1 is the dimensionality of the character embeddings. A normal LSTM can be denoted as:

$$\begin{aligned}
\boldsymbol{i}_t &= \sigma(\boldsymbol{W}_{ei}\boldsymbol{e}_{c_t} + \boldsymbol{W}_{hi}\boldsymbol{h}_{t-1} + \boldsymbol{b}_i),\\
\boldsymbol{f}_t &= \sigma(\boldsymbol{W}_{ef}\boldsymbol{e}_{c_t} + \boldsymbol{W}_{hf}\boldsymbol{h}_{t-1} + \boldsymbol{b}_f),\\
\boldsymbol{o}_t &= \sigma(\boldsymbol{W}_{eo}\boldsymbol{e}_{c_t} + \boldsymbol{W}_{ho}\boldsymbol{h}_{t-1} + \boldsymbol{b}_o),\\
\boldsymbol{g}_t &= Relu(\boldsymbol{W}_{ec}\boldsymbol{e}_{c_t} + \boldsymbol{W}_{hc}\boldsymbol{h}_{t-1} + \boldsymbol{b}_c),\\
\boldsymbol{c}_t &= \boldsymbol{f}_t \odot \boldsymbol{c}_{t-1} + \boldsymbol{i}_t \odot \boldsymbol{g}_t,\\
\boldsymbol{h}_t &= \boldsymbol{o}_t \odot tanh(\boldsymbol{c}_t),
\end{aligned}$$

where $\odot$ denotes element-wise multiplication. Then a bi-directional LSTM neural network extends it as follows, by denoting the procedure of generating $\boldsymbol{h}_t$ as $\mathcal{H}$:

$$\begin{aligned}
\overrightarrow{\boldsymbol{h}}_t &= \mathcal{H}(\boldsymbol{W}_{e\overrightarrow{h}}\boldsymbol{e}_{c_t} + \boldsymbol{W}_{\overrightarrow{h}\overrightarrow{h}}\overrightarrow{\boldsymbol{h}}_{t-1} + \boldsymbol{b}_{\overrightarrow{h}}),\\
\overleftarrow{\boldsymbol{h}}_t &= \mathcal{H}(\boldsymbol{W}_{e\overleftarrow{h}}\boldsymbol{e}_{c_t} + \boldsymbol{W}_{\overleftarrow{h}\overleftarrow{h}}\overleftarrow{\boldsymbol{h}}_{t-1} + \boldsymbol{b}_{\overleftarrow{h}}),
\end{aligned}$$

where $\boldsymbol{e}_{c_t}$ here is the character embedding for character c in position t in a word.

The inputs to the MLP are word embeddings $\boldsymbol{e}_v \in \mathbb{R}^{k_2}$ for each word v, where k_2 is the dimensionality of the vector, concatenated with the final representation generated by the bi-directional LSTM over the characters of that word: $\boldsymbol{u} = [\boldsymbol{e}_v; \overrightarrow{\boldsymbol{h}}_v; \overleftarrow{\boldsymbol{h}}_v]$. In order to leverage the capacity of the CRF model, we use a word and its context together to generate the unary potential. More specifically, we adopt a concatenation $\boldsymbol{v}_t = [\boldsymbol{u}_{t-(w-1)/2}; \cdots; \boldsymbol{u}_{t-1}; \boldsymbol{u}_t; \boldsymbol{u}_{t+1}; \cdots; \boldsymbol{u}_{t+(w-1)/2}]$ as the inputs to the MLP model, where t denotes the position in a sequence, and w being an odd number indicates the context size. Further, in order to enhance the generality of our model, we add a dropout layer on the input right before the MLP layer as a regularizer. Notice that different from a normal MLP, the activation function of the last layer is no more a softmax function, but a linear function generates the log-linear part $\phi_t(\boldsymbol{x}, y_t)$ of the CRF model:

$$\begin{aligned}
\boldsymbol{h}_t &= Relu(\boldsymbol{W}\boldsymbol{v}_t + \boldsymbol{b})\\
\phi_t &= \boldsymbol{w}_y^{\intercal}\boldsymbol{h}_t + b_y.
\end{aligned}$$

The transition score $\psi(y_{t-1}, y_t)$ is a single scalar representing the interactive potential. We use a transition matrix $\boldsymbol{\Psi}$ to cover all the transitions between different labels, and $\boldsymbol{\Psi}$ is part of the encoder parameters $\boldsymbol{\Lambda}$.

All the parameters in the neuralized encoder are updated when the loss function is minimized via error back-propagation through all the structures of the neural networks and the transition matrix.

The detailed structure of the neural CRF encoder is demonstrated in Fig 2. Note that the MLP layer is also interchangeable with a recurrent neural network (RNN) layer or LSTM layer. But in our pilot experiments, we found a single MLP structure yields better performance, which we conjecture is due to over-fitting caused by the high complexity of those alternatives.

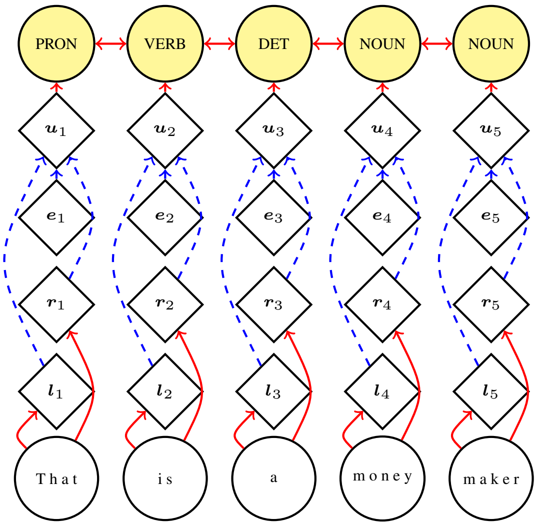


Figure 2: A demonstration of the neural CRF encoder. $\boldsymbol{l}_t$ and $\boldsymbol{r}_t$ are the output of the forward and backward character-level LSTM of the word at position t in a sentence, and $\boldsymbol{e}_t$ is the word-level embedding of that word. $\boldsymbol{u}_t$ is the concatenation of $\boldsymbol{e}_t, \boldsymbol{l}_t$ and $\boldsymbol{r}_t$, denoted by blue dashed arrows.

3.2 Generative Decoder

In our NCRF-AE, we assume the generative process follows several multinomial distributions: each label y has the probability $\theta_{y\to x}$ to reconstruct the corresponding word x, i.e., $P(x|y) = \theta_{y\to x}$. This setting naturally leads to a constraint $\sum_x \theta_{y\to x} = 1$. The number of parameters of the decoder is $|\mathcal{Y}| \times |\mathcal{X}|$. For a whole sequence, the reconstruction probability is $P_{\boldsymbol{\Theta}}(\hat{\boldsymbol{x}}|\boldsymbol{y}) = \prod_t P(\hat{x}_t|y_t)$.

4 A Unified Learning Framework

We first constructed two loss functions for labeled and unlabeled data using the same model. Our model is trained in an on-line fashion: given a labeled or unlabeled sentence, our NCRF-AE optimizes the loss function by choosing the corresponding one. In an analogy to coordinate descent, we optimize the loss function of the NCRF-

AE by alternatively updating the parameters $\mathbf{\Theta}$ in the decoder and the parameters $\mathbf{\Lambda}$ in the encoder. The parameters $\mathbf{\Theta}$ in the decoder are updated via a variation of the Expectation-Maximization (EM) algorithm, and the the parameters $\mathbf{\Lambda}$ in the encoder are updated through a gradient-based method due to the non-convexity of the neuralized CRF. In contrast to the early autoencoder models (Ammar et al., 2014; Lin et al., 2015), our model has two distinctions: First, we have two loss functions to model labeled example and unlabeled examples; Second, we designed a variant of EM algorithm to alternatively learn the parameters of the encoder and the decoder at the same time.

4.1 Unified Loss Functions for Labeled and unlabeled Data

For a sequential input with labels, the complete data likelihood given by our NCRF-AE is

$$\begin{aligned} P_{\mathbf{\Theta},\mathbf{\Lambda}}(\hat{\boldsymbol{x}},\boldsymbol{y}|\boldsymbol{x}) &= P_{\mathbf{\Theta}}(\hat{\boldsymbol{x}}|\boldsymbol{y})P_{\mathbf{\Lambda}}(\boldsymbol{y}|\boldsymbol{x}) \\ &= \left[\prod_t P(\hat{x}_t|y_t)\right]\frac{e^{\Phi(\boldsymbol{x},\boldsymbol{y})}}{Z} \\ &= \frac{e^{\sum_t s_t(\boldsymbol{x},\boldsymbol{y})}}{Z}, \end{aligned}$$

where

$$s_t(\boldsymbol{x},\boldsymbol{y}) = \log P(x_t|y_t) + \phi(\boldsymbol{x},y_t) + \psi(y_{t-1},y_t).$$

If the input sequence is unlabeled, we can simply marginalize over all the possible assignment to labels. The probability is formulated as

$$\begin{aligned} P_{\mathbf{\Theta},\mathbf{\Lambda}}(\hat{\boldsymbol{x}}|\boldsymbol{x}) &= \sum_{\boldsymbol{y}} P(\hat{\boldsymbol{x}},\boldsymbol{y}|\boldsymbol{x}) \\ &= \frac{U}{Z}, \end{aligned}$$

where $U = \sum_{\boldsymbol{y}} e^{\sum_t s_t(\boldsymbol{x},\boldsymbol{y})}$.

Our formulation have two advantages. First, term U is different from but in a similar form as term Z, such that to calculate the probability $P(\hat{\boldsymbol{x}}|\boldsymbol{x})$ for an unlabeled sequence, the forward-backward algorithm to compute the partition function Z can also be applied to compute U efficiently. Second, our NCRF-AE highlights a unified structure of different loss functions for labeled and unlabeled data with shared parameters. Thus during training, our model can address both labeled and unlabeled data well by alternating the loss functions. Using negative log-likelihood as our loss function, if the data is labeled, the loss function is:

$$\begin{aligned} loss_l &= -\log P_{\mathbf{\Theta},\mathbf{\Lambda}}(\hat{\boldsymbol{x}},\boldsymbol{y}|\boldsymbol{x}) \\ &= -(\sum_t s_t(\boldsymbol{x},\boldsymbol{y}) - \log Z) \end{aligned}$$

If the data is unlabeled, the loss function is:

$$\begin{aligned} loss_u &= -\log P_{\mathbf{\Theta},\mathbf{\Lambda}}(\hat{\boldsymbol{x}}|\boldsymbol{x}) \\ &= -(\log U - \log Z). \end{aligned}$$

Thus, during training, based on whether the encountered data is labeled or unlabeled, our model can select the appropriate loss function for learning parameters. In practice, we found for labeled data, using a combination of $loss_l$ and $loss_u$ actually yields better performance.

5 Mixed Expectation-Maximization Algorithm

The Expectation-Maximization (EM) algorithm (Dempster et al., 1977) was applied to a wide range of problems. Generally, it establishes a lower-bound of the objective function by using Jensen's Inequality. It first tries to find the posterior distribution of the latent variables, and then based on the posterior distribution of the latent variables, it maximizes the lower-bound. By alternating expectation (E) and maximization (M) steps, the algorithm iteratively improves the lower-bound of the objective function.

In this section we describe the mixed Expectation-Maximization (EM) algorithm used in our study. Parameterized by the encoding parameters $\mathbf{\Lambda}$ and the reconstruction parameters $\mathbf{\Theta}$, our NCRF-AE consists of the encoder and the decoder, which together forms the log-likelihood a highly non-convex function. However, a careful observation shows that if we fix the encoder, the lower bound derived in the E step, is convex with respect to the reconstruction parameters $\mathbf{\Theta}$ in the M step. Hence, in the M step we can analytically obtain the global optimum of $\mathbf{\Theta}$. In terms of the reconstruction parameters $\mathbf{\Theta}$ by fixing $\mathbf{\Lambda}$, we describe our EM algorithm in iteration t as follows:

In the E-step, we let $Q(\boldsymbol{y}_i) = P(\boldsymbol{y}_i|\boldsymbol{x}_i,\hat{\boldsymbol{x}}_i)$, and treat $\boldsymbol{y_i}$ the latent variable as it is not observable in unlabeled data. We derive the lower-bound of the log-likelihood using $Q(\boldsymbol{y}_i)$:

$$\begin{aligned}\sum_i \log P(\hat{\boldsymbol{x}}_i|\boldsymbol{x}_i) &= \sum_i \log \sum_{\boldsymbol{y}_i} Q(\boldsymbol{y}_i) \frac{P(\hat{\boldsymbol{x}}_i, \boldsymbol{y}_i|\boldsymbol{x}_i)}{Q(\boldsymbol{y}_i)} \\ &\geq \sum_i \sum_{\boldsymbol{y}_i} Q(\boldsymbol{y}_i) \log \frac{P(\hat{\boldsymbol{x}}_i, \boldsymbol{y}_i|\boldsymbol{x}_i)}{Q(\boldsymbol{y}_i)},\end{aligned}$$

where $Q(\boldsymbol{y}_i)$ is computed using parameters $\boldsymbol{\Theta}^{(t-1)}$ in the previous iteration $t-1$.

In the M-step, we try to improve the aforementioned lower-bound using all examples:

$$\begin{aligned}&\arg\max_{\boldsymbol{\Theta}^{(t)}} \sum_i \sum_{\boldsymbol{y}_i} Q(\boldsymbol{y}_i) \log \frac{P_{\boldsymbol{\Theta}^{(t)}}(\hat{\boldsymbol{x}}_i|\boldsymbol{y}_i) P_{\boldsymbol{\Lambda}}(\boldsymbol{y}_i|\boldsymbol{x}_i)}{Q(\boldsymbol{y}_i)} \\ &\arg\max_{\boldsymbol{\Theta}^{(t)}} \sum_i \sum_{\boldsymbol{y}_i} Q(\boldsymbol{y}_i) \log P_{\boldsymbol{\Theta}^{(t)}}(\hat{\boldsymbol{x}}_i|\boldsymbol{y}_i) + const \\ &\arg\max_{\boldsymbol{\Theta}^{(t)}} \sum_{y \to x} \log \theta^{(t)}_{y \to x} \sum_y Q(y) C(y,x) \\ &\arg\max_{\boldsymbol{\Theta}^{(t)}} \sum_{y \to x} \log \theta^{(t)}_{y \to x} \mathrm{E}_{y \sim Q}[C(y,x)] \\ &\qquad s.t. \sum_x \theta^{(t)}_{y \to x} = 1.\end{aligned}$$

In this formulation, *const* is a constant with respect to the parameters we are updating. $Q(y)$ is the distribution of a label y at any position by marginalizing labels at all other positions in a sequence. By denoting $C(y,x)$ as the number of times that (x,y) co-occurs, $\mathrm{E}_{y \sim Q_{\boldsymbol{\Theta}^{(t-1)}}}[C(y,x)]$ is the expected count of a particular reconstruction at any position, which can also be calculated using Baum-Welch algorithm (Welch, 2003), and can be summed over for all examples in the dataset (In the labeled data, it is just a real count). The algorithm we used to calculate the expected count is described in Algorithm 1. Therefore, it can be shown that the aforementioned global optimum can be calculated by simply normalizing the expected counts. In terms of the encoder's parameters $\boldsymbol{\Lambda}$, they are first updated via a gradient-based optimization before each EM iteration. Based on the above discussion, our Mixed EM Algorithm is presented in Algorithm 2.

Algorithm 1 Obtain Expected Count (T_e)

```
Require: the expected count table $T_e$
for an unlabeled data example $\boldsymbol{x}_i$ do
    Compute the forward messages: $\alpha(y,t)$  $\forall y,t$.    ▷ $t$ is the position in a sequence.
    Compute the backward messages: $\beta(y,t)$  $\forall y,t$.
    Calculate the expected count for each $x$ in $\boldsymbol{x}_i$: $P(y_t|x_t) \propto \alpha(y,t) \times \beta(y,t)$.
    $T_e(x_t,y_t) \leftarrow T_e(x_t,y_t) + P(y_t|x_t)$    ▷ $T_e$ is the expected count table.
end for
```

Algorithm 2 Mixed Expectation-Maximization

```
Initialize expected count table $T_e$ using labeled data $\{\boldsymbol{x},\boldsymbol{y}\}^l_i$ and use it as $\boldsymbol{\Theta}^{(0)}$ in the decoder.
Initialize $\boldsymbol{\Lambda}^{(0)}$ in the encoder randomly.
for $t$ in epochs do
    Train the encoder on labeled data $\{\boldsymbol{x},\boldsymbol{y}\}^l$ and unlabeled data $\{\boldsymbol{x}\}^u$ to update $\boldsymbol{\Lambda}^{(t-1)}$ to $\boldsymbol{\Lambda}^{(t)}$.
    Re-initialize expected count table $T_e$ with 0s.
    Use labeled data $\{\boldsymbol{x},\boldsymbol{y}\}^l$ to calculate real counts and update $T_e$.
    Use unlabeled data $\{\boldsymbol{x}\}^u$ to compute the expected counts with parameters $\boldsymbol{\Lambda}^{(t)}$ and $\boldsymbol{\Theta}^{(t-1)}$ and update $T_e$.
    Obtain $\boldsymbol{\Theta}^{(t)}$ globally and analytically based on $T_e$.
end for
```

This mixed EM algorithm is a combination of the gradient-based approach to optimize the encoder by minimizing the negative log-likelihood as the loss function, and the EM approach to update the decoder's parameters by improving the lower-bound of the log-likelihood.

6 Experiments

6.1 Experimental Settings

Dataset We evaluated our model on the POS tagging task, in both the supervised and semi-supervised learning settings, over eight different languages from the UD (Universal Dependencies) 1.4 dataset (Mcdonald et al., 2013). The task is defined over 17 different POS tags, used across the different languages. We followed the original

UD division for training, development and testing in our experiments. The statistics of the data used in our experiments are described in table 1. The UD dataset includes several low-resource languages which are of particular interest to our semi-supervised model.

Input Representation and Neural Architecture Our model uses word embeddings as input. In our pilot experiments, we compared the performance on the English dataset of the pre-trained embedding from Google News (Mikolov et al., 2013) and the embeddings we trained directly on the UD dataset using the skip-gram algorithm (Mikolov et al., 2013). We found these two types of embeddings yield very similar performance on the POS tagging task. So in our experiments, we used embeddings of different languages directly trained on the UD dataset as input to our model, whose dimension is 200. For the MLP neural network layer, the number of hidden nodes in the hidden layer is 20, which is the same for the hidden layer in the character-level LSTM. The dimension of the character-level embeddings sent into the LSTM layer is 15, which is randomly initialized. In order to incorporate the global information of the input sequence, we set the context window size to 3. The dropout rate for the dropout layer is set to 0.5.

Learning We used ADADELTA (Zeiler, 2012) to update parameters $\mathbf{\Lambda}$ in the encoder, as ADADELTA dynamically adapts learning rate over time using only first order information and has minimal computational overhead beyond vanilla stochastic gradient descent (SGD). The authors of ADADELTA also argue this method appears robust to noisy gradient information, different model architecture choices, various data modalities and selection of hyper-parameters. We observed that ADADELTA indeed had faster convergence than vanilla SGD optimization. In our experiments, we include word embeddings and character embeddings as parameters as well. We used Theano to implement our algorithm, and all the experiments were run on NVIDIA GPUs. To prevent over-fitting, we used the "early-stop" strategy to determine the appropriate number of epochs during training. We did not take efforts to tune those hyper-parameters and they remained the same in both our supervised and semi-supervised learning experiments.

6.2 Supervised Learning

In these settings our Neural CRF autoencoder model had access to the full amount of annotated training data in the UD dataset. As described in Section 5, the decoder's parameters $\mathbf{\Theta}$ were estimated using real counts from the labeled data.

We compared our model with existing sequence labeling models including HMM, CRF, LSTM and neural CRF (NCRF) on all the 8 languages. Among these models, the NCRF can be most directly compared to our model, as it is used as the base of our model, but without the decoder (and as a result, can only be used for supervised learning).

The results, summarized in Table 2, show that our NCRF-AE consistently outperformed all other systems, on all the 8 languages, including Russian, Indonesian and Croatian which had considerably less data compared to other languages. Interestingly, the NCRF consistently came second to our model, which demonstrates the efficacy of the expressivity added to our model by the decoder, together with an appropriate optimization approach.

To better understand the performance difference by different models, we performed error analysis, using an illustrative example, described in Figure 3.

In this example, the LSTM incorrectly predicted the POS tag of the word "*search*" as a verb, instead of a noun (part of the NP "*nice search engine*"), while predicting correctly the preceding word, "*nice*", as an adjective. We attribute the error to LSTM lacking an explicit output transition scoring function, which would penalize the ungrammatical transition between "ADJ" and "VERB".

Models	English	French	German	Italian	Russian	Spanish	Indonesian	Croatian

Figure 3: An example from the test set to compare the predicted results of our NCRF-AE model, the NCRF model and the LSTM model.

The NCRF, which does score such transitions, correctly predicted that word. However, it incorrectly predicted "*Google*" as a noun rather than a proper-noun. This is a subtle mistake, as the two are grammatically and semantically similar. This mistake appeared consistently in the NCRF results, while NCRF-AE predictions were correct.

We attribute this success to the superior expressivity of our model: The prediction is done jointly by the encoder and the decoder, as the reconstruction decision is defined over all output sequences, picking the jointly optimal sequence. From another perspective, our NCRF-AE model is a combination of discriminative and generative models, in that sense the decoder can be regarded as a soft constraint that supplements the encoder. Such that, the decoder performs as a regularizer to check-balance the choices made by the encoder.

6.3 Semi-supervised Learning

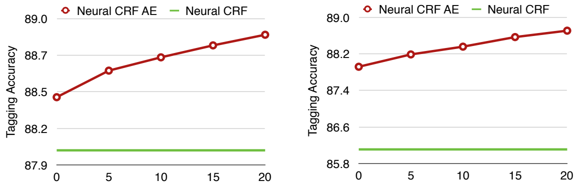
In the semi-supervised settings we compared our models with other semi-supervised structured prediction models. In addition, we studied how varying the amount of unlabeled data would change the performance of our model.

As described in Sec. 5, the decoder's parameters $\boldsymbol{\Theta}$ are initialized by the labeled dataset using real counts and updated in training.

6.3.1 Varying Unlabeled Data Proportion

We first experimented with varying the proportion of unlabeled data, while fixing the amount of labeled data. We conducted these experiments over two languages, English and low-resource language Croatian. We fixed the proportion of labeled data at 20%, and gradually added more unlabeled data from 0% to 20% (from full supervision to semi-supervision). The unlabeled data was sampled from the same dataset (without overlapping with the labeled data), with the labels removed. The results are shown in Figure 4.

The left most point of both sub-figures is the accuracy of fully supervised learning with 20% of the whole data. As we can observe, the tagging accuracy increased as the proportion of unlabeled data increased.



(a) English

(b) Croatian

Figure 4: UD English and Croatian POS tagging accuracy versus increasing proportion of unlabeled sequences using 20% labeled data. The green straight line is the performance of the neural CRF, trained over the labeled data.

6.3.2 Semi-supervised POS Tagging on Multiple Languages

We compared our NCRF-AE model with other semi-supervised learning models, including the HMM-EM algorithm and the hard-EM version of our NCRF-AE. The hard EM version of our model can be considered as a variant of self-training, as it infers the missing labels using the current model in the E-step, and uses the real counts of these labels to update the model in the M-step. To contextualize the results, we also provide the results of the NCRF model and the supervised version our NCRF-AE model trained on 20% of the data. We set the proportion of labeled data to 20% for each language and set the proportion of unlabeled data to 50% of the dataset. There was no overlap between labeled and unlabeled data.

The results are summarized in Table 3. Similar to the supervised experiments, the supervised version of our NCRF-AE, trained over 20% of the labeled data, outperforms the NCRF model. Our model was able to successfully use the unlabeled data, leading to improved performance in all languages, over both the supervised version of our model, as well as the HMM-EM and Hard-EM models that were also trained over both the labeled and unlabeled data.

6.3.3 Varying Sizes of Labeled Data on English

As is known to all, semi-supervised approaches tend to work well when given a small size of labeled training data. But with the increase of labeled training data size, we might get diminishing effectiveness. To verify this conjecture, we conducted additional experiments to show how varying sizes of labeled training data affect the effectiveness of our NCRF-AE model. In these experiments, we gradually increased the proportion of labeled data, and in accordance decreased the proportion of unlabeled data.

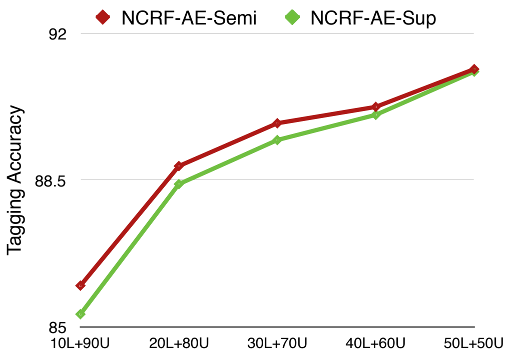


Figure 5: Performance of the NCRF-AE model on different proportion of labeled and unlabeled data. The green line shows the results on only labeled data, and the red line on both labeled and unlabeled data. The difference between the red line and the green line are gradually vanishing.

The results of these experiments are demonstrated in Figure 5. As we speculated, we observed diminishing effectiveness when increasing the proportion of labeled data in training.

7 Conclusion

We proposed an end-to-end neural CRF autoencoder (NCRF-AE) model for semi-supervised sequence labeling. Our NCRF-AE is an integration of a discriminative model and generative model which extends the generalized autoencoder by using a neural CRF model as its encoder and a generative decoder built on top of it. We suggest a variant of the EM algorithm to learn the parameters of our NCRF-AE model.

We evaluated our model in both supervised and semi-supervised scenarios over multiple languages, and show it can outperform other supervised and semi-supervised methods. Additional experiments suggest how varying sizes of labeled training data affect the effectiveness of our model.

These results demonstrate the strength of our model, as it was able to utilize the small amount of labeled data and exploit the hidden information from the large amount of unlabeled data, without additional feature engineering which is often needed in order to get semi-supervised and weakly-supervised systems to perform well. The superior performance on the low resource language also suggests its potential in practical use.

Abstract

We present supertagging-based models for Tree Adjoining Grammar parsing that use neural network architectures and dense vector representation of supertags (elementary trees) to achieve state-of-the-art performance in unlabeled and labeled attachment scores. The shift-reduce parsing model eschews lexical information entirely, and uses only the 1-best supertags to parse a sentence, providing further support for the claim that supertagging is "almost parsing." We demonstrate that the embedding vector representations the parser induces for supertags possess linguistically interpretable structure, supporting analogies between grammatical structures like those familiar from recent work in distributional semantics. This dense representation of supertags overcomes the drawbacks for statistical models of TAG as compared to CCG parsing, raising the possibility that TAG is a viable alternative for NLP tasks that require the assignment of richer structural descriptions to sentences.

1 Introduction

Recent work has applied Combinatory Categorial Grammar (CCG, Steedman and Baldridge (2011)) to the problem of broad-coverage parsing in order to derive grammatical representations that are sufficiently rich to support tasks requiring deeper representation of a sentence's meaning (Lewis et al., 2015; Reddy et al., 2016; Nadejde et al., 2017). Yet CCG is only one of a number of mildly context-sensitive grammar formalisms that can provide such rich representations, and each has distinct advantages. In this paper we explore the applicability of another formalism, Tree Adjoining Grammar (TAG, Joshi and Schabes (1997)), to the task of broad-coverage parsing.

TAG and CCG share the property of lexicalization: words are associated with elementary units of grammatical structure which are composed during a derivation using one of a small set of operations to produce a parse tree. The task of parsing involves the construction of a derivation tree that encodes the application of this set of actions to a set of elementary lexically-associated objects. TAG differs from CCG in having an even richer set of lexical units, so that the identification of these units in a derivation could be even more informative for subsequent tasks involving semantic interpretation, translation and the like, which have been the focus of CCG-based work.

The elementary units of CCG and TAG (categories for CCG, and elementary trees for TAG) determine a word's combinatory potential, in a way that is not the case for the usual part-of-speech tags used in parsing. Indeed, the assignment of elementary objects to the words in a sentence almost determines the possible parse for a sentence. The near uniqueness of a parse given a sequence of lexical units motivated Bangalore and Joshi (1999) to decompose the parsing problem into two phases: *supertagging*, where elementary objects, or supertags, are assigned to each word, and *stapling*, where these supertags are combined together. They claim that given a perfect supertagger, a parse of a sentence follows from syntactic features provided by the supertags, and therefore, supertagging is "almost parsing." This claim has been confirmed in subsequent work: it has been shown that the task of parsing given a gold sequence of supertags can achieve high accuracy (TAG: (Bangalore et al., 2009; Chung et al., 2016), CCG: (Lewis et al., 2016)). However, it has also been revealed that the difficulty of supertagging, because of the large set of possible supertags, re-

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1712–1722
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

sults in inaccuracies that prevent us from effectively utilizing syntactic information provided by the imperfect set of supertags that are assigned. This problem is even more severe for TAG parsing. TAG differs from CCG in having a smaller set of combinatory operations, but a more varied set of elementary objects: the TAG-annotated version of the Penn Treebank that we use (Chen, 2001) includes 4727 distinct supertags (2165 occur once) while the CCG-annotated version (Hockenmaier and Steedman, 2007) includes 1286 distinct supertags (439 occur once). As a result, building a robust, broad-coverage TAG parser has proven difficult.

In this work, we show that robust supertagging-based parsing of TAG is indeed possible by using a dense representation of supertags that is induced using neural networks. In the first half of the paper, we present a neural network supertagger based on a bi-directional LSTM (BLSTM) architecture, inspired by the work of Xu (2015) and Lewis et al. (2016) in CCG, and we make crucial use of synchronized dropout (Gal and Ghahramani, 2016). This supertagger achieves the state-of-the-art accuracy on the WSJ Penn Treebank. When combined with an existing TAG chart parser (Bangalore et al., 2009), the LSTM-based supertagger already yields state-of-the-art unlabeled and labeled attachment scores.

In the second half of the work, we present a shift-reduce parsing model based on a feed-forward neural network that makes use of dense supertag embeddings. Although this approach has much in common with the approach to shift-reduce CCG parsing taken by Zhang and Clark (2011), it differs in its additive structures in supertag embeddings. When a CCG operation combines two supertags (categories), it yields a resulting category that is typically distinct from the two that are combined, and CCG shift-reduce parsers (e.g. Xu (2015)) make use of this result to guide subsequent actions. When the resulting category is the same as some lexical category assignment (for example when function application over $(S\backslash NP)/NP$ NP yields $S\backslash NP$, the same as an intransitive verb), the parser will benefit from sharing statistics across these contexts. For TAG however, substitution or adjoining of one elementary tree into another does not change the nature of the elementary tree into which the operation has taken place. Consequently, the results of partial derivations are not identified with atomic lexical entries, resulting in sparser data. We propose a solution to this problem for TAG by introducing vector representations that are added to the supertag embedding when an operation has been applied to an elementary tree. Not only does this result in a TAG-parser with the best known performance over the WSJ Penn Treebank, but the resulting supertag embeddings turn out to contain linguistically sensible linear structure that we illustrate.

2 TAG Parsing and Dependency Parsing

TAG is a tree-rewriting system, and typically the elementary structures of a TAG are phrase structure trees. Thus, TAG-derived structures are also phrase structure trees. In addition, a TAG derivation also yields a record of the derivational operations (substitutions, adjunctions) used to produce the derived tree. Since these operations are context-free, this record also forms a tree, called the *derivation tree*, whose nodes are the elementary objects and the edges are combinatory operations. If we assume the TAG is lexicalized (i.e., each elementary structure is anchored by at least one terminal symbol), then we can label the nodes of the derivation tree with the tree names and also the anchors of the elementary trees, and we obtain what is *formally* a dependency tree.[1] Since each node is also labeled with an elementary tree from the grammar, we can associate rich linguistic structure with that node, such as passive voice or empty subject.

In addition, it has long been observed that the derivation tree can also be interpreted *linguistically* as a dependency tree (Rambow and Joshi, 1997), if certain assumptions are made about the shape of the elementary trees in the grammar (Frank, 2001). The substitution operation corresponds to the obligatory addition of an argument, and adjunction is used to add adjuncts, as well as function words to a lexical head. The one exception is the treatment of long distance *wh*-movement in TAG. Here, a matrix clause is represented by a *predicative auxiliary tree* which is adjoined into the embedded clause, so that the *wh*-element moved from the embedded clause can still be substituted locally into the tree headed by its verb. As a result, the dependency between the matrix and embedded verbs is inverted relative to the

[1] For the difference between formal and linguistic dependency, see Rambow (2010).

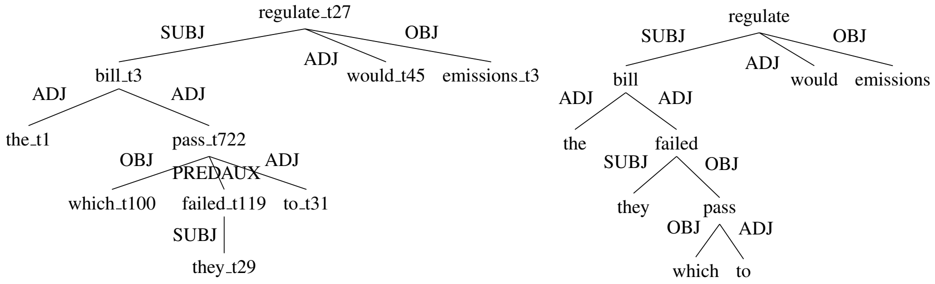

Figure 1: TAG derivation tree (left) and closely related dependency tree (right) for *The bill, which they failed to pass, would regulate emissions*. Substitution edges are labeled SUBJ or OBJ, predicative auxiliary edges are labeled PREDAUX, while all other adjoining edges are labeled ADJ. We use the same edge labels in the dependency tree. The derivation tree also carries the name of the elementary tree used during the derivation, which can be used to look up rich syntactic information about that word in context.

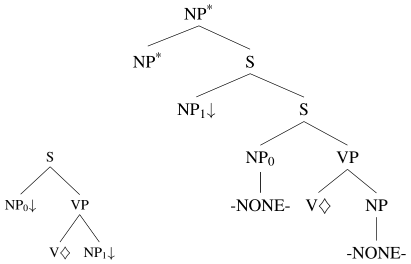

Figure 2: The elementary trees for t27 (left) and t722 (right).

normally assumed dependency. This can be seen in Figure 1, where in the linguistically motivated dependency tree (right) *pass* depends on *failed* as the latter's object, while in the TAG derivation tree (left), *failed* depends on *pass*, linked by an arc marked PREDAUX for predicative auxiliary. These cases can be detected automatically because of the trees used; as a result of this inversion, there is almost no non-projectivity in English. In summary, TAG parsing into derivation trees is very closely related to dependency parsing. In this paper, we are interested in extracting derivation trees, not the derived trees (which can be recovered from the derivation trees).

The corpus we use is obtained by extracting a TAG grammar from the WSJ part of the Penn Treebank corpus, resulting in a grammar and derivation trees labeled with the grammar Chen (2001). For example, in Figure 1, t27 is the basic tree for a transitive verb (*regulate*), while t722 is the tree for a transitive verb which forms an object relative clause with an overt relative pronoun but an empty subject (Figure 2).[2] The corpus and grammar were iteratively refined to obtain linguistically plausible derivation trees which could serve as input for a generation task (Bangalore and Rambow, 2000). As a result, the dependency structure is similar to Universal Dependency (Nivre et al., 2016), apart from the different treatment of long-distance *wh*-movement noted above: the primary dependencies are between the core meaning-bearing lexical words, while function words (auxiliaries, determiners, complementizers) depend on their lexical head and have no dependents.[3] We label verbal argument arcs with deep dependency labels: Subject, Object, and Indirect Object normalized for passive and dative shift. All other arcs are labeled as Adjuncts. This means that our label set is small, but determining the argument labels requires detection of voice alternations and dative shift.

3 TAG Supertagging

3.1 Long-Distance Dependencies and LSTMs

In CCG, a transitive verb is uniformly associated with the category $(S\backslash NP)/NP$, and variation in the word order of a clause is addressed through the use of different combinatory operations. This results in greater parsing ambiguity given a sequence of categories. In TAG, the set of operations is more restricted. While this has the positive effect of reducing parsing ambiguity given a sequence of elementary trees, it necessitates a proliferation in the number of elementary trees. For example, a TAG will associate different elementary trees for the same transitive verb in order to derive canonical clauses, subject and object relatives, and subject and object questions. Not only does this lead to a larger number of supertags, it

[2] Our full grammar is shown at http://mica.lif.univ-mrs.fr/d6.clean2-backup.pdf

[3] One difference should be noted: UD considers prepositions always to be function words, while our TAG grammar treats them as core words unless the Penn Treebank marks them as closely related to the verb.

also means that the determination of the correct supertag requires sensitivity to long-distance dependencies. For example, in the question *Who does Bill think Harry likes?*, the category of the verb *like* requires sensitivity to the first word of the sentence. To address this problem, we make use of a supertagging model that is based on a recurrent network architecture, the Long Short-Term Memory (LSTM, Hochreiter and Schmidhuber (1997)), which is constructed so that its update rule avoids the vanishing/exploding gradient problem.

3.2 Supertagger Model

The model architecture we adopt is depicted in Figure 3, a BLSTM. The input for each word is represented via the concatenation of a 100-dimensional embedding of the word, a 5-dimensional embedding of a predicted part of speech tag, and a 10-dimensional embedding of a suffix vector (which encodes the presence of 1 and 2 character suffixes of the word). We initialize the word embeddings to be the pre-trained GloVe vectors (Pennington et al., 2014); for words which do not have a corresponding GloVe vector, we initialize their embedding to a zero vector. The other embeddings are randomly initialized. Features for each word are fed into the BLSTMs. To produce an output for the network, we concatenate the output vectors from the two LSTM directions and apply an affine transformation before the softmax function to obtain a probability distribution over the 4727 supertags. We train this network, including the embeddings, by optimizing the negative log-likelihood of the observed sequences of supertags in a mini-batch stochastic fashion with the Adam optimization algorithm with $l = 0.001$ (Kingma and Ba, 2015).

Since neural networks have numerous parameters, regularization plays a key role in training. This is typically accomplished by using dropout (Srivastava et al., 2014). Although dropout training has been successful on feed-forward neural networks, performing dropout on recurrent neural networks has been problematic (Gal and Ghahramani, 2016). Armed with a novel interpretation of dropout based on variational inference on parameters, Gal and Ghahramani (2016) propose that dropout noise should be shared across the time steps. We apply this technique to the training of our LSTM network, and achieve an improvement of approximately 2% in accuracy.

4 Transition-based Parsing for TAG

As discussed in Section 2, TAG parsing into derivation trees is closely related to dependency parsing; it is natural to make use of techniques from dependency parsing to reconstruct a TAG derivation tree. We make use of this approach here, eschewing complete chart-based parsing algorithms in favor of greedy or beam-search-based explorations of possible parses.

4.1 Shift-Reduce Parsing Algorithm

We employ the arc-eager system of shift-reduce parsing, familiar from the MALT parser (Nivre et al., 2006). In this system, an oracle is trained to predict a sequence of transition operations from an initial state to a terminal state for each sentence. Each state is represented by $c = (s, b, A)$ where s, b, and A denote the stack, buffer and set of dependency relations derived so far. Therefore, our objective is to predict a transition operation given the configuration set c. The initial configuration is defined as $s = [ROOT]$, $b = [w_1, \cdots w_n]$, and $A = \emptyset$ where n is the number of tokens in the sentence $w_1 w_2 \cdots w_n$. At a particular state, denote the top ith element of the stack and the buffer by s_i and b_i respectively. The arc-eager system defines four types of operations with corresponding preconditions: LEFT-ARC, RIGHT-ARC, SHIFT and REDUCE. For the present parser, the LEFT-ARC and RIGHT-ARC operations are each further divided into seven different types depending on the derivational operation involved and the location: Substitution 0-4, Adjoining, and Co-anchor attachment. Substitution n represents an instance of substitution into an argument slot of an elementary tree that is uniquely annotated with the number n (we discuss the interpretation of such numbers below). Adjoining represents an application of the adjoining operation. It is not further subdivided, as the current parser does not distinguish among different loci of adjoining within an elementary tree. Co-anchor attachment represents the substitution into a node that is construed as a cohead of an elementary tree. An example of this is the insertion of a particle into a verbally headed tree associated with a verb-particle construction, such as the insertion of *up* into the *pick*-headed tree to generate *I picked up the book*. The transitions terminate when the buffer is empty.

This system will fail to capture non-projective TAG derivation structures. However, as noted in Section 2, there is almost no non-projectivity in TAG derivation structures of English. Concretely, we find that WSJ Sections 01-22 contain only 26 non-projective sentences (0.065%), and those sentences are discarded during training. WSJ Section 00 does not have any non-projective sentences.

On the other hand, WSJ Sections 01-22 contain 0.6% of non-projective sentences in dependency grammar (Chen and Manning, 2014), an order of magnitude more than non-projectivity for TAG. This suggests that the problem of TAG parsing is more compatible with standard shift-reduce parsing than dependency grammar parsing is.[4]

4.2 Parser Model

In this work, we use a non-lexicalized parser, which does not have access to the identities of the words of the sentence to be parsed.[5] Instead, the parser's decisions will be guided by the supertags of the top k elements from the stack and the first k elements of the buffer. Using these features as input, we build a two-layer feed-forward network to predict the action for the parser to take. As noted above, the identity of the supertag does not allow the parser to encode whether a particular node in an elementary tree has already been targeted by a substitution operation. In order to overcome this deficiency, we augment the parser's state with *substitution memory*, which encodes for each possible substitution site (from 0 to 4) in a supertag T whether that substitution has already applied in T.

Each supertag is mapped to a d-dimensional vector by an embedding matrix $E \in \mathbb{R}^{d\times(N+2)}$ where N denotes the number of supertags; we also have additional vectors representing the empty state and $ROOT$. Substitution memory is similarly transformed, with a *substitution memory embedding matrix* $M \in \mathbb{R}^{d\times 5}$, to a d-dimensional vector that encodes in a distributed manner where substitution has applied. Each column in M is the vector corresponding to a specific substitution type. Each element from the stack and buffer is then represented by adding the supertag T embedding to the embedding associated with each vector from M corresponding to the substitution operations already performed on T, if any. Mathematically, suppose that we are at the configuration $c = (s, b, A)$, and $p^{(i)} \in \mathbb{R}^5$ denotes the substitution history of s_i. $p^{(i)}$ is an indicator vector that $p^{(i)}_j = 1$ if and only if we have already performed substitution j into s_i in the parser, and 0 otherwise. Define $p^{(k+1)}$ in the same way for b_1.[6] Then, the input vector to the network can be expressed as

$$[Es_1 + Mp^{(1)}; \cdots ; Es_k + Mp^{(k)};\\ Eb_1 + Mp^{(k+1)}; \cdots ; Eb_k]$$

This model with the additive substitution memory has several conceptual advantages. First, the additive structure gives us an unbounded scope of the past transition, avoiding making decisions that lead to substitution collisions without a computationally expensive architecture such as an ensemble of LSTMs (Xu, 2015). Moreover, as TAG supertags encode rich syntactic features, the parsing data for some supertags tend to become scarce. The most common 300 supertags in the Penn Tree Bank WSJ Sections 01-22 cover 96.8% of the data. In a situation of such data sparsity, it becomes crucial to link, for example, the behaviors of intransitive verbs with those of transitive verbs. With substitution memory, the network can develop representations under which addition of appropriate substitution vectors serves to transform

[4] We recognize alternatives to shift-reduce parsing. For instance, Dozat and Manning (2017) propose a graph-based parser that accommodates non-projectivity. It remains open whether such alternatives will work for TAG parsing, and we leave this for the future. We emphasize, however, that because of the nature of TAG derivations, the issue of non-projectivity is much less severe than dependency parsing.

[5] We have tried adding word embeddings as inputs to the parser with different choices of hyperparameters (e.g., the number of embedding dimensions). Unfortunately, our experiments yielded degraded performance. It should be noted, however, that TAG supertags typically provide enough information for deriving correct parses; the only cases that supertags cannot disambiguate are ambiguous attachments to identical nonterminals (e.g. *The picture of my friend with green eyes*).

[6] Notice that no substitution should have happened on $b_2, b_3, \ldots$ by construction.

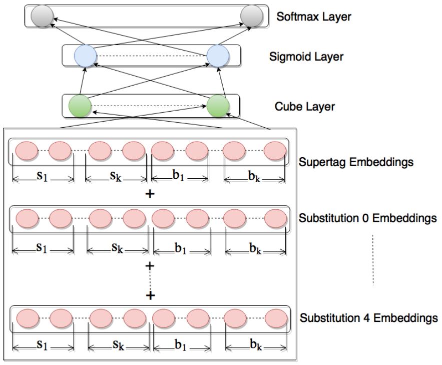

Figure 4: Shift-Reduce Parser Neural Network Architecture.

one supertag into another, allowing the generalization across these contexts. Indeed, as we will show in a later section, the substitution memory embeddings and supertag embeddings turn out to yield interpretable and linguistically sensible structures.

Finally, we concatenate the vectors associated with the relevant elements from the stack and buffer into a $2dk$ dimensional vector and feed it to the network to obtain a probability distribution over the possible transition actions. The architecture is visualized in Figure 4. Following Chen and Manning (2014), we use the cube activation function for the first layer, which could better capture interactions. We, again, optimize the negative log-likelihood in a mini-batch stochastic fashion with the Adam optimization algorithm with $l = 0.001$ (Kingma and Ba, 2015). With regards to decoding, we consider both greedy parsing as well as a beam search algorithm, where we keep transition action hypotheses at each time step, in the experiments we report below.

4.3 Supertag Input to the Parser

We consider three types of supertag inputs to the neural network parser: gold supertags, 1-best supertags from the BLSTM supertagger, and 1-best supertags from the MICA chart parser (Bangalore et al., 2009). MICA searches through n-best supertags with their corresponding probabilities and produces a full parse forest that abides by the TAG grammar. To generate the 1-best supertags from MICA, we first feed 10-best supertags from the BLSTM supertagger to the MICA chart parser, and retain only the supertags of the best parse. These supertags have the special property that there exists a feasible parse in the TAG grammar for every sentence, which does not necessarily hold for the 1-best supertags from the BLSTM supertagger.

5 Experiments

5.1 Experimental Setups

In order to ensure comparability with past work on TAG parsing, we follow the protocol of Bangalore et al. (2009) and Chung et al. (2016), and use the grammar and the TAG-annotated WSJ Penn Tree Bank described in Section 2. Following that work, we use Sections 01-22 as the training set, Section 00 as the development set, and Section 23 as the test set. The training, development, and test sets comprise 39832, 1921, and 2415 sentences, respectively. The development set contains 177 sentences with at least one supertag that was absent from the training set. We implement the networks in TensorFlow (Abadi et al., 2015). During training, we shuffle the order of the sentences in the training set to form mini-batches. Each mini-batch consists of 100 sentences, except the last which contains 32 sentences.

For supertagging, we first generate predicted POS tags for both the training set and the development set. The POS-tagger architecture is similar to that of the supertagger shown in Figure 3, except that, obviously, we do not feed it POS embeddings. The BLSTMs each contain 128 units, and we do not apply dropout at this stage. To derive predicted POS tags for the supertagger training set, we perform 10-fold jackknife training over the training set. For the supertagger, each direction of LSTM computation involves two layers, and each LSTM contains 512 units. The hidden units, layer-to-layer, and input units dropout rates are 0.5, 0.5, and 0.2 respectively. After each training epoch, we test the parser on the development set. When classification accuracy does not improve on two consecutive epochs, we end the training.

For the parser, we initialize the supertag embedding matrix E and the substitution memory embedding matrix M according to $Uniform(-\frac{1}{\sqrt{d}}, \frac{1}{\sqrt{d}})$. For all of the experiments reported here, we fix the hyper-parameters as follows: the embedding dimensions d for the supertag and substitution memory embeddings are 50, the number of units is 200 on both of the two hidden layers, and the input dropout rate is 0.2 and the hidden dropout rate is 0.3. We choose $k = 3$ or 5 for the stack/buffer scope. After each training epoch, we test the parser on the development set, and when the greedy accuracy fails to improving on two consecutive epochs, we terminate the training.

5.2 Supertagging Results

We achieve on Section 00 supertagging accuracy of 89.32%, 90.67% if we disregard the 177 sentences that contain an unseen supertag. This performance surpasses previous results on this task: Bangalore et al. (2009) report 88.52% accuracy using a maxent supertagger combined with a chart parser (MICA), which is the best result over a tag set of this complexity, though better results are reported for considerably smaller tag sets (on the order of 300 supertags). The n-best and β pruning accuracy (Clark and Curran, 2007) are given in Figure 5. In the β pruning scheme, we pick supertags whose probabilities are greater than β times the probability of the most likely supertag. We show the results for $\beta \in [0.075, 0.03, 0.01, 0.005, 0.001, 0.0001]$. It is noteworthy that with $\beta = 0.005$, the average number of supertags picked for each token (ambiguity level) is about 2, but the accuracy surpasses 98%, suggesting that incorporating the β pruning method in the *stapling* phase of TAG parsing will enhance the parser. We also obtain comparable accuracy of 89.44% on Section 23.

As discussed above, TAG supertags alone provide rich syntactic information. In order to understand how much such information our supertagger sucessfully captures, we analyze the 1-best supertag results on the basis of the syntactic properties of the elementary trees defined in Chung et al. (2016). Extending the notion of binary precision and recall, we define the macro-averaging precision and recall as the simple average over precision or recall corresponding to each class (Sokolova and Lapalme, 2009). We also compute accuracy, which is simply the ratio of correctly classified examples to the entire number of examples. Table 1 shows the results along with those for the maxent supertagger (Bangalore et al., 2009). Recall tends to be lower than precision; we can attribute this pattern to the nature of the macro-averaging scheme that equally treats each class regardless of the size; poor recall performance on a small class, such as the class of dative shift verbs, influences the overall recall as much as performance on a large class. Observe, however, that the BLSTM supertagger yields significantly better performance on recall in general, and it outperforms the maxent supertagger by a large margin in handling long dependencies of *wh*-movement and relativization.

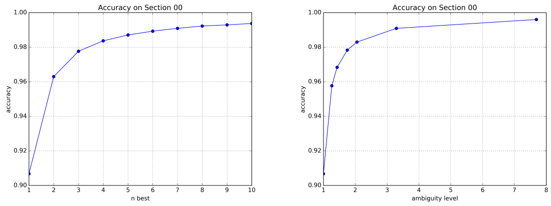

Figure 5: Section 00 n-best accuracy (left), and β pruning accuracy (right). Sentences with unseen supertags are disregarded.

Table 1: 1-best Supertag Analysis on Section 00. # indicates the number of possible classes in a property. The Prec and Rec columns show macro-averaging precision and recall. The Acc columns indicate simple accuracy. For a complete description of the properties, see Chung et al. (2016).

Lastly, we interpret our supertagging performance in the context of prepositional phrase (PP) attachment ambiguity. Normally, in dependency parsing, PP attachment is resolved by the parser. However, in our case, it can be resolved before parsing, during the supertagging step. This is because the supertags for prepositions vary depending on the type of constituent modified by the PP containing the preposition; for example, $t4$ is the supertag for a preposition whose PP modifies an NP, while $t13$ is the supertag for a preposition whose PP modifies a VP.

To test how well our supertagger resolves PP attachment ambiguity, we used the dataset from Ratnaparkhi et al. (1994) (derived from the PTB WSJ) to extract a test set of sentences with PPs that are ambiguous between attaching to a VP or to an NP.[7]

[7] We were unable to use the full test set because, in order to run the supertagger on the test set, we had to map the test examples back to their full sentences, but some of those original sentences are no longer available in PTB3.

We then supertagged these sentences and checked whether the supertag for the preposition in the ambiguous PP is a VP modifier or an NP modifier. Of our test set of 1951 sentences, 1616 had supertags modifying the correct part of speech, to give an accuracy of 0.826. Table 2 compares this result to past work. The supertagger outperforms all other models besides the Word Vector model. Since this Word Vector model (like the MaxEnt model) is specifically trained for this task, and given that our supertagger is not trained for this particular task, the accuracy is reasonably encouraging. This result suggests that TAG supertagging is a reasonable intermediate level between only resolving PP attachment and conducting full parsing.

System	PP Attachment Accuracy
Malt (Nivre et al., 2006)	79.7*
MaxEnt (Ratnaparkhi et al., 1994)	81.6*
Word Vector (Belinkov et al., 2014)	**88.7***
Parsey McParseface (Andor et al., 2016)	82.3
BLSTM Supertagger	82.6

Table 2: Various PP attachment results. * denotes the results on a different dataset.

5.3 Parsing Results

Parsing results and comparison with prior models are summarized in Tables 3, 4 (Section 00), and 5 (Section 23). From Table 4, we see that the combination of the BLSTM supertagger, MICA chart parser, and the neural network parser achieves state-of-the-art performance, even compared to parsers that make use of lexical information, POS tags, and hand-engineered features. With gold supertags, the neural network parser with beam size 16 performs slightly better than the chart parser. As shown in Table 5, our supertag-based parser outperforms SyntaxNet (Andor et al., 2016) with the computationally expensive global normalization. This suggests that, besides providing the grammars and linguistic features that can be used in downstream tasks in addition to derivation trees (Semantic Role Labeling: (Chen and Rambow, 2003), Textual Entailments: (Xu et al., 2017)), supertagging also improves parsing performance.

5.4 Learned Vector Representation

We motivated the use of embeddings in the parser to encode properties of the supertags and the substitution operations performed on them. We can examine their structure in a way similar to what Mikolov et al. (2013) did for word embeddings by performing analogy tests on the learned supertag embeddings. Consider, for example, the analogy that an elementary tree representing a clause headed by a transitive verb (t27) is to a clause headed by an intransitive verb (t81) as a subject relative clause headed by a transitive verb (t99) is to a subject relative headed by an intransitive verb (t109). Following Mikolov et al. (2013), we can express this analogy with the equation $t27 - t81 \approx t99 - t109$, which can be rearranged as $t27 - t81 + t109 \approx t99$. By seeing if this approximate equality holds when the embeddings of the relevant supertags have been added and subtracted, we can test how well the embeddings capture syntactic properties of the supertags.

To create a set of such analogies, we extracted all pairs (stag1, stag2) such that stag2 is the result of excising exactly one substitution node from stag1. The idea here is that, once a substitution node is filled within a supertag, the result behaves like a supertag without that substitution node; for example, a transitive verb with its object filled behaves like an intransitive verb. We then create analogies by choosing two such pairs, (stag1, stag2) and (stag3, stag4), chosen so that stag1 and stag2 are related in the same way that stag3 and stag4 are related. From these two pairs we then form an equation of the form $\mathrm{stag1} - \mathrm{stag2} + \mathrm{stag4} \approx \mathrm{stag3}$.

We considered three different criteria for choosing which pairs of pairs can form analogies: **A-1**, where both pairs must have the same deep syntactic role (Drole) for the excised substitution node; **A-2**, where both pairs must have the same Drole and POS for the excised substitution node; and **A-3**, where both pairs must have the same Drole and same POS for the excised substitution node, and the heads of all supertags in the analogy must have the same POS. For each analogy generated, we computed the left hand side by adding and subtracting the relevant supertag embeddings and used cosine similarity to determine the most similar embeddings to the result and whether the intended right hand side was among the closest neighbors. We used four metrics for evaluation: *Acc*, the proportion of analogies for which the closest neighbor was the correct supertag; *Acc-300*, the proportion of analogies for which the closest neighbor amongst the 300 most common supertags was the correct supertag; *Avg Rank*, the average position of the correct choice in the ranked list of the closest neighbors; and *Avg Rank-300*,

Table 6: Analogy Task Results.

the average position of the correct choice in the ranked list of the closest neighbors amongst the 300 most common supertags.

We expect that the embeddings for common supertags would be better representations than embeddings for rare supertags. Thus, we restricted our experiment to analogies between supertags among the 300 most common ones in the training set. (Indeed, experiments that included rare supertags in the analogies produced poor results.)

Table 6 provides the results for the 3 types of analogies, which are very promising, particularly type A-3. We can visualize these results by performing PCA on the embedding vectors. Figure 6a shows the first 2 PCA components of A-3 analogies involving supertags containing transitive and intransitive predicates across a variety of structures. We see that virtually all pairs differ from one another by a similar vector, and in fact this difference is essentially the vector associated with substitution 1 in the substitution embedding memory (shown in blue). Figure 6b shows the case of pairs of canonical sentence elementary trees (*read* in *I read the book*) and their subject relative analogs (*read* in *the guy who read the book*). This again shows a systematic mapping between grammatically related embeddings, suggesting that the embeddings encode relevant structural properties.

6 Conclusions and Future Work

We presented a state-of-the-art TAG supertagger and parser, the former based on a BLSTM architecture, and the latter on a non-lexicalized shift-reduce parser using a feed-forward network. The parser makes crucial use of supertag embeddings that provide linguistically interpretable vector representations of the supertags. These positive results suggest that TAG can provide the foundation of NLP systems for tasks requiring deeper analysis than current dependency parsers provide, and we will apply our parser to such tasks in the future. Nonetheless, a large discrepancy remains in parser performance with gold supertags and predicted supertags, indicating that supertagging is still a bottleneck. We will explore ways to leverage our supertagger's high β-pruning accuracy in parsing.

Global Normalization of Convolutional Neural Networks for Joint Entity and Relation Classification

Heike Adel and **Hinrich Schütze**

LMU Munich, Germany
heike@cis.lmu.de

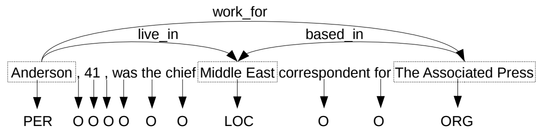
Abstract

We introduce globally normalized convolutional neural networks for joint entity classification and relation extraction. In particular, we propose a way to utilize a linear-chain conditional random field output layer for predicting entity types and relations between entities at the same time. Our experiments show that global normalization outperforms a locally normalized softmax layer on a benchmark dataset.

1 Introduction

Named entity classification (EC) and relation extraction (RE) are important topics in natural language processing. They are relevant, e.g., for populating knowledge bases or answering questions from text, such as "Where does X live?"

Most approaches consider the two tasks independent from each other or treat them as a sequential pipeline by first applying a named entity recognition tool and then classifying relations between entity pairs. However, named entity types and relations are often mutually dependent. If the types of entities are known, the search space of possible relations between them can be reduced and vice versa. This can help, for example, to resolve ambiguities, such as in the case of "Mercedes", which can be a person, organization and location. However, knowing that in the given context, it is the second argument for the relation "live_in" helps concluding that it is a location. Therefore, we propose a single neural network (NN) for both tasks. In contrast to joint training and multitask learning, which calculate task-wise costs, we propose to learn a *joint classification layer* which is *globally normalized* on the outputs of both tasks. In particular, we train the NN parameters based on the loss of a linear-chain conditional random field (CRF) (Lafferty et al., 2001). CRF layers for NNs have been introduced for token-labeling tasks like named entity recognition (NER) or part-of-speech tagging (Collobert et al., 2011; Lample et al., 2016; Andor et al., 2016). Instead of labeling each input token as in previous work, we model the joint entity and relation classification problem as a sequence of length three for the CRF layer. In particular, we identify the types of two candidate entities (words or short phrases) given a sentence (we call this entity classification to distinguish it from the token-labeling task NER) as well as the relation between them. To the best of our knowledge, this architecture for combining entity and relation classification in a single neural network is novel. Figure 1 shows an example of how we model the task: For each sentence, candidate entities are identified. Every possible combination of candidate entities (query entity pair) then forms the input to our model which predicts the classes for the two query entities as well as for the relation between them.



Model inputs (query entity pairs) ⇒ Model outputs:
("Anderson", ",") ⇒ PER - N - O
("Anderson", "41") ⇒ PER - N - O
...
("Anderson", "chief") ⇒ PER - N - O
("Anderson", "Middle East") ⇒ PER - live_in - LOC
...
("was", "for") ⇒ O - N - O
...
("for", "The Associated Press") ⇒ O - N - ORG

Figure 1: Examples of our task

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1723–1729

To sum up, our contributions are as follows: We introduce globally normalized convolutional neural networks for a sentence classification task. In particular, we present an architecture which allows us to model joint entity and relation classification with a single neural network and classify entities and relations at the same time, normalizing their scores globally. Our experiments confirm that a CNN with a CRF output layer outperforms a CNN with locally normalized softmax layers. Our source code is available at `http://cistern.cis.lmu.de`.

2 Related Work

Some work on joint entity and relation classification uses distant supervision for building their own datasets, e.g., (Yao et al., 2010; Yaghoobzadeh et al., 2016). Other studies, which are described in more detail in the following, use the "entity and relation recognition" (ERR) dataset from (Roth and Yih, 2004, 2007) as we do in this paper. Roth and Yih (2004) develop constraints and use linear programming to globally normalize entity types and relations. Giuliano et al. (2007) use entity type information for relation extraction but do not train both tasks jointly. Kate and Mooney (2010) train task-specific support vector machines and develop a card-pyramid parsing algorithm to jointly model both tasks. Miwa and Sasaki (2014) use the same dataset but model the tasks as a table filling problem (see Section 4.2). Their model uses both a local and a global scoring function. Recently, Gupta et al. (2016) apply recurrent neural networks to fill the table. They train them in a multitask fashion. Previous work also uses a variety of linguistic features, such as part-of-speech tags. In contrast, we use convolutional neural networks and only word embeddings as input. Furthermore, we are the first to adopt global normalization of neural networks for this task.

Several studies propose different variants of non-neural CRF models for information extraction tasks but model them as token-labeling problems (Sutton and McCallum, 2006; Sarawagi et al., 2004; Culotta et al., 2006; Zhu et al., 2005; Peng and McCallum, 2006). In contrast, we propose a simpler linear-chain CRF model which directly connects entity and relation classes instead of assigning a label to each token of the input sequence. This is more similar to the factor graph by Yao et al. (2010) but computationally simpler. Xu and Sarikaya (2013) also apply a CRF layer on top of continuous representations obtained by a CNN. However, they use it for a token labeling task (semantic slot filling) while we apply the model to a sentence classification task, motivated by the fact that a CNN creates single representations for whole phrases or sentences.

3 Model

3.1 Modeling Context and Entities

Figure 2 illustrates our model.

Input. Given an input sentence and two query entities, our model identifies the *types of the entities* and the *relation* between them; see Figure 1. The input tokens are represented by word embeddings trained on Wikipedia with word2vec (Mikolov et al., 2013). For identifying the class of an entity e_k, the model uses the context to its left, the words constituting e_k and the context to its right. For classifying the relation between two entities e_i and e_j, the sentence is split into six parts: left of e_i, e_i, right of e_i, left of e_j, e_j, right of e_j.[1] For the example sentence in Figure 1 and the entity pair ("Anderson", "chief"), the context split is: [] [Anderson] [, 41 , was the chief Middle ...] [Anderson , 41 , was the] [chief] [Middle East correspondent for ...]

Sentence Representation. For representing the different parts of the input sentence, we use convolutional neural networks (CNNs). CNNs are suitable for RE since a relation is usually expressed by the semantics of a whole phrase or sentence. Moreover, they have proven effective for RE in previous work (Vu et al., 2016). We train one CNN layer for convolving the entities and one for the contexts. Using two CNN layers instead of one gives our model more flexibility. Since entities are usually shorter than contexts, the filter width for entities can be smaller than for contexts. Furthermore, this architecture simplifies changing the entity representation from words to characters in future work.

After convolution, we apply k-max pooling for both the entities and the contexts and concatenate the results. The concatenated vector $c_z \in \mathbb{R}^{C_z}$, $z \in \{EC, RE\}$ is forwarded to a task-specific hidden layer of size H_z which learns patterns across the different input parts:

$$h_z = \tanh(V_z^T c_z + b_z) \qquad (1)$$

[1] The ERR dataset we use provides boundaries for entities to concentrate on the classification task (Roth and Yih, 2004).

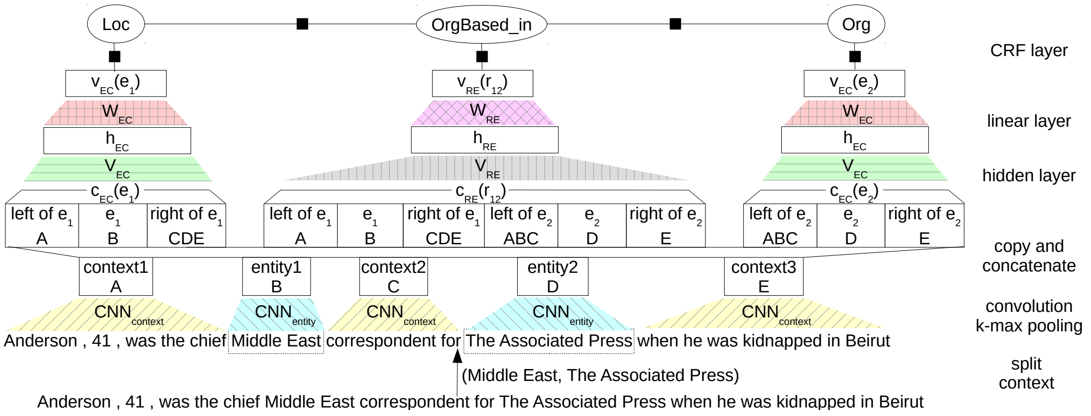

Figure 2: Model overview; the colors/shades show which model parts share parameters

with weights $V_z \in \mathbb{R}^{C_z \times H_z}$ and bias $b_z \in \mathbb{R}^{H_z}$.

3.2 Global Normalization Layer

For global normalization, we adopt the linear-chain CRF layer by Lampple et al. (2016).[2] It expects scores for the different classes as input. Therefore, we apply a linear layer first which maps the representations $h_z \in \mathbb{R}^{H_z}$ to a vector v_z of the size of the output classes $N = N_{EC} + N_{RE}$:

$$v_z = W_z^T h_z \tag{2}$$

with $W_z \in \mathbb{R}^{H_z \times N}$. For a sentence classification task, the input sequence for the CRF layer is not inherentely clear. Therefore, we propose to model the joint entity and relation classification problem with the following sequence of scores (cf., Figure 2):

$$d = [v_{EC}(e_1), v_{RE}(r_{12}), v_{EC}(e_2)] \tag{3}$$

with r_{ij} being the relation between e_i und e_j. Thus, we approximate the joint probability of entity types T_{e_1}, T_{e_2} and relations $R_{e_1 e_2}$ as follows:

$$\begin{aligned} &P(T_{e_1} R_{e_1 e_2} T_{e_2}) \\ \approx &P(T_{e_1}) \cdot P(R_{e_1 e_2} | T_{e_1}) \cdot P(T_{e_2} | R_{e_1 e_2}) \end{aligned} \tag{4}$$

Our intuition is that the dependence between relation and entities is stronger than the dependence between the two entities.

The CRF layer pads its input of length $n = 3$ with begin and end tags and computes the following score for a sequence of predictions y:

$$s(y) = \sum_{i=0}^{n} Q_{y_i y_{i+1}} + \sum_{i=1}^{n} d_{i,y_i} \tag{5}$$

with $Q_{k,l}$ being the transition score from class k to class l and $d_{p,q}$ being the score of class q at position p in the sequence. The scores are summed because all the variables of the CRF layer live in the log space. The matrix of transition scores $Q \in \mathbb{R}^{(n+2)\times(n+2)}$ is learned during training.[3] For training, the forward algorithm computes the scores for all possible label sequences Y to get the log-probability of the correct label sequence $\hat{y}$:

$$log(p(\hat{y})) = \frac{e^{s(\hat{y})}}{\sum_{\tilde{y} \in Y} e^{s(\tilde{y})}} \tag{6}$$

For testing, Viterbi is applied to obtain the label sequence y^* with the maximum score:

$$y^* = \arg\max_{\tilde{y} \in Y} s(\tilde{y}) \tag{7}$$

4 Experiments and Analysis

4.1 Data and Evaluation Measure

We use the "entity and relation recognition" (ERR) dataset from (Roth and Yih, 2004)[4] with the train-test split by Gupta et al. (2016). We tune the parameters on a held-out part of train. The data is labeled with entity types and relations (see Table 1). For entity pairs without a relation, we use the label N. Dataset statistics and model parameters are provided in the appendix.

Following previous work, we compute F_1 of the individual classes for EC and RE, as well as a task-wise macro F_1 score. We also report the average of scores across tasks (Avg EC+RE).

Figure 3: Entity-relation table

4.2 Experimental Setups

Setup 1: Entity Pair Relations. Roth and Yih (2004, 2007); Kate and Mooney (2010) train separate models for EC and RE on the ERR dataset. For RE, they only identify relations between named entity pairs. In this setup, the query entities for our model are only named entity pairs. Note that this facilitates EC in our experiments.

Setup 2: Table Filling. Following Miwa and Sasaki (2014); Gupta et al. (2016), we also model the joint task of EC and RE as a table filling task. For a sentence with length m, we create a quadratic table. Cell (i, j) contains the relation between word i and word j (or N for no relation). A diagonal cell (k, k) contains the entity type of word k. Following previous work, we only predict classes for half of the table, i.e. for $m(m + 1)/2$ cells. Figure 3 shows the table for the example sentence from Figure 1. In this setup, each cell (i, j) with $i \neq j$ is a separate input query to our model. Our model outputs a prediction for cell (i, j) (the relation between i and j) and predictions for cells (i, i) and (j, j) (the types of i and j). To fill the diagonal with entity classes, we aggregate all predictions for the particular entity by using majority vote. Section 4.4 shows that the individual predictions agree with the majority vote in almost all cases.

Setup 3: Table Filling Without Entity Boundaries. The table from setup 2 includes one row/column per multi-token entity, utilizing the given entity boundaries of the ERR dataset. In order to investigate the impact of the entity boundaries on the classification results, we also consider another table filling setup where we ignore the boundaries and assign one row/column per token. Note that this setup is also used by prior work on table filling (Miwa and Sasaki, 2014; Gupta et al., 2016). For evaluation, we follow Gupta et al. (2016) and score a multi-token entity as correct if at least one of its comprising cells has been classified correctly.

Comparison. The most important difference between setup 1 and setup 2 is the number of entity pairs with no relation (test set: ≈3k for setup 1, ≈121k for setup 2). This makes setup 2 more challenging. The same holds for setup 3 which considers the same number of entity pairs with no relation as setup 2. To cope with this, we randomly subsample negative instances in the train set of setup 2 and 3. Setup 3 considers the most query entity pairs in total since multi-token entities are split into their comprising tokens. However, setup 3 represents a more realistic scenario than setup 1 or setup 2 because in most cases, entity boundaries are not given. In order to apply setup 1 or 2 to another dataset without entity boundaries, a preprocessing step, such as entity boundary recognition or chunking would be required.

4.3 Experimental Results

Table 1 shows the results of our globally normalized model in comparison to the same model with locally normalized softmax output layers (one for EC and one for RE). For setup 1, the CRF layer performs comparable or better than the softmax layer. For setup 2 and 3, the improvements are more apparent. We assume that the model can benefit more from global normalization in the case of table filling because it is the more challenging setup. The comparison between setup 2 and setup 3 shows that the entity classification suffers from not given entity boundaries (in setup 3). A reason could be that the model cannot convolve the token embeddings of the multi-token entities anymore when computing the entity representation (context B and D in Figure 2). Nevertheless, the relation classification performance is comparable in setup 2 and setup 3. This shows that the model can internally account for potentially wrong entity classification results due to missing entity boundaries.

The overall results (Avg EC+RE) of the CRF are better than the results of the softmax layer for all three setups. To sum up, the improvements of the linear-chain CRF show that (i) joint EC and RE benefits from global normalization and (ii) our way of creating the input sequence for the CRF for joint EC and RE is effective.

Comparison to State of the Art. Table 2 shows our results in the context of state-of-the-art results: (Roth and Yih, 2007), (Kate and Mooney, 2010),

Table 2: Comparison to state of the art (S: setup)

(Miwa and Sasaki, 2014), (Gupta et al., 2016).[5] Note that the results are not comparable because of the different setups and different train-test splits.[6]

Our results are best comparable with (Gupta et al., 2016) since we use the same setup and train-test splits. However, their model is more complicated with a lot of hand-crafted features and various iterations of modeling dependencies among entity and relation classes. In contrast, we only use pre-trained word embeddings and train our model end-to-end with only one iteration per entity pair. When we compare with their model without additional features (G et al. 2016 (2)), our model performs worse for EC but better for RE and comparable for Avg EC+RE.

4.4 Analysis of Entity Type Aggregation

As described in Section 4.2, we aggregate the EC results by majority vote. Now, we analyze their disagreement. For our best model, there are only 9 entities (0.12%) with disagreement in the test data. For those, the max, min and median disagreement with the majority label is 36%, 2%, and 8%, resp. Thus, the disagreement is negligibly small.

Figure 4: Most strongly correlated entity types and relations according to CRF transition matrix

4.5 Analysis of CRF Transition Matrix

To analyze the CRF layer, we extract which transitions have scores above 0.5. Figure 4 shows that the layer has learned correct correlations between entity types and relations.

5 Conclusion and Future Work

In this paper, we presented the first study on global normalization of neural networks for a sentence classification task without transforming it into a token-labeling problem. We trained a convolutional neural network with a linear-chain conditional random field output layer on joint entity and relation classification and showed that it outperformed using a locally normalized softmax layer.

An interesting future direction is the extension of the linear-chain CRF to jointly normalize all predictions for table filling in a single model pass. Furthermore, we plan to verify our results on other datasets in future work.

Acknowledgments

Heike Adel is a recipient of the Google European Doctoral Fellowship in Natural Language Processing and this research is supported by this fellowship. This work was also supported by DFG (SCHU 2246/4-2).

[5] We only show results of single models, no ensembles. Following previous studies, we omit the entity class "Other" when computing the EC score.

[6] Our results on EC in setup 1 are also not comparable since we only input named entities into our model.

2	CRF	500	100	200	50
3	CRF	500	100	100	50

Table 4: Hyperparameter optimization results

Table 4 provides the hyperparameters we optimized on dev (nk_C: number of convolutional filters for the CNN convolving the contexts, nk_E: number of convolutional filters for the CNN convolving the entities; h_C: number of hidden units for creating the final context representation, h_E: number of hidden units for creating the final entity representation).

For all models, we use a filter width of 3 for the context CNN and a filter width of 2 for the entity CNN (tuned in prior experiments and fixed for the optimization of the parameters in Table 4).

For training, we apply gradient descent with a batch size of 10 and an initial learning rate of 0.1. When the performance on dev decreases, we halve the learning rate. The model is trained with early stopping on dev, with a maximum number of 20 epochs. We apply L2 regularization with $\lambda = 10^{-3}$.

End-to-End Neural Relation Extraction with Global Optimization

Abstract

Neural networks have shown promising results for relation extraction. State-of-the-art models cast the task as an end-to-end problem, solved incrementally using a local classifier. Yet previous work using statistical models have demonstrated that global optimization can achieve better performances compared to local classification. We build a globally optimized neural model for end-to-end relation extraction, proposing novel LSTM features in order to better learn context representations. In addition, we present a novel method to integrate syntactic information to facilitate global learning, yet requiring little background on syntactic grammars thus being easy to extend. Experimental results show that our proposed model is highly effective, achieving the best performances on two standard benchmarks.

1 Introduction

Extracting entities (Florian et al., 2006, 2010) and relations (Zhao and Grishman, 2005; Jiang and Zhai, 2007; Sun et al., 2011; Plank and Moschitti, 2013) from unstructured texts have been two central tasks in information extraction (Grishman, 1997; Doddington et al., 2004). Traditional approaches to relation extraction take entity recognition as a predecessor step in a pipeline (Zelenko et al., 2003; Chan and Roth, 2011), predicting relations between given entities.

In recent years, there has been a surge of interest in performing end-to-end relation extraction, jointly recognizing entities and relations given free text inputs (Li and Ji, 2014; Miwa and Sasaki, 2014; Miwa and Bansal, 2016; Gupta et al., 2016). End-to-end learning prevents error propagation in the pipeline approach, and allows cross-task dependencies to be modeled explicitly for entity recognition. As a result, it gives better relation extraction accuracies compared to pipelines.

Miwa and Bansal (2016) were among the first to use neural networks for end-to-end relation extraction, showing highly promising results. In particular, they used bidirectional LSTM (Graves et al., 2013) to learn hidden word representations under a sentential context, and further leveraged tree-structured LSTM (Tai et al., 2015) to encode syntactic information, given the output of a parser. The resulting representations are then used for making local decisions for entity and relation extraction incrementally, leading to much improved results compared with the best statistical model (Li and Ji, 2014). This demonstrates the strength of neural representation learning for end-to-end relation extraction.

On the other hand, Miwa and Bansal (2016)'s model is trained locally, without considering structural correspondences between incremental decisions. This is unlike existing statistical methods, which utilize well-studied structured prediction methods to address the problem (Li and Ji, 2014; Miwa and Sasaki, 2014). As has been commonly understood, learning local decisions for structured prediction can lead to label bias (Lafferty et al., 2001), which prevents globally optimal structures from receiving optimal scores by the model. We address this potential issue by building a structural neural model for end-to-end relation extraction, following a recent line of efforts on globally optimized models for neural structured prediction (Zhou et al., 2015; Watanabe and Sumita, 2015; Andor et al., 2016; Wiseman and Rush, 2016).

In particular, we follow Miwa and Sasaki (2014), casting the task as an end-to-end table-filling problem. This is different from the action-based method of Li and Ji (2014), yet has shown to

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1730–1740
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

be more flexible and accurate (Miwa and Sasaki, 2014). We take a different approach to representation learning, addressing two potential limitations of Miwa and Bansal (2016).

First, Miwa and Bansal (2016) rely on external syntactic parsers for obtaining syntactic information, which is crucial for relation extraction (Culotta and Sorensen, 2004; Zhou et al., 2005; Bunescu and Mooney, 2005; Qian et al., 2008). However, parsing errors can lead to encoding inaccuracies of tree-LSTMs, thereby hurting relation extraction potentially. We take an alternative approach to integrating syntactic information, by taking the hidden LSTM layers of a bi-affine attention parser (Dozat and Manning, 2016) to augment input representations. Pretrained for parsing, such hidden layers contain rich syntactic information on each word, yet do not explicitly represent parsing decisions, thereby avoiding potential issues caused by incorrect parses.

Our method is also free from a particular syntactic formalism, such as dependency grammar, constituent grammar or combinatory categorial grammar, requiring only hidden representations on word that contain syntactic information. In contrast, the method of Miwa and Bansal (2016) must consider tree LSTM formulations that are specific to grammar formalisms, which can be structurally different (Tai et al., 2015).

Second, Miwa and Bansal (2016) did not explicitly learn the representation of segments when predicting entity boundaries or making relation classification decisions, which can be intuitively highly useful, and has been investigated in several studies (Wang and Chang, 2016; Zhang et al., 2016). We take the LSTM-Minus method of Wang and Chang (2016), modelling a segment as the difference between its last and first LSTM hidden vectors. This method is highly efficient, yet gives as accurate results as compared to more complex neural network structures to model a span of words (Cross and Huang, 2016).

Evaluation on two benchmark datasets shows that our method outperforms previous methods of Miwa and Bansal (2016), Li and Ji (2014) and Miwa and Sasaki (2014), giving the best reported results on both benchmarks. Detailed analysis shows that our integration of syntactic features is as effective as traditional approaches based on discrete parser outputs. We make our code publicly available under Apache License 2.0.[1]

2 Model

2.1 Task Definition

As shown in Figure 1, the goal of relation extraction is to mine relations from raw texts. It consists of two sub-tasks, namely entity detection, which recognizes valid entities, and relation classification, which determines the relation categories over entity pairs. We follow recent studies and recognize entities and relations as one single task.

2.2 Method

We follow Miwa and Sasaki (2014) and Gupta et al. (2016), treating relation extraction as a table-filling problem, performing entity detection and relation classification using a single incremental model, which is similar in spirit to Miwa and Bansal (2016) by performing the task end-to-end.

Formally, given a sentence $w_1 w_2 \cdots w_n$, we maintain a table $T^{n \times n}$, where $T(i,j)$ denotes the relation between w_i and w_j. When $i = j$, $T(i,j)$ denotes an entity boundary label. We map entity words into labels under the BILOU (Begin, Inside, Last, Outside, Unit) scheme, assuming that there are no overlapping entities in one sentence (Li and Ji, 2014; Miwa and Sasaki, 2014; Miwa and Bansal, 2016). Only the upper triangular table is necessary for indicating the relations.

We adopt the close-first left-to-right order (Miwa and Sasaki, 2014) to map the two-dimensional table into a sequence, in order to fill the table incrementally. As shown in Figure 2, first $\{T(i,i)\}$ are filled by growing i, and then the sequence $\{T(i,i+1)\}$ is filled, and then $\{T(i,i+2)\}, \cdots, \{T(i,i+n)\}$ are filled incrementally, until the table is fully annotated.

During the table-filling process, we take two label sets for entity detection ($i = j$) and relation

classification ($i < j$), respectively. The labels for entity detection include {B-*, I-*, L-*, O, U-* }, where * denotes the entity type, and the labels for relation classification are $\{\overrightarrow{*}, \overleftarrow{*}, \perp\}$, where * denotes the relation category and $\perp$ denotes a NULL relation.[2]

At each step, given a partially-filled table T, we determine the most suitable label l for the next step using a scoring function:

$$\text{score}(T, l) = W_l h_T, \tag{1}$$

where W_l is a model parameter and h_T is the vector representation of T. Based on the function, we aim to find the best label sequence $l_1 \cdots l_m$, where $m = \frac{n(n+1)}{2}$, and the resulting sequence of partially-filled tables is $T_0 T_1 \cdots T_m$, where $T_i = \text{FILL}(T_{i-1}, l_i)$, and T_0 is an empty table. Different from previous work, we investigate a structural model that is optimized for the label sequence $l_1 \cdots l_m$ globally, rather than for each l_i locally.

2.3 Representation Learning

At the ith step, we determine the label l_i of the next table slot based on the current hypothesis T_{i-1}. Following Miwa and Bansal (2016), we use a neural network to learn the vector representation of T_{i-1}, and then use Equation 1 to rank candidate next labels. There are two types of input features, including the word sequence $w_1 w_2 \cdots w_n$, and the readily filled label sequence $l_1 l_2 \cdots l_{i-1}$. We build a neural network to represent T_{i-1}.

2.3.1 Word Representation

Shown in Figure 3, we represent each word w_i by a vector h_i^w using its word form, POS tag and characters. Two different forms of embeddings are used based on the word form, one being obtained by using a randomly initialized look-up table E_w, tuned during training and represented by e_w, and the other being a pre-trained external word embedding from E'_w, which is fixed and represented by e'_w.[3] For a POS tag t, its embedding e_t is obtained from a look-up table E_t similar to E_w.

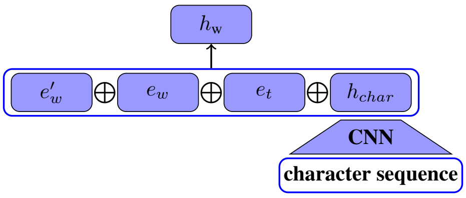

Figure 3: Word representations.

The above two components have also been used by Miwa and Bansal (2016). We further enhance the word representation by using its character sequence (Ballesteros et al., 2015; Lample et al., 2016), taking a convolution neural network (CNN) to derive a character-based word representation h_{char}, which has been demonstrated effective for several NLP tasks (dos Santos and Gatti, 2014). We obtain the final h_i^w based on a non-linear feed-forward layer on $e'_w \oplus e_w \oplus e_t \oplus h_{char}$, where $\oplus$ denotes concatenation.

2.3.2 Label Representation

In addition to the word sequence, the history label sequence $l_1 l_2 \cdots l_{i-1}$, and especially the labels representing detected entities, are also useful disambiguation. For example, the previous entity boundary label can be helpful to deciding the boundary label of the current word. During relation classification, the types of the entities involved can indicate the relation category between them. We exploit the diagonal label sequence of partial table T, which denotes entity boundaries, to enhance the representation learning. A word's entity boundary label embedding e_l is obtained by

[2] We remove the illegal table-filling labels during decoding for training and testing. For example, $T(i, j)$ must be $\perp$ if $T(i, i)$ or $T(j, j)$ equals O.

[3] We use the set of pre-trained glove word embeddings available at http://nlp.stanford.edu/data/glove.6B.zip as external word embeddings.

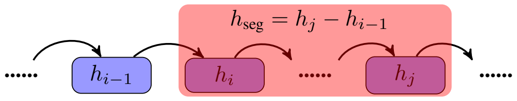

Figure 4: Segment representation.

using a randomly initialized looking-up table E_l.

2.3.3 LSTM Features

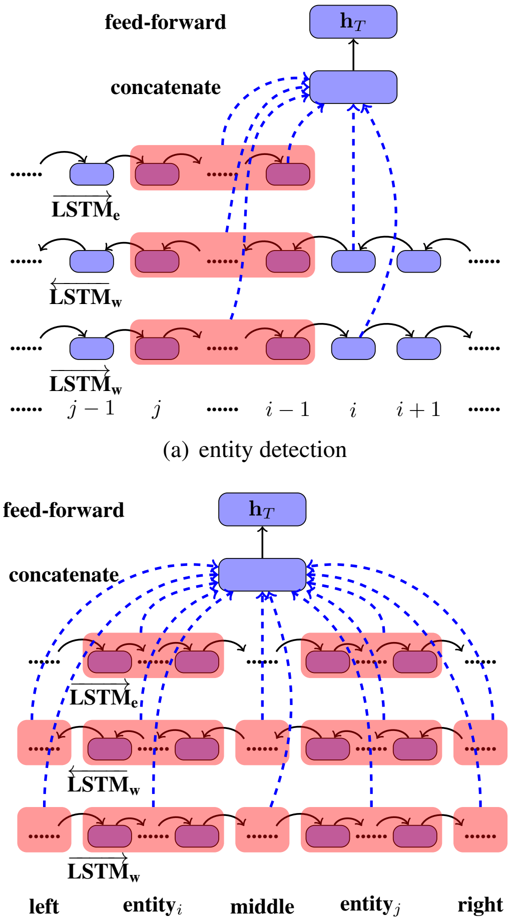
We follow Miwa and Bansal (2016), learning global context representations using LSTMs. Three *basic* LSTM structures are used: a left-to-right word LSTM ($\overrightarrow{\text{LSTM}}_w$), a right-to-left word LSTM ($\overleftarrow{\text{LSTM}}_w$) and a left-to-right entity boundary label LSTM ($\overrightarrow{\text{LSTM}}_e$). Each LSTM derives a sequence of hidden vectors for inputs. For example, for $w_1 w_2 \cdots w_n$, $\overrightarrow{\text{LSTM}}_w$ gives $h_1^{w,\rightarrow} h_2^{w,\rightarrow} \cdots h_n^{w,\rightarrow}$.

Different from Miwa and Bansal (2016), who use the output hidden vectors $\{h_i\}$ of LSTMs to represent words, we exploit *segment* representations as well. In particular, for a segment of text $[i, j]$, the representation is computed by using LSTM-Minus (Wang and Chang, 2016), shown by Figure 4, where $h_j - h_{i-1}$ in a left-to-right LSTM and $h_i - h_{j+1}$ in a right-to-left LSTM are used to represent the segment $[i, j]$. The segment representations can reflect entities in a sentence, and thus can be potentially useful for both entity detection and relation extraction.

2.3.4 Feature Representation

We use separate feature representations for entity detection and relation classification, both of which are extracted from the above three LSTM structures. In particular, we first extract a set of base neural features, and then concatenate them and feed them into a non-linear neural layer for entity detection and relation classification, respectively. Figure 5 shows the overall representation.

[Entity Detection] Figure 5(a) shows the feature representation for the entity detection. First, we extract six feature vectors from the three basic LSTMs, three of which are word features, namely $h_i^{w,\rightarrow}$, $h_i^{w,\leftarrow}$ and $h_{i-1}^{e,\rightarrow}$, and the remaining are segment features, namely $h_{[j,i-1]}^{w,\rightarrow}$, $h_{[j,i-1]}^{w,\leftarrow}$ and $h_{[j,i-1]}^{e,\rightarrow}$, where j denotes the start position of the previous entity.[4] The segment features are computed dynamically from the partial outputs of entity detection, according to the boundaries of the lastly-formed entity during the decoding. The six vectors are concatenated and then fed into a non-linear layer for entity detection.



(a) entity detection

(b) relation classification

Figure 5: Feature representation.

[Relation Classification] Figure 5(b) shows the feature representation for relation classification. Similar to entity detection, we extract a set of features from the basic LSTMs ($\overrightarrow{\text{LSTM}}_w$, $\overleftarrow{\text{LSTM}}_w$ and $\overrightarrow{\text{LSTM}}_e$), and then concatenate them for a non-linear classification layer. The differences between relation classification with entity detection lie in the range of hidden layers from LSTMs. For relation classification between i and j, we split each LSTM into five segments according to the two entities ended with i and j. Formally, let $[s(i), i]$ and $[s(j), j]$ denote the two entities above, where $s(\cdot)$ denotes the start position of an entity, the resulted segments are $[0, s(i)-1]$ (i.e., **left**, in Figure 5(b)), $[s(i), i]$ (i.e., **entity**$_i$), $[i+1, s(j)-1]$ (i.e., **middle**), $[s(j), j]$ (i.e., **entity**$_j$) and $[j+1, n]$ (i.e., **right**), respectively. For the word LSTMs, we extract all five segment features, while the en-

[4] The non-entity word is treated as a special unit entity to extract segmental features.

Models	Encoder	LAS

Table 1: Encoder structures and performances of three state-of-the-art dependency parsers, where S-LSTM (2015) refers to Dyer et al. (2015), K&G (2016) refers to the best parser of Kiperwasser and Goldberg (2016), D&M (2016) refers to Dozat and Manning (2016), and LAS (labeled attachment score) is the major evaluation metric.

tity label LSTM, we only use the segment features of $\textbf{entity}_i$ and $\textbf{entity}_j$.

2.3.5 Syntactic Features

Previous work has shown that syntactic features are useful for relation extraction (Zhou et al., 2005). For example, the shortest dependency path has been used by several relation extraction models (Bunescu and Mooney, 2005; Miwa and Bansal, 2016). Here we propose a novel method to integrate syntax, without need for prior knowledge on concrete syntactic structures.

In particular, we take state-of-the-art syntactic parsers that use encoder-decoder neural models (Buys and Blunsom, 2015; Kiperwasser and Goldberg, 2016), where the encoder represents the syntactic features of the input sentences. For example, LSTM hidden states over the input word/tag sequences has been used frequently as syntactic features (Kiperwasser and Goldberg, 2016). Such features represent input words with syntactic information. The parser decoder also leverages partially-parsed results, such as features from partial syntactic trees, although we do not use explicit output features. Table 1 shows the encoder structures of three state-of-the-art dependency parsers.

Our method is to leverage trained syntactic parsers, dumping the encoder feature representations given our inputs, using them directly as part of input embeddings in our proposed model. Denoting the dumped syntactic features on each word as $h_1^{\text{syn}} h_2^{\text{syn}} \cdots h_n^{\text{syn}}$, we feed them into a nonlinear neural layer, and then generate two LSTMs (bi-directional) based on the outputs, namely $\overrightarrow{\text{LSTM}}_{syn}$ and $\overleftarrow{\text{LSTM}}_{syn}$, respectively, augmenting the original three LSTMs into five LSTMs. Features are extracted from the two new LSTMs in the same way as from the basic bi-directional word LSTMs.

In this paper, we exploit the parser of Dozat and Manning (2016), since it achieves the current best performance for dependency parsing. Our method can be easily generalized to other parsers, which are potentially useful for our task as well. For example, we can use a constituent parser in the same way by dumping the implicit encoder features.

Our exploration of syntactic features has two main advantages over the method of Miwa and Bansal (2016), where dependency path LSTMs are used for relation classification. On the one hand, incorrect dependency paths between entity pairs can propagate to relation classification in Miwa and Bansal (2016), because these paths rely on explicit discrete outputs from a syntactic parser. Our method can avoid the problem since we do not compute parser outputs. On the other hand, the computation complexity is largely reduced by using our method since sequential LSTMs are based on inputs only, while the dependency path LSTMs should be computed based on the dynamic entity detection outputs. When beam search is exploited during decoding, increasing number of dependency paths can be used by a surge of entity pairs from beam outputs.

Our method can be extended into neural stacking Wang et al. (2017), by doing back-propagation training of the parser parameters during model training, which are leave for future work.

2.4 Training and Search

2.4.1 Local Optimization

Previous work (Miwa and Bansal, 2016; Gupta et al., 2016) trains model parameters by modeling each step for labeling one input sentence separately. Given a partial table T, its neural representation h_T is first obtained, and then compute the next label scores $\{l_1, l_2, \cdots, l_s\}$ using Equation 1. The output scores are regularized into a probability distribution $\{p_{l_1}, p_{l_2}, \cdots, p_{l_s}\}$ by using a softmax layer. The training objective is to minimize the cross-entropy loss between this output distribution with the gold-standard distribution:

$$\text{loss}(T, l_i^g, \Theta) = -\log p_{l_i^g}, \qquad (2)$$

where l_i^g is the gold-standard next label for T, and Θ is the set of all model parameters. We refer this training method as *local optimization*, because it maximizes the score of the gold-standard label at each step locally.

Algorithm 1 Beam-search.

```
$agenda \leftarrow \{$ ($empty\ table$, score=0.0) $\}$
for $i$ in $1 \cdots$ max-step
    $next\_scored\_tables \leftarrow \{\ \}$
    for $scored\_table$ in $agenda$
        $labels \leftarrow$ NEXTLABELS($scored\_table$)
        for next_label in labels
            new $\leftarrow$ FILL(scored_table, $next\_label$)
            ADDITEM($next\_scored\_tables$, $new$)
    $agenda \leftarrow$ TOP-B($next\_scored\_tables$, $B$)
```

During the decoding phase, the greedy search strategy is applied in consistence with the training. At each step, we find the highest-scored label based on the current partial table, before going on to the next step.

2.4.2 Global Optimization

We exploit the global optimization strategy of Zhou et al. (2015) and Andor et al. (2016), maximizing the cumulative score of the gold-standard label sequence for one sentence as a unit. Global optimization has achieved success for several NLP tasks under the neural setting (Zhou et al., 2015; Watanabe and Sumita, 2015). For relation extraction, global learning gives the best performances under the discrete setting (Li and Ji, 2014; Miwa and Sasaki, 2014). We study such models here for neural network models.

Given a label sequence of $l_1 l_2 \cdots l_i$, the score of T_i is defined as follows:

$$\begin{aligned}\text{score}(T_i) &= \sum_{j=0}^{i} \text{score}(T_{j-1}, l_j) \\ &= \text{score}(T_{i-1}) + \text{score}(T_{i-1}, l_i),\end{aligned} \quad (3)$$

where $\text{score}(T_0) = 0$ and $\text{score}(T_{i-1}, l_i)$ is computed by Equation 1. By this definition, we maximize the scores of all gold-standard partial tables.

Again cross-entropy loss is used to perform model updates. At each step i, the objective function is defined by:

$$\begin{aligned}\text{loss}(x, T_i^g, \Theta) &= -\log p_{T_i^g} \\ &= -\log \frac{\text{score}(T_i^g)}{\sum_{T_i'} \text{score}(T_i')},\end{aligned} \quad (4)$$

where x denotes the input sentence, T_i^g denotes the gold-standard state at step i, and T_i' are all partial tables that can be reached at step i.

The major challenge is to compute $p_{T_i^g}$, because we cannot traverse all partial tables that are valid at step i, since their count increases exponentially by the step number. We follow Andor et al. (2016), approximating the probability by using beam search and early-update.

Shown in Algorithm 1, we use standard beam search, maintaining the B highest-scored partially-filled tables in an agenda at each step. When each action of table filling is taken, all hypotheses in the agenda are expanded by enumerating the next labels, and the B highest-scored resulting tables are used to replace the agenda for the next step. Search begins with the agenda containing an empty table, and finishes when all cells of the tables in the agenda have been filled. When the beam size is 1, the algorithm is the same as greedy decoding. When the beam size is larger than 1, however, error propagation is alleviated. For training, the same beam search algorithm is applied to training examples, and early-update (Collins and Roark, 2004) is used to fix search errors.

3 Experiments

3.1 Data and Evaluation

We evaluate the proposed model on two datasets, namely the ACE05 data and the corpus of Roth and Yih (2004) (CONLL04), respectively. The ACE05 dataset defines seven coarse-grained entity types and six coarse-grained relation categories, while the CONLL04 dataset defines four entity types and five relation categories.

For the ACE05 dataset, we follow Li and Ji (2014) and Miwa and Bansal (2016), splitting and preprocessing the dataset into training, development and test sets.[5] For the CONLL04 dataset, we follow Miwa and Sasaki (2014) to split the data into training and test corpora, and then divide 10% of the training corpus for development.

We use the micro F1-measure as the major metric to evaluate model performances, treating an entity as correct when its head region and type are both correct,[6] and regard a relation as correct when the argument entities and the relation category are all correct. We exploit pairwise t-test for measuring significance values.

[5] https://github.com/tticoin/LSTM-ER/.

[6] For the ACE05 dataset, the head region is defined by the corpus, and for the CONLL04 dataset, the head region covers the entire scope of an entity.

Local(+SS)	1	51.2	95.1
Global	1	51.4	95.3
	3	51.8	52.0
	5	**52.6**	36.9

Table 4: Comparisons between local and global models, where SS denotes scheduled sampling, and speed is measured by the number of sentences per second.

3.2 Parameter Tuning

We update all model parameters by back propagation using Adam (Kingma and Ba, 2014) with a learning rate 10^{-3}, using gradient clipping by a max norm 10 and l_2-regularization by a parameter 10^{-5}. The dimension sizes of various vectors in neural network structure are shown in Table 2. All the hyper-parameters are tuned by development experiments. All experiments are conducted using gcc version 4.9.4 (Ubuntu 4.9.4-2ubuntu1 14.04.1), on an Intel(R) Xeon(R) CPU E5-2670 @ 2.60GHz.

Online training is used to learn parameters, traversing over the entire training examples by 300 iterations. We select the best iteration number according to the development results. In particular, we exploit pre-training techniques (Wiseman and Rush, 2016) to learn better model parameters. For the local model, we follow Miwa and Bansal (2016), training parameters only for entity detection during the first 20 iterations. For the global model, we pretrain our model using local optimization for 40 iterations, before conducting beam global optimization.

3.3 Development Experiments

We conduct several development experiments on the ACE05 development dataset.

3.3.1 Feature Ablation Tests

We consider the baseline system with no syntactic features using local training. Compared with Miwa and Bansal (2016), we introduce character-level features, and in addition exploit segmental features for entity detection. Feature ablation experiments are conducted for the two types of features. Table 3 shows the experimental results, which demonstrate that the character-level features and the segment features we use are both useful for relation extraction.

3.3.2 Local v.s. Global Training

We study the influence of training strategies for relation extraction without using syntactic features. For the local model, we apply scheduled sampling (Bengio et al., 2015), which has been shown to improve the performance of relation extraction by Miwa and Bansal (2016).

Table 4 shows the results. Scheduled sampling achieves improved F-measure scores for the local model. With the same greedy search strategy, the globally normalized model gives slightly better results than the local model with scheduled sampling. The performance of the global model increases with a larger beam size. When beam size 5 is exploited, we obtain a further gain of 1.2% on the relation F-measure, which is significantly better than our baseline local model with scheduled sampling ($p \approx 10^{-4}$). However, the decoding speed becomes intolerably slow when the beam size increases beyond 5. Thus we exploit a beam size of 5 for global training considering both performance and efficiency.

3.3.3 Syntactic Features

We examine the effectiveness of the proposed implicit syntactic features. Table 5 shows the development results using both local and global optimization. The proposed features improve the relation performances significantly under both settings ($p < 10^{-4}$), demonstrating that our use of syntactic features is highly effective.

We also compare our feature integration method with the traditional methods based on syntactic

Model	Features	Entity F1	Relation F1
Local	all	**81.6**	**53.0**
	-syn	81.5	50.9
Global	all	**81.9**	**54.2**
	-syn	81.6	52.6

Table 5: The influence of syntactic features.

model	ACE05		CONLL04	
	Entity	Relation	Entity	Relation
Our Model	**83.6**	**57.5**	**85.6**	**67.8**
M&B (2016)	83.4	55.6	—	—
L&J (2014)	80.8	49.5	—	—
M&S (2014)	—	—	80.7	61.0

Table 6: Final results on the test datasets.

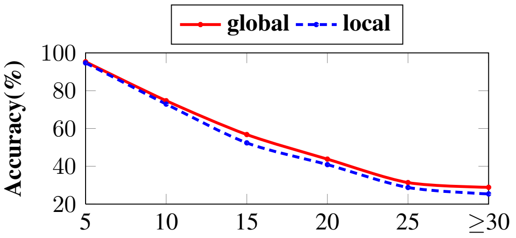

Figure 6: Sentence-level accuracies with respect to sentence length.

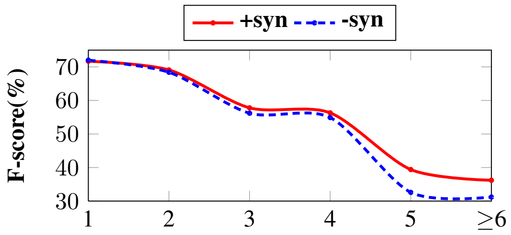

Figure 7: F-scores with respect to the distance between entity pairs.

outputs which Miwa and Bansal (2016) and all previous methods use. We use the same parser of Dozat and Manning (2016), building features on its dependency outputs. We exploit the bidirectional tree LSTM of Teng and Zhang (2016) to extract neural features, and then exploit a nonlinear feed-forward neural network to combine the two features. Similarly, we extract segment features but by using max pooling instead over the sequential outputs of the feed-forward layer, since the vector minus is nonsense here. The final relation results are 53.1% and 53.9% for the local and global models, respectively, which have no significantly differences compared with our models. On the other hand, our method is relatively more efficient, and flexible to the grammar formalism.

3.4 Final Results

Table 6 shows the final results on the test datasets of ACE05 and CONLL04. We show several top-performing systems in the table as well, where M&B (2016) refers to Miwa and Bansal (2016), who exploit end-to-end LSTM neural networks with local optimization, and L&J (2014) and M&S (2014) refer to Li and Ji (2014) and Miwa and Sasaki (2014), respectively, which are both globally optimized models using discrete features, giving the top F-scores among statistical models.[7]

Overall, neural models give better performances than statistical models, and global optimization can give improved performances as well. Our final model achieves the best performances on both datasets. Compared with the best reported results, our model gives improvements of 1.9% on ACE05, and 6.8% on CONLL04.

3.5 Analysis

We conduct analysis on the ACE05 test dataset in order to better understand our models, on its two major contributions, first examining the influences of global optimization, and then studying the gains by using the proposed syntactic features.

Intuitively global optimization should give better accuracies at the sentence level. We verify this by examining the sentence-level accuracies, where one sentence is regarded as correct when all the labels in the resulted table are correct. Figure 6 shows the result, which is consistent with our intuition. The sentence-level accuracies of the globally normalized model are consistently better than the local model. In addition, the accuracy decreases sharply as the sentence length increases, with the local model suffering more severely from larger sentences.

To understand the effectiveness of the proposed syntactic features, we examine the relation F-scores with respect to entity distances. Miwa and Bansal (2016) exploit the shortest dependency path, which can make the distance between two entities closer compared with their sequential dis-

[7] Gupta et al. (2016) proposed a locally optimized model but used a different test dataset from CONLL04 and a different evaluation method, reporting entity and relation F-scores of 93.6% and 72.1%, respectively. Their results are not directly comparable to the results in Table 6. In particular, they regard an entity as correct if at least one token is tagged correctly, which influences the results significantly since multi-word entities accounts for over 50% of all entities.

tance, thus facilitating relation extraction. We verify whether the proposed syntactic features can benefit our model similarly. As shown in Figure 7, the F-scores of entity-pairs with large distances see apparent improvements, demonstrating that our use of syntactic features has a similar effect compared to the shortest dependency path.

4 Related Work

Entity recognition (Florian et al., 2004, 2006; Ratinov and Roth, 2009; Florian et al., 2010; Kuru et al., 2016) and relation extraction (Zhao and Grishman, 2005; Jiang and Zhai, 2007; Zhou et al., 2007; Qian and Zhou, 2010; Chan and Roth, 2010; Sun et al., 2011; Plank and Moschitti, 2013; Verga et al., 2016) have received much attention in the NLP community. The dominant methods treat the two tasks separately, where relation extraction is performed assuming that entity boundaries have been given (Zelenko et al., 2003; Miwa et al., 2009; Chan and Roth, 2011; Lin et al., 2016).

Several studies find that extracting entities and relations jointly can benefit both tasks. Early work conducts joint inference for separate models (Ji and Grishman, 2005; Roth and Yih, 2004, 2007). Recent work shows that joint learning and decoding with a single model brings more benefits for the two tasks (Li and Ji, 2014; Miwa and Sasaki, 2014; Miwa and Bansal, 2016; Gupta et al., 2016), and we follow this line of work in the study.

LSTM features have been extensively exploited for NLP tasks, including tagging (Huang et al., 2015; Lample et al., 2016), parsing (Kiperwasser and Goldberg, 2016; Dozat and Manning, 2016), relation classification (Xu et al., 2015; Vu et al., 2016; Miwa and Bansal, 2016) and sentiment analysis (Li et al., 2015; Teng et al., 2016). Based on the output of LSTM structures, Wang and Chang (2016) introduce segment features, and apply it to dependency parsing. The same method is applied to constituent parsing by Cross and Huang (2016). We exploit this segmental representation for relation extraction.

Global optimization and normalization has been successfully applied on many NLP tasks that involve structural prediction (Lafferty et al., 2001; Collins, 2002; McDonald et al., 2010; Zhang and Clark, 2011), using traditional discrete features. For neural models, it has recently received increasing interests (Zhou et al., 2015; Andor et al., 2016; Xu, 2016; Wiseman and Rush, 2016), and improved performances can be achieved with global optimization accompanied by beam search. Our work is in line with these efforts. To our knowledge, we are the first to apply globally optimized neural models for end-to-end relation extraction, achieving the best results on standard benchmarks.

5 Conclusion

We investigated a globally normalized end-to-end relation extraction model using neural network, based on the table-filling framework proposed by Miwa and Sasaki (2014). Feature representations are learned from several LSTM structures over the inputs, and a novel simple method is used to integrate syntactic information. Experiments show the effectiveness of both global normalization and syntactic features. Our final model achieved the best performances on two benchmark datasets.

KGEval: Accuracy Estimation of Automatically Constructed Knowledge Graphs

Prakhar Ojha

Abstract

Automatic construction of large knowledge graphs (KG) by mining web-scale text datasets has received considerable attention recently. Estimating accuracy of such automatically constructed KGs is a challenging problem due to their size and diversity and has largely been ignored in prior research. In this work, we try to fill this gap by proposing KGEval. KGEval uses *coupling constraints* to bind facts and crowdsource those few that can *infer* large parts of the graph. We demonstrate that the objective optimized by KGEval is submodular and NP-hard, allowing guarantees for our approximation algorithm. Through experiments on real-world datasets, we demonstrate that KGEval best estimates KG accuracy compared to other baselines, while requiring significantly lesser number of human evaluations.

1 Introduction

Automatic construction of Knowledge Graphs (KGs) from Web documents has received significant interest over the last few years, resulting in the development of several large KGs consisting of hundreds of predicates (e.g., *isCity*, *stadiumLocatedInCity(Stadium, City)*) and millions of their instances called beliefs (e.g., *(Joe Luis Arena, stadiumLocatedInCity, Detroit)*). Examples of such KGs include NELL (Mitchell et al., 2015), Knowledge-Vault (Dong et al., 2014) etc.

Due to imperfections in the automatic KG construction process, many incorrect beliefs are also found in these KGs. Knowing accuracy for each predicate in the KG can provide targeted feedback for improvement and highlight its strengths from weaknesses, whereas overall accuracy of a KG can quantify the effectiveness of its construction-process. Knowing accuracy at predicate-level granularity is immensely helpful for Question-Answering (QA) systems that integrate opinions from multiple KGs (Samadi et al., 2015). For such systems, being aware that a particular KG is more accurate than others in a certain domain, say sports, helps in restricting the search over relevant and accurate subsets of KGs, thereby improving QA-precision and response time. In comparison to the large body of recent work focused on construction of KGs, the important problem of accuracy estimation of such large KGs is unexplored – we address this gap in this paper.

True accuracy of a predicate may be estimated by aggregating human judgments on correctness of each and every belief in the predicate[1]. Even though crowdsourcing marketplaces such as Amazon Mechanical Turk (AMT) provide a convenient way to collect human judgments, accumulating such judgments at the scale of larges KGs is prohibitively expensive. We shall refer to the task of manually classifying a single belief as true or false as a Belief Evaluation Task (BET). Thus, the crucial problem is: *How can we select a subset of beliefs to evaluate which will best estimate the true (but unknown) accuracy of KG and its predicates?*

A naive and popular approach is to evaluate randomly sampled subset of beliefs from the KG. Since random sampling ignores relational-couplings present among the beliefs, it usually results in oversampling and poor accuracy estimates. Let us motivate this through an example.

[1] Note that belief evaluation can not be completely automated and will require human-judgment. If an algorithm could accurately predict correctness of a belief, then it may as well be used during KG construction rather than during evaluation.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1741–1750
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

Motivating example: We motivate efficient accuracy estimation through the KG fragment shown in Figure 1. Here, each belief is an edge-triple in the graph, for example (*RedWings, isA, SportsTeam*). There are six correct and two incorrect beliefs (the two incident on *Taj Mahal*), resulting in an overall accuracy of $75\% (= 6/8)$ which we would like to estimate. Additionally, we would also like to estimate accuracies of the predicates: *homeStadiumOf*, *homeCity*, *stadiumLocatedInCity*, *cityInState* and *isA*.

We now demonstrate how evaluation labels of beliefs are constrained by each other. *Type consistency* is one such coupling constraint. For instance, we know from KG ontology that the *homeStadiumOf* predicate connects an entity from *Stadium* category to another entity in *Sports Team* category. Now, if *(Joe Louis Arena, homeStadiumOf, Red Wings)* is evaluated to be correct, then from these *type constraints* we can infer that *(Joe Louis Arena, isA, Stadium)* and *(Red Wings, isA, Sports Team)* are also correct. Similarly, by evaluating *(Taj Mahal, isA, State)* as false, we can infer that *(Detroit, cityInState, TajMahal)* is incorrect.

Additionally, we have *Horn-clause coupling constraints* (Mitchell et al., 2015; Lao et al., 2011), such as *homeStadiumOf(x, y)* ∧ *homeCity(y, z)* → *stadiumLocatedInCity(x, z)*. By evaluating *(Red Wings, homeCity, Detroit)* and applying this horn-clause to the already evaluated facts mentioned above, we infer that *(Joe Louis Arena, stadiumLocatedInCity, Detroit)* is also correct. We explore generalized forms of these constraints in Section 3.1.

Thus, evaluating only three beliefs, and exploiting constraints among them, we exactly estimate the *overall* true accuracy as 75% and also cover all predicates. In contrast, the empirical accuracy by randomly evaluating three beliefs, averaged over 5 trials, is 66.7%.

Our contributions in this paper are the following: (1). Systematic study into the important problem of evaluation of automatically constructed Knowledge Graphs. (2). A novel crowdsourcing-based system KGEval to estimate accuracy of large knowledge graphs (KGs) by exploiting dependencies among beliefs for more accurate and faster KG accuracy estimation. (3). Extensive experiments on real-world KGs to demonstrate KGEval's effectiveness and also evaluate its robustness and scalability.

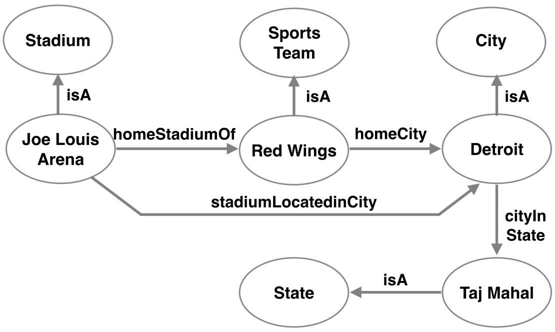

Figure 1: Sample knowledge-graph (KG) fragment that is consistent but has erroneous beliefs.

All the data and code used in the paper are available at http://talukdar.net/mall-lab/KGEval

2 Overview and Problem Statement

2.1 KGEval: Overview

We try to estimate correctness of as many beliefs as possible while evaluating only a subset of them through crowdsourcing. KGEval achieves this goal using an iterative algorithm which alternates between the following two stages:

- **Control Mechanism** (Section 3.4): In this step, KGEval selects the belief which is to be evaluated next using crowdsourcing.
- **Inference Mechanism** (Section 3.3): Coupling constraints are applied over evaluated beliefs to automatically estimate correctness of additional beliefs.

This iterative process is repeated until there are no more beliefs to be evaluated. Single iteration of KGEval over the KG fragment from Figure 1 is shown in Figure 2 where, belief *(John Louis Arena, homeStadiumOf, Red Wings)* is selected and evaluated by crowdsourcing. Subsequently, the inference mechanism uses type coupling constraints to infer *(JL Arena, isA, Stadium)* and *(R. Wings, isA, Team)* also as true. Next, we formalize the notations used in this paper.

2.2 Notations and Problem Statement

We are given a KG with n beliefs. Evaluating a single belief as true or false forms a Belief Evaluation Task (BET). Coupling constraints are derived by determining relationships among BETs, which we further discuss in Section 3.1. Notations are also summarized in Table 1.

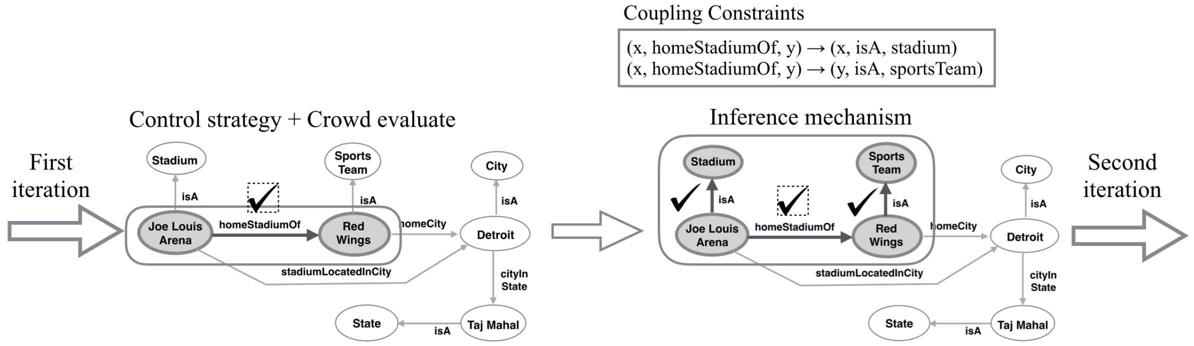

Figure 2: Demonstration of one iteration of KGEval. Control mechanism selects a belief whose correctness is evaluated from crowd. In the above example, *(J.L. Arena, homeStadiumOf, Red Wings)* is crowd-evaluated to be true (indicated by tick with dotted square). (Section 2.1 and Section 3).

Symbol	Description
$\mathcal{H} = \{h_1, \ldots, h_n\}$	Set of all n Belief Evaluation Tasks (BETs)
$c(h) \in \mathbb{R}_+$	Cost of labeling h from crowd
$\mathcal{C} = \{(\mathcal{C}_i, \theta_i)\}$	Coupling constraints $\mathcal{C}_i$ with weights $\theta_i \in \mathbb{R}_+$
$t(h) \in \{0, 1\}$	True label of h
$l(h) \in \{0, 1\}$	Estimated label of h
$\mathcal{H}_i = \text{Dom}(\mathcal{C}_i)$	$\mathcal{H}_i \subseteq \mathcal{H}$ which participate in $\mathcal{C}_i$
$G = (\mathcal{H} \cup \mathcal{C}, \mathcal{E})$	Evaluation Coupling Graph, $e \in \mathcal{E}$ between $\mathcal{H}_j$ and $\mathcal{C}_j$ denotes $\mathcal{H}_j \in \text{Dom}(\mathcal{C}_j)$.
$\mathcal{Q} \subseteq \mathcal{H}$	BETs evaluated using crowd
$\mathcal{I}(G, \mathcal{Q}) \subseteq \mathcal{H}$	Inferable set for evidence $\mathcal{Q}$:
$\Phi(\mathcal{Q}) = \frac{1}{\lvert\mathcal{Q}\rvert} \sum_{h \in \mathcal{Q}} t(h)$	True accuracy of evaluated BETs $\mathcal{Q}$

Table 1: Summary of notations used (Section 2.2).

Inference algorithm helps us work out evaluation labels of other BETs using constraints $\mathcal{C}$. For a set of already evaluated BETs $\mathcal{Q} \subseteq \mathcal{H}$, we define *inferable set* $\mathcal{I}(G, \mathcal{Q}) \subseteq \mathcal{H}$ as BETs whose evaluation labels can be deduced by the inference algorithm. We calculate the average true accuracy of a given set of evaluated BETs $\mathcal{Q} \subseteq \mathcal{I}(G, \mathcal{Q}) \subseteq \mathcal{H}$ by $\Phi(\mathcal{Q}) = \frac{1}{|\mathcal{Q}|} \sum_{h \in \mathcal{Q}} t(h)$.

KGEval aims to sample and crowdsource a BET set $\mathcal{Q}$ with the largest inferable set, and solves the optimization problem:

$$\arg\max_{\mathcal{Q} \subseteq \mathcal{H}} \left|\mathcal{I}(G, \mathcal{Q})\right| \qquad (1)$$

3 KGEval: Method Details

In this section, we describe various components of KGEval.

3.1 Coupling Constraints

The evaluation labels of beliefs are often dependent on each other due to rich relational structure of KGs. In this work, we derive coupling constraints $\mathcal{C}$ from the KG ontology and link-prediction algorithms, such as PRA (Lao et al., 2011) over NELL and AMIE (Galárraga et al., 2013) over Yago. These rules are jointly learned over entire KG with millions of facts and are assumed true.

We use conjunction-form first-order-logic rules and refer to them as *Horn clauses*. Examples of a few such coupling constraints are shown below.

$\mathcal{C}_2$: *(x, homeStadiumOf, y) → (y, isA, sportsTeam)*
$\mathcal{C}_5$: *(x, homeStadiumOf, y) ∧ (y, homeCity, z) →*
(x, stadiumLocatedInCity, z)

Each coupling constraint $\mathcal{C}_i$ operates over $\mathcal{H}_i \subseteq \mathcal{H}$ to the left of its arrow and infers label of the BET on the right of its arrow. $\mathcal{C}_2$ enforces *type consistency* and $\mathcal{C}_5$ is an instance of PRA path. These constraints have also been successfully employed earlier during knowledge extraction (Mitchell et al., 2015) and integration (Pujara et al., 2013). Note that the constraints are *directional* and inference propagates in forward direction.

3.2 Evaluation Coupling Graph (ECG)

To combine all beliefs and constraints at a common place, for all $\mathcal{H}$ and $\mathcal{C}$, we construct a graph with two types of nodes: (1) a node for each BET $h \in \mathcal{H}$, and (2) a node for each constraint $\mathcal{C}_i \in \mathcal{C}$. Each $\mathcal{C}_i$ node is connected to all h nodes that participate in it. We call this graph the *Evaluation Coupling Graph* (*ECG*), represented as $G = (\mathcal{H} \cup \mathcal{C}, \mathcal{E})$ with set of edges $\mathcal{E} = \{(\mathcal{C}_i, h) \mid h \in \text{Dom}(\mathcal{C}_i)\ \forall \mathcal{C}_i \in \mathcal{C}\}$. Note that ECG is a bipartite *factor graph* (Kschischang et al., 2001) with h as variable-nodes and $\mathcal{C}_i$ as factor-nodes.

Figure 3: Evaluation Coupling Graph (ECG) constructed for example in Figure 1. (Section 3.2)

Figure 3 shows ECG constructed out of the motivating example in Figure 1 with $|\mathcal{C}| = 8$ and separate nodes for each of the edges (beliefs or BETs) in KG. We pose the KG evaluation problem as classification of BET nodes in the ECG by allotting them a label of 1 or 0 to represent true or false respectively.

3.3 Inference Mechanism

Inference mechanism helps propagate true/false labels of evaluated beliefs to other non-evaluated beliefs using available coupling constraints (Bragg et al., 2013). We use Probabilistic Soft Logic (PSL), (Broecheler et al., 2010) as our inference engine.Below we briefly describe the internal workings of our inference engine for accuracy estimation problem.

Potential function ψ_j is defined for each $\mathcal{C}_j$ using Lukaseiwicz t-norm and it depicts how satisfactorily constraint $\mathcal{C}_j$ is satisfied. For example, $\mathcal{C}_5$ mentioned earlier is transformed from first-order logical form to a real valued number by

$$\psi_j(\mathcal{C}_5) = \Big(\max\{0, h_x + h_y - 1 - h_w\}\Big)^2 \quad (2)$$

where $\mathcal{C}_5 = h_x \wedge h_y \rightarrow h_w$, where h_x denotes the evaluation score $\in [0, 1]$ associated with the BETs.

The probability distribution over label assignment is so structured such that labels which satisfy more coupling constraints are more probable. Probability of any label assignment $\Omega(\mathcal{H}) \in \{0, 1\}^{|\mathcal{H}|}$ over BETs in G is given by

$$\mathbb{P}(\Omega(\mathcal{H})) = \frac{1}{Z} \exp\Big[-\sum_{j=1}^{|\mathcal{C}|} \theta_j \psi_j(\mathcal{C}_j)\Big] \quad (3)$$

where Z is the normalizing constant and ψ_j corresponds to potential function acting over BETs $h \in \text{Dom}(\mathcal{C}_j)$. Final assignment of $\Omega(\mathcal{H})_{PSL} \in \{1, 0\}^{|\mathcal{H}|}$ labels is obtained by solving the *maximum a-posteriori (MAP)* optimization problem

$$\Omega(\mathcal{H})_{PSL} = \underset{\Omega(\mathcal{H})}{\arg\max}\ \mathbb{P}\Big(\Omega(\mathcal{H})\Big)$$

We denote by $M_{PSL}(h, \gamma) \in [0, 1]$ the PSL-estimated score for label $\gamma \in \{1, 0\}$ on BET h in the optimization above.

Inferable Set using PSL: We define estimated label for each BET h as shown below.

$$l(h) = \begin{cases} 1 \text{ if } M_{PSL}(h, 1) \geq \tau \\ 0 \text{ if } M_{PSL}(h, 0) \geq \tau \\ \varnothing \text{ otherwise} \end{cases}$$

where threshold τ is system hyper-parameter. Inferable set is composed of BETs for which inference algorithm (PSL) confidently propagates labels.

$$\mathcal{I}(G, \mathcal{Q}) = \{h \in \mathcal{H} \mid l(h) \neq \varnothing\}$$

Note that two BET nodes from ECG can interact with varying strengths through different constraint nodes; this multi-relational structure requires soft probabilistic propagation.

3.4 Control Mechanism

Control mechanism selects the BET to be crowd-evaluated at every iteration. We first present the following two theorems involving KGEval's optimization in Equation (1). Please refer Appendix for proofs of both theorems.

Theorem 1. [Submodularity] *The function optimized by KGEval (Equation (1)) using the PSL-based inference mechanism is submodular (Lovász, 1983).*

The proof follows from the fact that all pairs of BETs satisfy the regularity condition (Jegelka and Bilmes, 2011; Kolmogorov and Zabih, 2004), further used by a proven conjecture (Mossel and Roch, 2007).

Theorem 2. [NP-Hardness] *The problem of selecting optimal solution in KGEval's optimization (Equation (1)) is NP-Hard.*

Proof follows by reducing NP-complete Set-cover Problem (SCP) to selecting $\mathcal{Q}$ which covers $\mathcal{I}(G, \mathcal{Q})$.

Justification for Greedy Strategy: From Theorem 1 and 2, we observe that the function optimized by KGEval is NP-hard and submodular.

Algorithm 1 KGEval: Accuracy Estimation of Knowledge Graphs

```
Require: $\mathcal{H}$: BETs, $\mathcal{C}$: coupling constraints, $\mathbb{B}$:
    assigned budget, $\mathcal{S}$: seed set, $c(h)$: BET cost
 1: $G = \text{BUILDECG}(\mathcal{H}, \mathcal{C})$
 2: $B_r = \mathbb{B}$
 3: $\mathcal{Q}_0 = \mathcal{S}, t = 1$
 4: repeat
 5:     $h^* = \arg\max_{h \in \mathcal{H}-\mathcal{Q}} |\mathcal{I}(G, \mathcal{Q}_{t-1} \cup \{h\})|$
 6:     $\text{CROWDEVALUATE}(h^*)$
 7:     $\text{RUNINFERENCE}(\mathcal{Q}_{t-1} \cup h^*)$
 8:     $\mathcal{Q}_t = \mathcal{I}(G, \mathcal{Q}_{t-1} \cup \{h^*\})$
 9:     $B_r = B_r - c(h^*)$
10:     $\mathcal{Q} = \mathcal{Q} \cup \mathcal{Q}_t$
11:     if $\mathcal{Q} \equiv \mathcal{H}$ then
12:         EXIT
13:     end if
14:     $\mathrm{Acc_t} = \frac{1}{|\mathcal{Q}|} \sum_{h \in \mathcal{Q}} l(h)$
15:     $t = t + 1$
16: until CONVERGENCE
17: return $\mathrm{Acc_t}$
```

Results from (Nemhauser et al., 1978) prove that greedy hill-climbing algorithms solve such maximization problem within an approximation factor of $(1-1/e) \approx 63\%$ of the optimal solution. Hence we iteratively select the next BET which gives the greatest increase in size of inferable set.

We acknowledge the importance of crowdsourcing aspects such as label-aggregation, worker's quality estimation etc. Appendix A.1 presents a mechanism to handle noisy crowd workers under limited budget.

3.5 Bringing it All Together

Algorithm 1 presents KGEval. In Lines 1-3, we build the Evaluation Coupling Graph $G = (\mathcal{H} \cup \mathcal{C}, \mathcal{E})$ and use the labels of seed set $\mathcal{S}$ to initialize G. In lines 4-16, we repetitively run our inference mechanism, until either the accuracy estimates have converged, or all the BETs are covered. In each iteration, the BET with the largest inferable set is identified and evaluated using crowdsourcing (Lines 5-6). The new inferable set $\mathcal{Q}_t$ is estimated. These automatically annotated nodes are added to $\mathcal{Q}$ (Lines 7-10).

Convergence: In this paper, we define convergence whenever the variance of sequence of accuracy estimates [$\mathrm{Acc_{t-k}}, \ldots, \mathrm{Acc_{t-1}}, \mathrm{Acc_t}$] is less than α. We set $k = 9$ and $\alpha = 0.002$ for our experiments.

4 Experiments

To assess the effectiveness of KGEval, we ask the following questions: (1).How effective is KGEval in estimating KG accuracy, both at predicate-level and at overall KG-level? (Section 4.3). (2). What is the importance of coupling constraints on its performance? (Section 4.4). (3). And lastly, how robust is KGEval to estimating accuracy of KGs with varying quality? (Section 4.5).

4.1 Model Description

Evaluation set	$\mathcal{H}_N$	$\mathcal{H}_Y$
#BETs	1860	1386
#Constraints	$\lvert\mathcal{C}_N\rvert = 130$	$\lvert\mathcal{C}_Y\rvert = 28$
#Predicates	18	16
Gold Acc.	91.34%	99.20%

Table 2: Details of BET subsets used for accuracy evaluation. (Section 4.1.2).

4.1.1 Setup

Datasets: For experiments, we consider two KGs: NELL and Yago2. From NELL (NELL), we choose a sub-graph of sports related beliefs **NELL-sports**, mostly pertaining to athletes, coaches, teams, leagues, stadiums etc. We construct coupling constraints set $\mathcal{C}_\mathbf{N}$ using top-ranked PRA inference rules for available predicate-relations (Lao et al., 2011). The confidence score returned by PRA are used as weights θ_i. We use NELL-ontology's predicate-signatures to get information for *type* constraints. Please note that PSL is capable of handling weighted constraints and also learn their weights (relative importance). So, it is not critical to provide absolutely correct constraints. We also select **YAGO2-sample** (YAGO) , which unlike NELL-sports, is not domain specific. We use AMIE horn clauses (Galárraga et al., 2013) to construct multi-relational coupling constraints $\mathcal{C}_\mathbf{Y}$. For each $\mathcal{C}_i$, the score returned by AMIE is used as rule weight θ_i. Table 2 reports the statistics of datasets used, their true accuracy and number of coupling constraints. Obtaining gold-labels for millions of facts is non-trivial and expensive as crowdsourcing over full KG incurs significant cost.

Size of evaluation set: NELL-sport consists of $23,422$ beliefs with $13,290$ unique entities and 53 unique predicates. Whereas YAGO-sample has $31,720$ beliefs, with unique $32,103$ entities and 17 predicates. In order to calculate accuracy, we require gold evaluation of all beliefs in the evaluation set. Since obtaining gold evaluation of the entire (or large subsets of) NELL and Yago2 KGs will be prohibitively expensive, we take subset of these KGs for evaluation. (KGEval) consists of datasets used, their crowdsourced labels, coupling constraints and code for inference/control.

Initialization: Algorithm 1 requires initial seed set $\mathcal{S}$ which we generate by randomly evaluating $|\mathcal{S}| = 50$ beliefs from $\mathcal{H}$. To maintain fairness, all baselines start from $\mathcal{S}$. For asserting true (or false) value for beliefs, we set a high soft label confidence threshold at $\tau = 0.8$ (see Section 3.3).

4.1.2 Crowdsourcing of BETs

To compare KGEval predictions against human evaluations, we evaluate all BETs $\{\mathcal{H}_N \cup \mathcal{H}_Y\}$ on AMT. For the ease of workers, we translate each *entity-relation-entity* belief into human readable format before posting to crowd.

We published BETs on AMT under 'classification project' category. We hired AMT recognized master workers for high quality labels and paid \$0.01 per BET. To compare between 'master' and 'noisy' workers, we correlated their labels individually to expert labels on random subset and observed that master workers were better correlated (93%) as compared to three non-masters (89%). Consequently we consider votes of master workers for $\{\mathcal{H}_N \cup \mathcal{H}_Y\}$ as gold labels, which we would like our inference algorithm to be able to predict. As the average turnaround time for AMT tasks runs into a few minutes (Dupuis et al., 2013), KGEval is effectively real-time within such turnaround time range.

4.1.3 Performance Evaluation Metrics

Performance of various methods are evaluated using the following two metrics. To capture accuracy at the predicate level, we define $\Delta_{predicate}$ as the average of difference between gold and estimated accuracy of each of the R predicates in KG.

$$\Delta_{predicate} = \frac{1}{|R|}\left(\sum_{\forall r \in R}\left|\Phi(\mathcal{H}_r) - \frac{1}{|\mathcal{H}_r|}\sum_{\forall h \in \mathcal{H}_r} l(h)\right|\right)$$

We define $\Delta_{overall}$ as the difference between gold and estimated accuracy over the entire evaluation set.

$$\Delta_{overall} = \left|\Phi(\mathcal{H}) - \frac{1}{|\mathcal{H}|}\sum_{\forall h \in \mathcal{H}} l(h)\right|$$

Above, $\Phi(\mathcal{H})$ is the overall gold accuracy, $\Phi(\mathcal{H}_r)$ is the gold accuracy of predicate r and $l(h)$ is the label assigned by the currently evaluated method. $\Delta_{overall}$ treats entire KG as a single bag of BETs whereas $\Delta_{predicate}$ segregates beliefs based on their type of predicate-relation. For both metrics, lower is better.

4.2 Baseline Methods

Since accuracy estimation of large multi-relational KGs is a relatively unexplored problem, there are no well established baselines for this task (apart from random sampling). We present below the baselines which we compared against KGEval.

Random: Randomly sample a BET $h \in \mathcal{H}$ without replacement and crowdsource for its correctness. Selection of every subsequent BET is independent of previous selections.

Max-Degree: Sort the BETs in decreasing order of their degrees in ECG and select them from top for evaluation; this method favors selection of more centrally connected BETs first.

Independent Cascade: This method is based on contagion transmission model where nodes only infect their immediate neighbors (Kempe et al., 2003). At every time iteration t, we choose a BET which is not evaluated yet, crowdsource for its label and let it propagate its evaluation label in ECG.

KGEval: Method proposed in Algorithm 1.

4.3 Effectiveness of KGEval

Experimental results of all methods comparing $\Delta_{overall}$ and $\Delta_{predicate}$ at convergence, are presented in Table 3. We observe that KGEval is able to achieve the best estimate across both datasets and metrics. Due to the significant positive bias in $\mathcal{H}_Y$ (see Table 2), all methods do fairly well as per $\Delta_{overall}$ on this dataset, even though KGEval still outperforms others. Also, KGEval is able to estimate KG accuracy most closely while utilizing least number of crowd-evaluated queries. This clearly demonstrates KGEval's effectiveness.

Nodes in coupling graph with higher degrees are those which participate in large number of constraints. In real KGs, such facts tend to be correct as they interact with several other facts. Hence, MaxDegree overestimates the accuracy by propagating True label. In contrast, Random samples True and False labels in unbiased fashion.

Predicate-level Analysis: Here, we consider the top two baselines from Table 3, viz., Random and

NELL sports dataset ($\mathcal{H}_N$)			
Method	$\Delta_{predicate}$ (%)	$\Delta_{overall}$ (%)	# Queries
Random	4.9	1.3	623
Max-Deg	7.7	2.9	1370
Ind-Casc	9.8	0.8	232
KGEval	**3.6**	**0.5**	**140**
Yago dataset ($\mathcal{H}_Y$)			
Random	1.3	0.3	513
Max-Deg	1.7	0.5	550
Ind-Casc	1.1	0.7	649
KGEval	**0.7**	**0.1**	**204**

Table 3: $\Delta_{predicate}(\%)$ and $\Delta_{overall}(\%)$ estimates (lower is better) of various methods with number of crowd-evaluated queries (BET evaluations) to reach the $\Delta_{overall}$ converged estimate. (See Section 4.3)

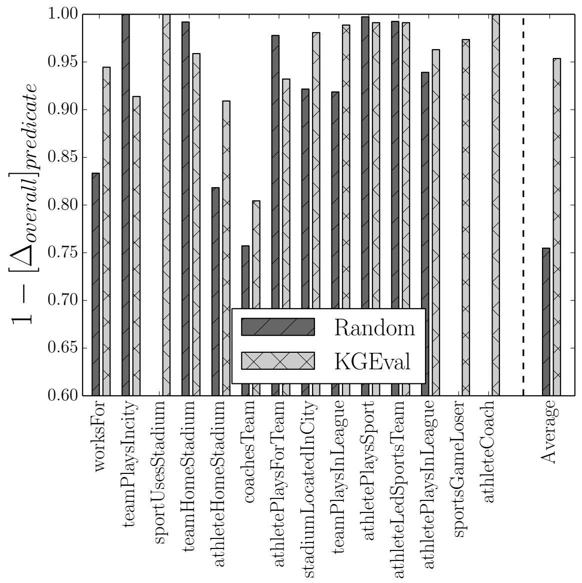

Figure 4: Comparing $(1-[\Delta_{overall}]_{predicate})$ of individual predicates (higher is better) in $\mathcal{H}_N$ between KGEval and Random, the two top performing systems in Table 3. (see Section 4.3)

KGEval, and compare performance on the $\mathcal{H}_N$ dataset. We use $(1-[\Delta_{overall}]_{predicate})$ as the metric, which means $\Delta_{overall}$ computed over individual predicates. Here, we are interested in evaluating how well the two methods have estimated per-predicate accuracy when KGEval's $\Delta_{overall}$ has converged. Comparison of per-predicate performances of the two methods is shown in Figure 4. Observe that KGEval significantly outperforms Random baseline. Its advantage lies in exploiting the coupling constraints among beliefs, where evaluating a belief from certain predicate helps infer beliefs from other predicates.

Constraint Set	Iterations to Convergence	$\Delta_{overall}(\%)$
$\mathcal{C}$	**140**	**0.5**
$\mathcal{C}-\mathcal{C}_{b3}$	259	0.9
$\mathcal{C}-\mathcal{C}_{b3}-\mathcal{C}_{b2}$	335	1.1

Table 4: Performance of KGEval with ablated constraint sets. Additional constraints help in better estimation with lesser iterations.(see Section 4.4)

4.4 Importance of Coupling Constraints

This paper is largely motivated by the thesis – *exploiting richer relational couplings among BETs may result in faster and more accurate evaluations*. To evaluate this thesis, we successively ablated Horn clause coupling constraints of body-length 2 and 3 from $\mathcal{C}_N$.

We observe that with the full (non-ablated) constraint set $\mathcal{C}_N$, KGEval takes least number of crowd evaluations of BETs to convergence, while providing best accuracy estimate. Whereas with ablated constraint sets, KGEval takes up to 2.4x more crowd-evaluation queries for convergence; thus validating our thesis.

4.5 Additional Experiments

Other Baselines along with Inference: In order to evaluate how Random and Max-degree perform in conjunction with inference mechanism, we replaced KGEval's greedy control mechanism in Line 5 of Algorithm 1 with these two control mechanisms. In our experiments, we observed that both *Random+inference* and *Max-degree+inference* are able to estimate accuracy more accurately than their control-only variants. Secondly, even though the accuracies estimated by *Random+inference* and *Max-degree+inference* were comparable to that of KGEval, they required larger number of crowd-evaluation queries – 1.2x and 1.35x more, respectively. This shows effectiveness of greedy mechanism.

Rate of Coverage: In case of large KGs with scarce budget, it is imperative to have a mechanism which covers greater parts of KG with lesser number of crowdsource queries. Figure 5 shows the fraction of total beliefs whose evaluations were automatically inferred by different methods as a function of number of crowd-evaluated beliefs. We observe that KGEval infers evaluation for the largest number of BETs at each supervision level.

Robustness to Noise: In order to test robustness of the methods in estimating accuracies

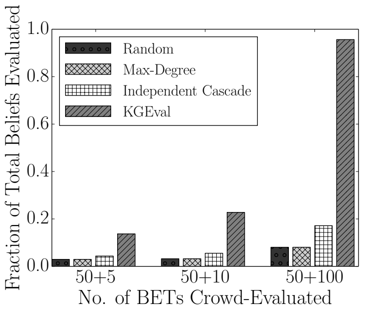

Figure 5: Fraction of total beliefs whose evaluation where automatically inferred by different methods for varying number of crowd-evaluated queries (x-axis) in $\mathcal{H}_N$.

NELL sports + 5% noise ($\mathcal{H}_{N5}$)		
Method	$\Delta_{overall}$ (%)	# Queries
Random	1.8	563
Max-Degree	4.2	1249
Ind-Cascade	1.2	370
KGEval	**0.8**	**106**
NELL sports + 10% noise ($\mathcal{H}_{N10}$)		
Random	1.8	728
Max-Degree	6.2	1501
Ind-Cascade	1.2	406
KGEval	**0.2**	**115**

Table 5: Accuracy estimate (higher is better) over entire KG by various baselines in the presence of noise.

of KGs with different gold accuracies, we artificially added noise to $\mathcal{H}_N$ by flipping a fixed fraction of edges, otherwise following the same evaluation procedure as in Section 3.5. We analyze $\Delta_{overall}$ (and not $\Delta_{predicate}$) because flipping edges in KG distorts predicate-relations dependencies and present in Table 5. We evaluated all the methods and observed that while performance of other methods degraded significantly with diminishing KG quality (more noise), KGEval was significantly robust to noise.

Scalability comparisons with MLN: Markov Logic Networks (Richardson and Domingos, 2006) can serve as a candidate for Inference Mechanism. We compared the runtime performance of KGEval with PSL and MLN as inference engines. While PSL took 320 seconds to complete one iteration, the MLN implementation (PyMLN) could not finish grounding the rules even after 7 hours. This justifies our choice of PSL as the inference engine for KGEval.

5 Related Work

Even though Knowledge Graph (KG) construction is an active area of research, we are not aware of any previous research which systematically studies the important problem of estimating accuracy of such automatically constructed KGs. Random sampling has traditionally been the most preferred way for large-scale KG accuracy estimation (Mitchell et al., 2015).

Traditional crowdsourcing research has typically considered atomic allocation of tasks where the requester posts them *independently*. KGEval operates in a rather novel crowdsourcing setting as it exploits dependencies among its tasks (BETs or belief evaluations). Our notion of interdependence (coupling constraints) among tasks is more general and different than related ideas explored in the crowdsourcing literature before (Kolobov et al., 2013; Bragg et al., 2013; Sun et al., 2015). Even though coupling constraints have been used for KG construction (Nakashole et al., 2011; Galárraga et al., 2013; Mitchell et al., 2015), they have so far not been exploited for KG evaluation. We address this gap in this paper.

The task of knowledge corroboration (Kasneci et al., 2010) proposes probabilistic model to utilize a fixed set of basic first-order logic rules for label propagation and is closely aligned with our motivations. However, unlike KGEval, it does not try to reduce the number of queries to crowdsource or maximize coverage.

6 Conclusion

In this paper, we have initiated a systematic study into the important problem of evaluation of automatically constructed Knowledge Graphs. In order to address this challenge, we have proposed KGEval, an instance of a novel crowdsourcing paradigm where dependencies among tasks presented to humans (BETs) are exploited. To the best of our knowledge, this is the first method of its kind. We demonstrated that the objective optimized by KGEval is in fact NP-Hard and submodular, and hence allows for the application of simple greedy algorithms with guarantees. Through extensive experiments on real datasets, we demonstrated effectiveness of KGEval. We hope to extend KGEval to incorporate varying evaluation cost, and also explore more sophisticated evaluation aggregation.

A Appendix

Submodularity: A real valued function f, which acts over subsets of any finite set $\mathcal{H}$, is said to be *submodular* if $\forall R, S \subset \mathcal{H}$ it fulfills

$$f(R) + f(S) \geq f(R \cup S) + f(R \cap S).$$

We call potential function ψ as pairwise *regular* if for all pairs of BETs $\{p, q\} \in \mathcal{H}$ it satisfies

Proof. **(for Theorem 1)** The additional utility, in terms of label inference, obtained by adding a BET to larger set is lesser than adding it to any smaller subset. By construction, any two BETs which share a common factor node $\mathcal{C}_j$ are encouraged to have similar labels in G.

Potential functions ψ_j of Equation (3) satisfy pairwise regularity property i.e., for all BETs $\{p, q\} \in \mathcal{H}$

$$\psi(0,1) + \psi(1,0) \geq \psi(0,0) + \psi(1,1) \tag{4}$$

where $\{1, 0\}$ represent true/false. Equivalence of *submodular* and *regular* properties are established (Kolmogorov and Zabih, 2004; Jegelka and Bilmes, 2011). Using non-negative summation property (Lovász, 1983), $\sum_{j \in C} \theta_j \psi_j$ is submodular for positive weights $\theta_j \geq 0$.

We consider a BET h to be confidently inferred when the soft score of its label assignment in $\mathcal{I}(G, \mathcal{Q})$ is greater than threshold $\tau_h \in [0, 1]$. From above we know that $\mathbb{P}(l(h)|\mathcal{Q})$ is submodular with respect to fixed initial set $\mathcal{Q}$. Although $\max$ or $\min$ of submodular functions are not submodular in general, but (Kempe et al., 2003) conjectured that global function of Equation (1) is submodular if local threshold function $\mathbb{P}(h|\mathcal{Q}) \geq \tau_h$ respected submodularity, which holds good in our case of Equation (3). This conjecture was further proved in (Mossel and Roch, 2007) and thus making our global optimization function of Equation (1) submodular. □

Proof. **(for Theorem 2)** We reduce KGEval to NP-complete Set-cover Problem (SCP) so as to select $\mathcal{Q}$ which covers $\mathcal{I}(G, \mathcal{Q})$. For the proof to remain consistent with earlier notations, we define SCP by collection of subsets $\mathcal{I}_1, \mathcal{I}_2, \ldots, \mathcal{I}_m$ from set $\mathcal{H} = \{h_1, h_2, \ldots, h_n\}$ and we want to determine if there exist k subsets whose union equals $\mathcal{H}$. We define a bipartite graph with $m + n$ nodes corresponding to $\mathcal{I}_i$'s and h_j's respectively and construct edge $(\mathcal{I}_i, h_j)$ if $h_j \in \mathcal{I}_i$. We need to find a set $\mathcal{Q}$, with cardinality k, such that $|\mathcal{I}(G, \mathcal{Q})| \geq n + k$.

Choosing our BET-set $\mathcal{Q}$ from SCP solution and further inferring evaluations of other remaining BETs using PSL will solve the problem in hand. □

A.1 Noisy Crowd Workers and Budget

Here, we provide a scheme to allot crowd workers so as to remain within specified budget and upper bound total error on accuracy estimate. We have not integrated this mechanism with Algorithm 1 to maintain its simplicity.

We resort to majority voting in our analysis and assume that crowd workers are not adversarial. So expectation over responses $r_h(u)$ for a task h with respect to multiple workers u is close to its true label $t(h)$ (Tran-Thanh et al., 2013), i.e.,

$$\left| \mathbb{E}_{u \sim \mathbb{D}(u,h)}[r_h(u)] - t(h) \right| \leq \frac{1}{2} \tag{5}$$

where $\mathbb{D}$ is joint probability distribution of workers u and tasks h.

Our key idea is that we want to be more confident about BETs h with larger inferable set (as they impact larger parts of KG) and hence allocate them more budget to post to more workers. We determine the number of workers $\{w_{h_1}, \ldots, w_{h_n}\}$ for each task such that h_t with larger inference set have higher w_{h_t}. For total budget B, we allocate

$$w_{h_t} = \left\lfloor \tfrac{B\ i_t\ (1-\gamma)}{c\ i_{max}} \right\rfloor$$

where i_t denotes the cardinality of inferable set $\mathcal{I}(G, \mathcal{Q} \cup h_t)$, c the cost of querying crowd worker, i_{max} the size of largest inferable set and $\gamma \in [0, 1]$ constant.

This allocation mechanism easily integrates with Algorithm 1; in (Line 8) we determine size of inferable set $i_t = |\mathcal{Q}_t|$ for task h and allocate w_h crowd workers. Budget depletion (Line 9) is modified to $B_r = B_r - w_h c(h)$. The following theorem bounds the error with such allocation scheme.

Theorem 3. [Error bounds] *The allocation scheme of redundantly posing h_t to w_{h_t} workers does not exceed the total budget B and its expected estimation error is upper bounded by $e^{-O(i_t)}$, keeping other parameters fixed. The expected estimation error over all tasks is upper bounded by $e^{-O(B)}$.*

Proof. Let $\gamma \in [0, 1]$ control the reduction in size of inferable set by $i_{t+1} = \gamma\, i_t$. By allocating w_{h_t} redundant workers for task $h_t, \forall t \in \{1 \cdots n\}$ with size of inferable set i_t, we incur total cost of

$$\begin{aligned}
\sum_{t=1}^{n} c\, w_{h_t} &= \sum_{t=1}^{n} \frac{B\ i_t\ (1-\gamma)}{c\ i_{max}} \cdot c \\
&= \left(\sum_{t=1}^{n} i_t\right) \cdot \left(\frac{B\ (1-\gamma)}{i_{max}}\right) \\
&= \left(\frac{i_{max}\ (1-\gamma^T)}{(1-\gamma)}\right) \cdot \left(\frac{B\ (1-\gamma)}{i_{max}}\right) \\
&\leq B
\end{aligned}$$

Note that the above geometric approximation helps in estimating summation $\sum_{t=1}^{n} i_t$ at iteration $t \leq n$.

Error Bounds: Here we show that the expected error of estimating of h_t for any time t decreases exponentially in the size of inferable set i_t. We use majority voting to aggregate w_{h_t} worker responses for h_t, denoted by $\hat{r}_{h_t} \in \{0, 1\}$

$$\hat{r}_{h_t} = \left\lfloor \frac{1}{w_{h_t}} \sum_{k=1}^{w_{h_t}} r_{h_t}(u_k) - \frac{1}{2} \right\rfloor + 1 \tag{6}$$

where $r_{h_t}(u_k)$ is the response by k^{th} worker for h_t. The error from aggregated response can be given by $\Delta(h_t) = |\hat{r}_{h_t} - t(h_t)|$, where $t(h_t)$ is its true label. From Equation (5) and Hoeffding-Azuma bounds over w_{h_t} i.i.d responses and error margin ε_t, we have

$$\begin{aligned}
\Delta(h_t) &= \mathbb{P}\left\{ \left| \frac{1}{w_{h_t}} \sum_{k=1}^{w_{h_t}} r_{h_t}(u_k) - \mathbb{E}(r_h(u)) \right| \geq \varepsilon_t \right\} \\
&= 2 \exp\left(-2\, \frac{B\ i_t\ (1-\gamma)}{c\ i_{max}}\ \varepsilon_t^2 \right)
\end{aligned}$$

For fixed budget B and given error margin ε_t, we have $\Delta(h_t) = e^{-O(i_t)}$. Summing up over all tasks t, by union bounds we get the total expected error from absolute truth as $\Delta(B) = \sum_{t=1}^{n} \Delta(h_t)$.

$$\begin{aligned}
\Delta(B) &\leq \sum_{t=1}^{n} 2 \exp\left(-2\, \frac{B\ i_t\ (1-\gamma)}{c\ i_{max}}\ \varepsilon_t^2 \right) \\
&\leq n \cdot 2 \exp\left(-2\, \frac{B\ i_{min}\ (1-\gamma)}{c\ i_{max}}\ \varepsilon_{min}^2 \right)
\end{aligned}$$

The accuracy estimation error will decay exponentially with increase in total budget for fixed parameters. □

Sparsity and Noise:
Where Knowledge Graph Embeddings Fall Short

Abstract

Knowledge graph (KG) embedding techniques use structured relationships between entities to learn low-dimensional representations of entities and relations. One prominent goal of these approaches is to improve the quality of knowledge graphs by removing errors and adding missing facts. Surprisingly, most embedding techniques have been evaluated on benchmark datasets consisting of dense and reliable subsets of human-curated KGs, which tend to be fairly complete and have few errors. In this paper, we consider the problem of applying embedding techniques to KGs extracted from text, which are often incomplete and contain errors. We compare the sparsity and unreliability of different KGs and perform empirical experiments demonstrating how embedding approaches degrade as sparsity and unreliability increase.

1 Introduction

Recently knowledge graphs (KGs), structured representations of knowledge bases, have become an essential component of systems that perform question-answering (Berant et al., 2013), provide decision support, and enable exploration and discovery (Dong et al., 2014). Initial efforts to create KGs focused on structured information sources or relied extensively on manual curation. However, the diversity of knowledge available on resources like the World Wide Web have spurred many projects that tackle the more difficult task of automatically constructing KGs (Nickel et al., 2016a).

Unfortunately, information extraction approaches for KG construction must overcome complex, unreliable, and incomplete data. Many machine learning methods have been proposed to address the challenge of cleaning and completing KGs. One popular class of methods learn embeddings that translate entities and relationships into a latent subspace, then use this latent representation to derive additional, unobserved facts and score existing facts (Bordes et al., 2013; Wang et al., 2014; Lin et al., 2015).

Embedding methods have shown state-of-the-art results on several benchmark datasets. However, by construction, these benchmark datasets differ from data in real KGs. First, benchmark datasets have largely been restricted to the most frequently occurring entities in the KG. However in most KGs, entities are associated with a sparse set of observations. Second, benchmark datasets consist only of highly reliable facts from curated knowledge bases. In contrast, many KG construction projects extract knowledge from noisy data such as text or images, which introduces unreliable information.

In this paper, we evaluate popular KG embedding approaches on KGs that have sparse entities and unreliable candidate facts. We apply embedding methods to an extracted KG and modify existing benchmarks by varying the sparsity and reliability of training data used to learn embedding models. Using this suite of datasets, we characterize where embedding approaches are successful and the conditions that result in degrading results. Based on our insights, we provide recommendations for improving embedding models and identify promising areas of future exploration.

Dataset	Triples	$\|E\|$	$\|R\|$	EE	RE	ED	RD	prec
Freebase	1B	124M	15K	14	3.2	16	68K	1
WordNet	380K	116K	27	21	2.3	7	21K	1
NELL1000	92M	4.8M	435	21	4.9	19	210K	0.45
FB15K	592K	15K	1.3K	16	5.1	79	440	1
WN18	151K	40K	18	19	2.1	7	8.4K	1
NELL165	1M	820K	221	25	1.5	3	4.7K	0.35

Table 1: Statistics of knowledge graphs and extracted datasets. Triples are the number of individual facts in the knowledge graph. $\|E\|$ and $\|R\|$ are unique entities and relations in the KG, respectively. EE and RE are measures of entropy, ED and RD measures of density, and prec is the precision of triples.

2 Background and Related Work

Diverse strategies for knowledge base construction include manually-crafted ontologies for common-sense reasoning (Lenat, 1995), community-driven collaborative efforts (Bollacker et al., 2008), ontology-based extraction from structured and textual sources (Mitchell et al., 2015), and "open" approaches that rely on textual information (Mausam et al., 2012). In this paper, we contrast the properties of two knowledge graphs that have clean, human-vetted facts with two knowledge graphs that are extracted from textual data.

Semantically meaningful embeddings of text have been a longstanding topic of study in NLP research (Turney and Pantel, 2010). More recently, knowledge graphs, which capture structured relationships between entities, has inspired methods such as matrix factorization (Riedel et al., 2013), tensor factorization (Nickel et al., 2011), and deep learning (Socher et al., 2013) that embed entities while preserving this relationship structure. We consider four state-of-the-art embedding methods (Bordes et al., 2013; Wang et al., 2014; Nickel et al., 2016b; Nguyen et al., 2016) and assess their performance on knowledge graphs with different properties.

3 Comparing Properties of KGs

In Table 1, we introduce three knowledge graphs and a parallel set of benchmark datasets derived from these KGs. Each KG takes the form of triples that specify a relationship between a subject and an object. The first two KGs, Freebase and WordNet, benefit from human curation that results in precisely defined entities and relationships and highly reliable facts. The third KG, NELL, is extracted from a large Web text corpus using an iterative co-training process and a pre-defined set of relations and types. Due to the iterative nature, NELL is a dynamic dataset and the table reports statistics of the 1000th iteration. FB15K and WN18, derived from Freebase and WordNet, respectively, have been used to train and evaluate many embedding strategies. NELL165, based on an earlier iteration of NELL, has been used as a benchmark for probabilistic models. We compare the vital statistics of these six datasets.

3.1 Size and Sampling

Despite the reliance on curation, Freebase is the largest KG with more facts ($\|T\|$), unique entities ($\|E\|$), and relationship types ($\|R\|$) than others. NELL, is a tenth the size of Freebase with substantially fewer entities and limited relations. WordNet, focused on NLP, is the smallest and expresses only 27 relationships between different words. The derived benchmark datasets are substantially smaller than the source KGs, with the largest, NELL, containing 1M facts. FB15K is generated by sampling a subset of the KG centered around 15K entities. WN18 is generated by restricting to 18 relations. NELL165 performs no sampling, but is limited by the comprehensiveness of patterns learned during training.

3.2 Diversity

To understand the distribution of entities and relationships in the KG, we introduce an entropy-based measure using the probability an entity or relation will occur in a randomly selected triple. For triples T of the form (s, p, o), relations R, entities E, We define the entity and relation probabilities as the probability that a randomly selected triple will contain a particular relation or entity. More formally, we define these probabilities:

$$P(r) = \frac{|t.p = r|}{\|T\|}\ ;\quad P(e) = \frac{|t.s = e| + |t.o = e|}{\|T\|}$$

Using these definitions, we define:

$$RE = \sum_{r \in R} -P(r) \log P(r)$$

We compute entity entropy (EE) and relation entropy (RE) for each dataset. Higher entropy values indicate more uniform distributions of facts across entities and relations, lower values signal biases in the facts. For example, the low RE values for Freebase and NELL165 are due to an abundance of facts specifying entity types (such as person), relative to other relations between entities. While Freebase has the most facts and entities, these facts are less diverse compared to other KGs. Through sampling, FB15K rebalances Freebase, increasing the diversity of entities and relations. In contrast, WordNet and WN18 have similar diversity statistics. Compared to NELL1000, NELL165 has a more diverse set of entities and a less diverse set of relations. All KGs have much higher EE than RE, since they use a manually defined set of relations but include many diverse entities.

3.3 Sparsity

In addition to diversity, KGs have differing levels of factual information for each entity or relation. One sparsity metric is information density, defined as the average triples per entity or relation. We formally define densities:

$$RD = \frac{\|T\|}{\|R\|}; \quad ED = \frac{2\|T\|}{\|E\|}$$

We compare the datasets using entity density (ED) and relational density (RD). Most datasets have a similar ED, but the benchmark dataset FB15K has much higher entity density while the benchmark dataset NELL165 has a much lower entity density. NELL1000 has the highest RD, since extractions are focused on a small set of relations, while FB15K has a particularly low RD value due to the entity-centric approach to construction. We note that FB15K has much higher ED and much lower RD than parent Freebase, due to the sampling choices made during its construction.

3.4 Reliability

Embedding approaches rely on using facts that are reliable. Human-curated KGs generally have high precision due to strong oversight. In contrast, extracted KGs are far noisier, including erroneous relationships between entities. Extracted KGs are often evaluated on small, manually-labeled evaluation sets to estimate precision. In recent evaluations (Mitchell et al., 2015) using 11K annotations, NELL facts had a precision of ranging from 0.75-0.85 for confident extractions and 0.35-0.45 across the broader set of extractions.

4 Empirical Evaluation

To better understand embedding performance with sparse and unreliable data, we select four popular embedding approaches and perform four empirical analyses. We evaluate embedding techniques TransE (Bordes et al., 2013), TransH (Wang et al., 2014), HolE (Nickel et al., 2016b), and STransE (Nguyen et al., 2016), that use increasingly sophisticated learning methods to represent entities and relations. To learn embeddings, we used the public implementations of Lin et al. (2015); Nickel et al. (2016b); Nguyen et al. (2016). We conduct four experiments to characterize the performance of these embeddings methods. The first set of experiments evaluate the performance of embeddings on the extracted NELL165 KG. The second set of experiments modify the existing FB15K benchmark to isolate the impact of sparsity on embedding quality. The third set of experiments decrease the reliability of FB15K and determine how performance degrades as a result. The final experiments explore the tradeoff between sparsity and reliability by beginning with a sparse trainng set and incrementally adding unreliable triples at differing noise levels.[1]

[1] Code for experiments is available at `https://www.github.com/linqs/pujara-emnlp17`

Method	AUPRC	F1
Baseline	0.873	0.828
NELL	0.765	0.673
TransH	0.701	0.783
HolE	0.710	0.783
TransE	0.726	0.783
STransE	0.784	0.783
PSL-KGI	**0.891**	**0.848**

Table 2: Embedding performance on the sparse and noisy NELL165 benchmark is poor, failing to beat a baseline that simply selects the top extractions, and substantially underperforming probabilistic models.

4.1 Extracted Knowledge Graphs

In Section 3, we noted that the extracted NELL165 dataset is sparse, with fewer (candidate) facts per relation or entity than the FB15K benchmarks. Moreover, the precision of these candidates can be far lower than benchmark datasets. To evaluate whether embeddings can succeed under such challenging conditions, we applied four state-of-the-art embedding techniques,

We evaluated all methods on 4.5K manually-labeled facts (Jiang et al., 2012), reporting the area under the precision-recall curve (AUPRC) and the F1 score, computed with parameters that maximize performance on the labeled training set. We compare against a baseline that simply applies a threshold to NELL extractor confidences (but cannot score novel facts), the NELL promotion strategy, and a probabilistic approach PSL-KGI (Pujara et al., 2015), that reasons collectively about KG facts using ontological constraints and supports open-world reasoning. The results, in Table 2, suggest that embedding approaches cannot cope with the sparse and low-quality extractions, performing more poorly than the baseline approaches and substantially trailing the probabilistic model. In the next two experiments, we analyze whether this failure can be attributed to sparsity or sensitivity to noise.

4.2 Sensitivity to Sparsity

One potential explanation for the lackluster performance of embedding approaches on extracted KGs is the sparsity of these datasets. To assess the impact of sparsity on the quality of learned embeddings, we remove triples from FB15K using two different techniques. The first technique, `sparse`, removes triples uniformly at random, with a constraint that such removal does not eliminate any entity or relation from the dataset. The second technique, `stable`, removes all triples for a particular relation, leaving other relations intact. `stable` is calibrated so that the training set size does not vary more than 2% between techniques.

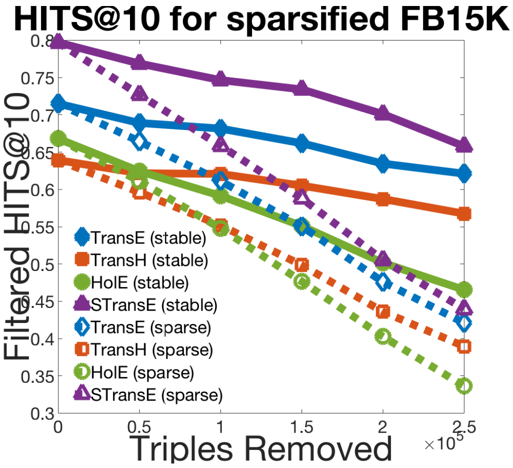

Figure 1: Triples are removed from FB15K to preserve relational density (`stable`, solid) or to increase sparsity (`sparse`, dotted). Sparse training sets have a pronounced impact on the learned embedding, as measured by HITS@10 on the test set.

Fig. 1 shows the filtered hits@10 metric (proportion of correct triples in top ten triples excluding training data) for both `sparse` and `stable` using the TransE, TransH, HolE, and STransE embeddings. Performance universally decreases as the training set diminishes. However, in the `sparse` treatment, performance deteriorates much more rapidly than in `stable`. Our experiments show that more complex representations such as TransH and HolE suffer more from sparsity, while TransE and the more sophisticated STransE have somewhat better performance. Ultimately, when half the triples have been randomly removed, corresponding to a (relatively high) RD value of 220, the `stable` outperforms `sparse` by as much as 60%. The contrast between a dense set of facts for each relation (`stable`) and a sparse set of relational training data is a vivid demonstration that embedding quality relies on dense training data.

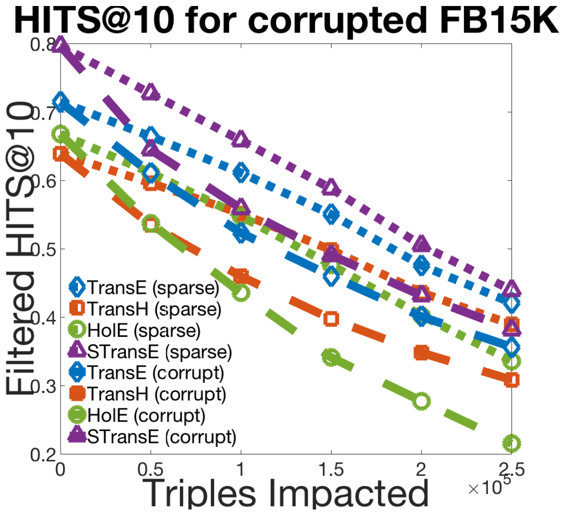

Figure 2: Randomly corrupting triples (`corrupt`, dashed) during training decreases embedding quality relative to randomly removing triples (`sparse`, dotted).

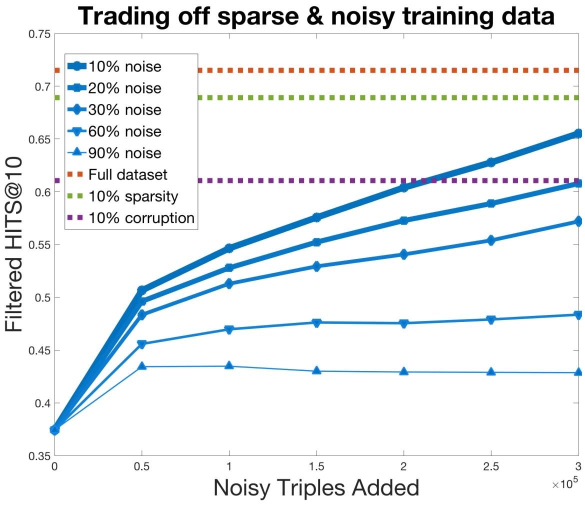

Figure 3: Starting with a sparse training set, adding unreliable triples can help embedding performance recover if the noise level is low.

4.3 Sensitivity to Unreliability

Beyond sparsity, candidate facts generated by knowledge extraction approaches can also be unreliable. To understand the sensitivity of embedding techniques to noise, we modified the FB15K dataset to include unreliable triples. Our approach to introducing noise, `corrupt` involved "corrupting" triples, substituting a replacement entity or relation for the true subject, predicate or object. The embedding approach is then trained with a corrupted version of the benchmark. Fig. 2 show how the Hits@10 metric suffers as increasing numbers of facts are either corrupted (`corrupt`) or removed (`sparse`). We find that across all methods, removing training data is better than providing incorrect training data to the learning algorithm, but surprisingly the deficit between `sparse` and `corrupt` remains relatively stable across all embeddings.

4.4 Trading off Sparsity and Noise

In many real-world scenarios, constructing a KG requires navigating a tradeoff between sparsity and noise. A sparse, high-quality set of extractions may be insufficient to learn meaningful embeddings. However, the benefit of incorporating additional, unreliable facts may also be questionable. We explore this tradeoff by randomly removing $300K$ triples from FB15K and incrementally adding unreliable triples at differing noise levels, where noise measures the probability a newly-added training triple is corrupted. We generate training sets for each noise level and size, train TransE, and compute the filtered Hits@10 metric on the test set. Fig. 2 shows all embeddings have an initial benefit from new training data, but noise level dictates the improvement as more data is introduced. For low noise settings, performance climbs steadily, while higher noise results in plateauing or diminishing performance. Surprisingly, even with 90% noise embeddings demonstrate a small net improvement, suggesting that for embedding methods a large, unreliable corpus may be better than an extremely sparse, high-quality one.

5 Conclusion

In this paper, we analyze several knowledge graphs and discuss key metrics for diversity, sparsity, and unreliability in realistic KGs. Our experimental evaluation concludes that KG embeddings are sensitive to sparse and unreliable data, and perform poorly on KGs extracted from text. These findings suggest a rich area of future research, determining new strategies to extend embeddings to cope with sparse and unreliable data. Three promising approaches include revising the closed-world assumption frequently used in training embeddings, combining embeddings and collective probabilistic models that perform well on extracted KGs, and devising an optimization approach for embeddings that exploits confidence from knowledge extraction systems.

Dual Tensor Model for Detecting Asymmetric Lexico-Semantic Relations

Goran Glavaš and **Simone Paolo Ponzetto**
Data and Web Science Group
University of Mannheim
B6, 26, DE-68159 Mannheim, Germany
{goran, simone}@informatik.uni-mannheim.de

Abstract

Detection of lexico-semantic relations is one of the central tasks of computational semantics. Although some fundamental relations (e.g., hypernymy) are asymmetric, most existing models account for asymmetry only implicitly and use the same concept representations to support detection of symmetric and asymmetric relations alike. In this work, we propose the Dual Tensor model, a neural architecture with which we explicitly model the asymmetry and capture the translation between unspecialized and specialized word embeddings via a pair of tensors. Although our Dual Tensor model needs only unspecialized embeddings as input, our experiments on hypernymy and meronymy detection suggest that it can outperform more complex and resource-intensive models. We further demonstrate that the model can account for polysemy and that it exhibits stable performance across languages.

1 Introduction

Detection of semantic relations that hold between words is the central task of lexical semantics, tightly coupled with obtaining representations that capture meaning of words (Mikolov et al., 2013; Wieting et al., 2015; Mrkšić et al., 2016, *inter alia*). As such, robust detection of lexico-semantic relations may benefit virtually any natural language processing application.

Because lexico-semantic knowledge bases (KBs) like WordNet (Fellbaum, 1998) are general and of limited coverage, numerous methods for detecting lexico-semantic relations rely on distributional word representations obtained from large corpora. Although distributional models have evolved over time, from count-based (Landauer et al., 1998) and generative (Blei et al., 2003) to prediction-based (Mikolov et al., 2013), the similarity between distributional vectors still indicates only the abstract semantic association and not a precise semantic relation (e.g., vectors of antonyms may be as similar as vectors of synonyms).

Consequently, a number of approaches have been proposed for specializing distributional spaces for specific lexico-semantic relations, either by (1) modifying the learning objective or regularization of the original embedding model by incorporating linguistic constraints (Yu and Dredze, 2014; Kiela et al., 2015) or (2) retroactively fitting the pre-trained unspecialized embeddings to linguistic constraints (Faruqui et al., 2015; Mrkšić et al., 2016). However, these methods specialize distributional vector spaces primarily for detecting the symmetric relation of *semantic similarity* (i.e., graded synonymy) and not for asymmetric lexico-semantic relations such as *hypernymy* and *meronymy*. On the other hand, models for embedding KBs (Bordes et al., 2013; Socher et al., 2013; Yang et al., 2015) uniformly model both symmetric and asymmetric relations. They learn a single vector representation (i.e., embedding) for each KB concept, assuming implicitly that the same concept representation is equally useful for predicting symmetric and asymmetric relations alike.

Relation-specific learning-based models have, to the largest extent, targeted hypernymy. Distributional models predict the hypernymy relations by combining raw distributional vectors of concepts in a pair (Baroni et al., 2012; Roller et al., 2014; Santus et al., 2014), whereas path-based models base predictions on lexico-syntactic paths from co-occurrence contexts obtained from a large corpus (Snow et al., 2004; Nakashole et al., 2012; Shwartz et al., 2016). Shwartz et al. (2016) combine the path-based and distributional models to

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1757–1767
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

reach state-of-the-art performance in hypernymy detection. Both distributional and path-based methods, however, model asymmetry only implicitly (e.g., via the order of embeddings in the concatenation). Besides, path-based models are language-dependent since they require syntactically preprocessed data as input.

In this work, we propose the Dual Tensor model, a neural architecture that (1) models asymmetry more explicitly than existing models and (2) explicitly captures the translation of unspecialized distributional vectors into specialized embeddings better suited to detect the asymmetric relation of interest. The Dual Tensor model can be considered distributional as it requires only distributional vectors of words as input. Consequently, in contrast to path-based methods, it is language-independent and more widely applicable. Experimental results on hypernymy and meronymy detection show that the Dual Tensor model outperforms both distributional and path-based models. We additionally demonstrate that our approach exhibits stable performance across languages and can, to some extent, diminish the negative effects of polysemy.

2 Related Work

Specializing Word Embeddings. Unspecialized word embeddings (Mikolov et al., 2013; Pennington et al., 2014) capture general semantic properties of words, but are unable to differentiate between different types of semantic relations (e.g., vectors of *car* and *driver* might be as similar as vectors of *car* and *vehicle*). However, we often need embeddings to be similar only if an exact lexico-semantic relation holds between the words. Numerous methods for specializing word embeddings for particular relations have been proposed (Yu and Dredze, 2014; Faruqui et al., 2015; Kiela et al., 2015; Mrkšić et al., 2016, *inter alia*), primarily aiming to differentiate synonymic similarity from other types of semantic relatedness.

Some methods modify the objective or regularization of general embedding algorithms like CBOW or skip-gram (Mikolov et al., 2013) in order to directly train relation-specific embeddings from large corpora. Yu and Dredze (2014) extend the CBOW objective with synonymy constraints from WordNet and Paraphrase Database (PPDB) (Ganitkevitch et al., 2013). Similarly, Kiela et al. (2015) add synonyms as additional contexts for the skip-gram objective.

Other models update the whole unspecialized embedding space by moving closer together vectors of words standing in a particular relation. Starting with unspecialized embeddings of concepts, Faruqui et al. (2015) run a belief propagation algorithm on a graph induced from WordNet or PPDB. Wieting et al. (2015) couple an objective maximizing the similarity of PPDB pairs with the smart selection of the negative examples. Mrkšić et al. (2016) take this idea further by using antonym pairs from WordNet as negative examples.

All aforementioned models either directly train specialized embeddings or derive them by updating the unspecialized embeddings. In contrast, via dual tensors, we explicitly capture the function that transforms unspecialized embeddings to specialized embeddings that are better suited to detect the asymmetric relation of interest.

Embedding Knowledge Graphs. Recently, various models for embedding KB concepts and relations have been proposed (Bordes et al., 2013; Socher et al., 2013; Yang et al., 2015; Nickel et al., 2016, *inter alia*). These models predict existence of relations between entities by arithmetically combining concept vectors and relation matrices or tensors. The scoring functions of KG embedding models combine the concept embeddings via linear product (i.e., relation tensor multiplies the concatenation of concept vectors of the two entities) (Bordes et al., 2011), bilinear product (i.e., relation tensor first multiplies the left concept embedding and the result multiplies the embedding of the second concept) (Yang et al., 2015), or the combination of the two (Socher et al., 2013). Both linear and bilinear scoring functions implicitly model asymmetry as they are not commutative with respect to concept embeddings. In this work, we choose to leverage the bilinear product in our model, following the findings of Yang et al. (2015) who report bilinear product outperforming other scoring combinations.

KG embedding models employ the same concept embeddings for predicting all relations, symmetric and asymmetric alike. By directly updating concept embeddings in training, they cannot make relation predictions for concepts outside of the training set.

Hypernymy and Meronymy Detection. Hypernymy and meronymy are arguably the two most prominent asymmetric lexico-semantic relations. Methods for their detection can roughly be classified as either distributional or path-based. Path-based methods consider lexico-syntactic paths connecting pairs of words in their co-occurrence contexts in large corpus. Early approaches, e.g., Hearst (1992) for hypernymy and Berland and Charniak (1999) for meronymy, exploited a small set of manually created lexico-syntactic patterns that imply a relation of interest (e.g., *a such as b*). Subsequent approaches looked at ways to eliminate the need for manual compilation of extraction patterns. Pantel and Pennacchiotti (2006) and Girju et al. (2006) proposed bootstrapping approaches to meronymy detection, starting from a seed set of part-whole pairs. Snow et al. (2004) provided all dependency paths connecting the concepts in corpus to a logistic regression classifier for hypernymy detection.

Distributional methods detect asymmetric relations using only distributional vectors of words as input. Distributional models come in both unsupervised and supervised flavors. Unsupervised metrics for hypernymy detection assume either that the hyponym's contexts are included in the hypernym's contexts (Weeds and Weir, 2003; Kotlerman et al., 2010) or that the linguistics contexts of a hyponym are more informative than the contexts of its hypernyms (Rimell, 2014; Santus et al., 2014). Supervised hypernymy classifiers represent the pair of words by combining their distributional vectors in different ways – concatenating them (Baroni et al., 2012) or subtracting them (Roller et al., 2014) – and feeding the resulting vector to a supervised classifier like logistic regression. Most recently, Shwartz et al. (2016) coupled path-based and distributional information with a recurrent neural network (RNN), yielding state-of-the-art hypernymy detection performance. Although our Dual Tensor model is purely distributional, we show that it may outperform such a hybrid model which additionally exploits syntactic information.

Distributional and path-based models have been used to discriminate between multiple lexico-semantic relations, including hypernymy and meronymy, at once (Santus et al., 2016; Shwartz and Dagan, 2016). However, as pointed out by (Chersoni et al., 2016), distributional vectors and scores based on their comparison fail to discriminate between multiple relation types at once. In this work, we focus on binary classification for a single relation (hypernymy and meronymy) at a time.

3 Dual Tensor Model

The following assumptions and desirable properties guided the design of the Dual Tensor model for detection of asymmetric lexico-semantic relations:

(1) Unspecialized distributional vectors are not good signals for detecting specific lexico-semantic relations. We thus need to derive specialized representations that are better suited for detecting the specific asymmetric relation of interest.

(2) The transformation from unspecialized distributional vectors of words to their relation-specialized embeddings should be captured explicitly, via a well-defined transformation function. Having an explicit embedding specialization function alleviates the need to specialize the entire unspecialized embedding space at once, like existing models do (Faruqui et al., 2015; Mrkšić et al., 2016).

(3) Each concept should have two different relation-specialized embeddings – one for each end of an asymmetric relation. For instance, for hypernymy, the concept's specialized embedding for pairs in which it is considered to be a hyponym (e.g., *dog* in *dog–animal*) should differ from its embedding in pairs in which it is tested as a hypernym (e.g., *dog* in *maltese–dog*).

(4) An unspecialized distributional vector of the word might – for each end of the asymmetric relation – be transformed into several specialized vectors instead of only one. This way the model may implicitly account for polysemy – i.e., different specialized vectors might capture asymmetric properties of different senses of polysemous words. E.g., the hyponym properties of *bank* in the pair *bank* vs. *building* may be different from those in the pair *bank* vs. *company*).

Figure 1 depicts the overall architecture of the Dual Tensor model, incorporating all four of above-mentioned design guidelines.

3.1 Dual Tensors

For a given pair of concepts (c_1, c_2), Dual Tensor model computes the score $s(c_1, c_2)$ indicating the likelihood that an asymmetric lexico-semantic relation holds between the concepts (e.g., for meronymy, how likely it is that c_1 is a *part of* c_2). The model takes as input the unspecialized embeddings of the two concepts, e_1 and e_2. For single-word concepts these are simply pre-trained word embeddings, whereas for multi-word concepts, similar to (Socher et al., 2013), we average the pre-trained embeddings of constituent words.

The unspecialized input embeddings are next translated into specialized embeddings, meant to

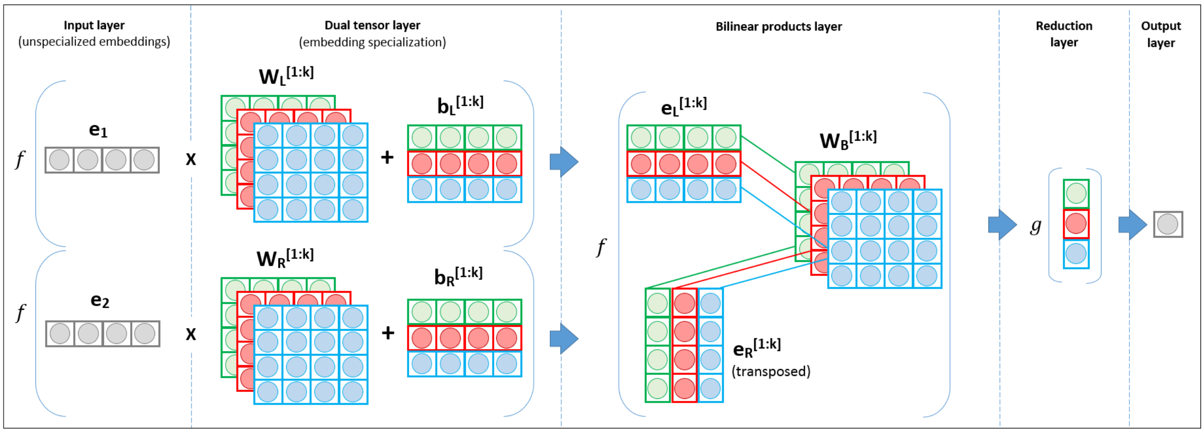

Figure 1: The architecture of the Dual Tensor model.

better capture the existence of the asymmetric relation between the concepts, via *specialization tensors*. By introducing dedicated tensors we – unlike existing models, which directly propagate updates to unspecialized embeddings (Faruqui et al., 2015; Mrkšić et al., 2016) – explicitly learn the specialization function. With an explicit specialization function, we do not have to specialize the whole embedding space at once. Also, unlike KG completion models (Bordes et al., 2013; Socher et al., 2013), we can make predictions for pairs involving concepts unseen in the training data.

We explicitly model asymmetry by introducing two specialization tensors (hence the model name) that differently specialize the unspecialized input embeddings of concepts. The left tensor, $\mathbf{W_L^{[1:k]}}$ (with the corresponding set of bias vectors $\mathbf{b_L^{[1:k]}}$), specializes the concept embedding if the concept is the first element of the pair, whereas the right tensor, $\mathbf{W_R^{[1:k]}}$ (with bias vectors $\mathbf{b_R^{[1:k]}}$), specializes the concept embedding when the concept is the second element of the pair:

$$\mathbf{e_L^{[1:k]}} = tanh\left(e_1\mathbf{W_L^{[1:k]}} + \mathbf{b_L^{[1:k]}}\right)$$
$$\mathbf{e_R^{[1:k]}} = tanh\left(e_2\mathbf{W_R^{[1:k]}} + \mathbf{b_R^{[1:k]}}\right)$$

When predicting hypernymy, for example, dual tensors ensure that the specialized representation for concept *cat* in pairs like *cat–animal* differs from its specialized representation in pairs like *birman–cat*.

Specialization tensors map an unspecialized embedding into a set of k specialized embeddings – each slice of the tensor, W_L^i (W_R^i), together with the corresponding bias vector b_L^i (b_R^i), produces one specialized vector e_L^i (e_R^i). By using specialization tensors with k slices instead of specialization matrices we make the model more general. The tensor-based model trivially degrades to the matrix-based model by setting $k = 1$. We obtain the final specialized representation of a concept by non-linearly transforming (hyperbolic tangent) the product of an unspecialized input embedding and the specialization tensor.[1]

3.2 Bilinear Product and Scoring

Using dual tensors, we transform unspecialized embeddings into asymmetrically specialized representations – sets of specialized vectors – which we next use to predict whether the asymmetric relation holds between the concepts. Our scoring function is based on bilinear products between (1) specialized vectors $\mathbf{e_L^{[1:k]}}$ of the first concept, (2) relation tensor $\mathbf{W_B^{[1:k]}}$, and (3) specialized vectors $\mathbf{e_R^{[1:k]}}$ of the second concept. For each pair of specialized vectors e_L^i and $e_R^i, i \in \{1, \dots, k\}$, we compute the bilinear product score, using the corresponding slice W_B^i of the relation tensor $\mathbf{W_B^{[1:k]}}$:

$$b^i = e_L^i W_B^i (e_R^i)^T.$$

The final relation score $s(c_1, c_2)$ for a given pair of concepts is computed by reducing the vector of bilinear product scores $\mathbf{b}$ to the mean value (function g in Figure 1)[2] and non-linearly bounding the resulting score to the $[-1, 1]$ range:

$$s(c_1, c_2) = tanh\left(\frac{1}{k}\sum_{i=1}^{k} b^i\right).$$

[1] Preliminary experiments without applying a non-linear transformation yielded consistently poorer performance.

[2] We also experimented with min- and max-reduction, but the reduction to the mean yielded best preliminary results.

3.3 Optimization

Dual Tensor model is parametrized by the specialization tensors, their corresponding bias vectors, and the relation tensor, namely, $\mathbf{\Omega} = \{\mathbf{W}_{\mathbf{L}}^{[1:k]}, \mathbf{W}_{\mathbf{R}}^{[1:k]}, \mathbf{b}_{\mathbf{L}}^{[1:k]}, \mathbf{b}_{\mathbf{R}}^{[1:k]}, \mathbf{W}_{\mathbf{B}}^{[1:k]}\}$. Let A be the set of concept pairs in the training set, $A = \{p^i = (c_1^i, c_2^i)\}_{i=1}^N$. We learn model's parameters by minimizing the margin-based objective:

$$J(\mathbf{\Omega}) = \lambda\|\mathbf{\Omega}\|_2 + \sum_{p^i \in A} max\left(0, 1 - s(p^i) \cdot y(p^i)\right)$$

where $s(p^i)$ is model's prediction for the pair (c_1^i, c_2^i), $y(p^i) \in \{-1, 1\}$ is the true label of that pair, and λ is the regularization coefficient. In all our experiments, we trained the model in mini-batches, optimizing the parameters with the RMSProp algorithm (Tieleman and Hinton, 2012).

The model has three hyperparameters: the length of the unspecialized input embeddings l, the number of tensor slices k, and the regularization factor λ. We optimize the hyperparameters (together with the starting learning rate value) via grid-search, by maximizing performance on the validation portion of each dataset. In all our experiments, except the multilingual comparison (Section 5.3), we evaluated variants of the Dual Tensor model using pre-trained English GloVe word embeddings (Pennington et al., 2014) with varying length, $l \in \{50, 100, 200, 300\}$ and tensors with $k \in \{1, \ldots, 5\}$ slices. In most experiments, the optimal configuration was $l = 300$ and $k = 3$.

4 Evaluation

We evaluate the Dual Tensor model on several datasets for detecting hypernymy and meronymy, two arguably most prominent asymmetric lexico-semantic relations. In all experiments, we compare the model's performance with state-of-the-art results on respective datasets. Additionally, aiming to quantify the effects that different components of the Dual Tensor model have on prediction performance, we evaluate two reduced models variants.

4.1 Datasets

We evaluate the Dual Tensor model on the following hypernymy and meronymy detection datasets:

HypeNet dataset. Arguing that existing datasets were too small for training their recurrent network, Shwartz et al. (2016) compiled this dataset for hypernymy detection from several external KBs, taking only pairs of concepts in direct relation (i.e., no transitive closure).

Other hypernymy detection datasets. We additionally evaluate the Dual Tensor model on four smaller datasets for hypernymy detection: (1) BLESS dataset (Baroni and Lenci, 2011) and EVALuation dataset (Santus et al., 2015) contain instances of hypernymy and four other relations. BLESS additionally contains random word pairs; (2) Weeds dataset (Weeds et al., 2014) contains hypernymy and co-hyponymy pairs; (3) Benotto dataset (Benotto, 2015) couples hypernymy pairs with synonymy and antonymy pairs. Because these datasets contain at most several thousand pairs, we only use them to evaluate the performance of models trained on larger datasets;

WN-Hy and WN-Me datasets. We create these datasets by taking concept pairs from WordNet. We take all instances from the transitive closure of hypernymy (all parts of speech) and meronymy (nouns) relations and couple them with all synonym and antonym relations (all parts of speech), as well as lexical entailment relations (verbs).

For the WN-Hy dataset we designate all hypernymy relations (i.e., both direct and indirect) as positive instances and their inverses (i.e., hyponymy relations) together with all other relations as negative instances. Finally, we balance the dataset by randomly sampling negative instances to match the number of positive instances. Analogously, we create the WN-Me dataset by taking meronymy relations as positive instances. We compile three different WN-Hy datasets: WN-Hy-EN using English WordNet (Fellbaum, 1998), WN-Hy-ES using Spanish WordNet (Gonzalez-Agirre et al., 2012), and WN-Hy-FR using French WordNet (Sagot and Fišer, 2008). To allow for fair comparison of model's performance across languages, we randomly sample two larger dataset (English and French) to match in size the smallest (Spanish).

Lexical and Random Splits. Levy et al. (2015) showed that supervised distributional models for classifying lexico-semantic relations suffer from overfitting in settings with significant lexical overlap between the training and test set. In such settings models tend to learn properties of individual words (e.g., that a word is a prototypical hypernym) instead of relations between words. The reported results on such datasets are thus overly optimistic estimates of models' true performance.

Dataset	Train	Val.	Test
HypeNet (rand)	49.5K (20%)	3.5K (19%)	17.7K (20%)
HypeNet (lex)	20.3K (20%)	1.4K (20%)	6.6K (20%)

Table 2: Hypernymy classification performance.

To eliminate the effect of lexical memorization, Levy et al. (2015) propose dataset splits with no lexical overlap between the train and test portions. However, model's performance in a lexically-split setting is an overly pessimistic estimate of models' true performance – in a realistic scenario, the model will occasionally make predictions for pairs involving some of the concepts from the training set. Because the true model performance is likely between the performance on a randomly-split and performance on a lexically-split dataset, we report models' performance in both of these settings.

We show the sizes of all dataset variants used in our experiments in Table 1. We additionally report the proportion of positive instances (in brackets), as this percentage directly affects some evaluation metrics (precision, F_1-score, average precision).

4.2 Baselines

In addition to specific models yielding best performance on particular datasets, we compare the Dual Tensor model (DUAL-T) with these baselines:

Supervised distributional baseline (CONCAT-SVM). We train SVM model with RBF kernel on concatenation of unspecialized concept embeddings (Baroni et al., 2012), following Levy et al. (2015), who report this model outperforming other types of embedding composition;

Bilinear product (BILIN-PROD). This model is the simple bilinear product between the unspecialized concept embeddings, parametrized only by the relation matrix W_B. That is, the prediction score for a pair of concepts is given as $s(c_1, c_2) = e_1 W_B e_2^T$. The bilinear model implicitly captures asymmetry by learning a non-symmetric relation matrix W_B. By comparing the performances of BILIN-PROD and DUAL-T, we jointly quantify the effects of (1) explicit modeling of asymmetry and (2) relation-specific embedding specialization;

Single tensor model (SINGLE-T). This is the reduction of the Dual Tensor model in which we use only one specialization tensor, i.e., $\mathbf{W_L^{[1:k]}} = \mathbf{W_R^{[1:k]}}$. In other words, SINGLE-T model always specializes the unspecialized embedding of a concept the same way, regardless of the concept's position in a candidate pair. By comparing the performance of the DUAL-T model with that of SINGLE-T, we measure the effect of asymmetrically specializing unspecialized embeddings.

Same as for the DUAL-T model, we optimize the hyperparameters of the baselines on the validation portions of the datasets used for evaluation.

4.3 Classification Experiments

Binary classification is the most straightforward evaluation setting for relation detection models. For a pair of concepts, we make the binary asymmetric relation prediction $r_a(c_1, c_2)$ simply by thresholding the model's prediction scores, i.e., $r_a(c_1, c_2) = I\{s(c_1, c_2) > 0\}$, where I is the indicator function.

Hypernymy classification. We first evaluate the DUAL-T model and the baselines on the HypeNet dataset (Shwartz et al., 2016). We show the performance of the DUAL-T model in Table 2, together with the path-based and hybrid (combination of path-based and distributional signal) variants of the the state-of-the-art RNN model of Shwartz et al. (2016). On the more challenging, lexically-split dataset DUAL-T model significantly[3] outperforms the more complex hybrid HypeNet model (Shwartz et al., 2016), an RNN model coupling representations of syntactic paths from a large corpus with

[3] All performance differences were tested using the non-parametric stratified shuffling test (Yeh, 2000) with $\alpha = 0.05$.

	Lex. split			Rand. split

Dual-T	76.5	**61.1**	**67.9**	**87.7**	**85.3**	**86.5**

Table 3: Meronymy classification performance.

unspecialized concept embeddings. In both settings Dual-T outperforms Single-T which, in turn, outperforms Bilin-Prod. This empirically justifies both our explicit modeling of asymmetry and relation-specific embedding specialization.

Meronymy classification. We next evaluate the meronymy classification performance of the models on the WN-Me dataset. The results are shown in Table 3. Same as in the case of hypernymy classification, Dual-T significantly outperforms all three baselines, with Single-T outperforming Bilin-Prod. All distributional models we evaluate achieve poorer performance on meronymy than hypernymy detection, especially considering that WN-Me is a balanced dataset, whereas HypeNet is heavily skewed towards negative instances.

4.4 Ranking Experiments

Shwartz et al. (2017) propose ranking as an alternative evaluation setting for hypernymy detection. The goal is to rank positive relation pairs higher than negative ones. Our Dual-T model (and associated baselines) rank the concept pairs in decreasing order of assigned relations scores $s(c_1, c_2)$. Following Shwartz et al. (2017), we report performance in terms of overall average precision (AP) and average precision at rank 100 (AP@100).

Hypernymy ranking. We evaluate the ranking performance on four small hypernymy test sets: BLESS, EVALuation, Benotto, and Weeds (cf. Table 1). As these datasets are not big enough to train neural models, we train all models on the HypeNet dataset. For each test set we eliminate the lexical overlap by removing from the HypeNet dataset pairs containing any concept from that test set.

Table 4 displays ranking performance for Dual-T model, the supervised baselines, and the best-performing unsupervised hypernymy detection score (Best-unsup, performance taken from (Shwartz et al., 2017)). Hypernymy ranking results depict the effectiveness of the Dual-T model with respect to supervised baselines even more clearly than hypernymy classification results. All supervised models outperform the best unsupervised model in terms of AP, but only Dual-T is consistently better when considering only 100 top-ranked pairs (AP@100). This adds to the conclusion that explicit modeling of asymmetry using dual tensors yields crucial performance boost.

Meronymy ranking. We measure the ranking performance for meronymy detection on the WN-Me dataset, reporting the results for both randomly- and lexically-split variants of the dataset in Table 5. Meronymy ranking results are in line with performance figures for hypernymy ranking. Again, Dual-T consistently outperforms all three baselines. Absolute AP scores for meronymy are higher than those we report for hypernymy, but this is merely because WN-Me is a balanced dataset, whereas the hypernymy ranking test sets (with the exception of the Weeds dataset) are substantially skewed in favor of negative concept pairs.

5 Analysis

We perform additional analyses, providing further insights into Dual-T model's performance. We analyze how model's performance depends on concept distance in WordNet and on number of concept senses. We also examine the stability of Dual-T model's performance across different languages.

5.1 WordNet Distance

Unlike the HypeNet dataset (Shwartz et al., 2016), which contains only pairs of concepts that exist in a direct relation in some external knowledge base, our WN-Hy and WN-Me datasets (cf. Section 4.1) contain pairs of concepts of varying distance in WordNet, allowing for a more fine-grained analysis of the Dual Tensor model's performance.

We divide the test sets of WN-Hy-EN and WN-Me into five buckets according to the shortest path distance between concepts in WordNet.[4] We show hypernymy and meronymy prediction accuracies for all buckets in Figure 2. For hypernymy, we observe significantly lower accuracy for pairs of concepts appearing close in WordNet hierarchy. Close hyponym-hypernym pairs (e.g., *car–vehicle*) tend to occur in similar contexts and consequently have similar unspecialized embeddings. Such hypernymy instances are difficult to discern from syn-

[4] For any concept with multiple senses, we considered the WordNet synset of its dominant sense.

Table 5: Meronymy detection, ranking results.

onymous pairs (e.g., *car–automobile*). The same effect is, however, not observed for meronymy – part-whole relations between close concepts are as detectable as between more distant concepts. This is probably because *part* concepts appear in different contexts than *whole* concepts (e.g., *wheel-car*), resulting in distinct unspecialized embeddings in the first place. For both relations we observe a drop in performance for pairs of very distant concepts. Such pairs typically contain one very abstract concept (e.g., *object*), but embeddings of abstract concepts are not superpositions of embeddings of their hyponyms (Rimell, 2014) nor their meronyms.

5.2 Effects of Polysemy

Given that our Dual Tensor model takes unspecialized concept embeddings as input and that unspecialized embeddings do not discern between different senses of words, our Dual Tensor model treats monosemous and polysemous concepts equally. Intuitively, predicting asymmetric relations for pairs involving polysemous concepts should be more difficult than for pairs of monosemous concepts, because the models in such cases additionally need to learn to discern between different concept senses.

While designing the Dual Tensor model, we hypothesized that different tensor slices might be able to accommodate for asymmetric relations involving different senses of polysemous words. In order to closer examine the effects of polysemy on the performance of the Dual Tensor model, we partitioned the test portions of the WN-Hy and WN-Me datasets according to number of senses of the concept pair (we average the number of senses of the two concepts in a candidate pair). We show the Dual Tensor model's performance ($k = 3, l = 300$) on different number-of-senses buckets, both for hypernymy and meronymy prediction, in Figure 3.

For hypernymy, the general trend is as expected: the larger the average number of senses of concepts in the candidate pair, the lower the prediction accuracy. The exception is the bucket $(3, 5]$ for which the performance is higher than for the previous bucket $(1, 3]$. The drop in performance is not drastic as long as the model is not dealing with highly

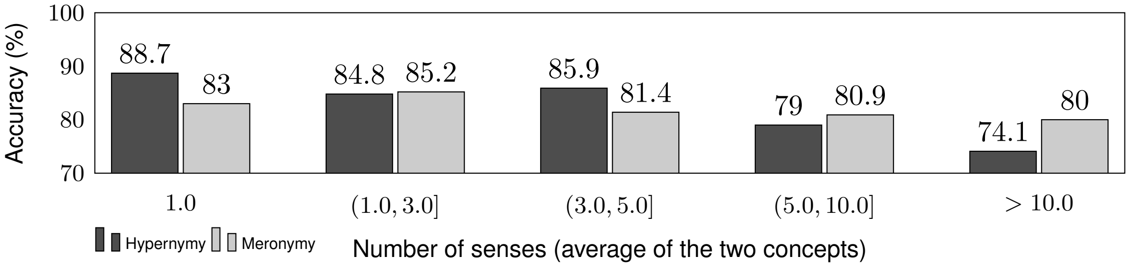

Figure 3: Hypernymy and meronymy performance with respect to concept polysemy.

polysemous concepts (with more than five senses). These performance figures suggest that, via the multiple tensor slices, the DUAL-T model can, to some extent, alleviate the effects that polysemy has on predicting asymmetric lexico-semantic relations.

Somewhat surprisingly, the polysemy seems not to have a clear negative effect for meronymy. Prediction accuracy on pairs of highly polysemous concepts seems to be similar to that on monosemous concept pairs. An instance-level inspection reveals that meronymy detection is more sensitive to the number of senses of the *part* candidate concept than of the *whole* concept. In other words, if we partition the test set only according to the number of senses of the *part* concept, then the trends are similar to those observed for hypernymy.

5.3 Multilingual Comparison

To examine how the Dual Tensor model performs across languages, we evaluate its performance on equally-sized hypernymy detection datasets in English, Spanish, and French (cf. Section 4.1 and Table 1). To increase the comparability of results, for each of the three languages we trained word embeddings using the CBOW algorithm (Mikolov et al., 2013) on the Wikipedia dump of respective language. Also, for all three models we select the hyperparameter configuration that turned out to be optimal most often in previous experiments – we set the length of unspecialized embeddings to $l = 300$ and number of tensor slices to $k = 3$. Hypernymy classification performance for different languages is shown in Table 6. The results suggest that Dual Tensor model exhibits stable performance across languages. The small performance differences between languages may be attributed to different sizes of respective Wikipedia dumps (on which we train unspecialized embeddings) as well as to inherent differences in language complexity (e.g., English being morpho-syntactically simpler).

Language	Dataset	P	R	F_1
English	WN-Hy-EN	89.9	86.1	87.9
Spanish	WN-Hy-ES	88.7	82.1	85.3
French	WN-Hy-FR	86.2	82.7	84.4

Table 6: Hypernymy classification performance for different languages.

6 Conclusion

We have presented a neural model for detecting asymmetric semantic relations. Unlike existing models, which uniformly treat asymmetric and symmetric relations, our Dual Tensor model captures asymmetry explicitly using a pair of specialization tensors that produce two different embedding specializations, depending on the concept's role in the relation. Instead of just updating unspecialized embeddings, with specialization tensors we also explicitly capture the mapping function.

The results from a battery of hypernymy and meronymy experiments show that via asymmetric specialization of concept embeddings the Dual Tensor model is able to outperform (1) the supervised model directly using unspecialized embeddings as well as (2) the more complex neural architecture that additionally exploits syntactic information. We have additionally shown that our model can diminish the negative effects of polysemy and that it exhibits stable performance across languages.

As future work, we plan to develop similar models based on explicit specialization tensors for detecting symmetric relations (e.g., synonymy, antonymy). We will also seek to exploit the Dual Tensor model in different downstream tasks, e.g., hypernymy detection for taxonomy induction (Faralli et al., 2017) or recognizing textual entailment.

Downloads. We make the code of the models and all datasets available at `https://bitbucket.org/gg42554/dual-tensors/`.

Abstract

Distantly supervised relation extraction has been widely used to find novel relational facts from plain text. To predict the relation between a pair of two target entities, existing methods solely rely on those direct sentences containing both entities. In fact, there are also many sentences containing only one of the target entities, which also provide rich useful information but not yet employed by relation extraction. To address this issue, we build inference chains between two target entities via intermediate entities, and propose a path-based neural relation extraction model to encode the relational semantics from both direct sentences and inference chains. Experimental results on real-world datasets show that, our model can make full use of those sentences containing only one target entity, and achieves significant and consistent improvements on relation extraction as compared with strong baselines. The source code of this paper can be obtained from `https://github.com/thunlp/PathNRE`.

1 Introduction

Knowledge Bases (KBs) provide effective structured information for real world facts and have been used as crucial resources for several natural language processing (NLP) applications such as Web search and question answering. Typical KBs such as Freebase (Bollacker et al., 2008), DBpedia (Auer et al., 2007) and YAGO (Suchanek et al., 2007) usually describe knowledge as multi-relational data and represent them as triple facts. As the real-world facts are infinite and increasing every day, existing KBs are still far from complete. Recently, petabytes of natural-language text containing thousands of different structure types are readily available, which is an important resource for automatically finding unknown relational facts. Hence, relation extraction (RE), defined as the task of extracting structured information from plain text, has attracted much interest.

Most existing supervised RE systems usually suffer from the issue that lacks sufficient labelled relation-specific training data. Manual annotation is very time consuming and labor intensive. One promising approach to address this limitation is distant supervision. (Mintz et al., 2009) generates training data automatically by aligning a KB with plain text. They assume that if two target entities have a relation in KB, then all sentences that contain these two entities will express this relation and can be regarded as a positive training instance. Since neural models have been verified to be effective for classifying relations from plain text (Socher et al., 2012; Zeng et al., 2014; dos Santos et al., 2015), (Zeng et al., 2015; Lin et al., 2016) incorporate neural networks method with distant supervision relation extraction. Further, (Ye et al., 2016) considers finer-grained information, and achieves the state-of-the-art performance.

Although existing RE systems have achieved promising results with the help of distant supervision and neural models, they still suffer from a major drawback: the models only learn from those sentences contain both two target entities. However, those sentences containing only one of the entities could also provide useful information and help build inference chains. For example, if we know that "h is the father of e" and "e is the father of t", we can infer that h is the grandfather of t.

In this work, as illustrated in Fig. 1, we introduce a path-based neural relation extraction model

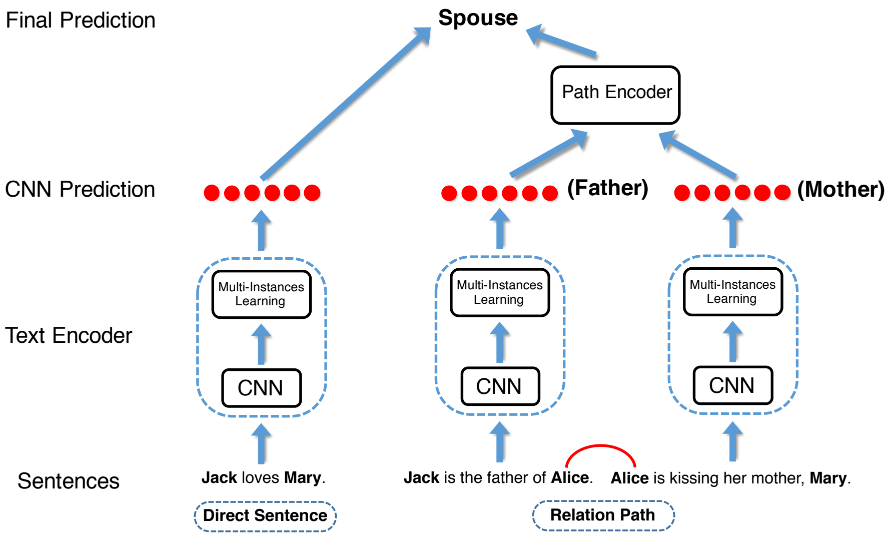

Figure 1: The architecture of our neural relation extraction model with relation paths.

with relation paths. First, we employ convolutional neural networks (CNN) to embed the semantics of sentences. Afterward, we build a relation path encoder, which measures the probability of relations given an inference chain in the text. Finally, we combine information from direct sentences and relation paths to predict the relation.

We evaluate our model on a real-world dataset for relation extraction. The experimental results show that our model achieves significant and consistent improvements as compared with baselines. Besides, with the help of those sentences containing one of the target entities, our model is more robust and performs well even when the number of noisy instances increases. To the best of our knowledge, this is the first effort to consider the information of relation path in plain text for neural relation extraction.

2 Related Work

2.1 Distant Supervision

Distant supervision for RE is originally proposed in (Craven et al., 1999). They focus on extracting binary relations between proteins using a protein KB as the source of distant supervision. Afterward, (Mintz et al., 2009) aligns plain text with Freebase, by using distant supervision . However, most of these methods heuristically transform distant supervision to traditional supervised learning, by regarding it as a single-instance single-label problem, while in reality, one instance could correspond with multiple labels in different scenarios and vice versa. To alleviate the issue, (Riedel et al., 2010) regards each sentence as a training instance and allows multiple instances to share the same label but disallows more than one label. Further, (Hoffmann et al., 2011; Surdeanu et al., 2012) adopt multi-instance multi-label learning in relation extraction. The main drawback of these methods is that they obtain most features directly from NLP tools with inevitable errors, and these errors will propagate to the relation extraction system and limit the performance.

2.2 Neural Relation Extraction

Recently, deep learning (Bengio, 2009) has been successfully applied in various areas, including computer vision, speech recognition and so on. Meanwhile, its effectiveness has also been verified in many NLP tasks such as sentiment analysis (dos Santos and Gatti, 2014), parsing (Socher et al., 2013), summarization (Rush et al., 2015) and machine translation (Sutskever et al., 2014). With the advances of deep learning, there are growing works that design neural networks for relation extraction. (Socher et al., 2012) uses a recursive neural network in relation extraction, and (Xu et al., 2015; Miwa and Bansal, 2016) further use LSTM. (Zeng et al., 2014; dos Santos et al., 2015) adopt CNN in this task, and (Zeng et al., 2015; Lin et al., 2016) combine attention-based multi-instance learning which shows promising results. However, these above models merely learn from those sentences which directly contain both two target entities. The important information of those relation paths hidden in the text is ignored. In this paper, we propose a novel path-based neural RE model to address this issue. Besides, although we choose CNN to test the effectiveness of our model, other neural models could also be easily adapted to our architecture.

2.3 Relation Path Modeling

Relation paths have been taken into consideration on large-scale KBs for relation inference. Path Ranking algorithm (PRA) (Lao and Cohen, 2010) has been adopted for expert finding (Lao and Cohen, 2010), information retrieval (Lao et al., 2012), and further for relation classification based on KB structure (Lao et al., 2011; Gardner et al., 2013). (Neelakantan et al., 2015; Lin et al., 2015; Das et al., 2016; Wu et al., 2016) use recurrent neural networks (RNN) to represent relation paths based on all involved relations in KBs.(Guu et al., 2015) proposes an embedding-based compositional training method to connect the triple knowledge for KB completion. Different from the above work of modeling relation paths in KBs, our model aims to utilize relation paths in text corpus, and help to extract knowledge directly from plain text.

3 Our Method

Given a pair of target entities, a set of corresponding direct sentences $S = \{s_1, s_2, \cdots, s_n\}$ which contains this entity pair, and a set of relation paths $P = \{p_1, p_2, \cdots, p_m\}$, our model aims to measure the confidence of each relation for this entity pair. In this section, we will introduce our model in three parts: (1) **Text Encoder.** Given the sentence with two corresponding target entities, we use a CNN to embed the sentence into a semantic space, and measure the probability of each relation given this sentence. (2) **Relation Path Encoder.** Given a relation path between the target entities, we measure the probability of each relation r, conditioned on the relation path. (3) **Joint Model.** We integrate the information from both direct sentences and relation paths, then predict the confidence of each relation.

3.1 Text Encoder

As shown in Fig. 2, we use a CNN to extract information from text. Given a set of sentences of an entity pair, we first transform each sentence s into its distributed representation $\mathbf{s}$, and then predict relation using the most representative sentence via a multi-instance learning mechanism.

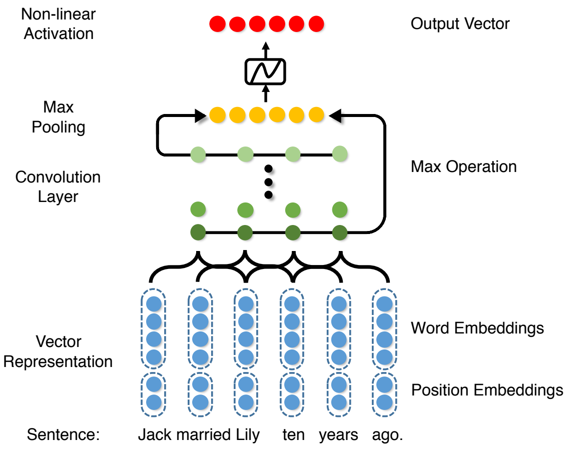

Figure 2: The architecture of CNN used for text encoder.

3.1.1 Input Vector

First, we transform the words $\{w_1, w_2, \cdots, w_l\}$ in sentence s into vectors of dimension d. For each word w_i, we use word embedding to encode its syntactic and semantic meanings, and use position embedding to encode its position information. We then concatenate both word embedding and position embedding to form the input vector of w_i for CNN. (See Figure 2.)

3.1.2 Convolution and Max-pooling Layers

When processing a sentence, it is a great challenge that important information could probably appear in all parts of that sentence. In addition, the length l of a sentence could also vary a lot. Therefore, we apply CNN to encode all local features regardless sentence length. We first apply a convolution layer to extract all possible local features, and then select the most important one via max-pooling layer.

To extract local features, the convolution layer first concatenates a sequence of word embeddings within a sliding window to be vector $\mathbf{q}_i$ of dimension $k \times d$:

$$\mathbf{q}_i = \mathbf{w}_{[i-k+1:i]} (1 \le i \le l + k - 1), \qquad (1)$$

where k is the size of the window, and we also set all out-of-index words to be zero vectors. It then multiplies $\mathbf{q}_i$ by a convolution matrix $\mathbf{W} \in \mathbb{R}^{d_c \times (k \times d)}$, where d_c is the dimension of sentence embeddings. Hence, the output of convolution layer could be expressed as $\mathbf{h} = \{\mathbf{h}_1, \mathbf{h}_2, \cdots, \mathbf{h}_{l+k-1}\}$:

$$\mathbf{h}_i = \mathbf{W}\mathbf{q}_i + \mathbf{b}, \qquad (2)$$

where $\mathbf{b}$ is a bias vector. Finally, the max-pooling layer takes a max operation, followed by a hyperbolic tangent activation, over the sequence of $\mathbf{h}_i$ to select the most important information, namely,

$$[\mathbf{s}]_j = \mathbf{tanh}(\max_i [\mathbf{h}_i]_j). \tag{3}$$

3.1.3 Multi-Instance Learning

Next, we apply a softmax classifier upon the sentence representation $\mathbf{s}$ to predict the corresponding relation. We define the condition probability of relation r as follows,

$$p(r|\theta, \mathbf{s}) = \frac{\exp(e_r)}{\sum_{i=1}^{n_r} \exp(e_i)}, \tag{4}$$

where e_i, a component of $\mathbf{e}$, measures how well this sentence matches relation r_i, and n_r is the number of relations. More specifically, $\mathbf{e}$ could be calculated from:

$$\mathbf{e} = \mathbf{U}\mathbf{s} + \mathbf{v}, \tag{5}$$

where $\mathbf{U} \in \mathbb{R}^{n_r \times d_c}$ is the coefficient matrix of relations and $\mathbf{v} \in \mathbb{R}^{n_r}$ is a bias vector.

We use multi-instance learning to alleviate the wrong-labeling issue in distant supervision, by choosing one sentence in the set of all direct sentences $S = \{s_1, s_2, \cdots, s_m\}$ which corresponds to the entity pair (h, t). Similar to (Zeng et al., 2015), we define the score function of this entity pair and its corresponding relation r as a max-one setting:

$$E(h, r, t|S) = \max_i p(r|\theta, \mathbf{s}_i). \tag{6}$$

where E reflects the direct information we derive from sentences. We can also set a random setting as a baseline:

$$E(h, r, t|S) = p(r|\theta, \mathbf{s}_i), \tag{7}$$

where s_i is randomly selected from S.

3.2 Relation Path Encoder

We use Relation Path Encoder to embed the inference information of relation paths. Relation Path Encoder measures the probability of each relation r given a relation path in the text. This will utilize the inference chain structure to help make predictions. More specifically, we define a path p_1 between (h, t) as $\{(h, e), (e, t)\}$, and the corresponding relations are r_A, r_B. Each of (h, e) and (e, t) corresponds to at least one sentence in the text. Our model calculates the probability of relation r conditioned on p_1 as follows,

$$p(r|r_A, r_B) = \frac{\exp(o_r)}{\sum_{i=1}^{n_r} \exp(o_i)}, \tag{8}$$

where o_i measures how well relation r matches with the relation path (r_A, r_B). Inspired by the work on relation path representation learning (Lin et al., 2015), our model first transforms relation r to its distributed representation, i.e. vector $\mathbf{r} \in \mathbb{R}^{d_R}$, and builds the path embeddings by composition of relation embeddings. Then, the similarity o_i is calculated as follows:

$$o_i = -\|\mathbf{r}_i - (\mathbf{r}_A + \mathbf{r}_B)\|_{L_1}. \tag{9}$$

Therefore, if $\mathbf{r}_i$ gets more similar to $(\mathbf{r}_A + \mathbf{r}_B)$, the conditioned predicting probability of r_i will become larger. Here, we make an implicit assumption that if r_i is semantically similar to relation path $p_i : h \xrightarrow{r_A} e \xrightarrow{r_B} t$, the embedding $\mathbf{r}_i$ will be closer to the relation path embedding $(\mathbf{r}_A + \mathbf{r}_B)$. Finally, for this relation path $p_i : h \xrightarrow{r_A} e \xrightarrow{r_B} t$, we define an relation-path score function,

$$G(h, r, t|p_i) = E(h, r_A, e)E(e, r_B, t)p(r|r_A, r_B), \tag{10}$$

where $E(h, r_A, e)$ and $E(e, r_B, t)$ measure the probabilities of relational facts (h, r_A, e) and (e, r_B, t) from text, and $p(r|r_A, r_B)$ measures the probability of relation r given relation path (r_A, r_B).

In reality, there are usually multiple relation paths between two entities. Hence, we define the inferring correlation between relation r and several sentence paths P as,

$$G(h, r, t|P) = \max_i G(h, r, t|p_i), \tag{11}$$

where we use max operation to filter out those noisy paths and select the most representative path.

3.3 Joint Model

Given any entity pair (h, t), those sentences S directly mentioning them and relation paths P between them, we define the global score function with respect to a candidate relation r as,

$$L(h, r, t) = E(h, r, t|S) + \alpha G(h, r, t|P), \tag{12}$$

where $E(h, r, t|S)$ models the correlation between r and (h, t) calculated from direct sentences,

$G(h, r, t|P)$ models the inferring correlation between relation r and several sentence paths P. α equals to $(1 - E(h, r, t|S))$ times a constant β. This term serves to depict the relative weight between direct sentences and relation paths, since we don't need to pay much attention on extra information when CNN has already given a confident prediction, namely $E(h, r, t|S)$ is large.

One of the advantages of this joint model is to alleviate the issue of error propagation. The uncertainty of information from Text Encoder and Relation Path encoder is characterized by its confidence, and could be integrated and corrected in this joint model step. Furthermore, since we treat relation paths in a probabilistic way, our model could fully utilize all relation paths, i.e. those always hold and those likely to hold.

3.4 Optimization and Implementation Details

The overall objective function is defined as:

$$J(\theta) = \sum_{(h,r,t)} \log(L(h, r, t)), \tag{13}$$

where the summing runs over the log loss of all entity pairs in text and θ represents the model parameters. To solve this optimization problem, we use mini-batch stochastic gradient descent (SGD) to maximize our objective function. We initialize $\mathbf{W}_E$ with the results from Skip-gram model, and initialize other parameters randomly. We also adopt dropout (Srivastava et al., 2014) upon the output layer of CNN.

We implement our model using C++. We train our model on Intel(R) Xeon(R) CPU E5-2620, and the training roughly takes half a day. The word embedding and other parameters are updated via back-propagation simultaneously, while the relation path structure is extracted before training and stored afterward.

4 Dataset

We build a novel dataset for evaluating relation extraction task. We first describe the most commonly used previous dataset and then explain the reason and how we construct the new dataset.

4.1 Previous Datasets & Reasons for New Dataset

A commonly used benchmark dataset for this task was developed by (Riedel et al., 2010). This dataset was built by aligning Freebase (Dec. 2009 Snapshot) with New York Times corpus (NYT). There are 53 possible relationships between two entities, including a special relation type NA, meaning that there is no relation between head and tail entities. For each relational fact in a filtered Freebase dataset, a sentence from NYT would be regarded as a mention of this relation if both the head and tail entity appear in that sentence.

While this previous dataset has been frequently used for evaluating relation extraction systems, we observe some limitations of it. First, the relational facts are extracted from a 2009 snapshot of Freebase. Therefore, this dataset is too old to contain many updated facts. This will underestimate the performance of a relation extraction system, since some real-world facts are missing from the dataset and labeled as NA. Second, the relational facts in this dataset are scattered, i.e. there are not sufficient relation paths in this dataset, while relational facts in real-world always have connections with each other. Third, Freebase will no longer update after 2016.These limitations mean that this dataset is somewhat improper for evaluating RE systems.

Although other relation extraction datasets exist, e.g. ACE[1] and (Hendrickx et al., 2009), they are too small to train an effective neural relation extraction model. Moreover, each relational fact in (Hendrickx et al., 2009) only corresponds with one sentence, which prevents it from evaluating multi-instance relation extraction systems. Hence, we constructed a novel relation extraction dataset to address these issues, and will make it available to the community.

4.2 Dataset Construction

Datasets	Sets	# sentences	# entity pairs	# facts
Riedel et.al.	Train	522,611	281,270	18,252
	Valid	-	-	-
	Test	172,448	96,678	1,950
Ours	Train	647,827	266,118	50,031
	Valid	234,350	121,160	5,609
	Test	235,609	121,837	5,756

Table 1: Statistics of datasets.

Our dataset contains more updated facts and richer structures of relations, e.g. more relations / relation paths, as compared to existing similar datasets. The dataset is expected to be more similar to real-world cases, and thus be more appropriate for evaluating RE systems' performances.

We build the dataset by aligning Wikidata[2] re-

[1] https://catalog.ldc.upenn.edu/LDC2006T06

[2] https://www.wikidata.org/

lations with the New York Times Corpus (NYT). Wikidata is a large, growing knowledge base, which contains more than 80 million triple facts and 20 million entities. Different from Freebase, Wikidata is still in maintenance and could be easily accessed by APIs. We first pick those entities simultaneously appeared in both Wikidata and Freebase, and relational facts associated with them. Then, we filtered out a subset S, reserving those facts associating with the 99 highest frequency relations. This results in $4,574,665$ triples with $1,045,385$ entities and 99 relations.

Next, we align those facts with NYT corpus, following the assumption of distant supervision. For each pair of entities appearing in our S, we traverse the corpus and pick those sentences where both entities appear. These sentences will be regarded as mentions of this fact, and labeled by this relation type. To simulate noise in the real world, we also add sentences corresponding to "No Relation" entity pairs into our dataset. To get those "No Relation" instances, we first create a fake knowledge base S^- by randomly replacing the head or tail entities in triples, i.e., $S^- = \{(h', r, t)\} \cup \{(h, r, t')\}$ and then align them with NYT corpus. Finally, we randomly split all those selected sentences into training, validation and testing set, assuring that a relational fact could be only mentioned by sentences in one set. The statistics of our dataset and (Riedel et al., 2010) are listed in Table 1.

5 Experiments

Following the previous work (Mintz et al., 2009), we evaluate our model by extracting relational facts from the sentences in test set, and compare them with those in Wikidata. We report Precision/Recall curves, Precision@N (P@N) and F1 scores for comparison in our experiments.

5.1 Initialization and Parameter Settings

In this paper, we use the word2vec tool [3] to pre-train word embeddings on NYT corpus. We keep the words which appear more than 100 times in the corpus as vocabulary. We tune our model on the validation set, using grid search to determine the optimal parameters, which are shown in boldface. We select learning rate for SGD $\lambda \in \{0.1, \mathbf{0.01}, 0.001\}$, the sentence embedding size $d_c \in \{50, 60, \cdots, \mathbf{230}, \cdots, 300\}$, the window size $k \in \{1, 2, \mathbf{3}, 4, 5\}$, and the mini-batch size $B \in \{40, \mathbf{160}, 640\}$. Besides, we select the relation embeddings size $d_R \in \{5, 10, \cdots, \mathbf{40}, \cdots, 60\}$, and the weight for information from relation paths $\beta \in \{0.01, 0.1, 0.2, \mathbf{0.5}, 1, \cdots, 5\}$. For other parameters which have little effect on the system performance, we follow the settings used in (Zeng et al., 2015): word embedding size d_w is 50, position embedding size d_p is 5 and dropout rate p is 0.5. For training, the iteration number over all training data is 25.

5.2 Effectiveness of Incorporating Relation Paths

5.2.1 Precision-Recall Curve Comparison

To demonstrate the effect of our approach, we empirically compare it with other neural relation extraction methods via held-out evaluation. (1) **CNN+rand** represents the CNN model reported in (Zeng et al., 2014). (2) **CNN+max** represents the CNN model with multi-instances learning used in (Zeng et al., 2015). (3) **Path+rand/max** is our model with those two multi-instance settings. We implement (1), (2) by ourselves which achieve comparable results as reported in those papers.

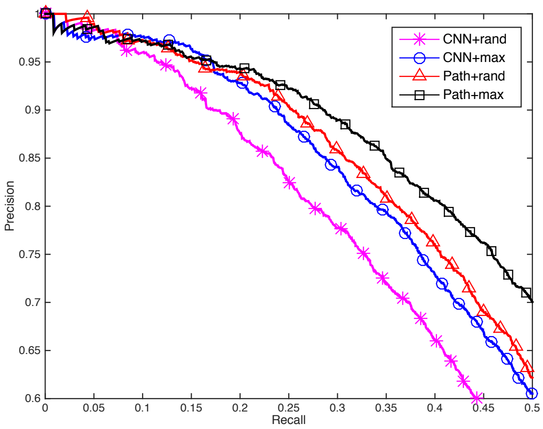

Figure 3: Aggregate precision/recall curve for CNN+rand, CNN+max, Path+rand, Path+max.

Fig. 3 shows the precision/recall curves of all methods. From the figure, we can observe that: (1) Our methods outperform their counterpart methods, achieving higher precision over almost entire range of recall. They also enhance recall by 20% without decrease of precision. These results prove the effectiveness of our approach. We notice that the improvements of our methods over

[3] https://code.google.com/p/word2vec/

Test Settings (Noise)	75%				85%				95%			
P@N (%)	10%	20%	50%	F1	10%	20%	50%	F1	10%	20%	50%	F1
CNN+rand	86.7	67.0	38.9	57.5	84.6	66.4	37.5	55.0	79.9	61.8	35.2	51.4
CNN+max	86.0	68.5	38.3	57.2	85.4	67.6	37.7	56.5	84.4	66.0	36.6	54.8
Path+rand	**89.4**	**71.7**	**39.9**	59.3	88.2	70.2	39.0	58.1	86.0	67.2	37.0	55.6
Path+max	89.0	71.5	39.8	**59.6**	**89.0**	**71.4**	**39.6**	**59.4**	**88.6**	**71.0**	**39.1**	**59.1**

Table 2: P@N and F1 for relation extraction in texts containing different percentage of no-relation facts.

baselines are relatively small at small recall value, which corresponds to high predicting confidence. This phenomenon is intuitive since our joint model could dynamically leverage the importance of direct sentence and relation paths, and tends to trust the Text Encoder when the confidence is high. (2) As the recall increases, our models exhibit larger improvements compared with CNN in terms of percentage. This is due to the fact that sometimes CNNs cannot extract reliable information from direct sentences, while our methods could alleviate this issue by considering more information from inference chains, and thus still maintain high precision. (3) Both CNN+max and Path+rand are variations of CNN+rand, aiming to alleviate the problem of noisy data. We see that Path+rand outperforms CNN+max over all range, which indicates that considering path information is a better way to solve this issue. Meanwhile, combining paths information and max operation, Path+max, gives the best performance. (4) Path+rand shows a larger improvement over CNN+rand, compared with those of Path+max and CNN+max. This furthermore proves the effectiveness of considering relation path information: CNN+rand has much more severe problem suffering from noise, so using our method to incorporate paths information to alleviate this issue could perform better.

5.2.2 Comparison on Long Tail Situation

	$N_s \leq 1$	$N_s \leq 2$	$N_s \leq 5$	All
CNN+rand	53.9	54.0	52.0	51.4
Path+rand	**58.4**	**58.1**	**56.0**	**55.6**
CNN+max	57.8	58.3	56.5	55.7
Path+max	**63.6 (+5.8)**	**62.5 (+4.2)**	**60.2 (+3.7)**	**59.1 (+3.4)**

Table 3: F1 score for long tail situation.

Real-world data follows long-tail distribution (power law). In the testing set, we also observe a fact that about 40% triple facts appear only in single sentence, and thus a multi-instance relation extraction system, e.g. CNN+max, could only rely on limited information and the multi-instance mechanism will not work well. Our system, on the contrary, can still utilize information from relation paths in this case, and is expected to perform much better in the long tail situation.

We evaluate the models on different parts of the long-tail distribution. To get testing instances from different parts of the distribution, we extract all the triple facts appearing less than N_s sentences in the testing set, and those sentences associating with them. All text related to 'No Relation' entity pair are also reserved in order to simulate noise. We then evaluate different models on those sampled testing set, and report the results of F1 score in Table 3.

From Table 3, we could observe that: (1) Incorporating relation paths is indeed effective in predicting relations, and our models have significant improvements compared with the baselines. (2) Path+max indeed has larger improvements over CNN+max when N_s is small, which is consistent with our previous expectation. Also notice that the gap between Path+rand and CNN+rand is relatively constant. This is due to the fact that both these methods only use one random sentence, regardless of how many sentences there are associating with an entity pair.

5.3 Model Robustness under Different Percentages of Noise

In the task of relation extraction, there are lots of noise in text which may hurt the model's performance. More specifically, “No Relation” entity pair is a kind of noise, since “No Relation” could actually contain many unknown relation types, and thus might confuse the relation extraction systems. Therefore, it is important to verify the robustness of our model in the presence of massive noise. Here, we evaluate those models in three settings, with the same relational facts and different percentages of “No Relation” sentences in the testing sets. In each experiment, we extract top 20,000 predicting relational facts according to the model's predicting scores, and report the precision @top 10%, @top 20%, @top 50% and F1 score in Table 2.

From the table, we can see that: (1) In terms of all evaluations, our models achieve the best perfor-

	Relation	Text
Path #1	mother	**Rebecca** gave birth to twin sons, **Esau** and Jacob, ...
Path #2	has_child	...**Isaac**'s marriage to Rebecca, by whom he has two sons, **Esau** and jacob, ...
Test	spouse	... **Isaac** and **Rebecca** and the female and male evil spirits ...
Path #1	shares_border_with	... in **Somalia**, ... soldiers and marines stationed in neighboring **Djibouti** ...
Path #2	shares_border_with	... **Ethiopia** have had the effect of making neighboring **Djibouti** ...
Test	shares_border_with	The next day, **Ethiopia** struck, its military pushing deep into **Somalia** ...

Table 4: Some representative examples of inference chians in NYT corpus. The bold is target entities.

mance as compared with other methods in all test settings. It demonstrates the effectiveness of our approach. (2) Even though the scores of all models drop as the increasing of noise, we find that Path+rand/max's scores decrease much less than their counterparts. This result proves the effectiveness of taking inference chains into consideration. Since we utilize more information to make predictions, our model is more robust to the presence of mass noise.

5.4 Effectiveness of Learned Features in Zero-Shot Scenario

It has been proved that CNN could automatically extract useful features, encoding syntactic and semantic meaning of sentences. These features are sometimes fed to subsequent models to solve other tasks. In this experiment, we demonstrate the effectiveness of the extracted features from our model. Since CNN-based models have already succeeded in extracting relations from single sentences, we set our experiment in a new scenario: predicting the relation between entities which have not appeared in the same sentence.

A natural approach is to build a relation path between this zero-shot entity pair. We assume that we can make a prediction about (h, t), once we know the information of (h, e) and (e, t). Therefore, we build the training set by extracting all such relation paths and their sentences from training text, and similar for testing set. To test the effectiveness of features, we encode sentences by CNN+rand/max, Path+rand/max respectively, and then feed the concatenation of sentence vectors to a logistic classifier.

Feature	Accuracy
CNN+rand	56.9
CNN+max	57.3
Path+rand	58.5
Path+max	**60.4**

Table 5: Accuracy of different models in zero-shot situation.

From Table 5, we could observe that: (1) The result using CNN+rand features is comparable to the result using CNN+max features. It shows that using max operation to train the features does not greatly improve the features' behavior in this task, even though it performs well in previous tasks. The reason is that, both CNN+rand and CNN+max only encode the information from a single sentence, and they are unable to capture the correlations between relations. (2) Feature from Path+rand/max shows its effectiveness over those from other methods. It indicates that our method is able to model the correlations between relations, while also keeps the syntactic and semantic meaning of a sentence. Therefore, the features extracted from Path+rand/max are useful for a wider range of applications, especially in those tasks which need the information from relations.

5.5 Case study

Table 4 shows some representative inference chains from the testing dataset. These examples can not be predicted correctly by the original CNN model, but are later corrected using our model. We show the test instances and their correct relations, as well as the inference chains the model uses. In the first example, the test sentence does not directly express the relation `spouse`, the proof of this relation appears in a further context in NYT. However, using path#1 and path#2, we could easily infer that *Rebecca* and *Issac* are `spouse`. The second example doesn't show the relation either. But with the help of intermediate entity, *Dijibouti*, our model predicts that *Somalia* shares the border with *Ethiopia*. Note that this inference chain doesn't always hold, but our model could capture this uncertainty well via a softmax operation. In general, our model can utilize common sense from inference chains. It helps make correct predictions even if the inference is not explicit.

6 Conclusion and Future Work

In this paper, we propose a neural relation extraction model which encodes the information of relation paths. As compared to existing neural relation extraction models, our model is able to utilize the sentences which contain both two target entities and only one target entity and is more robust for noisy data. Experimental results on real-world datasets show that our model achieves significant and consistent improvements on relation extraction as compared with baselines.

In the future, we will explore the following directions: **(1)** We will explore the combination of relation paths from both plain texts and KBs for relation extraction. **(2)** We may take advantages of probabilistic graphical model or recurrent neural network to encode more complicated correlations between relation paths, e.g. multi-step relation paths, for relation extraction.

Abstract

Adversarial training is a mean of regularizing classification algorithms by generating adversarial noise to the training data. We apply adversarial training in relation extraction within the multi-instance multi-label learning framework. We evaluate various neural network architectures on two different datasets. Experimental results demonstrate that adversarial training is generally effective for both CNN and RNN models and significantly improves the precision of predicted relations.

1 Introduction

Despite the recent successes of deep neural networks on various applications, neural network models tend to be overconfident about the noise in input signals. *Adversarial examples* (Szegedy et al., 2013) are examples generated by adding noise in the form of small perturbations to the original data, which are often indistinguishable for humans but drastically increase the loss incurred in a deep model. *Adversarial training* (Goodfellow et al., 2014) is a technique for regularizing deep models by encouraging the neural network to correctly classify both unmodified examples and perturbed ones, which in practice not only enhances the robustness of the neural network but also improves its generalizability. Previous work has largely applied adversarial training on straightforward classification tasks, including image classification (Goodfellow et al., 2014) and text classification (Miyato et al., 2016), where the goal is simply predicting a single label for every example and the training examples are able to provide strong supervision. It remains unclear whether adversarial training could be still effective for tasks with much weaker supervision, e.g., distant supervision (Mintz et al., 2009), or a different evaluation metric other than prediction accuracy (e.g., F1 score).

This paper focuses on the task of *relation extraction*, where the goal is to predict the relation that exists between a particular entity pair given several text mentions. One popular way to handle this problem is the multi-instance multi-label learning framework (MIML) (Hoffmann et al., 2011; Surdeanu et al., 2012) with distant supervision (Mintz et al., 2009), where the mentions for an entity pair are aligned with the relations in Freebase (Bollacker et al., 2008). In this setting, relation extraction is much harder than the canonical classification problem in two respects: (1) although distant supervision can provide a large amount of data, the training labels are very noisy, and due to the multi-instance framework, the supervision is much weaker; (2) the evaluation metric of relation extraction is often the precision-recall curve or F1 score, which cannot be represented (and thereby optimized) directly in the loss function.

In order to evaluate the effectiveness of adversarial training for relation extraction, we apply it to two different architectures (a convoluational neural network and a recurrent neural network) on two different datasets. Experimental results show that even on this harder task with much weaker supervision, adversarial training can still improve the performance on all of the cases we studied.

2 Related Work

Neural Relation Extraction: In recent years, neural network models have shown superior performance over approaches using hand-crafted features in various tasks. Convolutional neural networks (CNN) are among the first deep models that have been applied to relation extrac-

tion (Santos et al., 2015; Nguyen and Grishman, 2015). Variants of convolutional networks include piecewise-CNN (PCNN) (Zeng et al., 2014), split CNN (Adel et al., 2016), CNN with sentence-wise pooling (Jiang et al., 2016) and attention CNN (Wang et al., 2016). Recurrent neural networks (RNN) are another popular choice, and have been used in recent work in the form of recurrent CNNs (Cai et al., 2016) and attention RNNs (Zhou et al., 2016). An instance-level selective attention mechanism was introduced for MIML by Lin et al. (2016), and has significantly improved the prediction accuracy for several of these base deep models.

Adversarial Training: Adversarial training (AT) (Goodfellow et al., 2014) was originally introduced in the context of image classification tasks where the input data is continuous. Miyato et al. (2015, 2016) adapts AT to text classification by adding perturbations on word embeddings and also extends AT to a semi-supervised setting by minimizing the entropy of the predicted label distributions on unlabeled data.

AT introduces an end-to-end and deterministic way of data perturbation by utilizing the gradient information. There are also other works for regularizing classifiers by adding random noise to the data, such as dropout (Srivastava et al., 2014) and its variant for NLP tasks, word dropout (Iyyer et al., 2015). Xie et al. (2017) discusses various data noising techniques for language models. Søgaard (2013) and Li et al. (2017) focus on linguistic adversaries.

3 Methodology

We first introduce MIML and then describe the base neural network models we consider:[1] piecewise CNN (Zeng et al., 2015) (PCNN) and bidirectional GRU (Cho et al., 2014) (RNN). We also utilize the *selective attention* mechanism in Lin et al. (2016) for both PCNN and RNN models. Adversarial training is presented at the end of this section.

3.1 Preliminaries

In MIML, we consider the set of text sentences $X = \{x_1, x_2, \ldots, x_n\}$ for each entity pair. Supposing we have R predefined relations (including *NA*) to extract, we want to predict the probability of each of the R relations given the mentions. Formally, for each relation r, we want to predict $P(r \mid x_1, \ldots, x_n)$.

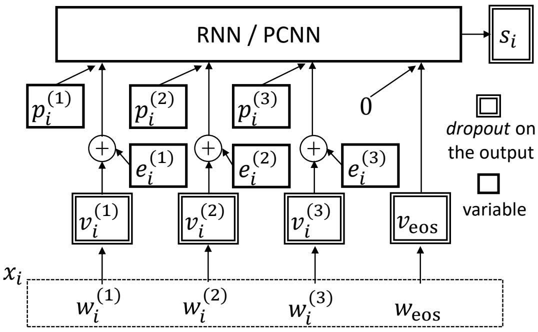

Figure 1: The computation graph of encoding a sentence x_i with adversarial training. e_i denotes the adversarial perturbation w.r.t. x_i. Dropout is placed on the output of the variables in the double-lined rectangles.

Note that since an entity pair may have no relations, we introduce a special relation *NA* to the label set. Hence, we simply assume there will be *at least* one relation existing for every entity pair. During evaluation, we ignore the probability predicted for the *NA* relation.

3.2 Neural Architectures

Input Representation: For each sentence x_i, we use pretrained word embeddings to project each word token into d_w-dimensional space. Note that we also need to include the entity position information in x_i. Here we introduce an extra feature vector $p_i^{(w)}$ for each word w to encode the entities' positions. One choice is the *position embedding* (Zeng et al., 2014): for each word w, we compute the relative distances to the two entities and embed the distances in two d_p-dimensional vectors, which are then concatenated as $p_i^{(w)}$. Position embedding introduces extra variables in the model and slows down the training time. We also investigate a simpler choice, *indicator encoding*: when a word w is exactly an entity, we generate a d_p-dimensional $\vec{1}$ vector and a $\vec{0}$ vector otherwise. In our experiments, position embedding is crucial for PCNN due to the spatial invariance of CNN. For RNN, position embedding helps little (likely because an RNN has the capacity of exploiting temporal dependencies) so we adopt indicator encoding instead.

Sentence Encoder: For a sentence x_i, we want to apply a non-linear transformation to the vector

[1] We primarily focus on effectiveness of AT. Other techniques in Sec. 2 are complementary to our focus.

representation of x_i to derive a feature vector $s_i = f(x_i;\theta)$ given a set of parameters θ. We consider both PCNN and RNN as $f(x_i;\theta)$.

For PCNN, inheriting the settings from (Zeng et al., 2014), we adopt a convolution kernel with window size 3 and d_s output channels and then apply piecewise pooling and ReLU (Nair and Hinton, 2010) as an activation function to eventually obtain a $3 \cdot d_s$-dimensional feature vector s_i.

For RNN, we adopt bidirectional GRU with d_s hidden units and concatenate the hidden states of the last timesteps from both the forward and the backward RNN as a $2 \cdot d_s$-dimensional feature vector s_i.

Selective Attention: Following Lin et al. (2016), for each relation r, we aim to softly select an attended sentence s_r by taking a weighted average of $s_1, s_2, \ldots, s_n$, namely $s_r = \sum_i \alpha_i^r s_i$. Here α^r denotes the attention weights w.r.t. relation r. For computing the weights, we define a *query vector* q_r for each relation r and compute $\alpha^r = \mathrm{softmax}(u^r)$ where $u_i^r = \tanh(s_i)^\top q_r$. The query vector q_r can be considered as the embedding vector for the relation r, which is jointly learned with other model parameters.

Loss Function: For an entity pair, we compute the probability of relation r by $P(r \mid X;\theta) = \mathrm{softmax}(As_r + b)$, where A is the projection matrix and b is the bias. For the multi-label setting, suppose K relations $r_1, \ldots, r_K$ exist for X. Simply taking the summation over the log probabilities of all those labels yields the final loss function

$$L(X;\theta) = -\sum_{i=1}^{K} \log P(r_i \mid X;\theta). \qquad (1)$$

Dropout: For regularizing the parameters, we apply dropout (Srivastava et al., 2014) to both the word embedding and the sentence feature vector s_i. Note that we do not perform dropout on the position embedding p_i.

3.3 Adversarial Training

Adversarial training (AT) is a way of regularizing the classifier to improve robustness to small *worst-case* perturbations by computing the gradient direction of a loss function w.r.t. the data. AT generates continuous perturbations, so we add the adversarial noise at the level of the word embeddings, similar to Miyato et al. (2016). Formally, consider the input data X and suppose the word embedding of all the words in X is V. AT adds a small adversarial perturbation e_{adv} to V and optimizes the following objective instead of Eq.(1).

Dataset	#Rel	#Ent-Pair	#Mention	Sent-Len
NYT-Train	58	290429	577434	145
UW-Train	5	132419	546731	120

Table 1: Dataset statistics (#Rel includes *NA*).

$$L_{\text{adv}}(X;\theta) = L(X + e_{\text{adv}};\theta), \text{ where} \qquad (2)$$

$$e_{\text{adv}} = \arg\max_{\|e\|\le\epsilon} L(X + e;\hat{\theta}) \qquad (3)$$

Here $\hat{\theta}$ denotes a fixed copy of the current value of θ. Since Eq.(3) is computationally intractable for neural nets, Goodfellow et al. (2014) proposes to approximate Eq.(3) by linearizing $L(X;\hat{\theta})$ near X:

$$e_{\text{adv}} = \epsilon g/\|g\|, \text{ where } g = \nabla_V L(X;\hat{\theta}). \qquad (4)$$

Here V denotes the word embedding of *all* the words in X. Accordingly, in Eq. 4, $\|g\|$ denotes the norm of gradients over *all* the words from *all* the sentences in X. In addition, we do not perturb the feature vector p for entity positions. A visualization of the process is demonstrated in Fig. 1.

4 Experiments

To measure the effectiveness of adversarial training on relation extraction, we evaluate both the CNN (PCNN) and RNN (bi-GRU) models on two different datasets, the NYT dataset (NYT) developed by Riedel et al. (2010) and the UW dataset (UW) by Liu et al. (2016). All code is implemented in Tensorflow (Abadi et al., 2016) and available at `https://github.com/jxwuyi/AtNRE`. We adopt Adam optimizer (Kingma and Ba, 2014) with learning rate 0.001, batch size 50 and dropout rate 0.5. For adversarial training, the only parameter is ϵ. In each of the following experiments, we fixed all the hyper-parameters of the base model, performed a binary search solely on ϵ and showed the most effective value of ϵ.

4.1 Datasets

The statistics of the two datasets are summarized in Table 1. We exclude sentences longer than *Sent-Len* during training and randomly split data for entity pairs with more than 500 mentions. Note that the number of target relations in these two datasets are significantly different, which helps

Recall	0.1	0.2	0.3	0.4	AUC
PCNN	0.667	0.572	0.476	0.392	0.329
PCNN-Adv	0.717	0.589	0.511	0.407	0.356
RNN	0.668	0.586	0.524	0.442	0.351
RNN-Adv	**0.728**	**0.646**	**0.553**	**0.481**	**0.382**

Table 2: Precisions of various models for different recalls on the NYT dataset, with best values in bold.

Recall	0.1	0.2	0.3	0.4	AUC

PCNN-Adv	0.844	0.750	0.738	0.707	0.619
RNN	0.823	0.822	0.791	0.752	0.631
RNN-Adv	**0.929**	**0.878**	**0.850**	**0.779**	**0.671**

Table 3: Precisions of various models for different recalls on the UW dataset, with best values in bold.

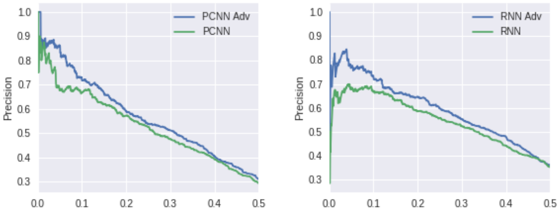

Figure 2: PR curves for PCNN (left) and RNN (right) on the NYT dataset with (blue) and without (green) adversarial training.

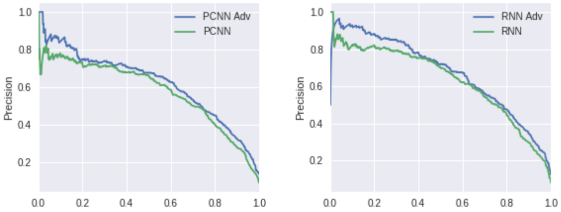

Figure 3: PR curves for PCNN (left) and RNN (right) on the UW dataset with (blue) and without (green) adversarial training.

demonstrate the applicability of adversarial training on various evaluation settings.

Since the test set of the UW dataset only contains 200 sentences, we adopt a subset of the test set from the NYT dataset: all the entity pairs with the corresponding 4 relations in UW and another 1500 randomly selected *NA* pairs.

4.2 Practical Performances

The NYT dataset:

We utilize the word embeddings released by Lin et al. (2016), which has $d_w = 50$ dimensions. For model parameters, we set $d_e = 5$ (dimension of the entity position feature vector) and $d_s = 230$ (dimension of sentence feature vector) for PCNN and $d_e = 3$ and $d_s = 150$ for RNN. For adversarial training, we choose $\epsilon = 0.01$ for PCNN and $\epsilon = 0.02$ for RNN. We empirically observed that when adding dropout to the word embeddings, PCNN performs significantly worse. Hence we only apply dropout to s_i for PCNN. However, even with a dropout rate of 0.5, RNN still performs well. We conjecture that it is due to PCNN being more sensitive to input signals and the dimensionality of the word embedding ($d_w = 50$) being very small.

The precision-recall curves for different models on the test set are shown in Fig. 2. Since the precision drops significantly with large recalls on the NYT dataset, we emphasize a part of the curve with recall number smaller than 0.5 in the figure. Adversarial training significantly improves the precision for both PCNN and RNN models. We also show the precision numbers for some particular recalls as well as the AUC (for the whole PR curve) in Table 2, where RNN generally leads to better precision.

The UW dataset:

We train a word embedding of $d_w = 200$ dimensions using Glove (Pennington et al., 2014) on the New York Times Corpus in this experiment. For model parameters, we set the entity feature dimension $d_e = 5$ and sentence feature dimension $d_s = 250$ for PCNN and $d_e = 3$ and $d_s = 200$ for RNN. For adversarial training, we choose $\epsilon = 0.05$ for PCNN and $\epsilon = 0.5$ for RNN. Since here word embedding dimension d_w is larger than that used for the NYT dataset, which implies that we now have word embeddings with larger norms, accordingly the optimal value of ϵ increases. The precision-recall curves on the test data are shown in Fig. 3, where adversarial training again significantly improves the precision for both models. The precision numbers for some particular recall values as well as the AUC numbers are demonstrated in Table 3. Similarly RNN yields superior performances on the UW dataset.

4.3 Discussion

CNN vs RNN: In the experiments, RNN generally produces more precise predictions than CNN due to its rich model capacity and also has high robustness to input embeddings. The CNN, in contrast, has far fewer parameters which leads to much faster training and testing, which suggests a practical trade-off.

Notably, although the improvement under AUC by adversarial training are roughly the same for both RNN and CNN, the optimal ϵ value for RNN is always much larger than CNN. This implies that empirically RNN is more robust under adversarial attacks than CNN, which also helps RNN maintain higher precision as recall increases.

Choice of ϵ: When $\epsilon = 0$, the AT loss (Eq.(2)) degenerates to the original loss (Eq.(1)); when ϵ becomes too large, the noise can change the semantics of a sentence[2] and make the model extremely hard to correctly classify the adversarial examples.

Notably, the optimal value of ϵ is much smaller than the norm of the word embedding, which implies adversarial training works most effectively when only producing tiny perturbations on word features while keeping the semantics of sentences unchanged[3].

Connection to other approaches: Li et al. (2017); Xie et al. (2017) proposes linguistic adversaries techniques to enhance the robustness of the model by randomly changing the word tokens in a sentence. This explicitly modifies the semantics of a sentence. By contrast, adversarial training focuses on smaller and continuous perturbations in the embedding space while preserving the semantics of sentences. Hence, adversarial training is complementary to linguistic adversaries.

Context-Aware Representations for Knowledge Base Relation Extraction

Abstract

We demonstrate that for sentence-level relation extraction it is beneficial to consider other relations in the sentential context while predicting the target relation. Our architecture uses an LSTM-based encoder to jointly learn representations for all relations in a single sentence. We combine the context representations with an attention mechanism to make the final prediction.

We use the Wikidata knowledge base to construct a dataset of multiple relations per sentence and to evaluate our approach. Compared to a baseline system, our method results in an average error reduction of 24% on a held-out set of relations.

The code and the dataset to replicate the experiments are made available at https://github.com/ukplab.

1 Introduction

The main goal of relation extraction is to determine a type of relation between two target entities that appear together in a text. In this paper, we consider the sentential relation extraction task: to each occurrence of the target entity pair $\langle e_1, e_2 \rangle$ in some sentence s one has to assign a relation type r from a given set R (Hoffmann et al., 2011). A triple $\langle e_1, r, e_2 \rangle$ is called a *relation instance* and we refer to the relation of the target entity pair as *target relation*. Relation extraction is a fundamental task that enables a wide range of semantic applications from question answering (Xu et al., 2016) to fact checking (Vlachos and Riedel, 2014).

For relation extraction, it is crucial to be able to extract relevant features from the sentential context (Riedel et al., 2010; Zeng et al., 2015). Modern approaches focus just on the relation between the target entities and disregard other relations that might be present in the same sentence (Zeng et al., 2015; Lin et al., 2016). For example, in order to correctly identify the relation type between the movie e_1 and the director e_2 in (1), it is important to separate out the INSTANCE_OF relation between the movie and its type e_3:

(1) [e_1 **Star Wars VII**] is an American [e_3 **space opera epic film**] directed by [e_2 **J. J. Abrams**].

We present a novel architecture that considers other relations in the sentence as a context for predicting the label of the target relation. We use the term *context relations* to refer to them throughout the paper. Our architecture uses an LSTM-based encoder to jointly learn representations for all relations in a single sentence. The representation of the target relation and representations of the context relations are combined to make the final prediction.

To facilitate the experiments we construct a dataset that contains multiple positive and negative relation instances per sentence. We employ a fast growing community managed knowledge base (KB) Wikidata (Vrandečić and Krötzsch, 2014) to build the dataset.

Our main contribution is the new neural network architecture for extracting relations between an entity pair that takes into account other relations in the sentence.

2 Related Work

We employ a neural network to automatically encode the target relation and the sentential context into a fixed-size feature vector. Mintz et al. (2009) and Riedel et al. (2010) have used manually engineered features based on part-of-speech tags and dependency parses to represent the target relations. Recently, Zeng et al. (2015) and Zhao et al. (2015) have shown that one can successfully apply convo-

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1784–1789
Copenhagen, Denmark, September 7–11, 2017.

lutional neural networks to extract sentence-level features automatically.

Most of the methods (Riedel et al., 2010; Zeng et al., 2015; Lin et al., 2016) focus on predicting a single relation type based on the combined evidence from all of the occurrences of an entity pair. Hoffmann et al. (2011) and Surdeanu et al. (2012) assign multiple relation types to each entity pair, such that the predictions are tied to particular occurrences of the entity pair. We regard the relation extraction task similarly and predict relation types on the sentence level.

We use a distant supervision approach (Mintz et al., 2009) to construct the dataset. Mintz et al. (2009) and Riedel et al. (2010) have applied it to create relation extraction datasets for a large-scale KB. In contrast to our dataset, their data contains a single relation instance per sentence. That makes it incompatible with our method.

All of the aforementioned approaches consider just the relation between the target entities and disregard other relations that might be present in the same sentence. Our method uses context relations to predict the target relation. One can also use other types of structured information from the nearby context to improve relation extraction. Roth and Yih (2004) have combined named entity recognition and relation extraction in a structured prediction approach to improve both tasks. Later, Miwa and Bansal (2016) have implemented an end-to-end neural network to construct a context representation for joint entity and relation extraction. Finally, Li et al. (2013) have designed global features and constraints to extract multiple events and their arguments from the same sentence.

We don't implement global constraints in our approach, since unlike events and arguments, there are no restrictions as to what relations can appear together. Instead we encode all relations in the same context into fixed-size vectors and use an attention mechanism to combine them.

3 Data generation with Wikidata

Wikidata is a collaboratively constructed KB that encodes common world knowledge in a form of binary relation instances (e.g. CAPITAL:P36 (*Hawaii*:Q782, *Honolulu*:Q18094))[1]. It contains more than 28 million entities and 160 million relation instances.[2] A broad community oversight, similar to Wikipedia, ensures a higher data quality compared to other KBs (Färber et al., 2015).

	Train	Validation	Held-out
# of relation triples	284,295	113,852	287,902
# of relation inst.	578,199	190,160	600,804

Table 1: Statistics of the generated dataset.

We use the complete English Wikipedia corpus to generate training and evaluation data. Wikipedia and Wikidata are tightly integrated which enables us to employ manual wiki annotations to extract high quality data. From each sentence in a complete article we extract link annotations and retrieve Wikidata entity IDs corresponding to the linked articles. There is an unambiguous one-to-one mapping between Wikidata entities and Wikipedia articles. For example:

```
1: Input  Born in [[Honolulu|Honolulu,
   Hawaii]], Obama is a graduate of
   [[Columbia University]].
2: Links to Wikidata Ids Honolulu ↦ Q18094
          Columbia_University ↦ Q49088
```

For further processing, we filter out sentences that contain fewer than 3 annotated entities, since we need to have multiple relations per sentence for training (see Section 4).

We extract named entities and noun chunks from the input sentences with the Stanford CoreNLP toolkit (Manning et al., 2014) to identify entities that are not covered by the Wikipedia annotations (e.g. Obama in the sentence above). We retrieve IDs for those entities by searching through entity labels in Wikidata. We use HeidelTime (Strötgen and Gertz, 2013) to extract dates.

For each pair of entities, we query Wikidata for relation types that connect them. We discard an occurrence of an entity pair if the relation is ambiguous, i. e. multiple relation types were retrieved. For comparison, Surdeanu et al. (2012) report that only 7.5% of entity pairs have more than one corresponding relation type in the distantly supervised dataset of Riedel et al. (2010). The entity pairs that have no relation in the knowledge base are stored as negative instances.

The constructed dataset features 353 different relation types (out of approximately 1700 non-meta relation types in the Wikidata scheme). We split

[1] Unique IDs in Wikidata have a Q-prefix for entities and a P-prefix for relations.

[2] https://www.wikidata.org/wiki/Special:Statistics

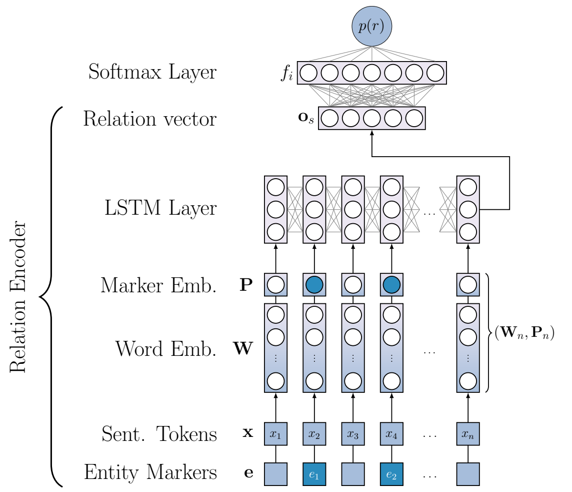

Figure 1: The architecture of the relation encoder

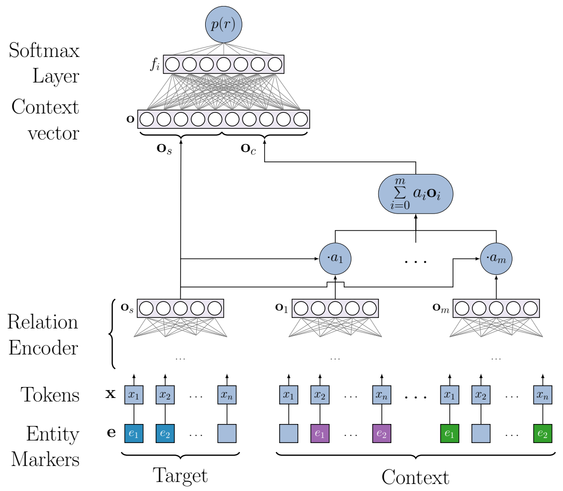

Figure 2: Incorporation of the context relations. For the ContextSum model variant $a_i = 1$.

it into train, validation and held-out sets, ensuring that there is no overlap in either sentences or relation triples between the three sets. Table 1 summarizes the statistics about the dataset. We assessed the quality of the distant supervision set-up on 200 manually verified sentences from the training set: 79.5% of relations in those sentences were correctly labeled with distant supervision (86.9 if one entity is linked, 74.7 if both are linked).

4 Model architecture

4.1 Relation encoder

The relation encoder produces a fixed-size vector representation $\mathbf{o}_s$ of a relation between two entities in a sentence (see Figure 1).

First, each token of the sentence $\mathbf{x} = \{x_1, x_2 \dots x_n\}$ is mapped to a k-dimensional embedding vector using a matrix $\mathbf{W} \in \mathbb{R}^{|V| \times k}$, where $|V|$ is the size of the vocabulary. Throughout the experiments in this paper, we use 50-dimensional GloVe embeddings pre-trained on a 6 billion corpus (Pennington et al., 2014).

Second, we mark each token in the sentence as either belonging to the first entity e_1, the second entity e_2 or to neither of those. A marker embedding matrix $\mathbf{P} \in \mathbb{R}^{3 \times d}$ is randomly initialized (d is the dimension of the position embedding and there are three marker types). For each token, we concatenate the marker embedding with the word embedding: $(\mathbf{W}_n, \mathbf{P}_n)$.

We apply a recurrent neural network (RNN) on the token embeddings. The length n naturally varies from sentence to sentence and an RNN provides a way to accommodate inputs of various sizes. It maps a sequence of n vectors to a fixed-size output vector $\mathbf{o}_s \in \mathbb{R}^o$. We take the output vector $\mathbf{o}_s$ as the representation of the relation between the target entities in the sentence. We use the Long Short-Term Memory (LSTM) variant of RNN (Hochreiter and Schmidhuber, 1997) that was successfully applied to information extraction before (Miwa and Bansal, 2016).

4.2 Model variants

LSTM baseline As the first model variant, we feed the output vector $\mathbf{o}_s$ of the relation encoder to a softmax layer to predict the final relation type for the target entity (see the upper part of Figure 1):

$$p(r|\langle e_1, e_2\rangle, \mathbf{x}; \theta) = \frac{\exp(f_r)}{\sum_{i=1}^{n_r} \exp(f_i)}, \qquad (1)$$
$$f_i = \mathbf{y}_i \cdot \mathbf{o}_s + b_i,$$

where $\mathbf{y}_i$ is a weight vector and b_i is a bias.

ContextSum We argue that for predicting a relation type for a target entity pair other context relations in the same sentence are relevant. Some relation types may tend to co-occur, such as DIRECTED_BY and PRODUCED_BY, whereas others may be restrictive (e. g. one can only have a single PLACE_OF_BIRTH).

Therefore, in addition to the target entity pair, we take other entities from the same sentence that were extracted at the data generation step. We construct a set of context relations by taking each possible pair of entities.[3] Example (2) shows a target entity pair $\langle e_1, e_2\rangle$ and context entities highlighted in bold.

[3] We limit the maximum number of relations in a sentence to 7 for computational reasons.

(2) [**Swag It Out**] is the official [**debut single**] by [**American singer**] [e_1**Zendaya**], known for starring in the series [e_2 **Shake It Up**].

We apply the same relation encoder on the target and context relations (see Figure 2). That ensures that representation for target and context relations are learned jointly. We sum the context relation representations: $\mathbf{o}_c = \sum_{i=0}^{m} \mathbf{o}_i$, where each element $\mathbf{o}_i$ is a vector representation of a single context relation. The resulting context representation $\mathbf{o}_c \in \mathbb{R}^o$ is concatenated with the vector representation of the target relation: $\mathbf{o} = [\mathbf{o}_s, \mathbf{o}_c]$. We feed the concatenated vector to the softmax layer in Eq. 1 to predict the final relation type for the target entity pair (see the upper part of Figure 2).

ContextAtt In this variant, we use a weighted sum of the context relation representation at the penultimate step:

$$\mathbf{o}_c = \sum_{i=0}^{m} a_i \mathbf{o}_i, \quad a_i = \frac{\exp(g(\mathbf{o}_i, \mathbf{o}_s))}{\sum_{j=0}^{m} \exp(g(\mathbf{o}_j, \mathbf{o}_s))}, \qquad (2)$$

where g_i computes an attention score for a context relation with respect to the target relation: $g(\mathbf{o}_i, \mathbf{o}_s) = \mathbf{o}_i \mathbf{A} \mathbf{o}_s$, and $\mathbf{A}$ is a weight matrix that is learned.

5 Experiments

5.1 Training the models

All models were trained using the Adam optimizer (Kingma and Ba, 2014) with categorical cross-entropy as the loss function. We use an early stopping criterion on the validation data to determine the number of training epochs. The learning rate is fixed to 0.01 and the rest of the optimization parameters are set as recommended in Kingma and Ba (2014): $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\varepsilon = 1e-08$. The training is performed in batches of 128 instances.

We apply Dropout (Srivastava et al., 2014) on the penultimate layer as well as on the embeddings layer with a probability of 0.5. We choose the size of the layers (RNN layer size $o = 256$) and entity marker embeddings ($d = 3$) with a random search on the validation set.[4]

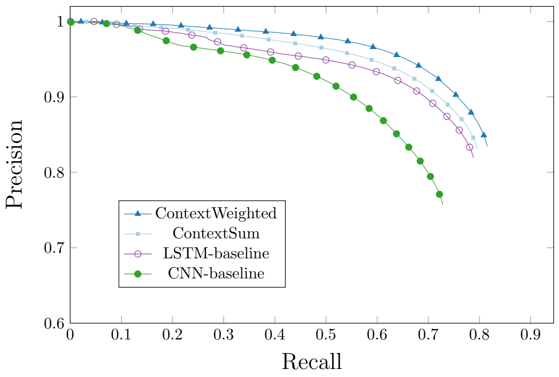

Figure 3: Aggregated precision-recall curves for the implemented models.

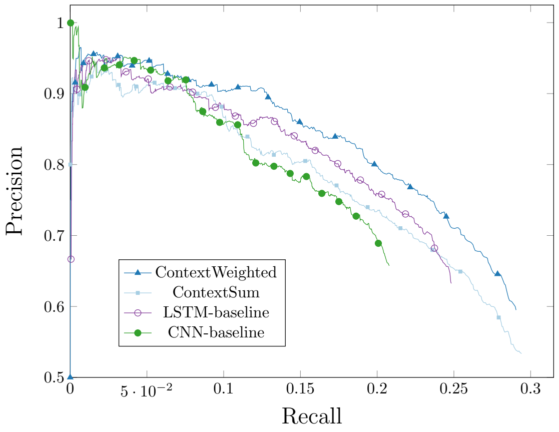

Figure 4: Aggregated macro precision-recall curves for the implemented models.

5.2 Held-out evaluation

As an additional baseline, we re-implement a sentence-level model based on convolutional neural networks (CNNs) described in Lin et al. (2016). This is a state-of-the-art model for fine-grained relation extraction that was previously tested on the single-relation dataset from Riedel et al. (2010). In addition to CNNs, their architecture uses a different position encoding scheme: position markers encode a relative position of each word with respect to the target entities.[5] We use the same GloVe word embeddings for this model and perform a hyper-parameter optimization on the validation set.

Our dataset lets us compare the baseline models and the models that use context relations on the same data. Following the previous work on rela-

[4] We test for the RNN layer size the values $\{64, 128, 256, 512\}$, for entity marker embeddings the values $\{1, 3, 5, 7\}$ and for the Dropout rate the values in the range 0.0–0.75.

[5] We have briefly experimented with such position markers for our models, but found no improvements.

Relation type	LSTM-Baseline P	 R	ContextAtt P	 R
COUNTRY	0.8899	0.9344	0.9130	0.9382
LOCATED IN	0.8329	0.8832	0.8655	0.8994

Table 2: Precision (P) and recall (R) for the top relations.

tion extraction, we report the aggregated precision-recall curves for each model on the held-out data (Figure 3).[6] To compute the curves, we rank the predictions of each model by their confidence and traverse this list top to bottom measuring the precision and recall at each step.

The models that take the context into account perform similar to the baselines at the smallest recall numbers, but start to positively deviate from them at higher recall rates. In particular, the ContextAtt model performs better than any other system in our study over the entire recall range. Compared to the competitive LSTM-baseline that uses the same relation encoder, the ContextAtt model achieves a 24% reduction of the average error: from 0.2096 ± 0.002 to 0.1590 ± 0.002. The difference between the models is statistically significant ($p = 0.009$).[7]

We also compute macro precision-recall curves that give equal weights to all relations in the dataset. Figure 4 shows that the ContextAtt model performs best over all relation types. One can also see that the ContextSum doesn't universally outperforms the LSTM-baseline. It demonstrates again that using attention is crucial to extract relevant information from the context relations.

On the relation-specific results (Table 2) we observe that the context-enabled model demonstrates the most improvement on precision and seems to be especially useful for taxonomy relations (see SUBCLASS OF, PART OF).

6 Conclusions

We have introduced a neural network architecture for relation extraction on the sentence level that takes into account other relations from the same context. We have shown by comparison with competitive baselines that these context relations are beneficial for relation extraction with a large set of relation types.

Our approach can be easily applied to other types of relation extraction models as well. For instance, Lin et al. (2016) extract sentence-level features and then combine features from multiple sentences with a selective attention mechanism. It would be possible to replace their sentence-level feature extractor with our model.

Abstract

Distant-supervised relation extraction inevitably suffers from wrong labeling problems because it heuristically labels relational facts with knowledge bases. Previous sentence level denoise models don't achieve satisfying performances because they use hard labels which are determined by distant supervision and immutable during training. To this end, we introduce an entity-pair level denoise method which exploits semantic information from correctly labeled entity pairs to correct wrong labels dynamically during training. We propose a joint score function which combines the relational scores based on the entity-pair representation and the confidence of the hard label to obtain a new label, namely a soft label, for certain entity pair. During training, soft labels instead of hard labels serve as gold labels. Experiments on the benchmark dataset show that our method dramatically reduces noisy instances and outperforms the state-of-the-art systems.

1 Introduction

Relation Extraction (RE) aims to obtain relational facts from plain text. Traditional supervised RE systems suffer from lack of manually labeled data. Mintz et al. (2009) proposes distant supervision, which exploits relational facts in knowledge bases (KBs). Distant supervision automatically generates training examples by aligning entity mentions in plain text with those in KB and labeling entity pairs with their relations in KB. If there's no relation link between certain entity pair in KB, it will be labeled as negative instance (NA). However, the automatic labeling inevitably accompanies with wrong labels because the relations of entity pairs might be missing from KBs or mislabeled.

Multi-instances learning (MIL) is proposed by Riedel et al. (2010) to combat the noise. The method divides the training set into multiple bags of entity pairs (shown in Fig 1) and labels the bags with the relations of entity pairs in the KB. Each bag consists of sentences mentioning both head and tail entities. Much effort has been made in reducing the influence of noisy sentences within the bag, including methods based on at-least-one assumption (Hoffmann et al., 2011; Ritter et al., 2013; Zeng et al., 2015) and attention mechanisms over instances (Lin et al., 2016; Ji et al., 2017).

However, the sentence level denoise methods can't fully address the wrong labeling problem largely because they use a hard-label method in which the labels of entity pairs are immutable dur-

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1790–1795
Copenhagen, Denmark, September 7–11, 2017.

ing training, no matter whether they are correct or not. As shown in Fig 1, due to the absence of (*Jan Eliasson*[1] *, Sweden*) from *Nationality* relation in the KB, the entity pair is mislabeled as NA. However, we find the sentences in the bag of (*Jan Eliasson, Sweden*) share similar semantic pattern *"X of Y"* with correctly labeled instances (blue). In the false positive instance, *Sebastian Roch* is indeed from *France*, but the syntactic pattern of the sentence in the bag differs greatly from those of correctly labeled instances. Actually, the reliability of a distant-supervised (DS) label can be determined by the syntactic/semantic similarity between certain instance and the potential correctly labeled instances. Soft-label method intends to utilize corresponding similarities to correct wrong DS labels in the training stage dynamically, which means the same bag may have different soft labels in different epochs of training. The basis of soft-label method is the dominance of correctly labeled instances. Fortunately, Xu et al. (2013) proves that correctly labeled instances account for 94.4% (including true negatives) in the distant-supervised New York Times corpus (benchmark dataset).

To this end, we introduce a soft-label method to correct wrong labels at entity-pair level during training by exploiting semantic/syntactic information from correctly labeled instances. In our model, the representation of certain entity pair is a weighted combination of related sentences which are encoded by piecewise convolutional neural network (PCNN) (Zeng et al., 2015). Besides, we propose a joint score function to obtain soft labels during training by taking both the confidence of DS labels and the entity-pair representations into consideration. Our contributions are three-fold:

- To the best of our knowledge, we first propose an entity-pair level noise-tolerant method while previous works only focused on sentence level noise.

- We propose a simple but effective method called soft-label method to dynamically correct wrong labels during training. Case study shows our corrections are of high accuracy.

- We evaluate our model on the benchmark dataset and achieve substantial improvement compared with the state-of-the-art systems.

[1] Jan Eliasson is a Swedish diplomat.

2 Methodology

Multi-instances learning (MIL) framework splits the training set $\mathbf{M}$ into multiple entity-pair bags $\{\langle h_1, t_1\rangle, \langle h_2, t_2\rangle, \cdots, \langle h_n, t_n\rangle\}$. Each bag $\langle h_i, t_i\rangle$ contains sentences $\{x_1, x_2, \cdots, x_c\}$ which mention both head entity h_i and tail entity t_i. The representation $\mathbf{s}_i$ of bag $\langle h_i, t_i\rangle$ is a weighted combination of related sentence vectors $\{\mathbf{x}_1, \mathbf{x}_2, \cdots, \mathbf{x}_c\}$ which are encoded by CNN. Finally, we use soft-label score function to correct wrong labels of bags of entity pairs while computing probabilities for each relation type.

2.1 Sentence Encoder

We get the representation of certain sentence $\mathbf{x}_i = \{\mathbf{w}_1, \mathbf{w}_2, \cdots, \mathbf{w}_m\}$ by concatenating word embeddings $\{w_1, w_2, \cdots, w_m\}$ and position embeddings (Zeng et al., 2014) $\{p_1, p_2, \cdots, p_m\}$, where $\mathbf{w}_i \in \mathbb{R}^d, w_i \in \mathbb{R}^{d_w}, p_i \in \mathbb{R}^{d_p} (d = d_w + d_p)$.

Convolution layer utilizes a sliding window of size l. We define $\mathbf{q}_i \in \mathbb{R}^{l \times d}$ as the concatenation of words within the i-th window.

$$\mathbf{q}_i = \mathbf{w}_{i-l+1:i} (1 \leq i \leq m + l - 1) \quad (1)$$

The convolution matrix is denoted by $\mathbf{W}_c \in \mathbb{R}^{d_c \times (l \times d)}$, where d_c is the sentence embedding size. The i-th filter of the convolutional layer is computed as:

$$\mathbf{f}_i = [\mathbf{W}_c \mathbf{q} + \mathbf{b}]_i \quad (2)$$

Afterwards, Piecewise max-pooling (Zeng et al., 2015) is used to divide convolutional filter $\mathbf{f}_i$ into three parts $\{\mathbf{f}_i^1, \mathbf{f}_i^2, \mathbf{f}_i^3\}$ by head and tail entities. For example, the sentence "*Barack Obama* was born in *Honulul*u in 1961" are divided into '*Barack Obama*', 'was born in *Honululu*' and 'in 1961'. We perform max-pooling on these three parts separately, and the i-th element of sentence vector $\mathbf{x} \in \mathbb{R}^{d_c}$ is defined as the concatenation of them:

$$\mathbf{x}_i = [max(\mathbf{f}_i^1); max(\mathbf{f}_i^2); max(\mathbf{f}_i^3)] \quad (3)$$

2.2 Sentence Level Weight distribution

The representation of entity pair $\langle h_i, t_i\rangle$ is defined as a weighted combination of sentences in the bag. **At-least-one:** At-least-one assumption is a down sampling method which assumes at least one sentence in the bag will express the relation between two entities, and select the most likely sentence in the bag for training and prediction. To be more specific, the weight of the selected sentence is 1 while those of other sentences in the bag are all 0.

Selective Attention: Lin et al. (2016) proposes selective attention mechanism to reduce weights of noisy instances within the entity-pair bag.

$$\mathbf{s} = \sum_i \alpha_i \mathbf{x}_i; \alpha_i = \frac{\exp(\mathbf{x}_i \mathbf{A} \mathbf{r})}{\sum_k \exp(\mathbf{x}_k \mathbf{A} \mathbf{r})} \qquad (4)$$

where α_i is the weight of sentence vector $\mathbf{x}_i$, $\mathbf{A}$ and $\mathbf{r}$ are diagonal and relation query parameters.

2.3 Soft-label Adjustment

The key of our method is to derive a soft label as the gold label for each bag dynamically during training, which is not necessarily the same label as the distant supervised (DS) label. We still use DS labels while testing.

The soft label is determined dynamically, which means the same bag may have different soft labels in different training epochs. we propose following joint function to determine the soft label r_i for entity pair $\langle h_i, t_i \rangle$:

$$r_i = \arg\max(\mathbf{o} + \max(\mathbf{o})\mathbf{A} \odot L_i) \qquad (5)$$

where $\mathbf{o}, \mathbf{A}, L_i \in \mathbb{R}^{d_r}$ (d_r is the number of predefined relations). One-hot vector L_i indicates the DS label of $\langle h_i, t_i \rangle$. Relation Confidence vector $\mathbf{A}$ represents the reliability of DS labels. Each element in $\mathbf{A}$ is a decimal between 0 and 1, which indicates the confidence of corresponding DS labeled relation type. $\odot$ operation represents element-wise production. $\mathbf{o}$ is the vector of relational scores based on the entity-pair representation $\mathbf{s}_i$ of $\langle h_i, t_i \rangle$. $\max(\mathbf{o})$ is a scaling constant which restricts the effect of the DS label. The score of the t-th relation type $\mathbf{o}_t$ is calculated based on the trained relation matrice $\mathbf{M}$ and bias $\mathbf{b}$:

$$\mathbf{o}_t = \frac{\exp(\mathbf{M}\mathbf{s}_t + \mathbf{b})}{\sum_k \exp(\mathbf{M}\mathbf{s}_k + \mathbf{b})} \qquad (6)$$

We use entity-pair level cross-entropy loss function using soft labels as gold labels while training:

$$J(\theta) = \sum_{i=1}^{n} \log p(r_i | \mathbf{s}_i; \theta) \qquad (7)$$

In the testing stage, we still use the DS label l_i of certain entity pair $\langle h_i, t_i \rangle$ as the gold label:

$$G(\theta) = \sum_{i=1}^{n} \log p(l_i | \mathbf{s}_i; \theta) \qquad (8)$$

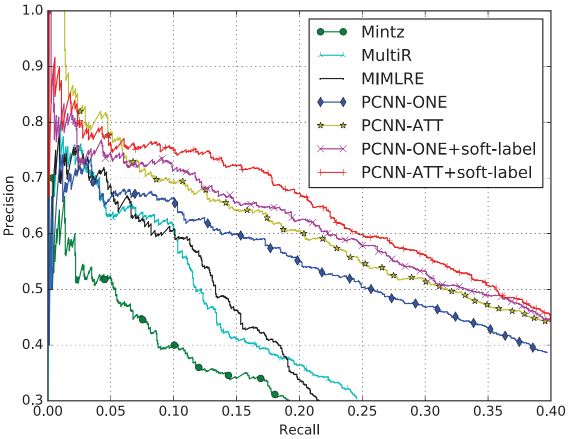

Figure 2: Precision/Recall curves of our model and previous state-of-the-art systems. Mintz (Mintz et al., 2009), MultiR (Hoffmann et al., 2011) and MIMLRE (Surdeanu et al., 2012) are feature-based models. ONE (Zeng et al., 2015) and ATT (Lin et al., 2016) are neural network models based on at-least-one assumption and selective attention, respectively.

3 Experiments

In this section, we first introduce the dataset and evaluation metrics in our experiments. Then, we demonstrate the parameter settings in our experiments. Besides, we compare the performance of our method with state-of-the-art feature-based and neural network baselines. Case study shows our soft-label corrections are of high accuracy.

3.1 Dataset and Evaluation Metrics

We evaluate our model on the benchmark dataset proposed by Mintz et al. (2009), which has also been used by Riedel et al. (2010), Hoffmann et al. (2011), Zeng et al. (2015) and Lin et al. (2016). The dataset uses Freebase (Bollacker et al., 2008) as distant-supervised knowledge base and New York Times (NYT) corpus as text resource. Sentences in NYT of the years 2005-2006 are used as training set while sentences in NYT of 2007 are used as testing set. There are 53 possible relations including NA which indicates no relation. The training data contains 522611 sentences, 281270 entity pairs and 18252 relational facts. The testing data contains 172448 sentences, 96678 entity pairs and 1950 relational facts.

Similar to the previous work, We report both aggregate precision/recall curves and top-N precision (P@N).

Window size	Word dimension	Position dimension	Filter dimension	Batch size	Learning rate	Dropout
$l = 3$	$d_w = 50$	$d_p = 5$	$d_c = 230$	$B = 160$	$\lambda = 0.001$	$p = 0.5$

Table 2: Top-N precision (P@N) for relation extraction in the entity pairs with different number of sentences. Following (Lin et al., 2016), One, Two and All test settings random select one/two/all sentences on the bags of entity pairs from the testing set which have more than one sentence to predict relation.

3.2 Comparison with previous work

Mintz (Mintz et al., 2009), MultiR (Hoffmann et al., 2011) and MIMLRE (Surdeanu et al., 2012) are feature-based models. PCNN-ONE (Zeng et al., 2015) and PCNN-ATT (Lin et al., 2016) are piecewise convolutional neural network (PCNN) models based on at-least-one assumption and selective attention, which are introduced in Section 2.2, respectively. All the results of compared models come from the data reported in their papers.

3.3 Experimental Settings

We use cross-validation to determine the parameters in our model. Soft-label method uses PCNN-ONE/PCNN-ATT to represent the bags of entity pairs, and we don't tune on the parameters of PCNN-ONE/PCNN-ATT for fair comparsion. So we use the same pre-trained word embeddings and parameters of CNN encoder as those of Lin et al. (2016). Detailed parameter settings are shown in Table 1. Moreover, we use Adam optimizer. Besides, to avoid negative effects of dominant NA instances in the begining of training, soft-label method is adopted after 3000 steps of parameter updates. The confidence vector **A** is heuristically set as $[0.9, 0.7, \cdots, 0.7]$ (the confidence of NA is 0.9 while confidence of other relations are all 0.7).

3.4 Precision Recall Curve

We have following observations from Figure 2: (1) For both ATT and ONE configuration, soft-label method achieves higher precision than baselines when recall is greater than 0.05. After manual evaluation, we find that most wrong instances with less than 0.05 recall are wrong labeling entity pairs in test set. (2) Even weaker baseline PCNN-ONE using soft labels gets a slightly better performance than PCNN-ATT. (3) When recall is between 0.05 and 0.15, the curve of our model ATT+soft-label is relatively stable, which demonstrates soft-label can obtain relatively stable performance in extracting relational facts.

Table 3: Some examples of soft-label corrections while training

3.5 Top N precision

Table 2 shows top-N precision (P@N) of the state-of-the-art systems and our model. We can see that (1) For both PCNN-ONE and PCNN-ATT model, soft-label method improves the precisions by over 10% in all test settings, which demonstrates the effects of our model. (2) Even a weaker baseline (PCNN-ONE) with soft-label method achieves higher precision than a strong model (PCNN-ATT). It shows that entity-pair level denoise model performs much better than the models which only focus on sentence level noise.

Case 1: **Place of Birth** → Nationality

Case 2: **Location Contains** → NA
···, he is from neighboring towns in ***Georgia*** (such as Blairsville and ***Young Harris***)

Table 4: Two typical wrong corrections of soft-label adjustment during training.

3.6 Case Study

Some examples of soft-label corrections during training are shown in Table 3. We can see that soft-label method can recognize both false positives and false negatives during training and correct wrong labels successfully. The two sentences above are mislabeled as *place lived* because triple facts *(Fernand nault, place lived, Montreal)* and *(Alexandra pelosi, place lived, San francisco)* exist in Freebase. However, the two sentences fail to express *place lived* relation. Our model can automatically correct them by soft-label adjustment. The two sentences below show that our model can also change false negative (NA) examples caused by missing facts in Freebase to correct ones.

Besides, our model has strong ability to distinguish different relational patterns, even for similar relations like *Place lived, Place of born, Place of Death*.

4 Error Analysis

We randomly select 200 instances of soft-label corrections during training for PCNN-ONE and PCNN-ATT respectively and check them manually. The accuracy of soft-label corrections for PCNN-ONE is 88.5% (177/200) while that for PCNN-ATT is 92% (184/200). We notice that the accuarcy of PCNN-ATT+soft-label is slightly higher than that of PCNN-ONE+soft-label. The condition is the same as our expectation. As explained in Sec 2.2, PCNN-ATT has better bag representations than PCNN-ONE because it can reduce the effect of noisy instances within the bag. The soft-label of certain bag is determined by its bag representation and the confidence of corresponding DS label. So the accuracy of soft-label corrections for PCNN-ATT can benefit from better bag representations.

Although most of soft-label corrections are of high accuracy (90.25%), there are still several wrong corrections. Table 4 lists two typical wrong corrections during training. Wrong corrections like Case 1 fail to distinguish similar relations (both *Nationality* and *place of birth* are relations between people and locations) between entities because of their similar sentence patterns. However, wrong corrections like Case 1 are rare (5/39) in our experiments. Soft-label method can still distinguish most similiar relations as shown in Sec 3.6. In Case 2, factual relation *location contains* is mistaken as NA partially because the relational pattern of this sentence is somewhat different from the regular *location contains* pattern. Additionally, soft-label method has a tendency to label ambiguous facts as NA because negative instances (NA) are dominated in the corpus. However, most bags which are soft-labeled as NA are still well-labeled in our experiments.

We argue that the minor wrong corrections of relational facts during training don't affect the overall performance much because distant supervision doesn't lack instances of relational facts due to its strong ability to automatically label large web text.

5 Conclusion and Future Work

This paper proposes a noise-tolerant method to combat wrong labels in distant-supervised relation extraction with soft labels. Our model focuses on entity-pair level noise while previous models only dealt with sentence level noise. Our model achieves significant improvement over baselines on the benchmark dataset. Case study shows that soft-label corrections are of high accuracy.

In the future, we plan to develop a new measurement for the reliability of certain distantly supervised label by evaluating the corresponding similarity between certain instance and the potential correctly labeled instances instead of using heuristically set confidence vector. In addition, we tend to find a more suitable sentence encoder rather than piece-wise CNN for our soft-label method.

A Sequential Model for Classifying Temporal Relations between Intra-Sentence Events

Prafulla Kumar Choubey and **Ruihong Huang**
Department of Computer Science and Engineering
Texas A&M University
(prafulla.choubey, huangrh)@tamu.edu

Abstract

We present a sequential model for temporal relation classification between intra-sentence events. The key observation is that the overall syntactic structure and compositional meanings of the multi-word context between events are important for distinguishing among fine-grained temporal relations. Specifically, our approach first extracts a sequence of context words that indicates the temporal relation between two events, which well align with the dependency path between two event mentions. The context word sequence, together with a parts-of-speech tag sequence and a dependency relation sequence that are generated corresponding to the word sequence, are then provided as input to bidirectional recurrent neural network (LSTM) models. The neural nets learn compositional syntactic and semantic representations of contexts surrounding the two events and predict the temporal relation between them. Evaluation of the proposed approach on TimeBank corpus shows that sequential modeling is capable of accurately recognizing temporal relations between events, which outperforms a neural net model using various discrete features as input that imitates previous feature based models.

1 Introduction

Identifying temporal relations between events is crucial to constructing events timeline. It has direct application in tasks such as question answering, event timeline generation and document summarization.

Bush said he saw little reason to be optimistic about a settlement of the **dispute**, which stems from Iraq's **invasion** of oil-wealthy Kuwait and its subsequent military **buildup** on the border of Saudi Arabia.
Relations: (dispute $after^{rel_1}$ invasion, invasion $ibefore^{rel_2}$ buildup, dispute $after^{rel_3}$ buildup)

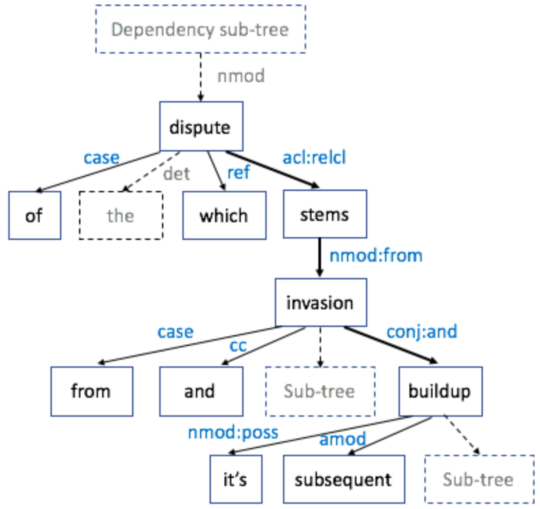

Figure 1: Example sentence to illustrate the temporal context for event pairs.

Previous works studied this task as the classification problem based on discrete features defined over lexico-syntactic, semantic and discourse features. However, these features are often derived from local contexts of two events and are only capable of capturing direct evidences indicating the temporal relation. Specifically, when two events are distantly located or are separated by other events in between, feature based approaches often fail to utilize compositional evidences, which are hard to encode using discrete features.

Consider the example sentence in Figure 1. Here, the first two temporal re-

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1796–1802
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

lations, $dispute$ $\textbf{after}^{\textbf{rel}_1}$ $invasion$ and $invation$ $\textbf{ibefore}^{\textbf{rel}_2}$ $buildup$, involve events that are close by and discrete features, such as dependency relations and bag-of-words extracted from local contexts of two events, might be sufficient to correctly detect their relations. However, for the temporal relation $dispute$ $\textbf{after}^{\textbf{rel}_3}$ $buildup$, the context between the two events is long, complex and involves another event ($invasion$) as well, which makes it challenging for any individual feature or feature combinations to capture the temporal relation.

We propose that the overall syntactic structure of in-between contexts including the linear order of words as well as the compositional semantics of multi-word contexts are critical for predicting the temporal relation between two events. Furthermore, the most important syntactic and semantic structures are derived along dependency paths between two event mentions[1]. This aligns well with the observation that semantic composition relates to grammatical dependency relations (Monroe and Wang, 2014; Reddy et al., 2016).

Our approach defines rules on dependency parse trees to extract temporal relation indicating contexts. First, we extract the dependency path between two event mentions. Then we apply two heuristic rules to enrich extracted dependency paths and deal with complex syntactic structures such as punctuations. Empirically, we found that parts-of-speech tags (POS) and dependency sequences generated following the dependency path provide evidences to predict the temporal relation as well.

We use neural net sequence models to capture structural and semantic compositionality in describing temporal relations between events. Specifically, we generate three sequences for each dependency path, the word sequence, the POS tag sequence and the dependency relation sequence. Using the three types of sequences as input, we train bi-directional LSTM models that consume each of the three sequences and model compositional structural information, both syntactically and semantically.

The evaluation shows that each type of sequences is useful to temporal relation classification between events. Our complete neural net model taking all the three types of sequences performs the best, which clearly outperforms feature based models.

2 Related Works

Most of the previous works on temporal relation classification are based on feature-based classifiers. Mani et al. (2006) built MaxEnt classifier on hand-tagged features in the corpus, including tense, aspect, modality, polarity and event class for classifying temporal relations. Later Chambers et al. (2007) used a two-stage classifier which first learned imperfect event attributes and then combined them with other linguistic features in the second stage to perform the classification.

The following works mostly expanded the feature sets (Cheng et al., 2007; Bethard and Martin, 2007; UzZaman et al., 2012; Bethard, 2013; Kolomiyets et al., 2012; Chambers, 2013; Laokulrat et al., 2013). Specifically, Chambers (2013) used direct dependency path between event pairs to capture syntactic context. Laokulrat et al. (2013) used 3-grams of paths between two event mentions in a dependency tree as features instead of full paths as those are too sparse. We found that modeling the entire path as one sequence provides greater compositional evidence on the temporal relation. In addition, modifiers attached to the words in a path with specific dependency relations like *nmod:tmod* are also informative.

Ng (2013) proposed a hybrid system for temporal relation classification that combines the learned classifier with 437 hand-coded rules. Their system first applied high-accuracy rules and then used the learned classifier, trained on rich features including those high-accuracy rules as features, to classify the cases that were not handled by the rules. Ng et al. (2013) also showed the effectiveness of different discourse analysis frameworks for this task. Later Mirza and Tonelli (2014) showed that a simpler approach based on lexico-syntactic features achieved results comparable to Ng (2013). They also reported that dependency order between events, either governor-dependent or dependent-governor, was not useful in their experiments. However, we show that dependency relations, when modeled as a sequence, contribute significantly to this task.

3 Temporal Link Labeling

In this section, we describe the task of temporal relation classification, dataset, context words se-

[1] In this paper, we restrict ourselves to study temporal relation classification between event mentions that are within one sentence.

quence extraction model and the used recurrent neural net based classifier.

3.1 Task description

Early works on temporal relation classification Mani et al. (2006); Chambers et al. (2007) and the first two versions of TempEval (Verhagen et al., 2007, 2010) simplified the task by considering only six relation types. They combined the pair of relation types that are the inverse of each other and ignored the relations *during* and *during_inv*. Then TempEval-3 (Uzzaman et al., 2013) extended the task to complete 14 class classification problem and all later works have considered all 14 relations. Our model performs 14-class classification following the recent works, as this is arguably more challenging (Ng, 2013). Also, we consider gold annotated event pairs, mainly because the corpus is small and distribution of relations is very skewed. All previous works focusing on the problem of classifying temporal relation types assumed gold annotation.

3.2 Dataset

Relations	Train	Validate	Test

During	11	1	3
Ends	9	2	3
Total	1612	229	467

Table 1: Distribution of temporal relations in TimeBank v1.2.

We have used TimeBank corpus v1.2 for training and evaluating our model. The corpus consists of 14 temporal relations between 2308 event pairs, which are within the same sentence. These relations (Saurı et al., 2006) are *simultaneous, before, after, ibefore, iafter, begins, begun_by, ends, ended_by, includes, is_included, during, during_inv, identity*. Six pairs among them are inverse of each other and other two types are commutative ($e_1 \mathcal{R} e_2 \equiv e_2 \mathcal{R} e_1$, $\mathcal{R} \in \{$*identical, simultaneous*$\}$). Our sequential model requires that relation should always be between e_1 and e_2, where e_1 occurs before e_2 in the sentence. Therefore, before extracting the sequence, we inverted the relation types in cases where relation type was annotated in opposite order. Final distribution of dataset is given in Table 1.

3.3 Extracting Context Word Sequence

First, we extract words that are in the dependency path between two event mentions. However, event pairs can be very far in a sentence and are involved in complex syntactic structures. Therefore, we also apply two heuristic rules to deal with complex syntactic structures, e.g., two event mentions are in separate clauses and have a punctuation sign in their context. We describe our specific rules below. We used the Stanford parser (Chen and Manning, 2014) for generating dependency relations and parts-of-speech tags and all notations follow enhanced universal dependencies (De Marneffe and Manning, 2008).

Rule 1 (punctuation): Comma directly influences the meaning in text and omitting it may alter the meaning of phrase. Therefore, include comma if it precedes or follows e_1, e_2 or their modifiers.

Rule 2 (children): Modifiers like *now, then, will, yesterday, subsequent, when, was, etc.* contains information on the temporal order of events and help in grounding events to the timeline. These modifiers are often related to event mentions with a specific class of dependency relations. Include all such children of e_1, e_2 and other words in the path between them, which are connected with dependency relations nmod:tmod, mark, case, aux, conj, expl, cc, cop, amod, advmod, punct, ref.

3.4 Sequences and Classifier

We form three sequences on the extracted context words (with *t* words), which are based on (i) parts-of-speech tags: $\mathcal{P_T} = p_1, p_2, ..., p_t$ (ii) dependency relations: $\mathcal{D_T} = d_1, d_2, ..., d_n$[2] and (iii) word forms: $\mathcal{W_T} = w_1, w_2, ..., w_t$.

We transform each p_i and d_i to a one-hot vector and each w_i to a pre-trained embedding vector (Pennington et al., 2014). Then each sequence of vectors are encoded using their corresponding forward ($LSTM_f$) and backward ($LSTM_b$) LSTM layers.

Classifier: Figure 2 shows an overview of our model. It consists of six LSTM (Hochreiter and

[2] we only consider dependency relations for words in path connecting e_1 and e_2.

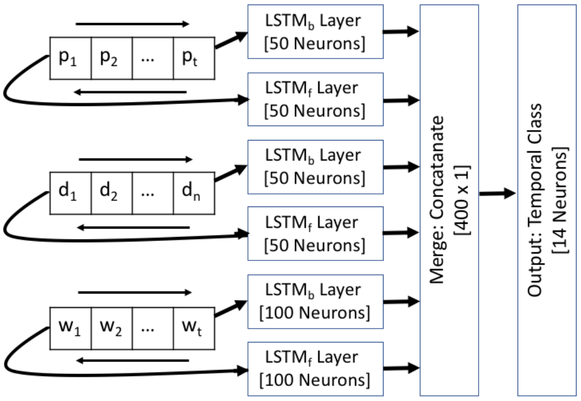

Figure 2: Bi-directional LSTM based classifier used for temporal relations classification.

Schmidhuber, 1997) layers, three of them encode feature sequences in forward order and remaining in reverse order. LSTM layers for POS tag and dependency relation have 50 neurons and have dropouts of 0.20. LSTM layers for word form have 100 neurons and have dropout of 0.25. All LSTM layers use 'tanh' activation function. Forward and backward embeddings of all sequences are concatenated and fed into another neural layer with 14 neurons corresponding to 14 fine-grained temporal relations. This neural layer uses softmax activation function. We train model for 100 iterations using rmsprop optimizer on batch size of 100 and error defined by categorical cross-entropy (Chollet, 2015) .

4 Evaluation

We evaluate our model using accuracy which has been used in previous research works for temporal relation classification. We also compare model performance using per-class F-score and macro F-score. We briefly describe all the systems we have used for evaluation.

Majority Class: assigns "after" relation to all event pairs.

Unidirectional LSTMs: use single LSTM layer to encode each sequence (POS tags, dependency relation and word forms) individually for extracted phrase in forward order.

Bidirectional LSTMs: use two LSTM layers to encode each sequence individually, taken from POS tags, dependency and word forms sequences. The first layer encodes sequence in forward and second in reverse order.

2 Sequences: bi-directional LSTM based models considering all combinations of two sequences taken from POS tags, dependency and word forms sequences.

Full model: our complete sequential model considering POS, dependency and word forms sequences.

Direct dependency path: the same as **Full model** except that the two heuristic rules were not applied in extracting sequences.

Baseline I: a neural network classifier using discrete features described in Mirza and Tonelli (2014); Ng (2013). The features used are: POS tag, dependency relation, token and lemma of $e_1(e_2)$; dependency relations between $e_1(e_2)$ and their children; binary features indicating if e_1 and e_2 are related with the 'happens-before' or the 'similar' relation according to VerbOcean (Chklovski and Pantel, 2004), if e_1 and e_2 have the same POS tag, or if $e_1(e_2)$ is the root and e_1 modifies (or governs) e_2; the dependency relation between e_1 and e_2 if they are directly connected in the dependency parse tree; prepositions that modify (or govern) $e_1(e_2)$; signal words (Derczynski and Gaizauskas, 2012) and entity distance between e_1 and e_2. These features are concatenated and fed into an output neural layer with 14 neurons.

Baseline II: a neural network classifier using POS tags and word forms of words in the *surface path* as input. The *surface path* consists of words that lie in between two event mentions based on the original sentence. The classifier uses four LSTM layers to encode both POS tag and word sequences in forward and backward order. The output neural layer and parameters for all LSTM layers are kept the same as the *Full model*.

Baseline III: a neural network classifier based on event embeddings for both event mentions that were learned using bidirectional LSTMs (Kiperwasser and Goldberg, 2016). The learning uses two LSTM layers, each with 150 neurons and dropout of 0.2, to embed the forward and backward representations for each event mention. The input to LSTM layers are sequences of concatenated word embeddings and POS tags; each sequence corresponding to 19 context words to the left or to the right side of an event mention for the forward or the backward LSTM layer respectively. Event embeddings are then concatenated and fed into an output neural layer with 14 neurons.

All baselines are trained using rmsprop optimizer on an objective function defined by categorical cross entropy and their output layer uses softmax activation function.

4.1 Results and Discussion

Models	*Accuracy*
Majority Class	25.69
Baseline I	41.97
Unidirectional LSTM: only POS	34.90
only Word	35.12
only Dependency	34.48
Bidirectional LSTMs: only POS	39.19
only Word	37.69
only Dependency	40.04

Macro Av.	**0.44**	**0.37**	**0.40**	0.23	0.22	0.22

Table 3: Per-class results of our best system and the baseline I.

Table 2 reports accuracy scores for all the systems. We see that simple sequential models outperform the strong feature based system, *Baseline I*, which used various discrete features. Note that dependency relation and POS tag sequences alone achieve reasonably high accuracies. This implies that an important aspect of temporal relation is contained in the syntactic context of event mentions. Moreover, Mirza and Tonelli (2014) observed that discrete features based on dependency parse tree did not contribute to improving their classifier's accuracy. On the contrary, using the sequence of dependency relations yields a high accuracy in our setting which signifies the advantages of using sequential representations for this task. Our *Full Model* achieves a performance gain of 11.35% over *Baseline I*.

We developed two more baselines (*Baseline II and III*) that do not require syntactic information as well as the *Direct dependency path* model that used no rules. The *Full Model* outperformed them by 9.42%, 8.57% and 4.07% respectively. This affirms that the most useful syntactic and semantic structures are derived along dependency paths and additional context words, including prepositions, signal words and punctuations that are indirectly attached to event words, entail evidence on temporal relations as well.

Table 3 compares precision, recall and F_1 scores of our *Full Model* with *Baseline I*. Our model performs reasonably well compared to the baseline system for most of the classes. In addition, it is able to identify relations present in small proportion like *begun_by, ibefore, iafter etc.*, which the baseline system couldn't identify. A similar observation was also reported by Mirza and Tonelli (2014) that relation types *begins, ibefore, ends* and *during* are difficult to identify using feature based systems, which often generate false positives for *before* and *after* relations.

5 Conclusion and Future work

In this paper, we have focused on modeling syntactic structural information and compositional semantics of contexts in predicting temporal relations between events in the same sentence. Our approach extracts lexical and syntactic sequences from contexts between two events and feed them to recurrent neural nets. The evaluation shows that our sequential models are promising in distinguishing among fine-grained temporal relations.

In the future, we will extend our sequential models to predict temporal relations for event pairs spanning across multiple sentences, for instance by incorporating discourse relations between sentences in a sequence.

Acknowledgments

We want to thank our anonymous reviewers for their insightful review comments and suggestions that helped making evaluations more extensive.

Abstract

Deep residual learning (ResNet) (He et al., 2016) is a new method for training very deep neural networks using identity mapping for shortcut connections. ResNet has won the ImageNet ILSVRC 2015 classification task, and achieved state-of-the-art performances in many computer vision tasks. However, the effect of residual learning on noisy natural language processing tasks is still not well understood. In this paper, we design a novel convolutional neural network (CNN) with residual learning, and investigate its impacts on the task of distantly supervised noisy relation extraction. In contradictory to popular beliefs that ResNet only works well for very deep networks, we found that even with 9 layers of CNNs, using identity mapping could significantly improve the performance for distantly-supervised relation extraction.

1 Introduction

Relation extraction is the task of predicting attributes and relations for entities in a sentence (Zelenko et al., 2003; Bunescu and Mooney, 2005; GuoDong et al., 2005). For example, given a sentence *"**Barack Obama** was born in **Honolulu**, Hawaii."*, a relation classifier aims at predicting the relation of *"**bornInCity**"*. Relation extraction is the key component for building relation knowledge graphs, and it is of crucial significance to natural language processing applications such as structured search, sentiment analysis, question answering, and summarization.

A major issue for relation extraction is the lack of labeled training data. In recent years, distant supervision (Mintz et al., 2009; Hoffmann et al., 2011; Surdeanu et al., 2012) emerges as the most popular method for relation extraction— it uses knowledge base facts to select a set of noisy instances from unlabeled data. Among all the machine learning approaches for distant supervision, the recently proposed Convolutional Neural Networks (CNNs) model (Zeng et al., 2014) achieved the state-of-the-art performance. Following their success, Zeng et al. (2015) proposed a piece-wise max-pooling strategy to improve the CNNs. Various attention strategies (Lin et al., 2016; Shen and Huang, 2016) for CNNs are also proposed, obtaining impressive results. However, most of these neural relation extraction models are relatively shallow CNNs—typically only one convolutional layer and one fully connected layer were involved, and it was not clear whether deeper models could have benefits on distilling signals from noisy inputs in this task.

In this paper, we investigate the effects of training deeper CNNs for distantly-supervised relation extraction. More specifically, we designed a convolutional neural network based on residual learning (He et al., 2016)—we show how one can incorporate word embeddings and position embeddings into a deep residual network, while feeding identity feedback to convolutional layers for this noisy relation prediction task. Empirically, we evaluate on the NYT-Freebase dataset (Riedel et al., 2010), and demonstrate the state-of-the-art performance using deep CNNs with identify mapping and shortcuts. In contrast to popular beliefs in vision that deep residual network only works for very deep CNNs, we show that even with a moderately deep CNNs, there are substantial improvements over vanilla CNNs for relation extraction. Our contributions are three-fold:

- We are the first to consider deeper convolutional neural networks for weakly-supervised

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1803–1807
Copenhagen, Denmark, September 7–11, 2017.

relation extraction using residual learning;

- We show that our deep residual network model outperforms CNNs by a large margin empirically, obtaining state-of-the-art performances;
- Our identity mapping with shortcut feedback approach can be easily applicable to any variants of CNNs for relation extraction.

2 Deep Residual Networks for Relation Extraction

In this section, we describe a novel deep residual learning architecture for distantly supervised relation extraction. Figure 1 describes the architecture of our model.

2.1 Vector Representation

Let $\mathbf{x}_i$ be the *i*-th word in the sentence and *e1*, *e2* be the two corresponding entities. Each word will access two embedding look-up tables to get the word embedding $\mathbf{WF}_i$ and the position embedding $\mathbf{PF}_i$. Then, we concatenate the two embeddings and denote each word as a vector of $\mathbf{v}_i = [\mathbf{WF}_i, \mathbf{PF}_i]$.

2.1.1 Word Embeddings

Each representation $\mathbf{v}_i$ corresponding to $\mathbf{x}_i$ is a real-valued vector. All of the vectors are encoded in an embeddings matrix $\mathbf{V}_w \in \mathbb{R}^{d_w \times |V|}$ where V is a fixed-sized vocabulary.

2.1.2 Position Embeddings

In relation classification, we focus on finding a relation for entity pairs. Following (Zeng et al., 2014), a PF is the combination of the relative distances of the current word to the first entity e_1 and the second entity e_2. For instance, in the sentence ”*Steve_Jobs is the founder of Apple.*”, the relative distances from *founder* to e_1 (*Steve_Job*) and e_2 are 3 and -2, respectively. We then transform the relative distances into real valued vectors by looking up one randomly initialized position embedding matrices $\mathbf{V}_p \in \mathbb{R}^{d_p \times \|P\|}$ where P is fixed-sized distance set. It should be noted that if a word is too far from entities, it may be not related to the relation. Therefore, we choose maximum value e_{max} and minimum value e_{min} for the relative distance.

In the example shown in Figure 1, it is assumed that d_w is 4 and d_p is 1. There are two position embeddings: one for e_1, the other for e_2. Finally, we concatenate the word embeddings and position embeddings of all words and denote a sentence of length *n* (padded where necessary) as a vector

$$\mathbf{v} = \mathbf{v}_1 \oplus \mathbf{v}_2 \oplus \ldots \oplus \mathbf{v}_n$$

where $\oplus$ is the concatenation operator and $\mathbf{v}_i \in \mathbb{R}^d$ $(d = d_w + d_p \times 2)$.

2.2 Convolution

Let $\mathbf{v}_{i:i+j}$ refer to the concatenation of words $\mathbf{v}_i, \mathbf{v}_{i+1}, \ldots, \mathbf{v}_{i+j}$. A convolution operation involves a *filter* $\mathbf{w} \in \mathbb{R}^{hd}$, which is applied to a window of *h* words to produce a new feature. A feature c_i is generated from a window of word $\mathbf{v}_{i:i+h-1}$ by

$$c_i = f(\mathbf{w} \cdot \mathbf{x}_{i:i+h-1} + b)$$

Here $b \in \mathbb{R}$ is a bias term and f is a non-linear function. This filter is applied to each possible window of words from $\mathbf{v}_1$ to $\mathbf{v}_n$ to produce *feature* $\mathbf{c} = [c_1, c_2, \ldots, c_{n-h+1}]$ with $\mathbf{c} \in \mathbb{R}^s (s = n - h + 1)$.

2.3 Residual Convolution Block

Residual learning connects low-level to high-level representations directly, and tackles the vanishing gradient problem in deep networks. In our model, we design the residual convolution block by applying shortcut connections. Each residual convolutional block is a sequence of two convolutional layers, each one followed by an ReLU activation. The kernel size of all convolutions is h, with padding such that the new feature will have the same size as the original one. Here are two convolutional *filter* $\mathbf{w}_1$, $\mathbf{w}_2 \in \mathbb{R}^{h \times 1}$. For the first convolutional layer:

$$\tilde{c}_i = f(\mathbf{w}_1 \cdot c_{i:i+h-1} + b_1)$$

For the second convolutional layer:

$$\acute{c}_i = f(\mathbf{w}_2 \cdot \tilde{c}_{i:i+h-1} + b_2)$$

Here b_1, b_2 are bias terms. For the residual learning operation:

$$\mathbf{c} = \mathbf{c} + \acute{\mathbf{c}}$$

Conveniently, the notation of $\mathbf{c}$ on the left is changed to define as the output vectors of the block. This operation is performed by a shortcut connection and element-wise addition. This block will be multiply concatenated in our architecture.

2.4 Max Pooling, Softmax Output

We then apply a max-pooling operation over the *feature* and take the maximum value $\hat{c} = max\{\mathbf{c}\}$.

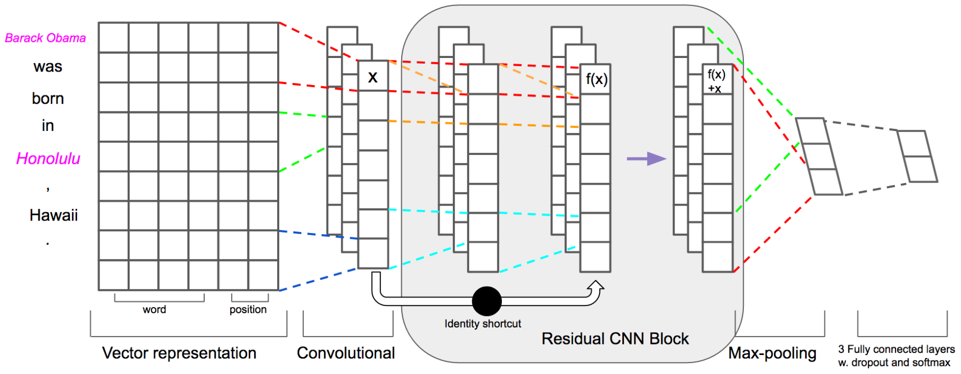

Figure 1: The architecture of ResCNN used for relation extraction.

We have described the process by which *one* feature is extracted from *one* filter. Take all features into one high level extracted feature $\mathbf{z} = [\hat{c}_1, \hat{c}_2, ..., \hat{c}_m]$(note that here we have m filters). Then, these features are passed to a fully connected softmax layer whose output is the probability distribution over relations. Instead of using $y = \mathbf{w} \cdot \mathbf{z} + b$ for output unit y in forward propagation, dropout uses $y = \mathbf{w} \cdot (\mathbf{z} \circ \mathbf{r}) + b$ where $\circ$ is the element-wise multiplication operation and $\mathbf{r} \in \mathbb{R}^m$ is a 'masking' vector of Bernoulli random variables with probability p of being 1. In the test procedure, the learned weight vectors are scaled by p such that $\hat{\mathbf{w}} = p\mathbf{w}$ and used (without dropout) to score unseen instances.

3 Experiments

3.1 Experimental Settings

In this paper, we use the word embeddings released by (Lin et al., 2016) which are trained on the NYT-Freebase corpus (Riedel et al., 2010). We fine tune our model using validation on the training data. The word embedding is of size 50. The input text is padded to a fixed size of 100. Training is performed with tensorflow adam optimizer, using a mini-batch of size 64, an initial learning rate of 0.001. We initialize our convolutional layers following (Glorot and Bengio, 2010). The implementation is done using Tensorflow 0.11. All experiments are performed on a single NVidia Titan X (Pascal) GPU. In Table 1 we show all parameters used in the experiments.
We experiment with several state-of-the-art baselines and variants of our model.

- **CNN-B**: Our implementation of the CNN baseline (Zeng et al., 2014) which contains one convolutional layer, and one fully connected layer.

Window size h	3
Word dimension d_w	50
Position dimension d_p	5
Position maximum distance e_{max}	30
Position minimum distance e_{min}	-30
Number of filters m	128
Batch size B	64
Learning rate λ	0.001
Dropout probability p	0.5

Table 1: Parameter settings

- **CNN+ATT**: CNN-B with attention over instance learning (Lin et al., 2016).
- **PCNN+ATT**: Piecewise CNN-B with attention over instance learning (Lin et al., 2016).
- **CNN**: Our CNN model which includes one convolutional layer and three fully connected layers.
- **CNN-x**: Deeper CNN model which has x convolutional layers. For example, CNN-9 is a model constructed with 9 convolutional layers (1 + 4 residual cnn block without identity shortcut) and three fully connected layers.
- **ResCNN-x**: Our proposed CNN-x model with residual identity shortcuts.

We evaluate our models on the widely used NYT freebase larger dataset (Riedel et al., 2010). Note that ImageNet dataset used by the original ResNet paper (He et al., 2016) has 1.28 million training instances. NYT freebase dataset includes 522K training sentences, which is the largest dataset in relation extraction, and it is the only suitable dataset to train deeper CNNs.

3.2 NYT-Freebase Dataset Performance

The advantage of this dataset is that there are 522,611 sentences in training data and 172,448 sentences in testing data and this size can support

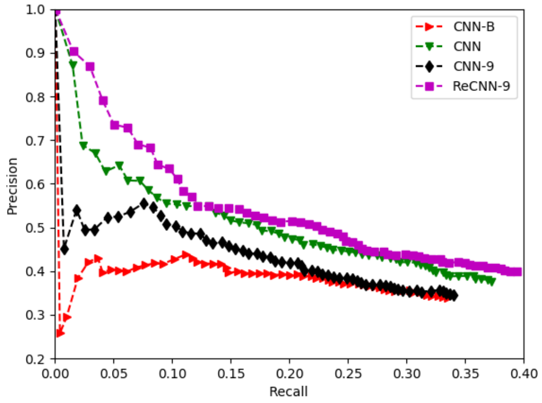

Figure 2: Comparing ResCNN to different CNNs.

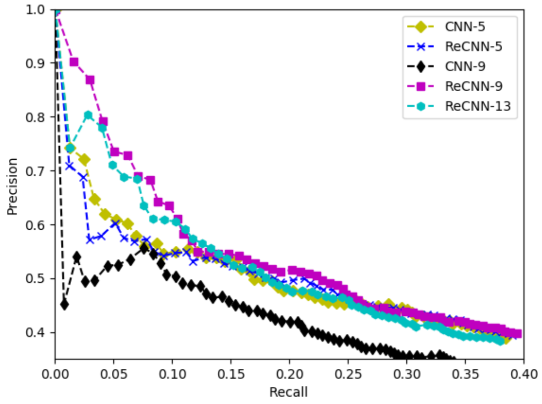

Figure 3: Varying the depths of our models.

us to train a deep network. Similar to previous work (Zeng et al., 2015; Lin et al., 2016), we evaluate our model using the held-out evaluation. We report both the aggregate curves precision/recall curves and Precision@N (P@N).

In Figure 2, we compare the proposed ResCNN model with various CNNs. First, CNNs with multiple fully-connected layers obtained very good results, which is a novel finding. Second, the results also suggest that deeper CNNs with residual learning help extracting signals from noisy distant supervision data. We observe that overfitting happened when we try to add more layers and the performance of CNN-9 is much worse than CNN. We find that ResNet can solve this problem and ResCNN-9 obtains better performance as compared to CNN-B and CNN and dominates the precision/recall curve overall.

We show the effect of depth in residual networks in Figure 3. We observe that ResCNN-5 is worse than CNN-5 because the ResNet does not work well for shallow CNNs, and this is consistent with the original ResNet paper. As we increase the network depth, we see that CNN-9 does overfit to the training data. With residual learning, both ResCNN-9 and ResCNN-13 provide significant improvements over CNN-5 and ResCNN-5 models. In contradictory to popular beliefs that ResNet only works well for very deep networks, we found that even with 9 layers of CNNs, using identity mapping could significantly improve the performance learning in a noisy input setting.

P@N(%)	100	200	300	Mean
CNN+ATT	76.2	68.6	59.8	68.2
PCNN+ATT	**76.2**	**73.1**	**67.4**	**72.2**
CNN-B	41.0	40.0	41.0	40.7
CNN	64.0	61.0	55.3	60.1
CNN-5	64.0	58.5	54.3	58.9
ResCNN-5	57.0	57.0	54.3	56.1
CNN-9	56.0	54.0	49.7	53.2
ResCNN-9	**79.0**	**69.0**	**61.0**	**69.7**
ResCNN-13	76.0	65.0	60.3	67.1

Table 2: P@N for relation extraction with different models. Top: models that select training data. Bottom: models without selective attention.

The intuition of ResNet help this task in two aspect. First, if the lower, middle, and higher levels learn hidden lexical, syntactic, and semantic representations respectively, sometimes it helps to bypass the syntax to connect lexical and semantic space directly. Second, ResNet tackles the vanishing gradient problem which will decrease the effect of noise in distant supervision data.

In Table 2, we compare the performance of our models to state-of-the-art baselines. We show that our ResCNN-9 outperforms all models that do not select training instances. And even without piecewise max-pooling and instance-based attention, our model is on par with the PCNN+ATT model.

For the more practical evaluation, we compare the results for precision@N where N is small (1, 5, 10, 20, 50) in Table 3. We observe that our ResCNN-9 model dominates the performance when we predict the relation in the range of higher probability. ResNet helps CNNs to focus on the highly possible candidate and mitigate the noise effect of distant supervision. We believe that residual connections actually can be seen as a form of renormalizing the gradients, which prevents the model from overfitting to the noisy distant supervision data.

In our distant-supervised relation extraction experience, we have two important observations: (1) We get significant improvements with CNNs adding multiple fully-connected layers. (2) Resid-

P@N(%)	1	5	10	20	50
PCNN+ATT	**1**	0.8	**0.9**	0.75	0.7

Table 3: P@N for relation extraction with different models where N is small. We get the result of PCNN+ATT using their public source code.

ual learning could significantly improve the performance for deeper CNNs.

4 Conclusion

In this paper, we introduce a deep residual learning method for distantly-supervised relation extraction. We show that deeper convolutional models help distill signals from noisy inputs. With shortcut connections and identify mapping, the performances are significantly improved. These results aligned with a recent study (Conneau et al., 2017), suggesting that deeper CNNs do have positive effects on noisy NLP problems.

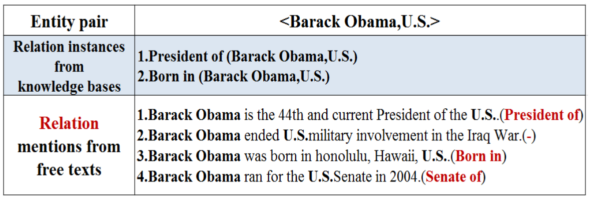
Noise-Clustered Distant Supervision for Relation Extraction: A Nonparametric Bayesian Perspective

Qing Zhang and **Houfeng Wang**
Key Laboratory of Computational Linguistics (Peking University) Ministry of Education, China
{zqicl,wanghf}@pku.edu.cn

Abstract

For the task of relation extraction, distant supervision is an efficient approach to generate labeled data by aligning knowledge base with free texts. The essence of it is a challenging incomplete multi-label classification problem with sparse and noisy features. To address the challenge, this work presents a novel nonparametric Bayesian formulation for the task. Experiment results show substantially higher top-precision improvements over the traditional state-of-the-art approaches.



Entity pair	<Barack Obama,U.S.>
Relation instances from knowledge bases	1.President of (Barack Obama,U.S.) 2.Born in (Barack Obama,U.S.)
Relation mentions from free texts	1.**Barack Obama** is the 44th and current President of the **U.S.**.(**President of**) 2.**Barack Obama** ended **U.S.**military involvement in the Iraq War.(-) 3.**Barack Obama** was born in honolulu, Hawaii, **U.S.**.(**Born in**) 4.**Barack Obama** ran for the **U.S.**Senate in 2004.(**Senate of**)

Figure 1: Aligned Example (Fan et al., 2014): the relation instances related to the entity pair $\langle BarackObama, U.S. \rangle$ in the KB, and its mentions in the free text.

1 Introduction

To efficiently generate structured relation information from free texts, the research on distantly supervised Relation Extraction (RE) (Mintz et al., 2009; Riedel et al., 2013; Hoffmann et al., 2011) has been attracting much attention, because it can greatly reduce the manual annotation for training. It essentially based on the assumption that the relation between two entities in a Knowledge Base (KB), is also likely hold within a sentence that mentions the two entities in free texts. This assumption plays a crucial role in distant supervision, which is quite effective in real applications.

However, the assumption of distant alignment can also lead to the noisy training corpus problem (Fan et al., 2014), which is challenging for the task as follows: **i) Noisy features.** Not all relations existed in a KB keep the same meaning of that relation for the corresponding entities in a free text. For example, the second relation mention in Figure 1 does not explicitly describe any relation instance, so features extracted from this sentence can be noisy. Such analogous cases commonly exist in feature extraction. **ii) Incomplete labels.** Similar to noisy features, the generated label can be incomplete due to the incomplete knowledge base (Ritter et al., 2013). For example, the fourth relation mention in Figure 1 should be labeled by the relation Senate-of. However, the corresponding relation instance (Senate-of(Barack Obama, U.S.)) is missing in the knowledge base. Such analogous cases are also common in real applications. **iii) Sparse features.** Sophisticated features extracted from the mentions can result in a large number of sparse features (Riedel et al., 2013). The generalization ability of feature based prediction models will be badly hurt, when the features do not match between testing and training.

To tackle the problem, we develop a novel distant supervision approach from a nonparametric Bayesian perspective (Blei et al., 2016), along with the previously most effective research line (Petroni et al., 2015) of using matrix completion (Fan et al., 2014) for relation extraction. Our goal is to design a noise-tolerant relation extraction model for distantly supervised corpus with noise and sparsity problems. Different from (Fan et al., 2014) as one state-of-the-art method in this line, we model noisy data corpus using adaptive variance modeling approach (Chen et al., 2015), based on *Dirichlet Process* (Blei and Jordan, 2004) instead of a fixed way of controlling complex noise weighting. To the best of our knowledge, we are

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1808–1813
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

the first to apply this technique on relation extraction with distant supervision.

2 Approach

The essence of the task is a multi-label classification problem (Cabral et al., 2011) with noisy patterns (Han and Sun, 2014). One simple way, to solve the problem, is to learn separate classifiers for each of relation labels, using n samples with d features, by optimizing $b \in R^{1\times 1}$ and $\mathbf{w} \in R^{d\times 1}$,

$$\text{argmin}_{b,\mathbf{w}}\ l(\mathbf{y_{train}}, [\mathbf{1}\ X_{train}] \begin{bmatrix} b \\ \mathbf{w} \end{bmatrix}), \tag{1}$$

where $\mathbf{1}$ is the all-one column vector; $X_{train} \in R^{n\times d}$ and $\mathbf{y_{train}} \in R^{n\times 1}$ are the corresponding feature matrix and label vector respectively. However, label correlations are not considered in the above formulation. To jointly consider feature correlations and label correlations, (Cabral et al., 2011) formulated the multi-label classification as a matrix completion problem. As a powerful framework, it has been successfully applied to relation extraction task with distant supervision.

2.1 Previous Formulation

The work in (Fan et al., 2014) first adopted the mentioned framework, as a general joint learning and inference framework (Cabral et al., 2011), to learn *noise-tolerant* distant supervision for relation extraction. It achieves the state-of-the-art performance. Suppose we have a training corpus, including n instances (entity pairs) including both training and test data, with d-dimensional features and t relation labels, which is built according to the basic alignment assumption. The task can be modeled with a sparse matrix $Z \in R^{nx(d+t)}$, defined as

$$Z = \begin{bmatrix} X_{train} & Y_{train} \\ X_{test} & Y_{test} \end{bmatrix}, \tag{2}$$

where each row in Z represents entity pair, and each column represents noisy textual feature in X or incomplete relation label in Y. In such a way, relation extraction is transformed into a problem of completing the unknown labels in Y_{test} for the test data X_{test} in Z. The rational of this modeling is that noisy features and incomplete labels are semantically correlated, which can be explained in an underlying low-rank structure (Riedel et al., 2013). Taking noise into consideration, Z is further defined as

$$Z = Z^* + E, \tag{3}$$

where Z^* is the underlying low-rank matrix

$$Z^* = \begin{bmatrix} X^*_{train} & Y^*_{train} \\ X^*_{test} & Y^*_{test} \end{bmatrix}, \tag{4}$$

and E is the error (noise) matrix

$$E = \begin{bmatrix} E_{X_{train}} & E_{Y_{train}} \\ E_{X_{test}} & 0 \end{bmatrix}. \tag{5}$$

This error (noise) modeling approach has been successfully applied to distantly supervised relation extraction. However, it still has clear limitations. The noise model is limited to a single source without considering the intrinsic clustering structures of data. In addition, the true rank is usually hard to determine, for adaptively modeling the correlations among features and labels.

2.2 Nonparametric Bayesian Modeling

The use of nonparametric Bayesian modeling has been widely adopted in Natural Language Processing (NLP) (Chen et al., 2014). Instead of imposing assumptions that might be wrong, it "lets the data speak for itself", without requiring optimizing parameters blindly by hands (Blei and Jordan, 2004). To take advantage of these merits, we here adopt it for the task, with the following motivations:

Motivation 1: Adaptive Noise-Clustered Attention. The goal is to find an adaptive *cluster specific* noise *parameterization* for the complex noisy corpus, *without* making overly strong assumptions about the noise distribution in real applications.

Motivation 2: Adaptive Latent Feature Space Selection. The goal is to automatically find better *dense representations* of latent entity-pair, feature and label *without* pre-specifying the rank values by laboriously retraining models.

2.2.1 Nonparametric Bayesian Formulation

We develop a novel formulation for distantly supervised relation extraction, using a nonparametric Bayesian approach, based on the Dirichlet Process, which can been seen as an infinite Dirichlet distribution, with clustering effect for modeling categorical variables adaptively.

Noise component modeling. Instead of using a single fixed noise model, we redefine $E = [\varepsilon_{i,j}] \in R^{n\times(d+t)}$ in Eq.(5). $\varepsilon_{i,j}$ is modeled by a summation of infinite noise models (Chen et al., 2015),

$$p(\varepsilon_{i,j}) = \sum_{k=1}^{\infty} \theta_k N(\varepsilon_{i,j}|0, \sigma_k), \tag{6}$$

where θ_k is the mixing proportion for the k-th gaussian component $N(\varepsilon_{i,j}|0, \sigma_k)$ with mean zero and variance σ_k. The θ is obtained from the stick-breaking process (Blei and Jordan, 2004), with $\sum_{k=1}^{\infty} \theta_k = 1$,

$$\theta_k = \beta_k \prod_{l=1}^{k-1} (1 - \beta_l), \tag{7}$$

where β_k are independent draws from the beta distribution $\beta(1, \alpha)$. As a result, the noise entries will cluster themselves into K groups without requiring a complicated model selection procedure. Since a mixture of Gaussians can approximate any continuous probability distribution (Zhao et al., 2014), this structural noise formulation can adapt much wider range of real noises than previous formulation (Fan et al., 2014) for relation extraction.

Low-rank component modeling. Different from (Fan et al., 2014), instead of directly minimizing the rank of Z^* in Eq.(3), we decompose Z^* into two low-rank matrices U and V, from probabilistic perspective (Salakhutdinov and Mnih, 2007). This modeling approach can lead to a more flexible way of estimating the optimal rank values for latent feature spaces. To determine the appropriate rank automatically, we adopt the *Automatic Relevance Determination* (ARD) method (Babacan et al., 2012) by imposing a prior on each dimmension (column) of U and V. Specifically, we impose the Gaussian priors with variance λ_r on the r-th columns of U and V, i.e., $u_{.r}$ and $v_{.r}$:

$$\begin{aligned} p(\mathbf{U}|\lambda) &= \prod_{r=1}^{R} N(u_{.r}|0, \lambda_r \mathbf{I_U}), \\ p(\mathbf{V}|\lambda) &= \prod_{r=1}^{R} N(v_{.r}|0, \lambda_r \mathbf{I_V}), \\ \lambda_r &\sim IG(a_1, b_1), \end{aligned} \tag{8}$$

where IG is an Inverse Gamma distribution for modeling the variance λ_r. Considering a column as latent factor in U or V with a zero mean in the prior, a very small variance indicates that this column will shrink to zero. Thus, the irrelevant columns hurting the performance will be eliminated adaptively, without pre-specifying the rank values by retraining models laboriously as in the previous modeling (Fan et al., 2014) for the task.

Prediction component modeling. We can leverage the above presented low-rank component for U, V and noise component for $\varepsilon_{i,j}$, to build Eq.(9) for prediction. Different from the state-of-the-art multi-label classification framework as adopted in (Fan et al., 2014), for simplicity, we design noise model for features and labels jointly,

$$p(y_{i,j}) = N(y_{i,j}| \underbrace{u_{i.} v_{j.}^T}_{low-rank\ component}, \underbrace{\varepsilon_{i,j}}_{noise\ component}), \tag{9}$$

where $u_{i.}$ and $v_{j.}$ are defined in Eq.(8) as rows of U and V respectively.

For each interaction between entity-pair and feature (or relation), $\varepsilon_{i,j}$ as defined in Eq.(6) can be injected into Eq.(9) (Chen et al., 2015) by

$$\begin{aligned} \varepsilon_{i,j} &= \sigma_{z_{ij}}, \\ \sigma_{z_{ij}} &\sim IG(a_0, b_0), \\ z_{ij} &= k \sim Mult(\theta_k), \end{aligned} \tag{10}$$

where θ_k is modeled in Eq.(7); Mult is a Multinomial distribution.

The mechanism of the introduced clustered noise component for relation extraction can be easily understood through considering its role in the Gaussian distribution. As shown in Eq.(9), $\varepsilon_{i,j}$ is used to control the variance. Large variance value means low confidence, and the small value means high confidence, for fitting $y_{i,j}$ with $u_{i.} v_{j.}^T$. The variance parameter $\varepsilon_{i,j}$, generated by noise component Eq.(7,10), serves as a confidence parameter for training instance. In the algebra view of likelihood, variance parameter is just the weight of training instance (i.e., the interaction between "entity pair and feature" or "entity pair and label"), measuring the importance for its contribution to the total likelihood. We can treat this mechanism as an importance weighting mechanism, for selecting noisy interactions y_{ij} with different clustering structures adaptively.

In this mechanism, for each $y_{i,j}$ in noisy corpus, it allows $1 \rightarrow 0$ (noisy feature) for features, and allow $1 \rightarrow 0$ (label with no supportive features) or $0 \rightarrow 1$ (incomplete label) for labels. In addition, for the task, we expect that our method can automatically adjust the importance weight for reducing the effect of common features, to differentiate two instances with different labels. To achieve the goal, in matrix Z, we fit both "1" (observed) and "0" for training labels as discriminative supervision, while we only fit "1" (observed) for features.

Dataset	#training	#testing	%more than one label	#features	#relation labels

Learning. To combine Eqs. (7)-(10), we can construct the full Bayesian model. The goal turns to infer the posterior of all involved variables:

$$p(\mathbf{U}, \mathbf{V}, \lambda, \sigma, \mathbf{z}, \beta | \mathbf{X}_{observed}, \mathbf{Y}_{observed}), \quad (11)$$

where $\mathbf{X}_{observed}, \mathbf{Y}_{observed}$ are the observed binary features (fitting 1) and labels (fitting both 1 and 0). Variational inference is adopted as shown in (Chen et al., 2015).

Prediction. After learning[1], we use the expectation $E(P(y_{i,j}))$ in Eq.(9) to complete the entries in Y_{test}. Finally, we can acquire Top-N predicted relations via ranking the values $E(P(y_{i,j}))$, given entity pair i, for different relations j.

3 Experiments

We evaluate our method on two widely used datasets as shown in Table 1 with the same setting in (Fan et al., 2014).

Dataset. *NYT'10*, was developed by (Riedel et al., 2010). *NYT'13*, was also released by (Riedel et al., 2013), in which they only regarded the lexicalized dependency path between two entities as features. Both are automatically generated by aligning Freebase to New York Times corpus.

Parameter setting. For all the conducted experiments, the model hyperparameters are fixed without further tuning: $a_0 = b_0 = 10^{-4}$, $a_1 = b_1 = 0.1$ and $\alpha = 1$.

Model comparison. Since (Fan et al., 2014) achieves the state-of-the-art performance on the two datasets, we mainly compare our method with that in the same setting, to verify the effectiveness. *NYT'10 dataset*: Table 2 indicates that our model achieves the highest precision performance among all of the competitors. Although the recall performance is not competitive, the F1 score is also comparable to DRMC-b. Figure 2(a) further shows the strong precision performance when the recall is not large. *NYT'13 dataset*: Figure 2(b) illustrates that our approach outperforms the state-of-the-art methods, which shows that our approach can maintain a fairly high precision even when recall is larger. In addition, in practical applications, we also concern about the precision on

Top-N predicted instances. Table 3 shows that our model achieves much significant improvements on that. Moreover, Table 4 shows that our method can achieve the best F1, compared with the baselines.

NYT'10 and NYT'13 have different performance records, which could be explained as follows. From the dataset perspective, NYT'10 is a dataset with multi-label instances, which is more complex than NYT'13 only having single label instances. This is one reason of why the trends are quite different between them. More essentially, we further discuss the differences from the model mechanism perspective, to explain the reasons. In (Fan et al., 2014)'s work, it has no explicit noise modeling mechanism. The noise is modeled implicitly as the error of cost functions. From the probabilistic view, that error is sampled from single Gaussian with zero mean and fixed variance. In contrast, our method uses infinite Gaussian with automatically learnt variance. It may cause overfitting for complex dataset with sparse features. In addition, we guess the reason is that in (Fan et al., 2014)'s work, they use two separate cost functions for features and labels, while in our work we use one unified noise component for both of them, which shows the promising precision performance in NYT'10 when recall is less than 0.4.

In addition, in our experiments, we found that early stopping is crucial for achieving good results while model learning. This also verifies that the potential overfitting problem should be further considered while using the more flexible nonparametric method for NLP task.

4 Related Work

Our work is closest to (Fan et al., 2014), since we focus on the same noisy corpus problem. Although from different perspectives, we study it along with the same line of using matrix factorization (Petroni et al., 2015) for relation extraction. In this line, (Riedel et al., 2013) initially considered the task as a matrix factorization problem. Their method consists of several models, such as PCA (Collins et al., 2001) and collaborative filtering (Koren, 2008). However, the data noise brought by the assumption of distant supervision (Mintz et al., 2009), is not considered in the work. Another line addressing the problem uses deep neural networks (Zeng et al., 2015; Wang et al., 2015). The difference is that it is a supervised learning approach, while our focused one is a joint learning approach with transductive style, in which both training and test data are exploited simultaneously. In addition, (Han and Sun, 2016) explored Markov logic technique to enrich supervision knowledge, which can incorporate indirect supervision globally. Our method could be further augmented by that idea, using additional logical constraint to reduce the uncertainty for the clustered noise modeling.

5 Conclusion

In this paper, building on recent advances from the nonparametric Bayesian literature, we reformulate the task of relation extraction with distant supervision, based on the adaptive variance learning with intrinsic clustering structures. For the task, it can solve the sparsity problem via the learnt low-rank dense representations and can allow fitting noisy corpus through adaptive variance adjustment. Meanwhile, it can avoid turning a large number of parameters. Experiments suggest substantially higher top-precision than the competitors. In the future work, we plan to develop more sophisticated noise models for features and labels separately, and try to explore logical information, particularly in this context of nonparametric noise modeling, for further benefiting this task.

Abstract

Word embeddings are used with success for a variety of tasks involving lexical semantic similarities between individual words. Using unsupervised methods and just cosine similarity, encouraging results were obtained for analogical similarities. In this paper, we explore the potential of pre-trained word embeddings to identify generic types of semantic relations in an unsupervised experiment. We propose a new relational similarity measure based on the combination of word2vec's CBOW input and output vectors which outperforms alternative vector representations, when used for unsupervised clustering on SemEval 2010 Relation Classification data.

1 Introduction

Vector space word representations or *word embeddings*, both 'count' models (Turney and Pantel, 2010) and learned vectors (Mikolov et al., 2013a; Pennington et al., 2014), were proven useful for a variety of semantic tasks (Mikolov et al., 2013b; Baroni et al., 2014). Word vectors are used with success because they capture a notion of semantics directly extracted from corpora. Distributional representations allow to compute a functional or topical semantic similarity between two words or, more recently, bigger text units (Le and Mikolov, 2014). The more similar two entities are semantically, the closer they are in the vector space (quantified usually, but not necessarily in terms of cosine similarity). Semantic similarity can be exploited for lexical substitution, synonym detection, subcategorization learning etc. Recent studies suggest that neural word embeddings show higher performance than count models (Baroni et al., 2014; Krebs and Paperno, 2016) for most semantic tasks, although Levy et al. (2015a) argue that this is only due to some specific hyperparameters that can be adapted to count vectors. In what follows, we will concentrate on exploring whether and how pre-trained, general-purpose word embeddings encode relational similarities.

1.1 Relational analogies as vector offsets

Relation extraction and classification deal with identifying the semantic relation linking two entities or concepts based on different kinds of information, such as their respective contexts, their co-occurrences in a corpus and their position in an ontology or other kind of semantic hierarchy. Whether the vector spaces of pre-trained word embeddings are appropriate for discovering or identifying *relational* similarities remains to be seen. Mikolov et al. (2013b) claimed that the embeddings created by a recursive neural network indeed encode a specific kind of relational similarities, i.e. *analogies* between pairs of words. He found that by using simple vector arithmetic, analogy questions in the form of "a_1 is to a_2 as b_1 is to b_2" (*man ~king :: woman ~queen*) could be solved. Relationships are assumed to be present as vector offsets, so that in the embedding space, all pairs of words sharing a particular relation are related by the same constant offset. Vector arithmetics give us the vector which fills the analogy, and we can search for the word b_2 whose embedding vector has the greatest similarity to it:

$$argmax_{b_2} = sim(b_2, (b_1 - a_1 + a_2)) \qquad (1)$$

Levy et al. (2015a) suggested that instead of a vector offset method, this calculation can also be considered as a combination of similarities. Using cosine similarity for sim, equation 1 can be written as a combination of similarities (Levy et al., 2015a)

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1814–1823
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

as

$$argmax_{b_2} = sim(b_2, b_1) - sim(b_2, a_1) + \\ + sim(b_2, a_2) \quad (2)$$

Analogy pairs, however, are a special case of relational similarity because not only a_1 (*man*) relates to a_2 (*king*) the same way that b_1 (*woman*) relates to b_2 (*queen*); the relation between a_1 (*man*) and b_1 (*woman*) is also parallel to the relation between a_2 (*king*) and b_2 (*queen*.) This is not always the case: when it comes to different types of semantic relations, their instances may or may not be analogical.

1.2 Criticism of the vector offset method

As precise as neural word embeddings combined with cosine similarity may be for calculating semantic proximity between individual words, recent results seem to suggest that their value in identifying relational analogies using vector arithmetics is limited. In fact, a big part of their merits is likely to come from the precise calculation of individual similarities instead of relational similarities. Hence, they can be approximated using relation-independent baselines. Linzen (2016) remarks that currently used analogy tasks evaluate not only the consistency of the offsets $a_1 - a_2$ and $b_1 - b_2$, but also the neighborhood structure of the words in the vector space. Concretely, "if a_1 and a_2 are very similar to each other (...) the nearest word to b_2 may simply be the nearest neighbor of b_1 (...) regardless of offset consistency" (Linzen, 2016). Moreover, some of the success obtained by the vector offset method on analogies can also be obtained by baselines that ignore a_2, or even both a_1 and a_2.
Levy et al. (2015b) point out similar limitations: word embedding combinations in supervised learning of taxonomical relations do not seem to learn the relations themselves, but individual properties of words. They tested previously suggested vector compositions for supervised learning of inference relations: concatenation, difference, comparing only the first or only the second element of the pairs. The study concludes that the classifiers only learn individual properties (e.g. a "category" type word is a good hypernym candidate), but not semantic relations between words. Altogether, these studies suggest that the semantic information obtained from word embeddings is correct for identifying similar or related units, but is already self-contained and difficult to enrich in order to retrieve more specific semantic contents such as relational similarities or specific relations.

In this paper, we aim to challenge this conclusion within a large scale semantic relation classification experiment, and show that it is possible to achieve improvements compared to baselines and current methods. We apply known vector composition methods, and propose a new one, to unsupervised large-scale clustering of entity pairs categorized according to their semantic relation. While large scale semantic relation classification is a very difficult task and the state of the art does not perform yet at human level, we expect that the experiment provides information to compare the potential of different vector/similarity combinations in a setting (i.e. clustering) that is more reliant on the global structure of the data instead of the close neighborhood structure of selected items.

2 Semantic Relations in Vector Spaces

2.1 Related work

Relation classification includes the task of finding the instances of the semantic relations, i.e. the entity tuples, and categorizing their relation according to an existing typology. In an unsupervised framework, relation types are inferred directly from the data. Supervised systems rely on a list of predefined relations and categorized examples, as described in the shared tasks of MUC, ACE or SemEval campaigns (Hobbs and Riloff, 2010; Jurgens et al., 2012; Hendrickx et al., 2010). Competing systems extract different kinds of features eventually combined with external knowledge sources, and build classifiers to categorize new relationship mentions (Zhou et al., 2005). A commonly used method, initiated by Turney (2005; 2006), is to represent entity pairs by a pair-pattern matrix and calculate similarities over the distribution of the pairs. Another way of constructing a distributional vector space to represent quantifiable context features for relation extraction is to combine the vectors of the two entities. Different combinations were proposed to represent compositional meaning (Mitchell and Lapata, 2010; Baroni and Zamparelli, 2010; Baroni et al., 2012). Popular methods include addition (Mitchell and Lapata, 2010), concatenating the two vectors (Baroni et al., 2012) or taking their difference (Weeds et al., 2014; Roller et al., 2014). As of now, these vector combinations had two types of applications in semantic relation classification.

The first one aims to find specific types of semantic or functional analogies (Herdağdelen and Baroni, 2009; Makrai et al., 2013; Levy et al., 2015a). The second one tries to infer taxonomical relations, i.e. hypernymy, or lexical entailment, in supervised experiments (Weeds et al., 2014; Turney and Mohammad, 2014). For the hypernymy detection task, relation directionality can be captured by the inclusion of the hyponym's context in the broader term (Kotlerman et al., 2010), as well as by measuring the informativeness of their contexts (Santus et al., 2014).

A few experiments have been specifically targeted at combining different kinds of linguistic information for calculating relational similarities. Turney (2012) suggested a dual distributional feature space, composed of a *domain space* and a syntactic *function space*, for supervised classification. Herdağdelen and Baroni (2009) combine individual entity vectors with co-occurrence contexts in their vector space. These works either aim to identify very specific relation types (typically taxonomical relations) with a mixture of features and a supervised classifier, or target analogy pairs: a task in which, as we have seen, relation-unaware baselines approximate relation-aware representations. However, more recently, Shwartz et al. (2016) achieved promising results on the hypernymy detection task by combining dependency path-based context representations with distributional vectors; this finding can be relevant for a broader range of semantic relations as well.

2.2 Task definition

Whether we use the vector offset method or any pairwise similarity combination, finding the missing word in an analogy depends on two factors:

1. Vector quality (do semantically close elements have a higher cosine similarity?);
2. Density and structure of the vector space.

If we adapt 1) above to the more generic relational similarity task, the question can be formulated as follows:

3. How much information about the semantic relation is actually in the text and how fit is the vector combination method to encode this information?

In accordance with Linzen (2016) and Levy et al. (2015b), we also think that analogy test sets are not optimal to answer this question. It was already confirmed that word embeddings are precise in identifying closely related items, while it is an open question whether they are useful for inferring a global structure from potentially noisy data in a large scale experiment. We propose to study relational similarity using a more generic and large scale relation classification task (Hendrickx et al., 2010), and clustering pairs according to semantic relations, instead of finding the one missing word in an analogy. This way, we rely less on the neighborhood structure and more on actual "linguistic regularities".

We evaluate different vector combination methods, and propose a new one, for calculating relational similarities. The evaluation concentrates on the aspects above. We test whether cosine similarity over these vector spaces is adapted for discovering groups and classifying individual instances. We report clustering results and compare the vector combinations by their performance.

2.3 Motivation

The semantic relation classification task, supervised or not, is a difficult one with a strong upper bound: relations vary considerably with respect to the way they are defined and expressed in the text. Some relation types are more lexical by nature: relations such as *dog* is an *animal*; a *teacher* works at a *school*; a *car* is kept at a *parking lot*, can be identified out of context. On the other hand, many relations are contextual; they are time-anchored or tied to extra-linguistic, situational context. Contextual relations (e.g. "the *accident* was caused by the *woman*") tend to be expressed explicitly, but rarely, in a corpus. A similar distinction underlies the notion of *classical* vs *non-classical* lexical semantic relations coined by Morris and Hirst (2004); however, their distinction is made on the level of relation *types*, while different instances of the same relation type can also be different with respect to their lexical or contextual nature. Other types of relations are defined exclusively through examples or analogies (e.g. *badge* is to *policeman* as *crown* is to *king*).

Semantic relations can also be viewed as binary predicates, and such predicates have semantic constraints on their arguments, similarly to verb subcategorization. Indeed, the relations are often expressed by verbs, and we expect specific arguments of relations to belong to a specific semantic type, e.g. Message (*chapters* in this book investigate issues), Instrument (*telescope* assists the eye), Collection (essays collected in this *volume*), Container (image is hidden in a *carafe*). We expect vector space models (VSMs) to capture such semantic groups through pairwise similarity combinations.

Semantic relation types and instances differ with respect to the degree of semantic constraint on their arguments, the analogical nature of the relation, and the lexical/contextual aspect. We expect distributional VSMs to contribute to capture analogical similarities, as well as the semantic types of the arguments and lexical or prototypical relation instances. Since their ability to capture contextual relations is limited, they need to be complemented with e.g. pattern-based or dependency-based approaches when it comes to less typical examples.

In the scope of the current experiment, our primary goal is to argue that vector combinations may encode lexical relational similarities in themselves. If a representation is more capable than others to group together word pairs according to relational similarities, this potential can further be exploited in unsupervised as well as in supervised experiments.

The current task requires a change of perspective compared to the analogical task: when we look for missing elements in an analogy, we know the word exists and we presume to know where it will be in the vector space. In unsupervised clustering, our aim is to infer a global structure from the data.

2.4 Semantic relation data

The SemEval 2010 Task 8 data we used (Hendrickx et al., 2010) contains examples of relation instances for 9 relations with sufficiently broad coverage to be of general and practical interest (Table 1).

There is no overlap between classes, but there are two groups of strongly related relations to assess models' ability to make fine-grained distinctions (CONTENT-CONTAINER, COMPONENT-WHOLE, MEMBER-COLLECTION and ENTITY-ORIGIN, ENTITY-DESTINATION). Human agreement rates, when annotated in context, range from 58.2% to 98.5% depending on the relation type (Hendrickx et al., 2010). This data set is very challenging, not only because of the fine semantic distinctions, but also because semantic relations were annotated in context and contain many less typical relation instances. In the current experiment, the goal we set for ourselves is to explore models' abilities to capture the structure of the data, rather then in achieving a classification precision close to that of humans.

We used 6637 pairs of single word instances from the training data. Contexts in the training data were discarded. Class bias is present: the most frequent relation has 979 instances, the least frequent has 486.

3 Vector combination methods

If a_1, a_2, b_1, b_2 are entities (nouns or nominal compositions) from a corpus, each of them assigned a pre-trained word embedding, we would like to classify entity pairs $a = (a_1, a_2)$ and $b = (b_1, b_2)$ according to their semantic relation. This means that we are looking for an efficient combination of a_1, a_2 and b_1, b_2 vectors that encode their relational attributes. We aim to find effective methods to calculate a relational similarity $sim(a, b)$ by combining entity vectors a_1, a_2 and b_1, b_2.

Pairwise similarities build on the idea that if a_1 is semantically similar to b_1 and a_2 is similar to b_2, the relation between a_1 and a_2 is similar to the relation between b_1 and b_2. The recall of this approach is expected to be limited: the same relation can hold between different types of entities.

Analogical similarities presume that $b_1 - b_2$ shares the direction with $a_1 - a_2$, ignoring the pairwise similarities. We adapt this measure, while aware that analogy pairs are a specific case of relational similarity in that analogies work both ways (*man ~king* :: *woman ~queen* and also *man ~woman* :: *king ~queen*).

IN-OUT similarities: a new combination that builds on the integration of second order similarities.

Only a_1 : In this baseline solution, the similarity between two pairs is calculated as the similarity between the first entity of each pair, the other pair being ignored.

$$sim(a, b) = sim(a_1, b_1) \tag{3}$$

3.1 Pairwise similarities

Different combinations proposed in the literature were compared.

- **concatenative** : one vector for each entity pair is defined as the concatenation of the vec-

Relation	Instances in training data	Typical examples	Atypical examples
Cause-Effect	979	$suicide - death, injury - discomfort$	$women - accident$
Component-Whole	978	$claw - owl, walls - hospital$	$image - photos$
Entity-Destination	789	$solvent - flask, hay - barn$	$chair - corporation$
Product-Producer	775	$industry - models, artist - design$	$officer - oath$
Entity-Origin	762	$relics - culture, plane - runway$	$error - definition$
Member-Collection	729	$stable - hounds, ensemble - ladies$	$mission - monkeys$
Message-Topic	622	$pages - scene, speech - measures$	$exhibition - glamour$
Instrument-Agency	517	$user - console, eye - telescope$	$companies - governments$
Content-Container	486	$document - folder, pictures - box$	$message - paper$

Table 1: Semantic Relation Classification data

tors of the two entities.

$$sim(a, b) = sim((a_1 \oplus a_2), (b_1 \oplus b_2)) \quad (4)$$

- **pairwise addition** Pairwise similarities between respective entities are added up. If we use cosine similarity, this is only slightly different from the concatenative method. Vector addition proved to work well as a compositional representation (Mitchell and Lapata, 2010), despite the fact that word order is ignored.

$$sim(a, b) = sim(a_1, b_1) + sim(a_2, b_2) \quad (5)$$

A potential problem with this addition objective is that different properties of words are expressed on a different scale and, as a consequence, terms sharing these properties have a higher cosine similarity than terms that are similar with respect to a flatter property. It can be overcome by using multiplication instead of addition (Levy and Goldberg, 2014):

- **pairwise multiplication**

$$sim(a, b) = sim(a_1, b_1) \times sim(a_2, b_2) \quad (6)$$

3.2 Analogies

This is an adaptation of the measure proposed for *queen* = *king* - *man* + *woman* (Mikolov et al., 2013b). Vector arithmetics give us the vector which fills the analogy, and we can search for the word b_2 whose embedding vector has the greatest similarity to it:

$$argmax_{b_2} = sim(b_2, (b_1 - a_1 + a_2)) \quad (7)$$

which, using cosine similarity for sim, can be written as a combination of similarities (Levy et al., 2015a), as

$$argmax_{b_2} = sim(b_2, b_1) - sim(b_2, a_1) + sim(b_2, a_2) \quad (8)$$

Mikolov (2013b) notes that this measure is qualitatively similar to the relational similarity model in (Turney, 2012), which predicts similarity between members of the word pairs $(x_b, x_d), (x_c, x_d)$ and dissimilarity for (x_a, x_d).

In the current context, we do not look for the missing b_2 which maximizes the equation. Instead, we have different pairs a and b, and we aim to calculate $sim(a, b)$ to quantify how much the analogy *queen* - *woman* = *king* - *man* holds.

- **difference** Focuses on the similarity of b_1, b_2 and a_1, a_2, but does not take into account the pairwise distances between the individual entity vectors.

$$sim(a, b) = sim((a_1 - a_2), (b_1 - b_2)) \quad (9)$$

Levy et al. (2015a) propose a multiplicative version of the analogy formula. We tried to adapt it; however, this measure is not symmetrical (conceived to find b_2 which maximizes the form) and the adaptation produced bad results.

3.3 IN-OUT similarities

This metric is a combination of first order and second order similarities between the two entity pairs, adapted to relational similarity: a and b are similar if a_1 is similar to b_1 and also similar to the *contexts of* b_2, the opposite entity in b.

In the current experiment, second order similarities are estimated using both input and output vectors generated by word2vec's CBOW model. In this model, the IN vectors of words get closer to the OUT vectors of other words that they co-occur with.

Words with a high input-output similarity tend to appear in the context of each other. This similarity combination was recently included for a few, different tasks. It was shown to improve information retrieval (Nalisnick et al., 2016). Pennington et al. (2014) propose to use second-order similarity to improve similarity calculation between words. Their proposed formula combines first and second order similarity, normalized by the reflective second order similarity of the words with themselves. Finally, Melamud et al. (2015) used a combination of input-output similarities for lexical substitution.

In these contexts, the use of second-order similarities[1] is based on the observation that words are similar if they tend to appear in similar contexts, or if they tend to appear in the contexts of each other. In our experiment, second order similarities are used in a different way and with a different purpose. Second-order similarities are calculated between *opposite elements* of the entity pairs. We combine those similarities by taking the in-in similarity between a_1 and b_1, and the in-out similarities between a_1 and b_2, and between a_2 and b_1. Our motivation is to add relational information in a form which also preserves pairwise similarity information, as both are relevant for calculating relational similarities. We do it by using a co-occurrence component which gives higher score between more prototypical example pairs. A pairwise similarity can be high even if the entities are similar, but their relation is not: an obvious example is ambiguity (when they are similar with respect to a meaning, but co-occur with their pair in an other meaning). If an entity is similar to one argument of a relation and is also likely to appear in the context of the other argument, it indicates a higher likelihood of being an instance of the same relation.

- **additive in-out**

$$sim(a,b) = sim(a_1,b_1) + sim(a_2,b_2) + sim_2(a_1,b_2) + sim_2(a_2,b_1) \quad (10)$$

where sim_2 designates the second order similarity and is calculated as follows:

$$sim_2(x_1,y_2) = sim(x_1^{in}, y_2^{out}) + sim(x_1^{out}, y_2^{in}) \quad (11)$$

- **multiplicative in-out**: The same as above, but addition is replaced by multiplication in sim and sim_2.

$$sim(a,b) = sim(a_1,b_1) * sim(a_2,b_2) * sim_2(a_1,b_2) * sim_2(a_2,b_1) \quad (12)$$

where

$$sim_2(x_1,y_2) = sim(x_1^{in}, y_2^{out}) * sim(x_1^{out}, y_2^{in}) \quad (13)$$

4 Clustering Experiments

For supervised classification tasks, it is desirable to adapt word2vec's hyperparameters to the task and the data at hand (Levy et al., 2015a). The interaction between hyperparameters is also to be considered (Krebs and Paperno, 2016). However, our experiment is a clustering scenario aimed at exploratory analysis on a vector space created by pre-trained word embeddings; therefore, we set the parameters once and in advance.

We trained a word2vec CBOW model (Mikolov et al., 2013a) with negative sampling and a window size of 10 words on the ukWaC corpus (Baroni et al., 2009), and extracted both input and output vectors of size = 400 to build the vector combinations above. This size corresponds to the best performing model in the comparative paper by Baroni et al. (2012). An adjacency matrix was constructed for each vector/similarity combination using cosine similarity.

Clustering was implemented with Cluto's (Zhao et al., 2005) clustering function which takes the adjacency matrix as input. We used a hierarchical agglomerative clustering with the unweighted average distance (UPGMA) criterion function[2].

4.1 Evaluation as classification

At first, we ran the clustering with 9 clusters (the number of classes in the standard) and tried to make one-to-one correspondences between the standard and the output. Every cluster is mapped to the standard class that shares the more elements with. We

[1] Note that we use the term "second order similarity" in the sense of word-to-context similarity, unlike Pennington et al. (2014).

[2] We observed that these settings are sensitive to the chaining effect and there is probably room for improvement by experimenting with different task-specific clustering parameters.

then calculate precision and recall for each standard class (zero if the class doesn't show up as a majority class in any cluster). Average class-based precision and recall is reported, as well as the number of classes in the standard that could be assigned. These scores were published for the SemEval task participants, but ours are not comparable because we only consider one cluster for each class, and because we did the clustering on the training data.

diff	5	**0.3762**	0.0918	0.1476

Table 2: Class-based results for 9 clusters

4.2 Evaluation as clustering

While the scores above can be indicative of the potential of different representations, they do not provide information on other aspects as cluster stability, purity, the amount of post-processing needed. Above all, in a completely unsupervised setting, the number of classes in the standard is not known and cluster quality (precision) plays an important role with respect to interpretability: it is easier to unify two homogeneous clusters than to separate a noisy one. We ran complementary experiments with different numbers of clusters. Table 3 indicates results for 20 and 30 clusters. The input-output combination method still has an advantage, and concatenation and multiplication also perform well. However, the advantages over the baseline are less significant than when the number of clusters was identical to the standard.

In the next runs, we measure how stable the different clustering solutions are with settings that are structurally very different from the standard, i.e. have significantly more clusters. Class-based precision and recall are less relevant measures in this setting, since they take the average over the nine standard classes and not over the produced clusters. We therefore decided to use *modified purity* (Korhonen et al., 2008), adapted for structurally different clustering solution. Modified purity gives the proportion of word pairs belonging to the majority class c in their cluster k:

$$PUR = \frac{\sum_{i=1}^{|K|} \max_j |w\ in\ k_i \cap w\ in\ c_j|}{\sum_{i=1}^{|K|} w\ in\ k_i} \quad (14)$$

INPUT	#clust	P	R	F
a_1(base)	20	**0.3429**	0.1642	0.2221
add	20	0.2434	0.1843	0.2098
conc	20	0.2718	**0.2116**	0.2380

diff	30	0.3770	0.1318	0.1953

Table 3: Class-based results for 20 and 30 clusters

Modified purity is indicative of the quality and interpretability of the clusters. It favorizes small clusters, but singleton clusters were discarded. This measure corresponds to prediction accuracy in classification if we assign the majority label to clusters. Two series of runs were evaluated: for 10, 20... up to 50, and for 60, 70... up to 100 clusters. Average results are reported. These scores indicate the average purity of clusters over different runs.

5 Discussion

We note that the baseline and the simple pairwise combinations have a high performance because they already capture arguments' semantic types successfully. This also lies behind previous success on the analogy dataset. Moreover, the nature of semantic spaces and of semantic datasets is such that they typically contain close or quasi-identical variants for the same phenomenon, that the baselines identify easily.

The additive input-output combination shows promising results, especially when it comes to capturing the structure: in the clustering setting with 9 clusters, it identifies 8 classes out of 9 in the standard. This indicates a good potential in differentiating between relation types, especially because the standard is conceived in a way that it contains strongly related classes. It outperforms every other measure until the number of clusters grows significantly above those in the standard (Table 5), when the concatenative measure catches up. The baseline performs well, but additive methods all beat it, while difference is especially weak. Pairwise multiplication is good at recognizing the structure (7 classes out of 9), but not good at assigning elements.

Multiplicative methods show a fluctuating performance, especially the multiplicative input-output combination. This is due to the higher variance in similarities obtained by multiplication (in the case of input-output combination, 6 operands are multiplied), combined with the agglomerative clustering, which is sensitive to chaining.

The very high precision of the baseline method with a large number of clusters (Table 3) is noteworthy but not unexpected. Individual similarities have a strong precision for the easily identifiable clusters, while additional relational information is mostly expected to improve recall.

6 Conclusion and Future Work

We presented an experiment to identify relational similarities in word embedding compositions at a large scale, using an unsupervised approach. On the one hand, our results confirm the recent finding that many of the success attributed to vector arithmetics for analogies come from similarities between individual elements. On the other hand, taking second order similarity into account, we can improve relational similarities and take a step toward a meaningful representation for entity couples in a semantic relation.

The baseline performs well and is difficult to enrich with relation-aware information. The results indicate that the vector offset method for analogies, which replaces the pairwise similarity, is the least efficient in capturing generic semantic relations at a large scale. The vector difference representation does not conserve pairwise similarities and the offsets do not prove to be constant enough for unsupervised clustering. Multiplicative methods do not scale up either, although to a lesser extent: they capture some of the relational information, but this happens at the expense of losing precision from individual similarities. Pairwise similarities can be better exploited in an additive or concatenative setting. Moreover, they can be meaningfully complemented by including second order similarities without losing too much information for precise classification. The input-output combination measure coherently outperformed the other combinations in almost every setting, indicating a better potential for unsupervised experiments.

Unsupervised relation classification is a very challenging task for several reasons. Some relation instances are lexical by nature and, therefore, can be expected to show up in the same cluster based on distributional cues. On the other hand, contextual relation instances tend to have relation-specific indicators when they co-occur, but their individual vectors will not reveal this information (unless they co-occur very often). Moreover, semantic relations differ with respect to the semantic constraints they put on their arguments. For instance, the second argument of the Content-Container relation tend to belong to a specific semantic class in the standard (*bag, box, trunk, case, drawer...*), while both arguments of the Cause-Effect relation are much freer (*gas, prices, pain, acts, species* and *pyrolysis, collapse, contraction, society, noise*). Any future development towards an automated unsupervised classification needs to take these aspects into account and work towards a hybrid solution by separating relations with semantically constrained arguments from free ones, as well as adapting the clustering method to handle outliers.

Abstract

This paper deals with using word embedding models to trace the temporal dynamics of semantic relations between pairs of words. The set-up is similar to the well-known analogies task, but expanded with a time dimension. To this end, we apply incremental updating of the models with new training texts, including incremental vocabulary expansion, coupled with learned transformation matrices that let us map between members of the relation. The proposed approach is evaluated on the task of predicting insurgent armed groups based on geographical locations. The gold standard data for the time span 1994–2010 is extracted from the UCDP Armed Conflicts dataset. The results show that the method is feasible and outperforms the baselines, but also that important work still remains to be done.

1 Introduction and related work

In this research, we make an attempt to model the dynamics of worldwide armed conflicts on the basis of English news texts. To this end, we employ the well-known framework of Continuous Bag-of-Words modeling (Mikolov et al., 2013c) for training word embeddings on the English Gigaword news text corpus (Parker et al., 2011). We learn linear projections from the embeddings of geographical locations where violent armed groups were active to the embeddings of these groups. These projections are then applied to the embeddings and gold standard data from the subsequent year, thus predicting what entities act as violent groups in the next time slice. To evaluate our approach, we adapt the UCDP Armed Conflict Dataset (Gleditsch et al., 2002; Allansson et al., 2017) (see Section 2 for details).

Here is a simplified example of the task: given that in 2003, the *Kashmir Liberation Front* and *ULFA* were involved in armed conflicts in India, and *Lord's Resistance Army* in Uganda, predict entities playing the same role in 2004 in Iraq (the correct answers are *Ansar al-Islam*, *al-Mahdi Army* and *Islamic State*). The nature of the task is conceptually similar to that of analogical reasoning, but with the added complexity of temporal change.

Attempts to detect semantic change using unsupervised methods have a long history. Significant results have already been achieved in employing word embeddings to study diachronic language change. Among others, Eger and Mehler (2016) show that the embedding of a given word for a given time period to a large extent is a linear combination of its embeddings for the previous time periods. Hamilton et al. (2016) proposed an important distinction between cultural shifts and linguistic drifts. They proved that global embedding-based measures (comparing the similarities of words to all other words in the lexicon) are sensitive to regular processes of linguistic drift, while local measures (comparing nearest neighbors' lists) are a better fit for more irregular cultural shifts in word meaning.

Our focus here is on cultural shifts: it is not the dictionary meanings of the names denoting locations and armed groups that change, but rather their 'image' in the analyzed texts. Our measurement approach can also be defined as 'local' to some extent: the linear projections that we learn are mostly based and evaluated on the nearest neighborhood data. However, this method is different in that its scope is not single words but pairs of typed entities ('*location*' and '*armed group*' in our case) and the semantic relations between them.

Copenhagen, Denmark, September 7–11, 2017.

1.1 Contributions

The main contributions of this paper are:

1. We show that distributional semantic models, in particular word embeddings, can be used not only to trace diachronic semantic shifts in words, but also the temporal dynamics of semantic relations between pairs of words.

2. The necessary prerequisites for achieving decent performance in this task are incremental updating of the models with new textual data (instead of training from scratch each time new data is added) and some way of expanding the vocabulary of the models.

2 Gold standard data on armed conflicts

The UCDP/PRIO Armed Conflict Dataset maintained by the Uppsala Conflict Data Program and the Peace Research Institute Oslo is a manually annotated geographical and temporal dataset with information on armed conflicts, in the time period from 1946 to the present (Gleditsch et al., 2002; Allansson et al., 2017). It encodes conflicts, where at least one party is the government of a state. The Armed Conflict Dataset is widely used in statistical and macro-level conflict research; however, it was adapted and introduced to the NLP field only recently, starting with (Kutuzov et al., 2017). Whereas that work was focused on detecting the onset/endpoint of armed conflicts, the current paper further extends on this by using the dataset to evaluate the detection of changes in the semantic relation holding between participants of armed conflicts and their locations.

Two essential notions in the UCDP data are those of *event* and *armed conflict*. *Events* can evolve into full-scale *armed conflicts*, defined as contested incompatibilities that concern government and/or territory where the use of armed force between two parties, of which at least one is the government of a state, results in at least 25 battle-related deaths (Sundberg and Melander, 2013).

The subset of the data that we employ is the *UCDP Conflict Termination dataset* (Kreutz, 2010). It contains entries on starting and ending dates of about 2000 conflicts. We limit ourselves to the conflicts taking place between 1994 and 2010 (the Gigaword time span). Almost always, the first actor of the conflict (*sideA*) is the government of the corresponding location, and the second actor (*sideB*) is some insurgent armed group we are interested in. We omitted the conflicts where both sides were governments (about 2% of the entries) or where one of the sides was mentioned in the Gigaword less than 100 times (about 1% of the entries). In cases when the UCDP described the conflict as featuring several groups on the *sideB*, we created a separate entry for each.

This resulted in a test set of 673 conflicts, with 137 unique *Location–Insurgent* pairs throughout the whole time span (many pairs appear several times in different years). In total, it mentions 52 locations (with *India* being the most frequent) and 128 armed insurgent groups (with *ULFA* or *United Liberation Front of Assam* being the most frequent). This test set is available for subsequent reuse (http://ltr.uio.no/~andreku/armedconflicts/).

3 Predicting armed conflict participants

In this section, we provide a detailed description of our approach, starting with a synchronic example in 3.1 and then moving on to a toy diachronic example on one pair of years in 3.2. In the next section 4, we conduct evaluation on the full test set.

3.1 Synchronic modeling

We first conducted preliminary experiments to assess the hypothesis that the embeddings contain semantic relationships of the type ‘insurgent participant of an armed conflict in the location’. To this end, we trained a CBOW model on the full English Gigaword corpus (about 4.8 billion tokens in total), with a symmetric context window of 5 words, vector size 300, 10 negative samples and 5 iterations. Words with a frequency less than 100 were ignored during training. We used Gensim (Řehůřek and Sojka, 2010) for training, and in terms of corpus pre-processing we performed lemmatization, PoS-tagging and NER using Stanford CoreNLP (Manning et al., 2014). Named entities were concatenated to one token (for example, *United States* became *United::States_PROPN*).

Then, we used the 137 *Location–Insurgent* pairs derived in Section 2 to learn a projection matrix from the embeddings for locations to the embeddings for insurgents. The idea and the theory behind this approach are extensively described in (Mikolov et al., 2013b) and (Kutuzov et al., 2016), but essentially it involves training a linear regression which minimizes the error in transforming

one set of vectors into another. Finding the optimal transformation matrix amounts to solving i normal equations (where i is the vector size in the embedding model being used), as shown in Equation 1:

$$\boldsymbol{\beta}_i = (\mathbf{X}^\intercal * \mathbf{X} + \lambda * L)^{-1} * \mathbf{X}^\intercal * y_i \qquad (1)$$

where $\mathbf{X}$ is the matrix of 137 location word vectors (input), y_i is the array of the ith components of 137 corresponding insurgent word vectors (correct predictions), L is the identity matrix of the size i, with 0 at the top left cell, and λ is a real number used to tune the influence of regularization term (if $\lambda = 0$, there is no regularization). $\boldsymbol{\beta}_i$ is the array of i optimal coefficients which transform an arbitrary location vector into the ith component of the corresponding insurgent vector. After learning such an array for each vector component, we have a linear projection matrix which can 'predict' an insurgent embedding from a location embedding.

To evaluate the resulting projections, we employed leave-one-out cross-validation, i.e., measuring the average accuracy of predictions on each pair from the test set, after training the matrix on all the pairs except the one used for the testing. The transformation matrix was dot-multiplied by the location vector from the test pair. Then, we found n nearest neighbors in the word embedding model for this predicted vector. If the real insurgent in the test pair was present in these n neighbors, the accuracy for this pair was 1, otherwise 0. In Table 1, the average accuracies with different values of λ and n are reported.

The relations of this kind are not symmetric: it is much easier to predict the location based on the insurgent than vice versa (see the right part of Table 1). Moreover, we find that the achieved results are roughly consistent with the performance of the same approach on the Google Analogies test set (Mikolov et al., 2013a). We converted the semantic sections in the Analogies test set containing only nouns (*capitals–common*, *capitals–world*, *cities in states*, *currency* and *family*) to sets of unique pairs. Then, linear projections with $\lambda = 1.0$ were learned and evaluated for each of them. The average accuracies over these sections were 13.0@1, 48.77@5 and 62.96@10.

The results on predicting armed groups are still worse than on the Google Analogies, because of 3 factors: 1) one-to-many relationships in the UCDP dataset (multiple armed groups can be active in the same location) make learning the transformation matrix more difficult; 2) the frequency of words denoting armed groups is lower than any of the words in the Google Analogies data set, thus, embeddings for them are of lower quality; 3) training the matrix on the whole Gigaword model is suboptimal, as the majority of armed groups were not active throughout all its time span.

All our experiments were also conducted using the very similar Continuous Skipgram models. However, as CBOW proved to consistently outperform Skipgram for our tasks, we only report results for CBOW, due to limited space.[1]

To sum up this section, many-to-one semantic relations between locations and insurgents do exist in the word embedding models. They are less expressed than one-to-one relations like those in the Google Analogies test set, but still can be found using linear projections. In the next section, we trace the dynamics of these relations as the models are updated with new data.

3.2 Diachronic modeling

Our approach to using learned transformation matrices to trace armed conflict dynamics through time consists of the following. We first train a CBOW model on the subsection of Gigaword texts belonging to the year 1994. Then, we incrementally update (train) this same model with new texts, saving a new model after each subsequent year. The size of the yearly subcorpora is about 250–320 million content words each. Importantly, we also use vocabulary expansion: new words are added to the vocabulary of the model if their frequency in the new yearly data satisfy our minimal threshold of 15.[2] Each yearly training session is performed in 5 iterations, with linearly decreasing learning rate. Note that we do not use any model alignment method (Procrustes, etc): our

[1] It seems CBOW is often better than Skipgram with linear projections; cf. the same claim in (Kutuzov et al., 2016).

[2] We did not experiment with different thresholds. It was initially set to the value which produced a reasonable vocabulary size of several hundred thousand words.

Pairs (size)	@1	@5	@10
All (38)	44.7	73.7	84.2
New (7)	14.3	28.6	42.9

Table 2: Projection accuracy for the isolated example experiment mapping from 2000 → 2001.

models are simply trained further with the new texts. A possible alternative to this can be incremental training of hierarchical softmax functions proposed in (Peng et al., 2017) or incremental negative sampling proposed in (Kaji and Kobayashi, 2017); we leave it for future work.

The experiment involves applying a learned transformation matrix across pairs of models. While in Section 4 we evaluate the approach across the entire Gigaword time period, this section reports a preliminary example experiment for the transition from 2000 to 2001 alone. This means we will have one model saved after sequential training for the years up to 2000, and one saved after year 2001. Our aim is to find out whether the *Location–Insurgent* projection learned on the first model is able to reveal conflicts that appear in 2001. Thus, we extract from the UCDP dataset all the pairs related to the conflicts which took place between 1994 and 2000 (91 pairs total). The projection is trained on their embeddings from the first model (actually, on 79 pairs, as 12 armed group names were not present in the 2000 model and subsequently skipped). Then, this projection is applied to the second model embeddings of the 47 locations, which are subject to armed conflicts in the year 2001 (38 after skipping pairs with out-of-vocabulary elements). Table 2 demonstrates the resulting performance (reflecting how close the predicted vectors are to the actual armed groups active in this or that location).

Note that out of 38 pairs from 2001, 31 were already present in the previous data set (ongoing conflicts). This explains why the evaluation on all the pairs gives high results. However, even for the new conflicts, the projection performance is encouraging. Among others, it managed to precisely spot the 2001 insurgency of the members of the *Kosovo Liberation Army* in Macedonia, notwithstanding the fact that the initial set of training pairs did not mention Macedonia at all. Thus, it seems that the models at least partially 'align' new data along the existing semantic axis trained before.

In the next section, we systematically evaluate our approach on the whole set of UCDP conflicts in the Gigaword years (1994–2010).

4 Evaluation of diachronic models

To evaluate our approach on all the UCDP data, we again tested how good it is in predicting the future conflicts based on the projection matrices learned from the previous years. We did this for all the years between 1994 and 2010. The evaluation metrics are the same as in the Section 3: we calculated the ratio of correctly predicted armed groups names from the conflict pairs, for which the UCDP datasets stated that these conflicts were active in this particular year. As before, the models employed in the experiment were incrementally trained on each successive year with vocabulary expansion. Words present in the gold standard but absent from the models under analysis were skipped. At the worst case, 25% of pairs were skipped from the test set; on average, 13% were skipped each year (but see the note below about the **incr. static** baseline). At test time, all the entities were lowercased.

We employ 3 baselines: 1) yearly models trained separately from scratch on the corpora containing texts from each year only (referred to as **separate** hereafter); 2) yearly models trained from scratch on all the texts from the particular year and the previous years (**cumulative** hereafter); 3) incrementally trained models without vocabulary expansion (**incr. static** hereafter).

Initially, the linear projections for all models were trained on all the conflict pairs from the past and present years, similar to Section 3.2 (dubbed **up-to-now** hereafter). However, the information about conflicts having ended several years before might not be strongly expressed in the model after it was incrementally updated with the data from all the subsequent years. For example, the 2005 model hardly contains much knowledge about the conflict relations between Mexico and the *Popular Revolutionary Army (EPR)* which stopped its activities after 1996. Thus, we additionally conducted a similar experiment, but this time the projections were learned only on the salient pairs (dubbed **previous**): that is, the pairs active in the last year up to which the model was trained.

Table 3 presents the results for these experiments, as well as baselines (averaged across 15 years). For the proposed **incr. dynamic** approach, the performance of the **previous** projections is

	Only in-vocabulary pairs						**All pairs, including OOV**					
	up-to-now			**previous**			**up-to-now**			**previous**		
	@1	@5	@10	@1	@5	@10	@1	@5	@10	@1	@5	@10
Separate	0.0	0.7	2.1	0.5	1.1	2.4	0.0	0.5	1.6	0.4	0.8	1.8
Cumulative	1.7	8.3	13.8	2.9	9.6	15.2	1.5	7.4	12.2	2.5	8.5	13.4
Incr. static	54.9	82.8	90.1	60.4	79.6	84.8	20.8	31.5	34.2	23.0	30.3	32.2
Incr. dynamic	32.5	64.5	72.2	42.6	64.8	71.5	28.1	56.1	**62.9**	**37.3**	**56.7**	62.6

Table 3: Average accuracies of predicting next-year insurgents on the basis of locations, using projections trained on the conflicts from all the preceding years (**up-to-now**) or the preceding year only (**previous**). Results for 3 baselines are shown along with the proposed **incremental dynamic** approach.

comparable to that of the **up-to-now** projections on the accuracies @5 and @10, and is even higher on the accuracy @1 (statistically significant with *t-test*, $p < 0.01$). Thus, the single-year projections are somewhat more 'focused', while taking much less time to learn, because of less training pairs.

The fact that our models were incrementally updated, not trained from scratch, is crucial. The results of the **separate** baseline look more like random jitter. The **cumulative** baseline results are slightly better, probably simply because they are trained on more data. However, they still perform much worse than the models trained using incremental updates. This is because the former models are not connected to each other, and thus are initialized with a different layout of words in the vector space. This gives rise to formally different directions of semantic relations in each yearly model (the relations themselves are still there, but they are rotated and scaled differently).

The results for the **incr. static** baseline, when tested only on the words present in the test model vocabulary (the left part of the table), seem better than those of the proposed **incr. dynamic** approach. This stems from the fact that incremental updating with static vocabulary means that we never add new words to the models; thus, they contain only the vocabulary learned from the 1994 texts. The result is that at test time we skip many more pairs than with the other approaches (about 62% in average). Subsequently, the projections are tested only on a minor part of the test sets.

Of course, skipping large parts of the data would be a major drawback for any realistic application, so the **incr. static** baseline is not really plausible. For comparison, the right part of Table 3 provides the accuracies for the setup in which all the pairs are evaluated (for pairs with OOV words the accuracy is always 0). Other tested approaches are not much affected by this change, but for **incr. static** the performance drops drastically. As a result, for the all pairs scenario, incremental updating with vocabulary expansion outperforms all the baselines (the differences are statistically significant with *t-test*, $p < 0.01$).

5 Conclusion

We have here shown how incrementally updated word embedding models with vocabulary expansion and linear projection matrices are able to trace the dynamics of subtle semantic relations over time. We applied this approach to the task of predicting armed groups active in particular geographical locations and showed that it significantly outperforms the baselines. However, it can be used for any kind of semantic relations. We believe that studying temporal shifts of such projections can lead to interesting findings far beyond the usual example of 'king is to queen as man is to woman'.

To our best knowledge, the behavior of semantic relations in updated word embedding models was not explored before. Our experiments show that the models do preserve these 'directions' and that the learned projections not only hold for the word pairs known to the initial model, but can also be used to predict relations for the new words.

In terms of future work, we plan to trace how quickly incremental updates to the model 'dilute' the projections, rendering them useless with time. We observed this performance drop in our experiments, and it would be interesting to know more about the regularities governing this deterioration. Also, for the particular task of analyzing armed conflicts, we plan to research ways of improving accuracy in predicting completely new armed groups not present in the training data, and the methods of filtering out locations not involved in armed conflicts.

Abstract

Understanding a long document requires tracking how entities are introduced and evolve over time. We present a new type of language model, ENTITYNLM, that can explicitly model entities, dynamically update their representations, and contextually generate their mentions. Our model is generative and flexible; it can model an arbitrary number of entities in context while generating each entity mention at an arbitrary length. In addition, it can be used for several different tasks such as language modeling, coreference resolution, and entity prediction. Experimental results with all these tasks demonstrate that our model consistently outperforms strong baselines and prior work.

1 Introduction

Understanding a narrative requires keeping track of its participants over a long-term context. As a story unfolds, the information a reader associates with each character in a story increases, and expectations about what will happen next change accordingly. At present, models of natural language do not explicitly track entities; indeed, in today's language models, entities are no more than the words used to mention them.

In this paper, we endow a generative language model with the ability to build up a dynamic representation of each entity mentioned in the text. Our language model defines a probability distribution over the whole text, with a distinct generative story for entity mentions. It explicitly groups those mentions that corefer and associates with each entity a continuous representation that is updated by every contextualized mention of the entity, and that in turn affects the text that follows.

[*John*]$_1$ wanted to go to [*the coffee shop*]$_2$ in [*downtown Copenhagen*]$_3$. [*He*]$_1$ was told that [*it*]$_2$ sold [*the best beans*]$_4$.

Figure 1: ENTITYNLM explicitly tracks entities in a text, including coreferring relationships between entities like [*John*]$_1$ and [*He*]$_1$. As a language model, it is designed to predict that a coreferent of [*the coffee shop*]$_2$ is likely to follow "*told that*," that the referring expression will be "*it*", and that "*sold the best beans*" is likely to come next, by using entity information encoded in the dynamic distributed representation.

Our method builds on recent advances in representation learning, creating local probability distributions from neural networks. It can be understood as a recurrent neural network language model, augmented with random variables for entity mentions that capture coreference, and with dynamic representations of entities. We estimate the model's parameters from data that is annotated with entity mentions and coreference.

Because our model is generative, it can be queried in different ways. Marginalizing everything except the words, it can play the role of a language model. In §5.1, we find that it outperforms both a strong n-gram language model and a strong recurrent neural network language model on the English test set of the CoNLL 2012 shared task on coreference evaluation (Pradhan et al., 2012). The model can also identify entity mentions and coreference relationships among them. In §5.2, we show that it can easily be used to add a performance boost to a strong coreference resolution system, by reranking a list of k-best candidate outputs. On the CoNLL 2012 shared task test set, the reranked outputs are significantly better than the original top choices from the same system. Fi-

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1830–1839
Copenhagen, Denmark, September 7–11, 2017.

nally, the model can perform entity cloze tasks. As presented in §5.3, it achieves state-of-the-art performance on the InScript corpus (Modi et al., 2017).

2 Model

A language model defines a distribution over sequences of word tokens; let X_t denote the random variable for the tth word in the sequence, x_t denote the value of X_t and $\mathbf{x}_t$ the distributed representation (embedding) of this word. Our starting point for language modeling is a recurrent neural network (Mikolov et al., 2010), which defines

$$p(X_t \mid \text{history}) = \operatorname{softmax}(\mathbf{W}_h \mathbf{h}_{t-1} + \mathbf{b}) \quad (1)$$

$$\mathbf{h}_{t-1} = \textsc{LSTM}(\mathbf{h}_{t-2}, \mathbf{x}_{t-1}) \quad (2)$$

where $\mathbf{W}_h$ and $\mathbf{b}$ are parameters of the model (along with word embeddings $\mathbf{x}_t$), LSTM is the widely used recurrent function known as "long short-term memory" (Hochreiter and Schmidhuber, 1997), and $\mathbf{h}_t$ is a LSTM hidden state encoding the history of the sequence up to the tth word.

Great success has been reported for this model (Zaremba et al., 2015), which posits nothing explicitly about the words appearing in the text sequence. Its generative story is simple: the value of each X_t is randomly chosen conditioned on the vector $\mathbf{h}_{t-1}$ encoding its history.

2.1 Additional random variables and representations for entities

To introduce our model, we associate with each word an additional set of random variables. At position t,

- R_t is a binary random variable that indicates whether x_t belongs to an entity mention ($R_t = 1$) or not ($R_t = 0$). Though not explored here, this is easily generalized to a categorial variable for the *type* of the entity (e.g., person, organization, etc.).

- $L_t \in \{1, \ldots, \ell_{max}\}$ is a categorical random variable if $R_t = 1$, which indicates the number of remaining words in this mention, including the current word (i.e., $L_t = 1$ for the last word in any mention). ℓ_{max} is a predefined maximum length fixed to be 25, which is an empirical value derived from the training corpora used in the experiments. If $R_t = 0$, then $L_t = 1$. We denote the value of L_t by ℓ_t.

- $E_t \in \mathcal{E}_t$ is the index of the entity referred to, if $R_t = 1$. The set $\mathcal{E}_t$ consists of $\{1, \ldots, 1 + \max_{t'<t} e_{t'}\}$, i.e., the indices of all previously mentioned entities plus an additional value for a new entity. Thus $\mathcal{E}_t$ starts as $\{1\}$ and grows monotonically with t, allowing for an arbitrary number of entities to be mentioned. We denote the value of E_t by e_t. If $R_t = 0$, then E_t is fixed to a special value $\varnothing$.

The values of these random variables for our running example are shown in Figure 2.

In addition to using symbolic variables to encode mentions and coreference relationships, we maintain a vector representation of each entity that evolves over time. For the ith entity, let $\mathbf{e}_{i,t}$ be its representation at time t. These vectors are different from word vectors ($\mathbf{x}_t$), in that they are not parameters of the model. They are similar to history representations ($\mathbf{h}_t$), in that they are derived through parameterized functions of the random variables' values, which we will describe in the next subsections.

2.2 Generative story

The generative story for the word (and other variables) at timestep t is as follows; forward-referenced equations are in the detailed discussion that follows.

1. If $\ell_{t-1} = 1$ (i.e., x_t is *not* continuing an already-started entity mention):
   - Choose r_t (Equation 3).
   - If $r_t = 0$, set $\ell_t = 1$ and $e_t = \varnothing$; then go to step 3. Otherwise:
     - If there is no embedding for the new candidate entity with index $1 + \max_{t'<t} e_{t'}$, create one following §2.4.
     - Select the entity e_t from $\{1, \ldots, 1 + \max_{t'<t} e_{t'}\}$ (Equation 4).
     - Set $\mathbf{e}_{current} = \mathbf{e}_{e_t, t-1}$, which is the entity embedding of e_t before timestep t.
     - Select the length of the mention, ℓ_t (Equation 5).
2. Otherwise,
   - Set $\ell_t = \ell_{t-1} - 1$, $r_t = r_{t-1}$, $e_t = e_{t-1}$.
3. Sample x_t from the word distribution given the LSTM hidden state $\mathbf{h}_{t-1}$ and the current

$X_{1:12}$:	John	wanted	to	go	to	the	coffee	shop	in	downtown	Copenhagen	.
$R_{1:12}$:	1	0	0	0	0	1	1	1	0	1	1	0
$E_{1:12}$:	1	$\emptyset$	$\emptyset$	$\emptyset$	$\emptyset$	2	2	2	$\emptyset$	3	3	$\emptyset$
$L_{1:12}$:	1	1	1	1	1	3	2	1	1	2	1	1

$X_{13:22}$:	He	was	told	that	it	sold	the	best	beans	.
$R_{13:22}$:	1	0	0	0	1	0	1	1	1	.
$E_{13:22}$:	1	$\emptyset$	$\emptyset$	$\emptyset$	2	$\emptyset$	4	4	4	$\emptyset$
$L_{13:22}$:	1	1	1	1	1	1	3	2	1	0

Figure 2: The random variable values in ENTITYNLM for the running example in Figure 1.

(or most recent) entity embedding $\mathbf{e}_{current}$ (Equation 6). (If $r_t = 0$, then $\mathbf{e}_{current}$ still represents the most recently mentioned entity.)

4. Advance the RNN, i.e., feed it the word vector $\mathbf{x}_t$ to compute $\mathbf{h}_t$ (Equation 2).

5. If $r_t = 1$, update $\mathbf{e}_{e_t,t}$ using $\mathbf{e}_{e_t,t-1}$ and $\mathbf{h}_t$, then set $\mathbf{e}_{current} = \mathbf{e}_{e_t,t}$. Details of the entity updating are given in §2.4.

6. For every entity $e_\iota \in \mathcal{E}_t \setminus \{e_t\}$, set $\mathbf{e}_{\iota,t} = \mathbf{e}_{\iota,t-1}$ (i.e., no changes to other entities' representations).

Note that at any given time step t, $\mathbf{e}_{current}$ will always contain the most recent vector representation of the most recently mentioned entity.

A generative model with a similar hierarchical structure was used by Haghighi and Klein (2010) for coreference resolution. Our approach differs in two important ways. First, our model defines a joint distribution over all of the text, not just the entity mentions. Second, we use representation learning rather than Bayesian nonparametrics, allowing natural integration with the language model.

2.3 Probability distributions

The generative story above referenced several parametric distributions defined based on vector representations of histories and entities. These are defined as follows.

For $r \in \{0, 1\}$,

$$p(R_t = r \mid \mathbf{h}_{t-1}) \propto \exp(\mathbf{h}_{t-1}^\top \mathbf{W}_r \mathbf{r}), \tag{3}$$

where $\mathbf{r}$ is the parameterized embedding associated with r, which paves the way for exploring entity type representations in future work; $\mathbf{W}_r$ is a parameter matrix for the bilinear score for $\mathbf{h}_{t-1}$ and $\mathbf{r}$.

To give the possibility of predicting a new entity, we need an entity embedding beforehand with index $(1 + \max_{t'<t} e_{t'})$, which is randomly sampled from Equation 7. Then, for every $e \in \{1, \ldots, 1 + \max_{t'<t} e_{t'}\}$:

$$\begin{aligned} &p(E_t = e \mid R_t = 1, \mathbf{h}_{t-1}) \\ &\quad \propto \exp(\mathbf{h}_{t-1}^\top \mathbf{W}_{entity} \mathbf{e}_{e,t-1} + \mathbf{w}_{dist}^\top \mathbf{f}(e)), \end{aligned} \tag{4}$$

where $\mathbf{e}_{e,t-1}$ is the embedding of entity e at time step $t-1$ and $\mathbf{W}_{entity}$ is the weight matrix for predicting entities using their continuous representations. The score above is normalized over values $\{1, \ldots, 1 + \max_{t'<t} e_{t'}\}$. $\mathbf{f}(e)$ represents a vector of distance features associated with e and the mentions of the existing entities. Hence two information sources are used to predict the next entity: (i) contextual information $\mathbf{h}_{t-1}$, and (ii) distance features $\mathbf{f}(e)$ from the current mention to the closest mention from each previously mentioned entity. $\mathbf{f}(e) = \mathbf{0}$ if e is a new entity. This term can also be extended to include other surface-form features for coreference resolution (Martschat and Strube, 2015; Clark and Manning, 2016b).

For the chosen entity e_t from Equation 4, the distribution over its mention length is drawn according to

$$\begin{aligned} &p(L_t = \ell \mid \mathbf{h}_{t-1}, \mathbf{e}_{e_t,t-1}) \\ &\qquad \propto \exp(\mathbf{W}_{length,\ell}^\top [\mathbf{h}_{t-1}; \mathbf{e}_{e_t,t-1}]), \end{aligned} \tag{5}$$

where $\mathbf{e}_{e_t,t-1}$ is the most recent embedding of the entity e_t, not updated with $\mathbf{h}_t$. The intuition is that $\mathbf{e}_{e_t,t-1}$ will help contextual information $\mathbf{h}_{t-1}$ to select the residual length of entity e_t. $\mathbf{W}_{length}$ is the weight matrix for length prediction, with $\ell_{max} = 25$ rows.

Finally, the probability of a word x as the next token is jointly modeled by $\mathbf{h}_{t-1}$ and the vector representation of the most recently mentioned entity $\mathbf{e}_{current}$:

$$\begin{aligned} &p(X_t = x \mid \mathbf{h}_{t-1}, \mathbf{e}_{current}) \\ &\qquad \propto \text{CFSM}(\mathbf{h}_{t-1} + \mathbf{W}_e \mathbf{e}_{current}), \end{aligned} \tag{6}$$

where $\mathbf{W}_e$ is a transformation matrix to adjust the dimensionality of $\mathbf{e}_{current}$. CFSM is a class factorized softmax function (Goodman, 2001; Baltescu and Blunsom, 2015). It uses a two-step prediction with predefined word classes instead of direct prediction on the whole vocabulary, and reduces the time complexity to the log of vocabulary size.

2.4 Dynamic entity representations

Before predicting the entity at step t, we need an embedding for the new candidate entity with index $e' = 1 + \max_{t'<t} e_{t'}$ if it does not exist. The new embedding is generated randomly, according to a normal distribution, then projected onto the unit ball:

$$\begin{aligned} \mathbf{u} &\sim \mathcal{N}(\mathbf{r}_1, \sigma^2 \mathbf{I}); \\ \mathbf{e}_{e',t-1} &= \frac{\mathbf{u}}{\|\mathbf{u}\|_2}, \end{aligned} \tag{7}$$

where $\sigma = 0.01$. The time step $t-1$ in $\mathbf{e}_{e',t-1}$ means the current embedding contains no information from step t, although it will be updated once we have $\mathbf{h}_t$ and if $E_t = e'$. $\mathbf{r}_1$ is the parameterized embedding for $R_t = 1$, which will be jointly optimized with other parameters and is expected to encode some generic information about entities. All the initial entity embeddings are centered on the mean $\mathbf{r}_1$, which is used in Equation 3 to determine whether the next token belongs to an entity mention. Another choice would be to initialize with a zero vector, although our preliminary experiments showed this did not work as well as random initialization in Equation 7.

Assume $R_t = 1$ and $E_t = e_t$, which means x_t is part of a mention of entity e_t. Then, we need to update $\mathbf{e}_{e_t,t-1}$ based on the new information we have from $\mathbf{h}_t$. The new embedding $\mathbf{e}_{e_t,t}$ is a convex combination of the old embedding ($\mathbf{e}_{e_t,t-1}$) and current LSTM hidden state ($\mathbf{h}_t$) with the interpolation (δ_t) determined dynamically based on a bilinear function:

$$\begin{aligned} \delta_t &= \sigma(\mathbf{h}_t^\top \mathbf{W}_\delta \mathbf{e}_{e_t,t-1}); \\ \mathbf{u} &= \delta_t \mathbf{e}_{e_t,t-1} + (1-\delta_t)\mathbf{h}_t; \\ \mathbf{e}_{e_t,t} &= \frac{\mathbf{u}}{\|\mathbf{u}\|_2}, \end{aligned} \tag{8}$$

This updating scheme will be used to update e_t in *each* of all the following ℓ_t steps. The projection in the last step keeps the magnitude of the entity embedding fixed, avoiding numeric overflow. A similar updating scheme has been used by Henaff et al. (2016) for the "memory blocks" in their recurrent entity network models. The difference is that their model updates all memory blocks in each time step. Instead, our updating scheme in Equation 8 only applies to the selected entity e_t at time step t.

2.5 Training objective

The model is trained to maximize the log of the joint probability of $\mathbf{R}, \mathbf{E}, \mathbf{L}$, and $\mathbf{X}$:

$$\begin{aligned} \ell(\boldsymbol{\theta}) &= \log P(\mathbf{R}, \mathbf{E}, \mathbf{L}, \mathbf{X}; \boldsymbol{\theta}) \\ &= \sum_t \log P(R_t, E_t, L_t, X_t; \boldsymbol{\theta}), \end{aligned} \tag{9}$$

where $\boldsymbol{\theta}$ is the collection of all the parameters in this model. Based on the formulation in §2.3, Equation 9 can be decomposed as the sum of conditional log-probabilities of each random variable at each time step.

This objective requires the training data annotated as in Figure 2. We do not assume that these variables are observed at test time.

3 Implementation Details

Our model is implemented with DyNet (Neubig et al., 2017) and available at https://github.com/jiyfeng/entitynlm. We use AdaGrad (Duchi et al., 2011) with learning rate $\lambda = 0.1$ and ADAM (Kingma and Ba, 2014) with default learning rate $\lambda = 0.001$ as the candidate optimizers of our model. For all the parameters, we use the initialization tricks recommended by Glorot and Bengio (2010). To avoid overfitting, we also employ dropout (Srivastava et al., 2014) with the candidate rates as $\{0.2, 0.5\}$.

In addition, there are two tunable hyperparameters of ENTITYNLM: the size of word embeddings and the dimension of LSTM hidden states. For both of them, we consider the values $\{32, 48, 64, 128, 256\}$. We also experiment with the option to either use the pretrained GloVe word embeddings (Pennington et al., 2014) or randomly initialized word embeddings (then updated during training). For all experiments, the best configuration of hyperparameters and optimizers is selected based on the objective value on the development data.

4 Evaluation Tasks and Datasets

We evaluate our model in diverse use scenarios: (i) language modeling, (ii) coreference resolution, and (iii) entity prediction. The evaluation on language modeling shows how the internal entity representation, when marginalized out, can improve the perplexity of language models. The evaluation on coreference resolution experiment shows how our new language model can improve a competitive coreference resolution system. Finally, we employ an entity cloze task to demonstrate the generative performance of our model in predicting the next entity given the previous context.

We use two datasets for the three evaluation tasks. For language modeling and coreference resolution, we use the English benchmark data from the CoNLL 2012 shared task on coreference resolution (Pradhan et al., 2012). We employ the standard training/development/test split, which includes 2,802/343/348 documents with roughly 1M/150K/150K tokens, respectively. We follow the coreference annotation in the CoNLL dataset to extract entities and ignore the singleton mentions in texts.

For entity prediction, we employ the InScript corpus created by Modi et al. (2017). It consists of 10 scenarios, including grocery shopping, taking a flight, etc. It includes 910 crowdsourced simple narrative texts in total and 18 stories were ignored due to labeling problems (Modi et al., 2017). On average, each story has 12.4 sentences, 24.9 entities and 217.2 tokens. Each entity mention is labeled with its entity index. We use the same training/development/test split as in (Modi et al., 2017), which includes 619, 91, 182 texts, respectively.

Data preprocessing

For the CoNLL dataset, we lowercase all tokens and remove any token that only contains a punctuation symbol unless it is in an entity mention. We also replace numbers in the documents with the special token NUM and low-frequency word types with UNK. The vocabulary size of the CoNLL data after preprocessing is 10K. For entity mention extraction, in the CoNLL dataset, one entity mention could be embedded in another. For embedded mentions, only the enclosing entity mention is kept. We use the same preprocessed data for both language modeling and coreference resolution evaluation.

For the InScript corpus, we apply similar data preprocessing to lowercase all tokens, and we replace low-frequency word types with UNK. The vocabulary size after preprocessing is 1K.

5 Experiments

In this section, we present the experimental results on the three evaluation tasks.

5.1 Language modeling

Task description. The goal of language modeling is to compute the marginal probability:

$$P(\mathbf{X}) = \sum_{\mathbf{R},\mathbf{E},\mathbf{L}} P(\mathbf{X},\mathbf{R},\mathbf{E},\mathbf{L}). \tag{10}$$

However, due to the long-range dependency in recurrent neural networks, the search space of $\mathbf{R},\mathbf{E},\mathbf{L}$ during inference grows exponentially. We thus use importance sampling to approximate the marginal distribution of $\mathbf{X}$. Specifically, with the samples from a proposal distribution $Q(\mathbf{R},\mathbf{E},\mathbf{L}|\mathbf{X})$, the approximated marginal probability is defined as

$$\begin{aligned} P(\mathbf{X}) &= \sum_{\mathbf{R},\mathbf{E},\mathbf{L}} P(\mathbf{X},\mathbf{R},\mathbf{E},\mathbf{L}) \\ &= \sum_{\mathbf{R},\mathbf{E},\mathbf{L}} Q(\mathbf{R},\mathbf{E},\mathbf{L}\mid\mathbf{X}) \frac{P(\mathbf{X},\mathbf{R},\mathbf{E},\mathbf{L})}{Q(\mathbf{R},\mathbf{E},\mathbf{L}\mid\mathbf{X})} \\ &\approx \frac{1}{N} \sum_{\{\mathbf{r}^{(i)},\mathbf{e}^{(i)},\ell^{(i)}\}\sim Q} \frac{P(\mathbf{r}^{(i)},\mathbf{e}^{(i)},\ell^{(i)},\mathbf{x})}{Q(\mathbf{r}^{(i)},\mathbf{e}^{(i)},\ell^{(i)}\mid\mathbf{x})} \end{aligned} \tag{11}$$

A similar idea of using importance sampling for language modeling evaluation has been used by Dyer et al. (2016).

For language modeling evaluation, we train our model on the training set from the CoNLL 2012 dataset with coreference annotation. On the test data, we treat coreference structure as latent variables and use importance sampling to approximate the marginal distribution of $\mathbf{X}$. For each document, the model randomly draws $N = 100$ samples from the proposal distribution, discussed next.

Proposal distribution. For implementation of Q, we use a discriminative variant of ENTITYNLM by taking the current word x_t for predicting the entity-related variables in the same time step. Specifically, in the generative story described in §2.2, we delete step 3 (words are not generated, but rather conditioned upon), move step 4 before step 1, and replace $\mathbf{h}_{t-1}$ with $\mathbf{h}_t$ in the steps for predicting entity type R_t, entity E_t and mention length L_t. This model variant provides a

Model	Perplexity
1. 5-gram LM	138.37
2. RNNLM	134.79
3. ENTITYNLM	**131.64**

Table 1: Language modeling evaluation on the test sets of the English section in the CoNLL 2012 shared task. As mentioned in §4, the vocabulary size is 10K. ENTITYNLM does not require any coreference annotation on the test data.

conditional probability $Q(R_t, E_t, L_t \mid X_t)$ at each timestep.

Baselines. We compare the language modeling performance with two competitive baselines: 5-gram language model implemented in KenLM (Heafield et al., 2013) and RNNLM with LSTM units implemented in DyNet (Neubig et al., 2017). For RNNLM, we use the same hyperparameters described in §3 and grid search on the development data to find the best configuration.

Results. The results of ENTITYNLM and the baselines on both development and test data are reported in Table 1. For ENTITYNLM, we use the value of $2^{-\frac{1}{T}\sum_{t=1}^{T}\log P(X_t,R_t,E_t,L_t)}$ on the development set with coreference annotation to select the best model configuration and report the best number. On the test data, we are able to calculate perplexity by marginalizing all other random variables using Equation 11. To compute the perplexity numbers on the test data, our model only takes account of log probabilities on word prediction. The difference is that coreference information is only used for training ENTITYNLM and not for test. All three models reported in Table 1 share the same vocabulary, therefore the numbers on the test data are directly comparable. As shown in Table 1, ENTITYNLM outperforms both the 5-gram language model and the RNNLM on the test data. Better performance of ENTITYNLM on language modeling can be expected, if we also use the marginalization method defined in Equation 11 on the development data to select the best configuration. However, we plan to use the same experimental setup for all experiments, instead of customizing our model for each individual task.

5.2 Coreference reranking

Task description. We show how ENTITYLM, which allows an efficient computation of the probability $P(\mathbf{R}, \mathbf{E}, \mathbf{L}, \mathbf{X})$, can be used as a coreference reranker to improve a competitive coreference resolution system due to Martschat and Strube (2015). This task is analogous to the reranking approach used in machine translation (Shen et al., 2004). The specific formulation is as follows:

$$\arg \max_{\{\mathbf{r}^{(i)},\mathbf{e}^{(i)},\mathbf{l}^{(i)}\}\in\mathcal{K}} P(\mathbf{r}^{(i)}, \mathbf{e}^{(i)}, \mathbf{l}^{(i)}, \mathbf{x}) \qquad (12)$$

where $\mathcal{K}$ is the k-best list for a given document. In our experiments, $k = 100$. To the best of our knowledge, the problem of obtaining k-best outputs of a coreference resolution system has not been studied before.

Approximate k-best decoding. We rerank the output of a system that predicts an antecedent for each mention by relying on pairwise scores for mention pairs. This is the dominant approach for coreference resolution (Martschat and Strube, 2015; Clark and Manning, 2016a). The predictions induce an antecedent tree, which represents antecedent decisions for all mentions in the document. Coreference chains are obtained by transitive closure over the antecedent decisions encoded in the tree. A mention also can have an empty mention as antecedent, which denotes that the mention is non-anaphoric.

For extending Martschat and Strube's greedy decoding approach to k-best inference, we cannot simply take the k highest scoring trees according to the sum of edge scores, because different trees may represent the same coreference chain. Instead, we use an heuristic that creates an approximate k-best list on candidate antecedent trees. The idea is to generate trees from the original system output by considering suboptimal antecedent choices that lead to different coreference chains. For each mention pair (m_j, m_i), we compute the difference of its score to the score of the optimal antecedent choice for m_j. We then sort pairs in ascending order according to this difference and iterate through the list of pairs. For each pair (m_j, m_i), we create a tree $t_{j,i}$ by replacing the antecedent of m_j in the original system output with m_i. If this yields a tree that encodes different coreference chains from all chains encoded by trees in the k-best list, we add $t_{i,j}$ to the k-best list. In the case that we cannot generate a given number of trees (particularly for a short document with a large k), we pad the list with the last item added to the list.

Evaluation measures. For coreference resolution evaluation, we employ the CoNLL scorer (Pradhan et al., 2014). It computes three commonly used evaluation measures MUC (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998), and CEAF$_e$ (Luo, 2005). We report the F_1 score of each evaluation measure and their average as the CoNLL score.

Competing systems. We employed CORT[1] (Martschat and Strube, 2015) as our baseline coreference resolution system. Here, we compare with the original (one best) outputs of CORT's latent ranking model, which is the best-performing model implemented in CORT. We consider two rerankers based on ENTITYNLM. The first reranking method only uses the log probability for ENTITYNLM to sort the candidate list (Equation 12). The second method uses a linear combination of both log probabilities from ENTITYNLM and the scores from CORT, where the coefficients were found via grid search with the CoNLL score on the development set.

Results. The reranked results on the CoNLL 2012 test set are reported in Table 2. The numbers of the baseline are higher than the results reported in Martschat and Strube (2015) since the feature set of CORT was subsequently extended. Lines 2 and 3 in Table 2 present the reranked best results. As shown in this table, both reranked results give more than 1% of CoNLL score improvement on the test set over CORT, which are significant based on an approximate randomization test[2].

Additional experiments also found that increasing k from 100 to 500 had a minor effect. That is because the diversity of each k-best list is limited by (i) the number of entity mentions in the document, (ii) the performance of the baseline coreference resolution system, and possibly (iii) the approximate nature of our k-best inference procedure. We suspect that a stronger baseline system (such as that of Clark and Manning, 2016a) could give greater improvements, if it can be adapted to provide k-best lists. Future work might incorporate the techniques embedded in such systems into ENTITYNLM.

[*I*]$_1$ was about to ride [*my*]$_1$ [*bicycle*]$_2$ to the [*park*]$_3$ one day when [*I*]$_1$ noticed that the front [*tire*]$_4$ was flat . [*I*]$_1$ realized that [*I*]$_1$ would have to repair [*it*]$_4$. [*I*]$_1$ went into [*my*]$_1$ [*garage*]$_5$ to get some [*tools*]$_5$. The first thing [*I*]$_1$ did was remove the xxxx

Figure 3: A short story on bicycles from the InScript corpus (Modi et al., 2017). The entity prediction task requires predicting xxxx given the preceding text either by choosing a previously mentioned entity or deciding that this is a "new entity". In this example, the ground-truth prediction is [*tire*]$_4$. For training, ENTITYNLM attempts to predict every entity. While, for testing, it predicts a maximum of 30 entities after the first three sentences, which is consistent with the experimental setup suggested by Modi et al. (2017).

5.3 Entity prediction

Task description. Based on Modi et al. (2017), we introduce a novel entity prediction task that tries to predict the next entity given the preceding text. For a given text as in Figure 3, this task makes a forward prediction based on only the left context. This is different from coreference resolution, where both left and right contexts from a given entity mention are used in decoding. It is also different from language modeling, since this task only requires predicting entities. Since ENTITYNLM is generative, it can be directly applied to this task. To predict entities in test data, R_t is always given and ENTITYNLM only needs to predict E_t when $R_t = 1$.

Baselines and human prediction. We introduce two baselines in this task: (i) the **always-new** baseline that always predicts "new entity"; (ii) a linear classification model using **shallow features** from Modi et al. (2017), including the recency of an entity's last mention and the frequency. We also compare with the model proposed by Modi et al. (2017). Their work assumes that the model has prior knowledge of all the participant types, which are specific to each scenario and fine-grained, e.g., rider in the bicycle narrative, and predicts participant types for new entities. This assumption is unrealistic for pure generative models like ours.

[1] https://github.com/smartschat/cort, we used version 0.2.4.5.

[2] https://github.com/smartschat/art

Model	CoNLL	MUC			B^3			CEAF$_e$		
		P	R	F_1	P	R	F_1	P	R	F_1
1. Baseline: CORT's one best	62.93	77.15	68.67	72.66	66.00	54.92	59.95	60.07	52.76	56.18
2. Rerank: EntityNLM	**64.00**	77.90	69.45	73.44	66.84	56.12	61.01	61.73	53.90	57.55
3. Rerank: EntityNLM + CORT	**64.04**	77.93	69.49	73.47	67.08	55.99	61.04	61.76	53.98	57.61

Table 2: Coreference resolution scores on the CoNLL 2012 test set. CORT is the best-performing model of Martschat and Strube (2015) with greedy decoding.

	Accuracy (%)
1. Baseline: always-new	31.08
2. Baseline: shallow features	45.34
3. Modi et al. (2017)	62.65
4. EntityNLM	**74.23**
5. *Human prediction*	77.35

Table 3: Entity prediction accuracy on the test set of the InScript corpus.

Therefore, we remove this assumption and adapt their prediction results to our formulation by mapping all the predicted entities that have not been mentioned to "new entity". We also compare to the adapted **human prediction** used in the InScript corpus. For each entity slot, Modi et al. (2017) acquired 20 human predictions, and the majority vote was selected. More details about human predictions are discussed in (Modi et al., 2017).

Results. Table 3 shows the prediction accuracies. EntityNLM (line 4) significantly outperforms both baselines (line 1 and 2) and prior work (line 3) ($p \ll 0.01$, paired t-test). The comparison between line 4 and 5 shows our model is even close to the human prediction performance.

6 Related Work

Rich-context language models. The originally proposed recurrent neural network language models only capture information within sentences. To extend the capacity of RNNLMs, various researchers have incorporated information beyond sentence boundaries. Previous work focuses on contextual information from previous sentences (Ji et al., 2016a) or discourse relations between adjacent sentences (Ji et al., 2016b), showing improvements to language modeling and related tasks like coherence evaluation and discourse relation prediction. In this work, EntityNLM adds explicit entity information to the language model, which is another way of adding a memory network for language modeling. Unlike the work by Tran et al. (2016), where memory blocks are used to store general contextual information for language modeling, EntityNLM assigns each memory block specifically to only one entity.

Entity-related models. Two recent approaches to modeling entities in text are closely related to our model. The first is the "reference-aware" language models proposed by Yang et al. (2016), where the referred entities are from either a predefined item list, an external database, or the context from the same document. Yang et al. (2016) present three models, one for each case. For modeling a document with entities, they use coreference links to recover entity clusters, though they only model entity mentions as containing a single word (an inappropriate assumption, in our view). Their entity updating method takes the latest hidden state (similar to $\mathbf{h}_t$ when $R_t = 1$ in our model) as the new representation of the current entity; no long-term history of the entity is maintained, just the current local context. In addition, their language model evaluation assumes that entity information is provided at test time (Yang, personal communication), which makes a direct comparison with our model impossible. Our entity updating scheme is similar to the "dynamic memory" method used by Henaff et al. (2016). Our entity representations are dynamically allocated and updated only when an entity appears up, while the EntNet from Henaff et al. (2016) does not model entities and their relationships explicitly. In their model, entity memory blocks are pre-allocated and updated simultaneously in each timestep. So there is no dedicated memory block for every entity and no distinction between entity mentions and non-mention words. As a consequence, it is not clear how to use their model for coreference reranking and entity prediction.

Coreference resolution. The hierarchical structure of our entity generation model is inspired by

Haghighi and Klein (2010). They implemented this idea as a probabillistic graphical model with the distance-dependent Chinese Restaurant Process (Pitman, 1995) for entity assignment, while our model is built on a recurrent neural network architecture. The reranking method considered in our coreference resolution evaluation could also be extended with samples from additional coreference resolution systems, to produce more variety (Ng, 2005). The benefit of such a system comes, we believe, from the explicit tracking of each entity throughout the text, providing entity-specific representations. In previous work, such information has been added as features (Luo et al., 2004; Björkelund and Kuhn, 2014) or by computing distributed entity representations (Wiseman et al., 2016; Clark and Manning, 2016b). Our approach complements these previous methods.

Entity prediction. The entity prediction task discussed in §5.3 is based on work by Modi et al. (2017). The main difference is that we do not assume that all entities belong to a previously known set of entity types specified for each narrative scenario. This task is also closely related to the "narrative cloze" task of Chambers and Jurafsky (2008) and the "story cloze test" of Mostafazadeh et al. (2016). Those studies aim to understand relationships between events, while our task focuses on predicting upcoming entity mentions.

7 Conclusion

We have presented a neural language model, EntityNLM, that defines a distribution over texts and the mentioned entities. It provides vector representations for the entities and updates them dynamically in context. The dynamic representations are further used to help generate specific entity mentions and the following text. This model outperforms strong baselines and prior work on three tasks: language modeling, coreference resolution, and entity prediction.

fabio.tamburini@unibo.it

Abstract

This paper presents a new approach for building Language Models using the Quantum Probability Theory, a Quantum Language Model (QLM). It mainly shows that relying on this probability calculus it is possible to build stochastic models able to benefit from quantum correlations due to interference and entanglement. We extensively tested our approach showing its superior performances, both in terms of model perplexity and inserting it into an automatic speech recognition evaluation setting, when compared with state-of-the-art language modelling techniques.

1 Introduction

Quantum Mechanics Theory (QMT) is one of the most successful theories in modern science. Despite its effectiveness in the physics realm, the attempts to apply it in other domains remain quite limited, excluding, of course, the large quantity of studies regarding Quantum Information Processing on quantum computers.

Only in recent years some scholars tried to embody principles derived from QMT into their specific fields, for example, by the Information Retrieval community (Zuccon et al., 2009; Melucci and van Rijsbergen, 2011; González and Caicedo, 2011; Melucci, 2015) and in the domain of cognitive sciences and decision making (Khrennikov, 2010; Busemeyer and Bruza, 2012; Aerts et al., 2013). In the machine learning field (Arjovsky et al., 2016; Wisdom et al., 2016; Jing et al., 2017) have used unitary evolution matrices for building deep neural networks obtaining interesting results, but we have to observe that their works do not adhere to QMT and use unitary evolution operators in a way not allowed by QMT. In recent years, also the Natural Language Processing (NLP) community started to look at QMT with interest and some studies using it have already been presented (Blacoe et al., 2013; Liu et al., 2013; Tamburini, 2014; Kartsaklis et al., 2016).

Language models (LM) are basic tools in NLP used in various applications, such as Automatic Speech Recognition (ASR), machine translation, part-of-speech tagging, etc., and were traditionally modeled by using N-grams and various smoothing techniques. Among the dozen of tools for computing N-gram LM, we will refer to CMU-SLM (with Good-Turing smoothing) (Clarkson and Rosenfeld, 1997) and IRSTLM (with Linear Witten-Bell smoothing) (Federico et al., 2008); the latter is the tool used in Kaldi (Povey et al., 2011b), one of the most powerful and used open-source ASR package that we will use for some of the experiments presented in the following sections.

In recent years new techniques from the Neural Networks (NN) domain have been introduced in order to enhance the performances of such models. Elman recurrent NN, as used in the RNNLM tool (Mikolov et al., 2010, 2011), or Long Short-Term Memory NN, as in the tool LSTMLM (Soutner and Müller, 2015), produce state-of-the-art performances for current language models.

This paper presents a different approach for building LM based on quantum probability theory. Actually, we present a QLM applicable only to problems defined on a small set of different tokens. This is a "proof-of-concept" study and our main aim is to show the potentialities of such approach rather than building a complete application for solving this problem for any setting.

The paper is organized as follows: we provide background on Quantum Probability Theory in Section 2 followed by the description of our proposed Quantum Language Model in Section 3. We then discuss some numerical issues mainly related

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1840–1849
Copenhagen, Denmark, September 7–11, 2017.

to the optimisation procedure in Section 4, and in Section 5 we present the experiments we did to validate our approach. In Section 6 we discuss our results and draw some provisional conclusions.

2 Quantum Probability Theory

In QMT the state of a system is usually described, in the most general case, by using density matrices over an Hilbert space $\mathcal{H}$. More specifically, a *density matrix* ρ is a positive semidefinite Hermitian matrix of unit trace, namely $\rho^\dagger = \rho, \quad \mathrm{Tr}(\rho) = 1$, and it is able to encode all the information about the state of a quantum system[1].

The measurable quantities, or *observables*, of the quantum system are associated to Hermitian matrices O defined on $\mathcal{H}$. The axioms of QMT specify how one can make predictions about the outcome of a measurement using a density matrix:

- the possible outcomes of a projective measurement of an observable O are its eigenvalues $\{\lambda_j\}$;
- the *probability* that the outcome of the measurement is λ_j is $P(\lambda_j) = \mathrm{Tr}(\rho\Pi_{\lambda_j}) = \mathrm{Tr}(\Pi_{\lambda_j}\rho)$, where Π_{λ_j} is the projector on the eigenspace of O associated to λ_j. Note that in the following we will use some properties of these kind of measurements, namely $\Pi^\dagger_{\lambda_j} = \Pi_{\lambda_j}$ and $\Pi^2_{\lambda_j} = \Pi_{\lambda_j}$;
- after the measurement the system state *collapses* in the following fashion: if the outcome of the measurement was λ_j, the collapse is
$$\rho' = \frac{\Pi_{\lambda_j}\rho\Pi_{\lambda_j}}{\mathrm{Tr}(\Pi_{\lambda_j}\rho\Pi_{\lambda_j})}$$
where the denominator is needed for trace normalization;
- time evolution of states using a fixed time step is described by a *unitary matrix* U over $\mathcal{H}$, i.e. $U^\dagger U = \mathbf{I}$, where $\mathbf{I}$ is the identity matrix. Given a state ρ_t, at a specific time t, the system evolution without measurements modifies the state as:
$$\rho_{t+1} = U\rho_t U^\dagger.$$

See for example (Nielsen and Chuang, 2010) or (Vedral, 2007) for a complete introduction on QPT.

3 Quantum Language Models

In this section we describe our approach to build QLM that can compute probabilities for the occurrence of a sequence $\mathbf{w} = (w_1, w_2, ..., w_n)$ of length n, composed using N different symbols, the vocabulary containing all the words in the model, i.e. for every symbol w in the sequence $w \in \{0, ..., N-1\}$. We define a set of orthogonal N-dimensional vectors $\{\mathbf{e}_w : w \in \{0, ..., N-1\}\}$, spanning the complex space $\mathcal{H} = \mathbb{C}^N$; to measure the probability of a symbol w, collapsing the state over the space spanned by $\mathbf{e}_w$, we use the projector $\Pi_w = \mathbf{e}_w\mathbf{e}_w^\dagger$. Note that all the words in the vocabulary have been encoded as numbers corresponding to the N dimensions of the vector space $\mathcal{H}$.

Our method is sequential, from QMT point of view, in the sense that we use a quantum system that produces a single symbol upon measurement.

The basic idea is that the probabilistic information for a given sequence $\mathbf{w} = (w_1, w_2, ..., w_n)$ is encoded in the density matrix that results from the following process:

- **Inititalisation**

  Cond.Prob.: $P(w_1; \rho_0, U) = \mathrm{Tr}(\rho_0\Pi_{w_1})$

  Projection: $\rho'_1 = \frac{\Pi_{w_1}\rho_0\Pi_{w_1}}{\mathrm{Tr}(\Pi_{w_1}\rho_0\Pi_{w_1})}$

  Evolution: $\rho_1 = U\rho'_1 U^\dagger$
- **Recurrence** $(i = 2, .., n)$

  Cond.Prob.: $P(w_i|w_1, ..., w_{i-1}; \rho_0, U) = \mathrm{Tr}(\rho_{i-1}\Pi_{w_i})$

  Projection: $\rho'_i = \frac{\Pi_{w_i}\rho_{i-1}\Pi_{w_i}}{\mathrm{Tr}(\Pi_{w_i}\rho_{i-1}\Pi_{w_i})}$

  Evolution: $\rho_i = U\rho'_i U^\dagger$
- **Termination**
$$P(\mathbf{w}|\rho_0, U) = P(w_1; \rho_0, U) \cdot \prod_{i=2}^{n} P(w_i|w_1, ..., w_{i-1}; \rho_0, U)$$

The total probability $P(\mathbf{w}|\rho_0, U)$ for the given sequence is thus obtained, in the termination step, by multiplying the conditional probability $P(w_i|w_1, ..., w_{i-1}; \rho_0, U)$ for each word in the sequence.

We then use the initial density matrix ρ_0 and the time evolution unitary matrix U as parameters to optimise the *perplexity* Γ, evaluated on a training

[1] $\dagger$ marks the conjugate transpose of a vector/matrix and $\mathrm{Tr}(\cdot)$ is the trace of a matrix.

corpus of sequences S,

$$\Gamma(\rho_0, U) = \exp\Big(-\frac{1}{C} \sum_{\mathbf{w} \in S} \log P(\mathbf{w}|\rho_0, U) \Big)$$

which quantifies the uncertainty of the model. C is the number of tokens in the corpus.

Minimising Γ is equivalent of learning a model by fixing all the model parameters, a typical procedure in the machine learning domain.

3.1 Ancillary system

The problem with this setup is that the 'quantum effects' are completely washed out by the measurements on the system by using projectors. The resulting expression for the probability $P(\mathbf{w}|\rho_0, U)$ for a sequence $\mathbf{w}$ is identical to that obtained using a classical Markov model.

To solve this issue, our approach is to *avoid the complete collapse* of the state after each symbol measurement using a common technique in QMT: we introduce an *ancillary system* described by a fictitious D-dimensional Hilbert space, $\mathcal{H}_{ancilla} = \mathbb{C}^D$, and we couple the original system to the ancillary system. The resulting DN-dimensional Hilbert space is

$$\mathcal{H}_2 \equiv \mathcal{H}_{ancilla} \otimes \mathcal{H} = \mathbb{C}^{DN}$$

where $\otimes$ denotes the Kronecker product for matrices and D can be seen as a free hyper-parameter of the model. On this new space the projectors are now given by $\Pi_w^{(2)} = \mathbf{I}_D \otimes \Pi_w$, where $\mathbf{I}_D$ is the D-dimensional identity matrix.

The advantage of using this method is that the time evolution for the coupled system creates non-trivial correlations between the two entangled systems such that measuring and collapsing the symbol state keeps some information about the whole sequence stored in the ancillary part of the state. This information is then reshuffled into the symbol state via time evolution, resulting in a 'memory effect' that takes the whole sequence of symbols into account, thereby extending the idea behind the N-grams approach. Larger D values will results in more memory of this system and, of course, in a larger number of parameters to learn.

3.2 System evolution

We need to specify the system evolution for our coupled system. The simplest approach is to use a unitary $DN \times DN$ matrix U that acts on the entangled Hilbert space as shown before; it can be specified by $(DN)^2$ real parameters with a suitable parametrization (Spengler et al., 2010) that ensures the unitarity of U. However, in our preliminary experiments this approach resulted in an insufficient 'memory' capability for the QLM and in a very complex and slow minimisation procedure.

A different approach could be introduced by using a specific unitary matrix for each word, but this would lead to an enormous amount of parameters to learn with the optimization procedure.

There are a lot of techniques in NLP to represent single words with dense vectors (see for example (Mikolov et al., 2013) for the so called *word embeddings*). Following this idea, we can represent every symbol in our system with a specific p-dimensional vector trained using one of the available techniques $w \mapsto (\alpha_1(w), ..., \alpha_p(w))$ or fixed randomly.

We then work with a set of p $DN \times DN$ unitary matrices $\mathbf{U} = (U_1, ..., U_p)$, one for each component of the word vector, that are used to dynamically build a different system evolution matrix for each word in this way:

$$V(w) \equiv \prod_{i=1}^{p} U_i^{\alpha_i(w)}$$

This results in $p(DN)^2$ complex or $2p(DN)^2$ real parameters to be learned.

Essentially, we treat the words in our problem in different ways: the evolution operator for each word $V(w)$ is build by using a combination of the operators $\mathbf{U}$ defined for each word-vector component, while, considering the system projection, we treat each word as one basis vector for the space $\mathcal{H}$.

Note that the choice to use a set $\{V(w)\}$ of operators, one for each word w, does not violate the linearity of quantum mechanics: let K be the quantum operation

$$K(\rho) = \sum_{w} V(w) \Pi_w^{(2)} \rho \, \Pi_w^{(2)} V^\dagger(w)$$

defined using projectors and evolution matrices. Then K is a valid (i.e. a Completely Positive Trace-preserving) evolution map that exactly reproduces our results in the sequence of evolutions and collapses.

The number of evolutionary operators is a trade-off: as we said before, defining only one operator U resulted in a poor performance of the proposed method in all the relevant experiments, while defining an operator for each word would produce too many parameters to be learned. The trade-off that we chose is to use one operator for each word-vector component, and build the set $\{V(w)\}$ from them as described above while preserving unitarity.

With regard to the initial density matrix ρ_0, we have to define it combining the initial density matrix of our system, ρ_0^s, and the initial density matrix of the ancilla, ρ_0^a. We defined ρ_0^s as a diagonal $N \times N$ matrix containing the classical Maximum Likelihood probability Estimation to have a specific symbol at the first sequence position:

$$\rho_0^s = \frac{1}{|S|} \sum_{\mathbf{w} \in S} \Pi_{w_1}$$

where S is again the set of all sequences in the training set and w_1 is the first word in each sequence $\mathbf{w}$. With regard to the ancilla system we do not know anything about it and thus we have to define ρ_0^a as the $D \times D$ diagonal matrix

$$\rho_0^a = \frac{\mathbf{I}_D}{\mathrm{Tr}(\mathbf{I}_D)} \,.$$

Consequently we can define ρ_0 as

$$\rho_0 = \rho_0^a \otimes \rho_0^s \,.$$

3.3 The final model

Putting all the ingredients together, we can finally write down the formula for the probability $P(\mathbf{w}|\rho_0, \mathbf{U})$ for a sequence $\mathbf{w}$ in the QLM specified by ρ_0 and $\mathbf{U}$. The product of conditional probabilities simplifies because of the normalising denominators added at each collapse and time evolution step. The result is:

$$\begin{aligned} P(\mathbf{w}|\rho_0, \mathbf{U}) = \mathrm{Tr}(&\Pi_{w_n}^{(2)} ... V^\dagger(w_2) \Pi_{w_2}^{(2)} V^\dagger(w_1) \\ &\Pi_{w_1}^{(2)} \rho \Pi_{w_1}^{(2)} V(w_1) \Pi_{w_2}^{(2)} V(w_2) ... \Pi_{w_n}^{(2)}) \end{aligned} \tag{1}$$

Using the fact that projectors have many zero entries one can also re-express this trace of the product of $DN \times DN$ matrices in terms of the trace of the product of $D \times D$ matrices. The formula for $P(\mathbf{w}|\rho_0, \mathbf{U})$ then simplifies to our final result

$$P(\mathbf{w}|\rho_0, \mathbf{U}) = \mathrm{Tr}(T^\dagger R T) \tag{2}$$

where the matrices R and T are defined as follows:

- in terms of entries $R_{i,j}$ with indices $i, j = 0, ..., D-1$, the matrix R is given by

  $$R_{i,j} = [\rho_0]_{Ni+w_1, Nj+w_1} \,.$$

  Note that only the value of first symbol in the sequence, w_1, enters in the expression. This is to be expected since R derives from the initial density matrix ρ_0;

- analogously, the matrix T that encodes the chain of combined collapses and time evolutions is given by the product $T = T^{(2)} T^{(3)} ... T^{(n)}$, where the matrices $T^{(k)}$ are given in entries, with indices $i, j = 0, ..., D-1$, by

  $$T_{i,j}^{(k)} = [V(w_{k-1})]_{Ni+w_{k-1}, Nj+w_k} \,.$$

  These matrices can be pre-calculated for every pair of the involved symbols, so that the calculation of $P(\mathbf{w}|\rho_0, \mathbf{U})$ for all the sequences will be very fast.

The detailed calculation for obtaining the equation (2) can be found in the supplementary material.

4 Optimisation and Numerical Issues

In order to optimise the parameters $\mathbf{U}$ we numerically minimise the perplexity Γ computed on a given training corpus of sequences S. This requires that the matrices $\mathbf{U}$ remain strictly unitary at every step of the minimisation procedure and it can be accomplished in various ways.

The most straightforward way is to employ an explicit parametrization for unitary matrices, as was done in (Spengler et al., 2010). Due to the transcendental functions employed in this parametrisation, this approach resulted in a functional form for Γ that has proven to be very challenging to minimise efficiently in our experiments.

A more elegant and efficient approach is to consider the entries of $\mathbf{U}$ as parameters (thereby ensuring a polynomial functional form for Γ) and to employ techniques of differential geometry to keep the parameters from leaving the unitary subspace at each minimisation step. This can be done using a modification of the approach outlined in (Tagare, 2011) that considers the unitary matrices subspace as a manifold, the *Stiefel manifold* $\mathrm{U}(DN)$. It is then possible to project the gradient ∇f of a generic function $f(M)$ of the matrix variable M on the tangent space of the Stiefel manifold and build a line search algorithm that sweeps out curves on this manifold so that at each point the parameters are guaranteed to form a unitary matrix.

In our case we have multiple unitary matrices $\mathbf{U} = (U_1, ..., U_p)$. This simply results having curves defined on $\mathrm{U}(DN)^p$, parametrised by a p-dimensional vector of $DN \times DN$ unitary matrices.

4.1 Formula for the gradient

To implement the curvilinear search method described in (Tagare, 2011) one needs an expression for the gradient $\mathbf{G} = (G_1, ..., G_p)$ of the probability function. This gradient is organised in a p-dimensional vector of $DN \times DN$ matrices, such that the component G_j is obtained by computing the matrix derivative of $P(\mathbf{w}|\rho_0, \mathbf{U})$ with respect to U_j either analytically or by applying some numerical estimate of the gradients, for example by using finite differences. The latter method, when working with thousands or millions of variables can be very time consuming and, usually, an explicit analytic formula for the gradient accelerates considerably all the required processing.

A lengthy analytic computation results in an explicit result. Firstly, we introduce the following objects:

- The *spectral decomposition* of U_j, given by $U_j = S_j D_j S_j^\dagger$, guaranteed to exist by the spectral theorem. S_j is unitary and the diagonal matrix D_j contains the eigenvalues $(u_{j1}, ..., u_{jDN})$ of U_j, $j = 1, ..., p$.

- The $DN \times DN$ matrices $C_j(\alpha)$ defined, in entries, by

$$[C_j(\alpha)]_{ab} = \frac{\overline{u_{ja}}^\alpha - \overline{u_{jb}}^\alpha}{\overline{u_{ja}} - \overline{u_{jb}}} \quad \text{if} \quad u_{ja} \neq u_{jb}$$

$$[C_j(\alpha)]_{ab} = \alpha \overline{u_{ja}}^{\alpha-1} \quad \text{if} \quad u_{ja} = u_{jb}$$

  where $\overline{u}$ is the complex conjugate of u.

- The $D \times DN$ matrices Q_k given in entries by

$$(Q_k)_{jA} = \delta_{Nj+w_k,A}$$

  where $j = 0, ..., D-1, \quad A = 0, ..., DN-1$.

- The *lesser* and *greater products* associated to the construction of system evolution matrices

$$V^{<j}(w) = \prod_{i=1}^{j-1} U_i^{\alpha_i(w)}$$

$$V^{>j}(w) = \prod_{i=j+1}^{n} U_i^{\alpha_i(w)}.$$

With these ingredients, the resulting formula for the components G_j of the gradient is

$$G_j = 2S_j \sum_{k=2}^{n} \Big\{ \Big[S_j^\dagger \Big(V^{<j}(w_{k-1})^\dagger Q_{k-1}^T \Big(\prod_{l=2}^{k-1} T^{(l)} \Big)^\dagger RT \Big(\prod_{l=k+1}^{n} T^{(l)} \Big)^\dagger Q_k V^{>j}(w_{k-1})^\dagger \Big) S_j \Big] \cdot C_j(\alpha_j(w_{k-1})) \Big\} S_j^\dagger \tag{3}$$

where $\cdot$ denotes the element-wise matrix product. Again, all the detailed calculations for obtaining the analytic expression (3) for the gradient G_j can be found in the supplementary material.

Using Tagare's method we can project the gradient onto the Stiefel manifold and build a curvilinear search algorithm for the minimisation.

To achieve this aim, Tagare proposed an Armijo-Wolfe line search inserted into a simple gradient descent procedure. We developed an extension of this algorithm combining the minimization over the Steifel manifold technique with a Moré-Thuente (1994) line search and a Conjugate Gradient minimisation algorithm that uses the Polak-Ribière method for the combination of gradients and search directions (Nocedal and Wright, 2006). All the experiments presented in the next section were performed using these methods.

The minimisation uses random mini-batches that increase their size during the training: they start with approximately one tenth of the training set dimension and increase to include all the instances using a parametrised logistic function. As stopping criterion we used the minimum of the perplexity function over the validation set as suggested in (Bengio, 2012; Prechelt, 2012) for other machine learning techniques.

5 Experiments and Results

5.1 Data

The TIMIT corpus is a read speech corpus designed to provide speech data for acoustic-phonetic studies and for the development and evaluation of automatic speech recognition systems (Garofolo et al., 1990). It contains broadband recordings of 630 speakers of eight major dialects of American English and includes time-aligned orthographic, phonetic and word transcriptions as well as a 16-bit, 16 kHz speech waveform file for each utterance.

In the speech community, the TIMIT corpus is the base for a standard phone-recognition task with specific evaluation procedures described in detail in (Lopes and Perdigao, 2011). We stick completely to this evaluation to test the effectiveness of our proposed model adopting, among the other procedures, the same splitting between the different data sets: the training set contains 3696 utterances (140225 phones), the validation set 400 utterances (15057 phones) and the test set 192 utterances (7215 phones).

5.2 Evaluation Results

We tested the proposed model by setting up two different evaluations: the first is an intrinsic evaluation of LM performances in terms of global perplexity on the TIMIT testset; the second is an extrinsic evaluation in which we replace the LM tools provided with the Kaldi ASR toolkit (Povey et al., 2011b) with our model in order to check the final system performances in a phone-recognition task and comparing them with the other state-of-the-art LM techniques briefly introduced in Section 1.

5.2.1 Intrinsic evaluation

The first experiment consisted in an evaluation of models perplexity (PPL) on the TIMIT testset. We compared the QLM model with two N-gram implementations, namely CMU-SLM (Clarkson and Rosenfeld, 1997) and IRSTLM (Federico et al., 2008), and two recurrent NN models able to produce state-of-the-art results in language modelling, the RNNLM (Mikolov et al., 2010, 2011) and the LSTMLM (Soutner and Müller, 2015) packages.

Table 1 shows the results of the intrinsic evaluation. With regard to RNNLM and LSTMLM results, only the best hyper-parameters combination after a lot of experiments, optimizing them on the validation set, has been inserted into the Table.

With regard to QLM, all the presented experiments are based on artificial word vectors produced randomly using values from the set $\{-1, 0, 1\}$ instead of real word embeddings. Every word vector is different from the others and we decided not to use real embeddings in order to test the core QMT method without adding the contextual information, contained in word embeddings, that could have helped our approach to obtain better performances, at least in principle.

Model	Parameters	PPL
CMU-SLM	2-gram	15.49
(Good-Turing	3-gram	14.28
smoothing)	4-gram	15.62
	5-gram	17.33
IRSTLM	2-gram	15.47

	N=48, p=4, D=20	**13.15**
	N=48, p=4, D=30	**13.10**
	N=48, p=4, D=40	**12.99**

Table 1: Perplexity (PPL) of the tested language-modelling techniques on the TIMIT testset. All the QLM results in bold face are better than the other systems we tested.

5.2.2 Extrinsic evaluation

The "TIMIT recipe" contained in the Kaldi distribution[2] reproduces exactly the same evaluation settings described in (Lopes and Perdigao, 2011) for a phone recognition task based on this corpus. Moreover, Kaldi provides some n-best rescoring scripts that apply RNNLM hypothesis rescoring and interpolate the results with the standard N-gram model results used in the evaluation. We slightly modified these scripts to work with LSTMLM and QLM in order to test different models using the same setting. This allowed us to replace the LM used in Kaldi and experiment with all the systems evaluated in the previous section.

Table 2 outlines the results we obtained replacing the LM technique into Kaldi ASR package w.r.t. the different ASR systems that the TIMIT recipe implements. These systems are built on top of MFCC, LDA, MLLT, fMLLR with CMN[3] features (see (Povey et al., 2011b; Rath et al., 2013) for all acronyms references and a complete feature

[2] https://github.com/kaldi-asr/kaldi

[3] MFCC: Mel-Frequency Cepstral Coefficients; LDA: Linear Discriminant Analysis; MLTT: Maximum Likelihood Linear Transform; fMLLR: feature space Maximum Likelihood Linear Regression; SAT: Speaker Adapted Training, i.e. train on fMLLR-adapted features; CMN: Cepstral Mean Normalization.

or recipe descriptions).

For this extrinsic evaluation we used the best models we obtained in the previous experiments interpolating their log-probability results for each utterance with the original bigram (or trigram) log-probability using a linear model with a ratio 0.25/0.75 between the original N-gram LM and the tested one as suggested in the standard Kaldi rescoring script. For this test we rescored the 10,000-best hypothesis.

We have to say that in this experiment we were not trying to build the best possible phone recogniser, but simply to compare the relative performances of the analysed LM techniques showing the effectiveness of QLM when used in a real application. Thus absolute Phone Error Rate is not so important here and it can be certainly possible to devise recognisers with better performances by applying more sophisticated techniques. For example (Peddinti et al., 2015) presented a method for lattice rescoring in Kaldi that exhibits better performances than the n-best rescoring we used to interpolate between n-grams and the tested models, but modifying it in order to test LSTMLM and QLM presented a lot of problems and thus we decided to use the simpler n-best approach. For completeness, the last column of Table 2 outlines the results obtained using this lattice rescoring method with RNNLM as described in (Peddinti et al., 2015).

6 Discussion and conclusions

We presented a new technique for building LM based on QMT, and its probability calculus, testing it extensively both with intrinsic and extrinsic evaluation methods.

The PPL results for the intrinsic evaluation, outlined in Table 1, show a clear superiority of the proposed method when compared with state-of-the-art techniques such as RNNLM and LSTMLM. It is interesting to note that even using $D = 20$, that means a system containing a quarter of parameters, therefore much less 'memory', w.r.t. the system with $D = 40$, we obtain a PPL performance better than the other methods.

With regard to the second experiment we made, an extrinsic evaluation where we replaced the LM of an ASR system with the LM produced by all the tested methods (see Table 2), QLM consistently exhibits the best performances for all the tested ASR systems from the Kaldi "TIMIT recipe". Despite using a n-best technique in this evaluation for hypothesis rescoring, that is known to perform worse than the lattice rescoring method proposed in (Peddinti et al., 2015), the QLM performances are even better than this method.

The approach we have presented in this paper is not without problems: the number of different word types in the considered language has to be small in order to keep the model computationally tractable. Even if the code we used in the evaluations is analytically highly optimised, the training of this model is rather slow and requires relevant computational resources even for small problems. On the contrary, inference is very quick, faster than the RNNLM and LSTMLM packages we tested.

The main research question that drove this work was to verify if the distinguishing properties of quantum probability theory, namely interference and system entaglement that could allow the ancilla to have a "potentially infinite" memory, were enough to build stochastic systems more powerful than those built using classical probabilities or those built using recurrent NN. Our main aim was not to build a complete model to handle all possible LM scenarios, but to present a "proof-of-concept" study to test the potentialities of this approach. For this reason we tried to keep the model as simple as possible using orthogonal projectors: for measuring probabilities, projecting the system state, each word is mapped onto a single basis vector and the dimension of the system Hilbert space, N, is equal to the number of different words. Given the matrix dimensions that we have to manage when we add the ancilla, $DN \times DN$, this setting does not scale to real LM problems (e.g. the Brown corpus), even though the calculations are performed using $D \times D$ submatrices, but allowed us to successfully verify the research question. For the same reason out-of-vocabulary words cannot be handled in this model because there are no basis vectors assigned to them.

In order to overcome these limitations, this work can be extended by using generalized quantum measurements projectors (POVM) and by using a different structure for the system Hilbert space: instead of mapping each word onto a single basis vector we can span this space using as basis the same p-basis vectors used to define the V matrices. In this way we will project the system state on a generic word vector built as a superposi-

tion on the p-basis. Such improvement would reduce dramatically the dimensions of the matrices to $Dp \times Dp$ potentially mitigating the computational issue. Moreover, this would solve also the problem of out-of-vocabulary words allowing for a proper management of the large set of different words typical of real applications.

We are still working on these improvements and we will hope to get a complete model soon.

With this contribution we would like to raise also some interest in the community to analyse and develop more effective techniques, both on the modelling and minimisation/learning sides, to allow to build real world application based on this framework. QMT and its probability calculus seem to be promising methodologies to enhance the performances of our systems in NLP and certainly deserve further investigations.

Abstract

We propose a general class of language models that treat reference as discrete stochastic latent variables. This decision allows for the creation of entity mentions by accessing external databases of referents (required by, e.g., dialogue generation) or past internal state (required to explicitly model coreferentiality). Beyond simple copying, our coreference model can additionally refer to a referent using varied mention forms (e.g., a reference to "Jane" can be realized as "she"), a characteristic feature of reference in natural languages. Experiments on three representative applications show our model variants outperform models based on deterministic attention and standard language modeling baselines.

1 Introduction

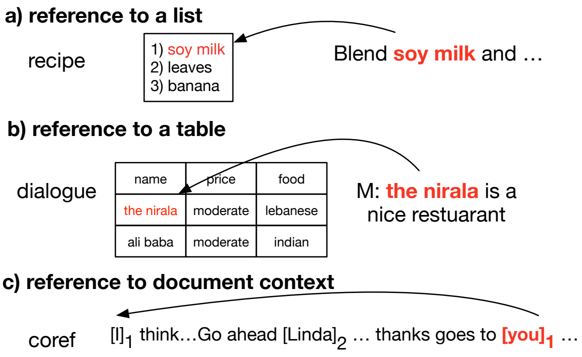

Figure 1: Reference-aware language models.

Referring expressions (REs) in natural language are noun phrases (proper nouns, common nouns, and pronouns) that identify objects, entities, and events in an environment. REs occur frequently and they play a key role in communicating information efficiently. While REs are common in natural language, most previous work does not model them explicitly, either treating REs as ordinary words in the model or replacing them with special tokens that are filled in with a post processing step (Wen et al., 2015; Luong et al., 2015). Here we propose a language modeling framework that explicitly incorporates reference decisions. In part, this is based on the principle of pointer networks in which copies are made from another source (Gülçehre et al., 2016; Gu et al., 2016; Ling et al., 2016; Vinyals et al., 2015; Ahn et al., 2016; Merity et al., 2016). However, in the full version of our model, we go beyond simple copying and enable coreferent mentions to have different forms, a key characteristic of natural language reference.

Figure 1 depicts examples of REs in the context of the three tasks that we consider in this work. First, many models need to refer to a list of items (Kiddon et al., 2016; Wen et al., 2015). In the task of recipe generation from a list of ingredients (Kiddon et al., 2016), the generation of the recipe will frequently refer to these items. As shown in Figure 1, in the recipe "Blend `soy milk` and ...", `soy milk` refers to the ingredient summaries. Second, reference to a database is crucial in many applications. One example is in task oriented dialogue where access to a database is necessary to answer a user's query (Young et al., 2013; Li et al., 2016; Vinyals and Le, 2015; Wen et al., 2015; Sordoni et al., 2015; Serban et al., 2016; Bordes and Weston, 2016; Williams and Zweig, 2016; Shang et al., 2015; Wen et al., 2016). Here we consider the domain of restaurant recommendation where a system refers to restaurants (name) and their attributes (address, phone number etc) in its responses. When the system

Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

says “`the nirala` is a nice restaurant”, it refers to the restaurant name `the nirala` from the database. Finally, we address references within a document (Mikolov et al., 2010; Ji et al., 2015; Wang and Cho, 2015), as the generation of words will often refer to previously generated words. For instance the same entity will often be referred to throughout a document. In Figure 1, the entity `you` refers to `I` in a previous utterance. In this case, copying is insufficient– although the referent is the same, the form of the mention is different.

In this work we develop a language model that has a specific module for generating REs. A series of decisions (should I generate a RE? If yes, which entity in the context should I refer to? How should the RE be rendered?) augment a traditional recurrent neural network language model and the two components are combined as a mixture model. Selecting an entity in context is similar to familiar models of attention (Bahdanau et al., 2014), but rather than being a soft decision that reweights representations of elements in the context, it is treated as a hard decision over contextual elements which are stochastically selected and then copied or, if the task warrants it, transformed (e.g., a pronoun rather than a proper name is produced as output). In cases when the stochastic decision is not available in training, we treat it as a latent variable and marginalize it out. For each of the three tasks, we pick one representative application and demonstrate our reference aware model's efficacy in evaluations against models that do not explicitly include a reference operation.

Our contributions are as follows:

- We propose a general framework to model reference in language. We consider reference to entries in lists, tables, and document context. We instantiate these tasks into three specific applications: recipe generation, dialogue modeling, and coreference based language models.
- We develop the first neural model of reference that goes being copying and can model (conditional on context) how to form the mention.
- We perform comprehensive evaluation of our models on the three data sets and verify our proposed models perform better than strong baselines.

2 Reference-aware language models

Here we propose a general framework for reference-aware language models.

We denote each document as a series of tokens $x_1, \ldots, x_L$, where L is the number of tokens. Our goal is to maximize $p(x_i \mid c_i)$, the probability of each word x_i given its previous context $c_i = x_1, \ldots, x_{i-1}$. In contrast to traditional neural language models, we introduce a variable z_i at each position, which controls the decision on which source x_i is generated from. Then the conditional probability is given by:

$$p(x_i, z_i \mid c_i) = p(x_i \mid z_i, c_i)p(z_i \mid c_i), \quad (1)$$

where z_i has different meanings in different contexts. If x_i is from a reference list or a database, then z_i is one dimensional and $z_i = 1$ denotes x_i is generated as a reference. z_i can also model more complex decisions. In coreference based language model, z_i denotes a series of sequential decisions, such as whether x_i is an entity, if yes, which entity x_i refers to. When z_i is not observed, we will train our model to maximize the marginal probability over z_i, i.e., $p(x_i|c_i) = \sum_{z_i} p(x_i|z_i, c_i)p(z_i|c_i)$.

2.1 Reference to lists

We begin to instantiate the framework by considering reference to a list of items. Referring to a list of items has broad applications, such as generating documents based on summaries etc. Here we specifically consider the application of recipe generation conditioning on the ingredient lists. Table. 1 illustrates the ingredient list and recipe for *Spinach and Banana Power Smoothie*. We can see that the ingredients `soy milk, spinach leaves, and banana` occur in the recipe.

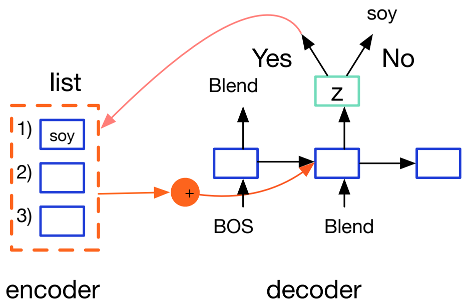

Figure 2: Recipe pointer

Let the ingredients of a recipe be $X = \{x_i\}_{i=1}^{T}$ and each ingredient contains L tokens $x_i =$

Ingredients	Recipe
1 cup plain `soy milk` 3/4 cup packed fresh `spinach leaves` 1 large `banana`, sliced	Blend `soy milk` and `spinach leaves` together in a blender until smooth. Add `banana` and pulse until thoroughly blended.

Table 1: Ingredients and recipe for *Spinach and Banana Power Smoothie*.

$\{x_{ij}\}_{j=1}^{L}$. The corresponding recipe is $y = \{y_v\}_{v=1}^{K}$. We would like to model $p(y|X) = \Pi_v p(y_v|X, y_{<v})$.

We first use a LSTM (Hochreiter and Schmidhuber, 1997) to encode each ingredient: $h_{i,j} = \text{LSTM}_\text{E}(W_E x_{ij}, h_{i,j-1}) \quad \forall i$. Then, we sum the resulting final state of each ingredient to obtain the starting LSTM state of the decoder. We use an attention based decoder:

$$\begin{aligned} s_v &= \text{LSTM}_\text{D}([W_\text{E} y_{v-1}, d_{v-1}], s_{v-1}), \\ p_v^{\text{copy}} &= \text{ATTN}(\{\{h_{i,j}\}_{i=1}^{T}\}_{j=1}^{L}, s_v), \\ d_v &= \sum_{ij} p_{v,i,j} h_{i,j}, \\ p(z_v|s_v) &= \text{sigmoid}(W[s_v, d_v]), \\ p_v^{\text{vocab}} &= \text{softmax}(W[s_v, d_v]), \end{aligned}$$

where $\text{ATTN}(h, q)$ is the attention function that returns the probability distribution over the set of vectors h, conditioned on any input representation q. A full description of this operation is described in (Bahdanau et al., 2014). The decision to copy from the ingredient list or generate a new word from the softmax is performed using a switch, denoted as $p(z_v|s_v)$. We can obtain a probability distribution of copying each of the words in the ingredients by computing $p_v^{\text{copy}} = \text{ATTN}(\{\{h_{i,j}\}_{i=1}^{T}\}_{j=1}^{L}, s_v)$ in the attention mechanism.

Objective: We can obtain the value of z_v through a string match of tokens in recipes with tokens in ingredients. If a token appears in the ingredients, we set $z_v = 1$ and $z_v = 0$ otherwise. We can train the model in a fully supervised fashion, i.e., we can obtain the probability of y_v as $p(y_v, z_v|s_v) = p_v^{\text{copy}}(y_v)p(1|s_v)$ if $z_v = 1$ and $p_v^{\text{vocab}}(y_v)(1 - p(1|s_{i,v}))$ otherwise.

However, it may be not be accurate. In many cases, the tokens that appear in the ingredients do not specifically refer to ingredients tokens. For examples, the recipe may start with “Prepare a cup of water”. The token “cup” does not refer to the “cup” in the ingredient list “1 cup plain soy milk”. To solve this problem, we treat z_i as a latent variable, we wish to maximize the marginal probability of y_v over all possible values of z_v. In this way, the model can automatically learn when to refer to tokens in the ingredients. Thus, the probability of generating token y_v is defined as:

$$\begin{aligned} p(y_v|s_v) &= p_v^{\text{vocab}}(y_v)p(0|s_v) + p_v^{\text{copy}}(y_v)p(1|s_v) \\ &= p_v^{\text{vocab}}(y_v)(1 - p(1|s_v)) + p_v^{\text{copy}}(y_v)p(1|s_v). \end{aligned}$$

If no string match is found for y_v, we simply set $p_v^{\text{copy}}(y_v) = 0$ in the above objective.

2.2 Reference to databases

We then consider the more complicated task of reference to database entries. Referring to databases is quite common in question answering and dialogue systems, in which databases are external knowledge and they are resorted to reply users’ query. In our paper, we consider the application of task-oriented dialogue systems in the domain of restaurant recommendations. Different from lists that are one dimensional, databases are two-dimensional and referring to table entries requires sophisticated model design.

To better understand the model, we first make a brief introduction of the data set. We use dialogues from the second Dialogue State Tracking Challenge (DSTC2) (Henderson et al., 2014). Table. 3 is one example dialogue from this dataset.

We can observe from this example, users get recommendations of restaurants based on queries that specify the area, price and food type of the restaurant. We can support the system’s decisions by incorporating a mechanism that allows the model to query the database to find restaurants that satisfy the users’ queries. A sample of our database (refer to data preparation part on how we construct the database) is shown in Table 2. We can observe that each restaurant contains 6 attributes that are generally referred in the dialogue dataset. As such, if the user requests a restaurant that serves “indian” food, we wish to train a model that can search for entries whose “food”

NAME	PRICE RANGE	FOOD	AREA	ADDRESS	POST CODE	PHONE
ali baba	moderate	lebanese	centre	59 Hills Road City Centre	CB 2, 1 NT	01462 432565
the nirala	moderate	indian	north	7 Milton Road Chesterton	CB 4, 1 UY	01223 360966

Table 2: Fragment of database for dialogue system.

M:	Hello, welcome to the Cambridge restaurant system? You can ask for restaurants by `area`, `price range` or `food type` . How may I help you?
U:	i want a `moderately priced` restaurant in the `north` town
M:	`the nirala` is a nice restaurant in the north of town in the moderate price range
U:	what is the `address`
M:	Sure , `the nirala` is on `7 Milton Road Chesterton`

Table 3: Example dialogue, M stands for Machine and U stands for User

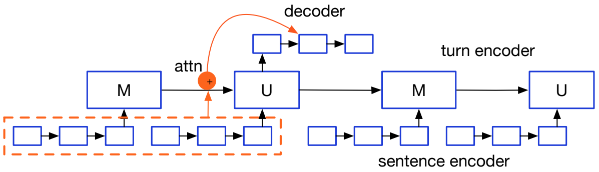

Figure 3: Hierarchical RNN Seq2Seq model. The red box denotes attention mechanism over the utterances in the previous turn.

column contains "indian". Now, we describe how we deploy a model that fulfills these requirements. We first introduce the basic dialogue framework in which we incorporates the table reference module.

Basic Dialogue Framework: We build a basic dialogue model based on the hierarchical RNN model described in (Serban et al., 2016), as in dialogues, the generation of the response is not only dependent on the previous sentence, but on all sentences leading to the response. We assume that a dialogue is alternated between a machine and a user. An illustration of the model is shown in Figure 3.

Consider a dialogue with T turns, the utterances from a user and a machines are denoted as $X = \{x_i\}_{i=1}^{T}$ and $Y = \{y_i\}_{i=1}^{T}$ respectively, where i is the i-th utterance. We define $x_i = \{x_{ij}\}_{j=1}^{|x_i|}$, $y_i = \{y_{iv}\}_{v=1}^{|y_i|}$, where x_{ij} (y_{iv}) denotes the j-th (v-th) token in the i-th utterance from the user (the machines). The dialogue sequence starts with a machine utterance and is given by $\{y_1, x_1, y_2, x_2, \ldots, y_T, x_T\}$. We would like to model the utterances from the machine

$$p(y_1, y_2, \ldots, y_T | x_1, x_2, \ldots, x_T) =$$
$$\prod_i p(y_i | y_{<i}, x_{<i}) = \prod_{i,v} p(y_{i,v} | y_{i,<v}, y_{<i}, x_{<i}).$$

We encode $y_{<i}$ and $x_{<i}$ into continuous space in a hierarchical way with LSTM: **Sentence Encoder**: For a given utterance x_i, We encode it as $h^x_{i,j} = \text{LSTM}_\text{E}(W_E x_{i,j}, h^x_{i,j-1})$. The representation of x_i is given by the $h^x_i = h^x_{i,|x_i|}$. The same process is applied to obtain the machine utterance representation $h^y_i = h^y_{i,|y_i|}$. **Turn Encoder**: We further encode the sequence $\{h^y_1, h^x_1, ..., h^y_i, h^x_i\}$ with another LSTM encoder. We shall refer the last hidden state as u_i, which can be seen as the hierarchical encoding of the previous i utterances. **Decoder**: We use u_{i-1} as the initial state of decoder LSTM and decode each token in y_i. We can express the decoder as:

$$s^y_{i,v} = \text{LSTM}_\text{D}(W_E y_{i,v-1}, s_{i,v-1}),$$
$$p^y_{i,v} = \text{softmax}(W s^y_{i,v}).$$

We can also incoroprate the attetionn mechanism in the decoder. As shown in Figure. 3, we use the attention mechanism over the utterance in the previous turn. Due to space limit, we don't present the attention based decoder mathmatically and readers can refer to (Bahdanau et al., 2014) for details.

2.2.1 Incorporating Table Reference

We now extend the decoder in order to allow the model to condition the generation on a database.

Pointer Switch: We use $z_{i,v} \in \{0, 1\}$ to denote the decision of whether to copy one cell from the table. We compute this probability as follows:

$$p(z_{i,v} | s_{i,v}) = \text{sigmoid}(W s_{i,v}).$$

Thus, if $z_{i,v} = 1$, the next token $y_{i,v}$ is generated from the database, whereas if $z_{i,v} = 0$, then the following token is generated from a softmax. We now describe how we generate tokens from the database.

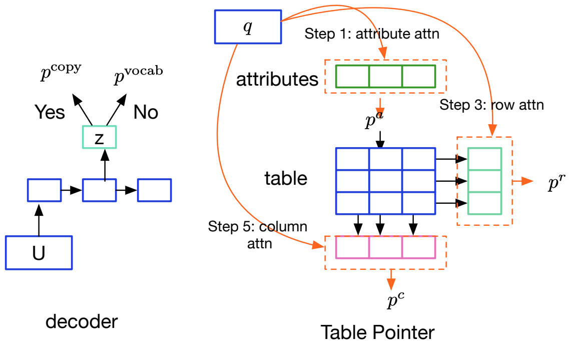

Figure 4: Decoder with table pointer.

We denote a table with R rows and C columns as $\{t_{r,c}\}, r \in [1, R], c \in [1, C]$, where $t_{r,c}$ is the cell in row r and column c. The attribute of each column is denoted as s_c, where c is the c-th attribute. $t_{r,c}$ and s_c are one-hot vector.

Table Encoding: To encode the table, we first build an attribute vector and then an encoding vector for each cell. The attribute vector is simply an embedding lookup $g_c = W_E s_c$. For the encoding of each cell, we first concatenate embedding lookup of the cell with the corresponding attribute vector g_c and then feed it through a one-layer MLP as follows: then $e_{r,c} = \tanh(W[W_E t_{r,c}, g_c])$.

Table Pointer: The detailed process of calculating the probability distribution over the table is shown in Figure 4. The attention over cells in the table is conditioned on a given vector q, similarly to the attention model for sequences. However, rather than a sequence of vectors, we now operate over a table.

Step 1: Attention over the attributes to find out the attributes that a user asks about, $p^a = \text{ATTN}(\{g_c\}, q)$. Suppose a user says `cheap`, then we should focus on the `price` attribute.

Step 2: Conditional row representation calculation, $e_r = \sum_c p^a_c e_{r,c} \quad \forall r$. So that e_r contains the price information of the restaurant in row r.

Step 3: Attention over e_r to find out the restaurants that satisfy users' query, $p^r = \text{ATTN}(\{e_r\}, q)$. Restaurants with `cheap` price will be picked.

Step 4: Using the probabilities p^r, we compute the weighted average over the all rows $e_c = \sum_r p^r_r e_{r,c}$. $\{e_r\}$ contains the information of `cheap` restaurant.

Step 5: Attention over columns $\{e_r\}$ to compute the probabilities of copying each column $p^c = \text{ATTN}(\{e_c\}, q)$.

Step 6: To get the probability matrix of copying each cell, we simply compute the outer product $p^{\text{copy}} = p^r \otimes p^c$.
The overall process is as follows:

$$\begin{aligned}
p^a &= \text{ATTN}(\{g_c\}, q), \\
e_r &= \sum_c p^a_c e_{r,c} \quad \forall r, \\
p^r &= \text{ATTN}(\{e_r\}, q), \\
e_c &= \sum_r p^r_r e_{r,c} \quad \forall c, \\
p^c &= \text{ATTN}(\{e_c\}, q), \\
p^{\text{copy}} &= p^r \otimes p^c.
\end{aligned}$$

If $z_{i,v} = 1$, we embed the above attention process in the decoder by replacing the conditioned state q with the current decoder state $s^y_{i,v}$.
Objective: As in previous task, we can train the model in a fully supervised fashion, or we can treat the decision as a latent variable. We can get $p(y_{i,v}|s_{i,v})$ in a similar way.

2.3 Reference to document context

Finally, we address the references that happen in a document itself and build a language model that uses coreference links to point to previous entities. Before generating a word, we first make the decision on whether it is an entity mention. If so, we decide which entity this mention belongs to, then we generate the word based on that entity. Denote the document as $X = \{x_i\}_{i=1}^L$, and the entities are $E = \{e_i\}_{i=1}^N$, each entity has M_i mentions, $e_i = \{m_{ij}\}_{j=1}^{M_i}$, such that $\{x_{m_{ij}}\}_{j=1}^{M_i}$ refer to the same entity. We use a LSTM to model the document, the hidden state of each token is $h_i = \text{LSTM}(W_E x_i, h_{i-1})$. We use a set $h^e = \{h^e_0, h^e_1, ..., h^e_M\}$ to keep track of the entity states, where h^e_j is the state of entity j.
Word generation: At each time step before generating the next word, we predict whether the word is an entity mention:

$$\begin{aligned}
p^{\text{coref}}(v_i|h_{i-1}, h^e) &= \text{ATTN}(h^e, h_{i-1}), \\
d_i &= \sum_{v_i} p(v_i) h^e_{v_i}, \\
p(z_i|h_{i-1}) &= \text{sigmoid}(W[h_{i-1}, d_i]),
\end{aligned}$$

where z_i denotes whether the next word is an entity and if yes v_i denotes which entity the next word corefers to. If the next word is an entity mention, then $p(x_i|v_i, h_{i-1}, h^e) =$

um and [I]$_1$ think that is whats - Go ahead [Linda]$_2$. Well and thanks goes to [you]$_1$ and to [the media]$_3$ to help [us]$_4$...So [our]$_4$ hat is off to all of [you]$_5$...

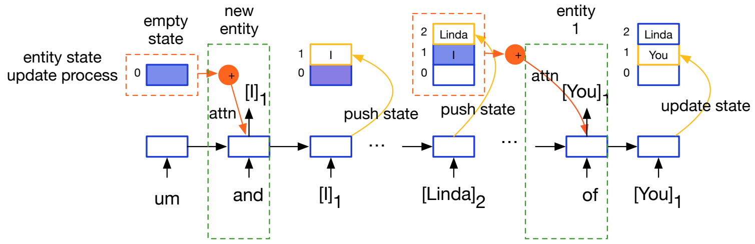

Figure 5: Coreference based language model, example taken from Wiseman et al. (2016).

softmax$(W_1 \tanh(W_2[h_{i-1}, h^e_{v_i}]))$ else $p(x_i|h_{i-1}) = \text{softmax}(W_1 h_{i-1})$. Hence,

$$p(x_i|x_{<i}) = \begin{cases} p(x_i|h_{i-1})p(z_i|h_{i-1}, h^e) & \text{if } z_i = 0. \\ p(x_i|v_i, h_{i-1}, h^e)\times & \\ \quad p^{\text{coref}}(v_i|h_{i-1}, h^e)p(z_i|h_{i-1}, h^e) & \text{if } z_i = 1. \end{cases}$$

Entity state update: Since there are multiple mentions for each entity and the mentions appear dynamically, we need to keep track of the entity state in order to use coreference information in entity mention prediction. We update the entity state h^e at each time step. In the beginning, $h^e = \{h^e_0\}$, h^e_0 denotes the state of an virtual empty entity and is a learnable variable. If $z_i = 1$ and $v_i = 0$, then it indicates the next word is a new entity mention, then in the next step, we append h_i to h^e, i.e., $h^e = \{h^e, h_i\}$, if $z_i = 1$ and $v_i > 0$, then we update the corresponding entity state with the new hidden state, $h^e[v_i] = h_i$. Another way to update the entity state is to use one LSTM to encode the mention states and get the new entity state. Here we use the latest entity mention state as the new entity state for simplicity. The detailed update process is shown in Figure 5.

Note that the stochastic decisions in this task are more complicated than previous two tasks. We need to make two sequential decisions: whether the next word is an entity mention, and if yes, which entity the mention corefers to. It is intractable to marginalize these decisions, so we train this model in a supervised fashion (refer to data preparation part on how we get coreference annotations).

3 Experiments

3.1 Data sets and preprocessing

Recipes: We crawled all recipes from `www.allrecipes.com`. There are about 31,000 recipes in total, and every recipe has an ingredient list and a corresponding recipe. We exclude the recipes that have less than 10 tokens or more than 500 tokens, those recipes take about 0.1% of all data set. On average each recipe has 118 tokens and 9 ingredients. We random shuffle the whole data set and take 80% as training and 10% for validation and test. We use a vocabulary size of 10,000 in the model.

Dialogue: We use the DSTC2 data set. We only use the dialogue transcripts from the data set. There are about 3,200 dialogues in total. The table is not available from DSTC2. To reconstruct the table, we crawled TripAdvisor for restaurants in the Cambridge area, where the dialog dataset was collected. Then, we remove restaurants that do not appear in the data set and create a database with 109 restaurants and their attributes (e.g. food type). Since this is a small data set, we use 5-fold cross validation and report the average result over the 5 partitions. There may be multiple tokens in each table cell, for example in Table. 2, the name, address, post code and phone number have multiple tokens, we replace them with one special token. For the name, address, post code and phone number of the j-th row, we replace the tokens in each cell with _NAME_j, _ADDR_j, _POSTCODE_j, _PHONE_j. If a table cell is empty, we replace it with an empty token _EMPTY. We do a string match in the transcript and replace the corresponding tokens in transcripts from the table with the special tokens. Each dialogue on average has 8 turns (16 sentences). We use a vocabulary size of 900, including about 400 table tokens and 500 words.

Coref LM: We use the Xinhua News data set from Gigaword Fifth Edition and sample 100,000 documents that has length in range from 100 to 500. Each document has on average 234 tokens, so there are 23 million tokens in total. We process the documents to get coreference annotations and use the annotations, i.e., z_i, v_i, in training. We take 80% as training and 10% as validation and test respectively. We ignore the entities that have only one mention and for the mentions that have multiple tokens, we take the token that is most frequent in the all the mentions for this entity. After preprocessing, tokens that are entity mentions take about 10% of all tokens. We use a vocabulary size of 50,000 in the model.

3.2 Baselines, model training and evaluation

We compare our model with baselines that do not model reference explicitly. For recipe generation and dialogue modeling, we compare our model with basic seq2seq and attention model. We also apply attention mechanism over the table for dialogue modeling as a baseline. For coreference based language model, we compare our model with simple RNN language model.

We train all models with simple stochastic gradient descent with gradient clipping. We use a one-layer LSTM for all RNN components. Hyperparameters are selected using grid search based on the validation set.

Evaluation of our model is challenging since it involves three rather different applications. We focus on evaluating the accuracy of predicting the reference tokens, which is the goal of our model. Specifically, we report the perplexity of all words, words that can be generated from reference and non-reference words. The perplexity is calculated by multiplying the probability of decision at each step all together. Note that for non-reference words, they also appear in the vocabulary. So it is a fair comparison to models that do not model reference explicitly. For the recipe task, we also generate the recipes using beam size of 10 and evaluate the generated recipes with BLEU. We didn't use BLEU for dialogue generation since the database entries take only a very small part of all tokens in utterances.

3.3 Results and analysis

The results for recipe generation, dialogue and coref based language model are shown in Table 4, 5, and 6 respectively. The recipe results in Table 4 verifies that modeling reference explicitly improves performance. Latent and Pointer perform better than Seq2Seq and Attn model. The Latent model performs better than the Pointer model since tokens in ingredients that match with recipes do not necessarily come from the ingredients. Imposing a supervised signal gives wrong information to the model and hence makes the result worse. With latent decision, the model learns to when to copy and when to generate it from the vocabulary.

The findings for dialogue basically follow that of recipe generation, as shown in Table 5. Conditioning table performs better in predicting table tokens in general. Table Pointer has the lowest perplexity for tokens in the table. Since the table tokens appear rarely in the dialogue transcripts, the overall perplexity does not differ much and the non-table token perplexity are similar. With attention mechanism over the table, the perplexity of table token improves over basic Seq2Seq model, but still not as good as directly pointing to cells in the table, which shows the advantage of modeling reference explicitly. As expected, using sentence attention improves significantly over models without sentence attention. Surprisingly, Table Latent performs much worse than Table Pointer. We also measure the perplexity of table tokens that appear only in test set. For models other than Table Pointer, because the tokens never appear in the training set, the perplexity is quite high, while Table Pointer can predict these tokens much more accurately. This verifies our conjecture that our model can learn reasoning over databases.

The coref based LM results are shown in Table 6. We find that coref based LM performs much better on the entity perplexity, but is a little bit worse for non-entity words. We found it was an optimization problem and the model was stuck in a local optimum. So we initialize the Pointer model with the weights learned from LM, the Pointer model performs better than LM both for entity perplexity and non-entity words perplexity.

In Appendix A, we also visualize the heat map of table reference and list items reference. The visualization shows that our model can correctly predict when to refer to which entries according to context.

4 Related Work

In terms of methodology, our work is closely related to previous works that incorporate copying mechanism with neural models (Gülçehre et al., 2016; Gu et al., 2016; Ling et al., 2016; Vinyals et al., 2015). Our models are similar to models proposed in (Ahn et al., 2016; Merity et al., 2016),

Model	val				test			
	PPL			BLEU	PPL			BLEU
	All	Ing	Word		All	Ing	Word	
Seq2Seq	5.60	11.26	**5.00**	14.07	5.52	11.26	**4.91**	14.39
Attn	5.25	6.86	5.03	14.84	5.19	6.92	4.95	15.15
Pointer	5.15	5.86	5.04	**15.06**	5.11	6.04	4.98	15.29
Latent	**5.02**	**5.10**	5.01	14.87	**4.97**	**5.19**	4.94	**15.41**

Table 4: Recipe results, evaluated in perplexity and BLEU score. All means all tokens, Ing denotes tokens from recipes that appear in ingredients. Word means non-table tokens. Pointer and Latent differs in that for Pointer, we provide supervised signal on when to generate a reference token, while in Latent it is a latent decision.

Model	All	Table	Table OOV	Word

Table 6: Coreference based LM. Pointer + init means we initialize the model with the LM weights.

where the generation of each word can be conditioned on a particular entry in knowledge lists and previous words. In our work, we describe a model with broader applications, allowing us to condition, on databases, lists and dynamic lists.

In terms of applications, our work is related to chit-chat dialogue (Li et al., 2016; Vinyals and Le, 2015; Sordoni et al., 2015; Serban et al., 2016; Shang et al., 2015) and task oriented dialogue (Wen et al., 2015; Bordes and Weston, 2016; Williams and Zweig, 2016; Wen et al., 2016). Most of previous works on task oriented dialogues embed the seq2seq model in traditional dialogue systems, in which the table query part is not differentiable, while our model queries the database directly. Recipe generation was proposed in (Kiddon et al., 2016). They use attention mechanism over the checklists, whereas our work models explicit references to them. Context dependent language models (Mikolov et al., 2010; Jozefowicz et al., 2016; Mikolov et al., 2010; Ji et al., 2015; Wang and Cho, 2015) are proposed to capture long term dependency of text. There are also lots of works on coreference resolution (Haghighi and Klein, 2010; Wiseman et al., 2016). We are the first to combine coreference with language modeling, to the best of our knowledge.

5 Conclusion

We introduce reference-aware language models which explicitly model the decision of from where to generate the token at each step. Our model can also learns the decision by treating it as a latent variable. We demonstrate on three applications, table based dialogue modeling, recipe generation and coref based LM, that our model performs better than attention based model, which does not incorporate this decision explicitly. There are several directions to explore further based on our framework. The current evaluation method is based on perplexity and BLEU. In task oriented dialogues, we can also try human evaluation to see if the model can reply users' query accurately. It is also interesting to use reinforcement learning to learn the actions in each step in coref based LM.

Abstract

In this study, we introduce a new approach for learning language models by training them to estimate word-context pointwise mutual information (PMI), and then deriving the desired conditional probabilities from PMI at test time. Specifically, we show that with minor modifications to *word2vec*'s algorithm, we get principled language models that are closely related to the well-established Noise Contrastive Estimation (NCE) based language models. A compelling aspect of our approach is that our models are trained with the same simple negative sampling objective function that is commonly used in *word2vec* to learn word embeddings.

1 Introduction

Language models (LMs) learn to estimate the probability of a word given a context of preceding words. Recurrent Neural Network (RNN) language models recently outperformed traditional n-gram LMs across a range of tasks (Jozefowicz et al., 2016). However, an important practical issue associated with such neural-network LMs is the high computational cost incurred. The key factor that limits the scalability of traditional neural LMs is the computation of the normalization term in the softmax output layer, whose cost is linearly proportional to the size of the word vocabulary.

Several methods have been proposed to cope with this scaling issue by replacing the softmax with a more computationally efficient component at train time.[1] These include importance sampling (Bengio and et al, 2003), hierarchical softmax (Minh and Hinton, 2008), BlackOut (Ji et al., 2016) and Noise Contrastive Estimation (NCE) (Gutmann and Hyvarinen, 2012). NCE has been applied to train neural LMs with large vocabularies (Mnih and Teh, 2012) and more recently was also successfully used to train LSTM-RNN LMs (Vaswani et al., 2013; Chen et al., 2015; Zoph et al., 2016). NCE-based language models achieved near state-of-the-art performance on language modeling tasks (Jozefowicz et al., 2016; Chen et al., 2016), and as we later show, are closely related to the method presented in this paper.

Continuous word embeddings were initially introduced as a 'by-product' of learning neural language models (Bengio and et al, 2003). However, they were later adopted in many other NLP tasks, and the most popular recent word embedding learning models are no longer proper language models. In particular, the skip-gram with negative sampling (NEG) embedding algorithm (Mikolov et al., 2013) as implemented in the *word2vec* toolkit, has become one of the most popular such models today. This is largely attributed to its scalability to huge volumes of data, which is critical for learning high-quality embeddings. Recently, Levy and Goldberg (2014) offered a motivation for the NEG objective function, showing that by maximizing this function, the skip-gram algorithm implicitly attempts to factorize a word-context pointwise mutual information (PMI) matrix. Melamud and Goldberger (2017) rederived this result by offering an information-theory interpretation of NEG.

The NEG objective function is considered a simplification of the NCE's objective, unsuitable for learning language models (Dyer, 2014). However, in this study, we show that despite its simplicity, it can be used in a principled way to effectively train a language model, based on PMI matrix factorization. More specifically, we use NEG to train

[1] An alternative recent approach for coping with large word vocabularies is to represent words as compositions of sub-word units, such as individual characters. This approach has notable merits (Jozefowicz et al., 2016; Sennrich et al., 2016), but is out of the scope of this paper.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1860–1865
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

a model for estimating the PMI between words and their preceding contexts, and then derive conditional probabilities from PMI at test time. The obtained *PMI-LM* can be viewed as a simple variant of *word2vec*'s algorithm, where the context of a predicted word is the preceding sequence of words, rather than a single word within a context window (skip-gram), or a bag-of-context-words (CBOW).

Our analysis shows that the proposed PMI-LM is very closely related to NCE language models (*NCE-LMs*). Similar to NCE-LMs, PMI-LM avoids the dependency of train run-time on the size of the word vocabulary by sampling from a negative (noise) distribution. Furthermore, conveniently, it also has a notably more simplified objective function formulation inherited from *word2vec*, which allows it to avoid the heuristic components and initialization procedures used in various implementations of NCE language models (Vaswani et al., 2013; Chen et al., 2015; Zoph et al., 2016).

Finally, we report on a perplexity evaluation of PMI and NCE language models on two standard language modeling datasets. The evaluation yielded comparable results, supporting our theoretical analysis.

2 NCE-based Language Modeling

Noise Contrastive Estimation (NCE) has recently been used to learn language models efficiently. NCE transforms the parameter learning problem into a binary classifier training problem. Let $p(w|c)$ be the probability of a word w given a context c that represents its entire preceding context, and let $p(w)$ be a 'noise' word distribution (e.g. a unigram distribution). The NCE approach assumes that the word w is sampled from a mixture distribution $\frac{1}{k+1}(p(w|c) + kp(w))$ such that the noise samples are k times more frequent than samples from the 'true' distribution $p(w|c)$. Let y be a binary random variable such that $y = 0$ and $y = 1$ correspond to a noise sample and a true sample, respectively, i.e. $p(w|c, y = 0) = p(w)$ and $p(w|c, y = 1) = p(w|c)$. Assume the distribution $p(w|c)$ has the following parametric form:

$$p_{nce}(w|c) = \frac{1}{Z_c} \exp(\vec{w} \cdot \vec{c} + b_w) \qquad (1)$$

such that $\vec{w}$ and $\vec{c}$ are vector representations of the word w and its context c. Applying Bayes rule, it can be easily verified that:

$$p_{nce}(y = 1|w, c) = \qquad (2)$$

$$\sigma(\vec{w} \cdot \vec{c} + b_w - \log Z_c - \log(p(w)k))$$

where $\sigma()$ is the sigmoid function.

NCE uses Eq. (2) and the following objective function to train a binary classifier that decides which distribution was used to sample w:

$$S_{nce} = \sum_{w,c \in D} \left[\log p(1|w, c) + \sum_{i=1}^{k} \log p(0|u_i, c) \right] \qquad (3)$$

such that w, c go over all the word-context co-occurrences in the learning corpus D and $u_1, ..., u_k$ are 'noise' samples drawn from the word unigram distribution.

Note that the normalization factor Z_c is not a free parameter and to obtain its value, one needs to compute $Z_c = \sum_{w \in V} \exp(\vec{w} \cdot \vec{c} + b_w)$ for each context c, where V is the word vocabulary. This computation is typically not feasible due to the large vocabulary size and the exponentially large number of possible contexts and therefore it was heuristically circumvented by prior work. Mnih and Teh (2012) found empirically that setting $Z_c = 1$ didn't hurt the performance (see also discussion in (Andreas and Klein, 2015)). Chen et al. (2015) reported that setting $\log(Z_c) = 9$ gave them the best results. Recent works (Vaswani et al., 2013; Zoph et al., 2016) used $Z_c = 1$ and also initialized NCE's bias term from Eq. (2) to $b_w = -\log |V|$. They reported that without these heuristics the training procedure did not converge to a meaningful model.

In the following section, we describe our proposed language model, which is derived from *word2vec*'s interpretation as a low-rank PMI matrix approximation. Interestingly, this model turns out to be a close variant of NCE language models, but with a simplified objective function that avoids the need for the normalization factor Z_c and the bias terms.

3 PMI-based Language Modeling

The skip-gram negative sampling word embedding algorithm represents each word w and each context word c as d-dimensional vectors, with the purpose that words that are "similar" to each other will have similar vector representations. The algorithm optimizes the following NEG objective function (Mikolov et al., 2013):

$$S_{neg} = \sum_{w,c \in D} \left[\log \sigma(\vec{w} \cdot \vec{c}) + \sum_{i=1}^{k} \log \sigma(-\vec{u}_i \cdot \vec{c}) \right] \tag{4}$$

such that w, c go over all the word-context co-occurrences in the learning corpus D, $u_1, ..., u_k$ are words independently sampled from the word unigram distribution, $\vec{x}$ is the embedding of x and $\sigma()$ is the sigmoid function. The objective function S_{neg} can be viewed as a log-likelihood function of a binary logistic regression classifier that treats a sample from a joint word-context distribution as a positive instance, and two independent samples from the word and context unigram distributions as a negative instance, while k is the proportion between negative and positive instances. Levy and Goldberg (2014) showed that this objective function achieves its maximal value when for every word-context pair w, c:

$$\vec{w} \cdot \vec{c} = \text{pmi}_k(w, c) = \log \frac{p(w|c)}{kp(w)} \tag{5}$$

where $\text{pmi}_k(w, c)$ is the word-context *PMI matrix*. Actually achieving this maximal value is typically infeasible, since the embedding dimensionality is intentionally limited. Therefore, learning word and context embeddings that optimize skip-gram's NEG objective function (4) can be viewed as finding a low-rank approximation of the word-context PMI matrix. An explicit expression of the approximation criterion optimized by the skip-gram algorithm can be found in (Melamud and Goldberger, 2017).

Our study is based on two simple observations regarding this finding of Levy and Goldberg (2014). First, Equation (5) can be reformulated as follows to derive an estimate of the conditional distribution $p(w|c)$:

$$\hat{p}(w|c) \propto \exp(\vec{w} \cdot \vec{c}) p(w) \tag{6}$$

where the constant k is dropped since $p(w|c)$ is a distribution. Second, while the above analysis had been originally applied to the case of word-context joint distributions $p(w, c)$, it is easy to see that the PMI matrix approximation analysis also holds for every Euclidean embedding of a joint distribution $p(x, y)$ of any two given random variables X and Y. In particular, we note that it holds for word-context joint distributions $p(w, c)$, where w is a single word, but c represents its entire preceding context, rather than just a single context word, and $\vec{c}$ is a vector representation of this entire context. Altogether, this allows us to use *word2vec*'s NEG objective function (4) to approximate the language modeling conditional probability $\hat{p}(w|c)$ (6), with c being the entire preceding context of the predicted word w.

We next describe the design details of the proposed PMI-based language modeling. We use a simple lookup table for the word representation $\vec{w}$, and an LSTM recurrent neural network to obtain a low dimensional representation of the entire preceding context $\vec{c}$. These representations are trained to maximize the NEG objective in Eq. (4), where this time w goes over every word token in the corpus, and c is its preceding context. We showed above that optimizing this objective seeks to obtain the best low-dimensional approximation of the PMI matrix associated with the joint distribution of the word and its preceding context (Eq. (5)). Hence, based on Eq. (6), for a reasonable embedding dimensionality and a good model for representing the preceding context, we expect $\hat{p}(w|c)$ to be a good estimate of the language modeling conditional distribution.

At test time, to obtain a proper distribution, we perform a normalization operation as done by all other comparable models. The train and test steps of the proposed language modeling algorithm are shown in algorithm box 1.

Note that while the NCE approach (1) learns to explicitly estimate normalized conditional distributions, our model learns to approximate the PMI matrix. Hence, we have no real motivation to include additional learned normalization parameters, as considered in comparable NCE language models (Mnih and Teh, 2012; Zoph et al., 2016).

The NEG and NCE objective functions share a similar form:

$$S = \sum_{w,c} \left[\log s(w, c) + \sum_{i=1}^{k} \log(1 - s(u_i, c)) \right] \tag{7}$$

with the differences summarized in Table 1. The comparison shows that PMI-LM's NEG objective function is much simpler. Furthermore, due to the component $\log(p(w)k))$ in NCE's objective function, its input to the sigmoid function is sensitive to the variable values in the unigram distribution, and

	Training objective function	Test probability estimate
NCE-LM	$s(w, c) = \sigma(\vec{w} \cdot \vec{c} + b_w - \log Z_c - \log(kp(w)))$	$\hat{p}(w\|c) \propto \exp(\vec{w} \cdot \vec{c} + b_w)$
PMI-LM	$s(w, c) = \sigma(\vec{w} \cdot \vec{c})$	$\hat{p}(w\|c) \propto \exp(\vec{w} \cdot \vec{c})p(w)$

Table 1: Comparison of the training objective functions (see Eq. (7)) and the respective test-time conditional word probability functions for NCE-LM and PMI-LM algorithms.

Algorithm 1 PMI Language Modeling

Training phase:

- Use a simple lookup table for the word representation and an LSTM recurrent neural network to obtain the preceding context representation.

- Train the word and preceding context embeddings to maximize the objective:

$$S_{neg} = \sum_{w,c \in D} \left[\log \sigma(\vec{w} \cdot \vec{c}) + \sum_{i=1}^{k} \log \sigma(-\vec{u}_i \cdot \vec{c}) \right]$$

such that w and c go over every word and it preceding context in the corpus D, and $u_1, ..., u_k$ are words independently sampled from the unigram distribution $p(w)$.

Test phase:

The conditional probability estimate for a word w given a preceding context c is:

$$\hat{p}(w|c) = \frac{\exp(\vec{w} \cdot \vec{c})p(w)}{\sum_{v \in V} \exp(\vec{v} \cdot \vec{c})p(v)}$$

where V is the word vocabulary.

therefore potentially more difficult to concentrate around zero with low variance to facilitate effective back-propagation. This may explain heuristics used by prior work for initializing the values of b_w (Vaswani et al., 2013; Zoph et al., 2016).

4 Experiments

The goal of the evaluation described in this section is to empirically establish PMI-LM as a sound language model. We do so by comparing its performance with the well-established NCE-LM, using the popular perplexity measure on two standard datasets, under the same terms. We describe our hyperparameter choices below and stress that for a fair comparison, we followed prior best practices and avoided hyperparameter optimization in favor of PMI-LM. All of the models described hereafter were implemented using the Chainer toolkit (Tokui et al., 2015).

For our NCE baseline, we used the heuristics that worked well in (Vaswani et al., 2013; Zoph et al., 2016), initializing NCE's bias term from Eq. (2) to $b_w = -\log |V|$, where V is the word vocabulary, and using $Z_c = 1$.

The first dataset we used is a version of the Penn Tree Bank (PTB), commonly used to evaluate language models.[2] It consists of 929K training words, 73K validation words and 82K test words with a 10K word vocabulary. To build and train the compared models in this setting, we followed the work of Zaremba et al. (2014), who achieved excellent results on this dataset. Specifically, we used a 2-layer 300-hidden-units LSTM with a 50% dropout ratio to represent the preceding (left-side) context of a predicted word.[3] We represented end-of-sentence as a special <eos> token and predicted this token like any other word. During training, we performed truncated back-propagation-through-time, unrolling the LSTM for 20 steps at a time without ever resetting the LSTM state. We trained our model for 39 epochs using Stochastic Gradient Descent (SGD) with a learning rate of 1, which is decreased by a factor of 1.2 after every epoch starting after epoch 6. We clipped the norms of the gradient to 5 and used a mini-batch size of 20. We set the negative sampling parameter to $k = 100$ following Zoph et al. (2016), who showed highly competitive performance with NCE LMs trained with this number of samples.

As the second dataset, we used the much larger WMT 1B-word benchmark introduced by Chelba et al. (2013). This dataset comprises about 0.8B training words and has a held-out set partitioned into 50 subsets. The test set is the first subset in the held-out, comprising 159K words, including the <eos> tokens. We used the second subset as the validation set with 165K words. The original vocabulary size of this dataset is 0.8M words after converting all

[2] Available from Tomas Mikolov at: `http://www.fit.vutbr.cz/~imikolov/rnnlm/simple-examples.tgz`

[3] Zaremba et al. (2014) used larger models with more units and also applied dropout to the output of the top LSTM layer, which we did not.

	PMI-LM	NCE-LM
PTB	**98.35**	104.33
WMT	**65.84**	69.28

Table 2: Perplexity results on test sets.

words that occur less than 3 times in the corpus to an <unk> token. However, we followed previous works (Williams et al., 2015; Ji et al., 2016) and trimmed the vocabulary further down to the top 64K most frequent words in order to successfully fit a neural model to this data using reasonably modest compute resources. To build and train our models, we used a similar method to the one used with PTB, with the following differences. We used a single-layer 512-hidden-unit LSTM to represent the preceding context. We followed Jozefowicz et al. (2016), who found a 10% dropout rate to be sufficient for relatively small models fitted to this large training corpus. We trained our model for only one epoch using the Adam optimizer (Kingma and Ba, 2014) with default parameters, which we found to converge more quickly and effectively than SGD. We used a mini-batch size of 1000.

The perplexity results achieved by the compared models appear in Table 2. As can be seen, the performance of our PMI-LM is competitive, slightly outperforming the NCE-LM on both test sets. To put these numbers in a broader context, we note that state-of-the-art results on these datasets are notably better. For example, on the small PTB test set, Zaremba et al. (2014) achieved 78.4 perplexity with a larger LSTM model and using the more costly softmax component. On the larger WMT dataset, Jozefowicz et al. (2016) achieved 46.1 and 43.7 perplexity numbers using NCE and importance sampling respectively, and with much larger LSTM models trained over the full vocabulary, rather than our trimmed one. They also achieved 23.7 with an ensemble method, which is the best result on this dataset to date. Yet, as intended, we argue that our experimental results affirm the claim that PMI-LM is a sound language model on par with NCE-LM.

5 Conclusions

In this work, we have shown that *word2vec*'s negative sampling objective function, popularized in the context of learning word representations, can also be used to effectively learn parametric language models. These language models are closely related to NCE language models, but utilize a simpler, potentially more robust objective function. More generally, our theoretical analysis shows that any *word2vec* model trained with negative sampling can be used in a principled way to estimate the conditional distribution $p(w|c)$, by following our proposed procedure at test time.

Abstract

Syllabification does not seem to improve word-level RNN language modeling quality when compared to character-based segmentation. However, our best syllable-aware language model, achieving performance comparable to the competitive character-aware model, has 18%–33% fewer parameters and is trained 1.2–2.2 times faster.

1 Introduction

Recent advances in neural language modeling (NLM) are connected with character-aware models (Kim et al., 2016; Ling et al., 2015b; Verwimp et al., 2017). This is a promising approach, and we propose the following direction related to it: We would like to make sure that in the pursuit of the most fine-grained representations one has not missed possible intermediate ways of segmentation, e.g., by syllables. Syllables, in our opinion, are better supported as linguistic units of language than single characters. In most languages, words can be naturally split into syllables:

ES: el par-la-men-to a-po-yó la en-mien-da
RU: пар-ла-мент под-дер-жал по-прав-ку
(EN: the parliament supported the amendment)

Based on this observation, we attempted to determine whether syllable-aware NLM has any advantages over character-aware NLM. We experimented with a variety of models but could not find any evidence to support this hypothesis: splitting words into syllables does not seem to improve the language modeling quality when compared to splitting into characters. However, there are some positive findings: while our best syllable-aware language model achieves performance comparable to the competitive character-aware model, it has 18%–33% fewer parameters and is 1.2–2.2 times faster to train.

2 Related Work

Much research has been done on subword-level and subword-aware[1] neural language modeling when subwords are characters (Ling et al., 2015b; Kim et al., 2016; Verwimp et al., 2017) or morphemes (Botha and Blunsom, 2014; Qiu et al., 2014; Cotterell and Schütze, 2015). However, not much work has been done on syllable-level or syllable-aware NLM. Mikolov et al. (2012) show that subword-level language models outperform character-level ones.[2] They keep the most frequent words untouched and split all other words into syllable-like units. Our approach differs mainly in the following aspects: we make predictions at the word level, use a more linguistically sound syllabification algorithm, and consider a variety of more advanced neural architectures.

We have recently come across a concurrent paper (Vania and Lopez, 2017) where the authors systematically compare different subword units (characters, character trigrams, BPE (Sennrich et al., 2016), morphemes) and different representation models (CNN, Bi-LSTM, summation) on languages with various morphological typology. However, they do not consider syllables, and they experiment with relatively small models on small data sets (0.6M–1.4M tokens).

3 Syllable-aware word embeddings

Let $\mathcal{W}$ and $\mathcal{S}$ be finite vocabularies of words and syllables respectively. We assume that both words

[1] *Subword-level* LMs rely on subword-level inputs and make predictions at the level of subwords; *subword-aware* LMs also rely on subword-level inputs but make predictions at the level of words.

[2] Not to be confused with character-aware ones, see the previous footnote.

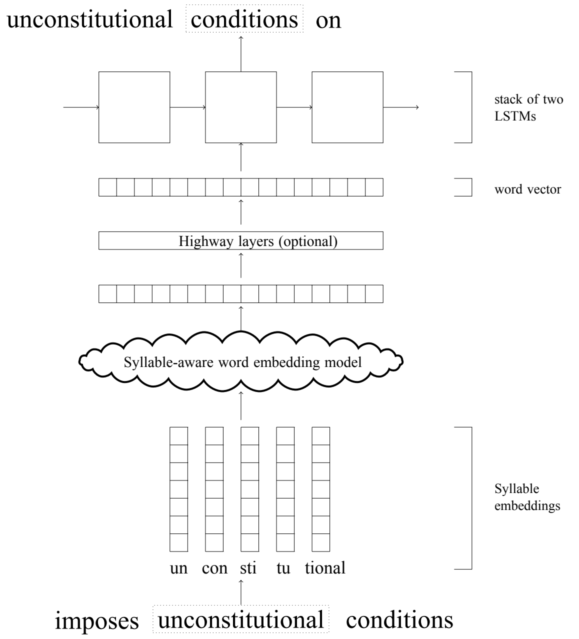

Figure 1: Syllable-aware language model.

and syllables have already been converted into indices. Let $\mathbf{E}_{\mathcal{S}} \in \mathbb{R}^{|\mathcal{S}| \times d_{\mathcal{S}}}$ be an embedding matrix for syllables — i.e., it is a matrix in which the sth row (denoted as $\mathbf{s}$) corresponds to an embedding of the syllable $s \in \mathcal{S}$. Any word $w \in \mathcal{W}$ is a sequence of its syllables $(s_1, s_2, \ldots, s_{n_w})$, and hence can be represented as a sequence of the corresponding syllable vectors:

$$[\mathbf{s_1}, \mathbf{s_2}, \ldots, \mathbf{s_{n_w}}]. \tag{1}$$

The question is: How shall we pack the sequence (1) into a single vector $\mathbf{x} \in \mathbb{R}^{d_W}$ to produce a better embedding of the word w?[3] In our case "better" means "better than a character-aware embedding of w via the Char-CNN model of Kim et al. (2016)". Below we present several viable approaches.

3.1 Recurrent sequential model (Syl-LSTM)

Since the syllables are coming in a sequence it is natural to try a recurrent sequential model:

$$\mathbf{h_t} = f(\mathbf{s_t}, \mathbf{h_{t-1}}), \qquad \mathbf{h_0} = \mathbf{0}, \tag{2}$$

which converts the sequence of syllable vectors (1) into a sequence of state vectors $\mathbf{h_{1:n_w}}$. The last state vector $\mathbf{h_{n_w}}$ is assumed to contain the information on the whole sequence (1), and is therefore used as a word embedding for w. There is a big variety of transformations from which one can choose f in (2); however, a recent thorough evaluation (Jozefowicz et al., 2015) shows that the LSTM (Hochreiter and Schmidhuber, 1997) with its forget bias initialized to 1 outperforms other popular architectures on almost all tasks, and we decided to use it for our experiments. We will refer to this model as *Syl-LSTM*.

3.2 Convolutional model (Syl-CNN)

Inspired by recent work on character-aware neural language models (Kim et al., 2016) we decided to try this approach (Char-CNN) on syllables. Our case differs mainly in the following two aspects:

1. The set of syllables $\mathcal{S}$ is usually bigger than the set of characters $\mathcal{C}$,[4] and also the dimensionality $d_{\mathcal{S}}$ of syllable vectors is expected to be greater than the dimensionality $d_{\mathcal{C}}$ of character vectors. Both of these factors result in allocating more parameters on syllable embeddings compared to character embeddings.
2. On average a word contains fewer syllables than characters, and therefore we need narrower convolutional filters for syllables. This results in spending fewer parameters per convolution.

This means that by varying $d_{\mathcal{S}}$ and the maximum width of convolutional filters L we can still fit the parameter budget of Kim et al. (2016) to allow fair comparison of the models.

Like in Char-CNN, our syllable-aware model, which is referred to as *Syl-CNN-[L]*, utilizes max-pooling and highway layers (Srivastava et al., 2015) to model interactions between the syllables. The dimensionality of a highway layer is denoted by d_{HW}.

3.3 Linear combinations

We also considered using linear combinations of syllable-vectors to represent the word embedding:

$$\mathbf{x} = \textstyle\sum_{t=1}^{n_w} \alpha_t(s_t) \cdot \mathbf{s_t}. \tag{3}$$

The choice for α_t is motivated mainly by the existing approaches (discussed below) which proved to be successful for other tasks.

Syl-Sum: Summing up syllable vectors to get a word vector can be obtained by setting $\alpha_t(s_t) = 1$. This approach was used by Botha and Blunsom (2014) to combine a word and its morpheme embeddings into a single word vector.

[3] The same question applies to any model that segments words into a sequence of characters or other subword units.

[4] In languages with alphabetic writing systems.

Syl-Avg: A simple average of syllable vectors can be obtained by setting $\alpha_t(s_t) = 1/n_w$. This can be also called a "continuous bag of syllables" in an analogy to a CBOW model (Mikolov et al., 2013), where vectors of neighboring words are averaged to get a word embedding of the current word.

Syl-Avg-A: We let the weights α_t in (3) be a function of parameters $(a_1, \dots, a_n)$ of the model, which are jointly trained together with other parameters. Here $n = \max_w\{n_w\}$ is a maximum word length in syllables. In order to have a weighted average in (3) we apply a softmax normalization:

$$\alpha_t = \text{softmax}(\mathbf{a})_t = \frac{\exp(a_t)}{\sum_{\tau=1}^{n}\exp(a_\tau)} \qquad (4)$$

Syl-Avg-B: We can let α_t depend on syllables and their positions:

$$\alpha_t = \alpha_t(s_t) = \text{softmax}(\mathbf{a}_{s_t} + \mathbf{b})_t$$

where $\mathbf{A} \in \mathbb{R}^{d_S \times n}$ (with elements $a_{s,t}$) is a set of parameters that determine the importance of each syllable type in each (relative) position, $\mathbf{b} \in \mathbb{R}^n$ is a bias, which is conditioned only on the relative position. This approach is motivated by recent work on using an attention mechanism in the CBOW model (Ling et al., 2015a).

We feed the resulting $\mathbf{x}$ from (3) into a stack of highway layers to allow interactions between the syllables.

3.4 Concatenation (Syl-Concat)

In this model we simply concatenate syllable vectors (1) into a single word vector:

$$\mathbf{x} = [\mathbf{s_1}; \mathbf{s_2}; \dots; \mathbf{s_{n_w}}; \underbrace{\mathbf{0}; \mathbf{0}; \dots; \mathbf{0}}_{n-n_w}]$$

We zero-pad $\mathbf{x}$ so that all word vectors have the same length $n \cdot d_S$ to allow batch processing, and then we feed $\mathbf{x}$ into a stack of highway layers.

4 Word-level language model

Once we have word embeddings $\mathbf{x_{1:k}}$ for a sequence of words $w_{1:k}$ we can use a word-level RNN language model to produce a sequence of states $\mathbf{h_{1:k}}$ and then predict the next word according to the probability distribution

$$\Pr(w_{k+1}|w_{1:k}) = \text{softmax}(\mathbf{h_k W} + \mathbf{b}),$$

where $\mathbf{W} \in \mathbb{R}^{d_{\text{LM}} \times |\mathcal{W}|}$, $\mathbf{b} \in \mathbb{R}^{|\mathcal{W}|}$, and d_{LM} is the hidden layer size of the RNN. Training the model involves minimizing the negative log-likelihood over the corpus $w_{1:K}$:

$$-\sum_{k=1}^{K} \log \Pr(w_k|w_{1:k-1}) \longrightarrow \min \qquad (5)$$

As was mentioned in Section 3.1 there is a huge variety of RNN architectures to choose from. The most advanced recurrent neural architectures, at the time of this writing, are recurrent highway networks (Zilly et al., 2017) and a novel model which was obtained through a neural architecture search with reinforcement learning (Zoph and Le, 2017). These models can be spiced up with the most recent regularization techniques for RNNs (Gal and Ghahramani, 2016) to reach state-of-the-art. However, to make our results directly comparable to those of Kim et al. (2016) we select a two-layer LSTM and regularize it as in Zaremba et al. (2014).

5 Experimental Setup

We search for the best model in two steps: first, we block the word-level LSTM's architecture and pre-select the three best models under a small parameter budget (5M), and then we tune these three best models' hyperparameters under a larger budget (20M).

Pre-selection: We fix d_{LM} (hidden layer size of the word-level LSTM) at 300 units per layer and run each syllable-aware word embedding method from Section 3 on the English PTB data set (Marcus et al., 1993), keeping the total parameter budget at 5M. The architectural choices are specified in Appendix A.

Hyperparameter tuning: The hyperparameters of the three best-performing models from the pre-selection step are then thoroughly tuned on the same English PTB data through a random search according to the marginal distributions:

- $d_S \sim U(20, 650)$,[5]
- $\log(d_{\text{HW}}) \sim U(\log(160), \log(2000))$,
- $\log(d_{\text{LM}}) \sim U(\log(300), \log(2000))$,

with the restriction $d_S < d_{\text{LM}}$. The total parameter budget is kept at 20M to allow for easy comparison to the results of Kim et al. (2016). Then these three best models (with their hyperparameters tuned on PTB) are trained and evaluated on small- (DATA-S) and medium-sized (DATA-L) data sets in six languages.

Optimizaton is performed in almost the same way as in the work of Zaremba et al. (2014). See Appendix B for details.

[5] $U(a, b)$ stands for a uniform distribution over (a, b).

Model	PPL	Model	PPL
LSTM-Word	88.0	Char-CNN	92.3
Syl-LSTM	88.7	Syl-Avg	88.5
Syl-CNN-2	86.6	Syl-Avg-A	91.4
Syl-CNN-3	**84.6**	Syl-Avg-B	88.5
Syl-CNN-4	86.8	Syl-Concat	**83.7**
Syl-Sum	**84.6**		

Table 1: Pre-selection results. PPL stands for test set perplexity, all models have $\approx$ 5M parameters.

Model	$d_{\mathcal{S}}$	d_{HW}	d_{LM}	Size	PPL
Syl-CNN	242	1170	380	15M	80.5
Syl-Sum	438	1256	435	18M	80.3
Syl-Concat	228	781	439	13M	**79.4**

Table 2: Hyperparameters tuning. In Syl-CNN, d_{HW} is a function of the primary hyperparameter $c = 195$ (see Appendix A).

Syllabification: The true syllabification of a word requires its grapheme-to-phoneme conversion and then splitting it into syllables based on some rules. Since these are not always available for less-resourced languages, we decided to utilize Liang's widely-used hyphenation algorithm (Liang, 1983).

6 Results

The results of the pre-selection are reported in Table 1. All syllable-aware models comfortably outperform the Char-CNN when the budget is limited to 5M parameters. Surprisingly, a pure word-level model,[6] LSTM-Word, also beats the character-aware one under such budget. The three best configurations are Syl-Concat, Syl-Sum, and Syl-CNN-3 (hereinafter referred to as Syl-CNN), and tuning their hyperparameters under 20M parameter budget gives the architectures in Table 2. The results of evaluating these three models on small (1M tokens) and medium-sized (17M–57M tokens) data sets against Char-CNN for different languages are provided in Table 3. The models demonstrate similar performance on small data, but Char-CNN scales significantly better on medium-sized data. From the three syllable-aware models, Syl-Concat looks the most advantageous as it demonstrates stable results and has the least number of parameters. Therefore in what follows we will make a more detailed comparison of Syl-Concat with Char-CNN.

Model	EN	FR	ES	DE	CS	RU	
Char-CNN	**78.9**	**184**	**165**	**239**	**371**	**261**	DATA-S
Syl-CNN	80.5	191	172	239	374	269	
Syl-Sum	80.3	193	170	243	389	273	
Syl-Concat	79.4	188	168	244	383	265	
Char-CNN	**160**	**124**	**118**	**198**	**392**	**190**	DATA-L
Syl-CNN[7]	–	–	–	–	–	–	
Syl-Sum	170	141	129	212	451	233	
Syl-Concat	176	139	129	225	449	225	

Table 3: Evaluation of the syllable-aware models against Char-CNN. In each case the smallest model, Syl-Concat, has 18%–33% less parameters than Char-CNN and is trained 1.2–2.2 times faster (Appendix C).

Shared errors: It is interesting to see whether Char-CNN and Syl-Concat are making similar errors. We say that a model gives an error if it assigns a probability less than p^* to a correct word from the test set. Figure 2 shows the percentage of errors which are shared by Syl-Concat and Char-CNN depending on the value of p^*. We see that the vast majority of errors are shared by both models even when p^* is small (0.01).

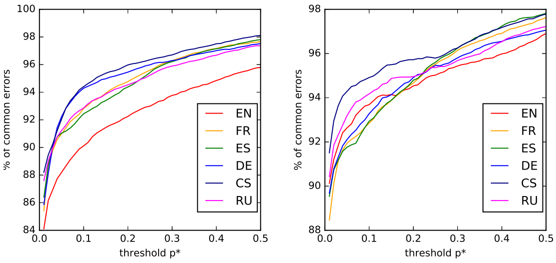

Figure 2: Percentage of errors shared by both Syl-Concat and Char-CNN on DATA-S (left) and DATA-L (right).

PPL breakdown by token frequency: To find out *how* Char-CNN outperforms Syl-Concat, we partition the test sets on token frequency, as computed on the training data. We can observe in Figure 3 that, on average, the more frequent the word is, the bigger the advantage of Char-CNN over Syl-Concat. The more Char-CNN sees a word in different contexts, the more it can learn about this word (due to its powerful CNN filters). Syl-Concat, on the other hand, has limitations – it cannot see below syllables, which prevents it from extracting the same amount of knowledge about the word.

PCA of word embeddings: The intrinsic advantage of Char-CNN over Syl-Concat is also sup-

[6] When words are directly embedded into $\mathbb{R}^{d_{\mathcal{W}}}$ through an embedding matrix $\mathbf{E}_{\mathcal{W}} \in \mathbb{R}^{|\mathcal{W}| \times d_{\mathcal{W}}}$.

[7] Syl-CNN results on DATA-L are not reported since computational resources were insufficient to run these configurations.

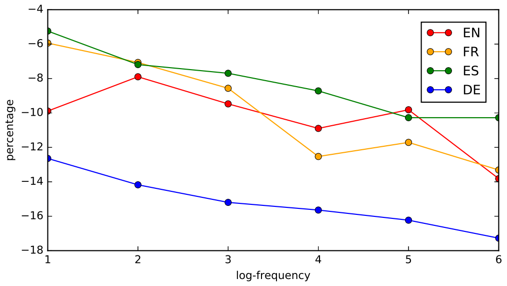

Figure 3: PPL reduction by token frequency, Char-CNN relative to Syl-Concat on DATA-L.

Model	80%	90%	95%	99%
Char-CNN	568	762	893	1038
Syl-Concat	515	729	875	1035

Table 4: Number of principle components when PCA is applied to word embeddings produced by each model, depending on % of variance to retain.

ported by the following experiment: We took word embeddings produced by both models on the English PTB, and applied PCA to them.[8] Regardless of the threshold percentage of variance to retain, the embeddings from Char-CNN always have more principal components than the embeddings from Syl-Concat (see Table 4). This means that Char-CNN embeds words into higher dimensional space than Syl-Concat, and thus can better distinguish them in different contexts.

LSTM limitations: During the hyperparameters tuning we noticed that increasing $d_{\mathcal{S}}$, d_{HW} and d_{LM} from the optimal values (in Table 2) did not result in better performance for Syl-Concat. Could it be due to the limitations of the word-level LSTM (the topmost layer in Fig. 1)? To find out whether this was the case we replaced the LSTM by a Variational RHN (Zilly et al., 2017), and that resulted in a significant reduction of perplexities on PTB for both Char-CNN and Syl-Concat (Table 5). Moreover, increasing d_{LM} from 439 to 650 did result in better performance for Syl-Concat. Optimization details are given in Appendix B.

Comparing syllable and morpheme embeddings: It is interesting to compare morphemes and syllables. We trained Morfessor 2.0 (Creutz and Lagus, 2007) in its default configuration on the PTB training data and used it instead of the syllabifier in our models. Interestingly, we got ≈3K unique morphemes, whereas the number of unique syllables was ≈6K. We then trained all our models on PTB under 5M parameter budget, keeping the state size of the word-level LSTM at 300 (as in our pre-selection step for syllable-aware models). The reduction in number of subword types allowed us to give them higher dimensionality $d_{\mathcal{M}} = 100$ (cf. $d_{\mathcal{S}} = 50$).[9]

Model	depth	d_{LM}	Size	PPL
RHN-Char-CNN	8	650	20M	67.6
RHN-Syl-Concat	8	439	13M	72.0
RHN-Syl-Concat	8	650	20M	69.4

Table 5: Replacing LSTM with Variational RHN.

Convolutional (Morph-CNN-3) and additive (Morph-Sum) models performed better than others with test set PPLs 83.0 and 83.9 respectively. Due to limited amount of time, we did not perform a thorough hyperparameter search under 20M budget. Instead, we ran two configurations for Morph-CNN-3 and two configurations for Morph-Sum with hyperparameters close to those, which were optimal for Syl-CNN-3 and Syl-Sum correspondingly. All told, our best morpheme-aware model is Morph-Sum with $d_{\mathcal{M}} = 550$, $d_{\text{HW}} = 1100$, $d_{\text{LM}} = 550$, and test set PPL 79.5, which is practically the same as the result of our best syllable-aware model Syl-Concat (79.4). This makes Morph-Sum a notable alternative to Char-CNN and Syl-Concat, and we defer its thorough study to future work.

Source code: The source code for the models discussed in this paper is available at `https://github.com/zh3nis/lstm-syl`.

7 Conclusion

It seems that syllable-aware language models fail to outperform competitive character-aware ones. However, usage of syllabification can reduce the total number of parameters and increase the training speed, albeit at the expense of language-dependent preprocessing. Morphological segmentation is a noteworthy alternative to syllabification: a simple morpheme-aware model which sums morpheme embeddings looks promising, and its study is deferred to future work.

[8] We equalized highway layer sizes d_{HW} in both models to have same dimensions for embeddings. In both cases, word vectors were standardized using the z-score transformation.

[9] $\mathcal{M}$ stands for morphemes.

A Pre-selection

In all models with highway layers there are two of them and the non-linear activation of any highway layer is a ReLU.

LSTM-Word: $d_{\mathcal{W}} = 108$, $d_{\text{LM}} = 300$.

Syl-LSTM: $d_{\mathcal{S}} = 50$, $d_{\text{LM}} = 300$.

Syl-CNN-[L]: $d_{\mathcal{S}} = 50$, convolutional filter widths are $[1, \ldots, L]$, the corresponding convolutional filter depths are $[c \cdot l]_{l=1}^{L}$, $d_{\text{HW}} = c \cdot (1 + \ldots + L)$. We experimented with $L = 2, 3, 4$. The corresponding values of c are chosen to be $120, 60, 35$ to fit the total parameter budget. CNN activation is tanh.

Linear combinations: We give higher dimensionality to syllable vectors here (compared to other models) since the resulting word vector will have the same size as syllable vectors (see (3)). $d_{\mathcal{S}} = 175$, $d_{\text{HW}} = 175$ in all models except the Syl-Avg-B, where we have $d_{\mathcal{S}} = 160$, $d_{\text{HW}} = 160$.

Syl-Concat: $d_{\mathcal{S}} = 50$, $d_{\text{HW}} = 300$.

B Optimization

LSTM-based models: We perform the training (5) by truncated BPTT (Werbos, 1990; Graves, 2013). We backpropagate for 70 time steps on DATA-S and for 35 time steps on DATA-L using stochastic gradient descent where the learning rate is initially set to 1.0 and halved if the perplexity does not decrease on the validation set after an epoch. We use batch sizes of 20 for DATA-S and 100 for DATA-L. We train for 50 epochs on DATA-S and for 25 epochs on DATA-L, picking the best-performing model on the validation set. Parameters of the models are randomly initialized uniformly in $[-0.05, 0.05]$, except the forget bias of the word-level LSTM, which is initialized to 1. For regularization we use dropout (Srivastava et al., 2014) with probability 0.5 between word-level LSTM layers and on the hidden-to-output softmax layer. We clip the norm of the gradients (normalized by minibatch size) at 5. These choices were guided by previous work on word-level language modeling with LSTMs (Zaremba et al., 2014).

To speed up training on DATA-L we use a sampled softmax (Jean et al., 2015) with the number of samples equal to 20% of the vocabulary size (Chen et al., 2016). Although Kim et al. (2016) used a hierarchical softmax (Morin and Bengio, 2005) for the same purpose, a recent study (Grave et al., 2016) shows that it is outperformed by sampled softmax on the Europarl corpus, from which DATA-L was derived (Botha and Blunsom, 2014).

RHN-based models are optimized as in Zilly et al. (2017), except that we unrolled the networks for 70 time steps in truncated BPTT, and dropout rates were chosen to be as follows: 0.2 for the embedding layer, 0.7 for the input to the gates, 0.7 for the hidden units and 0.2 for the output activations.

C Sizes and speeds

On DATA-S, Syl-Concat has 28%–33% fewer parameters than Char-CNN, and on DATA-L the reduction is 18%–27% (see Fig. 4).

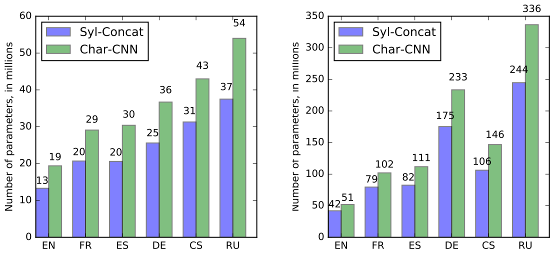

Figure 4: Model sizes on DATA-S (left) and DATA-L, in millions of trainable variables.

Training speeds are provided in the Table 6. Models were implemented in TensorFlow, and were run on NVIDIA Titan X (Pascal).

Model	EN	FR	ES	DE	CS	RU	
Char-CNN	9	8	8	7	6	6	S
Syl-Concat	14	12	12	11	10	9	
Char-CNN	10	8	7	5	7	4	L
Syl-Concat	22	13	13	6	10	5	

Table 6: Training speeds, in thousands of tokens per second.

Inducing Semantic Micro-Clusters from Deep Multi-View Representations of Novels

Lea Frermann

Abstract

Automatically understanding the plot of novels is important both for informing literary scholarship and applications such as summarization or recommendation. Various models have addressed this task, but their evaluation has remained largely intrinsic and qualitative. Here, we propose a principled and scalable framework leveraging expert-provided semantic tags (e.g., *mystery*, *pirates*) to evaluate plot representations in an extrinsic fashion, assessing their ability to produce locally coherent groupings of novels (*micro-clusters*) in model space. We present a deep recurrent autoencoder model that learns richly structured *multi-view* plot representations, and show that they i) yield better micro-clusters than less structured representations; and ii) are interpretable, and thus useful for further literary analysis or labelling of the emerging micro-clusters.

1 Introduction

For the literature aficionado, the quest for the next novel to read can be daunting: the sheer number of novels of different styles, topics and genres is difficult to navigate. It is intuitively clear that readers select novels based on specific but potentially diverse and structured preferences (e.g., they might prefer novels of a particular theme (*small-town romance*), mood (*dark*) or based on character types (*grumpy boss*), character relations (*love, enmity*) and their development). These preferences also manifest in the organization of online book stores or recommendation platforms.[1] For example, the Amazon book catalog contains semantic tags provided by experts (publishers), including labels of character types (*pirates*) or theme (*secret baby romance*) to aid focused search for novels of interest.

Although these tags are already fairly granular, many cover large sets of novels (e.g., the tag *secret baby romance* covers almost $4,000$ novels), limiting their utility for exhaustive exploration and call for even finer grained micro-groupings. Can we instead *automatically* induce fine-grained novel clusters in an unsupervised, data-driven way?

We propose a framework to learn structured, interpretable book representations that capture different aspects of the plot, and verify that such representations are rich enough to support downstream tasks like generating interpretable book groupings. A real-world application of this work is content-based book recommendation based on diverse and interpretable book characteristics. Content-based recommendation has been criticized by the limited complexity of typically employed features (*limited content analysis*; Lops et al. (2011); Adomavicius and Tuzhilin (2005)). This work addresses this problem by inducing complex, structured and interpretable representations. Our contributions are two-fold.

First, assuming that richly *structured* book tags call for rich content representations (which expert taggers arguably possess), we describe a deep unsupervised model for learning *multi-view* representations of novel plots. We use the term *view* to refer to specific types of plot characteristics (e.g., pertaining to events, characters or mood), and *multi-view* to refer to combinations of these views. We use multi-view book representations to construct meaningful and locally coherent neighbourhoods in model space, which we will refer to as *micro-clusters*. To this end, we extend a recent autoencoder model (Iyyer et al., 2016) to learn multi-view representations of books. Our model

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1873–1883
Copenhagen, Denmark, September 7–11, 2017.

encodes properties of characters (view v_1), relations between characters (view v_2), and their respective trajectories over the plot.[2] View-specific encodings are learnt in an unsupervised way from raw text as separate sets of word clusters which are jointly optimized to encode `relevant` and `distinct` information. These properties are crucial for applications such as book recommendation, because they allow to i) explain why particular books are similar based on the inferred latent structure and ii) find similarities based on important and distinct aspects of a novel (character types or interactions). Our framework of unsupervised multi-view learning is very flexible and can straightforwardly be applied to learn arbitrary kinds and numbers of views from raw text.

Secondly, we propose an empirical evaluation framework. Before we can use models to *extend* existing categories as discussed above, it must be shown that the representations capture *existing* associations. To this end, we investigate whether micro-clusters derived from induced representations resemble reference clusters defined as groups of novels sharing tags in the Amazon catalog. While automatic induction of plot representations has attracted considerable attention (see Jockers (2013)), evaluation has remained largely qualitative and intrinsic. To the best of our knowledge, we are the first to investigate the utility of automatically induced plot representations on an extrinsic task at scale. We evaluate micro-clusters as local neighbourhoods in model space containing $10,000$ novels under 50 reference tags.

We show that rich multi-view representations produce better micro-clusters compared to competitive but simpler models, and that interpretability of the learnt representations is not compromised despite the more complex objective. We also qualitatively demonstrate that high-quality micro-clusters emerge from a smaller, more homogeneous data set of Gutenberg[3] novels.

2 Related Work

Automatically learning representations of book plots, as structured summaries of their content, has attracted much attention (cf, Jockers (2013) for a review). Unsupervised models have been proposed which, given raw text, extract prototypical event structure (McIntyre and Lapata, 2010; Chambers and Jurafsky, 2009), prototypical characters (Bamman et al., 2013, 2014; Elsner, 2012) and their social networks (Elson et al., 2010).

Other work focused on the *dynamics* of a plot, learning trajectories of relations between two characters (Iyyer et al., 2016; Chaturvedi et al., 2017). Iyyer et al. (2016) combine dictionary learning (Olshausen and Field, 1997) with deep recurrent autoencoders to learn interpretable character relationship descriptors. They show that their deep model learns better representations than conceptually similar topic models (Gruber et al., 2007; Chang et al., 2009). Here, we extend the model of Iyyer et al. (2016) to simultaneously induce multiple views on the plot.

Methodologically, our work falls into the class of multi-view learning, and we propose a novel formulation of the model objective which encourages encoding of *distinct* information in the views. Our objective function is inspired by prior work in multi-task learning and deep domain adaptation for classification (Ganin and Lempitsky, 2015; Ganin et al., 2016). They train neural networks to simultaneously learn classifiers which are accurate on their target task and are agnostic about feature fluctuation pertaining to domain shift. We adapt this idea to unsupervised models with a reconstruction objective and learn multi-view representations which efficiently encode the input data and, at the same time, learn to *only* encode information relevant for the particular view.

Evaluating induced plot representations is notoriously difficult. Most evaluation has resorted to manual inspection, or crowd-sourced human judgments of the coherence and interpretability of the representations (Iyyer et al., 2016; Chaturvedi et al., 2017). While such evaluations demonstrated that the induced representations are qualitatively valuable, it is not clear whether they are rich and general enough to be used for downstream tasks and applications. Others have used automatically created gold-standards of re-occurring character names across scripts ('gang member') (Bamman et al., 2013), prototypical plot templates (tropes, e.g., 'corrupt corporate executive') or manually created gold-standards of character types (Vala et al., 2016) or their relations (Massey et al., 2015; Chaturvedi et al., 2017) to automatically measure the *intrinsic* value of learnt representations. Here,

[2] We argue that both characters, and their relations evolve throughout the plot: Heroes pick up new attitudes or skills, and utilize those to different extents; relations change and develop over time (hate to love, friendship to enmity and back).

[3] `https://www.gutenberg.org/`

we investigate how these results extend to *extrinsic* tasks, and use structured plot representations for the task of inducing micro-clusters of novels.

Elsner (2012) depart from the above pattern, suggesting an extrinsic, albeit artificial, evaluation paradigm. Approaching plot understanding from the angle of its utility for summarization, they use kernel methods to learn character-centric plot representations. They evaluate their trained models on their ability to differentiate between real and artificially distorted novels (e.g., with shuffled chapters). While this evaluation is extrinsic and quantitative, it leverages artificial data and it is not clear how the results extend to real-world summaries.

Language features were previously used in content-based book recommendation e.g., as bags-of-words (Mooney and Roy, 1999) or semantic frames (Clercq et al., 2014). Both works use structured databases and plot summaries rather than the raw book text. Other work used topic models to augment a recommender system of scientific articles (Wang and Blei, 2011). Similar to our work, these works emphasize the added value of *interpretable* representations and recommendations, however, they do not leverage the raw content of entire novels and the richness of information encoded in those.

3 Multi-View Novel Representations

We first provide an intuitive description of Relationship Modeling Networks (RMN; Iyyer et al. 2016), and our extension (henceforth MVPlot), which *jointly* induces temporally aware *multi-view* representations of novel plots. Afterwards we describe the MVPlot model in technical detail.

3.1 Intuition

Iyyer et al. (2016) introduce the RMN, an unsupervised model which learns interpretable plot representations in terms of types of relations between pairs of book characters, and their development over time. Given a book and a character pair, the model learns relation types as word clusters (not unlike topics in a topic model (Blei et al., 2003)) from local contexts mentioning both characters. In addition the RMN learns for each character pair how these relations vary over time as a trajectory of relations. Methodologically, the RMN combines a deep recurrent autoencoder with dictionary learning, where terms in the dictionary are relationship descriptors. The RMN learns to efficiently encode local text spans as a linear combination of these relation descriptors.

View	Descriptor
v_1	laugh scream laughing yell joke cringe disgrace embarrassment hate cursing
v_1	snug fleece warm comfortable wet blanket flannel cozy comfort roomy
v_1	excellency mademoiselle monsieur majesty duchess empress madame countess madam
v_2	love loving lovely dear sweetest dearest thank darling congratulation hello
v_2	associate assistant senior chairman executive leadership vice director liaison vice-president

Table 1: Example property (v_1) and relation (v_2) descriptors induced by MVPlot on the Gutenberg corpus, as their nearest neighbours in GloVe space.

We extend RMNs to induce temporally aware multi-view representations of novel plots. Multiple interpretable views are induced jointly within one process in an unsupervised way. The core of our model closely corresponds to the structure of the RMN (as technically described in Section 3.2). However, we provide the model with distinct types of informative input for each view, and, reformulate the objective in a way that jointly optimizes parameterizations of all views to encode *distinct* information (cf., Section 3.3).

Our MVPlot model learns two views: properties associated with individual characters (v_1), relations between character pairs (v_2, as in the RMN) and their respective development over the course of the plot (examples of descriptors learnt by MVPlot for both views are shown in Table 1). Our modeling framework, however, is very general in the sense that any number and type of views can be learnt jointly as long as input with relevant signals can be provided for each view. For example, we could naturally extend the model described here with a 'plot' view to capture properties of the story which are not related to any character.

3.2 The MVPlot Model

We now formally describe the MVPlot model for learning multi-view plot representations encoding individual character properties (v_1), character pair relationships (v_2), and their respective trajectories. The full model is shown in Figure 1.

Input to our model are two corpora of text spans, one for each view, S_{v1} and S_{v2}. The corpora consist of different sets of relevant view-specific local contexts as described in Section 5. Given a book b and a character c, $S_{v1}^{c,b}$ contains

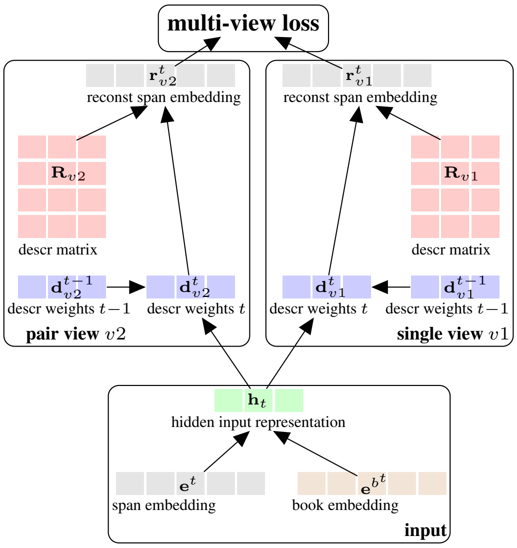

Figure 1: Visualization of the MVPlot model.

linearly ordered[4] sequences of text spans s^t at time t=$\{1...T\}$ in which character c is mentioned, but no other character,

$$S^{c,b}_{v1}=\{s^1,s^2,...,s^T\}\ s.th.\ \forall_t : c \in s^t$$

Similarly, $S^{c_1,c_2,b}_{v2}$, given a book b and a pair of characters c_1 and c_2, contains linearly ordered text spans which mention both c_1 and c_2, but no other character,

$$S_2^{c_1,c_2,b}=\{s^1,s^2,...,s^T\}\ s.th.\ \forall_t :\ c_1 \in s^t, c_2 \in s^t.$$

The rest of the input preparation follows Iyyer et al. (2016) as follows. We map text spans into word embedding space, by mapping each word w to its 300-dimensional GloVe embedding e_w (Pennington et al., 2014) pre-trained on Common-Crawl, and averaging the word embeddings,

$$\mathbf{e}^t = \frac{1}{|s^t|}\sum_{w \in s^t} e_w. \qquad (1)$$

We provide MVPlot with a trainable matrix $\mathbf{B}$ of dimensions $b \times n$, where b is the number of books in our data set, and each row $\mathbf{e}^b$ is an n-dimensional book embedding, encoding background information (e.g, about its general setting or style) which is relevant to neither view of MVPlot.[5] Finally the span embedding and the corresponding book embedding are concatenated, and passed through a ReLu non-linearity (cf., Figure 1, bottom),

$$\mathbf{h}^t = ReLu(\mathbf{W_h}[\mathbf{e}^t;\mathbf{e}^{b^t}]). \qquad (2)$$

Model architecture MVPlot uses the architecture of the RMN autoencoder, but replicates it for each input view, v_1 and v_2 (cf., Figure 1, center). Each part will induce an encoding of view-specific information. The feed-forward pass, described below, is identical for both parts, however, the loss and backpropagation will differ (cf., Section 3.3).

We describe the feed-forward pass for v_2, noting that it works analogously for v_1. The latent input representation $\mathbf{h}^t$ (eqn (2)) is passed through a softmax layer which returns a weight vector over descriptors, $\mathbf{d}^t_{v2} = softmax(\mathbf{W}^d_{v2}[\mathbf{h}^t])$. Descriptors are rows in the $k \times d$-dimensional descriptor matrix $\mathbf{R}_{v2}$, with each row k corresponding to one d-dimensional descriptor (similar to a topic in a topic model). The input $\mathbf{e}^t$ is reconstructed through the dot product of $\mathbf{d}^t_{v2}$ and the descriptor matrix $\mathbf{R}_{v2}$,

$$\mathbf{r}^t = \mathbf{d}^t_{v2}\mathbf{R}_{v2}. \qquad (3)$$

Like in the original RMN, we want to capture the *temporal* development of character relations or properties. Intuitively, we assume that the relations between (or properties of) characters at time t depend on their relations (or properties) at time $t-1$. As in the RMN, we factor the descriptor weights of the *previous* time step $\mathbf{d}^{t-1}$ into the representation at time t, such that

$$\mathbf{d}^t_{v2} = \alpha\ softmax(\mathbf{W}^d_{v2}[\mathbf{h}_t;\mathbf{d}^{t-1}_{v2}])+(1-\alpha)\mathbf{d}^{t-1}_{v2} \qquad (4)$$

Output First, the model induces property descriptors (rows in $\mathbf{R}_{v1}$) and the relationship descriptors (rows in $\mathbf{R}_{v2}$). Both sets of descriptors are optimized to reconstruct model input in GloVe embedding space (cf., Section 3.3 for details). They consequently themselves live in GloVe word embedding space, and can be visualized through their nearest neighbours in this space. In addition, for each book b, character c^b and character pair $\{c_1, c_2\}$, sequences of weight vectors over relations

$$\mathcal{T}^{c_1,c_2,b}_{v2} = \mathbf{d}^1_{v2}...\mathbf{d}^T_{v2},$$

and over properties

$$\mathcal{T}^{c,b}_{v1} = \mathbf{d}^1_{v1}...\mathbf{d}^T_{v1}$$

are induced, which encode their trajectory of relations and properties, respectively. We will utilize these trajectories for inducing micro-clusters of novels (Section 6.1).

[4] with respect to their occurrence in the novel

[5] The RMN learns background encodings for characters in addition to the book embeddings. We omit this for MVPlot as this information is explicitly learned in the views.

3.3 The Multi-View Loss

We formulate our loss as a Hinge loss within the contrastive max-margin framework. Our objective is to learn parameters for each view $\in \{v_1, v_2\}$ which efficiently encode view-specific input in a low-dimensional space from which the original input can be re-constructed with high accuracy. In addition, we want to learn view-specific parameters which encode *distinct* information such that when utilized together, they provide an improved embedding of the data. Intuitively, we achieve this by *discouraging* parameters of view v_1 from accurately reconstructing input spans from view v_2, and vice versa.

Our loss combines these two objectives as follows. The first part of the loss corresponds to the loss of the RMN. We use negative sampling to induce parameters for each view which reconstruct their respective view-specific input well. Formally, assuming model input from view v_1, $\mathbf{e}^t_{v1}$, we construct a set of 10 'negative inputs'$\{\mathbf{e}^{n_1}_{v1}, ...\mathbf{e}^{n_I}_{v1}\}$ which are sampled at random from the $v1$ input corpus. We want to learn parameters encoding view v_1 to reconstruct the input such that the inner product between the true input $\mathbf{e}^t_{v_1}$ and its reconstruction $\mathbf{r}^t_{v1}$ is higher than the inner product between $\mathbf{r}^t_{v1}$ and any of the negative samples $\mathbf{e}^{n_i}_{v1}$ by a margin of at least 1,

$$J(\theta) = \sum_t \sum_i max(0, 1 - \mathbf{r}^t_{v1}\mathbf{e}^t_{v1} + \mathbf{r}^t_{v1}\mathbf{e}^{n_i}_{v1}), \quad (5)$$

where θ refers to the set of all model parameters. We add an orthogonality-encouraging regularizing term to this objective in order to obtain view-specific descriptors which are distant from each other (Hyvärinen and Oja, 2000),

$$\begin{aligned} J(\theta) =& \sum_t \sum_i max(0, 1 - \mathbf{r}^t_{v1}\mathbf{e^t}_{v1} + \mathbf{r}^t_{v1}\mathbf{e}^{n_i}_{v1}) \\ &+ \lambda||\mathbf{R}_{v1}\mathbf{R}^T_{v1} - \mathbf{I}||. \end{aligned} \quad (6)$$

The loss is defined analogously for input of view v_2. Note that so far, the loss is defined in an entirely view-specific way, independent of the $v2$ parameters (e.g., the $v1$ loss in equation (6) is independent of the $v2$ parameters).

We break this independence by adding a second term to our loss function, which ensures that view-specific parameters encode *only relevant* information. That is, we want v_2-specific parameters to *only* encode v_2-specific information, and vice versa. Assuming model input from view v_1, $\mathbf{e}^t_{v_1}$, we learn parameters for to view v_2 that reconstruct the input poorly. Again, we use the max-margin framework, maximizing the margin between the (high) quality reconstruction of $\mathbf{e}^t_{v_1}$ from v_1 parameters, $\mathbf{r}^t_{v1}$, and the (poor) quality of the reconstruction from v_2 parameters, $\mathbf{r}^t_{v2}$,

$$K(\theta) = max(0, 1 - \mathbf{e}^t_{v_1}\mathbf{r}^t_{v1} + \mathbf{e}^t_{v_1}\mathbf{r}^t_{v2}). \quad (7)$$

The update is defined analogously, swapping $v1$ and $v2$ subscripts, when the true input stems from $v2$. The full loss is defined as a weighted linear combination of its terms (eqns (6) and (7)),

$$L(\theta) = \beta J(\theta) + (1 - \beta)K(\theta). \quad (8)$$

Genre	Example Tags
Mystery	British Detectives; FBI Agents; Female Protagonists; Private Investigators
Romance	Cowboys; Criminals & Outlaws; Doctors; Royalty & Aristocrats; Spies; Wealthy
SciFi	AIs; Aliens; Clones; Corporations; Mutants; Pirates; Psychics; Robots & Androids

Table 2: Example tags from the Amazon book catalog for the refinement `character type`.

4 Semantic Micro-Cluster Evaluation

MVPlot induces structured representations of a novel b as relation trajectories between characters pairs in b, and property trajectories of individual characters in b. Are those representations rich and informative enough to produce meaningful and interpretable micro-clusters of novels? In Section 6.1 we evaluate the quality of such micro-clusters, i.e., local novel neighbourhoods in model space. We propose an objective and empirical evaluation employing expert-provided semantic novel tags in the Amazon catalog.

Novels listed in the Amazon catalog are tagged with respect to their `genre` (e.g., *mystery, romance*). They are further labelled with *refinements* pertaining to diverse information like `character types` or `mood`, which take different sets of values, depending on the genre, and are as such predestined as an objective reference for evaluating the diverse information captured by our model. Table 2 lists example tags for the refinement `character type`.

All tags are provided by publishers and can consequently be taken as a reliable source of information. In our evaluation we assume that novels which share a tag are related to each other. We use this tag-overlap metric to evaluate local neighbourhoods of book representations in model space.

	# novels	# v_1 sequences	# v_2 sequences
Gutenberg	3,500	45,182	60,493
Amazon	10,000	91,511	70,156

Table 3: The number of novels and property (v_1) relation (v_2) input sequences for the Gutenberg and the Amazon corpus.

We selected a set of 50 representative tags from the Amazon catalog and did not tune this set for our evaluation. The full tag set is included in the supplementary material.

Note that while this scheme provides an empirical way of evaluating plot representations, it may not capture their full potential: our models are not explicitly tuned towards producing micro-clusters which are coherent with respect to our gold-standard tags, and may encode additional structure which is not probed in this evaluation. That said, we consider this evaluation as a good procedure to evaluate the *relative* quality of different models in the sense that a better model should produce micro-clusters that better correspond to reference clusters derived from gold-standard tags.

5 Data

We evaluate our model on two data sets. First, we create a diverse data set by sampling 10,000 digital novels under our 50 gold-standard tags (cf., Section 4) of the Amazon catalog (Amazon). Our second data set consists of 3,500 novels from Project Gutenberg, a large digital collection of freely available novels consisting primarily of classic literature (Gutenberg). The Amazon novels are already labelled with genre and refinement tags, such that evaluation using our gold-standard is straightforward. While Gutenberg novels come with the advantage of being freely available, they are unlabelled, and not fully covered by our 50 gold-standard tags. We therefore restrict our quantitative analysis to the Amazon data set. However, we also report qualitative results on the Gutenberg corpus, demonstrating that our model induces meaningful novel representations for corpora of varying size and diversity.

Both data sets were pre-processed with the BookNLP pipeline (Bamman et al., 2014) for coreference resolution of character mentions. We filtered stop-words and low-frequency words by discarding the 500 most frequent words and those which occur in less than 100 novels, and discarded novels less than 100 sentences long or containing fewer than 5 characters from our data set.

We created view-specific input corpora as follows: (1) a relation corpus of chronologically ordered sequences of text spans of 20 words for character pairs $\{c_1, c_2\}$ in a book b, $S_{v2}^{c_1,c_2,b}$, which mention *only* c_1 and c_2 with a margin of 10 words for the Amazon corpus (1 word for the smaller Gutenberg corpus) but no other character; and (2) a property corpus of chronologically ordered sequences of 20 word text spans for individual characters c in book b, $S_{v2}^{c_1,c_2,b}$, which mention *only* c, using the same margins as above.

We keep only sequences of length n time steps s.th., $5 \leq n \leq 250$. We only keep pair sequences if we also obtain sequences for each individual character confirming to the above criteria. Table 3 summarizes statistics on our input corpora.

6 Evaluation

Section 6.1 quantitatively evaluates the quality of local neighbourhoods in model space induced from the Amazon corpus against our proposed gold-standard. Section 6.2 evaluates the quality of the induced descriptors from both the Amazon and Gutenberg corpus both through crowd sourcing and illustrative examples.

Models We set the MVPlot performance into perspective comparing it against the RMN.[6] MVPlot induces both character properties and relations, and is trained on both the relation-view and property-view input, while the RMN only induces pair relationships and can only utilize relation-view input. In addition, we report a frequency baseline, which is trained on both property and relation-view input. We concatenate all input spans of a given view for a particular novel; construct its term frequency vector and use cosine similarity to compute the nearest neighbours to each novel.

Parameter settings Across all experiments and corpus-specific models, we set β=0.99 for MVPlot, and for both MVPlot and RMN we set α=0.5, λ=10^{-5}, k=50.[7] We train both RMN and MVPlot for 15 epochs using SGD and ADAM (Kingma and Ba, 2014).[8]

[6] We do not compare against topic model baselines because they were outperformed by RMN (Iyyer et al., 2016).

[7] Parameters were tuned on a small subset of books used in the nearest neighbourhood evaluation (Section 6.1).

[8] Our implementation builds on the available RMN code `https://github.com/miyyer/rmn`.

6.1 Nearest Neighbours Evaluation

We evaluate local neighbourhoods in model space using the 500 most popular novels by their number of Amazon reviews as reference novels from the Amazon corpus. For each reference novel we compute the 10 nearest neighbours as described below. We measure neighbourhood quality using the gold-standard tags from Section 4, regarding neighbours as *relevant* if at least one tag is shared with the reference novel. We report precision at rank 10 (P@10) and mean average precision (MAP).

Method MVPlot represents a book b in terms of trajectories of weight vectors over relation descriptors $\mathcal{T}_{v2}^{b}$ and property descriptors $\mathcal{T}_{v1}^{b}$. RMN only learns relation descriptors and their trajectories. For both models, we map each induced trajectory for book b to a fixed-sized k-dimensional vector representation by averaging the time-specific weight vectors, for example for a v_2 trajectory,

$$\mathcal{T}_{v2}^{c_1,c_2,b} = \frac{1}{\left|\mathcal{T}_{v2}^{c_1,c_2,b}\right|} \sum_{t\in\left|\mathcal{T}_{v2}^{c_1,c_2,b}\right|} \mathbf{d}_{v2}^{t}, \tag{9}$$

and equivalently for v_1 trajectories, $\mathcal{T}_{v1}^{c,b}$.

We compute the similarity between two books $\{b_r, b_c\}$ as follows. We align the v_2 trajectory for each character pair $\{c_1, c_2\}$ in b_r, $\mathcal{T}^{c_1,c_2,b_r}$, to its closest neighbouring character pair vector in b_c, $\mathcal{T}^{c'_1,c'_2,b_c}$, by Euclidean distance, and compute the overall book similarity in terms of character relations between b_r and b_c as the average over all distances.

$$sim_{v2}^{b_r,b_c} = \frac{1}{|\mathcal{T}_{v2}^{b_r}|} \sum_{\mathcal{T}\in\mathcal{T}_{v2}^{b_r}} \operatorname*{arg\,min}_{\mathcal{T}'\in\mathcal{T}_{v2}^{b_c}} dist(\mathcal{T},\mathcal{T}'). \tag{10}$$

We obtain $sim_{v1}^{b_r,b_c}$ in an analogous process. For $cosine$ and MVPlot we obtain a final, *multi-view* similarity by averaging similarity scores obtained in each view's space,

$$sim_{both}^{b_r,b_c} = \frac{1}{2}\left(sim_{v1}^{b_r,b_c} + sim_{v2}^{b_r,b_c}\right). \tag{11}$$

For RMN we compute similarity only in character relation space.

Model	**View**	P@10	MAP
cosine	v_1	0.516 ‡	0.392 †
	v_2	0.468 ‡	0.339 ‡
	$both$	0.512 ‡	0.390 ‡
RMN	v_2	0.479 ‡	0.347 ‡
MVPlot	v_1	0.529 †	0.401 †
	v_2	0.496 ‡	0.367 ‡
	$both$	**0.546**	**0.421**

Table 4: Micro-cluster quality results (Amazon corpus). Differences of $cosine$ and RMN compared to the best MVPlot result are significant with $p < 0.05$ (†) or $p < 0.01$ (‡) (paired t-test).

Results Table 4 presents micro-cluster quality in terms of $precision$@10 and MAP. The full MVPlot model statistically significantly outperfoms all other models.[9] The same pattern emerges when comparing models with the same underlying views: MVPlot $v2$ outperforms both cosine $v2$ and RMN $v2$ (similarly for MVPlot $v1$ and cosine $v1$), indicating that the MVPlot character relation representations are most informative for micro-cluster induction.

In order to shed light on the contribution of individual model components, we compare the full MVPlot model (*both*) to model versions with access to only $v1$ or $v2$ (Table 4 bottom). Combining information from both views boosts performance compared to the single-view versions. This confirms that MVPlot indeed encodes distinct and relevant information in the respective views.

While cosine is a strong baseline, its representations are not structured or interpretable. It consequently does not provide sufficient information for applications like book tagging or recommendation with respect to specific aspects or criteria. Similarly, RMN cannot learn representations of multiple, distinct views of the plot.

Advancing our understanding of the information encoded in the individual views of MVPlot, we took a closer look at the refinement tags for which the single view MVPlot model ($v1$) has the clearest advantage over the pair view MVPlot model ($v2$), and vice-versa. We computed tagwise F1-scores for the two MVPlot variants. Table 5 lists the book tags for which the scores of the two views diverge the most.

In terms of types of refinements, view $v2$ suffers most for predicting book categories, or topical tags ('sports', 'second changes'), while view $v1$ is particularly deficient for predicting character types. While this seems counterintuitive we hypothesize that character types are to a large extent defined by their interactions with, or relations to, other char-

[9] Also, intra-view comparisons except for MVPlot v_1 and cosine v_1 are statistically significant.

$F1\_v2 >> F1\_v1$		$F1\_v1 >> F1\_v2$	
Tag	**RefType**	**Tag**	**RefType**
Robots & Androids	Character	Hard SciFi	Category
Corporations	Character	Sports	Category
International	Theme	Horror	Theme
Aliens	Character	Second Chances	Theme
Cowboys	Character	Crime	Category

Table 5: The tags (Tag) and their refinement types (RefType) for which MVPlot $v1$ most clearly outperforms MVPlot $v2$ (left) and vice versa (right) in terms of tag-specific F1-measure.

acters. Topical information, however, is encoded robustly in the properties of individual characters.

6.2 Evaluating Induced Descriptors

This evaluation investigates whether induced relation descriptors indeed capture relational information. We evaluate the interpretability of the induced descriptors, comparing the v_2 (relation) descriptors induced by RMN and MVPlot. We apply both models to both the Amazon and the Gutenberg corpus, and report results on both data sets.

Method We collect crowdsourced judgments on Amazon Mechanical Turkto qualitatively evaluate the learnt descriptors, following Chaturvedi et al. (2017). In each task a worker is shown one induced descriptor as a set of its 10 closest words in GloVe space (like in Table 1), and is asked to indicate whether "the words in the group describe a relation, event or interaction between people". We compare the proportion of positive answers, i.e., the number of descriptors considered *relevant*, for RMN descriptors and MVPlot pair descriptors. We collect 30 judgments for each of k=50 descriptors induced by the respective models.

Results Figure 2 displays our results. We observe a similar pattern of ratings across models and corpora, e.g., around 50% of the descriptors are labelled as relevant by at least 50% of the annotators. None of the differences are statistically significant which lets us conclude that interpretability of induced descriptors is comparable for the RMN and MVPlot. This is encouraging because we confirm that representation interpretability is not compromised by MVPlot's more complex objective.

Table 1 displays examples of property and relation descriptors induced by MVPlot from the Gutenberg corpus. We can see that the different views indeed capture differing information (e.g., a v_1 descriptor refers to individuals' *titles*, while a v_2 descriptor refers to a *love* relation). Despite its smaller size and more homogeneous nature, we show that MVPlot learns meaningful representations from the Gutenberg corpus, demonstrating the flexibility of our model.

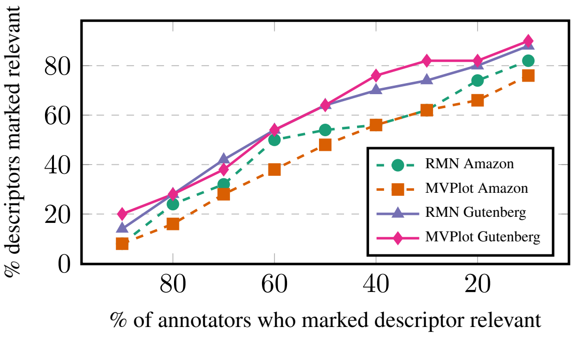

Figure 2: Results of descriptor interpretability. (% of descriptors marked as 'relevant descriptors of relations' by various proportions of annotators).

Figure 3 further illustrates this, displaying example local neighbourhoods of four reference novels (left) with their eight nearest neighbours ordered by proximity (left to right). The neighbourhoods are intuitively meaningful, and particularly impressive bearing in mind that the full model space contains $3,500$ novels. While most neighbourhoods are dominated by novels of the same author, some exceptions emerge. Row two, for example, contains novels by Thomas Hardy and Charles Dickens who both are known for biographical 17th century novels focusing on class and social changes.

7 Conclusions

Content-based micro-clustering of novels is a complex but interesting task. In order to eventually augment the diverse associations humans have, models must be able to pick up rich and structured signals from raw text. This paper presented a deep recurrent autoencoder which learns multi-view representations of plots, and introduced a principled evaluation framework using clusters based on expert-provided book tags.

Our evaluation showed that rich multi-view representations are better suited to recover such reference clusters compared to each individual view, as well as compared to simpler, but competitive models which induce less structured representations. Our view-specific representations are interpretable which allows to analyse and explain the emerging

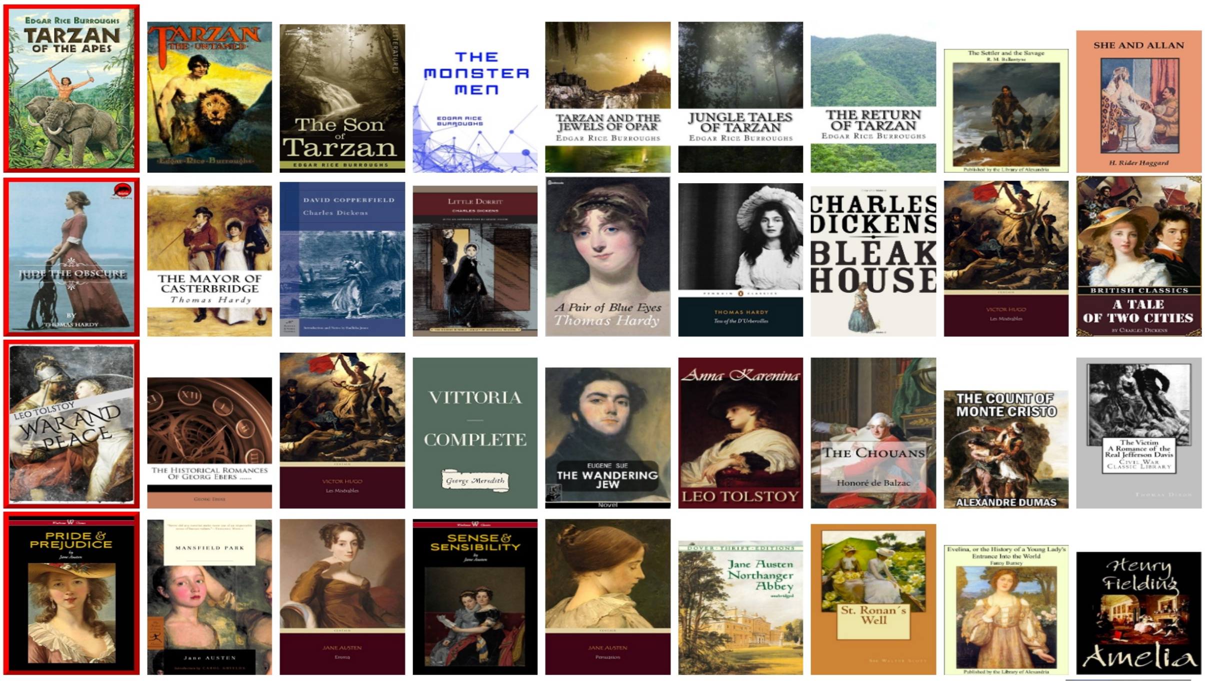

Figure 3: Nearest neighbours for four classic stories from the Gutenberg Corpus. Target novels on the left (with red border), and NNs are presented in the same row, ordered by their distance to the target novel.

micro-clusters, and might reveal previously unnoticed parallels between novels and may be useful for literary analysis or content-based recommendation. This is an exciting avenue for future work.

Our method is general and scalable both in terms of its input, utilizing raw text with only automatic pre-processing, and in terms of the number of distinct views it can learn. We described an objective function which triggers views to encode *distinct* information. In future work we plan to explore joint learning of more and different views.

Our approach relies strongly on the assumption that text spans mentioning two characters contain information about character relations, and that text spans mentioning one character contain information about the character's properties. While our results suggest that these assumptions are valid, they are arguably crude. In the future we plan to define more targeted input, e.g., by using semantic and syntactic information from dependency parses.

In this work we induced dual-view representations of book content, however, we emphasize that the proposed method is very general. The number and kinds of views, as well as underlying data are in no way constrained, as long as relevant view-specific input can be defined. In the context of novel representation it would be interesting to induce additional views, for example one that captures the mood of a novel. Another interesting avenue for future work would be to apply the framework to questions arising in the digital humanities, e.g., to extract different views from news articles.

The presented model and evaluation are designed with the objective to detect a different kinds of similarity between novels, with the ultimate goal to *enrich* human-provided genres and tags. We described a first step in this direction, verifying that the learnt information is meaningful and can *reproduce* human-created semantic book tags. Expert book tags exist for a wide variety of information (mood, theme, characters), and provide a rich evaluation environment for learnt representations. We invite the community to join us in exploring the full space of opportunities and evaluating induced representations *holistically* in the future.

Abstract

Convolutional Neural Networks (CNNs) are widely used in NLP tasks. This paper presents a novel weight initialization method to improve the CNNs for text classification. Instead of randomly initializing the convolutional filters, we encode semantic features into them, which helps the model focus on learning useful features at the beginning of the training. Experiments demonstrate the effectiveness of the initialization technique on seven text classification tasks, including sentiment analysis and topic classification.

1 Introduction

Recently, neural networks (NNs) dominate the state-of-the-art results on a wide range of natural language processing (NLP) tasks. The commonly used neural networks in NLP include Recurrent NNs, Convolutional NNs, Recursive NNs and their combinations. NNs are known for their strong abilities to learn features automatically. However, the lack of data or inappropriate parameter settings might greatly limit the generalization abilities of the models (Bengio et al., 2009; LeCun et al., 2015; Krizhevsky et al., 2012; Srivastava et al., 2014). To enhance the performance, a lot of improved methods have been proposed, e.g. developing advanced structures (Zhao et al., 2015; Zhang et al., 2016a), introducing prior knowledge (Hu et al., 2016) and utilizing external resources (Xie et al., 2016; Qian et al., 2016).

It is also noteworthy that the neural networks' performance is sensitive to weight initialization because their objectives are non-convex (Glorot and Bengio, 2010; Saxe et al., 2013; Mishkin and Matas, 2015). In fact, initialization techniques even play a role of catalyst for the revival of neural networks (Hinton et al., 2006; LeCun et al., 2015). Most improvements on initializing weights are based on mathematical methods, e.g. xavier initialization (Glorot and Bengio, 2010) and orthogonal initialization (Saxe et al., 2013). For NLP tasks, an influential technique is to use pre-trained word vectors to initialize embedding layers (Kim, 2014; Chen and Manning, 2014). Consider the embedding layers could be initialized by pre-trained word vectors, how about weights in other layers that are still randomly initialized?

Inspired by this question, we propose a simple yet effective method to improve CNNs by initializing convolutional layers (filters). Unlike the previous weight initialization based on mathematical methods, we encode semantic features into the filters instead of initializing them randomly. As CNNs exploit 1-D convolutional filters to extract n-gram features, our method aims at helping the filters focus on learning useful n-grams, e.g. "not bad" which is more useful than "watch a movie" for determining reviews' polarities. Specifically, we select n-grams from training data via a novel Naive Bayes (NB) weighting technique, and then cluster the n-gram embeddings with K-means algorithm. After that, we use the centroid vectors of the clusters to initialize the filters.

With this initialization method, CNN filters tend to extract important n-gram features at the beginning of the training process. By integrating our method into a classic CNN model for text classification (Kim, 2014), we observe significant im-

Copenhagen, Denmark, September 7–11, 2017.

provements in sentiment analysis and topic classification tasks. The advantages of our approach are as follows:

- Features are directly extracted from training data without involving any external resources;
- The computation brought by our method is relatively small, resulting in small additional training costs;
- The filter initialization is task independent. It could be easily applied to other NLP tasks.

Also, we further analyze the filters, shedding some light on the mechanism how our method influences the training process. The source code is released at https://github.com/shenshen-hungry/Semantic-CNN.

2 Related Work

Most recently, CNNs are becoming increasingly popular in a variety of NLP tasks. An influential one is the work of (Kim, 2014), where a simple CNN with a single layer of convolution is used for feature extraction. Despite its simple structure, the model achieves strong baselines on many sentence classification datasets. Following this work, several improved models are proposed. Zhang and Wallace (2015) improve the model by optimizing hyper-parameters and provide a detailed analysis of the CNN (Kim, 2014). Yin and Schütze (2016) and Zhang et al. (2016b) exploit different pre-trained word embeddings (e.g. word2vec and GloVe) to enhance the model.

In addition to initializing embedding layers with pre-trained word vectors, other pre-designed features also prove to be very effective in assisting the training of neural models. For example, in (Hu et al., 2016), neural models are harnessed by logic rules. Li et al. (2016) propose to use pre-calculated words' weights to guide Paragraph Vector model. Dai and Le (2015) combine the hidden layers of RNNs with linearly increasing weights. Xie et al. (2016) use entity descriptions from knowledge bases (e.g. Freebase) to learn knowledge representations for entity classification and knowledge graph completion. Qian et al. (2016) propose linguistically regularized LSTMs for sentiment analysis with sentiment lexicons, negation words, and intensity words. In this work, we encode semantic features into convolutional layers by initializing them with important n-grams. Being aware of which n-grams are important, CNN is able to extract more discriminative features for text classification.

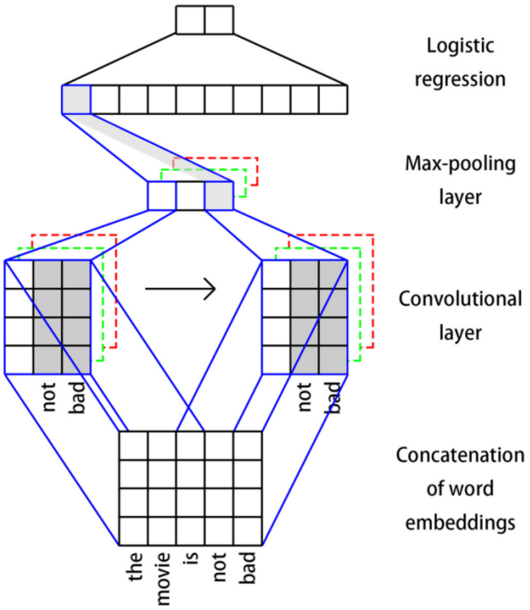

Figure 1: The framework of CNN with one layer of convolution and pooling.

3 Our Method

The intuition behind our method is simple: Since CNNs essentially capture semantic features of n-grams, we can use important n-grams to initialize the filters. As a result, the filters are able to focus on extracting those important n-gram features at the beginning of the training. As shown in Figure 1, we use embeddings of "not" and "bad" to initialize the filter. A larger score will be obtained when the "not bad" filter matches the bigram "not bad" in the text, otherwise a relatively smaller score will be returned.

3.1 N-gram Selection

Firstly, we extract important n-grams from the training data. Intuitively, n-gram "not bad" is much more important than "watch a movie" for determining reviews' polarities. Naive Bayes (NB) weighting is an effective technique for determining the words' importance (Martineau and Finin, 2009; Wang and Manning, 2012). NB weight $\mathbf{r}$ of a n-gram w in class c is calculated as follows:

$$\mathbf{r} = \frac{(\mathbf{p}_c^w + \alpha)/||\mathbf{p}_c||_1}{(\mathbf{p}_{\tilde{c}}^w + \alpha)/||\mathbf{p}_{\tilde{c}}||_1}$$

where $\mathbf{p}_c^w$ is the number of texts that contain

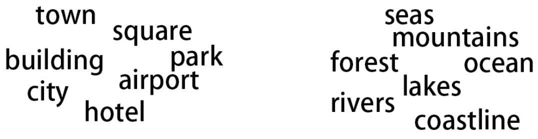

Figure 2: Uni-gram cluster examples.

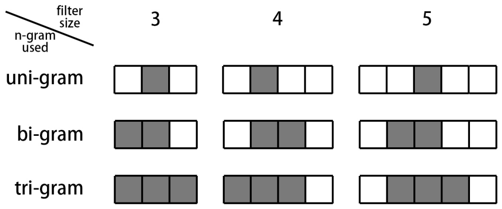

Figure 3: Filter initialization.

n-gram w in class c, $\mathbf{p}_{\bar{c}}^{w}$ is the number of texts that contain n-gram w in other classes, $||\mathbf{p}_c||_1$is the number of texts in class c, $||\mathbf{p}_{\bar{c}}||_1$ is the number of texts in other classes, α is a smoothing parameter. For *positive* class in movie review dataset, the ratios of n-grams like "amazing" and "not bad" should be large since they appear much more frequently in positive texts than in negative texts. For neutral n-grams like "of the" and "movie", their ratios should be around 1. For each class, we select the n-grams whose ratios are much higher than 1 for filter initialization. We give examples of n-grams selected by our method in Appendix.

3.2 Filter Initialization

We concatenate word embeddings to construct n-gram embeddings. For example, a tri-gram embedding has 3*100 dimensions when word embedding has 100 dimensions. This concatenation follows the mechanism of convolutional filters,where a filter with n*d dimensions is able to capture n-gram features (d is the dimension of word embedding). Because the number of filters in CNNs is much smaller than the number of n-grams, a filter tends to extract the features of a class of n-grams rather than an individual n-gram. Based on this observation, we don't use n-gram embeddings to initialize the filters directly. Instead, we firstly use K-means to cluster features of the selected n-grams, and then use the clusters' centroid vectors to initialize the filters. In this work, we consider clustering uni-gram (word), bi-gram and tri-gram features. Figure 2 shows two uni-gram cluster examples extracted from the location questions in TREC dataset (Li and Roth, 2002).

After obtaining the n-gram clusters, we feed their centroid vectors into the center of the filters. The remaining positions are still initialized randomly. Taking filters with size 3, 4, 5 as examples, Figure 3 shows how we fill uni, bi, and tri-gram features into the filters. By doing this, we encode semantic features into the filters. For example, in the TREC question classification task, the initialization will result in six types of filters which are sensitive to abbreviation, entity, description, human, location and number questions respectively.

4 Experiments

4.1 Datasets and Hyper-parameter Settings

CNN-non-static[1] (short for CNN) proposed by Kim (2014) is used as our baseline, which consists of one embedding layer, one convolutional layer, one max pooling layer, and one fully connected layer. The model proposed by Kim (2014) is a strong baseline in sentence classification. For details of the model, one can see (Kim, 2014; Zhang and Wallace, 2015). Pre-trained word embeddings on Google News via word2vec toolkit[2] are used for initializing the convolutional filters, besides initializing the embedding layer of CNN as in (Kim, 2014). For a fair comparison, we use the same seven datasets [3] and hyper-parameter setting with Kim (2014)'s work for training and testing. Uni, bi, and tri-gram features are used to initialize the filters. For a K-way classification problem, we select top *10%* n-grams in each class according to NB weighting. Since *300* filters are used in Kim (2014)'s work, we follow this setting and aggregate n-grams into *300/K* clusters for each class. Centroid vectors are used for filling the filters. Taking binary classification dataset MR as an example, *150* "positive" filters and *150* "negative" filters are obtained after initialization.

4.2 Effectiveness of Filter Initialization

In this section, we demonstrate the effectiveness of our initialization technique. We respectively use uni, bi and tri-gram centroid vectors to fill the filters. Table 1 lists the results. The CNN has provided very strong baselines. Our method

[1] The embedding layer in CNN-non-static is initialized with pre-trained vectors from word2vec toolkit and fine-tuned for each task.

further improves the accuracies significantly on all datasets except MPQA. The results are consistent with (Wang and Manning, 2012), where NB weighting produces little improvement over MPQA. We can also observe that the performance of uni, bi and tri-grams are comparable. None of them outperforms the others on all datasets.

4.3 Comparisons with State-of-the-arts

Table 2 lists the results of our model and other state-of-the-arts. Models in the first group are improved CNNs based on (Kim, 2014). Among them, MV-CNN and MGNC-CNN utilize multiple pre-trained embeddings as inputs, and CNN-Rule integrates logic rules. Our model achieves the best performance on three tasks without requiring any extra training costs and resources. With this simple initialization method, our model also gives competitive results against more sophisticated deep learning models in the second group, e.g. Adasent (Zhao et al., 2015) and DSCNN (Zhang et al., 2016a) that have complex structures or use the combinations of NNs.

Experiments show that our n-gram features make great contribution to both two-class and multi-class classification. Essentially, our method enables CNNs to obtain better generalization abilities. Furthermore, as the initialization does not rely on any external prior knowledge or resources, it could be easily applied to other NLP tasks or other languages.

	positive filters		negative filters	
	+	-	+	-
UNI	29.5	20.5	21.3	28.7
BI	31.3	18.7	18.1	31.9
TRI	31.4	18.6	17.2	32.8

Table 3: "+" and "-" are used to denote the number of positive and negative weights respectively. The data in the table are obtained from MR by the average of 10 times training. Every time we select 100 filters. 50 of them are initialized with positive n-grams and the rest are with negative n-grams.

4.4 Further Analysis of Filters

We further analyze the filter initialization with an example of binary sentiment classification. Through the initialization we have determined which filters are positive or negative in advance. The corresponding neurons of positive filters upon max-pooling layer are supposed to be activated by positive samples. Since positive (negative) samples have labels of 1 (0), the corresponding weights (in logistic regression) of those "positive" neurons tend to be positive. For the same reason, the negative filters tend to have negative weights. The results shown in Table 3 confirm our hypothesis: Positive/negative filters respectively tend to have positive(+)/negative(-) weights. The difference between positive and negative filters are more obvious in bi-gram and tri-gram cases. It is because bi and tri-gram centroid vectors could initialize more parameters of filters than uni-gram.

In Table 1, experiments show that different choices of uni, bi, and tri-grams have little influence on the results. The following is our assumption: Compared to uni-grams (words), bi and trigrams can cover more spaces of filters and introduce more NB information to filters. Filters initialized by them thus pay more attention to NB information than filters initialized by uni-grams according to Table 3. However, bi and tri-grams are also sparser in data than uni-grams. Their NB weights are not as accurate as those of uni-grams, even applied smoothing. As NB weight of a n-gram denotes its contribution to the classification, model initialized with tri-grams does not always perform the best.

5 Conclusion

This paper proposes a novel weight initialization technique for CNNs. We discover that convolutional filters that encode semantic features at the beginning of the training tend to produce better results than being randomly initialized. This has a similar effect with embedding layer initialization via pre-trained word vectors. Experimental results demonstrate the effectiveness of the initialization technique on multiple text classification tasks. In addition, our method requires few external resources and relatively small calculation, making it attractive for scenarios where training costs may be an issue.

In textual data, the features extracted by CNNs are n-grams. However, in fields like computer vision, features extracted by filters are more difficult to interpret. It still requires further exploration to apply our method to fields beyond NLP.

Abstract

In this paper, we present a novel document similarity measure based on the definition of a graph kernel between pairs of documents. The proposed measure takes into account both the terms contained in the documents and the relationships between them. By representing each document as a graph-of-words, we are able to model these relationships and then determine how similar two documents are by using a modified shortest-path graph kernel. We evaluate our approach on two tasks and compare it against several baseline approaches using various performance metrics such as DET curves and macro-average F1-score. Experimental results on a range of datasets showed that our proposed approach outperforms traditional techniques and is capable of measuring more accurately the similarity between two documents.

1 Introduction

In recent years, we have witnessed a tremendous growth in the volume of textual documents available on the Web. With this rapid increase in the number of available content, new opportunities for knowledge extraction have arisen. Many text mining tasks such as information retrieval, text categorization and document clustering involve the direct comparison of two documents. It is thus crucial to be able to determine accurately how similar two documents are by defining a document similarity measure.

Generally speaking, a similarity measure is a real-valued function that quantifies the common information shared by two objects (in our case documents). Determining the similarity between two documents is not a trivial task. Whether two documents are similar or different is not always clear and may vary from application to application.

Similarity measures that make use of the vector-space model (Salton et al., 1975) treat words in a document as if they were independent of one another, which is not realistic. In fact, words relate to one another to form meaningful phrases and to develop ideas. It is known that the human brain utilizes these relations between words to facilitate understanding (Altmann and Steedman, 1988). In general, we assume that two terms are related if they co-occur together in a small context, typically a phrase or a window of specific size, which resulted in n-gram features in many text mining tasks (an n-gram is a sequence of n terms in this paper). But n-grams correspond to sequences of words and thus fail to capture word inversion and subset matching (e. g., "article about news" vs. "news article"). To take into account these statistical relations, we propose to represent each document as a graph-of-words instead. And then, in order to measure the similarity between two documents, we capitalize on recent advances in graph kernels. Kernels can be thought of as measures of similarity between pairs of objects (Schölkopf and Smola, 2002). A graph kernel is a kernel function that measures the similarity between pairs of graphs.

Our aim in this paper is neither to define a similarity measure for only a certain category of documents based on background knowledge and features specific to that field nor to improve similarity estimation by using external knowledge. In-

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1890–1900
Copenhagen, Denmark, September 7–11, 2017.

stead, we propose to define a similarity measure that does not incorporate any background or external knowledge. Hence it is, without changes, applicable to all types of textual documents even if they come from different areas. The method takes as input a pair of documents and automatically computes how similar they are to each other based solely on their content.

The rest of this paper is organized as follows. Section 2 provides an overview of the related work and elaborates our contribution. Section 3 provides a detailed description of our proposed graph-of-words kernel. Section 4 evaluates the proposed approach on a wide range of tasks. Finally, Section 5 summarizes the work and presents potential future work.

2 Related Work

In this section, we review the related work published in the areas of *document similarity*, *graph kernels*, *kernel-based text categorization* and *graph-based text categorization*.

2.1 Document Similarity

There has been a variety of similarity measures defined to assess how close two objects are to each other, including documents. Let $< d_1, d_2 >$ be a pair of documents and D_1 (resp. D_2) the set of terms in d_1 (resp. d_2). Common similarity measures discussed by Manning (1999) are defined as follows:

$$Matching(d_1, d_2) = |D_1 \cap D_2|$$

$$Dice(d_1, d_2) = 2\frac{|D_1 \cap D_2|}{|D_1| + |D_2|}$$

$$Jaccard(d_1, d_2) = \frac{|D_1 \cap D_2|}{|D_1 \cup D_2|}$$

$$Overlap(d_1, d_2) = \frac{|D_1 \cap D_2|}{min(|D_1|, |D_2|)}$$

$$Cosine(d_1, d_2) = \frac{|D_1 \cap D_2|}{\sqrt{|D_1| \times |D_2|}}$$

The terms might be processed unigrams as well as processed n-grams present in the text. The set of operations described above are equivalent to vector operations when representing d_1 and d_2 as binary vectors.

2.2 Graph Kernels

Graph kernels are instances of the R-convolution kernels introduced by Haussler (1999). Convolution kernels have been proposed as a principled way of designing kernels on structured objects, such as sequences, trees and graphs. Graph kernels compute the similarity between pairs of graphs, based on common substructures they share. A wide variety of substructures has been proposed, such as random walks (Gärtner et al., 2003; Vishwanathan et al., 2010), shortest paths (Borgwardt and Kriegel, 2005), subtrees (Ramon and Gärtner, 2003), cycles (Horváth et al., 2004), and graphlets (Shervashidze et al., 2009).

2.3 Kernel-based Text Categorization

In recent years, there has been a great deal of work in using kernel methods, such as SVMs for text classification (Joachims, 1998; Dumais et al., 1998). Such work concentrates on building specialized kernels aimed at measuring similarity between documents. We outline some of these approaches below.

The works closest to ours are the ones reported by Lodhi et al. (2002) and by Cancedda et al. (2003). Lodhi et al. propose the use of string kernels as an alternative to the vector-space model. The feature space is generated by any ordered subsequence of characters found in the text not necessarily contiguously. Each subsequence consists of a specific number of characters and is weighted by an exponentially decaying factor of its full length in the text. Due to the enormous amount of computation needed to compute this feature vector, the authors present a dynamic programming technique, which allows the efficient calculation of the kernel values. Our work differs from theirs in that we use graph kernels instead of sequence kernels, and we concentrate on the word level instead of the character level. Cancedda et al. modified their string kernel to work with sequences of words rather than characters. Two sequences of words are considered similar if they have many common words in a given order. The similarity between two documents is assessed by the number of matching word sequences. Non-contiguous occurrences are penalized according to the number of gaps they contain. The proposed kernel is more appealing as it is more computationally efficient and it takes advantage of the standard linguistic preprocessing techniques. This approach differs in fundamental respects from our work since we represented documents as graphs-of-words in order to model word co-occurrence rather than sequences of words and we used a graph kernel instead of a sequence kernel to measure the similarity between pairs of documents. Other text categorization works use kernels that measure the semantic similarity between concepts extracted from the text (Bleik et al., 2013; Wang and Domeniconi, 2008).

2.4 Graph-based Text Categorization

Our work is also related to methods that represent documents as graphs and perform graph mining tasks to achieve improved classification performance. These methods either extract frequent subgraphs which are then used to produce feature vectors for the documents (Jiang et al., 2010; Rousseau et al., 2015) or they determine term weights to be used in the vector-space model based on centrality criteria or random walks (Hassan et al., 2007; Malliaros and Skianis, 2015).

3 A Graph Kernel for Document Similarity

In this section, we first discuss the essential definitions from graph theory. We then present our graph-of-words model for representing textual documents. And finally, we define our custom Shortest-Path Graph Kernel (SPGK) capable of measuring the similarity between pairs of documents.

3.1 Graph Concepts

Let $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ be an undirected and unweighted graph consisting of a set $\mathcal{V}$ of vertices and a set $\mathcal{E}$ of edges between them. In this paper, we will denote by n the number of vertices and by m the number of edges.

A labeled graph is a graph with labels on vertices and/or edges. Given a set of labels $\mathcal{L}$, $\ell : V \rightarrow \mathcal{L}$ is a function that assigns labels to the and/or edges of the graph. In our case, we deal with fully-labeled graphs as labels are assigned both to vertices and to edges.

A graph $\mathcal{G}$ can be represented by its adjacency matrix $\mathbf{A}$. The $(i,j)^{th}$ entry of $\mathbf{A}$ is 1 if the edge (v_i, v_j) between vertices v_i and v_j exists, and 0 otherwise.

A walk in a graph $\mathcal{G}$ is a sequence of vertices $v_1, v_2, \ldots, v_{k+1}$ where $v_i \in \mathcal{V}$ and $(v_i, v_{i+1}) \in \mathcal{E}$ for $1 \leq i \leq k$. The length of the walk is equal to the number of edges in the sequence, i. e. k in the above case. A walk in which $v_i \neq v_j \Leftrightarrow i \neq j$ is called a path. In other words, a path is a walk without repetition of nodes.

3.2 Graph-of-words

We chose to represent each textual document as a statistical graph-of-words, following earlier approaches in keyword extraction (Ohsawa et al., 1998; Mihalcea and Tarau, 2004) and more recent ones in ad hoc IR (Blanco and Lioma, 2012; Rousseau and Vazirgiannis, 2013) and in summarization (Meladianos et al., 2015).

The construction of each graph is preceded by a preprocessing phase where standard text processing tasks such as tokenization, stopword, punctuation and special character removal, and stemming are performed. The processed document is then transformed into an unweighted, undirected graph whose vertices represent unique terms and whose edges represent co-occurrences between the connected terms within a fixed-size window (hence the statistical denomination). The graph-of-words representation of text provides enhanced modeling capabilities compared to the bag-of-words representation. Besides the terms (vertices), it also models the relationships between them (edges). All the words present in a document have some relationships with one another, modulo a window size outside of which the relationship is not taken into consideration, and graphs are able to capture these dependencies. The extended modeling capabilities, however, come with an increase in complexity.

An example of a document represented as an unweighted undirected graph is given in Figure 1. The source text comes from Shakespeare's play "Hamlet": "to be or not to be: that is the question". For illustration purposes, only the colon is removed and no other text processing tasks are performed. The size of the window is set to 2, i. e. it captures bigram relationships. Hence, each word (vertex) is connected with an edge with its previous and its next word, if any.

3.3 Shortest-Path Graph-of-words Kernel (SPGK)

Our proposed approach measures the similarity between two textual documents by representing them as graphs-of-words, transforming these graphs into other graphs, and using graph kernels to calculate the similarity of the new graphs. Specifically, we capitalize on the shortest-path graph kernel (Borgwardt and Kriegel, 2005) and

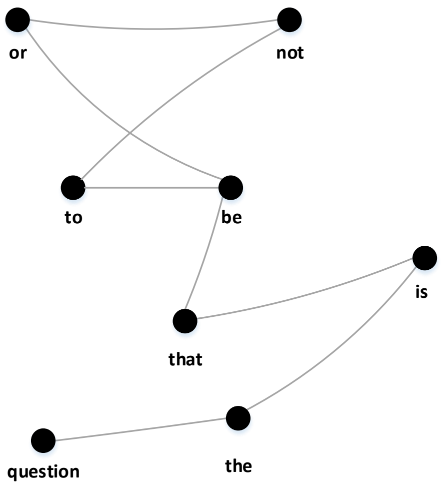

Figure 1: Example of the graph representation of a textual document.

we modify it to compare the graph representations of pairs of documents.

The first step of our proposed approach is to transform the graph-of-words representation of each document $\mathcal{G}$ into another graph $\mathcal{C}$ whose vertices are connected with an edge only if the shortest distance between them is not greater than a variable d. The emerging graph contains the same set of vertices as the graph-of-words from which it was generated. However, there exist edges only between vertices that are connected by a path of length at most d. Every node in $\mathcal{C}$ is labeled by the term that it represents, while every edge between two vertices is labeled by the shortest distance between these vertices given that it is no greater than d. Specifically, the label of an edge e that links two vertices whose shortest path is p is set equal to $label(e) = {}^{1}\!/_{p}$. For $d = 1$, the emerging network is equivalent in a structural sense to its corresponding graph-of-words. For greater values of d, it is very likely that the number of edges of the graph will have increased compared to its predecessor.

The commonly-used unigram bag-of-words representation assumes that words in a document are independent of one another. Although similarity measures based on this assumption have shown to work well in practice in many fields, it is not rational to completely ignore word order and word dependence. Hence, the distance between two terms in a document determines their relationship. This led us to explore alternative document similarity metrics that take into account the co-occurrence of words in the documents. More specifically, we assume that two terms are related given that they appear together inside a window. The underlying assumption is that each word present in a document has some relationship with the other words that are close to it. We set the size of the window over the processed text equal to 2. Therefore, in our graph-of-words representation of a document, each term is linked with its preceding and its following term with an edge. In our transformed graphs, terms are not only connected with terms that are next to them, but also with terms that are close to their neighbors ($d = 2$), with lower label values, and close to neighbors of their neighbors ($d = 3$), with even lower label values. Parameter d determines how far from the initial terms we allow the paths to go. Our intuition is that given an initial term, terms that are close to terms that are close to the initial term or beyond, may have also some relation with the initial term, and the strength of this relation decreases as the shortest path length increases. Therefore, although the proposed kernel does not incorporate any knowledge of the language being used, it does capture some statistical information and is thus capable of outperforming metrics based on the unigram and even n-gram vector-space model.

To determine the edge labels in the new graph $\mathcal{C}$, we can perform depth-first search (DFS) or breadth-first search (BFS) traversals from each vertex in the graph, limiting the depth to d. The complexity for calculating paths of length up to d from a source vertex to all other vertices using either DFS or BFS is at most $\mathcal{O}(b^d)$, where b is the average branching factor. The branching factor depends on the average degree of the vertices of the graphs-of-words $\mathcal{G}$ which, in its turn, depends on the selected size of the sliding window. For $W = 2$, the average degree of the vertices will be typically only slightly above 2 and the branching factor will be only slightly above 1. Calculating paths of length up to d for all vertices takes thus $\mathcal{O}(nb^d)$ time. This still yields reasonable time complexity estimates for small values of d.

After our original graphs have been transformed into the graphs described above, we can measure their similarity using the following kernel:

Definition 1 (Custom shortest-path graph kernel)**.** *Let $\mathcal{G}_1$, $\mathcal{G}_2$ denote two graph-of-words representations of two textual documents d_1, d_2 that are* *transformed into graphs $\mathcal{C}_1$, $\mathcal{C}_2$ through the process described above. The proposed Shortest-Path Graph Kernel (SPGK) on $\mathcal{C}_1 = (\mathcal{V}_1, \mathcal{E}_1)$ and $\mathcal{C}_2 = (\mathcal{V}_2, \mathcal{E}_2)$ is defined as follows:*

$$k(d_1, d_2) = \frac{\begin{pmatrix} \sum_{v_1 \in \mathcal{V}_1, v_2 \in \mathcal{V}_2} k_{node}(v_1, v_2) \\ + \sum_{e_1 \in \mathcal{E}_1, e_2 \in \mathcal{E}_2} k_{walk}^{(1)}(e_1, e_2) \end{pmatrix}}{norm} \tag{1}$$

where k_{node} is a positive definite kernel for comparing two vertices, $k_{walk}^{(1)}$ a positive definite kernel for comparing two edge walks of length 1 in $\mathcal{C}$ (i. e. up to d in $\mathcal{G}$) and $norm$ a normalization factor described next.

The similarity value generated by our custom shortest-path graph kernel is equal to the sum over the kernel values of all pairs of vertices on the transformed graphs plus the sum over the kernel values of all pairs of edge walks of length 1 over a positive normalization factor. The k_{node} kernel is a function for comparing two vertices. In practice, we use a delta kernel defined as:

$$k_{node}(v_1, v_2) = \begin{cases} 1 & \text{if } \ell(v_1) = \ell(v_2), \\ 0 & \text{otherwise} \end{cases} \tag{2}$$

but other works have considered distances in word embeddings for instance to account for word similarity at the cost of having to compare every node of a graph to every other nodes of the other graph (Srivastava et al., 2013).

The normalization factor is introduced because the nominator of the proposed kernel depends on the length of the compared documents. Specifically, given the adjacency matrices of the transformed graph representations of two documents $\mathbf{A}_1, \mathbf{A}_2$ where the value of each entry in the adjacency matrix is set equal to the label of the corresponding edge, and the diagonal matrices $\mathbf{D}_1, \mathbf{D}_2$ with diagonal entries set to 1 if the corresponding term exists in the corresponding document, we first compute the matrices M_1, M_2 as shown below:

$$\mathbf{M}_1 = \mathbf{A}_1 + \mathbf{D}_1$$

$$\mathbf{M}_2 = \mathbf{A}_2 + \mathbf{D}_2$$

and we then compute the normalization factor using the following formula:

$$norm = \|\mathbf{M}_1\|_F \times \|\mathbf{M}_2\|_F$$

where $\|\cdot\|_F$ is the Frobenius norm for matrices.

The $k_{walk}^{(1)}$ kernel can be expressed as the product of kernels on vertices and edges along the walk. Only walks of length 1 in $\mathcal{C}$ are considered, therefore, $k_{walk}^{(1)}$ can be calculated in terms of the original vertex, the destination vertex, and the edge connecting them.

Definition 2 (Custom edge walk kernel)**.** *Let u_1, v_1 be two vertices of graph $\mathcal{C}_1$ ($u_1, v_1 \in \mathcal{V}_1$) and e_1 the edge connecting them. Let also u_2, v_2 be two vertices of graph $\mathcal{C}_2$ ($u_2, v_2 \in \mathcal{V}_2$) and e_2 the edge connecting them. The edge walk kernel is defined as follows:*

$$k_{walk}^{(1)}(e_1, e_2) = k_{node}(u_1, u_2) \times k_{edge}(e_1, e_2) \\ \times k_{node}(v_1, v_2) \tag{3}$$

where k_{node} is the kernel function defined above and k_{edge} is a kernel function for comparing two edges defined as follows:

$$k_{edge}(e_1, e_2) = \begin{cases} \ell(e_1) \times \ell(e_2) & \text{if } e_1 \in \mathcal{E}_1 \wedge \\ & e_2 \in \mathcal{E}_2, \\ 0 & \text{otherwise} \end{cases} \tag{4}$$

The measure of similarity between two graphs depends on the kernel values corresponding to the vertices and edges that compose each walk, while the matching between two vertices or two edges is determined by comparing their labels. The values of our kernel function lie in the interval $[0, 1]$. It takes a value equal to 0 for documents with no common terms and a value equal to 1 for identical documents.

Lemma 1. *SPGK is a valid kernel.*

Proof. Based on the proofs presented in (Borgwardt and Kriegel, 2005) and (Borgwardt et al., 2005), we show that our custom shortest-path graph kernel is positive definite. The k_{node} kernel is a delta kernel, which is known to be positive definite (Schölkopf and Smola, 2002) and therefore a valid kernel. The k_{edge} kernel is also a delta kernel multiplied by a positive real number. Since the multiplication of a kernel by a positive constant preserves positive definiteness, this kernel is also valid. Regarding the $k_{walk}^{(1)}$ kernel, it is positive definite as the point-wise multiplication of positive definite kernels (k_{node}, k_{edge}) preserves positive definiteness. The $\sum_{v_1 \in \mathcal{V}_1, v_2 \in \mathcal{V}_2} k_{node}(v_1, v_2)$ function is the sum of valid kernel functions, hence, it is also positive definite. Regarding the $\sum_{e_1 \in \mathcal{E}_1, e_2 \in \mathcal{E}_2} k^{(1)}_{walk}(e_1, e_2)$ function, it is a walk kernel that takes into account only walks of length 1 on the transformed graphs and is zero-extended to the whole set of pairs of walks that do not satisfy the above constraint. Therefore, kernel values for walks with length greater than 1 are set to zero. This zero-extension is known to preserve positive definiteness (Haussler, 1999). This function is a convolution kernel, which is proven to be positive definite (Haussler, 1999). Finally, the kernel is divided by a positive constant and its positive definiteness is preserved. □

3.4 Run Time Complexity

We now determine the time complexity of our proposed kernel for measuring the similarity between two documents. Let us assume that the graph-of-words representations of the two documents consist of n vertices each. To determine the shortest paths of length at most d from a root vertex to all other vertices, we need $\mathcal{O}(b^d)$ time when using a graph traversal algorithm (depth-first or breadth-first search). There are also n vertices in the transformed graph, hence, the transformation will require $\mathcal{O}(nb^d)$ time for each graph. In order to determine the kernel value, it is necessary to compute the value of $k^{(1)}_{walk}$ for all pairs of edges between the two transformed graphs. The number of edges in the transformed graph can be at most n^2 in the case all the shortest paths in the original graph are no longer than d. Thus, there are at most $n^2 \cdot n^2 = n^4$ pairs of edges. However, due to the label enrichment that has been applied to the vertices of the transformed graphs, the number of matching nodes in the two graphs has been radically reduced and the number of pairs of edges that have to be considered is also reduced. Specifically, we have to consider n^2 pairs of edges as only paths between vertices whose label is the same in the two graphs are considered. The kernel value can thus be computed in $\mathcal{O}(n^2 + nb^d)$ time.

3.5 Alternative Computation Method for $d = 1$

In the case we consider only the common paths of length 1, there is a more efficient algorithm to compute the kernel values. The common paths of length 1 correspond to common edges between the graph representations of the documents. The emerging kernel takes into account the number of common vertices (terms) between the two graphs and the number of common edges (terms co-occurring in the same window) as well. More specifically, given two documents d_1 and d_2, the adjacency matrices of their graph representations $\mathbf{A}_1, \mathbf{A}_2$ where each entry in the adjacency matrix is set to 1 if the corresponding edge exists in the graph and the diagonal matrices $\mathbf{D}_1, \mathbf{D}_2$ with diagonal entries set to 1 if the corresponding term exists in the document, we first compute the matrices $\mathbf{M}_1, \mathbf{M}_2$ as described previously and then we compute the kernel value using the following formula:

$$k(d_1, d_2) = \frac{\sum \mathbf{M}_1 \circ \mathbf{M}_2}{\|\mathbf{M}_1\|_F \times \|\mathbf{M}_2\|_F} \qquad (5)$$

where $(\cdot \circ \cdot)$ is the Hadamard or element-wise product between matrices.

If n is the number of unique node labels, i. e. the length of the vocabulary, and m the number of edges, the computation of the kernel values requires $\mathcal{O}(n + m)$ time in the worst case scenario. For the baseline similarity measures, with unigram features, the computational cost is $\mathcal{O}(n)$ time but it goes up as we consider higher order n-grams.

4 Experiments and Evaluation

In this section, we present the experiments we conducted to evaluate and validate our proposed kernel between documents.

4.1 Evaluation Metrics

To assess the effectiveness of the different approaches, we employed a set of well-known evaluation metrics inherited from Information Retrieval: *accuracy*, *macro-average F1-score* and for the story link detection task *DET curves* (Martin et al., 1997).

The DET curve is a variant of the ROC curve that plots the *missed detection probability* ($P_{miss} = {}^{fn}/_{(tp+fn)}$) versus the *false alarm probability* ($P_{fa} = {}^{fp}/_{(tn+fp)}$) for various system operating points, which allows someone to get a greater insight into the effectiveness of the evaluated approaches. A method is considered to perform best at thresholds that correspond to points that are close to the lower-left of the graph (i. e. lower error probabilities) and the area under the curve should be minimal.

For the story link detection experiments, we also computed the normalized C_{Det} costs, the

Dataset	# training examples	# test examples	# classes	vocabulary size	avg. terms per document	avg. degree
WebKB	$2,803$	$1,396$	4	$7,772$	77.93	2.54
News	$32,604$	CV	7	$34,131$	25.57	2.08
Subjectivity	$10,000$	CV	2	$21,335$	20.74	2.08
Amazon	$6,400$	$1,600$	4	$39,133$	86.96	2.67
Polarity	$10,662$	CV	2	$18,777$	18.44	2.00

Table 1: Summary of the 5 datasets that were used in our text categorization experiments.

standard performance measure of TDT as described in (Fiscus and Wheatley, 2004).

4.2 Datasets

We evaluate the SPGK and the baselines on 5 standard datasets for text categorization: (1) `WebKB`: Web pages collected from Computer Science departments of various Universities manually classified into 7 categories (we removed Web pages that belong to the classes "staff", "department" and "other") (Craven et al., 1998). (2) `News`: News extracted from RSS feeds of popular newspaper websites classified into 7 categories based on the taxonomies of their publishing websites (Vitale et al., 2012). (3) `Subjectivity`: Subjective and objective sentences corresponding to movie reviews from Rotten Tomatoes and to plot summaries gathered from the Internet Movie Database respectively (Pang and Lee, 2004). (4) `Amazon`: Product reviews over four different sub-collections (Blitzer et al., 2007). (5) `Polarity`: Positive and negative snippets acquired from Rotten Tomatoes (Pang and Lee, 2005). Table 1 shows statistics of the datasets that were used for the evaluation. For the Story Link Detection task, we employed the TDT-5 corpus that contains stories from various newswire sources (Glenn et al., 2006; Graff and Kong, 2006). We only used the English part of the dataset for our experiments consisting of $221,306$ documents.

4.3 Baselines

The similarity measure presented in this paper is best suited for settings where the concept of a predefined corpus does not exist. For example, it could find applications in plagiarism detection and in cases where independent pairs of documents must be compared to each other. In such settings, due to the absense of a corpus, we cannot learn mappings of terms to a vector space (i. e. word embeddings) or use methods that take advantage of the corpus to increase their performance. Hence, our set of baselines includes methods that take as input two documents and output their similarity.

More specifically, the performance of our proposed kernel was compared to the performances of three baseline kernels based on similarity measures between pairs of documents $< d_1, d_2 >$ in the n-gram feature space (up to 4-grams):

1. The linear kernel, which uses the *dot product* as similarity measure: $k_{dp}(\vec{d_1}, \vec{d_2}) = \vec{d_1} \cdot \vec{d_2}$ where $\vec{d}$ is the n-gram feature vector associated with the document d;

2. *Cosine*, which measures the cosine of the angle between the two vectors: $k_c(\vec{d_1}, \vec{d_2}) = \frac{\vec{d_1} \cdot \vec{d_2}}{\|\vec{d_1}\| \times \|\vec{d_2}\|}$ where $\| \cdot \|$ is the L_2-norm.

3. *Tanimoto coefficient* (also known as Jaccard coefficient), which measures the intersection of features divided by their union: $k_{tc}(\vec{d_1}, \vec{d_2}) = \frac{\vec{d_1} \cdot \vec{d_2}}{\|\vec{d_1}\|^2 + \|\vec{d_2}\|^2 - \vec{d_1} \cdot \vec{d_2}}$

In the task of text categorization, we also compared the proposed kernel against the so-called Dynamic Convolutional Neural Network (*DCNN*) which is capable of generating representations for larger pieces of text such as sentences and documents (Kalchbrenner et al., 2014) and a convolutional neural network (CNN) architecture that has recently showed state-of-the-art results on many NLP sentence classification tasks (Kim, 2014). We used two variants of the CNN: (1) a model where all words are initialized to random vectors and are kept static during training (*CNN static,rand*), and (2) a model where again all words are initialized to random vectors, but are modified during training (*CNN non-static,rand*). The second model as well as DCNN have access to the whole corpus to generate word/document embeddings. Hence, it is not fair in a sense to compare the proposed kernel against these methods.

Table 2: Performance of the 6 approaches in text categorization. * indicates statistical significance in accuracy improvement at $p < 0.05$ using the micro sign test against the Cosine ($n = 2$) baseline of the same column. > 1 day indicates that the computation did not finish after 1 day.

4.4 Text Categorization

To perform text categorization, for all methods except the DCNN and the two CNNs, we employed a Support Vector Machine (SVM) classifier (Boser et al., 1992). It is interesting to note that all we need to train an SVM classifier is the kernel matrix of the training examples. We optimized the parameter C of the SVM by performing 10-fold cross-validation on the training set. We then made predictions on the test set using the optimal value of C. For DCNN the dimensionality of the generated embeddings was set to 100, while for the two CNNs it was set to 300. For DCNN and the two CNNs, the number of training epochs was set to 25. All similarity measures were coded in Python[1].

For each value of the parameter d, we obtain a new kernel and in turn the resultant kernel matrix contains different values. To study the effect of parameter d on the classification performance, we performed tests for values of d ranging from 1 to 4. We did not further increase the value of d since in most cases, for values greater than 4, the performance of the classifier stayed the same.

Table 2 shows the performance of the baseline methods and the proposed shortest-path graph kernel (SPGK), on the five datasets. Bold font marks the best performance in a column, while $*$ indicates statistical significance in accuracy improvement at $p < 0.05$ using the micro sign test (Yang and Liu, 1999) against the Cosine ($n = 2$) baseline of the same column. We chose to test for significance against that measure, as it corresponds to the best-performing baseline. On all datasets except one (News), SPGK outperforms the other three similarity measures and the neural network architectures. In addition, the results show a statistically significant improvement of at least one of our kernels over the Cosine ($n = 2$) approach on all datasets except two (News, Amazon). In general, our kernel is followed in performance by Cosine, Tanimoto, Dot Product in that order. The three neural network architectures fail to outperform the proposed kernel even on a single dataset. Furthermore, the approaches that make use of the whole corpus to generate embeddings (DCNN and CNN non-static,rand) do not seem to gain any advantage from having access to the whole dataset. This may be due to the fact that the size of the datasets is not large enough for learning high-quality representations.

4.5 Story Link Detection

Story link detection, as defined by the Topic Detection and Tracking (TDT) research program (Allan, 2002), is the task of determining whether two stories, such as news articles and radio broadcasts, are "linked" by the same event. According to TDT,

[1] Code available at: `http://www.db-net.aueb.gr/nikolentzos/code/spgk.zip`

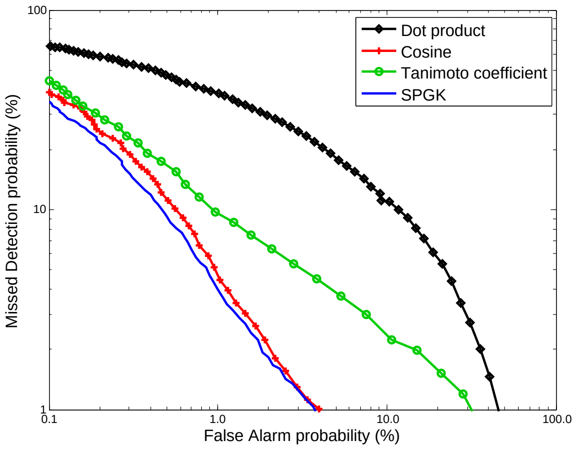

Figure 2: DET curves for all similarity measures on story link detection track.

Similarity measure		$(\mathrm{C_{det}})_{\mathrm{norm}}$
Dot product		0.3908
Cosine		0.0953
Tanimoto coefficient		0.1453
SPGK	$d = 1$	**0.0883**
	$d = 2$	0.0884
	$d = 3$	0.0888
	$d = 4$	0.0888

Table 3: Performance of all similarity measures in story link detection.

an event is something that happens at some specific time and place and two stories are "linked" if they discuss the same event.

In Figure 2, we plot the DET curves comparing the proposed approaches. For clarity, we only plot one curve for our SPGK approach ($d = 1$) since the plots overlapped, and the best performing curve for each of the baseline approaches. It is clear that our approach outperforms the baselines over the whole set of operating points. We also searched for the threshold values for which each approach maximizes its performance. Our next step was to compare the four systems in terms of detection effectiveness at that optimal threshold. Table 3 illustrates the normalized C_{det} of the proposed methods and the baselines. We can see that the proposed methods are better than baseline methods in terms of the normalized C_{det} metric.

5 Conclusion

In this paper, we presented a graph kernel for measuring the similarity between pairs of documents. The graph-of-words representation of textual documents allows us to model relationships between terms in documents and, hence, to go beyond the limits of the vector-space model. At the same time, it allows us to measure the similarity between two documents by comparing their graph representations using kernel functions. The effectiveness of the proposed kernel was empirically tested on two different tasks, namely text categorization and story link detection. The proposed measure showed improved performance on both tasks compared to the baselines.

Abstract

Models work best when they are optimized taking into account the evaluation criteria that people care about. For topic models, people often care about interpretability, which can be approximated using measures of lexical association. We integrate lexical association into topic optimization using *tree priors*, which provide a flexible framework that can take advantage of both first order word associations and the higher-order associations captured by word embeddings. Tree priors improve topic interpretability without hurting extrinsic performance.

1 Introduction

Goodman (1996) introduces a key insight for machine learning models in natural language processing: if you know how performance on a problem is evaluated, it makes more sense to optimize using *that* evaluation metric, rather than others. Goodman applies his insight to parsing algorithms, but this insight has had an even larger impact in machine translation, where the introduction of the fully automatic BLEU metric makes it possible to tune systems using a score correlated with human rankings of MT system performance (Papineni et al., 2002).

Chang et al. (2009) provide a similar insight for topic models (Blei et al., 2003, LDA): if what you care about is the interpretability of topics, the standard objective function for parameter inference (likelihood) is not only poorly correlated with a human-centered measurement of topic coherence, but *inversely* correlated. Nonetheless, most topic models are still trained using methods that optimize likelihood (McAuliffe and Blei, 2008; Nguyen et al., 2013).

We take the logical next step suggested when you bring together the insights of Goodman (1996) and Chang et al. (2009), namely incorporating an approximation of human topic interpretability into the topic model optimization process in a way that is effective and more straightforward than previous methods (Newman et al., 2011). We take advantage of the human-centered evaluation of Chang et al. (2009), which can be reasonably approximated using an automatic metric based on word associations derived from a large, more general corpus (Lau et al., 2014). We exploit LDA and its Bayesian formulation by bringing word associations into the picture using a prior—specifically, we use external lexical association to create a tree structure and then use *tree* LDA (Boyd-Graber et al., 2007, tLDA), which derives topics using a given tree prior.

We construct tree priors with combinations of two types of word association scores (skip-gram probability (Mikolov et al., 2013) and G2 likelihood ratio (Dunning, 1993)) and three construction algorithms (two-level, hierarchical clustering with and without leaf duplication). Then tLDA identifies topics with these tree priors in Amazon reviews and the 20NewsGroups datasets. tLDA topics are more coherent compared with "vanilla" LDA topics, while retaining and often slightly improving topics' extrinsic performance as features for supervised classification. Our approach can be viewed as a form of adaptation, and the flexibility of the tree prior approach—amenable to *any* kind of association score—suggests that there are many directions to pursue beyond the two flavors of association explored here.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1901–1906
Copenhagen, Denmark, September 7–11, 2017.

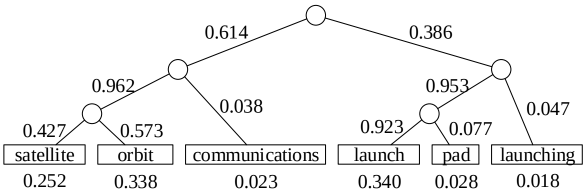

Figure 1: An example of a tree prior (the tree structure) and gold posterior edge and word probabilities learned by tLDA. Numbers beside the edges denote the probability of moving from the parent node to the child node. A word's probability, i.e., the number below the word, is the product of probabilities moving from the root to the leaf.

2 Tree LDA: LDA with Tree Priors

Tree priors organize the vocabulary of a dataset in a tree structure, contrasting with introducing topic correlations (Blei and Lafferty, 2007; He et al., 2017). Words are located at the leaf level and share ancestor internal nodes. In our use of tree priors, if two words have a lower association score, their common ancestor node will be closer to the root node, e.g., contrast (orbit, satellite) with (orbit, launch) in Figure 1.

Tree LDA (Boyd-Graber et al., 2007, tLDA) is an LDA extension that creates topics from a tree prior. A topic in tLDA is a multinomial distribution over the paths from the root to leaves. An internal node, i.e., the circles in Figure 1, is a multinomial distribution over its child nodes. The probability of a path is the product of probabilities of picking the nodes in the path, e.g., $\Pr(\text{satellite}) = 0.614 \times 0.962 \times 0.427 \approx 0.252$. Thus two paths with shared nodes have correlated weights in a topic. The generative process of tLDA is:

1. For topics $k \in \{1, \ldots, K\}$ and internal nodes n_i
   (a) Draw child distribution[1] $\boldsymbol{\pi_{k,i}} \sim \text{Dir}(\beta)$
2. For each document $d \in \{1, \ldots, D\}$
   (a) Draw topic distribution $\boldsymbol{\theta_d} \sim \text{Dir}(\alpha)$
   (b) For each token $t_{d,n}$ in document d
      i. Draw topic assignment $z_{d,n} \sim \text{Mult}(\boldsymbol{\theta_d})$
      ii. Draw path $y_{d,n}$ to word $w_{d,n}$ with probability $\prod_{(i,j)\in y_{d,n}} \pi_{z_{d,n},i,j}$

tLDA can perform different tasks using different tree priors. If we encode synonyms in the tree prior, tLDA disambiguates word senses (Boyd-Graber et al., 2007). With word translation priors, it is a multilingual topic model (Hu et al., 2014).

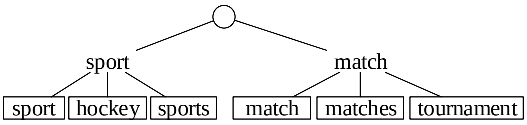

Figure 2: A two-level tree example with $N = 2$. The words in the internal nodes denote *concepts* and have no effect in tLDA.

3 Tree Prior Construction from Word Association Scores

A two-level tree is the most straightforward construction.[2] Each internal node, n_i, is a *concept* associated with a word v_i in the vocabulary. Then we sort all other words in descending order of their association scores with v_i and select the top N words (we use $N = 10$) as n_i's child leaf nodes. n_i has an additional child node which represents v_i, to ensure that every word appears at the leaf level at least once (Figure 2).[3] Thus, if the vocabulary size is V, there will be a total of $(N + 1)V$ leaf nodes.

3.1 Hierarchical Clustering (HAC)

While a two-level tree is bushy (high branching factor) and flat, hierarchical agglomerative clustering (Lukasová, 1979, HAC) reduces the number of leaf nodes and encodes levels of word association information in its hierarchy (Figure 1).

The HAC process starts from V clusters representing the V words in the vocabulary. It then repeatedly merges the two clusters with the highest association score until there is only one cluster left. If at least one of the two clusters, c_i and c_j, has multiple words, their association score is the average association score of the pairwise words from the two clusters:

$$S(c_i, c_j) = \frac{1}{|c_i||c_j|} \sum_{w_{i'} \in c_i} \sum_{w_{j'} \in c_j} S(w_{i'}, w_{j'}). \quad (1)$$

3.2 HAC with Leaf Duplication (HAC-LD)

HAC might merge words with multiple senses. For example, the word "spring" could mean either a season (similar to "summer") or a place with water (similar to "lake"). Assigning "spring" to either side will cause information loss on the other side.

To alleviate this problem, we first pair every word with its most similar word and create a cluster with the pair. Thus "spring" is paired with "summer" and "lake" simultaneously (Figure 3).

[1] Unlike other tree-based topic models such as Andrzejewski et al. (2009), all Dirichlet hyperparameters are the same for all internal nodes. Regardless of cardinality, all Dirichlet parameters are the same scalar β.

[2] The root node is not considered a level.

[3] All tree prior examples are real sub-trees of the priors built on Gigaword.

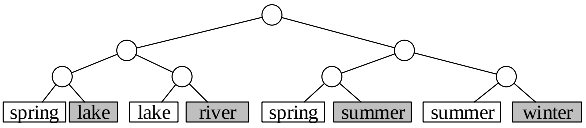

Figure 3: An example of HAC-LD for the words "spring", "summer", and "lake", whose paired words are shaded in gray. HAC-LD alleviates the problem in HAC that a word with multiple senses can only be assigned to a single cluster close to one of its senses.

Corpus	#Vocabulary	#Docs	#Tokens	#Classes
20NG	9,194	18,769	1.75M	20
Amazon	9,410	39,392	1.51M	2

Table 1: Corpus Statistics

4 Experiments

We compute two versions of word association scores from Gigaword, using word2vec (Mikolov et al., 2013) and G2 likelihood ratio (Dunning, 1993).[4] Given the word vectors $\boldsymbol{v_i}$ and $\boldsymbol{v_j}$, which represent words w_i and w_j, their word2vec association score is

$$S(w_i, w_j) = \frac{\exp\left(\boldsymbol{v_i} \cdot \boldsymbol{v_j}\right)}{\sum_k \exp\left(\boldsymbol{v_i} \cdot \boldsymbol{v_k}\right)}. \tag{2}$$

Then we apply the three tree construction algorithms to construct six tree priors. In the two-level trees, the value of N, i.e., the number of child nodes per internal node, is ten.

We use Amazon reviews (Jindal and Liu, 2008) and 20NewsGroups (Lang, 1995, 20NG). We apply the same tokenization and stopword removal methods. We then sort the words by their document frequencies and return the top words, while also removing words that appear in more than 30% of the documents (Table 1).

Both corpora are split into five folds. For classification tasks, each fold is further equally split into a development set and a test set. All the results are averaged across five-fold cross-validation using 20 topics with hyper-parameters $\alpha = \beta = 0.01$. For 20NewsGroups classification, a post's newsgroup is its label. For Amazon reviews, 4–5 star reviews have positive labels, 1–2 stars negative, and reviews with 3 stars are discarded.

Model	Tree	20NG	Amazon
LDA	–	2158.74	999.98
tLDA	G2-2LV	2214.99	1018.72
	G2-HAC	2234.34	1017.17
	G2-HAC-LD	2251.65	1015.06
tLDA	W2V-2LV	2204.94	1016.31
	W2V-HAC	2222.53	1013.07
	W2V-HAC-LD	2234.08	1017.77

Table 2: The average perplexity results on the test sets by various models. LDA gives the lowest perplexity, because tLDA models have constraint from the tree priors and sacrifice the perplexity.

4.1 Perplexity

Before evaluating topic quality, we conduct a sanity check of the models' average perplexity on the test sets (Table 2).

LDA achieves the lowest perplexity among all models on both corpora while tLDA models yield suboptimal perplexity results owing to the constraints given by tree priors. As shown in the following sections, the sacrifice in perplexity brings improvement in topic coherence, while not hurting or slightly improving extrinsic performance using topics as features in supervised classification.

Tree priors built from word2vec generally outperform the ones built using the G2 likelihood ratio. Among the three tree prior construction algorithms, the two-level is the best on the 20NewsGroups corpus. However, there is no such consistent pattern on Amazon reviews.

4.2 Topic Coherence

Instead of manually evaluating topic quality using word intrusion (Chang et al., 2009), we use an automatic alternative to compute topic coherence (Lau et al., 2014). For every topic, we extract its top ten words and compute average pairwise PMI on a reference corpus (Wikipedia as of October 8, 2014).

We include LDA and the latent concept topic model (Hu and Tsujii, 2016, LCTM) as baselines. LCTM also incorporates prior knowledge from word embeddings. It assumes that latent concepts exist in the embedding space and are Gaussian distributions over word embeddings, and a topic is a multinomial distribution over these concepts. We marginalize over concepts and obtain the probability mass of every word in every topic and compare against LDA and tLDA topics.

Topic	KLD	Model	Words
Christian	0.709	LDA	god, jesus, church, christ, christian, bible, man, christians, lord, sin
		tLDA	god, jesus, bible, christian, christ, church, christians, faith, people, lord
Security	0.720	LDA	key, encryption, chip, clipper, keys, government, public, security, system, law
		tLDA	key, encryption, chip, clipper, government, keys, privacy, security, system, public
Middle East	0.765	LDA	israel, jews, war, israeli, jewish, arab, people, world, peace, muslims
		tLDA	israel, jews, israeli, war, jewish, arab, muslims, people, peace, world
Sports	1.212	LDA	hockey, team, game, play, la, nhl, ca, period, pit, cup
		tLDA	game, team, year, games, play, players, hockey, season, win, baseball
University Research	1.647	LDA	university, information, national, april, states, year, research, number, united, american
		tLDA	university, research, information, april, national, **center**, **science**, year, number, **institute**
Health	1.914	LDA	medical, people, disease, health, cancer, *food*, *sex*, *cramer*, *men*, drug
		tLDA	health, medical, disease, drug, cancer, **patients**, **insurance**, **drugs**, **aids**, **treatment**
Images	1.995	LDA	image, ftp, software, graphics, *mail*, *data*, version, file, pub, images
		tLDA	file, image, **jpeg**, graphics, images, files, format, **bit**, **color**, program
Hardware	2.127	LDA	drive, card, mb, scsi, disk, *mac*, system, *pc*, *apple*, bit
		tLDA	drive, scsi, disk, mb, hard, **drives**, **dos**, **controller**, **ide**, system
People	2.512	LDA	armenian, people, turkish, armenians, armenia, turkey, turks, *didn*, soviet, *time*
		tLDA	armenian, turkish, armenians, armenia, turkey, turks, soviet, people, **russian**, genocide

Table 3: We sort topics into thirds by Kullback-Leibler divergence (KLD): low, medium, and high divergence between vanilla LDA and tLDA. Unique coherent words are in **black and bold**. Unique incoherent words are in *red and italic*. tLDA brings in more topic-relevant words.

Most tLDA models yield more coherent topics (Figure 4). Among all tLDA models, the two-level tree built on word2vec improves the most. LCTM performs poorly: after marginalizing out the concepts on 20NewsGroups, all its topics consist of words like "don", "dodgers", "au", "alot", "people", "alicea", "uw", "arabia", "sps", and "entry" with slight differences in ordering.

To show how subjective topic quality improves over LDA, we extract the topics given by LDA and tLDA (with two-level tree built on word2vec scores) on 20NewsGroups, pair them, and sort the pairs based on KL divergence (KLD). In Table 3, we select and present three topics from each of the top, middle, and bottom third of the sorted topics.

Topics with low KLD (Christian, Security, and Middle East) do not differ significantly. Although the topics of Sports have medium KLD and quite different words, they are generally coherent. As the KLD increases, tLDA topics have more coherent words. In University Research topics, tLDA includes more research-related words, e.g., "center", "science", and "institute". In Health topics, the tLDA topic has more coherent words like "patients", "insurance", "aids", and "treatment", while LDA includes less relevant words, e.g., "food", "sex", and "cramer".

In the topics with large KLD, tLDA topics are also more coherent. For instance, in the Images topics, the LDA topic contains less relevant words like "mail" and "data", while the tLDA topic mostly consists of words related to images, and even includes words like "jpeg", "color", and "bit" that are not among the top words in the LDA topic. In the topics for Hardware, there are more words closer to the hardware level for tLDA, e.g., "drives", "dos", "controller", and "ide", in contrast to LDA, e.g., "mac", "pc", and "apple". tLDA also ranks hardware-related words higher. For instance, "scsi" and "disk" come before "mb". The words in the topics for People are generally coherent, except "didn" and "time" in the LDA topic.

4.3 Extrinsic Classification

To extrinsically evaluate topic quality, we use binary and multi-class classification on Amazon reviews and 20NewsGroups corpora using SVM-light (Joachims, 1998) and SVM-multiclass.[5] We tune the parameter C, the trade-off between training error and margin, on the development set and apply the trained model with the best performance on the development set to the test set. The classification accuracies are given in Table 4.

We compare the accuracies of features of bag-of-words (BOW) and LDA/LCTM/tLDA topics. For the tLDA models with two-level and HAC-LD tree priors, the path assignment is an additional feature.[6] We also include the features of BOW and the average word vector for the document (BOW+VEC).

[5] SVM-light: http://svmlight.joachims.org/. SVM-multiclass: https://www.cs.cornell.edu/people/tj/svm_light/svm_multiclass.html.

[6] tLDA models with HAC prior do not have this feature, because the paths have a 1-to-1 mapping with the vocabulary.

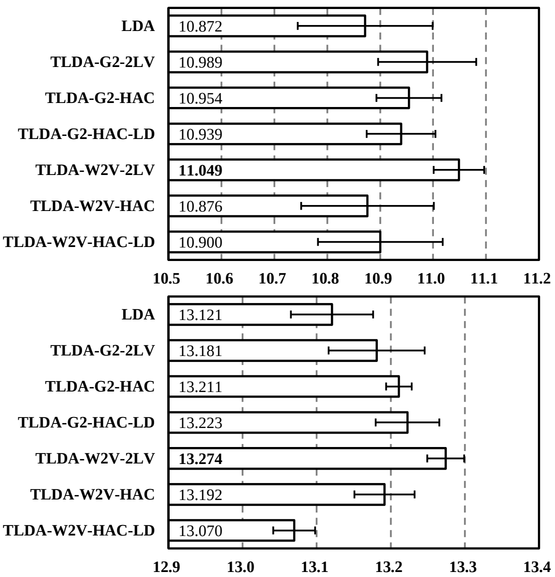

Figure 4: Average PMI of top 10 words in topics given by models on 20NewsGroups (upper) and Amazon (lower). Most tLDA topics are more coherent than LDA topics. The PMI of LCTM are too low to be included: 8.862±0.657 on 20NewsGroups and 6.340±1.208 on Amazon reviews.

Features based on most tLDA topics perform at least as well as LDA-based topic features; with no statistically significant differences, our tree priors do not sacrifice extrinsic performance for improving topic coherence. In addition, the path assignment feature improves topical classification but not sentiment classification. Although the word2vec feature (BOW+VEC) performs the best on Amazon reviews, it lacks the interpretability of topic models.

4.4 Learned Trees
