Abstract

We propose a new encoder-decoder approach to learn distributed sentence representations that are applicable to multiple purposes. The model is learned by using a convolutional neural network as an encoder to map an input sentence into a continuous vector, and using a long short-term memory recurrent neural network as a decoder. Several tasks are considered, including sentence reconstruction and future sentence prediction. Further, a hierarchical encoder-decoder model is proposed to encode a sentence to predict multiple future sentences. By training our models on a large collection of novels, we obtain a highly generic convolutional sentence encoder that performs well in practice. Experimental results on several benchmark datasets, and across a broad range of applications, demonstrate the superiority of the proposed model over competing methods.

1 Introduction

Learning sentence representations is central to many natural language modeling applications. The aim of a model for this task is to learn fixed-length feature vectors that encode the semantic and syntactic properties of sentences. Deep learning techniques have shown promising performance on sentence modeling, via feedforward neural networks (Huang et al., 2013), recurrent neural networks (RNNs) (Hochreiter and Schmidhuber, 1997), convolutional neural networks (CNNs) (Kalchbrenner et al., 2014; Kim, 2014; Shen et al., 2014), and recursive neural networks (Socher et al., 2013). Most of these models are *task-dependent*: they are trained specifically for a certain task. However, these methods may become inefficient when we need to repeatedly learn sentence representations for a large number of different tasks, because they may require retraining a new model for each individual task. In this paper, in contrast, we are primarily interested in learning *generic* sentence representations that can be used across domains.

Several approaches have been proposed for learning generic sentence embeddings. The paragraph-vector model of Le and Mikolov (2014) incorporates a global context vector into the log-linear neural language model (Mikolov et al., 2013) to learn the sentence representation; however, at prediction time, one needs to perform gradient descent to compute a new vector. The sequence autoencoder of Dai and Le (2015) describes an encoder-decoder model to reconstruct the input sentence, while the skip-thought model of Kiros et al. (2015) extends the encoder-decoder model to reconstruct the surrounding sentences of an input sentence. Both the encoder and decoder of the methods above are modeled as RNNs.

CNNs have recently achieved excellent results in various task-dependent natural language applications as the sentence encoder (Kalchbrenner et al., 2014; Kim, 2014; Hu et al., 2014). This motivates us to propose a CNN encoder for learning generic sentence representations within the framework of encoder-decoder models proposed by Sutskever et al. (2014); Cho et al. (2014). Specifically, a CNN encoder performs convolution and pooling operations on an input sentence, then uses a fully-connected layer to produce a fixed-length encoding of the sentence. This encoding vector is then fed into a long short-term memory (LSTM) recurrent network to produce a target sentence. Depending on the task, we propose three models: (*i*) *CNN-LSTM autoencoder*: this model seeks to reconstruct the original input sentence, by capturing the *intra*-sentence information; (*ii*) *CNN-LSTM future*

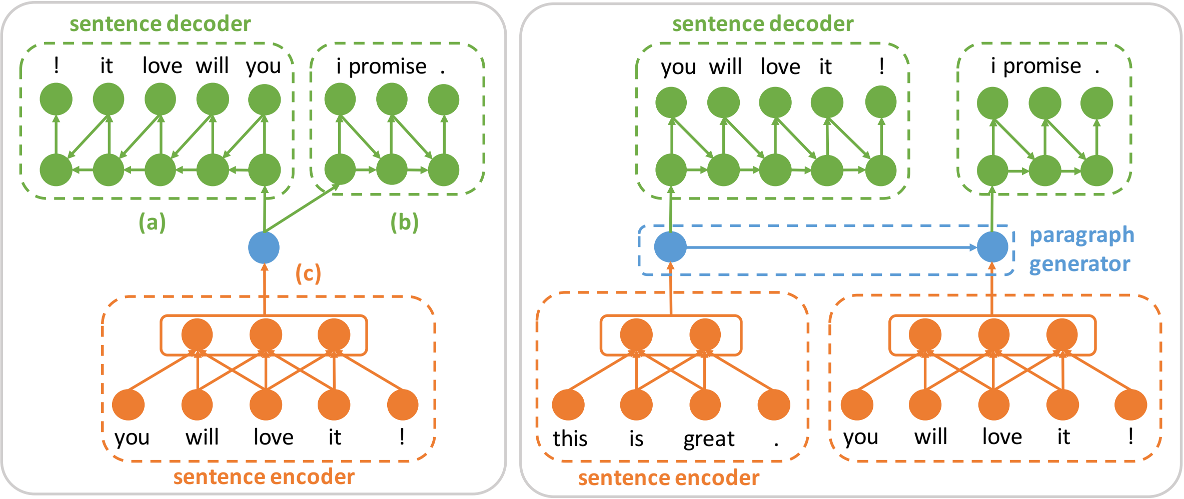

Figure 1: Illustration of the CNN-LSTM encoder-decoder models. The sentence encoder is a CNN, the sentence decoder is an LSTM, and the paragraph generator is another LSTM. (Left) (a)+(c) represents the autoencoder; (b)+(c) represents the future predictor; (a)+(b)+(c) represents the composite model. (Right) hierarchical model. In this example, the input contiguous sentences are: *this is great. you will love it! i promise*.

predictor: this model aims to predict a future sentence, by leveraging *inter*-sentence information; (*iii*) *CNN-LSTM composite model*: in this case, there are two LSTMs, decoding the representation to the input sentence itself and a future sentence. This composite model aims to learn a sentence encoder that captures both *intra*- and *inter*-sentence information.

The proposed CNN-LSTM future predictor model only considers the immediately subsequent sentence as context. In order to capture longer-term dependencies between sentences, we further introduce a hierarchical encoder-decoder model. This model abstracts the RNN language model of Mikolov et al. (2010) to the sentence level. That is, instead of using the current word in a sentence to predict future words (sentence continuation), we encode a sentence to predict multiple future sentences (paragraph continuation). This model is termed *hierarchical CNN-LSTM model*.

As in Kiros et al. (2015), we first train our proposed models on a large collection of novels. We then evaluate the CNN sentence encoder as a generic feature extractor for 8 tasks: semantic relatedness, paraphrase detection, image-sentence ranking and 5 standard classification benchmarks. In these experiments, we train a linear classifier on top of the extracted sentence features, without additional fine-tuning of the CNN. We show that our trained sentence encoder yields generic representations that perform as well as, or better, than those of Kiros et al. (2015); Hill et al. (2016), in all the tasks considered.

Summarizing, the main contribution of this paper is a new class of CNN-LSTM encoder-decoder models that is able to leverage the vast quantity of unlabeled text for learning generic sentence representations. Inspired by the skip-thought model (Kiros et al., 2015), we have further explored different variants: (*i*) CNN is used as the sentence encoder rather than RNN; (*ii*) larger context windows are considered: we propose the hierarchical CNN-LSTM model to encode a sentence for predicting multiple future sentences.

2 Model description

2.1 CNN-LSTM model

Consider the sentence pair (s_x, s_y). The encoder, a CNN, encodes the first sentence s_x into a feature vector $\boldsymbol{z}$, which is then fed into an LSTM decoder that predicts the second sentence s_y. Let $w_x^t \in \{1, \ldots, V\}$ represent the t-th word in sentences s_x, where w_x^t indexes one element in a V-dimensional set (vocabulary); w_y^t is defined similarly w.r.t. s_y. Each word w_x^t is embedded into a k-dimensional vector $\boldsymbol{x}_t = \mathbf{W}_e[w_x^t]$, where $\mathbf{W}_e \in \mathbb{R}^{k \times V}$ is a word embedding matrix (learned), and notation $\mathbf{W}_e[v]$ denotes the v-th column of matrix $\mathbf{W}_e$. Similarly, we let $\boldsymbol{y}_t = \mathbf{W}_e[w_y^t]$.

CNN encoder The CNN architecture in Kim (2014); Collobert et al. (2011) is used for sentence encoding, which consists of a convolution layer and a max-pooling operation over the entire sentence for each feature map. A sentence of length T (padded where necessary) is represented as a matrix $\mathbf{X} \in \mathbb{R}^{k \times T}$, by concatenating its word embeddings as columns, *i.e.*, the t-th column of $\mathbf{X}$ is $\boldsymbol{x}_t$.

A convolution operation involves a filter $\mathbf{W}_c \in \mathbb{R}^{k \times h}$, applied to a window of h words to produce a new feature. According to Collobert et al. (2011), we can induce one feature map $\boldsymbol{c} = f(\mathbf{X} * \mathbf{W}_c + \boldsymbol{b}) \in \mathbb{R}^{T-h+1}$, where $f(\cdot)$ is a nonlinear activation function such as the hyperbolic tangent used in our experiments, $\boldsymbol{b} \in \mathbb{R}^{T-h+1}$ is a bias vector, and $*$ denotes the convolutional operator. Convolving the same filter with the h-gram at every position in the sentence allows the features to be extracted independently of their position in the sentence. We then apply a max-over-time pooling operation (Collobert et al., 2011) to the feature map and take its maximum value, *i.e.*, $\hat{c} = \max\{\boldsymbol{c}\}$, as the feature corresponding to this particular filter. This pooling scheme tries to capture the most important feature, *i.e.*, the one with the highest value, for each feature map, effectively filtering out less informative compositions of words. Further, pooling also guarantees that the extracted features are independent of the length of the input sentence.

The above process describes how one feature is extracted from one filter. In practice, the model uses multiple filters with varying window sizes (Kim, 2014). Each filter can be considered as a linguistic feature detector that learns to recognize a specific class of n-grams (or h-grams, in the above notation). However, since the h-grams are computed in the embedding space, the model naturally handles similar h-grams composed of synonyms. Assume we have m window sizes, and for each window size, we use d filters; then we obtain a md-dimensional vector to represent a sentence.

Compared with the LSTM encoders used in Kiros et al. (2015); Dai and Le (2015); Hill et al. (2016), a CNN encoder may have the following advantages. First, the sparse connectivity of a CNN, which indicates fewer parameters are required, typically improves its statistical efficiency as well as reduces memory requirements (Goodfellow et al., 2016). For example, excluding the number of parameters used in the word embeddings, our trained CNN sentence encoder has 3 million parameters, while the skip-thought vector of Kiros et al. (2015) contains 40 million parameters. Second, a CNN is easy to implement in parallel over the whole sentence, while an LSTM needs sequential computation.

LSTM decoder The CNN encoder maps sentence s_x into a vector $\boldsymbol{z}$. The probability of a length-T sentence s_y given the encoded feature vector $\boldsymbol{z}$ is defined as

$$p(s_y|\boldsymbol{z}) = \prod_{t=1}^{T} p(w_y^t | w_y^0, \dots, w_y^{t-1}, \boldsymbol{z}) \quad (1)$$

where w_y^0 is defined as a special start-of-the-sentence token. All the words in the sentence are sequentially generated using the RNN, until the end-of-the-sentence symbol is generated. Specifically, each conditional $p(w_y^t | w_y^{<t}, \boldsymbol{z})$, where $< t = \{0, \dots, t-1\}$, is specified as softmax$(\mathbf{V}\boldsymbol{h}_t)$, where $\boldsymbol{h}_t$, the hidden units, are recursively updated through $\boldsymbol{h}_t = \mathcal{H}(\boldsymbol{y}_{t-1}, \boldsymbol{h}_{t-1}, \boldsymbol{z})$, and $\boldsymbol{h}_0$ is defined as a zero vector ($\boldsymbol{h}_0$ is not updated during training). $\mathbf{V}$ is a weight matrix used for computing a distribution over words. Bias terms are omitted for simplicity throughout the paper. The transition function $\mathcal{H}(\cdot)$ is implemented with an LSTM (Hochreiter and Schmidhuber, 1997).

Given the sentence pair (s_x, s_y), the objective function is the sum of the log-probabilities of the target sentence conditioned on the encoder representation in (1): $\sum_{t=1}^{T} \log p(w_y^t | w_y^{<t}, \boldsymbol{z})$. The total objective is the above objective summed over all the sentence pairs.

Applications Inspired by Srivastava et al. (2015), we propose three models: (*i*) an autoencoder, (*ii*) a future predictor, and (*iii*) the composite model. These models share the same CNN-LSTM model architecture, but are different in terms of the choices of the target sentence. An illustration of the proposed encoder-decoder models is shown in Figure 1(left).

The autoencoder (i) aims to reconstruct the same sentence as the input. The intuition behind this is that an autoencoder learns to represent the data using features that explain its own important factors of variation, and hence model the internal structure of sentences, effectively capturing the *intra*-sentence information. Another natural task is encoding an input sentence to predict the subsequent sentence. The future predictor (ii) achieves this, effectively capturing the *inter*-sentence information, which has been shown to be useful to learn the semantics of a sentence (Kiros et al., 2015). These two tasks can be combined to create a composite model (*iii*), where the CNN encoder is asked to learn a feature vector that is useful to simultaneously reconstruct the input sentence and predict a future sentence. This composite model encourages the sentence encoder to incorporate contextual information both within and beyond the sentence.

2.2 Hierarchical CNN-LSTM model

The future predictor described in Section 2.1 only considers the immediately subsequent sentence as context. By utilizing a larger surrounding context, it is likely that we can learn even higher-quality sentence representations. Inspired by the standard RNN-based language model (Mikolov et al., 2010) that uses the current word to predict future words, we propose a hierarchical encoder-decoder model that encodes the current sentence to predict multiple future sentences. An illustration of the hierarchical model is shown in Figure 1(right), with details provided in Figure 2.

Our proposed hierarchical model characterizes the hierarchy *word-sentence-paragraph*. A paragraph is modeled as a sequence of sentences, and each sentence is modeled as a sequence of words. Specifically, assume we are given a paragraph $D = (s_1, \ldots, s_L)$, that consists of L sentences. The probability for paragraph D is then defined as

$$p(D) = \prod_{\ell=1}^{L} p(s_\ell | s_{<\ell}) \qquad (2)$$

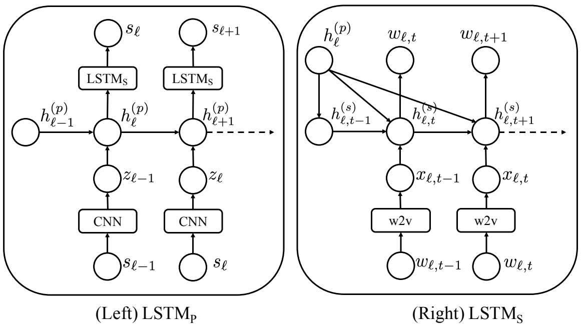
where s_0 is defined as a special start-of-the-paragraph token. As shown in Figure 2(left), each $p(s_\ell | s_{<\ell})$ in (2) is calculated as

$$p(s_\ell | s_{<\ell}) = p(s_\ell | \boldsymbol{h}_\ell^{(p)}) \qquad (3)$$

$$\boldsymbol{h}_\ell^{(p)} = \text{LSTM}_p(\boldsymbol{h}_{\ell-1}^{(p)}, \boldsymbol{z}_{\ell-1}) \qquad (4)$$

$$\boldsymbol{z}_{\ell-1} = \text{CNN}(s_{\ell-1}) \qquad (5)$$

where $\boldsymbol{h}_\ell^{(p)}$ denotes the ℓ-th hidden state of the LSTM paragraph generator, and $\boldsymbol{h}_0^{(p)}$ is fixed as a zero vector. The CNN in (5) is as described in Section 2.1, encoding the sentence $s_{\ell-1}$ into a vector representation $\boldsymbol{z}_{\ell-1}$.



(Left) LSTM$_\text{P}$ (Right) LSTM$_\text{S}$

Figure 2: Detailed illustration of the hierarchical CNN-LSTM model. (Left) LSTM paragraph generator. (Right) LSTM sentence decoder.

Equation (4) serves as the paragraph-level language model (Mikolov et al., 2010), which encodes all the previous sentence representations $\boldsymbol{z}_{<\ell}$ into a vector representation $\boldsymbol{h}_\ell^{(p)}$. This hidden state $\boldsymbol{h}_\ell^{(p)}$ is used to guide the generation of the ℓ-th sentence through the decoder (3), which is defined as

$$p(s_\ell | \boldsymbol{h}_\ell^{(p)}) = \prod_{t=1}^{T_\ell} p(w_{\ell,t} | w_{\ell,<t}, \boldsymbol{h}_\ell^{(p)}) \qquad (6)$$

where $w_{\ell,0}$ is defined as a special start-of-the-sentence token. T_ℓ is the length of sentence ℓ, and $w_{\ell,t}$ denotes the t-th word in sentence ℓ. As shown in Figure 2(right), each $p(w_{\ell,t} | w_{\ell,<t}, \boldsymbol{h}_\ell^{(p)})$ in (6) is calculated as

$$p(w_{\ell,t} | w_{\ell,<t}, \boldsymbol{h}_\ell^{(p)}) = \text{softmax}(\mathbf{V} \boldsymbol{h}_{\ell,t}^{(s)}) \qquad (7)$$

$$\boldsymbol{h}_{\ell,t}^{(s)} = \text{LSTM}_s(\boldsymbol{h}_{\ell,t-1}^{(s)}, \boldsymbol{x}_{\ell,t-1}, \boldsymbol{h}_\ell^{(p)}) \qquad (8)$$

where $\boldsymbol{h}_{\ell,t}^{(s)}$ denotes the t-th hidden state of the LSTM decoder for sentence ℓ, $\boldsymbol{x}_{\ell,t-1}$ denotes the word embedding for $w_{\ell,t-1}$, and $\boldsymbol{h}_{\ell,0}^{(s)}$ is fixed as a zero vector for all $\ell = 1, \ldots, L$. $\mathbf{V}$ is a weight matrix used for computing distribution over words.

3 Related work

Various methods have been proposed for sentence modeling, which generally fall into two categories. The first consists of models trained specifically for a certain task, typically combined with downstream applications. Several models have been proposed along this line, ranging from simple additional composition of the word vectors (Mitchell and Lapata, 2010; Yu and Dredze, 2015; Iyyer et al., 2015) to those based on complex nonlinear functions like recursive neural networks (Socher et al., 2011, 2013), convolutional neural networks (Kalchbrenner et al., 2014; Hu et al., 2014; Johnson and Zhang, 2015; Zhang et al., 2015; Gan et al., 2017), and recurrent neural networks (Tai et al., 2015; Lin et al., 2017).

The other category consists of methods aiming to learn generic sentence representations that can be used across domains. This includes the paragraph vector (Le and Mikolov, 2014), skip-thought vector (Kiros et al., 2015), and the sequential denoising autoencoders (Hill et al., 2016). Hill et al. (2016) also proposed a sentence-level log-linear bag-of-words (BoW) model, where a BoW representation of an input sentence is used to predict adjacent sentences that are also represented as BoW. Most recently, Wieting et al. (2016); Arora et al. (2017); Pagliardini et al. (2017) proposed methods in which sentences are represented as a weighted average of fixed (pre-trained) word vectors. Our model falls into this category, and is most related to Kiros et al. (2015).

However, there are two key aspects that make our model different from Kiros et al. (2015). First, we use CNN as the sentence encoder. The combination of CNN and LSTM has been considered in image captioning (Karpathy and Fei-Fei, 2015), and in some recent work on machine translation (Kalchbrenner and Blunsom, 2013; Meng et al., 2015; Gehring et al., 2016). Our utilization of a CNN is different, and more importantly, the ultimate goal of our model is different. Our work aims to use a CNN to learn generic sentence embeddings.

Second, we use the hierarchical CNN-LSTM model to predict multiple future sentences, rather than the surrounding two sentences as in Kiros et al. (2015). Utilizing a larger context window aids our model to learn better sentence representations, capturing longer-term dependencies between sentences. Similar work to this hierarchical language modeling can be found in Li et al. (2015); Sordoni et al. (2015); Lin et al. (2015); Wang and Cho (2016). Specifically, Li et al. (2015); Sordoni et al. (2015) uses an LSTM for the sentence encoder, while Lin et al. (2015) uses a bag-of-words to represent sentences.

4 Experiments

We first provide qualitative analysis of our CNN encoder, and then present experimental results on 8 tasks: 5 classification benchmarks, paraphrase detection, semantic relatedness and image-sentence ranking. As in Kiros et al. (2015), we evaluate the capabilities of our encoder as a generic feature extractor. To further demonstrate the advantage of our learned generic sentence representations, we also fine-tune our trained sentence encoder on the 5 classification benchmarks. All the CNN-LSTM models are trained using the BookCorpus dataset (Zhu et al., 2015), which consists of 70 million sentences from over 7000 books.

We train four models in total: (*i*) an autoencoder, (*ii*) a future predictor, (*iii*) the composite model, and (*iv*) the hierarchical model. For the CNN encoder, we employ filter windows (h) of sizes $\{3,4,5\}$ with 800 feature maps each, hence each sentence is represented as a 2400-dimensional vector. For both, the LSTM sentence decoder and paragraph generator, we use one hidden layer of 600 units.

The CNN-LSTM models are trained with a vocabulary size of 22,154 words. In order to learn a generic sentence encoder that can encode a large number of possible words, we use two methods of considering words not in the training set. Suppose we have a large pretrained word embedding matrix, such as the publicly available *word2vec* vectors (Mikolov et al., 2013), in which all test words are assumed to reside.

The first method learns a linear mapping between the *word2vec* embedding space $\mathcal{V}_{w2v}$ and the learned word embedding space $\mathcal{V}_{cnn}$ by solving a linear regression problem (Kiros et al., 2015). Thus, any word from $\mathcal{V}_{w2v}$ can be mapped into $\mathcal{V}_{cnn}$ for encoding sentences. The second method fixes the word vectors in $\mathcal{V}_{cnn}$ as the corresponding word vectors in $\mathcal{V}_{w2v}$, and we do not update the word embedding parameters during training. Thus, any word vector from $\mathcal{V}_{w2v}$ can be naturally used to encode sentences. By doing this, our trained sentence encoder can successfully encode 931,331 words.

For training, all weights in the CNN and non-recurrent weights in the LSTM are initialized from a uniform distribution in [-0.01,0.01]. Orthogonal initialization is employed on the recurrent matrices in the LSTM. All bias terms are initialized to zero. The initial forget gate bias for LSTM is set to 3. Gradients are clipped if the norm of the parameter vector exceeds 5 (Sutskever et al., 2014). The Adam algorithm (Kingma and Ba, 2015) with learning rate 2×10^{-4} is utilized for optimization. For all the CNN-LSTM models, we use mini-batches of size 64. For the hierarchical CNN-LSTM model, we use mini-batches of size 8, and each paragraph is composed of 8 sentences. We do not perform any regularization other than dropout (Srivastava et al., 2014). All experiments are implemented

A	you needed me?	this is great.	its lovely to see you.	he had thought he was going crazy.
B	you got me?	this is awesome.	its great to meet you.	i felt like i was going crazy.
C	i got you.	you are awesome.	its great to meet him.	i felt like to say the right thing.
D	i needed you.	you are great.	its lovely to see him.	he had thought to say the right thing.

Table 1: Vector “compositionality” using element-wise addition and subtraction. Let $z(s)$ denote the vector representation z of a given sentence s. We first calculate $z^{\star}$=z(A)-z(B)+z(C). The resulting vector is then sent to the LSTM to generate sentence D.

Query and nearest sentence
johnny nodded his curly head , and then his breath eased into an even rhythm . aiden looked at my face for a second , and then his eyes trailed to my extended hand .
i yelled in frustration , throwing my hands in the air . i stand up , holding my hands in the air .
i loved sydney , but i was feeling all sorts of homesickness . i loved timmy , but i thought i was a self-sufficient person .
“ i brought sad news to mistress betty , ” he said quickly , taking back his hand . “ i really appreciate you taking care of lilly for me , ” he said sincerely , handing me the money .
“ i am going to tell you a secret , ” she said quietly , and he leaned closer . “ you are very beautiful , ” he said , and he leaned in .
she kept glancing out the window at every sound , hoping it was jackson coming back . i kept checking the time every few minutes , hoping it would be five oclock .
leaning forward , he rested his elbows on his knees and let his hands dangle between his legs . stepping forward , i slid my arms around his neck and then pressed my body flush against his .
i take tris ’s hand and lead her to the other side of the car , so we can watch the city disappear behind us . i take emma ’s hand and lead her to the first taxi , everyone else taking the two remaining cars .

Table 2: Query-retrieval examples. In each case (block of rows), the first sentence is a query, while the second sentence is the retrieved result from a random subset of 1 million sentences from the BookCorpus dataset.

in Theano (Bastien et al., 2012), using a NVIDIA GeForce GTX TITAN X GPU with 12GB memory.

4.1 Qualitative analysis

We first demonstrate that the sentence representation learned by our model exhibits a structure that makes it possible to perform analogical reasoning using simple vector arithmetics, as illustrated in Table 1. It demonstrates that the arithmetic operations on the sentence representations correspond to word-level addition and subtractions. For instance, in the 3rd example, our encoder captures that the difference between sentence B and C is *“you"* and *“him"*, so that the former word in sentence A is replaced by the latter (*i.e.*, *“you”*-*“you”*+*“him”*=*“him”*), resulting in sentence D.

Table 2 shows nearest neighbors of sentences from a CNN-LSTM autoencoder trained on the BookCorpus dataset. Nearest neighbors are scored by cosine similarity from a random sample of 1 million sentences from the BookCorpus dataset. As can be seen, our encoder learns to accurately capture semantic and syntax of the sentences.

4.2 Quantitative evaluations

Classification benchmarks We first study the task of sentence classification on 5 datasets: *MR* (Pang and Lee, 2005), *CR* (Hu and Liu, 2004), *SUBJ* (Pang and Lee, 2004), *MPQA* (Wiebe et al., 2005) and *TREC* (Li and Roth, 2002). On all the datasets, we separately train a logistic regression model on top of the extracted sentence features. We restrict our comparison to methods that also aims to learn generic sentence embeddings for fair comparison. We also provide the state-of-the-art results using task-dependent learning methods for reference. Results are summarized in Table 3. Our CNN encoder provides better results than the combine-skip model of Kiros et al. (2015) on all the 5 datasets.

We highlight some observations. First, the autoencoder performs better than the future predictor, indicating that the *intra*-sentence information may be more important for classification than the *inter*-sentence information. Second, the hierarchi-

Table 3: Classification accuracies on several standard benchmarks. The last column shows results on the task of paraphrase detection, where the evaluation metrics are classification accuracy and F1 score. †The first and second block in our results were obtained using the first and second method of considering words not in the training set, respectively. ‡"combine" means concatenating the feature vectors learned from both the hierarchical model and the composite model.

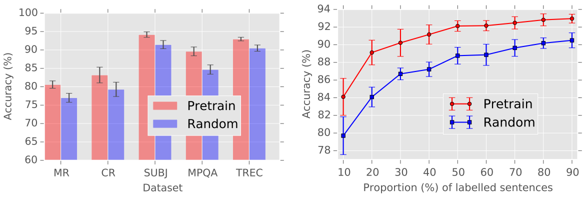

Figure 3: (Left) Effect of pretraining on the 5 classification benchmarks. The error bars are over 10 different runs. (Right) Effect of pretraining on accuracy for the TREC dataset, in terms of change in the size of the labeled training set. The error bars are over 10 different samples of training sets. Pretraining means initializing the CNN parameters from the trained CNN-LSTM composite model.

cal model performs better than the future predictor, demonstrating the importance of capturing long-term dependencies across *multiple* sentences. Our combined model, which concatenates the feature vectors learned from both the hierarchical model and the composite model, performs the best. This may be due to that: (*i*) both *intra-* and long-term *inter*-sentence information are leveraged; (*ii*) it is easier to linearly separate the feature vectors in higher dimensional spaces. Further, using (fixed) pre-trained word embeddings consistently provides better performance than using the learned word embeddings. This may be due to that *word2vec* provides more generic word representations, since it is trained on the large Google News dataset (containing 100 billion words) (Mikolov et al., 2013).

To further demonstrate the advantage of the learned generic representations, we train a CNN classifier (*i.e.*, a CNN encoder with a logistic regression model on top) with two different initialization strategies: random initialization and initialization with trained parameters from the CNN-LSTM composite model. Results are shown in Figure 3(left). The pretraining provides substantial improvements (3.52% on average) over random initialization of CNN parameters. Figure 3(right) shows the effect of pretraining as the number of labeled sentences is varied. For the TREC dataset, the performance improves from 79.7% to 84.1% when only 10% sentences are labeled. As the size of the set of labeled sentences grows, the improvement becomes smaller, as expected. For future work, our CNN-LSTM model can be also used for semi-supervised

learning, with the autoencoder on all the data (labeled and unlabled), and the classifier only on the labeled data.

Paraphrase detection Now we consider paraphrase detection on the *MSRP* dataset (Dolan et al., 2004). On this task, one needs to predict whether or not two sentences are paraphrases. The training set consists of 4076 sentence pairs, and the test set has 1725 pairs. As in Tai et al. (2015), given two sentence representations $\boldsymbol{z}_x$ and $\boldsymbol{z}_y$, we first compute their element-wise product $\boldsymbol{z}_x \odot \boldsymbol{z}_y$ and their absolute difference $|\boldsymbol{z}_x - \boldsymbol{z}_y|$, and then concatenate them together. A logistic regression model is trained on top of the concatenated features to predict whether two sentences are paraphrases. We present our results on the last column of Table 3. Our best result is better than the other results that use task-independent methods.

Image-sentence ranking We consider the task of image-sentence ranking, which aims to retrieve items in one modality given a query from the other. We use the COCO dataset (Lin et al., 2014), which contains 123,287 images each with 5 captions. For development and testing we use the same splits as Karpathy and Fei-Fei (2015). The development and test sets each contain 5000 images. We further split them into 5 random sets of 1000 images, and report the average performance over the 5 splits. Performance is evaluated using Recall@K, which measures the average times a correct item is found within the top-K retrieved results. We also report the median rank of the closest ground truth result in the ranked list.

We represent images using 4096-dimensional feature vectors from VggNet (Simonyan and Zisserman, 2015). Each caption is encoded using our trained CNN encoder. The training objective is the same pairwise ranking loss as used in Kiros et al. (2015), which takes the form of $\max(0, \alpha - f(x_n, y_n) + f(x_n, y_m))$, where $f(\cdot,\cdot)$ is the image-sentence score. (x_n, y_n) denotes the related image-sentence pair, and (x_n, y_m) is the randomly sampled unrelated image-sentence pair with $n \neq m$. For image retrieval from sentences, x denotes the caption, y denotes the image, and *vice versa*. The objective is to force the matching score of the related pair (x_n, y_n) to be greater than the unrelated pair (x_n, y_m) by a margin α, which is set to 0.1 in our experiments.

Table 4 shows our results. Consistent with previous experiments, we empirically found that the encoder trained using the fixed word embedding performed better on this task, hence only results using this method are reported. As can be seen, we obtain the same median rank as in Kiros et al. (2015), indicating that our encoder is as competitive as the skip-thought vectors (Kiros et al., 2015). The performance gain between our encoder and the combine-skip model of Kiros et al. (2015) on the R@1 score is significant, which shows that the CNN encoder has more discriminative power on retrieving the most correct item than the skip-thought vector.

Semantic relatedness For our final experiment, we consider the task of semantic relatedness on the *SICK* dataset (Marelli et al., 2014), consisting of 9927 sentence pairs. Given two sentences, our goal is to produce a real-valued score between $[1, 5]$ to indicate how semantically related two sentences are, based on human generated scores. We compute a feature vector representing the pair of sentences in the same way as on the MSRP dataset. We follow the method in Tai et al. (2015), and use the cross-entropy loss for training. Results are summarized in Table 5. Our result is better than the combine-skip model of Kiros et al. (2015). This suggests that CNN also provides competitive performance at matching human relatedness judgements.

5 Conclusion

We presented a new class of CNN-LSTM encoder-decoder models to learn sentence representations from unlabeled text. Our trained convolutional encoder is highly generic, and can be an alternative to the skip-thought vectors of Kiros et al. (2015). Compelling experimental results on several tasks demonstrated the advantages of our approach. In future work, we aim to use more advanced CNN architectures (Conneau et al., 2016) for learning generic sentence embeddings.

Repeat before Forgetting: Spaced Repetition for Efficient and Effective Training of Neural Networks

Hadi Amiri, Timothy A. Miller, Guergana Savova
Boston Children's Hospital Informatics Program, Harvard Medical School
{firstname.lastname}@childrens.harvard.edu

Abstract

We present a novel approach for training artificial neural networks. Our approach is inspired by broad evidence in psychology that shows human learners can learn efficiently and effectively by increasing intervals of time between subsequent reviews of previously learned materials (spaced repetition). We investigate the analogy between training neural models and findings in psychology about human memory model and develop an efficient and effective algorithm to train neural models. The core part of our algorithm is a cognitively-motivated scheduler according to which training instances and their "reviews" are spaced over time. Our algorithm uses only 34-50% of data per epoch, is 2.9-4.8 times faster than standard training, and outperforms competing state-of-the-art baselines.[1]

1 Introduction

Deep neural models are known to be computationally expensive to train even with fast hardware (Sutskever et al., 2014; Wu et al., 2016). For example, it takes three weeks to train a deep neural machine translation system on 100 Graphics Processing Units (GPUs) (Wu et al., 2016). Furthermore, a large amount of data is usually required to train effective neural models (Goodfellow et al., 2016; Hirschberg and Manning, 2015).

Bengio et al. (2009) and Kumar et al. (2010) developed training paradigms which are inspired by the learning principle that humans can learn more effectively when training starts with *easier* concepts and gradually proceeds with more *difficult* concepts. Since these approaches are motivated by a "starting small" strategy they are called *curriculum* or *self-paced* learning.

In this paper, we present a novel training paradigm which is inspired by the broad evidence in psychology that shows human ability to retain information improves with repeated exposure and exponentially decays with delay since last exposure (Cepeda et al., 2006; Averell and Heathcote, 2011). Spaced repetition was presented in psychology (Dempster, 1989) and forms the building block of many educational devices, including flashcards, in which small pieces of information are repeatedly presented to a learner on a schedule determined by a spaced repetition algorithm. Such algorithms show that human learners can learn efficiently and effectively by increasing intervals of time between subsequent reviews of previously learned materials (Dempster, 1989; Novikoff et al., 2012).

We investigate the analogy between training neural models and findings in psychology about human memory model and develop a spaced repetition algorithm (named Repeat before Forgetting, RbF) to efficiently and effectively train neural models. The core part of our algorithm is a scheduler that ensures a given neural network spends more time working on difficult training instances and less time on easier ones. Our scheduler is inspired by factors that affect human memory retention, namely, *difficulty* of learning materials, *delay* since their last review, and *strength* of memory. The scheduler uses these factors to lengthen or shorten review intervals with respect to individual learners and training instances. We evaluate schedulers based on their scheduling accuracy, i.e., accuracy in estimating network memory retention with respect to previously-seen instances, as well as their effect on the efficiency and effectiveness of downstream neural networks.[2]

[1] Our code is available at scholar.harvard.edu/hadi/RbF/

[2] In this paper, we use the terms memory retention, recall, and learning interchangeably.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2401–2410
Copenhagen, Denmark, September 7–11, 2017.

The contributions of this paper are: (1) we show that memory retention in neural networks is affected by the same (known) factors that affect memory retention in humans, (2) we present a novel training paradigm for neural networks based on spaced repetition, and (3) our approach can be applied without modification to any neural network.

Our best RbF algorithm uses 34-50% of training data per epoch while producing similar results to state-of-the-art systems on three tasks, namely sentiment classification, image categorization, and arithmetic addition.[3] It also runs 2.9-4.8 times faster than standard training, and outperforms competing state-of-the-art baselines.

2 Neural and Brain Memory Models

Research in psychology describes the following memory model for human learning: the probability that a human recalls a previously-seen item (e.g., the Korean translation of a given English word) depends on the *difficulty* of the item, *delay* since last review of the item, and the *strength* of the human memory. The relation between these indicators and memory retention has the following functional form (Reddy et al., 2016; Ebbinghaus, 1913):

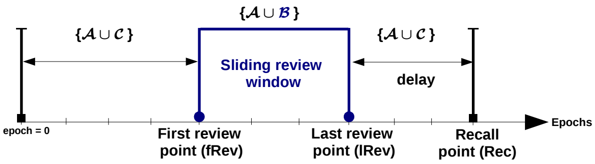
$$\Pr(recall) = \exp(-\frac{difficulty \times delay}{strength}). \quad (1)$$

An accurate memory model enables estimating the time by which an item might be forgotten by a learner so that a review can be scheduled for the learner before that time.

We investigate the analogy between the above memory model and memory model of artificial neural networks. Our intuition is that if the probability that a network recalls an item (e.g., correctly predicts its category) depends on the same factors (difficulty of the item, delay since last review of the item, or strength of the network), then we can develop spaced repetition algorithms to efficiently and effectively train neural networks.

2.1 Recall Indicators

We design a set of preliminarily experiments to directly evaluate the effect of the aforementioned factors (recall indicators) on memory retention in neural networks. For this purpose, we use a set of training instances that are partially made available to the network during training. This scheme will allow us to intrinsically examine the effect of recall indicators on memory retention in isolation from external effects such as size of training data, number of training epochs, etc.



{$\mathcal{A} \cup \mathcal{B}$}
{$\mathcal{A} \cup \mathcal{C}$}
Sliding review window
{$\mathcal{A} \cup \mathcal{C}$}
delay
epoch = 0
First review point (fRev)
Last review point (lRev)
Recall point (Rec)
Epochs

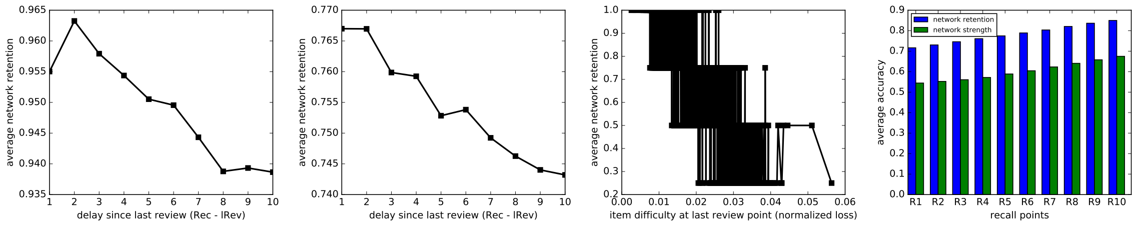
Figure 1: Effect of recall indicators on network retention. Training data is uniformly at random divided into three disjoint sets $\mathcal{A}$, $\mathcal{B}$, and $\mathcal{C}$ that respectively contain 80%, 10%, and 10% of the data. Network retention is computed against set $\mathcal{B}$ instances at recall point.

We first define the following concepts to ease understanding the experiments (see Figure 1):

- **First** and **Last review points (fRev and lRev)** of a training instance are the first and last epochs in which the instance is used to train the network respectively,
- **Recall point (Rec)** is the epoch in which *network retention* is computed against some training instances; network retention is the probability that a neural network recalls (i.e. correctly classifies) a previously-seen training instance, and
- **Delay since last review** of a training instance is the difference between the recall point and the last review point of the training instance.

Given training data and a neural network, we uniformly at random divide the data into three disjoint sets: a *base* set $\mathcal{A}$, a *review* set $\mathcal{B}$, and a *replacement* set $\mathcal{C}$ that respectively contain 80%, 10%, and 10% of the data. As depicted in Figure 1, instances of $\mathcal{A}$ are used for training at every epoch, while those in $\mathcal{B}$ and $\mathcal{C}$ are partially used for training. The network initially starts to train with $\{\mathcal{A} \cup \mathcal{C}\}$ instances. Then, starting from the first review point, we inject the review set $\mathcal{B}$ and remove $\mathcal{C}$, training with $\{\mathcal{A} \cup \mathcal{B}\}$ instances at every epoch until the last review point. The network will then continue training with $\{\mathcal{A} \cup \mathcal{C}\}$ instances until the recall point. At this point, network retention is computed against set $\mathcal{B}$ instances, with delay defined as the number of epochs since last review point. The intuition behind using review and replacement sets, $\mathcal{B}$ and $\mathcal{C}$ respectively, is to avoid external effects (e.g.

[3] We obtained similar results on QA tasks (Weston et al., 2016) but they are excluded due to space limit.



(a) Delay full

(b) Delay partial

(c) Item difficulty

(d) Network strength

Figure 2: (a) Delay since last review vs. average network retention (accuracy) on set $\mathcal{B}$ instances at recall point. Recall point is fixed and set to the epoch in which networks obtain their best performance based on rote training. (b) The same as (a) except that recall point is set to the epoch in which networks obtain half of their best performance based on rote training. (c) Item Difficulty (normalized loss at last review point) vs. average network retention at recall point on set $\mathcal{B}$ instances. (d) Network strength (network accuracy on validation data at recall point) vs. average network retention at recall point on set $\mathcal{B}$ instances. Length of sliding window is fixed throughout experiments and set to 5 epochs.

size of data or network generalization and learning capability) for our intrinsic evaluation purpose.

To conduct these experiments, we identify different neural models designed for different tasks.[4] For each network, we fix the recall point to either the epoch in which the network is fully trained (i.e., obtains its best performance based on standard or "rote" training in which all instances are used for training at every iteration), or partially trained (i.e., obtains half of its best performance based on rote training). We report average results across these networks for each experiment.

2.1.1 Delay since Last Review

As aforementioned, delay since last review of a training instance is the difference between the recall point (Rec) and the last review point (lRev) of the training instance. We evaluate the effect of delay on network retention (against set $\mathcal{B}$ instances) by keeping the recall point fixed while moving the sliding window in Figure 1. Figures 2(a) and 2(b) show average network retention across networks for the fully and partially trained recall points respectively. The results show an inverse relationship between network retention and delay since last review in neural networks.

2.1.2 Item Difficulty

We define difficulty of training instances by the loss values generated by a network for the instances. Figure 2(c) shows the difficulty of set $\mathcal{B}$ instances at the last review point against average network retention on these instances at recall point. We normalize loss values to unit vectors (to make them comparable across networks) and then average them across networks for both fully and partially trained recall points. As the results show, network retention decreases as item difficulty increases.

2.1.3 Network Strength

We define strength of a network by its performance on validation data. To understand the effect of network strength on its retention, we use the same experimental setup as before except that we keep the delay (difference between recall point and last review point) fixed while gradually increasing the recall point; this will make the networks stronger by training them for more epochs. Then, at every recall point, we record network retention on set $\mathcal{B}$ instances and network accuracy on validation data. Average results across networks for two sets of 10 consecutive recall points (before fully and partially trained recall points) are shown in Figure 2(d). As the results show, network retention increases as memory strength increases.

The above experiments show that memory retention in neural networks is affected by the same factors that affect memory retention in humans: (a) neural networks forget training examples after a certain period of intervening training data (b): the period of recall is shorter for more difficult examples, and (c): recall improves as networks achieve better overall performance. We conclude that delay since last review, item difficulty (loss values of training instances), and memory strength (network performance on validation data) are key indicators that affect network retention and propose to design spaced repetition algorithms that take such indicators into account in training neural networks.

[4] See section 4, we use Addition and CIFAR10 datasets and their corresponding neural networks for these experiments.

Algorithm 1. Leitner System

Input: $\mathbf{H}$: training data, $\mathbf{V}$: validation data, k : number of iterations, n : number of queues
Output: trained model

```
$Q = [q_0, q_1, \ldots, q_{n-1}]$
$q_0 = [\mathbf{H}]$, $q_i = []$ for $i$ in $[1, n-1]$
For $epoch = 1$ to $k$:
  $current\_batch = []$
  For $i = 0$ to $n-1$:
    If $epoch \% 2^i == 0$:
      $current\_batch = current\_batch + q_i$
  End For
  $pmos, dmos, model = \mathbf{train}(current\_batch, \mathbf{V})$
  $\mathbf{update\_queue}(Q, pmos, dmos)$
End for
return $model$
```

q_0 epochs = $\{1, 2, 3, 4, 5, \ldots\}$
q_1 epochs = $\{2, 4, 6, 8, 10, \ldots\}$
q_2 epochs = $\{4, 8, 12, 16, 20, \ldots\}$
$\ldots$

Figure 3: Leitner System. The $\mathbf{train}(.)$ function trains the network for one epoch using instances in the $current\_batch$, and the $\mathbf{update\_queue}(.)$ function promotes the recalled (correctly classified) instances, $pmos$, to the next queue and demotes the forgotten ones, $dmos$, to q_0.

3 Spaced Repetition

We present two spaced repetition-based algorithms: a modified version of the Leitner system developed in (Reddy et al., 2016) and our Repeat before Forgetting (RbF) model respectively.

3.1 Leitner System

Suppose we have n queues $\{q_0, q_1, \ldots, q_{n-1}\}$. The Leitner system initially places all training instances in the first queue, q_0. As Algorithm 1 shows, at each training iteration, the Leitner scheduler chooses some queues to train a downstream neural network. Only instances in the selected queues will be used for training the network. During training, if an instance from q_i is recalled (e.g. correctly classified) by the network, the instance will be "promoted" to q_{i+1}, otherwise it will be "demoted" to the first queue, q_0.[5]

The Leitner scheduler reviews instances of q_i at every 2^i iterations. Therefore, instance in lower queues (difficult/forgotten instances) are reviewed more frequently than those in higher queues (easy/recalled ones). Figure 3 (bottom) provides examples of queues and their processing epochs. Note that the overhead imposed on training by the Leitner system is $O(|current\_batch|)$ at every epoch for moving instances between queues.

3.2 RbF Model

3.2.1 RbF Memory Models

The challenge in developing memory models is to estimate the time by which a training instance should be reviewed before it is forgotten by the network. Accurate estimation of the review time leads to efficient and effective training. However, a heuristic scheduler such as Leitner system is suboptimal as its hard review schedules (i.e. only 2^i-iteration delays) may lead to early or late reviews.

We develop flexible schedulers that take recall indicators into account in the scheduling process. Our schedulers lengthen or shorten inter-repetition intervals with respect to individual training instances. In particular, we propose using density kernel functions to estimate the latest epoch in which a given training instance can be recalled. We aim to investigate how much improvement (in terms of efficiency and effectiveness) can be achieved using more flexible schedulers that utilize the recall indicators.

We propose considering density kernels as schedulers that favor (i.e., more confidently delay) less difficult training instances in stronger networks. As a kernel we can use any non-increasing function of the following quantity:

$$x_i = \frac{d_i \times t_i}{s_e}, \tag{2}$$

where d_i indicates the loss of network for a training instance $h_i \in \mathbf{H}$, t_i indicates the number of epochs to next review of h_i, and s_e indicates the performance of network— on validation data— at epoch e. We investigate the Gaussian, Laplace, Linear, Cosine, Quadratic, and Secant kernels as described below respectively:

$$f_{gau}(x, \tau) = \exp(-\tau x^2), \tag{3}$$

$$f_{lap}(x, \tau) = \exp(-\tau x), \tag{4}$$

$$f_{lin}(x, \tau) = \begin{cases} 1 - \tau x & x < \frac{1}{\tau} \\ 0 & \text{otherwise} \end{cases}, \tag{5}$$

$$f_{cos}(x, \tau) = \begin{cases} \frac{1}{2}\cos(\tau \pi x) + 1 & x < \frac{1}{\tau} \\ 0 & \text{otherwise} \end{cases}, \tag{6}$$

$$f_{qua}(x, \tau) = \begin{cases} 1 - \tau x^2 & x^2 < \frac{1}{\tau} \\ 0 & \text{otherwise} \end{cases}, \tag{7}$$

$$f_{sec}(x, \tau) = \frac{2}{\exp(-\tau x^2) + \exp(\tau x^2)}, \tag{8}$$

[5] Note that in (Reddy et al., 2016) demoted instances are moved to q_{i-1}. We observed significant improvement in Leitner system by moving such instances to q_0 instead of q_{i-1}.

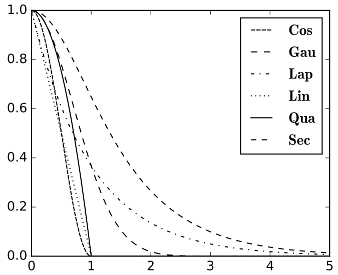


Figure 4: RbF kernel functions with $\tau = 1$.

where τ is a learning parameter. Figure 4 depicts these kernels with $\tau = 1$. As we will discuss in the next section, we use these kernels to optimize delay with respect to item difficulty and network strength for each training instance.

3.2.2 RbF Algorithm

Our Repeat before Forgetting (RbF) model is a spaced repetition algorithm that takes into account the previously validated recall indicators to train neural networks, see Algorithm 2. RbF divides training instances into *current* and *delayed* batches based on their delay values at each iteration. Instances in the current batch are those that RbF is less confident about their recall and therefore are reviewed (used to re-train the network) at current iteration. On the other hand, instances in the delayed batch are those that are likely to be recalled by the network in the future and therefore are not reviewed at current epoch. At each iteration, the RbF scheduler estimates the optimum delay (number of epochs to next review) for each training instance in the current batch. RbF makes such item-specific estimations as follows:

Given the difficulty of a training instance d_i, the memory strength of the neural network at epoch e, s_e, and an RbF memory model f (see section 3.2.1), RbF scheduler estimates the maximum delay $\hat{t_i}$ for the instance such that it can be recalled with a confidence greater than the given threshold $\eta \in (0, 1)$ at time $e + \hat{t_i}$. As described before, d_i and s_e can be represented by the current loss of the network for the instance and the current performance of the network on validation data respectively. Therefore, the maximum delay between the current (epoch e) and next reviews of the instance can be estimated as follows:

$$\hat{t_i} = \arg\min_{t_i} \big(f(x_i, \hat{\tau}) - \eta\big)^2, \quad (9)$$
$$s.t \quad 1 \leq t_i \leq k - e$$

Algorithm 2. RbF Training Model

Input: $\mathbf{H}$: training data, $\mathbf{V}$: validation data, k : number of iterations, f : RbF kernel, η: recall confidence
Output: trained model

```
0  $t_i = 1$ for $h_i \in \mathbf{H}$
1  For $epoch = 1$ to $k$:
2    $current\_batch = \{h_i : t_i <= 1\}$
3    $delayed\_batch = \{h_i : t_i > 1\}$
4    $s_{epoch}, model = \mathbf{train}(current\_batch, \mathbf{V})$
5    $\hat{\tau} = \arg\min_{\tau} \big(f(x_i, \tau) - a_i\big)^2 \quad \forall h_i \in \mathbf{V}, a_i \geq \eta$
6    $\hat{t_i} = \arg\min_{t_i} \big(f(x_i, \hat{\tau}) - \eta\big)^2 \forall h_i \in current\_batch$
7    $t_i = t_i - 1 \quad \forall h_i \in delayed\_bach$
8  End for
9  return $model$
```

Figure 5: RbF training model. The $\mathbf{train}(.)$ function at line 5 trains the network for one epoch using instances in the $current\_batch$. Note that at each iteration $epoch$, x_i is computed using Equation (2) and strength of the current model, s_{epoch}.

where $\hat{\tau}$ is the optimum value for the learning parameter obtained from validation data, see Equation (10). In principle, reviewing instances could be delayed for any number of epochs; in practice however, delay is bounded both below and above (e.g., by queues in the Leitner system). Thus, we assume that, at each epoch e, instances could be delayed for at least one iteration and at most $k - e$ iterations where k is the total number of training epochs. We also note that t_i is a lower bound of the maximum delay as s_e is expected to increase and d_i is expected to decrease as the network trains in next iterations.

Algorithm 2 shows the outline of the proposed RbF model. We estimate the optimum value of τ (line 5 of Algorithm 2) for RbF memory models using validation data. In particular, RbF uses the loss values of validation instances and strength of the network obtained at the previous epoch to estimate network retention for validation instances at the current epoch (therefore $t_i = 1$ for every validation instance). The parameter τ for each memory model is computed as follows:

$$\hat{\tau} = \arg\min_{\tau} \big(f(x_j, \tau) - a_j\big)^2, \forall h_j \in \mathbf{V}, a_j \geq \eta, \quad (10)$$

where $a_j \in (0, 1)$ is the current accuracy of the model for the validation instance h_j. RbF then predicts the delay for current batch instances and reduces the delay for those in the delayed batch by one epoch. The overhead of RbF is $O(|\mathbf{H}|)$ to compute delays and $O(|\mathbf{V}|)$ to compute $\hat{\tau}$. Note that (9) and (10) have closed form solutions.

Dataset	train, dev, test	Network	Task
IMDb	20K, 5K, 25K	MLP/fastext (Joulin et al., 2017), best epoch=8	sentiment analysis
CIFAR10	45K, 5K, 10K	CNN (Chan et al., 2015) best epoch=64	image classification
Addition	40K, 5K, 10K	LSTM (Sutskever et al., 2014) best epoch=32	arithmetic addition

Table 1: Datasets, models, and tasks.

4 Experiments

Table 1 describes the tasks, datasets, and models that we consider in our experiments. It also reports the training epochs for which the models produce their best performance on validation data (based on rote training). We note that the Addition dataset is randomly generated and contains numbers with at most 4 digits.[6]

We consider three schedulers as baselines: a slightly modified version of the Leitner scheduler (Lit) developed in Reddy et al. (2016) for human learners (see Footnote 5), curriculum learning (CL) in which training instances are scheduled with respect to their *easiness* (Jiang et al., 2015), and the uniform scheduler of rote training (Rote) in which all instances are used for training at every epoch. For Lit, we experimented with different queue lengths, $n = \{3, 5, 7\}$, and set $n = 5$ in the experiments as this value led to the best performance of this scheduler across all datasets.

Curriculum learning starts training with *easy* instances and gradually introduces more complex instances for training. Since easiness information is not readily available in most datasets, previous approaches have used heuristic techniques (Spitkovsky et al., 2010; Basu and Christensen, 2013) or optimization algorithms (Jiang et al., 2015, 2014) to quantify easiness of training instances. These approaches consider an instance as easy if its loss is smaller than a threshold (λ). We adopt this technique as follows: at each iteration e, we divide the entire training data into *easy* and *hard* sets using iteration-specific λ_e and the loss values of instances, obtained from the current partially-trained network. All easy instances in conjunction with $\alpha_e \in [0, 1]$ fraction of easiest hard instances (those with smallest loss values greater than λ_e) are used for training at iteration e. We set each λ_e to the average loss of training instances that are correctly classified by the current partially-trained network. Furthermore, at each iteration e, we set $\alpha_e = e/k$ to gradually introduce complex instances at every new iteration.[7] Note that we treat all instances as easy at $e = 0$.

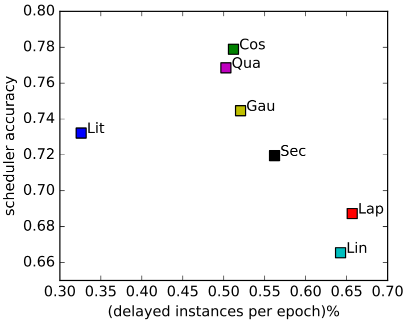

Figure 6: Accuracy of schedulers in predicting network retention. For these experiments recall confidence is set to its default value, $\eta = 0.5$.

Performance values reported in experiments are averaged over 10 runs of systems and the confidence parameter η is always set to 0.5 unless otherwise stated.

4.1 Evaluation of Memory Models

In these experiments, we evaluate memory schedulers with respect to their accuracy in predicting network retention for delayed instances. Since curriculum learning does not estimate delay for training instances, we only consider Leitner and RbF schedulers in these experiments.

For this evaluation, if a scheduler predicts a delay t for a training instance h at epoch e, we evaluate network retention with respect to h at epoch $e + t$. If the network recalls (correctly classifies) the instance at epoch $e + t$, the scheduler has correctly predicted network retention for h, and otherwise, it has made a wrong prediction. We use this binary outcome to evaluate the accuracy of each scheduler. Note that the performance of schedulers on instances that have not been delayed is not a major concern. Although failing to delay an item inversely affects efficiency, it makes the network stronger by providing more instances to train from. Therefore, we consider a good scheduler as the one that accurately delays more items.

Figure 6 depicts the average accuracy of schedulers in predicting networks' retention versus the average fraction of training instances that they delayed per epoch. As the results show, all schedulers

[6] https://github.com/fchollet/keras/blob/master/examples/addition_rnn.py

[7] k is the total number of iterations.

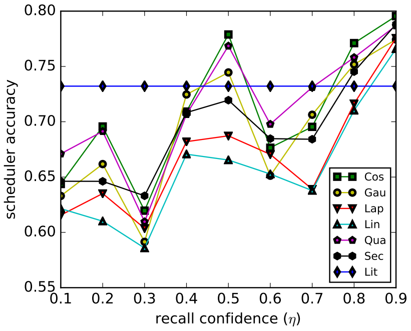

Figure 7: Effect of recall confidence η on the accuracy of different schedulers in predicting network retention (best seen in color.)

delay substantial amount of instances per epoch. In particular, Cos and Qua outperform Lit in both predicting network retention and delaying items, delaying around 50% of training instances per epoch. This is while Gau and Sec show comparable accuracy to Lit but delay more instances. On the other hand, Lap, which has been found effective in Psychology, and Lin are less accurate in predicting network retention. This is because of the tradeoff between delaying more instances and creating stronger networks. Since these schedulers are more flexible in delaying greater amount of instances, they might not provide networks with enough data to fully train.

Figure 7 shows the performance of RbF schedulers with respect to the recall confidence parameter η, see Equation (9). As the results show, schedulers have poor performance with smaller values of η. This is because smaller values of η make schedulers very flexible in delaying instances. However, the performance of schedulers are not dramatically low even with very small ηs. Our further analyses on the delay patterns show that although a smaller η leads to more delayed instances, the delays are significantly shorter. Therefore, most delayed instances will be "reviewed" shortly in next epochs. These bulk reviews make the network stronger and help it to recall most delayed instance in future iterations.

On the other hand, greater ηs lead to more accurate schedulers at the cost of using more training data. In fact, we found that larger ηs do not delay most training instances in the first few iterations. However, once the network obtains a reasonably high performance, schedulers start delaying instances for longer durations. We will further study this effect in the next section.

Model	Accuracy	TIPE	X Faster	Gain
CL	0.868	0.71	0.93	1.40
Lit	0.859	0.67	2.87	1.85
Gau	0.874	0.48	3.02	2.16
Lap	0.857	**0.34**	4.66	**3.15**
Lin	0.864	0.36	**4.78**	3.07
Cos	0.868	0.49	2.90	2.10
Qua	0.871	0.50	2.95	2.08
Sec	0.866	0.44	3.09	2.33
Cos $\eta = 0.9$	**0.880**	0.76	2.36	1.42
Rote	0.887	1.00	1.00	1.00

Table 2: Comparison of schedulers in terms of average network accuracy, average fraction of instances used for training per epoch (TIPE), and the extent to which a model runs faster than Rote training (X Times Faster). Gain column indicates the $\frac{Accuracy}{TIPE}$ improvement over rote training.

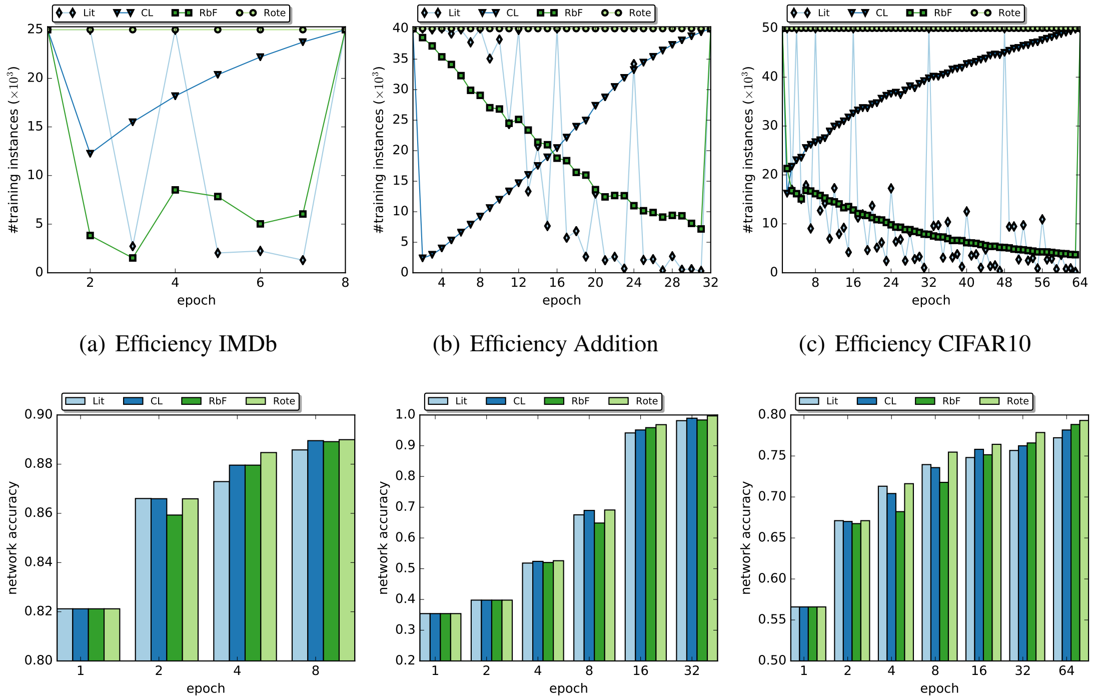
4.2 Efficiency and Effectiveness

We compare RbF against Leitner and curriculum learning in terms of efficiency of training and effectiveness of trained models. We define effectiveness as the accuracy of a trained network on balanced test data, and efficiency as (a): fraction of instances used for training per epoch, and (b): required time for training the networks. For RbF schedulers, we set η to 0.5 and consider the best performing kernel Cosine with $\eta = 0.9$ based on results in Figure 7.

The results in Table 2 show that all training paradigms have comparable effectiveness (Accuracy) to that of rote training (Rote). Our RbF schedulers use less data per epoch (34-50% of data) and run considerably faster than Rote (2.90-4.78 times faster for $\eta = 0.5$). The results also show that Lit is slightly less accurate but runs 2.87 time faster than Rote; note that, as a scheduler, Lit is less accurate than RbF models, see Figures 6 and 7.

In addition, CL leads to comparable performance to RbF but is considerably slower than other schedulers. This is because this scheduler has to identify easier instances and sort the harder ones to sample training data at each iteration. Overall, the performance of Lit, CL, Cos $\eta = .5$ and Cos $\eta = .9$ are only 2.76, 1.90, 1.88, and 0.67 absolute values lower than that of Rote respectively. Considering the achieved efficiency, these differences are negligible (see the overall gain in Table 2).

Figure 8 reports detailed efficiency and effectiveness results across datasets and networks. For clear illustration, we report accuracy at iterations 2^i $\forall i$ in which Lit is trained on the entire data, and consider Cos $\eta = .5$ as RbF scheduler. In terms of efficiency (first row of Figure 8), CL starts with (small set of)



(a) Efficiency IMDb

(b) Efficiency Addition

(c) Efficiency CIFAR10

(d) Effectiveness IMDb

(e) Effectiveness Addition

(f) Effectiveness CIFAR10

Figure 8: Efficiency and Effectiveness of schedulers across three datasets and networks. RbF uses Cos $\eta = .5$ as kernel. CL starts with (small set of) easier instances and gradually incorporate slightly harder instances at each iteration. Lit and RbF start big and gradually delay reviewing easy instances.

easier instances and gradually increases the amount of training data by adding slightly harder instances into its training set. On the other hand, Lit and RbF start big and gradually delay reviewing (easy) instances that the networks have learned. The difference between these two training paradigms is apparent in Figures 8(a)-8(c).

The results also show that the efficiency of a training paradigm depends on the initial effectiveness of the downstream neural network. For CL to be efficient, the neural network need to initially have *low* performance (accuracy) so that the scheduler works on smaller set of easy instances. For example, in case of Addition, Figures 8(b) and 8(e), the initial network accuracy is only 35%, therefore most instances are expected to be initially treated as hard instances and don't be used for training. On the other hand, CL shows a considerably lower efficiency for networks with slightly high initial accuracy, e.g. in case of IMDb or CIFAR10 where the initial network accuracy is above 56%, see Figures 8(a) and 8(d), and 8(c) and 8(f) respectively.

In contrast to CL, Lit and RbF are more efficient when the network has a relatively higher initial performance. A higher initial performance helps the schedulers to more confidently delay "reviewing" most instances and therefore train with a much smaller set of instances. For example, since the initial network accuracy in IMDb or CIFAR10 is above 56%, Lit and RbF are considerably more efficient from the beginning of the training process. However, in case of low initial performance, Lit and RbF tend to avoid delaying instances at lower iterations which leads to poor efficiency at the beginning. This is the case for the Addition dataset in which instances are gradually delayed by these two schedulers even at epoch 8 when the performance of the network reaches above 65%, see Figures 8(e) and 8(b). However, Lit gains its true efficiency after iteration 12, see Figure 8(b), while RbF still gradually improves the efficiency. This might be because of the lower bound delays that RbF estimates, see Equation (9).

Furthermore, the effectiveness results in Figure 8 (bottom) show that all schedulers produce comparable accuracy to the Rote scheduler throughout the training process, not just at specific iterations. This indicates that these training paradigms can much faster achieve the same generalizability as standard training, see Figures 8(b) and 8(e).

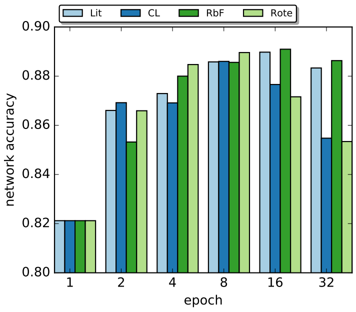


Figure 9: Robustness against overtraining.

4.3 Robustness against Overtraining

We investigate the effect of spaced repetition on overtraining. The optimal number of training epochs required to train `fastText` on the IMDb dataset is 8 epochs (see Table 1). In this experiment, we run `fastText` on IMDb for greater number of iterations to investigate the robustness of different schedulers against overtraining. The results in Figure 9 show that Lit and RbF (Cos $\eta = 0.5$) are more robust against overtraining. In fact, the performance of Lit and RbF further improve at epoch 16 while CL and Rote overfit at epoch 16 (note that CL and Rote also require considerably more amount of time to reach to higher iterations). We attribute the robustness of Lit and RbF to the scheduling mechanism which helps the networks to avoid retraining with easy instances. On the other hand, overtraining affects Lit and RbF at higher training iterations, compare performance of each scheduler at epochs 8 and 32. This might be because these training paradigms overfit the network by paying too much training attention to very hard instances which might introduce noise to the model.

5 Related Work

Ebbinghaus (1913, 2013), and recently Murre and Dros (2015), studied the hypothesis of the exponential nature of forgetting, i.e. how information is lost over time when there is no attempt to retain it. Previous research identified three critical indicators that affect the probability of recall: repeated exposure to learning materials, elapsed time since their last review (Ebbinghaus, 1913; Wixted, 1990; Dempster, 1989), and more recently item difficulty (Reddy et al., 2016). We based our investigation on these findings and validated that these indicators indeed affect memory retention in neural networks. We then developed training paradigms that utilize the above indicators to train networks.

Bengio et al. (2009) and Kumar et al. (2010) also developed cognitively-motivated training paradigms which are inspired by the principle that learning can be more effective when training starts with easier concepts and gradually proceeds with more difficult ones. Our idea is motivated by the spaced repetition principle which indicates learning improves with repeated exposure and decays with delay since last exposure (Ebbinghaus, 1913; Dempster, 1989). Based on this principle, we developed schedulers that space the reviews of training instances over time for efficient and effective training of neural networks.

6 Conclusion and Future Work

We developed a cognitively-motivated training paradigm (scheduler) that space instances over time for efficient and effective training of neural networks. Our scheduler only uses a small fraction of training data per epoch but still effectively train neural networks. It achieves this by estimating the time (number of epochs) by which training could be delayed for each instance. Our work was inspired by three recall indicators that affect memory retention in humans, namely difficulty of learning materials, delay since their last review, and memory strength of the learner, which we validated in the context of neural networks.

There are several avenues for future work including the extent to which our RbF model and its kernels could be combined with curriculum learning or Leitner system to either predict easiness of novel training instances to inform curriculum learning or incorporate Leitner's queueing mechanism to the RbF model. Other directions include extending RbF to dynamically learn the recall confidence parameter with respect to network behavior, or developing more flexible delay functions with theoretical analysis on their lower and upper bounds.

Abstract

In this work, we study the problem of part-of-speech tagging for Tweets. In contrast to newswire articles, Tweets are usually informal and contain numerous out-of-vocabulary words. Moreover, there is a lack of large scale labeled datasets for this domain. To tackle these challenges, we propose a novel neural network to make use of out-of-domain labeled data, unlabeled in-domain data, and labeled in-domain data. Inspired by adversarial neural networks, the proposed method tries to learn common features through adversarial discriminator. In addition, we hypothesize that domain-specific features of target domain should be preserved in some degree. Hence, the proposed method adopts a sequence-to-sequence autoencoder to perform this task. Experimental results on three different datasets show that our method achieves better performance than state-of-the-art methods.

1 Introduction

During the last decade, social media have become extremely popular, on which billions of user-generated contents are posted every day. Many users have been writing about their thoughts and lives on the go. The massive unstructured data from social media provides valuable information for a variety of applications such as stock prediction (Bollen et al., 2011), public health analysis (Wilson and Brownstein, 2009; Paul and Dredze, 2011), real-time event detection (Sakaki et al., 2010), and so on. The quality of these applications is highly impacted by the performance of natural language processing tasks.

Figure 1: An example of tagged Tweet, which contains nonstandard orthography, emoticon, and abbreviation. The tagset is defined similar as that of PTB (Marcus et al., 1993).

Part-of-speech (POS) tagging is one of the most important natural language processing tasks. It has also been widely used in the social media analysis systems (Ritter et al., 2012; Lamb et al., 2013; Kiritchenko et al., 2014). Most state-of-the-art POS tagging approaches are based on supervised methods. Hence, they usually require a large amount of annotated data to train models. Many datasets have been constructed for POS tagging task. Because newswire articles are carefully edited, benchmarks usually use them for annotation (Marcus et al., 1993). However, user-generated contents on social media are usually informal and contain many nonstandard lexical items. Moreover, the difference in domains between training data and evaluation data may heavily impact the performance of approaches based on supervised methods (Caruana and Niculescu-Mizil, 2006). Hence, most POS tagging methods cannot achieve the same performance as reported on newswire domain when applied on Twitter (Owoputi et al., 2013).

To perform the Twitter POS tagging task, some approaches have been proposed to perform the task. Gimpel et al. (2011) manually annotated 1,827 tweets and carefully studied various fea-

Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

tures. Ritter et al. (2011) also constructed a labeled dataset, which contained 787 tweets, to empirically evaluate the performance of supervised methods on Twitter. Owoputi et al. (2013) incorporated word clusters into the feature sets and further improved the performance. From these works, we can observe that the size of the training data was much smaller than the newswire domain's.

Besides the challenge of lack of training data, the frequent use of out-of-vocabulary words also makes this problem difficult to address. Social media users often use informal ways of expressing their ideas and often spell words phonetically (e.g., "2mor" for "tomorrow"). In addition, they also make extensive use of emoticons and abbreviations (e.g., ":-)" for smiling emotion and "LOL" for laughing out loud). Moreover, new symbols, abbreviations, and words are constantly being created. Figure 1 shows an example of tagged Tweet.

To tackle the challenges posed by the lack of training data and the out-of-vocabulary words, in this paper, we propose a novel recurrent neural network, which we call *Target Preserved Adversarial Neural Network* (TPANN) to perform the task. It can make use of a large quantity of annotated data from other resource-rich domains, unlabeled in-domain data, and a small amount of labeled in-domain data. All of these datasets can be easily obtained. To make use of unlabeled data, motivated by the work of Goodfellow et al. (2014) and Chen et al. (2016), the proposed method extends the bi-directional long short-term memory recurrent neural network (bi-LSTM) with an adversarial predictor. To overcome the defect that adversarial networks can merely learn the common features, we propose to use an autoencoder only acting on target dataset to preserve its own specific features. For tackling the out-of-vocabulary problem, the proposed method also incorporates a character level convolutional neutral network to leverage subword information.

The contributions of this work are as follows:

- We propose to incorporate large scale unlabeled in-domain data, out-of-domain labeled data, and in-domain labeled data for Twitter part-of-speech tagging task.

- We introduce a novel recurrent neural network, which can learn domain-invariant representations through in-domain and out-of-domain data and construct a cross domain POS tagger through the learned representations. The proposed method also tries to preserve the specific features of target domain.

- Experimental results demonstrate that the proposed method can lead to better performance in most of cases on three different datasets.

2 Approach

In this work, we propose a novel recurrent neural network, Target Preserved Adversarial Neural Network (TPANN), to learn common features between resource-rich domain and target domain, simultaneously to preserve target domain-specific features. It extends the bi-directional LSTM with adversarial network and autoencoder. The architecture of TPANN is illustrated in Figure 2. The model consists of four components: *Feature Extractor*, *POS Tagging Classifier*, *Domain Discriminator* and *Target Domain Autoencoder*. In the following sections, we will detail each part of the proposed architecture and training methods.

2.1 Feature Extractor

The feature extractor $\mathcal{F}$ adopts CNN to extract character embedding features, which can tackle the out-of-vocabulary word problem effectively. To incorporate word embedding features, we concatenate word embedding to character embedding as the input of bi-LSTM on the next layer. Utilizing a bi-LSTM to model sentences, $\mathcal{F}$ can extract sequential relations and context information.

We denote the input sentence as $\mathbf{x}$ and the i-th word as x_i. $x_i \in \mathcal{S}(x)$ and $x_i \in \mathcal{T}(x)$ represent input samples are from source domain and target domain, respectively. We denote the parameters of $\mathcal{F}$ as θ_f. Let $\mathcal{V}$ be the vocabulary of words, and $\mathcal{C}$ be the vocabulary of characters. d is the dimensionality of character embedding then $Q \in \mathbb{R}^{d\times|\mathcal{C}|}$ is the representation matrix of vocabulary. We assume that word $x_i \in \mathcal{V}$ is made up of a sequence of characters $\mathbf{C}^i = [c_1, c_2, \dots, c_l]$, where l is the max length of word and every word will be padded to this length. Then $\mathbf{C}^i \in \mathbb{R}^{d\times l}$ would be the inputs of CNN.

We apply a narrow convolution between $\mathbf{C}^i$ and filter $\mathbf{H} \in \mathbb{R}^{d\times k}$, where k is the width of the filter.

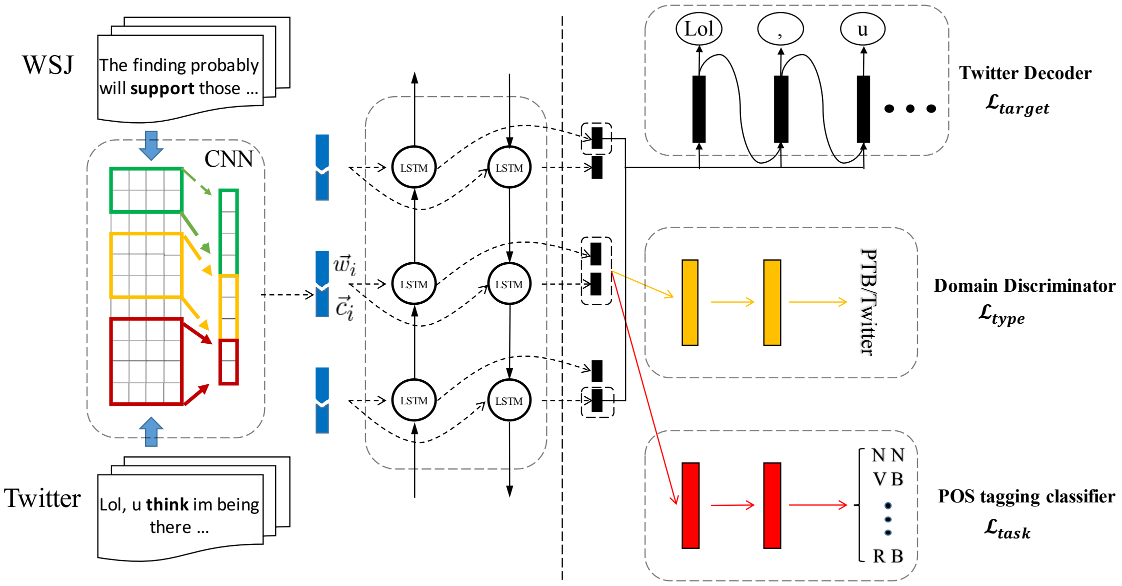

Figure 2: The general architecture of the proposed method.

After that we add a bias and apply nonlinearity to obtain a feature map $\mathbf{m}^i \in \mathbb{R}^{l-k+1}$. Specifically, the j-th element of $\mathbf{m}^i$ is given by:

$$\mathbf{i}^k[j] = \tanh(\langle \mathbf{C}^i[*, j : j+k-1], \mathbf{H} \rangle + b), \quad (1)$$

where $\mathbf{C}^k[*, j : j+k-1]$ is the j-to-$(j+k-1)$-th column of $\mathbf{C}^i$ and $\langle A, B \rangle = \text{Tr}(AB^T)$ is the Frobenius inner product. We then apply a max-over-time pooling operation (Collobert et al., 2011) over the feature map. CNN uses multiple filters with varying widths to obtain the feature vector $\vec{c}_i$ for word x_i. Then, the character-level feature vector $\vec{c}_i$ is concatenated to the word embedding $\vec{w}_i$ to form the input of bi-LSTM on the next layer. The word embedding $\vec{w}$ is pretrained on 30 million tweets. Then, the hidden states $\mathbf{h}$ of bi-LSTM turn into the features that will be transfered to $\mathcal{P}$, $\mathcal{Q}$ and $\mathcal{R}$, i.e. $\mathcal{F}(\mathbf{x}) = \mathbf{h}$.

2.2 POS Tagging Classifier and Domain Discriminator

POS tagging classifier $\mathcal{P}$ and domain discriminator $\mathcal{Q}$ take $\mathcal{F}(x)$ as input. They are standard feed-forward networks with a softmax layer for classification. $\mathcal{P}$ predicts POS tagging label to get classification capacity, and $\mathcal{Q}$ discriminates domain label to make $\mathcal{F}(x)$ domain-invariant.

The POS tagging classifier $\mathcal{P}$ maps the feature vector $\mathcal{F}(x_i)$ to its label. We denote the parameters of this mapping as θ_y. The POS tagging classifier is trained on N_s samples from the source domain with the cross entropy loss:

$$\mathcal{L}_{task} = -\sum_{i=1}^{N_s} y_i * \log \hat{y}_i, \quad (2)$$

where y_i is the one-hot vector of POS tagging label corresponding to $x_i \in \mathcal{S}(x)$, $\hat{y}_i$ is the output of top softmax layer: $\hat{y}_i = \mathcal{P}(\mathcal{F}(x_i))$. During the training time, The parameters θ_f and θ_y are optimized to minimize the classification loss $\mathcal{L}_{task}$. This ensures that $\mathcal{P}(\mathcal{F}(x_i))$ can make accurate prediction on the source domain.

Conversely, domain discriminator maps the same hidden states $\mathbf{h}$ to the domain labels with parameters θ_d. The domain discriminator aims to discriminate the domain label with following loss function:

$$\mathcal{L}_{type} = -\sum_{i=1}^{N_s+N_t} \{d_i \log \hat{d}_i + (1-d_i)\log(1-\hat{d}_i)\}, \quad (3)$$

where d_i is the ground truth domain label for sample i, $\hat{d}_i$ is the output of top layer: $\hat{d}_i = \mathcal{Q}(\mathcal{F}(x_i))$. N_t means N_t samples from the target domain. The domain discriminator is trained towards a saddle point of the loss function through minimizing the loss over θ_d while maximizing the loss over θ_f (Ganin et al., 2016). Optimizing θ_f ensures that the domain discriminator can't discriminate the domain, i.e., the feature extractor finds the common features between the two domains.

2.3 Target Domain Autoencoder

Through training adversarial networks, we can obtain domain-invariant features $\mathbf{h}_{common}$, but it will weaken some domain-specific features which are useful for POS tagging classification. Merely obtaining domain invariant features would therefore limit the classification ability.

Our model tries to tackle this defect by introducing domain-specific autoencoder $\mathcal{R}$, which attempts to reconstruct target domain data. Inspired by (Sutskever et al., 2014) but different from (Dai and Le, 2015), we treat the feature extractor $\mathcal{F}$ as encoder. In addition, we combine the last hidden states of the forward LSTM and backward LSTM in $\mathcal{F}$ as the initial state $h_0(dec)$ of the decoder LSTM. Hence, we don't need to reverse the order of words of the input sentences and the model avoids the difficulty of ”establish communication” between the input and the output (Sutskever et al., 2014).

Similar to (Zhang et al., 2016), we use $h_0(dec)$ and embedding vector of the previous word as the inputs of the decoder, but in a computationally more efficient manner by computing previous word representation. We assume that $(\hat{x}_1, \cdots, \hat{x}_T)$ is the output sequence. z_t is the t-th word representation: $z_t = MLP(h_t)$, and MLP is the multiple perceptron function. Hidden state $h_t = LSTM([h_0(dec) : z_{t-1}], h_{t-1})$, where $[\cdot : \cdot]$ is the concatenation operation. We estimate the conditional probability $p(\hat{x_1}, \cdots, \hat{x_T}|h_0(dec))$ as follows:

$$p(\hat{x_1}, \cdots, \hat{x_T}|h_0(dec)) = \prod_{t=1}^{T} p(\hat{x_t}|h_0(dec), z_1, \cdots, z_{t-1}), \tag{4}$$

where each $p(\hat{x_t}|h_0(dec), z_1, \cdots, z_{t-1})$ distribution is computed with softmax over all the words in the vacabulary.

Our aim is to minimize the following loss function with respect to parameters θ_r:

$$\mathcal{L}_{target} = -\sum_{i=1}^{N_t} x_i * \log \hat{x}_i, \tag{5}$$

where x_i is the one-hot vector of i-th word. This makes $h_0(dec)$ learn an undercomplete and most salient sentence representation of target domain data. When the adversarial networks try to optimize the hidden representation to common representation $\mathbf{h}_{common}$, The target domain autoencoder counteracts a tendency of the adversarial network to erase target domain features by optimizing the common representation to be informative on the target-domain data.

2.4 Training

Our model can be trained end-to-end with standard back-propagation, which we will detail in this section.

Our ultimate training goal is to minimize the total loss function with parameters $\{\theta_f, \theta_y, \theta_r, \theta_d\}$ as follows:

$$\mathcal{L}_{total} = \alpha\mathcal{L}_{task} + \beta\mathcal{L}_{target} + \gamma\mathcal{L}_{type}, \tag{6}$$

where α, β, γ are the weights to balance the effects of $\mathcal{P}$, $\mathcal{R}$ and $\mathcal{Q}$.

For obtaining domain-invariant representation $\mathbf{h}_{common}$, inspired by (Ganin and Lempitsky, 2015), we introduce a special gradient reversal layer (GRL), which does nothing during forward propagation, but negates the gradients if it receives backward propagation, i.e. $g(\mathcal{F}(x)) = \mathcal{F}(x)$ but $\nabla g(\mathcal{F}(x)) = -\lambda\nabla\mathcal{F}(x)$. We insert the GRL between $\mathcal{F}$ and $\mathcal{Q}$, which can run standard Stochastic Gradient Descent with respect to θ_f and θ_d. The parameter $-\lambda$ drives the parameters θ_f not to amplify the dissimilarity of features when minimize $\mathcal{L}_{tpye}$. So by introducing a GRL, $\mathcal{F}$ can drive its parameters θ_f to extract hidden representations that help the POS tagging classification and hamper the domain discrimination.

In order to preserve target domain-specific features, we only optimize the autoencoder on target domain data for reconstruction tasks.

Through above procedures, the model can learn the common features between domains, simultaneously preserve target domain-specific features. Finally, we can update the parameters as follows:

$$\begin{aligned}
\theta_f &= \theta_f - \mu(\alpha\frac{\partial\mathcal{L}^i_{task}}{\partial\theta_f} + \beta\frac{\partial\mathcal{L}^i_{target}}{\partial\theta_f} - \gamma\cdot\lambda\frac{\partial\mathcal{L}^i_{type}}{\partial\theta_f}) \\
\theta_y &= \theta_y - \mu\cdot\alpha\frac{\partial\mathcal{L}^i_{task}}{\partial\theta_y} \\
\theta_r &= \theta_r - \mu\cdot\beta\frac{\partial\mathcal{L}^i_{target}}{\partial\theta_r} \\
\theta_d &= \theta_d - \mu\cdot\gamma\frac{\partial\mathcal{L}^i_{type}}{\partial\theta_d},
\end{aligned} \tag{7}$$

Dataset		# Tokens

where μ is the learning rate. Because the size of the WSJ is more than 100 times that of the labeled Twitter dataset, if we directly train the model with the combined dataset, the final results are much worse than those using two training steps. So, we adopt adversarial training on WSJ and unlabeled Twitter dataset at the first step, then use a small number of in-domain labeled data to fine-tune the parameters with a low learning rate.

3 Experiments

In this section, we will detail the datasets used for experiments and experimental setup.

3.1 Datasets

The methods proposed in this work incorporate out-of-domain labeled data from resource-rich domains, large scale unlabeled in-domain data, and a small number of labeled in-domain data. The datasets used in this work are as follows:

Labeled out-of-domain data. We use a standard benchmark dataset for adversarial POS tagging, namely the Wall Street Journal (WSJ) data from the Penn TreeBank v3 (Marcus et al., 1993), sections 0-24 for the out-of-domain data.

Labeled in-domain data. For training and evaluating POS tagging approaches, we compare the proposed method with other approaches on three benchmarks: RIT-Twitter (Ritter et al., 2011), NPSCHAT (Forsyth, 2007), and ARK-Twitter (Gimpel et al., 2011).

Unlabeled in-domain data. For training the adversarial network, we need to use a dataset that has large scale unlabeled tweets. Hence, in this work, we construct large scale unlabeled data (UNL), from Twitter using its API.

The detailed data statistics of the datasets used in this work are listed in Table 1.

3.2 Experimental Setup

We select both state-of-the-art and classic methods for comparison, as follows:

- **Stanford POS Tagger**: Stanford POS Tagger is a widely used tool for newswire domains (Toutanova et al., 2003). In this work, we train it using two different sets, the WSJ (sections 0-18) and a WSJ, IRC, and Twitter mixed corpus. We use **Stanford-WSJ** and **Stanford-MIX** to represent them, respectively.

- **T-POS**: T-Pos (Ritter et al., 2011) adopts the Conditional Random Fields and clustering algorithm to perform the task. It was trained from a mixture of hand-annotated tweets and existing POS-labeled data.

- **GATE Tagger**: GATE tagger (Derczynski et al., 2013) is based on vote-constrained bootstrapping with unlabeled data. It combines cases where available taggers use different tagsets.

- **ARK Tagger**: ARK tagger (Owoputi et al., 2013) is a system that reports the best accuracy on the RIT dataset. It uses unsupervised word clustering and a variety of lexical features.

- **bi-LSTM**: Bidirectional Long Short-Term Memory (LSTM) networks have been widely used in a variety of sequence labeling tasks (Graves and Schmidhuber, 2005). In this work, we evaluate it at character level, word level, and combining them together. **bi-LSTM (word level)** uses one layer of bi-LSTM to extract word-level features and adopts a random initialization method to transform words to vectors. **bi-LSTM (character level)** represents a method that combines bi-LSTM and CNN-based character embedding, a similar approach with character-aware neural network described in (Kim et al., 2015) to handle the out-of-vocabulary words. **bi-LSTM (word level pretrain)** architecture is the same as that of bi-LSTM(word level) but adopts word2vec tool (Mikolov et al., 2013) to vectorize. **bi-LSTM (combine)** concatenates word to character features.

Methods	RIT-Test	RIT-Dev
Stanford-WSJ (Toutanova et al., 2003)	73.37%	83.29%
Stanford-MIX	83.14%	84.19%
T-POS (Ritter et al., 2011)	84.55%	84.83%
GATE Tagger (Derczynski et al., 2013)	88.69%	89.37%
ARK Tagger (Owoputi et al., 2013)	90.40%	-
bi-LSTM (word level)	75.91%	76.94%
bi-LSTM (word level pretrain)	85.99%	86.93%
bi-LSTM (character level)	82.85%	84.30%
bi-LSTM (combine)	89.48%	89.30%
bi-LSTM (combine + WSJ)	83.54%	83.64%
bi-LSTM (combine + WSJ + adversarial)	83.76%	84.45%
bi-LSTM (combine + WSJ + fine-tune)	89.87%	90.23%
bi-LSTM (combine + WSJ + adversarial + fine-tune)	90.60%	90.73%
TPANN (combine + WSJ + adversarial + fine-tune + autoencoder)	**90.92%**	**91.08%**

Table 2: Token level accuracies of different methods on RIT-Test and RIT-Dev. bi-LSTM(combine) refers to combining word level with character level. bi-LSTM(combine + WSJ) refers to the model trained on WSJ and tested on RIT. bi-LSTM(combine + WSJ + adversarial) refers to adversarial model trained on 1.1 million tokens of labeled WSJ data and the same scale of unlabeled Twitter data, then tested on RIT. Fine-tune means adding RIT-train data to fine-tune.

The hyper-parameters used for our model are as follows. AdaGrad optimizer trained with cross-entropy loss is used with 0.1 as the default learning rate. The dimensionality of word embedding is set to 200. The dimensionality for random initialized character embedding is set to 25. We adopt a bi-LSTM for encoding with each layer consisting of 250 hidden neurons. We set three layers of standard LSTM for decoding. Each LSTM layer consists of 500 hidden neurons. Adam optimizer trained with cross-entropy loss is used to fine-tune with 0.0001 as the default learning rate. Fine-tuning is run for 100 epochs using early stop.

4 Results and Discussion

In this section, we will report experimental results and a detailed analysis of the results for the three different datasets.

4.1 Evaluation on RIT-Twitter

The RIT-Twitter is split into training, development and evaluation sets (RIT-Train, RIT-Dev, RIT-Test). The splitting method is shown in (Derczynski et al., 2013), and the dataset statistics are listed in Table 1. Table 2 shows the results of our method and other approaches on the RIT-Twitter dataset. RIT-Twitter uses the PTB tagset with several Twitter-specific tags: retweets, @usernames, $hashtags$, and urls. Since words in these categories can be tagged almost perfectly using simple regular expressions, similar to (Owoputi et al., 2013), we use regular expressions to tags these words appropriately for all systems.

From the results of the Stanford-WSJ, we can observe that the newswire domain is different from Twitter. Although the token-level accuracy of the Stanford POS Tagger is higher than 97.0% on the PTB dataset, its performance on Twitter drops sharply to 73.37%. By incorporating some in-domain labeled data for training, the accuracy of Stanford POS Tagger can reach up to 83.14%. Taking a variety of linguistic features and many other resources into consideration, the T-POS, GATE tagger, and ARK tagger can achieve better performance.

The second part of Table 2 shows the results of the bi-LSTM based methods, which are trained on the RIT-Train dataset. According to the results of word level, we can see that word2vec can provide valuable information. The pre-trained word vectors in bi-LSTM(word level pretrain) give almost 10% higher accuracy than bi-LSTM(word level).

Comparing the character-level bi-LSTM with word-level bi-LSTM with random initialization, we can observe that the character-level method can achieve better performance than the word-level method. bi-LSTM(combine) combines word with character features, as described in Section 2.1,

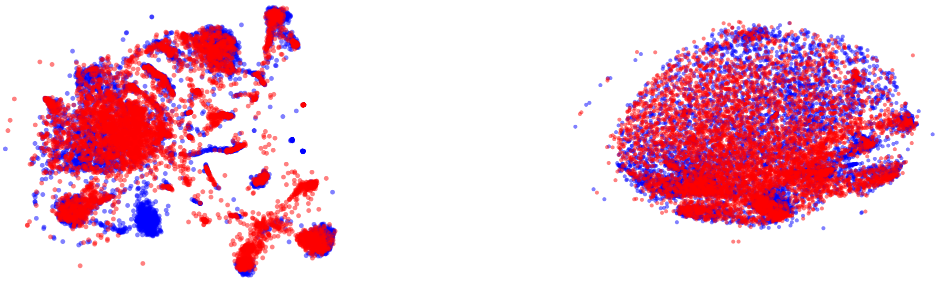

Figure 3: The visualization of bi-LSTM's outputs of the extracted features. The left figure shows the results when no adversary is performed. The right figure shows the results when the adversary procedure is incorporated into training. Blue points correspond to the source PTB domain examples, and red points correspond to the target Twitter domain.

which achieves the best results at 89.48% in the bi-LSTM based baseline systems and shows that the morphological features and pre-trained word vectors are both useful for POS tagging.

The third part of Table 2 shows the results of our methods incorporating out-of-domain labeled data, in-domain unlabeled data, and in-domain labeled data. Putting everything together, our model can achieve 90.92% on this dataset. Compared with the architecture without an adversarial model, our method is almost 1% better. It demonstrates that adversarial networks can significantly help with tasks of this nature. Through introducing the autoencoder in target domain, we can preserve domain-specific features for better performance. Compared with the ARK tagger, which achieves the previous best result on this dataset, our model is also 0.52% better, the error reduction rate is more than 5.5%.

To better understand why adversarial networks can help transfer domains from newswire to Twitter, in this work we also followed the method Ganin and Lempitsky (2015) used to visualize the outputs of LSTM with t-SNE (Van Der Maaten, 2013). Figure 3 shows the visualization results. From the figure, we can see that the adversary in our method makes the two distributions of features much more similar, which means that the outputs of bi-LSTM are domain-invariant. Hence, the PTB training data can provide much more help than directly combining PTB and RIT-Train together.

Methods	**Accuracy**
Forsyth (2007)	90.8%
ARK Tagger	93.4% ± 0.3%
TPANN	**94.1%**

Table 3: Tagging accuracies on NPSChat Corpus.

4.2 Evaluation on NPSChat

IRC, which contains Internet relay room messages from 2006, is a medium of online conversational text. Its content is very similar to tweets. We evaluate the proposed method on the NPSChat corpus (Forsyth, 2007), a PTB-part-of-speech annotated dataset of IRC.

We compared our method with a tagger in the same setup as experiments with (Forsyth, 2007). The training part contains 90% of the data. The testing part contains the other 10%. Table 3 shows the results of the ARK Tagger and our method. We used PTB, unlabeled Twitter, and the training part of NPSChat to train our model. From the results, we can see that our model achieved 94.1% accuracy. This is significantly better than the result Forsyth (2007) reported, which was 90.8%. They trained their tagger with a mix of several POS-annotated corpora (12K from Twitter, 40K from IRC, and 50K from PTB). Our method also outperforms state-of-the-art results 93.4%±0.3%, which was achieved by the ARK Tagger with various external corpus and features, e.g., Brown clustering, PTB, Freebase lists of celebrities, and video games.

Methods	Accuracy
Gimpel et al. (2011) version 0.2	90.8%
ARK Tagger	93.2%
TPANN	92.8%

Table 4: Tagging accuracies on DAILY547.

4.3 Evaluation on ARK-Twitter

ARK-Twitter data contains an entire dataset consisting of a number of tweets sampled from one particular day (October 27, 2010) described in (Gimpel et al., 2011). This part is used for training. They also created another dataset, which consists of 547 tweets, for evaluation (DAILY547). This dataset consists of one random English tweet from every day between January 1, 2011 and June 30, 2012. The distribution of training data may be slightly different from the testing data, for example a substantial fraction of the messages in the training data are about a basketball game. Since ARK-Twitter uses a different tagset with PTB, we manually construct a table to link tags for the two datasets.

Table 4 shows the results of different methods on this dataset. From the results, we can see that our method can achieve a better result than (Gimpel et al., 2011). However, the performance of our method is worse than the ARK Tagger. Through analyzing the errors, we find that 16.7% errors occurr between nouns and proper nouns. Since our method do not include any ontology or knowledge, proper nouns can not be easily detected. However, the ATK Tagge add a token-level name list feature. The name list is useful for proper nouns recognition, which fires on names from many sources, such as Freebase lists of celebrities, the Moby Words list of US Locations, proper names from Mark Kantrowitz's name corpus and so on. So, our model is also competitive when lacking of manual feature knowledge.

5 Related Work

Part-of-Speech tagging is an important preprocessing step and can provide valuable information for various natural language processing tasks. In recent years, deep learning algorithms have been successfully used for POS tagging. A number of approaches have been proposed and have achieved some progress. Santos and Guimaraes (2015) proposed using a character-based convolutional neural network to perform the POS tagging problem. Bi-LSTMs with word, character or unicode byte embedding were also introduced to achieve the POS tagging and named entity recognition tasks (Plank et al., 2016; Chiu and Nichols, 2015; Ma and Hovy, 2016). In this work, we study the problem from a domain adaption perspective. Inspired by these works, we also propose to use character-level methods to handle out-of-vocabulary words and bi-LSTMs to model the sequence relations.

Adversarial networks were successfully used for image generation (Goodfellow et al., 2014; Dosovitskiy et al., 2015; Denton et al., 2015), domain adaption (Tzeng et al., 2014; Ganin et al., 2016), and semi-supervised learning (Denton et al., 2016). The key idea of adversarial networks for domain adaption is to construct invariant features by optimizing the feature extractor as an adversary against the domain classifier (Zhang et al., 2017).

Sequence autoencoder reads the input sequence into a vector and then tries to reconstruct it. Dai and Le (2015) used the model on a number of different tasks and verified its validity. Li et al. (2015) introduced the model to hierarchically build an embedding for a paragraph, showing that the model was able to encode texts to preserve syntactic, semantic, and discourse coherence.

In this work, we incorporate adversarial networks with autoencoder to obtain domain-invariant features and keep domain-specific features. Our model is more suitable for target domain tasks.

6 Conclusion

In this work, we propose a novel adversarial neural network to address the POS tagging problem. Besides learning common representations between source domain and target domain, it can simultaneously preserve specific features of target domain. The proposed method leverages newswire resources and large scale in-domain unlabeled data to help POS tagging classification on Twitter, which has a few of labeled data. We evaluate the proposed method and several state-of-the-art methods on three different corpora. In most of the cases, the proposed method can achieve better performance than previous methods. Experimental results demonstrate that the proposed method can make full use of these resources, which can be easily obtained.

Abstract

The number of word embedding models is growing every year. Most of them are based on the co-occurrence information of words and their contexts. However, it is still an open question what is the best definition of context. We provide a systematical investigation of 4 different syntactic context types and context representations for learning word embeddings. Comprehensive experiments are conducted to evaluate their effectiveness on 6 extrinsic and intrinsic tasks. We hope that this paper, along with the published code, would be helpful for choosing the best context type and representation for a given task.

1 Introduction

Recently, there is a growing interest in word embedding models, where words are embedded into low-dimensional (dense) real-valued vectors. The trained word embeddings can be directly used for solving intrinsic tasks like word similarity and word analogy. They are also helpful for solving extrinsic tasks, such as part-of-speech tagging, chunking, named entity recognition (Collobert and Weston, 2008; Collobert et al., 2011) and text classification (Socher et al., 2013; Kim, 2014).

The training objectives of word embedding models are based on the Distributional Hypothesis (Harris, 1954) that can be stated as follows: "words that occur in similar contexts tend to have similar meanings". In most word embedding models, the "context" is defined as the words which precede and follow the target word within some fixed distance (Bengio et al., 2003; Mnih and Hinton, 2007; Mikolov et al., 2013a; Pennington et al., 2014). Among them, Global Vectors (GloVe) proposed by Pennington et al. (2014), Continuous Skip-Gram (CSG) [1] and Continuous Bag-Of-Words (CBOW) proposed by Mikolov et al. (2013b) achieve state-of-the-art results on a range of linguistic tasks, and scale to corpora with billions of words.

The traditional sparse vector-space models have explored many different types of context. Curran (2004); Padó and Lapata (2007); Clark (2012) have discussed a set of context definitions beyond simple linear context. For example, a sentence or document could be used as the boundary instead of window size. Contextual words could be associated with their relative sides (left/right) or positions (+1/-2) to the target word. They could also be associated with part-of-speech or grammatical relation labels. The weight of each contextual word can be explicitly defined. Moreover, words that are connected to target word in dependency parse

[1] Many researches refer to Continuous Skip-Gram as SG. However, in order to distinguish linear (continuous) context and DEPS (dependency-based) context, we refer it as CSG.

Table 1: Summary of prior research on word embedding models with different syntactic context types and context representations. For linear context, *bound* indicates words associated with positional information. For DEPS context, *bound* indicates words associated with dependency relation.

tree can be considered as context.

Recent word embedding models have also explored some of the above context types. Levy and Goldberg (2014b); Ling et al. (2015)[2] improve CSG and CBOW by introducing position-aware context representation. Levy and Goldberg (2014a) propose dependency-based context (DEPS) for CSG.

However, different types of syntactic context have not been systematically compared for different word embeddings. This paper explores two context types (linear or DEPS) and two context representations (bound or unbound), as shown in Table 1. Three popular word embedding models (CBOW, GloVe, and CSG) are compared on word similarity, word analogy, part-of-speech tagging, chunking, named entity recognition, and text classification tasks.

2 Related Work

Several studies directly compare different word embedding models. Lai et al. (2016) compare 6 word embedding models using different corpora and hyper-parameters. Nayak and Manning (2016) provide a set of evaluations, along with an online tool, for word embedding models. Levy and Goldberg (2014c) show the theoretical equivalence of CSG and PPMI matrix factorization. Levy et al. (2015) further discuss the connections between 4 word embedding models (PPMI, SVD, CSG, GloVe) and re-evaluate them with the same hyper-parameters. Suzuki and Nagata (2015) investigate different configurations of CSG and GloVe and merge them together. Yin and Schutze (2016) propose 4 ensemble methods and show their effectiveness over individual ones.

There is also research evaluating different context types in learning word embeddings. Heylen et al. (2008) compares dependency-based and linear vector space model for finding semantically related nouns in Dutch. Vulic and Korhonen (2016) compare CSG and dependency-based models on various languages. Their results suggest that dependency-based models are better at detecting functional similarity in English, although that does not necessarily hold for other languages. Bansal et al. (2014) show that DEPS context is preferable to linear context on parsing task. Melamud et al. (2016) investigate the performance of CSG, DEPS and a substitute-based word embedding model (Yatbaz et al., 2012)[3], which shows that different types of intrinsic tasks have clear preference for particular types of contexts. On the other hand, for extrinsic tasks, the optimal context types need to be carefully tuned on specific dataset.

The contribution of this study is that in addition to linear and dependency-based context we also consider bound and unbound context representations, as will be described below. Furthermore, we systematically evaluate three word embedding models: CSG, CBOW and GLoVe.

[2] In these two papers, the description of position-aware (bound) context are quite different. However, their ideas are actually identical.

[3] We do not consider this type of context, since in our pilot studies it performed consistently worse than the other two context types. The same observation is also made by Melamud et al. (2016); Vulic and Korhonen (2016).

3 Word Embeddings Models

In this section, we first introduce different contexts in detail, and discuss their strengths and weaknesses. We then show how CSG, CBOW and GloVe can be generalized to use these contexts.

3.1 Context Types

There are many different types of context, both on document and sentence level. For syntactic contexts, the current literature discusses mainly the linear (used in most word embedding models) and dependency-based contexts (DEPS (Levy and Goldberg, 2014a)). Linear context is defined as the positional neighbors of the target word in texts. DEPS context is defined as the syntactic neighbors of the target word based on dependency parse tree, as shown in Figure 1[4].

Compared to the linear context, DEPS context can capture more relevant words that are further away from the target word in the text. For example in Figure 1, linear context does not include the word-context pair "discovers telescope", while DEPS context contains this information. DEPS context can also exclude some uninformative word-context pairs like "with star" and "telescope with".

Note that dependency parsing is time-consuming. Despite its parallelizability, our implementation still takes nearly a month to finish dependency parsing for the Wikipedia corpus on a 32-core machine. it is only fair to compare linear and DEPS context if we ignore the time complexity. it is also worth noting that part-of-speech labels are required when performing dependency parsing.

3.2 Context Representations

In the original CSG, CBOW and GloVe models, contexts are represented by words without any additional information. Ling et al. (2015) modify CSG and CBOW by introducing position-bound words, where each contextual word is associated with their relative position to the target word. This allows CSG and CBOW to distinguish different sequential positions and capture the structural information from the context. We refer to methods that bind positional information with the contextual word as bound (context) representation, as opposed to unbound (context) representation where contextual words are treated the same irrespective of their positions with regards to the target word.

Context Type / Context Representation	Linear	DEPS
unbound	australian, scientist, star, with	scientist, star, telescope
bound	australian/-2, scientist/-1, star/+1, with/+2	scientist/nsubj, star/dobj, telescope/prep_with

Table 2: Illustration of bound and unbound representations under linear and DEPS context types. This example is based on Figure 1, and the target word is "discovers".

The original DEPS uses "bound" representation by default: each word is associated with its dependency relation to the target word. In this paper, we also investigate the simpler context representation where no dependency relation is associated with a word. This enables a fair comparison with conventional models like CSG, CBOW and GloVe, since they do not use bound representation either. An example of different syntactic context types and context representations is shown in Table 2.

Intuitively, bound representation should work better than unbound representation, since it uses information about relative word positions. However, this is not always the case in practice. An obvious drawback is that bound representation is more sparse than unbound representation, especially for DEPS context type. In our data, there were 47 dependency relations in dependency parse tree. Although not every combination of dependency relations and words appear in the word-context pair collection, in practice it still enlarges the contextual words' vocabulary about 5 times.

Both syntactic context types (linear and DEPS) and the choice of context representations (bound and unbound) have a dramatic effect on the word embeddings. Bound linear representation transfers each contextual word into a new one, and the

[4] This example is from Levy and Goldberg (2014a)

	Linear (window size 1)	DEPS
P	(**australian**, scientist) (**scientist**, australian) (**scientist**, discovers) (**discovers**, scientist) (**discovers**, star) ...	(**australian**, scientist) (**scientist**, australian) (**scientist**, discovers) (**discovers**, scientist) (**discovers**, star) (**discovers**, telescope) ...
M	(**australian**, scientist) (**scientist**, australian, discovers) (**discovers**, scientist, star) ...	(**australian**, scientist) (**scientist**, australian, discovers) (**discovers**, scientist, star, telescope) ...
$\overline{M}$	(**australian**, scientist, 1) (**scientist**, australian, 1) (**scientist**, discovers, 1) (**discovers**, scientist, 1) (**discovers**, star, 1) ...	(**australian**, scientist, 1) (**scientist**, australian, 1) (**scientist**, discovers, 1) (**discovers**, scientist, 1) (**discovers**, star, 1) (**discovers**, telescope, 1) ...

Table 3: Illustration of collection P, M and $\overline{M}$ for sentence "australian scientist discovers star with telescope". Unbound representation is used in this example. Words in the collections are **Bold**. .

word-context pairs are changed completely. DEPS, as compared to the linear contexts, increases the likelihood that the contextual words are in a meaningful relation with the target word, although some words captured by DEPS would also be found in the linear contexts if the window is wide enough. For example, in Table 2, "scientist" and "star" are considered as the contextual words of "discovers" in both linear and DEPS context types.

3.3 Generalization

Let P be a collection of word-context pairs. P can be merged based on the words to form a collection M with size of $|V|$, where V is the vocabulary. Each element $(w, c_1, c_2, .., c_{n_w}) \in M$ is word w and its contexts, where n_w is the number of word w's contexts. P can also be merged based on both words and contexts to form a collection $\overline{M}$. Each element $(w, c, \#(w, c)) \in \overline{M}$ is the word w, context c, and the times they appear in collection P. An example of these collections is shown in Table 3.

3.3.1 Generalized Bag-Of-Words

The objective function of Generalized Bag-Of-Words (GBOW) is defined as:

$$\sum_{(w,c_1,..,c_{n_w})\in M} \log p\left(w \middle| \sum_{i=1}^{n_w} \vec{c_i}\right) \tag{1}$$

With negative sampling technique, the log probability is calculated by:

$$\log \sigma\left(\vec{w} \cdot \sum_{i=1}^{n_w} \vec{c_i}\right) - \sum_{k=1}^{K} \log \sigma\left(\vec{w_{N_k}} \cdot \sum_{1=i}^{n_w} \vec{c_i}\right) \tag{2}$$

where σ is the sigmoid function, K is the negative sampling size, $\vec{w}$ and $\vec{c}$ is the vector for word w and c respectively. The negatively sampled word w_{N_k} is randomly selected on the basis of its unigram distribution $(\frac{\#(w)}{\sum_w \#(w)})^{ds}$, where $\#(w)$ is the number of times that word w appears in the corpus, and ds is the distribution smoothing hyper-parameter which is usually defined as 0.75.

Note that with negative sampling technique, both GBOW and original CBOW (Mikolov et al., 2013a) will learn two sets of embeddings (word embeddings and context embeddings). In the original CBOW, the context embeddings can also be considered as word embeddings, since the vocabulary set of words and contexts are the same. However, for bound context, the words (i.e. scientist) and contexts (i.e. scientist/nsubj) are quite different. It is necessary to distinguish conditioned and conditioning variables. For example, in Figure 1, the context "scientist/nsubj" can only be predicted by word "discovers". However, most of the word is connected to several contextual words. Due to this, the sum of contextual word embeddings should be used for predicting the target word.

3.3.2 Generalized Skip-Gram

For generalized Skip-Gram (GSG), the definition is more straightforward and the objective function actually needs no specification (Levy and Goldberg, 2014b). Nonetheless, in order to make it consistent with our GBOW, we also specify the conditioned and conditioning variables in the objective function:

$$\begin{aligned} &\sum_{(w,c)\in P} \log p\left(w|\vec{c}\right) \\ &= \sum_{(w,c)\in P} \left[\log \sigma\left(\vec{w} \cdot \vec{c}\right) - \sum_{k=1}^{K} \log \sigma\left(\vec{w_{N_k}} \cdot \vec{c}\right)\right] \end{aligned} \tag{3}$$

Note that this generalization does not change the nature of the models for linear context. In our pilot experiments on word analogy and word similarity, the performance of both GSG and GBOW is almost identical to their original versions.

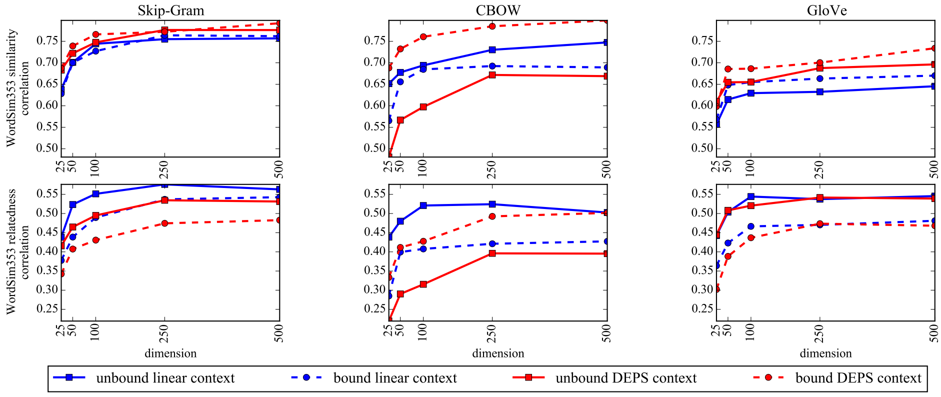

Figure 2: Correlation results for similarity and relatedness categories on WordSim353 (word similarity) dataset.

3.3.3 GloVe

Unlike GSG and GBOW, GloVe explicitly optimizes a log-bilinear regression model based on word co-occurrence matrix. Since GloVe is already a very generalized model, with the previous defined collection $\overline{M}$, the final objective function is written as:

$$\sum_{(w,c)\in\overline{M}} f(\#(w,c))(\vec{w}\cdot\vec{c}+\vec{b_w}+\vec{b_c}-\log\#(w,c)) \quad (4)$$

where $\vec{b_w}$ and $\vec{b_c}$ are biases for word and context. f is a non-decreasing weighting function and ensures that large $\#(w,c)$ is not over-weighted.

Note that the inputs of GSG, GBOW and Glove are the collections P, M and $\overline{M}$ respectively. Once the corpus and hyper-parameters are fixed, these collections (and thus the learned word embeddings) are determined only by the choice of context types and representations.

4 Experiments

We evaluate the effectiveness of different syntactic context types and context representations on word similarity, word analogy, part-of-speech tagging, chunking, named entity recognition, and text classification tasks. In this section we describe our models, and then report and discuss the experimental results on each task.

4.1 Word Embeddings

Previously, the `word2vecf` toolkit [5] (Levy et al., 2015) extended the `word2vec` toolkit [6] (Mikolov et al., 2013b) to accept the input of collection P rather than raw corpus. This makes CSG model accept arbitrary contexts (e.g. DEPS context). However, CBOW and GloVe are not considered in that toolkit. We implement `word2vecPM` toolkit, a further extension of `word2vecf`, which supports generalized CSG, CBOW and GloVe with the input of collection P, M and $\overline{M}$ respectively. For fair comparison, as suggested by Levy et al. (2015), we use the same hyper-parameters [7] for all embedding models. English Wikipedia (August 2013 dump) is used as the training corpus. The Stanford CoreNLP (Manning et al., 2014) is used for dependency parsing. After parsing, tokens are converted to lowercase. Words and contexts that appear fewer than 100 times in the collection P are ignored.

4.2 Word Similarity Task

Word similarity task aims at producing semantic similarity scores of word pairs, which are compared with the human scores using Spearman's correlation. The cosine distance is used for generating similarity scores between two word vectors. We use the WordSim353 (Finkelstein et al., 2001) dataset, divided into similarity and relatedness categories (Zesch et al., 2008; Agirre et al., 2009).

Previous research (Levy and Goldberg, 2014a; Melamud et al., 2016) concluded that compared to linear context, DEPS context can capture more functional similarity (e.g. tiger/cat) rather than topical similarity (relatedness) (e.g. tiger/jungle). However, their experiments do not distinguish the

[5] https://bitbucket.org/yoavgo/word2vecf

[6] http://code.google.com/p/word2vec/

[7] Negative sampling size is set to 5 for SG and 2 for CBOW. Distribution smoothing is set to 0.75. No dynamic context or "dirty" sub-sampling is used. The window size is fixed to 2. The number of iterations is set to 2, 5 and 30 for SG, CBOW and GloVe respectively.

effect of different context representations: unbound representation is used for linear context (Mikolov et al., 2013b), while bound representation is used for dependency-based context (Levy and Goldberg, 2014a). Moreover, only CSG model is considered.

We revisit those claims with more systematical experiments. As shown in the top-left sub-figure of Figure 2, DEPS does outperform the linear contextin GSG and GloVe in the similarity section of WordSim353, confirming its ability to capture functional similarity. However, the advantage of DEPS does not fully transfer to GBOW. Although bound DEPS context for GBOW is still the best performer, unbound DEPS context performs the worst, which shows the importance of bound vs unbound representation.

Note that the results are also reversed on WordSim353 relatedness section (the right subfigure of Figure 2), which shows that linear context is more suitable for capturing topical similarity.

Overall, DEPS context type does not get all the credit for capturing functional similarity. Context representations play an important role for word similarity task. it is only safe to say that DEPS context captures functional similarity with the "help" of bound representation. In contrast, linear context type captures topical similarity with the "help" of unbound representation.

However, the above findings come with a major caveat: a lot seems to depend on the particular dataset, in addition to the model and context type. We experimented with MEN dataset (Bruni et al., 2012), Mechanical Turk dataset (Radinsky et al., 2011), Rare Words dataset (Luong et al., 2013), and SimLex-999 dataset (Hill et al., 2016) (Table 4), and we were not able to observe uniform trends even for datasets that are supposed to capture the same relation - like the similarity part of WordSim353, Rare Words and SimLex.

Still, some models do favor a certain context type for both similarity and relatedness: e.g. GBOW favors linear unbound contexts, while GLoVE in most cases prefers DEPS over the linear context. In case of GCG, however, context type needs to be optimized for the particular dataset.

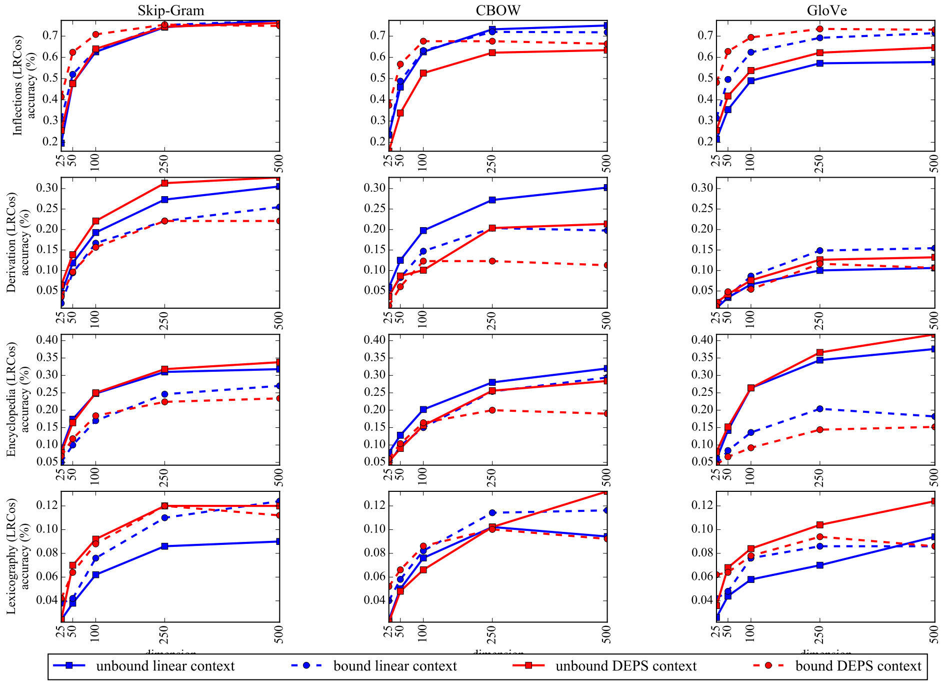

Figure 3: Averaged accuracy results for all Inflections, Derivation, Encyclopedia and Lexicography categories on BATS word analogy dataset.

4.3 Word Analogy Task

Word analogy task aims at answering the questions like "a is to a' as b is to __ ?", such as "London is to Britain as Tokyo is to Japan". We follow the evaluation protocol in Levy and Goldberg (2014b), which answers the questions using LRCos method (Drozd et al., 2016). LRCos shows significant improvement over the traditional vector offset method. We use BATS analogy dataset (Gladkova et al., 2016) in our experiments.

As shown in Figure 3, context representation plays an important role in word analogy task. The choice of context representation (bound or unbound) actually has much larger impact than the choice of context type (linear or DEPS). The results on Encyclopedia category are perhaps the most evident. The performance of unbound linear context and unbound DEPS context is similar. However, for most models and categories, bound representation seems to outperform unbound representation. When bound representation is used, the performance drops around $5 - 15$ percent for DEPS context in terms of accuracy. This is consistent with the findings of Levy and Goldberg (2014a), who report that DEPS context did not work well for the analogy task.

As shown in Table 5, we have also experimented on two much smaller datasets: MSR analogy dataset (Mikolov et al., 2013c), and Google analogy dataset (Mikolov et al., 2013a) (with semantic and syntactic questions). They also show that the choice of context representation has more impact than the choice of context type.

4.4 POS, Chunking and NER Tasks

Although intrinsic evaluations like word similarity and word analogy tasks could provide direct insights about different context types and representations, they have certain methodological problems (Gladkova and Drozd, 2016), and the experimental results above cannot be directly translated to the typical uses of word embeddings in downstream tasks (Schnabel et al., 2015; Linzen, 2016; Chiu et al., 2016). Thus extrinsic tasks should also be considered.

In this subsection, we evaluate the effectiveness of different word embedding models with different contexts on Part-of-Speech Tagging (POS), Chunking[8] and Named Entity Recognition (NER) tasks [9]. For these tasks, a NLP system assigns labels to elements of texts. Note that in practice, one should NOT use DEPS context for POS-tagging and chunking tasks, since their labels are used in

[8] CoNLL 2000 shared task http://www.cnts.ua.ac.be/conll2000/chunking

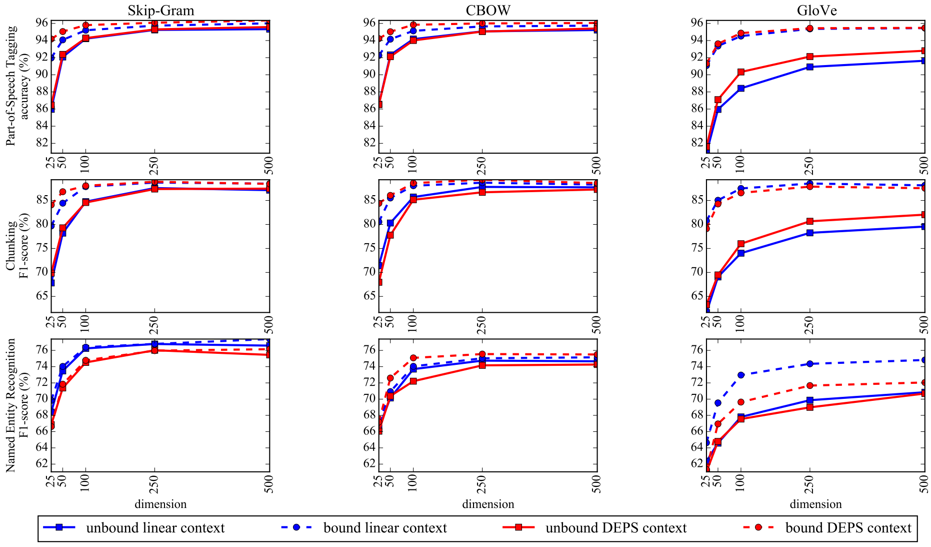

Figure 4: Accuracy or F_1-score results on Part-of-Speech Tagging, Chunking and Named Entity Recognition tasks.

parsing the source corpus.

Following the evaluation protocol used in Kiros et al. (2015), we restrict the predicting model to Logistic Regression Classifier[10]. The classifier's input for predicting the label of word w_i is simply the concatenation of word vectors $\vec{w_{i-2}}$, $\vec{w_{i-1}}$, $\vec{w_i}$, $\vec{w_{i+1}}$, $\vec{w_{i+2}}$. This ensures that the quality of embedding models is directly evaluated, and their strengths and weaknesses are easily observed.

Model	Context Type	Context Representation	POS	Chunking	NER

		bound	**96.0**	**88.6**	**75.5**
GloVe	linear	unbound	91.6	79.6	70.8
		bound	**95.5**	**88.2**	**74.8**
	dep	unbound	92.8	82.0	70.7
		bound	**95.5**	87.5	72.0

Table 6: Numerical results on Part-of-Speech Tagging, Chunking and Named Entity Recognition tasks. Best results in group are marked **Bold**.

As shown in Figure 4 and Table 6, GSG, GBOW and GloVe exhibit overall similar trends. When the same context type is used, bound representation outperforms unbound representation on all tasks. Sequence labeling tasks are not sensitive to syntax. For bound representation, the ignorance of syntax becomes beneficial, since it decreases the amount of noise and sparsity.

Moreover, DEPS context type works slightly better than linear context type in most cases. These results suggest that unbound linear context (as in traditional CSG and CBOW) may not be the best choice of input word vectors for sequence labeling. Bound representations should always be used and DEPS context type is also worth considering. Again, similar to the word analogy task, GloVe is more sensitive to different context representations than Skip-Gram and CBOW.

4.5 Text Classification Task

Finally, we evaluate the effectiveness of different word embedding models with different syntactic contexts on text classification task. Text classification is one of the most popular and well-studied tasks in natural language processing. Recently, deep neural networks achieve state-of-the-art results on this task (Socher et al., 2013; Kim, 2014; Dai and Le, 2015). They often need pre-trained word embeddings as inputs to improve their performances. Similarly to the previous evaluation of sequence labeling tasks, instead of building complex deep neural networks, we use a simpler classification method called Neural Bag-of-Words (Li et al., 2017) to directly evaluate the word embeddings: texts are first represented by the sum of their word vectors, then a Logistic Regression Classifier (the same as that in previous subsection)

Table 7: Accuracy results on 5 text classification datasets. Best results in group are **Bold**

is built upon these text representations for classification.

Different word embedding models are evaluated on 5 text classification datasets. The first 3 datasets are sentence-level: short movie review sentiment (MR) (Pang and Lee, 2005), customer product reviews (CR) (Nakagawa et al., 2010), and subjectivity/objectivity classification (SUBJ) (Pang and Lee, 2004). The other 2 datasets are document-level with multiple sentences: full-length movie review (RT-2k) (Pang and Lee, 2004), and IMDB movie review (IMDB) (Maas et al., 2011)[11].

As shown in Table 7, pre-trained word embeddings outperform random word embeddings by a large margin. This strengthens the previous claim that pre-trained word embeddings are highly useful for text classification (Iyyer et al., 2015; Li et al., 2017). Unlike in the other tasks, in text classification all models exhibit similar performance. Text classification has less focus on syntax and function similarity. Because of that, models with bound representation perform worse than those with unbound representation on almost all datasets except CR. Models with DEPS context type and linear context type are comparable. These observations suggest that simple unbound linear context type (as in traditional CSG and CBOW) is still the best choice of pre-training word embeddings for text classification, which is already used in most studies.

5 Conclusion

This paper provides a first systematical investigation of different syntactic context types (linear vs dependency-based) and different context representations (bound vs unbound) for learning word embeddings. We evaluate GSG, GBOW and GloVe models on intrinsic property analysis tasks (word similarity and word analogy), sequence labeling tasks (POS, Chunking and NER) and text classification task.

We find that most tasks have clear preference for different context types and representations. Context representation plays a more important role than context type for learning word embeddings. Only with the "help" of bound representation does DEPS context capture functional similarity. Word analogies seem to prefer unbound representation, although performance varies by question type No matter which syntactic context type is used, bound representation is essential for sequence labeling tasks, which benefits from its ability of capturing functional similarity. GSG with unbound linear context is still the best choice for text classification task. Linear context is sufficient for capturing topical similarity compared to more labor-intensive DEPS context. Words' position information is generally useless for text classification, which makes bound representation contribute less to this task.

In the spirit of transparent and reproducible experiments, the `word2vecPM` toolkit [12] is published along with this paper. We hope researchers will take advantage of the code for further improvements and applications to other tasks.

Acknowledgments

We thank the authors of the `word2vecf` toolkit and the accompanied evaluation scripts (Levy et al., 2015). Their work systematically investigated the effects of different hyper-parameters on various word embedding models, which directly influenced us a lot.

Does syntax help discourse segmentation? Not so much

Abstract

Discourse segmentation is the first step in building discourse parsers. Most work on discourse segmentation does not scale to real-world discourse parsing across languages, for two reasons: (i) models rely on constituent trees, and (ii) experiments have relied on gold standard identification of sentence and token boundaries. We therefore investigate to what extent constituents can be replaced with universal dependencies, or left out completely, as well as how state-of-the-art segmenters fare in the absence of sentence boundaries. Our results show that dependency information is less useful than expected, but we provide a fully scalable, robust model that only relies on part-of-speech information, and show that it performs well across languages in the absence of any gold-standard annotation.

1 Introduction

Discourse segmentation is the task of identifying, in a document, the minimal units of text – called Elementary Discourse Units (EDU) (Carlson et al., 2001) – that will be then linked by semantico-pragmatic relations – called discourse relations. Discourse segmentation is the first step when building a discourse parser, and has a large impact on the building of the final structure – predicted segmentation leads to a drop in performance of about 12-14% (Joty et al., 2015).

In this work, we focus on the Rhetorical Structure Theory (RST) (Mann and Thompson, 1988) in which discourse analysis is a tree covering an entire document. Most of the recent discourse parsers have been developed within this framework, making crucial the development of robust RST discourse segmenters. Many corpora have been annotated within this framework for several domains and languages – such as English with the RST Discourse Treebank (RST-DT) (Carlson et al., 2001), but also Spanish (da Cunha et al., 2011), Brazilian Portuguese (Cardoso et al., 2011; Collovini et al., 2007; Pardo and Seno, 2005; Pardo and Nunes, 2004) or German (Stede and Neumann, 2014).

State-of-the-art performance for discourse segmentation on the RST-DT is about 94% in F_1 (Xuan Bach et al., 2012). Most work on discourse parsing has focused on English and on the RST-DT (Ji and Eisenstein, 2014; Feng and Hirst, 2014; Li et al., 2014; Joty et al., 2013), and so discourse segmentation (Xuan Bach et al., 2012; Fisher and Roark, 2007; Subba and Di Eugenio, 2007). And while discourse parsing is a document level task, discourse segmentation is done at the sentence level, assuming that sentence boundaries are known. This prevents from using discourse information for a wider range of downstream tasks.

Moreover, while discourse parsing is a semantic task involving a large range of information, the annotation guidelines reflect that segmentation is merely based on syntax: in practice, an EDU can not overlap sentence boundaries – while some discourse trees can cross the sentence boundaries (van der Vliet and Redeker, 2011) –, and deciding whether a clause is an EDU in the RST-DT strongly depends on its syntactic function – e.g. "Clauses that are subjects or objects of a main verb are not treated as EDUs" (Carlson and Marcu, 2001). Consequently, existing discourse segmenters heavily rely on information derived from constituent trees usually following the Penn Treebank (PTB) (Marcus et al., 1993) guidelines. Nevertheless constituent trees are not easily available for any language. Finally, even for English, using predicted trees leads to a large drop in per-

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2432–2442
Copenhagen, Denmark, September 7–11, 2017.

formance for discourse segmentation.

Recently, Braud et al. (2017) proposed the first cross-lingual and cross-domain experiments for discourse segmentation, relying only on words and Part-of-Speech (POS) tags (morpho-syntactic level). However, they focus on document-level discourse segmentation – preventing from a comparison with previous work –, and they did not include any syntactic information. In this paper, we significantly extend their work by investigating the use of syntactic information, reporting results with various sets of features at the sentence level – varying the settings between gold and predicted, and fine-grained vs coarse grained information –, and studying the impact of tokenisation.

Our contributions

- We develop new discourse segmenters that can be used for many languages and domains since they rely on easily available resources;
- We investigate the usefulness of syntactic information when derived from Universal Dependencies (UD) (Nivre et al., 2016) parse trees, compare it to simpler representations and show that accurate POS tags are better than low quality parse trees;
- We compare different settings considering gold and predicted POS tags, tokenization and sentence segmentation.

2 Related work

First discourse segmenters on the RST-DT were based on hand-crafted rules, relying on punctuation, POS tags, discourse cues (e.g. "but", "because", "after") and syntactic information (Le Thanh et al., 2004; Tofiloski et al., 2009). Segmenters based on handwritten rules have also been developed for Brazilian Portuguese (Pardo and Nunes, 2008) (51.3% to 56.8%, depending on the genre), for Spanish (da Cunha et al., 2010, 2012) (80%) and for Dutch (van der Vliet, 2010) (73% with automatic parse, 82% with gold parse).[1]

More recent discourse segmenters on the RST-DT are based on binary classifiers at the word level (Soricut and Marcu, 2003; Fisher and Roark, 2007; Joty et al., 2015), possibly using a neural network architecture (Subba and Di Eugenio, 2007). Joty et al. (2015) also report results for the Instructional corpus (Subba and Di Eugenio, 2009) (F_1 80.9% on 10-fold).

Interestingly, Fisher and Roark (2007) investigate the utility of parse-derived features for the task. More precisely, they compare different sets of features derived from constituent trees, using n-grams or paths in a tree that could be a full constituent tree or a shallow parse (chunks). Their system thus requires chunker or constituent parser. In contrast, we investigate the usefulness of syntactic information derived from dependency parses, and we extend their work in also comparing our results to the use of only POS tags and words.

For English RST-DT, the best discourse segmentation results were presented in Xuan Bach et al. (2012) (F_1 91.0% with automatic parse, 93.7 with gold parse). They cast discourse segmentation as a sequence labeling problem, as also done in (Sporleder and Lapata, 2005; Hernault et al., 2010). More precisely, they develop a base system using CRF on top of which they add a reranking model. Their base system relies on lexico-syntactic features including words, POS tags – from the Penn Treebank (PTB) annotation scheme –, and paths in the constituent trees. The reranking systems then considers subtrees features, corresponding to the boundaries of a candidate EDU and the common boundary of two consecutive candidates EDUs. This post-processing only leads to small improvements: about 1.2% when using gold syntactic information, and only 0.3% with predicted trees.

All these systems rely on a quite large range of lexical and syntactic features (e.g. token, POS tags, chunks, lexicalized production rules, discourse connectives). Sporleder and Lapata (2005) present arguments for a knowledge-lean system that can be used for low-resourced languages. Their system, however, still relies on several tools and gold annotations (e.g. POS tagger, chunker, list of connectives, gold sentences). Moreover, previous work always rely on gold sentence boundaries, and only considers intra-sentential segment boundaries while sentence boundaries are not available for all languages.

Braud et al. (2017) recently proposed the first systems for discourse segmentation of entire documents directly applicable to low-resource languages. Their systems only rely on Universal De-

[1] For German, Sidarenka et al. (2015) propose a segmenter in clauses (that may be EDU or not).

pendencies POS tagging, for which models are available for many languages. As done in that study, we do sequence prediction using a neural network. However, we extend their work significantly in reporting results for intra-sentential segmentation, in comparing more settings concerning the availability of information (tokenisation, POS tags), and in including syntactic information into our systems.

3 Discourse segmentation

3.1 Binary task

Since the EDUs cover the documents entirely, discourse segmentation is generally cast as a binary task at the word level, where the goal is to find which word indicates an EDU boundary: A word is thus either beginning an EDU (label 'B'), or within an EDU (label 'I').

This design choice assumes that EDUs are adjacent spans of text, that is an EDU begins just after the end of the previous EDU. This is not entirely true in RST corpora, where embedded EDUs could break up another EDU, as in Example (1) taken from the RST-DT annotation manual (Carlson and Marcu, 2001). The units 1 and 3 form in fact one EDU, which is acknowledged by the annotation of a pseudo-relation SAME-UNIT between these segments.

(1) [But maintaining the key components (. . .)]$_1$
[– a stable exchange rate and high levels of imports –]$_2$
[will consume enormous amounts (. . .).]$_3$

We follow previous work on treating this as three segments, but note that this may not be the optimal solution. It introduces a bias: while most of the EDUs are full clauses, EDU 1 and 3 are fragments. Other designs are possible, especially a multi-label setting as done in (Afantenos et al., 2010) for a corpus annotated within the Segmented Discourse Representation Theory (Asher and Lascarides, 2003). While it seems relevant to deal with this issue during segmentation rather than using a pseudo-relation, it introduces new issues (i.e. the final structures are not trees anymore). We thus leave this question for future work.

3.2 Sentence *vs* document-level segmentation

Most of the existing work on discourse segmentation always assume a gold segmentation of the sentences: since an EDU boundary never crosses a sentence boundary,[2] these systems only perform intra-sentential segmentation. This is motivated by the quite high performance of sentence segmenters. In our experiments, we report intra-sentential results, in order to compare our systems to previous ones.

However, sentence boundaries are not always available. In a situation where both inter and intra-sentential segmentation is required, there are two alternatives: processing the tasks sequentially or simultaneously. In preliminary experiments we considered using the multilingual system UDPipe [3] (Straka et al., 2016) to segment document into sentences in an effort to use tools available in multiple languages. However, the segmentation is far from perfect: 7.5% of the words marked as beginning a sentence were not an EDU boundary in the RST-DT, thus corresponding to an error.

We thus rather decided to rely on a model performing both inter- and intra-sentential segmentation. We aim at building systems directly segmenting entire documents. Then in order to provide performance of discourse segmenters in a realistic setting, our final systems jointly predict sentence and intra-sentential EDU boundaries.

Finally, for the English RST-DT, we present two performance metrics:

- F_1 for intra-sentential boundaries only (see Section 7.1), in order to be comparable with state-of-the-art systems;
- and F_1 for all EDU boundaries, in order to set up a document-level baseline (see Section 7.2).

For the other languages and domains, since we do not have access to gold sentence boundaries, we only present results at the document level.

4 Approach

4.1 Neural network for sequence prediction

We model the task as a sequence prediction task using a neural network architecture. Our model consists of a stacked k-layer bi-LSTM, a variant of LSTM (Hochreiter and Schmidhuber, 1997) that

[2] With two exceptions in the RST DT, possibly due to errors in the discourse or syntactic annotation (Documents 2343 and 0678). As probably done in previous works, we do not consider these cases as separate sentences, following the discourse annotation.

[3] http://ufal.mff.cuni.cz/udpipe

reads the input in both regular and reversed order. This enables to take into account both left and right context (Graves and Schmidhuber, 2005). This is a crucial property for discourse segmentation, especially with the simplified representations we consider, since the decision depends on the context, e.g. coordinated NPs are not segmented while coordinated VPs are, our model must thus learn to distinguish a VP from a NP without using constituent parses.

The model takes as input a concatenation of randomly initialized and trainable embeddings of words and their morpho-syntactic features (see Section 4.3). The sequence goes through the k-stacked layers, and we output the concatenation of the backward and forward states. At the upper level, we compute the prediction using a Multi-Layer Perceptron. We used the Adam trainer. All other hyper parameters were tuned on development data; see Section 6.2 for a description of hyper-parameter tuning, and our final parameters. [4]

4.2 Tokenization and sentence splitting

In order to evaluate the impact of tokenization on discourse segmentation we propose two settings for English: one for which we evaluate on gold tokens – as done in all previous work –, and another one where tokenization is pre-processed using the UDPipe tokenizer. For the other languages, the task is always evaluated on non-gold tokens.

In the same way, we investigate the impact of gold sentence splitting by considering the traditional setting where discourse segmentation is only intra-sentential (gold sentences) and the more realistic one where we directly segment documents (sentence boundaries are unknown).

4.3 Features

To the best of our knowledge, we are the first to report the scores one can expect when not using syntactic trees and/or cue phrases, that is, only based on words or POS tags. These are interesting results, because they correspond to representations that can be built easily for any new language.

In addition, we investigate the impact of gold *vs* predicted features for discourse segmentation for English, and of automatic pre-processing of the data before feature extraction (tokenization). Until now, only the impact of using predicted constituent trees had been investigated. But since constituent treebanks are not readily available for many languages, we limit ourselves to (predicted) dependency trees.

Focusing on English allows us to set up a baseline using predicted feature information (document level) which could then be evaluated on other languages for which no gold features are available.

We evaluate both the performance when using single features and when combining the features described above, each corresponding to a (randomly intialized) real valued vector. The vectors for each features are concatenated to build a representation of a single word.

Lexical information Our first features are lexical. We use each token as a feature, being represented by a real-valued vector.

Morpho-syntactic features POS tags are also valuable information for the task, for example conjunctions and adverbs may often begin an EDU, because they can correspond to a discourse connective (e.g. “because”, “if”, “and”, “after”).

For English, we want to compare between gold and predicted information: gold PTB POS vs predicted PTB POS. For this last setting, we use predicted POS tag features for both training and testing our discourse segmenter in order to minimize the difference between training data and test data. We use our own POS-tagger,[5] which achieves 96.6% accuracy on test data, to predict the POS-tags. The test and development (discourse) data are tagged using a model trained on the entire training set, and the training data are tagged using a 10-fold cross-validation.

We also compare between scarce and available information (predicted setting): PTB POS (fine grained - 45 tags) vs UD POS (coarse grained - 17 tags). For predicting UD POS tags we make use of the UDPipe system (retrained on the v1.3 UD data).

Syntactic information We augment our representation with syntactic information available for many languages: supertags (STAGS) extracted from dependency parsed trees (predicted using UDpipe in the same setting as for POS-tags).

[4] Our system has been implemented with the Dynamic Neural Network Toolkit (Neubig et al., 2017).

[5] Bi-LSTM tagger (keras-based implementation) using non-supervised features about words (e.g. capitalization, suffixes).

Figure 1: Features extracted from a (part of a) sentence and its predicted UD dependency tree.

Our selection of supertags is first inspired by the work of Ouchi et al. (2016) on supertagging for dependency parsing, and second on our own expertise of discourse segmentation and UD scheme. Actually a large part of EDU boundaries which need syntactic information to be disambiguated are function words such as “to” or “and”. Since the UD scheme favors the attachments via content words rather than function words, the latter are often leaves in the dependency trees. It means that the valuable information for these words comes from their parents, their grand-parents or their siblings. We thus extract the following features for each token:

- *hlab*, the label of its incoming dependency (47 UD labels);
- *hhlab*, the label of its incoming dependency of the token's head (37 UD labels + NONE : 26% nmod, 23% root);
- *hdir*, the direction of its incoming dependency (3 tags : RIGHT, LEFT or ROOT);
- *hpos*, the UD POS-tag of its head (17 UD tags + ROOT : 41% NOUNs, 34% VERBs and 10% PROPNs);
- *htok*, its head token (11.483 different tokens);
- *hhtok*, the head of its head token (8.266 different tokens);
- *sleft*, the POS and incoming label of its left siblings (if it is a coordination or an object) (265 tags);
- *sright*, the POS and incoming label of its right siblings (if it is a coordination or an object) (331 tags).

An example for which supertags help to identify EDU boundaries is presented in Figure 1.

5 Corpora

Corpus	#Doc	#EDU	#Sent	#Word
En-SFU-DT	400	28, 260	16, 827	328, 362
En-DT	385	21, 789	9, 074	210, 584
Pt-DT	330	12, 594	4, 385	136, 346
Es-DT	266	3, 325	1, 816	57, 768
En-Instr-DT	176	5, 754	3, 090	56, 197
De-DT	174	2, 979	1, 805	33, 591

Table 1: Number of documents, EDUs, sentences and words (according to UDPipe).

For English, we use three corpora, allowing us to evaluate how robust is our model across domains. First, we report results on the RST-DT (from now on called En-DT), the most widely used corpus for this task. This corpus is composed of Wall Street Journal articles, it has been annotated over the Penn Treebank. We also report performance on the SFU review corpus[6] (En-SFU-DT)

[6] https://www.sfu.ca/~mtaboada

containing product reviews, and on the instructional corpus (En-Instr-DT) (Subba and Di Eugenio, 2009) built on instruction manuals.[7]

We also evaluate our model across languages. For Spanish, we report performance on the corpus (Es-DT) presented in (da Cunha et al., 2011),[8]. For German, we use the Postdam corpus (De-DT) (Stede, 2004; Stede and Neumann, 2014). For Brazilian Portuguese (Pt-DT), we merged four corpora (Cardoso et al., 2011; Collovini et al., 2007; Pardo and Seno, 2005; Pardo and Nunes, 2003, 2004) as done in (Maziero et al., 2015; Braud et al., 2017).

Table 1 summarizes statistics about the data.

6 Experiments

6.1 Evaluation

For English, on the En-DT, evaluation for discourse segmentation has been done under different conditions.

First, all previous systems were evaluated on the same set of 38 documents that initially contains 991 sentences – and more precisely on each sentence of this set for intra-sentential results. However, Soricut and Marcu (2003) do not consider sentences that are not exactly spanned by a discourse subtree (keeping only 941 sentences in the test set), and Sporleder and Lapata (2005) only keep the sentences that contain intra-sentential EDUs (608 sentences).

Since we want to give results at the document level, – with the sentence boundaries being predicted as the other EDU boundaries –, there is no reason to remove any sentences. We thus keep all the 991 sentences in the test set as done in (Fisher and Roark, 2007; Xuan Bach et al., 2012) at the sentence level, and in (Braud et al., 2017) at the document level.

For the other corpora (see Section 5), we either use the official test set (Es-DT, 84 documents) or build a test set containing 38 documents chosen randomly.

Second, since Soricut and Marcu (2003), the evaluation scores do not include the first boundary of a sentence. Exceptions are (Sporleder and Lapata, 2005), and some results in (Fisher and Roark, 2007) given to compare with the former.

For intra-sentential results, we also ignore the first boundary of each sentence when computing the final score. At the document level, we ignore the first boundary of each document (thus keeping the first boundary of the sentences within the document).

The reported score is the F_1 over the boundaries (the 'B' labels), ignoring the non-boundary words ('I' labels).

6.2 Hyper-parameters

The model has several hyper-parameters, all tuned on the development set over the F_1.

Concerning the dimensions of the input layer d, we tested several values when experimenting on models using only one type of feature (for the POS tags, we only tuned on PTB gold), with $d \in \{50, 100, 200, 300\}$ for the words, and $d \in \{4, 8, 16, 32, 64\}$ for the others.[9] We then keep the best values (300 for words, 64 for the POS tags and 32 for each supertag[10]) for each feature when concatenating.

We also tuned the number of hidden layers $n \in \{1, 2\}$, and the size of the hidden layers $h \in \{50, 100, 200, 400\}$ when experimenting on single features, and used 1 hidden layer of size 200 in our final experiments. Our output layer is of size 32.

The number of iterations i with $1 \leq i \leq 20$ is tuned on the development set for each experiment.

Note that this may not be optimal, as better results could be obtained by tuning all the hyper-parameters for each set of features. But we aim at providing a fair comparison between the models, and thus always keep the same architecture.

7 Results

7.1 Intra-sentential segmentation

Our results for intra-sentential segmentation are summarized in Table 2. Recall that these results are only on the En-DT.

Single features Using only words lead to 81.3% in F_1, which is already high considering that words are generally considered as a too sparse representation especially with a quite small dataset.

[7] We only report fully supervised results, we thus do not consider the GUM corpus and the corpus for Dutch, contrary to (Braud et al., 2017).

[8] We only use the test set from the annotator A.

[9] Supertags that correspond to words – i.e. "htok" and "hhtok" – are considered as words and thus correspond to vectors of the same dimension as other words.

[10] We report results using the supertags where the input is the concatenation of several vectors with 32 dimensions representing each supertag.

It is clear that lexical information can help, for example to identify EDUs corresponding to complements of attribution verbs – the verb could be the word at the end of the previous EDU as in example (2a) or the word beggining the EDU as in example (2b) –, these verbs being part of a limited list (e.g. “declared”, “said”, “reported”).

(2) a. [Mercedes officials said] [they expect flat sales next year]

b. [Kodak understands] [HDTV is where everybody is going,”] [says RIT’s Mr. Spaull.]

More precisely, we found out that only $1,409$ tokens are an EDU boundary in the En-DT training set (over about $16,577$ tokens in the vocabulary). Among them, 909 only appear once as a boundary, and 104 are a boundary more than 10 times making for 79.7% of all the boundaries. Lexical information is thus not so sparse for this task.

Using POS tags alone allows to improve these results, but only when using PTB gold POS (+3.7%). Contrary to words, 99.7% of the POS tags from the PTB appear as an EDU boundary more than 10 times, but only a few are almost always indicating the beginning of an EDU (i.e. more than 70% of the occurrences), namely WDT, -LRB-, WP, WRB and WP$. Our results demonstrate that our model is able to take into account the context in terms of the surrounding POS tags to identify a boundary.

As expected, using predicted PTB POS tags leads to lower results than gold ones (-3.4%), reflecting the impact of the noise introduced. Moreover, using fine grained PTB POS tags, even predicted ones, is better than using coarse grained POS UD (-5.4%), indicating that the UD scheme lacks fine distinctions needed for the task. For example, WDT and WP$ are mapped to DET in the UD scheme, and WP to PRON, two categories that become very ambiguous between indicating an EDU boundary or not (respectively, 28% and 10%), thus inducing more errors. Note that using words only is better, or similar to using predicted or coarse-grained POS tags, demonstrating once again the usefulness of the lexical information.

Finally, using supertags (STAGS) leads to results similar to using words or predicted PTB POS tags, but higher than the ones obtained with the POS UD (+4.8%), reflecting that they include more information. Among the supertags, we found that using “sleft” and “sright” does not make real difference when the supertags are used alone (80.9% with them, and 81% without). This could come from the huge sparsity of this feature.[11] We decided to not include them in the rest of the experiments.

System	(Morpho-)syntax	F_1
	Gold tokenization	
(Subba and Di Eugenio, 2007)	Gold	86.1

Table 2: Intra-sentential results on the En-DT. Xuan Bach et al. (2012) report the best results, Subba and Di Eugenio (2007) is a segmenter based on neural networks, Fisher and Roark (2007) proposed a study on syntactic information.

Combining features Combining words and gold PTB POS tags leads to our better results (91%), with a large increase over using only words (+9.7%) or PTB gold POS (+6%). Note that this score is as high as the one reported by (Xuan Bach et al., 2012; Fisher and Roark, 2007) when using predicted constituent trees: this indicates that a syntactic information that is noisy does not help that much, since perfect POS tags are enough to reach the same performance.

As previously, using predicted PTB POS tags or coarse-grained UD POS tags leads to a drop in performance compared to gold PTB POS tags,

[11] 94% of the tokens have no “sleft” tag and 90% no “sright” tag.

but the scores are still largely higher than when only one type of features is used, demonstrating that lexical and morpho-syntactic features bring complementary information. The gain in F_1 is even higher when using noisy/coarse grained POS tags than when using gold ones, showing that lexical information allows to replace part of the missing/incorrect information.

Finally, combining supertags leads to mixed results: they allow to improve over using only UD POS tags (+3.4%), showing that they convey new relevant information, but the scores are lowered compared to using only the supertags (-1.4%). Moreover, when combined also with words (Words+POS UD+STAGS), we observe a small drop in performance compared to only combining them with the UD POS tags (Words+POS UD, -1.3%). More importantly, using syntactic information does not lead to results as high as the ones obtained with gold PTB POS tags.

Predicted tokenization In general, relying on predicted tokens lowers the performance, probably because it leads to more errors for POS tagging (-2.2% when using only the UD POS tags compared to gold tokenization). However, it does not really affect performance with lexical information, and the other scores are similar to the ones obtained with gold tokens.

7.2 Document-level results

Multi-lingual and multi-domain results are presented in Table 3. Again, the use of syntactic information leads to mixed results: in general, results are similar with or without supertags, but it could also lead to a large drop in performance as it can be seen especially for the En-DT, the En-SFU-DT and the En-Instr-DT. It could come from more important differences in the annotation schemes for these very different domains.

Our results are in general better than the one reported in (Braud et al., 2017), which could come from the way features are incorporated (they encode each document as a sequence of words and POS tags, rather than directly combining the vectors). Our scores on the En-DT are a bit lower than those reported in (Braud et al., 2017), but note that these authors fine tuned their system at the document level, while we optimized it at the intra-sentential one.

	SOA	Words+UD	Words+UD+S-tags
En-DT (news)	**89.5**	89.0	87.0
En-SFU-DT	85.5	**87.6**	86.0
En-Instr-DT	87.1	**88.3**	86.4
Pt-DT	82.2	82.9	**83.0**
Es-DT	**79.3**	78.7	78.3
De-DT	85.1	85.8	**86.2**

Table 3: Multi-domain and multi-lingual document-level results. State-of-the-art (SOA) results reported in (Braud et al., 2017).

8 Discussion

In order to investigate the drop in F_1 between gold and predicted POS tags we looked at the distribution of the POS tags in the train set, and, for each POS, the percentage of instances being a discourse boundary and their accuracy when predicted.

Globally, the accuracy of POS-tagging on EDU boundaries is lower (95.6%) than on the non-EDU boundaries. However, the most frequent POS assigned to EDU boundaries (i.e. 'IN', 'CC', 'PRP', 'TO' and 'VBG') achieve accuracy between 97.4 and 100% and cover 50% of the EDU boundaries.

We also saw that some very frequent POS are rarely an EDU boundary, such as 'NN, 'JJ' or the comma.[12] But the low accuracy of some of these frequent POS tags (94.8 for 'NN' and 90.1 for 'JJ') can still hurt discourse segmentation as they often appear in the context of the EDU boundaries. On the contrary, some quite infrequent POS are really frequent EDU boundaries, such as 'WP' (Wh-pronoun), 'WDT' (Wh-determiner), 'WRB' (Wh-adverb), -LRB-, 'WP$' (Possessive wh-pronoun) and 'LS' (List item marker). Except for 'WDT' (90.8%) their POS-tagging scores are high (100% for 'WP', '-LRB-' and 'Wp$' and 98.3% for 'WRB'). But because they are infrequent, they could be hard to identify as boundaries. They could be even more difficult to identify using the UD scheme since these POS tags are mapped to frequent UD POS tags that cover very different tokens ('DET', 'PRON', 'ADV').

9 Conclusion

We proposed new discourse segmenters that make use of resources available for many languages and domains. We investigated the usefulness of syn-

[12] The only example with a comma corresponds probably to a segmentation error, the comma being preceded by a point corresponding to an acronym (Doc 1390).

tactic information when derived from dependency parse trees, and showed that this information is not as useful as expected, and that gold POS tags give as high results as using predicted constituent trees. We also showed that scores are lowered when considering a realistic setting, relying on predicted tokenization and not assuming gold sentences. We make our code available at https://bitbucket.org/chloebt/discourse/.

Abstract

Much of human dialogue occurs in semi-cooperative settings, where agents with different goals attempt to agree on common decisions. Negotiations require complex communication and reasoning skills, but success is easy to measure, making this an interesting task for AI. We gather a large dataset of human-human negotiations on a multi-issue bargaining task, where agents who cannot observe each other's reward functions must reach an agreement (or a deal) via natural language dialogue. For the first time, we show it is possible to train end-to-end models for negotiation, which must learn both linguistic and reasoning skills with no annotated dialogue states. We also introduce *dialogue rollouts*, in which the model plans ahead by simulating possible complete continuations of the conversation, and find that this technique dramatically improves performance. Our code and dataset are publicly available.[1]

1 Introduction

Intelligent agents often need to cooperate with others who have different goals, and typically use natural language to agree on decisions. Negotiation is simultaneously a linguistic and a reasoning problem, in which an intent must be formulated and then verbally realised. Such dialogues contain both cooperative and adversarial elements, and require agents to understand, plan, and generate utterances to achieve their goals (Traum et al., 2008; Asher et al., 2012).

We collect the first large dataset of natural language negotiations between two people, and show that end-to-end neural models can be trained to negotiate by maximizing the likelihood of human actions. This approach is scalable and domain-independent, but does not model the strategic skills required for negotiating well. We further show that models can be improved by training and decoding to maximize reward instead of likelihood—by training with self-play reinforcement learning, and using rollouts to estimate the expected reward of utterances during decoding.

To study semi-cooperative dialogue, we gather a dataset of 5808 dialogues between humans on a negotiation task. Users were shown a set of items with a value for each, and asked to agree how to divide the items with another user who has a different, unseen, value function (Figure 1).

We first train recurrent neural networks to imitate human actions. We find that models trained to maximise the likelihood of human utterances can generate fluent language, but make comparatively poor negotiators, which are overly willing to compromise. We therefore explore two methods for improving the model's strategic reasoning skills—both of which attempt to optimise for the agent's goals, rather than simply imitating humans:

Firstly, instead of training to optimise likelihood, we show that our agents can be considerably improved using *self play*, in which pre-trained models practice negotiating with each other in order to optimise performance. To avoid the models diverging from human language, we interleave reinforcement learning updates with supervised updates. For the first time, we show that end-to-end dialogue agents trained using reinforcement learning outperform their supervised counterparts in negotiations with humans.

Secondly, we introduce a new form of planning for dialogue called *dialogue rollouts*, in which an

agent simulates complete dialogues during decoding to estimate the reward of utterances. We show that decoding to maximise the reward function (rather than likelihood) significantly improves performance against both humans and machines.

Analysing the performance of our agents, we find evidence of sophisticated negotiation strategies. For example, we find instances of the model feigning interest in a valueless issue, so that it can later 'compromise' by conceding it. Deceit is a complex skill that requires hypothesising the other agent's beliefs, and is learnt relatively late in child development (Talwar and Lee, 2002). Our agents have *learnt to deceive* without any explicit human design, simply by trying to achieve their goals.

The rest of the paper proceeds as follows: §2 describes the collection of a large dataset of human-human negotiation dialogues. §3 describes a baseline supervised model, which we then show can be improved by goal-based training (§4) and decoding (§5). §6 measures the performance of our models and humans on this task, and §7 gives a detailed analysis and suggests future directions.

2 Data Collection

2.1 Overview

To enable end-to-end training of negotiation agents, we first develop a novel negotiation task and curate a dataset of human-human dialogues for this task. This task and dataset follow our proposed general framework for studying semi-cooperative dialogue. Initially, each agent is shown an input specifying a space of possible actions and a reward function which will score the outcome of the negotiation. Agents then sequentially take turns of either sending natural language messages, or selecting that a final decision has been reached. When one agent selects that an agreement has been made, both agents independently output what they think the agreed decision was. If conflicting decisions are made, both agents are given zero reward.

2.2 Task

Our task is an instance of *multi issue bargaining* (Fershtman, 1990), and is based on DeVault et al. (2015). Two agents are both shown the same collection of items, and instructed to divide them so that each item assigned to one agent.

Each agent is given a different randomly generated value function, which gives a non-negative value for each item. The value functions are constrained so that: (1) the total value for a user of all items is 10; (2) each item has non-zero value to at least one user; and (3) some items have non-zero value to both users. These constraints enforce that it is not possible for both agents to receive a maximum score, and that no item is worthless to both agents, so the negotiation will be competitive. After 10 turns, we allow agents the option to complete the negotiation with no agreement, which is worth 0 points to both users. We use 3 item types (*books*, *hats*, *balls*), and between 5 and 7 total items in the pool. Figure 1 shows our interface.

2.3 Data Collection

We collected a set of human-human dialogues using Amazon Mechanical Turk. Workers were paid \$0.15 per dialogue, with a \$0.05 bonus for maximal scores. We only used workers based in the United States with a 95% approval rating and at least 5000 previous HITs. Our data collection interface was adapted from that of Das et al. (2016).

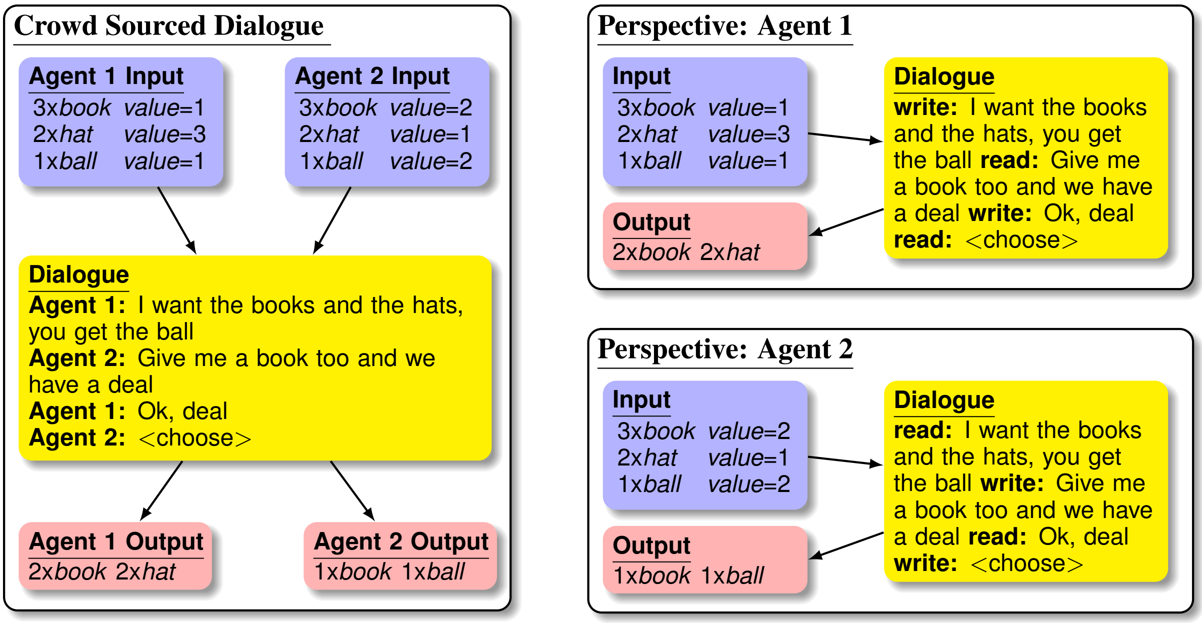

Figure 2: Converting a crowd-sourced dialogue (left) into two training examples (right), from the perspective of each user. The perspectives differ on their input goals, output choice, and in special tokens marking whether a statement was read or written. We train conditional language models to predict the dialogue given the input, and additional models to predict the output given the dialogue.

We collected a total of 5808 dialogues, based on 2236 unique scenarios (where a scenario is the available items and values for the two users). We held out a test set of 252 scenarios (526 dialogues). Holding out test scenarios means that models must generalise to new situations.

3 Likelihood Model

We propose a simple but effective baseline model for the conversational agent, in which a sequence-to-sequence model is trained to produce the complete dialogue, conditioned on an agent's input.

3.1 Data Representation

Each dialogue is converted into two training examples, showing the complete conversation from the perspective of each agent. The examples differ on their input goals, output choice, and whether utterances were read or written.

Training examples contain an input goal g, specifying the available items and their values, a dialogue x, and an output decision o specifying which items each agent will receive. Specifically, we represent g as a list of six integers corresponding to the count and value of each of the three item types. Dialogue x is a list of tokens $x_{0..T}$ containing the turns of each agent interleaved with symbols marking whether a turn was written by the agent or their partner, terminating in a special token indicating one agent has marked that an agreement has been made. Output o is six integers describing how many of each of the three item types are assigned to each agent. See Figure 2.

3.2 Supervised Learning

We train a sequence-to-sequence network to generate an agent's perspective of the dialogue conditioned on the agent's input goals (Figure 3a).

The model uses 4 recurrent neural networks, implemented as GRUs (Cho et al., 2014): GRU$_w$, GRU$_g$, GRU$_{\overrightarrow{o}}$, and GRU$_{\overleftarrow{o}}$.

The agent's input goals g are encoded using GRU$_g$. We refer to the final hidden state as h^g. The model then predicts each token x_t from left to right, conditioned on the previous tokens and h^g. At each time step t, GRU$_w$ takes as input the previous hidden state h_{t-1}, previous token x_{t-1} (embedded with a matrix E), and input encoding h^g. Conditioning on the input at each time step helps the model learn dependencies between language and goals.

$$h_t = \text{GRU}_w(h_{t-1}, [Ex_{t-1}, h^g]) \qquad (1)$$

The token at each time step is predicted with a softmax, which uses weight tying with the embed-

(a) Supervised Training

(b) Decoding, and Reinforcement Learning

Figure 3: Our model: tokens are predicted conditioned on previous words and the input, then the output is predicted using attention over the complete dialogue. In supervised training (3a), we train the model to predict the tokens of *both* agents. During decoding and reinforcement learning (3b) some tokens are sampled from the model, but some are generated by the other agent and are only encoded by the model.

ding matrix E (Mao et al., 2015):

$$p_\theta(x_t|x_{0..t-1}, g) \propto \exp(E^T h_t) \tag{2}$$

Note that the model predicts both agent's words, enabling its use as a forward model in Section 5.

At the end of the dialogue, the agent outputs a set of tokens o representing the decision. We generate each output conditionally independently, using a separate classifier for each. The classifiers share bidirectional GRUs and an attention mechanism (Bahdanau et al., 2014) over the dialogue, and additionally condition on the input goals.

$$h_t^{\overrightarrow{o}} = \text{GRU}_{\overrightarrow{o}}(h_{t-1}^{\overrightarrow{o}}, [Ex_t, h_t]) \tag{3}$$

$$h_t^{\overleftarrow{o}} = \text{GRU}_{\overleftarrow{o}}(h_{t+1}^{\overleftarrow{o}}, [Ex_t, h_t]) \tag{4}$$

$$h_t^o = [h_t^{\overleftarrow{o}}, h_t^{\overrightarrow{o}}] \tag{5}$$

$$h_t^a = W^a[\tanh(W^h h_t^o)] \tag{6}$$

$$\alpha_t = \frac{\exp(w \cdot h_t^a)}{\sum_{t'} \exp(w \cdot h_{t'}^a)} \tag{7}$$

$$h^s = \tanh(W^s[h^g, \sum_t \alpha_t h_t]) \tag{8}$$

The output tokens are predicted using softmax:

$$p_\theta(o_i|x_{0..t}, g) \propto \exp(W^{o_i} h^s) \tag{9}$$

The model is trained to minimize the negative log likelihood of the token sequence $x_{0..T}$ conditioned on the input goals g, and of the outputs o conditioned on x and g. The two terms are weighted with a hyperparameter α.

$$L(\theta) = -\underbrace{\sum_{x,g} \sum_t \log p_\theta(x_t|x_{0..t-1}, g)}_{\text{Token prediction loss}} - \alpha \underbrace{\sum_{x,g,o} \sum_j \log p_\theta(o_j|x_{0..T}, g)}_{\text{Output choice prediction loss}} \tag{10}$$

Unlike the Neural Conversational Model (Vinyals and Le, 2015), our approach shares all parameters for reading and generating tokens.

3.3 Decoding

During decoding, the model must generate an output token x_t conditioned on dialogue history $x_{0..t-1}$ and input goals g, by sampling from p_θ:

$$x_t \sim p_\theta(x_t|x_{0..t-1}, g) \tag{11}$$

If the model generates a special *end-of-turn* token, it then encodes a series of tokens output by the other agent, until its next turn (Figure 3b).

The dialogue ends when either agent outputs a special *end-of-dialogue* token. The model then outputs a set of choices o. We choose each item independently, but enforce consistency by checking the solution is in a feasible set O:

$$o^* = \operatorname*{argmax}_{o \in O} \prod_i p_\theta(o_i|x_{0..T}, g) \tag{12}$$

In our task, a solution is feasible if each item is assigned to exactly one agent. The space of solutions is small enough to be tractably enumerated.

4 Goal-based Training

Supervised learning aims to imitate the actions of human users, but does not explicitly attempt to maximise an agent's goals. Instead, we explore pre-training with supervised learning, and then fine-tuning against the evaluation metric using reinforcement learning. Similar two-stage learning strategies have been used previously (e.g. Li et al. (2016); Das et al. (2017)).

During reinforcement learning, an agent A attempts to improve its parameters from conversations with another agent B. While the other agent B could be a human, in our experiments we used

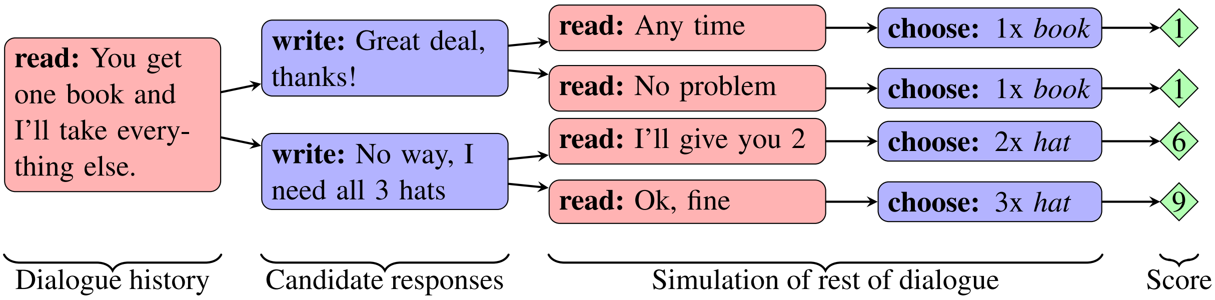

Figure 4: Decoding through rollouts: The model first generates a small set of candidate responses. For each candidate, it then simulates a number of possible complete future conversations by sampling, and estimates the expected future reward by averaging the scores. The system outputs the candidate with the highest expected reward.

our fixed supervised model that was trained to imitate humans. The second model is fixed as we found that updating the parameters of both agents led to divergence from human language. In effect, agent A learns to improve by simulating conversations with the help of a surrogate forward model.

Agent A reads its goals g and then generates tokens $x_{0..n}$ by sampling from p_θ. When x generates an end-of-turn marker, it then reads in tokens $x_{n+1..m}$ generated by agent B. These turns alternate until one agent emits a token ending the dialogue. Both agents then output a decision o and collect a reward from the environment (which will be 0 if they output different decisions). We denote the subset of tokens generated by A as X^A (e.g. tokens with incoming arrows in Figure 3b).

After a complete dialogue has been generated, we update agent A's parameters based on the outcome of the negotiation. Let r^A be the score agent A achieved in the completed dialogue, T be the length of the dialogue, γ be a discount factor that rewards actions at the end of the dialogue more strongly, and μ be a running average of completed dialogue rewards so far[2]. We define the future reward R for an action $x_t \in X^A$ as follows:

$$R(x_t) = \sum_{x_t \in X^A} \gamma^{T-t}(r^A(o) - \mu) \qquad (13)$$

We then optimise the expected reward of each action $x_t \in X^A$:

$$L_\theta^{RL} = \mathbb{E}_{x_t \sim p_\theta(x_t|x_{0..t-1},g)}[R(x_t)] \qquad (14)$$

The gradient of L_θ^{RL} is calculated as in REINFORCE (Williams, 1992):

$$\nabla_\theta L_\theta^{RL} = \sum_{x_t \in X^A} \mathbb{E}_{x_t}[R(x_t)\nabla_\theta \log(p_\theta(x_t|x_{0..t-1}, g))] \qquad (15)$$

5 Goal-based Decoding

Likelihood-based decoding (§3.3) may not be optimal. For instance, an agent may be choosing between accepting an offer, or making a counter offer. The former will often have a higher likelihood under our model, as there are fewer ways to agree than to make another offer, but the latter may lead to a better outcome. Goal-based decoding also allows more complex dialogue strategies. For example, a deceptive utterance is likely to have a low model score (as users were generally honest in the supervised data), but may achieve high reward.

We instead explore decoding by maximising expected reward. We achieve this by using p_θ as a forward model for the complete dialogue, and then deterministically computing the reward. Rewards for an utterance are averaged over samples to calculate expected future reward (Figure 4).

We use a two stage process: First, we generate c candidate utterances $U = u_{0..c}$, representing possible complete turns that the agent could make, which are generated by sampling from p_θ until the *end-of-turn* token is reached. Let $x_{0..n-1}$ be current dialogue history. We then calculate the expected reward $R(u)$ of candidate utterance $u = x_{n,n+k}$ by repeatedly sampling $x_{n+k+1,T}$ from p_θ, then choosing the best output o using Equation 12, and finally deterministically computing the reward $r(o)$. The reward is scaled by the probability of the output given the dialogue, be-

[2] As all rewards are non-negative, we instead re-scale them by subtracting the mean reward found during self play. Shifting in this way can reduce the variance of our estimator.

Algorithm 1 Dialogue Rollouts algorithm.

```
procedure ROLLOUT($x_{0..i}, g$)
  $u^* \leftarrow \varnothing$
  for $c \in \{1..C\}$ do                ▷ $C$ candidate moves

      $j \leftarrow j + 1$
      $x_j \sim p_\theta(x_j | x_{0..j-1}, g)$
    while $x_k \notin \{read:, choose:\}$
    $u \leftarrow x_{i+1}..x_j$          ▷ $u$ is candidate move
    for $s \in \{1..S\}$ do              ▷ $S$ samples per move
      $k \leftarrow j$                   ▷ Start rollout from end of $u$
      while $x_k \neq choose:$ do
      ▷ Rollout to end of dialogue
        $k \leftarrow k + 1$
        $x_k \sim p_\theta(x_k | x_{0..k-1}, g)$
      ▷ Calculate rollout output and reward
      $o \leftarrow \text{argmax}_{o' \in O}\, p(o' | x_{0..k}, g)$
      $R(u) \leftarrow R(u) + r(o) p(o' | x_{0..k}, g)$
    if $R(u) > R(u^*)$ then
      $u^* \leftarrow u$
  return $u^*$                           ▷ Return best move
```

cause if the agents select different outputs then they both receive 0 reward.

$$R(x_{n..n+k}) = \mathbb{E}_{x_{(n+k+1..T;o)} \sim p_\theta}[r(o) p_\theta(o | x_{0..T})] \tag{16}$$

We then return the utterance maximizing R.

$$u^* = \underset{u \in U}{\text{argmax}}\, R(u) \tag{17}$$

We use 5 rollouts for each of 10 candidate turns.

6 Experiments

6.1 Training Details

We implement our models using PyTorch. All hyper-parameters were chosen on a development dataset. The input tokens are embedded into a 64-dimensional space, while the dialogue tokens are embedded with 256-dimensional embeddings (with no pre-training). The input GRU_g has a hidden layer of size 64 and the dialogue GRU_w is of size 128. The output GRU$_{\overrightarrow{o}}$ and GRU$_{\overleftarrow{o}}$ both have a hidden state of size 256, the size of h^s is 256 as well. During supervised training, we optimise using stochastic gradient descent with a minibatch size of 16, an initial learning rate of 1.0, Nesterov momentum with μ=0.1 (Nesterov, 1983), and clipping gradients whose L^2 norm exceeds 0.5. We train the model for 30 epochs and pick the snapshot of the model with the best validation perplexity. We then annealed the learning rate by a factor of 5 each epoch. We weight the terms in the loss function (Equation 10) using α=0.5. We do not train against output decisions where humans selected different agreements. Tokens occurring fewer than 20 times are replaced with an ‘unknown’ token.

During reinforcement learning, we use a learning rate of 0.1, clip gradients above 1.0, and use a discount factor of γ=0.95. After every 4 reinforcement learning updates, we make a supervised update with mini-batch size 16 and learning rate 0.5, and we clip gradients at 1.0. We used 4086 simulated conversations.

When sampling words from p_θ, we reduce the variance by doubling the values of logits (i.e. using temperature of 0.5).

6.2 Comparison Systems

We compare the performance of the following: LIKELIHOOD uses supervised training and decoding (§3), RL is fine-tuned with goal-based self-play (§4), ROLLOUTS uses supervised training combined with goal-based decoding using rollouts (§5), and RL+ROLLOUTS uses rollouts with a base model trained with reinforcement learning.

6.3 Intrinsic Evaluation

For development, we use measured the perplexity of user generated utterances, conditioned on the input and previous dialogue.

Results are shown in Table 3, and show that the simple LIKELIHOOD model produces the most human-like responses, and the alternative training and decoding strategies cause a divergence from human language. Note however, that this divergence may not necessarily correspond to lower quality language—it may also indicate different strategic decisions about what to say. Results in §6.4 show all models could converse with humans.

6.4 End-to-End Evaluation

We measure end-to-end performance in dialogues both with the likelihood-based agent and with humans on Mechanical Turk, on held out scenarios.

Humans were told that they were interacting with other humans, as they had been during the collection of our dataset (and few appeared to realize they were in conversation with machines).

	vs. LIKELIHOOD				vs. Human			
Model	Score (all)	Score (agreed)	% Agreed	% Pareto Optimal	Score (all)	Score (agreed)	% Agreed	% Pareto Optimal
LIKELIHOOD	5.4 vs. 5.5	6.2 vs. 6.2	87.9	49.6	4.7 vs. 5.8	6.2 vs. 7.6	**76.5**	66.2
RL	7.1 vs. 4.2	7.9 vs. 4.7	89.9	58.6	4.3 vs. 5.0	6.4 vs. 7.5	67.3	69.1
ROLLOUTS	7.3 vs. 5.1	7.9 vs. 5.5	92.9	63.7	**5.2 vs. 5.4**	7.1 vs. 7.4	72.1	78.3
RL+ROLLOUTS	**8.3 vs. 4.2**	**8.8 vs. 4.5**	**94.4**	**74.8**	4.6 vs. 4.2	**8.0 vs. 7.1**	57.2	**82.4**

Table 1: End task evaluation on heldout scenarios, against the LIKELIHOOD model and humans from Mechanical Turk. The maximum score is 10. *Score (all)* gives 0 points when agents failed to agree.

Metric	Dataset
Number of Dialogues	5808
Average Turns per Dialogue	6.6
Average Words per Turn	7.6
% Agreed	80.1
Average Score (/10)	6.0
% Pareto Optimal	76.9

Table 2: Statistics on our dataset of crowdsourced dialogues between humans.

Model	Valid PPL	Test PPL	Test Avg. Rank
LIKELIHOOD	5.62	5.47	521.8
RL	6.03	5.86	517.6
ROLLOUTS	-	-	844.1
RL+ROLLOUTS	-	-	859.8

Table 3: Intrinsic evaluation showing the average perplexity of tokens and rank of complete turns (out of 2083 unique human messages from the test set). Lower is more human-like for both.

We measure the following statistics:

Score: The average score for each agent (which could be a human or model), out of 10.

Agreement: The percentage of dialogues where both agents agreed on the same decision.

Pareto Optimality: The percentage of Pareto optimal solutions for agreed deals (a solution is Pareto optimal if neither agent's score can be improved without lowering the other's score). Lower scores indicate inefficient negotiations.

Results are shown in Table 1. Firstly, we see that the RL and ROLLOUTS models achieve significantly better results when negotiating with the LIKELIHOOD model, particularly the RL+ROLLOUTS model. The percentage of Pareto optimal solutions also increases, showing a better exploration of the solution space. Compared to human-human negotiations (Table 2), the best models achieve a higher agreement rate, better scores, and similar Pareto efficiency. This result confirms that attempting to maximise reward can outperform simply imitating humans.

Similar trends hold in dialogues with humans, with goal-based reasoning outperforming imitation learning. The ROLLOUTS model achieves comparable scores to its human partners, and the RL+ROLLOUTS model actually achieves higher scores. However, we also find significantly more cases of the goal-based models failing to agree a deal with humans—largely a consequence of their more aggressive negotiation tactics (see §7).

7 Analysis

Table 1 shows large gains from goal-based methods. In this section, we explore the strengths and weaknesses of our models.

Goal-based models negotiate harder. The RL+ROLLOUTS model has much longer dialogues with humans than LIKELIHOOD (7.2 turns vs. 5.3 on average), indicating that the model is accepting deals less quickly, and negotiating harder.

A negative consequence of more aggressive negotiation strategies is that humans were more likely to walk away with no deal, resulting in lower agreement rates. Even though failing to agree was worth 0 points, people often preferred this course over capitulating to an uncompromising opponent—a factor not well captured by the simulated partner in reinforcement learning training or rollouts (as reflected by the larger gains from goal-based models in dialogues with the LIKELIHOOD model). In particular, the goal-based models are prone to simply rephrasing the same demand each turn, which is a more effective strategy against the LIKELIHOOD model than humans.

One approach to mitigating this issue would be to learn the impact of uncooperative strategies across multiple rounds of negotiation (Lerer and Peysakhovich, 2017). In single dialogues, failing to agree is never better than reaching some agreement. However, across multiple rounds, learning to walk away without a deal may incentivize partners to cooperate more in future.

Figure 5 shows an example of our goal-based

Input		
Human	1x**book** *value*=3 1x**hat** *value*=1 3x**ball** *value*=2	
RL+ROLLOUTS	1x**book** *value*=6 1x**hat** *value*=4 3x**ball** *value*=0	
RL+ROLLOUTS	You can have the balls if i can have the hat and book	
Human	Nope, give me the books and you can have everything else	
RL+ROLLOUTS	Ok. I will take the book and one hat	
Human	I get all the balls?	
RL+ROLLOUTS	Yes. I can do that.	
Human	Ok, deal	
Output		**Reward**
RL+ROLLOUTS	1x**book** 1x**hat**	10/10
Human	3x**ball**	6/10

Figure 5: Example of a model stubbornly holding out for maximum points in a dialogue.

Input		
Human	3x**book** *value*=2 3x**hat** *value*=1 1x**ball** *value*=1	
RL+ROLLOUTS	3x**book** *value*=1 3x**hat** *value*=2 1x**ball** *value*=1	
Human	I'd like the books and the hats.	
RL+ROLLOUTS	I will take the books and hats	
Human	I really need the books and at least one other object.	
RL+ROLLOUTS	Ok, you can have one book and one ball	
Human	If I can have all the books, I can leave you the rest.	
RL+ROLLOUTS	Deal	
Output		**Reward**
RL+ROLLOUTS	3x**hat** 1x**ball**	7/10
Human	3x**book**	6/10

Input		
RL+ROLLOUTS	4x**book** *value*=0 2x**hat** *value*=5 1x**ball** *value*=0	
Human	4x**book** *value*=1 2x**hat** *value*=2 1x**ball** *value*=2	
RL+ROLLOUTS	You can have the ball if I can have everything else.	
Human	No can't do that the ball is not going to give me anything	
RL+ROLLOUTS	I need the hats and you can have the rest	
Human	Deal	
RL+ROLLOUTS	Great! Thank you!	
Output		**Reward**
RL+ROLLOUTS	2x**hat**	10/10
Human	4x**book** 1x**ball**	6/10

Figure 7: Dialogue in which the model's initial interest in the valueless books allows it to compromise while achieving a maximum score.

model stubbornly negotiating until it achieves a good outcome.

Models learn to be deceptive. Deception can be an effective negotiation tactic. We found numerous cases of our models initially feigning interest in a valueless item, only to later 'compromise' by conceding it. Figure 7 shows an example. This strategy has previously been coded into negotiation agents by Gratch et al. (2016), whereas our agents have learned it from data.

Models produce meaningful novel sentences. One interesting question is whether our models are capable of generating novel sentences in the new circumstances they find themselves in, or if they simply repeat messages from the training data verbatim. We find that 76% of messages produced by the LIKELIHOOD model in self-play were found in the training data. We manually examined the novel utterances produced by our model, and found that the overwhelming majority were fluent English sentences in isolation—showing that the model has learnt a good language model for the domain (in addition to results that show it uses language effectively to achieve its goals). These results suggest that although neural models are prone to the safer option of repeating sentences from training data, they are capable of generalising when necessary. Future work should choose domains that force a higher degree of diversity in utterances.

Maintaining multi-sentence coherence is challenging. One common linguistic error we see RL+ROLLOUTS make is to start a message by indicating agreement (e.g. *I agree* or *Deal*), but then going on to propose a counter offer—a behaviour that human partners found frustrating. One explanation is that the model has learnt that in the supervised data, messages beginning with *I agree* are often at the end of the dialogue, and partners rarely reply with further negotiation—so the models using rollouts and reinforcement learning believe this tactic will help their offer to be accepted.

8 Related Work

Most work on goal orientated dialogue systems has assumed that state representations are annotated in the training data (Williams and Young, 2007; Henderson et al., 2014; Wen et al., 2016). The use of state annotations allows a cleaner separation of the reasoning and natural language aspects of dialogues, but our end-to-end approach makes data collection cheaper and allows tasks where it is unclear how to annotate state. Bordes and Weston (2016) explore end-to-end goal orientated dialogue with a supervised model—we show improvements over supervised learning with goal-based training and decoding. Recently, He et al. (2017) use task-specific rules to combine the task input and dialogue history into a more structured state representation than ours.

Reinforcement learning (RL) has been applied in many dialogue settings. RL has been widely used to improve dialogue managers, which manage transitions between dialogue states (Singh et al., 2002; Pietquin et al., 2011; Rieser and Lemon, 2011; Gašic et al., 2013; Fatemi et al., 2016). In contrast, our end-to-end approach has no explicit dialogue manager that can be updated in isolation, and we found it necessary to interleave RL and supervised learning to avoid RL reducing the quality of language generation. Li et al. (2016) improve metrics such as diversity for non-goal-orientated dialogue using RL, which would make an interesting extension to our work. Das et al. (2017) use reinforcement learning to improve cooperative bot-bot dialogues. RL has also been used to allow agents to invent new languages (Das et al., 2017; Mordatch and Abbeel, 2017). To our knowledge, our model is the first to use RL to improve the performance of an end-to-end goal orientated dialogue system in dialogues with humans.

Work on learning end-to-end dialogues has concentrated on 'chat' settings, without explicit goals (Ritter et al., 2011; Vinyals and Le, 2015; Li et al., 2015). These dialogues contain a much greater diversity of vocabulary than our domain, but do not have the challenging adversarial elements. Such models are notoriously hard to evaluate (Liu et al., 2016), because the huge diversity of reasonable responses, whereas our task has a clear objective. Our end-to-end approach would also be much more straightforward to integrate into a general-purpose dialogue agent than one that relied on annotated dialogue states (Dodge et al., 2016).

There is a substantial literature on multi-agent bargaining in game-theory, e.g. Nash Jr (1950). There has also been computational work on modelling negotiations (Baarslag et al., 2013)—our work differs in that agents communicate in unrestricted natural language, rather than pre-specified symbolic actions, and our focus on improving performance relative to humans rather than other automated systems. Our task is based on that of DeVault et al. (2015), who study natural language negotiations for pedagogical purposes—their version includes speech rather than textual dialogue, and embodied agents, which would make interesting extensions to our work. The only automated natural language negotiations systems we are aware of have first mapped language to domain-specific logical forms, and then focused on choosing the next dialogue act (Rosenfeld et al., 2014; Cuayáhuitl et al., 2015; Keizer et al., 2017). Our end-to-end approach is the first to learn comprehension, reasoning and generation skills in a domain-independent data driven way.

Our use of a combination of supervised and reinforcement learning for training, and stochastic rollouts for decoding, builds on strategies used in game playing agents such as AlphaGo (Silver et al., 2016). Our work is a step towards real-world applications for these techniques. Our use of rollouts could be extended by choosing the other agent's responses based on sampling, using Monte Carlo Tree Search (MCTS) (Kocsis and Szepesvári, 2006). However, our setting has a higher branching factor than in domains where MCTS has been successfully applied, such as Go (Silver et al., 2016)—future work should explore scaling tree search to dialogue modelling.

9 Conclusion

We have introduced end-to-end learning of natural language negotiations as a task for AI, arguing that it challenges both linguistic and reasoning skills while having robust evaluation metrics. We gathered a large dataset of human-human negotiations, which contain a variety of interesting tactics. We have shown that it is possible to train dialogue agents end-to-end, but that their ability can be much improved by training and decoding to maximise their goals, rather than likelihood. There remains much potential for future work, particularly in exploring other reasoning strategies, and in improving the diversity of utterances without diverging from human language. We will also explore other negotiation tasks, to investigate whether models can learn to share negotiation strategies across domains.

Abstract

Hand-crafted rules and reinforcement learning (RL) are two popular choices to obtain dialogue policy. The rule-based policy is often reliable within predefined scope but not self-adaptable, whereas RL is evolvable with data but often suffers from a bad initial performance. We employ a *companion learning* framework to integrate the two approaches for *on-line* dialogue policy learning, in which a predefined rule-based policy acts as a teacher and guides a data-driven RL system by giving example actions as well as additional rewards. A novel *agent-aware dropout* Deep Q-Network (AAD-DQN) is proposed to address the problem of when to consult the teacher and how to learn from the teacher's experiences. AAD-DQN, as a data-driven student policy, provides (1) two separate experience memories for student and teacher, (2) an uncertainty estimated by dropout to control the timing of consultation and learning. Simulation experiments showed that the proposed approach can significantly improve both *safety* and *efficiency* of on-line policy optimization compared to other companion learning approaches as well as supervised pre-training using static dialogue corpus.

1 Introduction

A task-oriented spoken dialogue system (SDS) is a system that can continuously interact with a human to accomplish a predefined task through speech. Dialogue manager, which maintains the dialogue state and decides how to respond, is the core of an SDS. In this paper, we focus on the dialogue policy.

At the early research, the spoken dialogue systems assume observable dialogue states. Dialogue policy is simply a set of hand-crafted mapping rules from state to machine action. This is referred to as rule-based policy, which often has acceptable performance but has no ability of self-adaption. Nowadays rule-based policy is popular in commercial dialogue systems.

However, in real world scenarios, unpredictable user behavior, inevitable automatic speech recognition, and spoken language understanding errors make it difficult to maintain the true dialogue state and make the decision. Hence, in recent years, there is a research trend towards statistical dialogue management. A well-founded theory for this is the partially observable Markov decision process (POMDP) (Kaelbling et al., 1998), which can provide robustness to errors from the input module and automatic policy optimization by reinforcement learning. Most POMDP based policy learning research is usually carried out using either user simulator or employed users (Williams and Young, 2007; Young et al., 2010). The trained policy is not guaranteed to work well in real world scenarios. Therefore, on-line policy training has been of great interest (Gašić et al., 2011). Recently, Chen et al. (2017) proposed two qualitative metrics [1] to measure on-line policy learning: *safety* and *efficiency*. Safety reflects whether the initial policy can satisfy the quality-of-service requirement in real-world scenarios during the on-line policy learning period. Efficiency reflects how long it takes for the on-line policy training algorithm to reach a satisfactory performance level.

Most traditional RL-based policy training suf-

[1] The quantitative evaluation metrics of safety and efficiency are proposed in section 4.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2454–2464
Copenhagen, Denmark, September 7–11, 2017.

fers poor initial performance, i.e. causes the safety problem. In light of above, Chen et al. (2017) proposed a safe and efficient on-line policy optimization framework, i.e. *companion teaching* (CT), in which a human teacher is added in the classic POMDP. The teacher has two missions: one is to show example actions, another is to act as a critic to give the student extra reward which can make the learning of policy more efficient. The example actions not only make the learning safer but also can be directly used by the training of the student policy. However, there are costs to the teaching of a human teacher.

Based on CT, *companion learning* (CL) framework is proposed to integrate rule-based policy and RL-based policy, resulting in *safe* and *efficient* on-line policy learning. Here, the rule-based policy acts as a virtual teacher which replaces the human teacher in CT. There are a few differences between these two kinds of teachers. First, because it has no marginal cost when it's deployed, the rule teacher can be consulted at any time if needed. On the other hand, the rule policy is not as good as the human teacher, therefore it's important to determine when and how much the student policy depends on the rule teacher. Here, we propose an *agent-aware dropout* Deep Q-Network (AAD-DQN) as the student statistical policy, which provides (1) two separate experience replay pools for student and teacher, (2) an uncertainty estimated by dropout which can be used to control the timing of consultation and learning.

In summary, our main contributions are three-folds: (1) *Companion learning* (CL) framework was proposed to integrate rule-based policy and RL-based policy. (2) An *agent-aware dropout* Deep Q-Network (AAD-DQN) was proposed as the statistical student policy. (3) Compared with other companion teaching approaches (Chen et al., 2017) as well as supervised pre-training using static dialogue corpus (Fatemi et al., 2016), CL with AAD-DQN can achieve better performance.

2 Related Work

Most previous studies of on-line policy learning have been focused on the *efficiency* issue, such as Gaussian Process Reinforcement Learning (GPRL) (Gašić et al., 2010). In GPRL, the kernel function defines prior correlations of the objective function given different belief states, which can significantly speed up the policy learning (Gašić and Young, 2014). Alternative methods include Kalman temporal difference reinforcement learning (Pietquin et al., 2011).

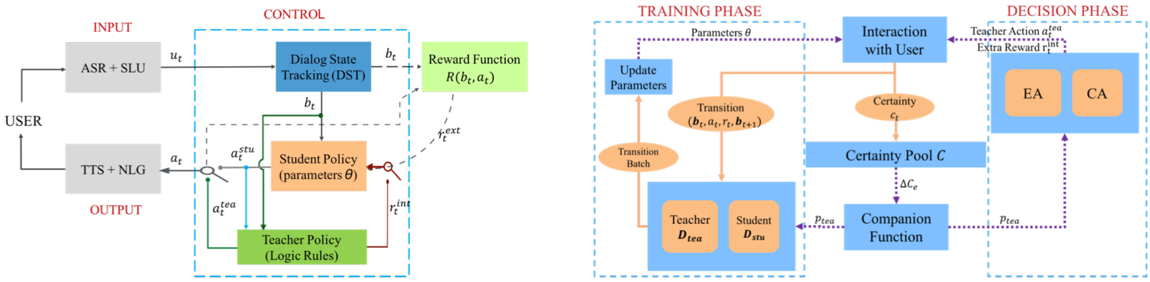
More recently, deep reinforcement learning (DRL) (Mnih et al., 2015) is applied in dialogue policy optimization, including deep Q-Network (DQN) (Cuayáhuitl et al., 2015; Fatemi et al., 2016; Zhao and Eskenazi, 2016; Lipton et al., 2016) and policy gradient (PG) methods, e.g. REINFORCE (Williams and Zweig, 2016; Su et al., 2016; Williams et al., 2017), Advantage Actor-Critic (A2C) (Fatemi et al., 2016). In order to speed up the learning of DQN, Lipton et al. (2016) proposed an efficient exploration technique based on Thompson sample from a Bayesian neural network. Furthermore, they showed that using a few successful dialogues generated by a rule-based policy to pre-fill the replay buffer can benefit the learning at the beginning. To improve the efficiency of PG methods, policy network is initialized with supervised learning (SL) before RL training (Williams and Zweig, 2016; Williams et al., 2017; Su et al., 2016, 2017; Fatemi et al., 2016), which is similar to the idea in (Silver et al., 2016). However, combining RL with SL for dialogue policy optimization is not new. Henderson et al. (2008) were among the first to prove the benefits of combining supervised and reinforcement learning. In the experiments, we will compare CL with these pre-training methods.

Although the improvement of efficiency can benefit the safety of learning process, no matter how efficient the algorithm is, an unsafe on-line learned policy can lead to bad user experience at the beginning of learning period and consequently fail to attract sufficient real users to continuously improve the policy. Therefore, it is important to address the *safety* issue. There are few works about the safety issue of on-line dialogue policy optimization. Williams (2008) proposed a method for integrating business rules and POMDPs. The rules act as the action mask, i.e. the rules nominate a set of one or more actions, and the POMDP chooses the optimal action.

3 Proposed Framework

3.1 Companion Learning for On-line Policy Optimization

In the CL framework, there are two agents: one is the student policy, another is the teacher policy. Here, *teacher policy* is the extra part com-



(a) **(b)**

Figure 1: (a) RL-based Companion Learning(CL) Framework with Logic Rules in an SDS. (b) Agent-Aware Dropout DQN (AAD-DQN) for CL.

pared with the classic statistical dialogue manager architecture (Young et al., 2013). The goal of online policy training is to optimize the student policy from data via interaction with users in real scenarios. The teacher guides the policy learning at each turn as a companion of the dialogue policy, hence, referred to as *companion learning* [2]. The CL framework is described in Figure 1(a).

At each turn, the input module (ASR and SLU) receives an acoustic input signal from the human user and the dialogue state tracker keeps the dialogue state up-to-date. The dialogue state is then transmitted to both the student policy and the teacher policy. The student policy first generates a candidate action a_t^{stu} and when it needs help from the teacher policy, it sends a_t^{stu} with some auxiliary information which will be transmitted to the teacher. The teacher policy can then help the student policy with one of the following ways or both:

- **Example Action (EA)**: The teacher generates an action a_t^{tea} instead of a_t^{stu} according to its policy. It corresponds to the left switch in Figure 1(a).
- **Critic Advice (CA)**: The teacher will not explicitly show an action. Instead, it gives an extra reward r_t^{int} to the student policy. It corresponds to the right switch in Figure 1(a).

The action from control module is then transmitted to the output module, which generates the nature text and audio. At each turn, an extrinsic reward signal r_t^{ext} will be given to the student policy by the environment, i.e. the user. The extrinsic reward r_t^{ext} with the extra intrinsic reward r_t^{int} will be used to update the policy parameters θ using reinforcement learning algorithms.

In the CL framework, there are two things that matter: one is when to consult the teacher, another is how to use the teacher's experiences. In this paper, an *agent-aware dropout* DQN (AAD-DQN) is proposed. As shown in Figure 1(b), the certainty information during the interaction is used to define a *companion function*, which controls how often to sample the teacher's experiences for updating parameters during the training phase (left), and when to use EA or CA teaching method during decision phase (right).

The rest of this section is organized as follows. The next subsection introduces the *agent-aware* experience replay in DQN. The definition of certainty in DQN and the companion function are presented in subsection 3.3. The rule-based teacher policy is described in subsection 3.4.

3.2 Agent-Aware Experience Replay in DQN

A Deep Q-Network (DQN) is a multi-layer neural network which maps a belief state $\mathbf{b}_t$ to the Q values of the possible actions a_t at that state, $Q(\mathbf{b}_t, a_t; \theta)$, where θ is the weight vector of the neural network. Neural networks for the approximation of value functions have long been investigated (Lin, 1993). However, these methods were previously quite unstable (Mnih et al., 2013). In DQN, Mnih et al. (2013, 2015) proposed two techniques to overcome this instability, namely experience replay and the use of a target network.

At every turn, the transition including the previous belief state $\mathbf{b}_t$, previous action a_t, corresponding reward r_t and current belief state $\mathbf{b}_{t+1}$ is put in a finite pool (Lin, 1993). In this pa-

[2] The name *companion learning* has another potential meaning that the agents can learn from each other, i.e. the rules guide the RL training, and the optimised RL policy can provide some intuition for the revision of rules. We will give some preliminary discussions about this point in section 5.3.

per, two pools $\mathcal{D}_{stu}$ and $\mathcal{D}_{tea}$ are used to store the student's experiences and the teacher's experiences respectively as shown in Figure 1(b). When the teaching method EA is used in the t-th turn, $a_t = a_t^{tea}$ and the transition is put in $\mathcal{D}_{tea}$, otherwise $a_t = a_t^{stu}$ and the transition is put in $\mathcal{D}_{stu}$. When CA is used, $r_t = r_t^{ext} + r_t^{int}$, otherwise $r_t = r_t^{ext}$. Once any of the pool has reached its predefined maximum size, adding a new transition results in deleting the oldest transition in the pool. During training, a pool is first selected from $\mathcal{D}_{tea}$ and $\mathcal{D}_{stu}$. The probability of selecting $\mathcal{D}_{tea}$ is p_{tea}, i.e. $\mathcal{D} \sim Ber(\mathcal{D}_{tea}, \mathcal{D}_{stu}; p_{tea})$ [3].Then a mini-batch of transitions is uniformly sampled from the selected pool, i.e. $(\mathbf{b}_t, a_t, r_t, \mathbf{b}_{t+1}) \sim U(\mathcal{D})$. We call this *agent-aware* experience replay.

Except for the experience replay, a target network with weight vector θ^- is used. This target network is similar to the Q-network except that its weights are only copied every K steps from the Q-network, and remain fixed during all the other steps. The loss function for the Q-network at each iteration takes the following form:

$$L(\theta) = \mathrm{E}_{\mathcal{D}\sim Ber(\mathcal{D}_{tea},\mathcal{D}_{stu};p_{tea}),\ (\mathbf{b}_t,a_t,r_t,\mathbf{b}_{t+1})\sim U(\mathcal{D})} \left[\left(r_t + \gamma \max_{a_{t+1}} Q(\mathbf{b}_{t+1}, a_{t+1}; \theta^-) - Q(\mathbf{b}_t, a_t; \theta) \right)^2 \right] \tag{1}$$

where $\gamma \in [0, 1]$ is the discount factor.

The probability p_{tea} controls how often the student learns from the teacher's experiences. As the learning goes on, the probability will decrease. More details will be described in the next section.

3.3 Companion Strategy

It's important for the student to estimate an appropriate point to end the reliance on the teacher. If the reliance is ended too early, the student itself may not reach an acceptable performance, resulting in the sharp drop of performance, which is the *safety* problem. However, if the student always relies on the teacher, it's hard to improve its performance to surpass the teacher's performance, which is the *efficiency* problem.

We get some inspirations from the studying process of a call center service agent. Consider how a new call center service agent gets started. At first, an experienced call center agent tells him some basic *rules* and the new agent works by often consulting these rules. His confidence about how to make decisions gradually increases during the continuous practice. Eventually, he is so confident about his own decisions that he no longer needs any consultation to these rules and even explores some better response ways through interaction with users which are not initially included in the rules. Similarly, we can use the uncertainty/certainty of the Q-network to determine the teaching time.

There are several methods to estimate the uncertainty/certainty in deep neural networks, e.g. Bayesian neural networks (Blundell et al., 2015), dropout (Gal and Ghahramani, 2016), bootstrap (Osband et al., 2016) . Here we use the dropout to estimate the certainty of Q-Network. We call this Q-network DropoutQNetwork. Dropout is a technique used to avoid over-fitting in neural networks. It was introduced several years ago by (Hinton et al., 2012) and studied more extensively in (Srivastava et al., 2014). When dropout is used in training, the elements of the output of each hidden layer $\mathbf{h}$ is randomly set to zero with probability p, i.e. $\mathbf{h}' = \mathbf{h} \odot \mathbf{z}$ [4] where $\mathbf{z}$ is binary vector and each element $z_i \sim Ber(1-p)$. $\mathbf{h}'$ is scaled by $\frac{1}{1-p}$ and then fed to the next layer. At test time the dropout is disabled, i.e. the output of each hidden layer $\mathbf{h}$ is directly fed to the next layer. Although dropout was suggested as an ad-hoc technique, recently it was theoretically proven that the dropout training in deep neural networks is an approximate Bayesian inference in deep Gaussian processes (Gal and Ghahramani, 2016). Therefore, a direct result of this theory gives us tools to model uncertainty with dropout neural networks. To obtain the uncertainty, similar with that at train phrase the dropout is enabled at test phrase. For each input instance (i.e. dialogue belief state) $\mathbf{b}_t$, performing N stochastic forward passes through the network and averaging the output $\mathbf{q}_i \triangleq [q_{i1}, \cdots, q_{iM}]$ to get the mean and the variance. Generally, the variance can be utilized to measure the uncertainty of output. However, it's not a normalized criteria, and it's hard to set a threshold below which we should be confident with the output.

Instead, we proposed a novel method to measure the certainty of the decision of student policy at t-th turn. For each stochastic forward passes, the action $a_{ti} = \arg\max_j q_{ij}$ is regarded as a vote. After N passes [5], there is a committee

[3] Ber is short for Bernoulli.

[4] Here $\odot$ is the element-wise product.

[5] The N forward passes can be done in parallel, e.g. the

$\{a_{t1}, \cdots, a_{tN}\}$ consisting of N votes. The action a_t^{stu} that should be taken in the belief state $\mathbf{b}_t$ is the one with the largest percentage of the votes, and the corresponding percentage is defined as certainty c_t. The process is described in Algorithm 1.

Algorithm 1 The Decision Procedure of Student Policy $\pi^{stu}(\mathbf{b}_t, N)$

```
Require:
    The repeat times $N$ and the belief state $\mathbf{b}_t$
Initial the probability vector $\mathbf{p} = [p_1, \cdots, p_M]$ with zero vector, where $M$ is the number of actions.
for $i = 1, N$ do
    $\mathbf{q}_i \leftarrow \mathsf{DropoutQNetwork}(\mathbf{b}_t)$
    $a_{ti} \leftarrow \arg\max_j q_{ij}$
    $\mathbf{p}[a_{ti}] \leftarrow \mathbf{p}[a_{ti}] + 1/N$
end for
$c_t \leftarrow \max_j p_j$
$a_t^{stu} \leftarrow \arg\max_j p_j$
return $a_t^{stu}$, $c_t$
```

At the end of e-th dialogue, the average certainty of all turns is computed, i.e. $C_e = \frac{1}{T_e}\sum_{t=0}^{T_e} c_t$, where T_e is the number of turns in e-th dialogue. Generally, the variance of C_e between successive dialogues is high. In order to the smooth the estimation, here we use the moving average of C_e in previous W dialogues to represent the certainty of student at current dialogue, i.e.

$$\overline{C}_e = \frac{1}{W}\sum_{i=e-W}^{e-1} C_i. \qquad (2)$$

As the training goes on, $\overline{C}_e$ grows until it converges. If $\overline{C}_e$ in all successive W dialogues are greater then a threshold C_{th} as shown in Figure 2, it's assumed that the student reaches a point where it is confident enough with its own decision steadily. Therefore, the teaching, both EA and CA, should be ended from now on.

Before the end of the teaching, CA is done in all turns. However, if EA is always done, the disappearance of the teacher may cause a dramatic change in the hybrid decision policy, which results in a sharp drop of performance. To deal with this issue, a monotonically increasing function of the relative certainty $P_{tea}(\Delta C_e)$ is proposed to control the frequency of EA teaching. ΔC_e represents the distance between $\overline{C}_e$ and C_{th}, i.e. $\Delta C_e = \max(0, C_{th} - \overline{C}_e)$. The effect of $P_{tea}(\Delta C_e)$ is that the closer $\overline{C}_e$ is to C_{th}, the more unlikely EA teaching is executed. Besides controlling how often the student directly consult the teacher, another mission of $P_{tea}(\Delta C_e)$ is to control how often the teacher's experiences are replayed, i.e. the probability p_{tea} described in section 3.2. Implementation details of $P_{tea}(\Delta C_e)$ are described in Appendix C.

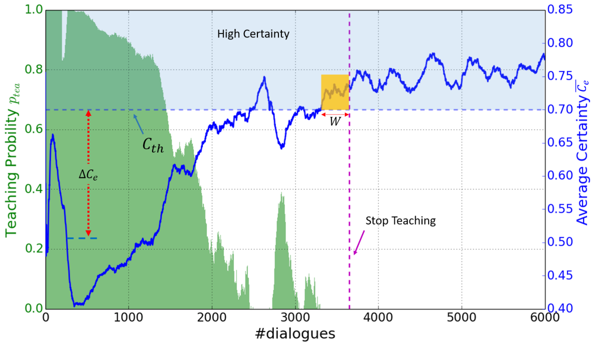


Figure 2: Illustration of average certainty $\overline{C}_e$ and the probability p_{tea}.

The full procedure of companion learning with logic rules is described in Algorithm 2.

3.4 Teacher Policy: Logic Rules

Rule-based policy is popular in commercial dialogue systems (Williams, 2008). The policy, i.e. the dialogue plan/flow, is designed by a domain expert. His knowledge of task domain and business rules is encoded in the rules. There are many methods to represent the decision rules, e.g. propositional logic, first-order logic, decision tree. Here, we use the ordered propositional logic rules, which can be easily translated into IF-THEN rules. When making the decision, these rules are executed in pre-defined order. If the conditions of any rule are satisfied, the decision process will be terminated and the output is the corresponding action. In this paper, three hand-crafted logic rules, R1, R2, and R3 , were used as the teacher:

- R1: confirm the most likely value in slots where the most likely value has probability between 0.1 and 0.6[6];
- R2: offer a restaurant if there is at least one slot in which the belief of most likely value is more than the belief of special value "*none*";

dialogue state can be repeated N times to form a mini-batch, then one forward is executed to get N outputs simultaneously.

[6] This threshold is the best one we have tried.

Algorithm 2 Companion Learning with Logic Rules

```
Require:
    The number of stochastic forward pass $N$, the maximal extra reward $\delta > 0$.
Initialize the parameters $\theta$ of student policy
Initialize replay pools $\mathcal{D}_{tea}$ and $\mathcal{D}_{stu}$ with $\{\}$, certainty memory $\mathcal{C}$ with $\{\}$, $teaching$ with $True$.
for $e = 1, E$ do
    Update the dialogue belief state $\mathbf{b}_0$
    Initialize the average certainty $C_e \leftarrow 0$
    if $teaching$ is $True$ then
        $teaching, p_{tea} \leftarrow \mathsf{Companion}(\mathcal{C})$
    end if
    for $t = 0, T_e$ do
        Set intrinsic reward $r_t^{int} \leftarrow 0$
        Get system action and the corresponding certainty, i.e. $a_t^{stu}, c_t \leftarrow \pi^{stu}(\mathbf{b}_t, N)$
        $C_e \leftarrow C_e + c_t$
        Get action from the rule-based policy, i.e. $a_t^{tea} \leftarrow \pi^{tea}(\mathbf{b}_t)$
        $EA \sim Ber(p_{tea})$
        if $teaching$ is $True$ and $EA$ is $True$ then
            $a_t \leftarrow a_t^{tea}$
        else
            $a_t \leftarrow a_t^{stu}$
        end if
        if $teaching$ is $True$ then
            $r_t^{int} \leftarrow (2 \times \mathbf{1}\{a_t = a_t^{tea}\} - 1)\delta$
        end if
        $C_e \leftarrow \frac{1}{T_e} C_e$, and store $C_e$ in $\mathcal{C}$
        Give the action $a_t$ to the environment, observe the extrinsic reward $r_t^{ext}$ and update the dialogue belief state $\mathbf{b}_{t+1}$
        $r_t \leftarrow r_t^{int} + r_t^{ext}$
        if $EA$ is $True$ then
            Store $\{\mathbf{b}_t, a_t, r_t, \mathbf{b}_{t+1}\}$ in $\mathcal{D}_{tea}$
        else
            Store $\{\mathbf{b}_t, a_t, r_t, \mathbf{b}_{t+1}\}$ in $\mathcal{D}_{stu}$
        end if
        Update the parameters $\theta$ of DropoutQNetwork according to the equation (1).
    end for
end for
return $\theta$
```

Algorithm 3 Companion Function $\mathsf{Companion}(\mathcal{C})$

```
Require:
    The average certainty memory $\mathcal{C}$ at $e$-th dialogue and the moving window size $W$.
Initialize $teaching$ with $False$, $p_{tea}$ with 0
for $i = 0, W$ do
    Compute the moving average certainty $\overline{C}_{e-i}$ in ($e$-$i$)-th dialogue with equation (2).
    if $\overline{C}_{e-i} < C_{th}$ then
        $teaching \leftarrow True$
        break
    end if
end for
if $teaching$ is $True$ then
    $\Delta C_e \leftarrow \max(0, C_{th} - \overline{C}_e)$
    $p_{tea} \leftarrow P_{tea}(\Delta C_e)$
end if
return $teaching, p_{tea}$
```

- R3: request values for a slot which is uniformly selected from a pre-defined slot list.

The corresponding pseudo-codes are presented in Appendix B.

4 Evaluation Metrics of On-line Policy Optimization

Most previous work on the evaluation of RL-based dialogue policy optimization focuses on the final performance (FP) when the system converges to a steady level. However, for on-line policy optimization, it's important to measure the learning process. Except for FP, we proposed two quantitative metrics: safety loss and efficiency loss.

4.1 Safety Loss

In the on-line training process, unless the performance of the system reaches the acceptable performance S_a, the interaction between users and the system will be unsafe and causes trouble to continuing training. So the safety of the system is defined to be the system's ability to maintain performance above the acceptable performance S_a.

We quantify the safety loss of the system by summing up the performance gap between the acceptable performance and the system performance S_e in every episode during the on-line learning. Suppose there are E dialogues, then $L_1 = \sum_{e=1}^{E} \max(0, S_a - S_e)$. The safety loss has an intuitive interpretation as the area of the region below the threshold and above training curve. This metric is similar to the integral of absolute error (IAE) (Shinners, 1998) metric commonly adopted in the evaluation of control systems (Gaing, 2004; Jesus and Tenreiro MacHado, 2008).

4.2 Efficiency Loss

Another important issue of on-line learning is efficiency. The efficiency indicates the speed at which the system reaches a specific performance level. In reality, we can tolerate a system to make mistakes at the beginning but it should improve at a significant speed until reaching the ideal performance S_i. Therefore, later failures should weight more than early failures to evaluate efficiency. Similar to the integral of time multiplied by absolute error (ITAE) (Shinners, 1998) metric, we propose a metric efficiency loss. We multiply the performance gap between ideal performance and current performance with the episode index, thus giving later failure greater penalty. Specifically, $L_2 = \sum_{e=1}^{E} \max(0, S_i - S_e)e$.

More illustrations about safety loss and efficiency loss are given in Appendix D.

5 Experiments

Our experiments have three objectives: (1) Comparing our proposed *dropout* DQN in Algorithm 1 with some baselines when there is no teacher. (2) Comparing CL with other two baselines when the teacher gets involved, and investigating the benefits of our proposed *agent-aware* experience replay. (3) Visually analyzing the differences in behaviors between the rule-based teacher policy and the optimized student policy.

An agenda-based user simulator (Schatzmann et al., 2007a) with error model (Schatzmann et al., 2007b) was implemented to emulate the behavior of the human user, and a rule-based policy with 0.695 success rate described in section 3.2 was used as the teacher in our experiments. The purpose of the user's interacting with SDS is to find restaurant information in the Cambridge (UK) area (Henderson and Thomson, 2014). This domain has 7 slots of which 4 can be used by the system to constrain the database search. The summary action space consists of 16 summary actions. More details are described in Appendix A.

For reward, at each turn, an extrinsic reward of -0.05 is given to the student policy. At the end of the dialogue, a reward of $+1$ is given for dialogue success. The maximal extra reward δ is 0.05.

For each set-up, 10000 dialogues are used for training, the moving dialogue success rate is recorded with a window size of 1000. The final results are the average of 40 runs.

5.1 Policy Learning without Teaching

In this section, four policies without teaching are compared:

- `DQN`: A vanilla deep Q-Network (Mnih et al., 2015) which has two hidden layers, each with 128 nodes.
- `A2C`: An advantage actor-critic policy which consists of an actor network and a critic network (Fatemi et al., 2016).
- `Dropout_DQN_1` and `Dropout_DQN_32`: They both have a dropout layer after each hidden layer. The dropout rate is 0.2. Their difference is that the number of stochastic forward pass N of `Dropout_DQN_32` in Algorithm 1 is 32, while that of `Dropout_DQN_1` is 1. `Dropout_DQN_1` makes decision according to one output of Q-network similar to that of vanilla `DQN`. `Dropout_DQN_1` was first proposed in (Gal and Ghahramani, 2016), and was confirmed that `Dropout_DQN_1` can obtain more efficient exploration.

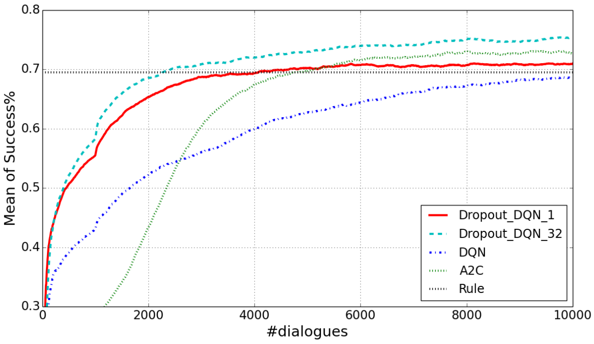

Figure 3: Comparison of four policies without teaching.

The learning curves are described in Figure 3 and the evaluation results are described in Table 1. Comparing `Dropout_DQN_1` with `DQN` in figure 3, the improvement of efficiency caused by

Metrics	**No Teaching**				**Teaching**			
	DQN	Dropout_DQN_1	Dropout_DQN_32	A2C	A2C_PreTrain	EA	CL_D	CL_AAD
Safety	1043.3	321.4	258.0	1020.8	176.9	48.8	30.6	**18.6**
Efficiency($\times 10^4$)	534.7	249.1	75.6	299.0	205.4	58.0	62.6	**53.5**
FP	0.684	0.709	0.749	0.727	0.726	**0.751**	0.749	**0.751**

Table 1: The quantitative evaluation results of different methods. Here final performance (FP) is the success rate of last 2000 dialogues. The FP of Dropout_DQN_32 0.749 is used as the ideal performance S_i for computing efficiency loss, and the performance of the rules 0.695 is used as the acceptable performance S_a for computing safety loss.

dropout can be observed as claimed in (Gal and Ghahramani, 2016). However, Dropout_DQN_1 seems to suffer premature and sub-optimal convergence, while our proposed Dropout_DQN_32, whose decision is based on multi votes (algorithm 1), can result in improvement of efficiency and better final performance. Moreover, Dropout_DQN_32 also performs much better than the policy gradient method A2C.

For the following experiments, the times of stochastic forward pass N in Algorithm 1 is 32.

5.2 Policy Learning with Teaching

In this section, four methods of teaching by the rule-based policy are compared:

- EA: 500 dialogues are taught with EA at the beginning (Chen et al., 2017).
- A2C_PreTrain: At the beginning, 500 dialogue are collected with rule-based policy. These examples are used to pre-train the actor network with supervised learning. After the pre-training, the policy is continuously optimized with the A2C algorithm (Fatemi et al., 2016).
- CL_AAD: Full CL with AAD-DQN described in section 3.
- CL_D: CL without agent-aware experience repay, i.e. the teacher's experiences and student's experiences are put in one pool and are uniformly sampled for the experience replay in equation (1).

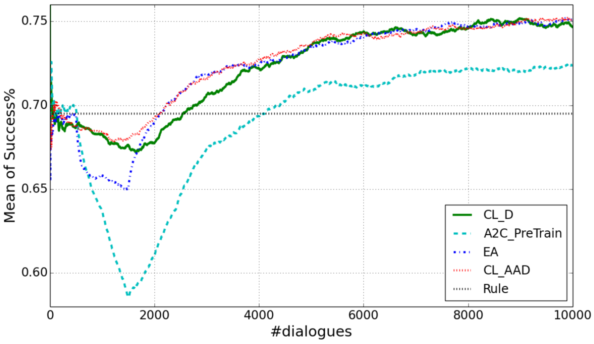

Figure 4: Comparison of four methods with teaching by rule-based teacher.

As can be seen in Figure 4, there is a big dip in the performance of A2C_PreTrain. One possible explanation is that because the rule-based policy is sub-optimal, the pre-training makes the student policy reach a local minimum point. The rl-training should first make it escape from the local minimum point, which results in a temporary loss in performance.

Comparing CL methods (CL_D and CL_AAD) with EA in Figure 4 and in Table 1, we can conclude that CL can significantly boost the safety of learning process. Moreover, except for safety, CL_AAD can boost the efficiency, which benefits from the *agent-aware* experience replay.

5.3 Comparison of Optimized Student Policy and Rule-based Teacher Policy

To interpret what the student has learnt, we further compare the rules and an optimized student policy with 76.7% success rate. The rule-based policy is used to collect 5000 dialogues, while in each turn the decision made by the student policy is also recorded. Figure 5 is a confusion matrix. The x-axis denotes the student's decision and the y-axis denotes the rules' decision. The numbers on the left are the statistics for each action in 5000 dialogues. Each element in the matrix denotes the normalized number of turns when the rule chooses the action in the corresponding line, the student chooses the action in the corresponding column.

As is shown in Figure 5, *offer* and *confirm* are two action types used most frequently. In more than half of turns when the rule-based pol-

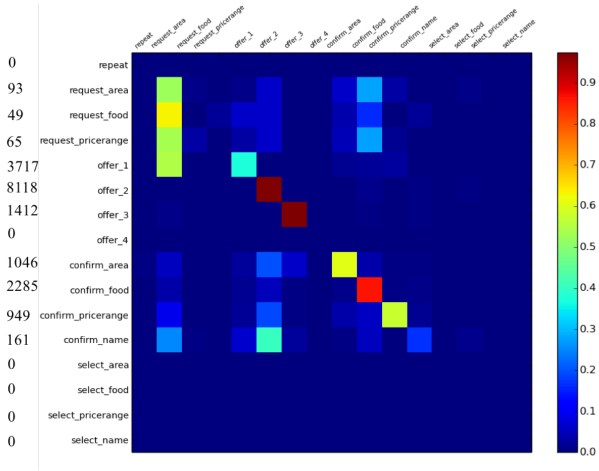

Figure 5: Confusion matrix between the decisions of rule-based policy and the decisions of the optimised student policy. The x-axis denotes the student's decision and the y-axis denotes the rules' decision.

icy chooses *offer_1*, the student policy will choose a different action. Furthermore, from the element in line *offer_1* and column *request_area*, we can find that in this situation the student policy prefers the action *request_area*. Inspired by this disagreement, we designed a new rule:

- R4: request values for slot area when there is only one other slot constraint for the database query.

Similarly, as can be seen in Figure 5, in a considerable proportion of turns when the rule-based policy chooses *confirm_area, confirm_pricerange*, or *confirm_name*, the student policy will choose the action *offer_2*, which may mean that for slots *area, pricerange*, or *name*, when there are values for database query, the system should offer a restaurant instead of confirming the slot-value constraints. Therefore, the rule R1 in section 3.2 was revised as follows:

- R1*: For slot food, confirm the most likely value has the probability between 0.1 and 0.6; For slot area, pricerange and name, confirm the most likely value, the belief of which is smaller than the belief of the special value "*none*" and is larger than 0.1.

Ordered Rules	**Success Rate**	**#Turn**	**Reward**
R1, R2, R3	0.695	4.58	0.4657
R1, R4, R2, R3	0.749	5.16	0.4910
R1*, R2, R3	0.705	4.44	0.4824
R1*, R4, R2, R3	**0.753**	4.98	**0.5042**

Table 2: Evaluation results of different ordered rules. As a reference, the performance of optimised student policy is success rate 0.767, #turn 5.10 and reward 0.5124.

Table 2 is the evaluation results of different ordered rules. The rule R4 can significantly boost the success rate (comparing line 2 with line 1), while the rule R1* can both boost the success rate and decrease the dialogue length (comparing line 3 with line 1). The combination of R4 and R1* takes respective advantages (comparing line 4 with line 1, line 2 and line 3). The performance of final order rules is comparable to the performance of optimized student policy.

It is worth noting that the primary rules R1, R2, and R3 in section 3.2 don't distinguish between different slots. However, the new rules R4 and R1* are all slot-specific, which it is difficult to design at the beginning.

6 Conclusion

This paper has proposed a *companion learning* framework to unify rule-based policy and RL-based policy. Here, the rule-based policy acts as a teacher, which either directly shows example action or gives an extra reward. Based on the uncertainty estimated using a dropout Q-Network, a companion strategy is proposed to control when the student policy directly consults rules and how often the student policy learns from the teacher's experiences. Simulation experiments showed that our proposed framework can significantly improve both *safety* and *efficiency* of on-line policy optimization. Additionally, we visually analyzed the differences in behaviors between the rule-based teacher policy and the optimized student policy, which gave us some inspirations to refine the rules.

Towards Debate Automation: a Recurrent Model for Predicting Debate Winners

Peter Potash and **Anna Rumshisky**

University of Massachusetts Lowell
{ppotash,arum}@cs.uml.edu

Abstract

In this paper we introduce a practical first step towards the creation of an automated debate agent: a state-of-the-art recurrent predictive model for predicting debate winners. By having an accurate predictive model, we are able to objectively rate the quality of a statement made at a specific turn in a debate. The model is based on a recurrent neural network architecture with attention, which allows the model to effectively account for the entire debate when making its prediction. Our model achieves state-of-the-art accuracy on a dataset of debate transcripts annotated with audience favorability of the debate teams. Finally, we discuss how future work can leverage our proposed model for the creation of an automated debate agent. We accomplish this by determining the model input that will maximize audience favorability toward a given side of a debate at an arbitrary turn.

1 Introduction

Conversational agents are a well-researched area of natural language generation (Pilato et al., 2007; Bigham et al., 2008; Augello et al., 2008; Agostaro et al., 2005; Bessho et al., 2012). Elsewhere in the field of natural language generation, there is work that seeks to generate persuasive text (Carenini and Moore, 2006; Reiter et al., 2003; Rosenfeld and Kraus, 2016), which is a logical first step towards creating an automated debate agent. One major deficiency of existing work in this area is its assessment of how convincing (or compelling) a piece of text is; the approaches use theory-driven models of persuasion, rather than being empirically motivated. Furthermore, none of these works provide a model that can optimize persuasiveness at an arbitrary point in a conversation.

One of the main reasons for a lack of empirically-driven persuasive generation systems is the absence of labeled data. In order to alleviate this problem (though not directly for the sake of producing an automated debate agent), Zhang et al. (2016) have introduced a dataset of debate transcripts from the "Intelligence Squared" (IQ2)[1] debates. In these debates, two teams are present, arguing either for or against a given topic. For each debate, an audience poll is conducted both prior to and after the debate. Whichever team has the largest gain in audience support between the pre/post debate polls is the winner. This is a natural way to account for the fact that some sides of a debate may be harder to argue than others, and that audience members may be initially biased given a debate topic.

Because of the sequential nature of debating, a Recurrent Neural Network (RNN) is an attractive choice for modeling the problem. Rather than just using the final hidded state for prediction, which likely has lost information from early in the debate, we propose to use an attention mechanism (Bahdanau et al., 2014) that creates a weighted sum over all hidden states, and is subsequently used for the final prediction. We motivate the use of an RNN, as opposed to a temporally flat classifier, for several reasons. First, using an RNN allows us to naturally incorporate predicting audience favorability at each turn while explicitly modeling the turn sequence. Logistic regression, on the other hand, would not allow us to model the sequence explicitly. Secondly, our model allows us to take raw features as input, without having to compute summary statistics necessary for the fea-

tures used in the model of Zhang et al. (2016). Finally, since our end goal is debate automation, an RNN is a natural choice for debate turn generation.

There are two major difficulties dealing with the IQ2 dataset: first, since the construction of the dataset is non-trivial, there are only 108 data points, resulting in Zhang et al.'s proposal for leave-one-out (LOO) evaluation. Second, considering the use of an RNN, the sequences are long, with an average length of 246 (and a standard deviation of 67). In order to overcome this, we incorporate signals based on implicit audience feedback during the debate into the model's loss function. Instead of just training the model based on error from the audience's final verdict, propogated through a substantial amount of timesteps, there are intermittent errors propogated backward through the network based on audience reactions, such as applauding or laughing. These internal signals also help regularize the network. In a way, they help generalize the hidden representation of the RNN, allowing it to better contain a distributed representation of the audience's favorability towards a given team.

In our proposed model, the audience's opinion is directly a function of the weighted hidden representations. Since the previous hidden representations are all fixed at a given timestep, and the current hidden representation is directly a function of these previous hidden representations as well as the current input, the audience's current poll depends directly on the timestep's input. Therefore, at a given timestep, our framework allows us to determine the input that would maximize the audience's favorability toward the orating team. This is due to the fact that the inputs are themselves representations of a given team's statement at a particular turn in the debate.

We evaluate our model on the dataset from Zhang et al., posting state-of-the-art accuracy. Our results show that our proposed regularization technique is imperative for the RNN-based model to perform competitively with the models previously proposed by Zhang et al.. The attention mechanism also contributes to the best performing system. Afterward, we show how our model can be used to track audience favorability throughout the debate, as well as the aforementioned input optimization, using it in a case study to instruct a debate team about optimal debate strategy at a given turn.

2 Related Work

Previous work that focuses on conversational language seeks to predict such qualities as disagreements (Allen et al., 2014; Wang and Cardie, 2016), divergence (Niculae and Danescu-Niculescu-Mizil, 2016), and participant stance (Sridhar et al., 2015; Somasundaran and Wiebe, 2010; Thomas et al., 2006; Rosenthal and McKeown, 2015). What is most relevant for our purposes are the methods these models use for dealing with conversational data. Allen et al. (2014) apply discourse parsing (Joty et al., 2013) and fragment quotation graph (Carenini et al., 2007) tools to detect disagreement in online discussion threads. Wang and Cardie (2016) believe that disagreement can be predicted by the presence of substantially long sequences of negative sentiment, motivating them to build a sequential sentiment prediction model using a particular kind of Conditional Random Field (Mao and Lebanon, 2007). Niculae and Danescu-Niculescu-Mizil (2016) use several novel features that capture the flow of ideas in the data, as well as team dynamics. Ultimately, however, all these models apply manually derived, preprocessed features and use a basic classifier, like Random Forest or Logistic Regression. In contrast, an RNN model is able to learn which interactions and overall sequences of rhetoric are important for predictive power.

There is much less work that approaches the problem of predicting persuasiveness of text. This is due primarily to the lack applicable datasets. However, Habernal and Gurevych (2016b) have recently presented a dataset where argument pairs are annotated for argument convincingness, as well as finer-grained annotations related to the effectiveness of arguments (Habernal and Gurevych, 2016a). The authors experimented with feature-based classifiers, as well as various RNN architectures to construct predictive models for the dataset.

The most relevant work for this paper is of course Zhang et al. (2016). The authors use a set of features derived from the notion of idea flow in the debate. More specifically, they follow the method of Monroe et al. (2008) to identify talking points used by the sides present in a debate. The authors then create features based on the coverage of talking points during the debate. Finally, a Logistic Regression model uses these features to predict which team wins the debate. We also note the work of Santos et al. (2016), which also makes predictions on a dataset derived from the IQ2 debates. In contrast, their work analyses speech signals, as opposed to textual data.

3 Predictive Model

In this section we explain how we apply an RNN to the task of predicting debate winners. We start by addressing the fact that for IQ2 dataset, each timestep involves a text span, as opposed to single tokens, and explaining how we convert this text span into a vector representation for RNN input. Secondly, we explain our RNN model architecture, including our use of an attention mechanism to create a weighted sum over all hidden states, as well as a regularization technique based on implicit audience reaction.

3.1 Representing Debate Turns

Our work follows that of Zhang et al. (2016), and uses talking point-based features, specifically a 'bag of talking points'. Talking points for each debate are identified using a term frequency inverse document frequency (tfidf) metric applied to text tokens. Token counts, whether at a document or corpus level, occur only for the introduction text, as done by Zhang et al. This is based on the belief that the introductory arguments best showcase potential talking points. We take the 10 tokens with highest tfidf scores for each debate, and, across all debates, each token ranking maps to a fixed index in the turn representation. This representation is binary.

Zhang et al.'s results suggest that the interaction of talking points between debate teams can possess strong predictive power. Therefore, we also calculate talking points at a team level within debates. We accomplish this by simply taking term frequency counts for tokens spoken by a given team. Like with the overall debate talking points, we chose the 10 highest ranked talking points from each side and include them in the input representation. Moreover, we believe we can use a simpler talking point metric than that proposed by Monroe et al. (2008) (and used by Zhang et al.) because the recurrent nature of the model will naturally capture the interaction, coverage, and ignorance of the two team's (and overall) talking points.

Aside from talking point-based features, we include the following linguistic features: 1) bag-of-words for tokens that have been used in at least 50 debates; 2) GloVe embeddings of tokens (Pennington et al., 2014). We use max pooling over all the tokens' embeddings to create the embedding features. We also use the following non-linguistic features: 1) whether the turn occurs during the opening, discussion, or conclusion phase of the debate; 2) whether the turn is from the 'for' or 'against' team, as well as moderator or other speakers, such as show host etc; 3) the initial audience poll is provided at each timestep. This is similar in spirit to Cho et al. (2014)'s decoder model that accesses the final encoder hidden state at each timestep.

We acknowledge that it would be possible to model individual turns (sequences of tokens) with a separate RNN. We choose to use hand-engineered features for two reasons: First, the current representation, mainly the talking points and BOW features, are easily interpretable given the goal of providing rhetorical strategy for debaters. Using an RNN for this purpose would require training a decoder in order to interpret the optimal rhetoric at a given turn (see Section 7). Secondly, it follows that having a trainable representation would introduce additional parameters into the model, which is a concern, given the limited amount of data.

3.2 Recurrent Architecture

Our RNN model uses a long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) component. At each timestep, the model receives as input a turn representation defined in Section 3.1. After consuming all turn representations, a simple model without attention woud pass the final hidden state, h_f, through two fully-connected layers (with an intermediate representation h_a to which we apply sigmoid activation), whose weights have subscripts $post$ to identify that this transformation happens after the debate:

$$h_a = \sigma(W^1_{post} h_f + b^1_{post}) \tag{1}$$

$$a = W^2_{post} h_a + b^2_{post} \tag{2}$$

where σ is the sigmoid function. This transformation outputs a vector with three dimensions, which corresponds to the fact that the audience poll has three possibilities: for, against, and undecided.

Since the polling is given as a percentage breakdown, we apply $softmax$ to create a valid probability probability distribution for the audience,

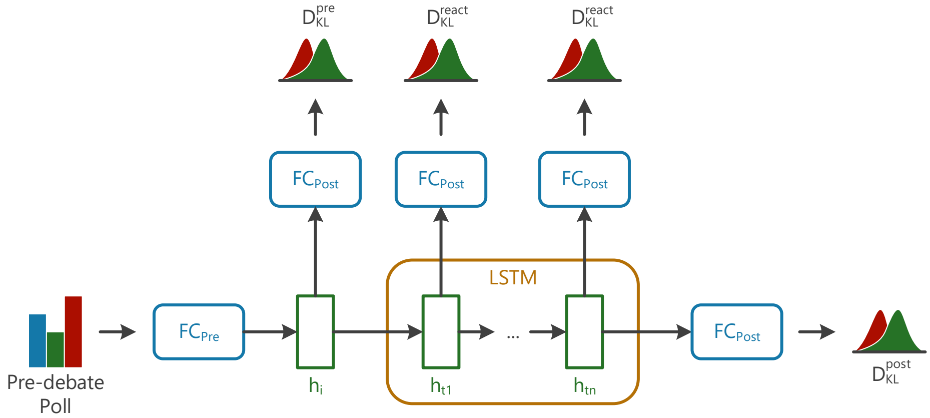

Figure 1: An illustration of our training objective from Equation 9 unrolled over time. FC_{pre} and FC_{post} refer to Equations 1/2 and 8, respectively.

$p(A)$:

$$p(A|\Theta) = \text{softmax}(a) \tag{3}$$

which is for a given set of model paramters, Θ.

We train the model to minimize the Kullback-Leibler (KL) divergence between the target and predicted audience poll percentages. Given a training corpus of debates D with target post-debate audience polls A_i^{target}, the optimization objective is:

$$\arg\min_{\Theta} \sum_{d \in D} D_{KL}(p(A_d^{target})||p(A_d|\Theta)) \tag{4}$$

which simply sums the KL-Divergence of the target and predicted audience poll percentages (probabilities) across all training examples. At test time, the model uses the percentages from $p(A|\Theta)$ to calculate which team increased their support from the audience the most, using the pre-debate audience poll, which is given. For notation purposes, we refer to this KL-divergence for post debate audience polling D_{KL}^{post}. The optimization objective from Equation 4 describes our base model. Shortly, we will describe how we regularize this base model using implicit audience feedback.

3.2.1 Attention Mechanism

The model we have described to this point uses the final hidden state to predict the final audience poll. A concern with this approach is that the final hidden state has a difficult time encoding the activity from the earlier parts of the debate. We propose to rectify this issue by creating a weighted sum over all hidden states, following the the attention mechanism from Bahdanau et al. (2014). Given hidden states from all RNN timesteps, $(h_1, ..., h_f)$, we determine the weight for h_i as follows. First, we compute a raw attention score:

$$r_i = v^T \tanh(W_a h_i + b_a) \tag{5}$$

where v, W_a, b_a are model parameters. h_i's weight is computed from applying softmax to r:

$$\alpha_i = \text{softmax}(r)_i \tag{6}$$

which we use to compute the weighted sum across all hidden states:

$$h_s = \sum_{i=1}^{f} \alpha_i h_i \tag{7}$$

Therefore, the attention version of our model uses h_s in Equation 1 to predict the final audience poll.

3.2.2 Initializing RNN Hidden State

As we have mentioned, audience polls occur both before and after the debate. Thus, we continue the theme of using the RNN hidden state to express audience polling by exploiting the initial audience poll to initialize the RNN hidden state, h_0. The model uses the initial audience poll, a_{pre}, and applies a fully-connected layer with parameters W_{pre} and b_{pre}:

$$h_0 = \tanh(W_{pre} a_{pre} + b_{pre}) \tag{8}$$

We choose $\tanh$ for the activation function because it is the same activation function used by the LSTM cell. The RNN now is initialized with a hidden state that reflects the audience's initial attitude towards a given debate topic.

3.2.3 Regularization via Implicit Audience Feedback

The IQ2 dataset offers two challenges for implementing an RNN-based approach. First, which is a difficulty for any type of supervised model, is the small dataset size. There are a total of 108 data points, which, even with LOO evaluation, leaves only 107 examples for training a model. For neural networks in particular, there is worry that overfitting easily occurs when the amount of model parameters is much greater than the dataset size (Lawrence et al., 1998; Ingrassia and Morlini, 2005). Aside from the dataset size, the sequences of debate turns are long, averaging 246. This means that, on average, our model will run for 246 timesteps, making it difficult to train the network (Bengio et al., 1994) (the structure of the LSTM memory cell was designed to solve this issue, which motivates our use of it in our model).

In order to overcome these difficulties, we propose to regularize our network based on implicit audience feedback that occurs during the debate, and is provided as metadata with the debate transcript. Specifically, provided along side each debate turn, there is a 'non-text' field that indicates if any sounds occurred during the turn such as applause or laughter from the audience. We view the presence of applause or laughter from the audience as a sign of endorsement during that particular turn. Therefore, at that particular timestep, the hidden state should be able to directly predict this occurrence. Considering applause as a sign of endorsement is not controversial, but laughter could be viewed as more ambiguous. However, consider the audience of the debates: the debates air on the Bloomberg network and National Public Radio, suggesting a higher level of maturity of the audience, which is less likely to laugh *at* the participants, rather than at their jokes. For example, here is a turn in the debate 'Men are Finished' wherein laughter occurs: "Wait. What was that phrase you used, surviving off the fumes of sexism? I think we are our finest example there." This is an intentional joke by the speaker, who is part of of the winning team in the debate.

This signal can be integrated in a supervised manner into the loss function by converting the audience reaction at a given timestep into a three-dimensional vector, representing the current, implied audience favorability. We create such a vector at a debate turn if either applause or laughter occurs at that timestep, and the speaker is one of the debate teams. On possibility is to create have a one-hot vector implying the audience favorability at the turn, with the mapping of side to index dictated by the target vector, A_i^{target}, and is set for the corpus. There is a major problem with using a one-hot vector: the probability distributions learned by the model will become too skewed, since the ultimate goal is to better generalize the prediction of debate polls, rarely are the polls so unbalanced toward one side. Moreover, the one-hot vector will only ever have mass in the indices for the 'for' and 'against' teams, and neglecting the 'undecided' index, which is an important sector in the polling. Therefore, we create a soft vector as follows: a random number, n, is chosen in the interval $(\frac{1}{3}, 1)$. The index corresponding to the speaking team at timestep i has value n. The remaining two indices have value $\frac{1-n}{2}$. This vector is notated A_{it}^{target}, specifying that the reaction occurred at timestep t for debate i. On average, such reactions occur 21 times during a debate, with a standard deviation of 10. Consequently, this approach adds 2,268 more supervised signals to the dataset.

As we did with the post-debate poll, we can compute a lost based on the kl-divergence between A_{it}^{target} and the prediction probability at timestep t, which is a function of h_t using the same transformations described in Equations 1, 2, and 3, but replacing h_f with h_t. The attention model can been used as well. In this case, we compute h_{s_t} by slicing r (from equation 5) to only include indices up to t. We denote the KL-divergence between target and prediction distributions across all timesteps of a training example is D_{KL}^{react}, since these signals are based on audience reaction.

The same strategy can be applied to h_i using the pre-debate polls. Although this signal does not propagate through the RNN, it can still train the weights of the fully-connected layers used in our model. We refer to this KL-divergence as D_{KL}^{pre}, since it uses the pre-debate poll. Bringing together these separate error signals, we arrive at the training objective of our full model:

$$\arg\min_{\Theta} \sum_{d \in D} D_{KL}^{pre} + D_{KL}^{react} + D_{KL}^{post} \qquad (9)$$

where Θ is the model parameters used to produce the prediction probabilities. Figure 1 provides an illustration of our training objective, unrolled over time.

With this new optimization objective, each example now trains our model based on (on average) 23 supervised signals. As a result, each training example allows the model to become more generalizable, particularly because the hidden states are now better-tuned to encode audience favorability. This methodology allows the model to better leverage the small dataset size. Moreover, the intermittent error signals from audience reaction, D_{KL}^{react}, combined with the pre-debate error signal, D_{KL}^{pre}, help assuage the difficulties of training our model based on a final error signal propagated for many timesteps. We would like to reiterate that this regularization technique is only used to *train* the model, and not used for prediction, and therefore will not be an issue when making predictions for new debates, nor will it create an unrealistic circumstance for using the model for creating a debate agent.

4 Experimental Design

Our experiments are conducted on the IQ2 dataset (Zhang et al., 2016). We use LOO evaluation, resulting in a training set of 107 examples. The evaluation metric is simply prediction accuracy for debate winners. The winning team is based on audience polling. Polls are conducted before and after the debate, and audience members can vote as being either for or against a given debate topic, as well as being undecided. The team that has the highest increase in audience support from the pre to post debate poll is the winning team. The model trains for 100 epochs. Once training is complete, we test on the held-out data point. As Zhang et al. note, there are three debates in the dataset that have a tie between the debate teams. Following their procedure, we do not test on these data points. However, we still include these examples in the training sets, because our training objective is to predict polls, not debate winners. The final test accuracy is averaged across the remaining 105 LOO runs. Furthermore, we note that the dataset is effectively balanced, as there are 53 and 52 examples with the two possible labels.

We implement all our models in TensorFlow (Abadi et al., 2016). We use the LSTM cell equipped with peephole connections (Gers et al., 2002). This architecture allows the gates to see the current cell state, along with the hidden state. We believe that because of the long sequences present in the dataset, it is important to have all the gates take into account the cell state when producing a hidden layer. This adds a stronger notion of memory to the model. While we expect the hidden state to represent audience favorability, we believe the cell state can capture the further latent notion of debate strategy, observable through the interaction of talking points between the debate teams. The models have cell and hidden size of 128, and the intermediate layer from Equation 2 has size 16. Lastly, we use a batch size of 8.

Model	Accuracy
LR BOW	0.50
LR React	0.60
LR Flow	0.63
LR Flow*	0.65
LSTM	0.55
LSTM + Att	0.57
LSTM + Reg	0.64
LSTM + Att, Reg	**0.71**
LSTM + Att, Drpt	0.60

Table 1: The results of LOO evaluation on the IQ2 dataset. See the beginning of Section 5 for an explanation of the models.

5 Results

The results of our experiment are presented in Table 1. Att means the model has the attention mechanism from Section 3.2.1; Reg means the model uses the optimization objective from Equation 9 (all other models use the optimization objective from Equation 4); Drpt means the model uses dropout (a popular regularization technique for neural networks (Srivastava et al., 2014)) of 0.5. We compare our results against the best models from Zhang et al. (2016). Each model uses a Logistic Regression (LR) classifier, and distinguishes itself by the features it uses. The main features developed by the authors relate to the interaction (flow) of talking points between the debate teams. There are two types of models that use the flow features: LR Flow and LR Flow*. Whereas the former uses all developed flow features, the latter uses feature selection to keep the most powerful flow features. LR React uses features based on audience reaction metadata, and LR BOW uses bag-of-words features.

The results show that the LSTM attention model regularized by audience reaction achieves the highest accuracy. Furthermore, the results highlight the importance of this regularization technique, since the simple LSTM model records the second lowest accuracy of any of the models presented. This leads us to believe that the regular LSTM model falls victim to the lack of training data, preventing the larger amount of model parameters (compared to a logistic regression model) from generalizing. The results also show that the attention model has higher performance than the regular LSTM model, and the difference in performance is heightened when the regularization technique is applied. We believe this is because the attention mechanism adds additional parameters to the model, so it seems reasonable that adding additional training signals helps the model to generalize better. Lastly, our proposed regularization technique is far superior for generalization than the popular dropout method. We believe the strong performance of the proposed regularization technique is because it causes the LSTM's hidden states to better generalize the notion of encoding audience favorability. Furthermore, our model's goal is to predict *distributions*, as opposed to labels. Whereas dropout can be effective at aiding in collapsing representations of the same class into neighboring points of a latent space, our model needs to be able to predict polls that it may have not encountered in training. Our regularization technique aids in this as well by providing more training data, more polls.

6 Tracking Audience Favorability

One of the advantages of mapping a recurrent model's hidden states to audience favorability is that we can produce a favorability poll at any turn (timestep) during the debate. In contrast, a temporally flat model, such as the logistic regression models from Zhang et al., produce a prediction of audience favorability based on features extracted from the entire debate. Using our mapping of hidden states to audience favorability, we can determine, at each turn, the current audience favorability, and track it throughout the entire debate. Figure 2 shows this applied to the "men are finished" debate, wherein the lines on the graph, cut vertically, represent predicted audience polls at a given debate turn. This debate saw the greatest increase in audience support from the pre to post debate poll: the 'for' increased their favorability by 46% (46 points). The three lines correspond to the three possible positions an audience member can take regarding the debate topic. This visualization can be particularly useful for rhetorical analysis of debate performance, because the resulting graph allows us to see inflection points in audience favorability. These inflection points suggest that a debate team used very effective (or ineffective) rhetoric at that particular turn.

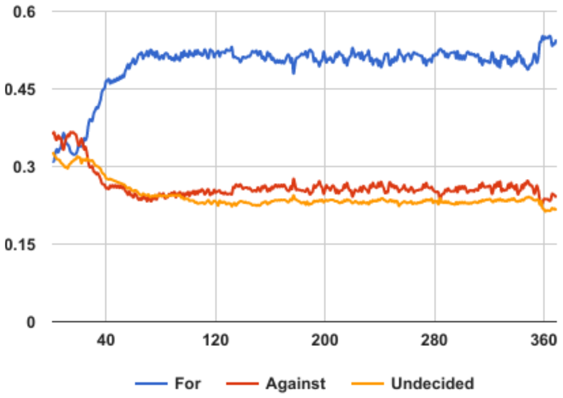

Figure 2: A visualization of audience favorability for the debate "men are finished". At each turn in the debate, our model predicts the audience favorability. The y-axis shows the percentage of the audience that supports a given side, and the x-axis show the turn number for a given poll. Even though these are purely predictions from the model, it is able to show the rise in audience favorability for the 'for' team, as well as the decline in favorability for the 'against' team. From the graph, we can see that the 'for' team had a large spike in audience support roughly between turns 20 and 40, which corresponds to the beginning of the debate's discussion section.

7 Optimizing Input for Audience Favorability

Aside from achieving a new state-of-the-art result on the IQ2 debate corpus, the main appeal of the model we have introduced is that it creates a mapping between the hidden states and audience favorability of the debate teams. This mapping is given in Equations 1 and 2, where a weighted sum over all over all hidden states (the actual notation in these equation apply the fully-connected transformation to a final hidden state, h_f, unlike the attention model which uses h_s from Equation 7) is transformed into a real-valued 3-dimensional vector a. The values of the vector indicate 'raw' favorability, which is realized as a probability distribution (or alternatively, a poll of the audience) after applying the softmax activation. Furthermore, given fixed model parameters Θ, the current hidden state is a function of the previous hidden states, previous cell state (if, like our model, an LSTM cell is used), as well as the current input. At a given timestep, the previous hidden and cell states are known. Therefore, a is directly a function of the current input x at a given timestep. This notion of optimizing input for a target 'class' is akin to the work of Simonyan et al. (2013), who use a trained convolutional neural network to find the optimal input image for a desired object class.

7.1 Input Optimization Objective

Similar to our approach in Section 3.2.3 to encode implicit audience feedback, we can construct a three-dimensional one-hot vector with the index switched on that corresponds to the debate team whose favorability we seek to optimize. We will call this vector A^{fav}. Given input x_i at timestep i, we seek to to optimize the probability of A^{fav} given x_i:

$$\arg\max_{x_i} p(A^{fav}|x_i, h_1, ..., h_{i-1}, c_{i-1}; \Theta) \quad (10)$$

Where $i \in (1, ..., T)$ and T is the maximum number of timesteps (turns) for a debate. In practice, we achieve this optimization by minimizing the cross-entropy between the the target one-hot vector and the output of applying the softmax function to a, as in Equation 3.

7.2 Applying Optimized Input for Persuasive Strategy

In the debate 'men are finished', the 'for' team won the debate, increasing their favorability by an astonishing 46% (conversely, the 'against' team saw a 25% *decrease* in favorability). According to our model's sequential predictions (and visible in Figure 2), a major turning point occurred at turn 27. Quantitatively, we can examine the turn-by-turn change in audience favorability: from this we see that one of the largest increases in audience favorability occurred at turn 27. It is not a surprise to find out that the team that spoke during turn 27 was the 'for' team. When asked by the moderator if there can be equality between the sexes without deeming men as being finished, the 'for' team said the following (the text is annotated for the presence of talking points, marked by a subscript that specifies whose talking point it is: A (against), F (for), or G, a general talking point based on overall token frequency (see Section 3.1)):

> It is possible, but it just doesn't work that way. I mean, if we can all agree that there was male dominance for a long time and that male dominance is over, then I think we agree that $\underline{\text{men}}_{G,A}$ are finished. So the resolution is about male dominance which we've taken for granted for so many tens of thousands of years. And so, even if you have parity, you have the end of male dominance. I mean, if you have $\underline{\text{women}}_{F}$ rising and catching up to $\underline{\text{men}}_{G,A}$, then you no longer have male dominance. And so that's what I meant when I, early on, tried to define the resolution as $\underline{\text{men}}_{G,A}$ are finished, the era of male dominance, it's finished, which we've taken for granted for all this time.

Note that the term 'women' is only a talking point for the 'for' team. In their response the 'against' team says:

> They are not finished. That's absurd. You agreed to it in your opening that you didn't want to say $\underline{\text{men}}_{G,A}$ are finished. You thought there might be inklings of a suggestion that it may be happening. But what you're defending now is that $\underline{\text{men}}_{G,A}$ are finished. I'm saying it's absurd. I'm saying that some $\underline{\text{men}}_{G,A}$ are in trouble. But rather than declare their extinction, we should be doing what we can to help them.

To determine our model's strategy immediately after the 27th turn, we apply the previous hidden and cell states to the optimization objective in Equation 10, taking the place of $h_1, ..., hi - 1$ and c_{i-1}, respectively. We fit the training objective to the current states, as well as the weights of the previously trained predictive model, and examine the resulting optimized input vector. We train the optimized input model for 15,000 epochs, which goes very fast because there is a 'single' training data point, and the model is not recurrent. As we can see in the actual 'against' team's response, the only talking point brought up is 'men', which can hardly be viewed as an enlightening notion in the context of the debate. Alternatively, the highest rated talking point from the optimized input is in fact the exact talking point brought up by the 'for' team: 'women'. This suggestion by our model is in line with the hypothesis of Zhang et al. (2016), that winning teams are effective in adopting their opponent's talking points. In terms of bag-of-word features: the optimized input ranks the following tokens as the ten highest (in descending order of score, and note the tokens have been stemmed): 'sound', 'present', 'recent', 'line', 'decid', 'veri', 'spent', 'save', 'moder', and 'found'. Most of these tokens remain somewhat vague with respect to their relevance to the debate. The token 'recent' seems relevant, given that the debate topic has an inherent temporal nature. 'Save' is relevant in that some of the debate discussion approaches the question of whether men need saving. In the top 20 tokens we also find 'done', 'compar', 'grow', and 'without', which are all relevant: 'done' is synonymous with 'finished', 'compar' given that the debate is often comparing men to women, 'grow' could refer to the growth of women in society, and 'without' is a token specifically in the question the moderator asked prior to turn 27 (equality between the sexes without deeming men as being finished).

8 Conclusion

We have presented an RNN model for predicting debate winners, with the specific goal of predicting the final (or intermediate) audience poll. The model takes at each timestep a representation of a given debate turn. The model uses an attention mechanism that creates a weighted sum over all hidden states. In order to achieve state-of-the-art results on a corpus of debate transcripts (Zhang et al., 2016), we regularize the RNN model by propagating errors based on implicit audience reaction. Our results show that this regularization technique is critical for obtaining a state-of-the-art result. We have also shown the practical application of our model in two scenarios. First, the model can be used to make a prediction of audience polling at every debate turn. This allows for an analysis of the key turning points during the debate, based on inflections in audience favorability. Second, the model can be used to determine the optimal input at a given debate turn. Knowledge of this input can inform debaters as to the best current persuasive strategy. Future work can leverage optimal inputs to create a language model that can become an automated debate agent. However, since the input is partially based on the knowledge of talking points, there is a potential for an information retrieval-based task to provide the talking points for the debate agent (if one desires a fully-automated system than can work without the presence of introductory remarks, from which talking points are currently extracted). Finally, future work can also examine the trained model itself in further detail, seeking to understand the debate strategy.

Further Investigation into Reference Bias in Monolingual Evaluation of Machine Translation

Abstract

Monolingual evaluation of Machine Translation (MT) aims to simplify human assessment by requiring assessors to compare the meaning of the MT output with a reference translation, opening up the task to a much larger pool of genuinely qualified evaluators. Monolingual evaluation runs the risk, however, of bias in favour of MT systems that happen to produce translations superficially similar to the reference and, consistent with this intuition, previous investigations have concluded monolingual assessment to be strongly biased in this respect. On re-examination of past analyses, we identify a series of potential analytical errors that force some important questions to be raised about the reliability of past conclusions, however. We subsequently carry out further investigation into reference bias via direct human assessment of MT adequacy via quality controlled crowd-sourcing. Contrary to both intuition and past conclusions, results show no significant evidence of reference bias in monolingual evaluation of MT.

1 Introduction

Despite it being known for some time now that automatic metrics, such as BLEU (Papineni et al., 2002), provide a less than perfect substitute for human assessment (Callison-Burch et al., 2006), evaluation in MT more often than not still comprises BLEU scores. Besides increased time and resources required by the alternative, human evaluation of systems, human assessment of MT faces additional challenges, in particular the fact that human assessors of translation quality tend to be highly inconsistent. In recent Conference on Machine Translation (WMT) shared tasks, for example, manual evaluators complete a relative ranking (RR) of the output of five alternate MT systems, where they must rank the quality of competing translations from best to worst. Within this set-up, when presented with the same pair of MT output translations, human assessors often disagree with one another's preference, and even their own previous judgment about which translation is better (Callison-Burch et al., 2007; Bojar et al., 2016). Low levels of inter-annotator agreement in human evaluation of MT not only cause problems with respect to the reliability of MT system evaluations, but unfortunately have an additional knock-on effect with respect to the meta-evaluation of metrics, in providing an unstable gold standard. As such, provision of a fair and reliable human evaluation of MT remains a high priority for empirical evaluation.

Direct assessment (DA) (Graham et al., 2013, 2014, 2016) is a relatively new human evaluation approach that overcomes previous challenges with respect to lack of reliability of human judges. DA collects assessments of translations separately in the form of both fluency and adequacy on a 0–100 rating scale, and, by combination of repeat judgments for translations, produces scores that have been shown to be highly reliable in self-replication experiments (Graham et al., 2015). The main component of DA used to provide a primary ranking of systems is *adequacy*, where the MT output is assessed via a monolingual similarity of meaning assessment. A reference translation is displayed to the human assessor (rendered in gray) and below it the MT output (in black), with the human judge asked to state the degree to which they agree that *The black text adequately expresses the meaning of the gray text in English.*[1] The motivation behind

[1] Instructions are translated into a given target language.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2476–2485
Copenhagen, Denmark, September 7–11, 2017.

constructing DA as a monolingual MT evaluation are as follows:

- Monolingual assessment of MT opens up the annotation task to a larger pool of genuinely qualified human assessors;
- Crowd-sourced workers are unlikely to make use of information that is not entirely necessary for completing a given task; and are therefore unlikely to use the source language input if the reference is also displayed or to make use of the source input inconsistently;
- Displaying only the source without a reference greatly increases both the difficulty of the task and the time required to complete each annotation, which is too serious a trade-off when we wish to carry out human assessment on a very large scale;
- Varying levels of proficiency in the source language across different human assessors could contribute to inconsistency in bilingual MT evaluations.

Although DA has been shown to overcome the long-standing challenge of lack of reliability in human evaluation of MT, the possibility still exists that, although scores collected with DA have been shown to be almost perfectly reliable in self-replication experiments, both sets of scores, although consistent with each other, could in fact both be biased in the same way. Graham et al. (2013) include in the design of DA a number of criteria aimed at minimizing such bias: (i) assessment of individual translations in isolation from others to avoid a given system being scored unfairly low due to its translations being assessed more frequently alongside high quality translations (Bojar et al., 2011); (ii) elicit assessment scores via a Likert-style question without intermediate labeling, motivated by medical research showing patients' ratings of their own health to be highly dependent on the exact wording of descriptors (Seymour et al., 1985); (iii) accurate quality control by assessing the consistency of judges with reference only to their own rating distributions, to accurately remove inconsistent crowd-sourced data while avoiding removal of data that legitimately diverges from the scoring strategy of a given expert judge; and (iv) score standardization to avoid bias introduced by legitimate variations in scoring strategies.

Despite efforts to avoid bias in Graham et al. (2013), since DA is a monolingual evaluation of MT that operates via comparison of MT output with a reference translation, it is therefore still possible, while avoiding other sources of bias, that DA incurs reference bias where the level of superficial similarity of translations with reference translations results in an unfair gain, or indeed an unfair disadvantage for systems that yield translations that legitimately deviate from the surface form of reference translations. Following this intuition, Fomicheva and Specia (2016) carry out an investigation into bias in monolingual evaluation of MT and conclude that in a monolingual setting, human assessors of MT are strongly biased by the reference translation. In this paper, we provide further analysis of experiments originally provided in Fomicheva and Specia (2016), in addition to further investigation into the degree to which the intuition about reference bias can be supported.

2 Background

Fomicheva and Specia (2016) provide an investigation into reference bias in monolingual evaluation of MT. 100 Chinese to English MT output translations are assessed by 25 human judges on a five-point scale, in the form of their response (*None*, *Little*, *Much*, *Most*, or *All*) to the following question: *how much of the meaning of the human translation is also expressed in the machine translation?*. Precisely the same 100 translations were assessed by all 25 judges. Human judges were divided into five groups of five: Group 1 (G_1) was shown the source language input and the MT output only and carried out a bilingual assessment, while Groups 2–5 (G_2–G_5) were not shown the source input but instead compared the MT output to a human-generated reference translation. A distinct set of reference translations was assigned to each group G_2–G_5. Inter-annotator agreement (IAA) was measured for pairs of judges as follows (the total number of judge pairs resulting from each setting is provided in parentheses):

- SOURCE: a given pair of judges assessed translations in a bilingual setting (all possible pairs within $G_1 = \binom{5}{2} = 10$ pairs);
- SAME: a given pair of judges assessed translations in a monolingual setting by comparison with precisely the *same reference translation* (the sum of all possible pairs result-

DIFF	SAME	SOURCE
0.163 ± 0.01	0.197 ±0.01	0.190 ± 0.02

Table 1: Average Kappa coefficients and 99% confidence intervals reported in Fomicheva and Specia (2016)

ing from each individual group G$_2$–G$_5$ = $\binom{5}{2} + \binom{5}{2} + \binom{5}{2} + \binom{5}{2} = 40$ pairs);

- DIFF: a given pair of judges assessed translations in a monolingual setting by comparison with a *distinct reference translation* (cross product of judges belonging to the four groups G$_2$–G$_5$ = G$_2$×G$_3$×G$_4$×G$_5$ = 150 pairs).

Reference bias is investigated by comparison of levels of IAA, via Cohen's Kappa (κ) and weighted Kappa coefficients. The hypothesis, although not explicitly stated, is that if agreement of human assessors of MT in SAME is *higher* than that of assessors in DIFF, then the likely cause is reference bias in human assessment scores. Agreement in terms of Cohen's Kappa reported in Fomicheva and Specia (2016) are reproduced here in Table 1, where a small increase of 0.034 in average Kappa is shown for pairs of human assessors in SAME over that of DIFF. To avoid drawing conclusions from a difference that is likely to have occurred simply by chance, confidence intervals (CIs) are provided and the non-overlapping CIs for SAME and DIFF shown in Table 1 provide the basis for the conclusion that IAA is significantly higher for SAME compared to DIFF and subsequently that monolingual evaluation of MT is strongly biased by the reference translation. On examination of the analysis that led to the conclusion of strong reference bias, we unfortunately discover a series of methodological issues with respect to confidence interval estimation, however, that raise doubt about the reliability of this conclusion.[2]

A clear indication of the precise approach to CI estimation attempted in Fomicheva and Specia (2016) is unfortunately not explicitly stated but out of the range of methods that exist the approach that is applied most resembles bootstrap resampling. Conventionally speaking, bootstrap resampling can be applied to CI estimation of a point estimate for a *sample*, D, of size N, by simulating the variance in the *population* sampling distribution (Efron and Tibshirani, 1993). A standard method of estimating CIs via bootstrap resampling is to generate a bootstrap distribution for the statistic of interest made up of M repeat computations of it, each time drawing a random sample of size N from D with replacement. Although most similar to bootstrap resampling, the application in Fomicheva and Specia (2016) to CI estimation of Kappa coefficients diverges in some important ways from a standard application, however. We therefore provide a comparison of the analysis drawn in Fomicheva and Specia (2016) with a standard bootstrap implementation.

Figure 1(a) shows SAME and DIFF bootstrap distributions, reproduced from code released with Fomicheva and Specia (2016), originally yielding non-overlapping CIs that led to the conclusion of strong reference bias.[3] Although the level of statistical significance is reported to be 99%, CIs in Figure 1(a) show that the proportion of each bootstrap distribution was substantially underestimated leading to overly narrow CI limits for both SAME and DIFF. In contrast, Figure 1(b) shows CIs resulting from an accurately computed proportion of 95% of the same bootstrap distribution, where even at the lower level of 95% significance (as opposed to 99%) CIs for SAME and DIFF now overlap, reversing the conclusion of strong reference bias.

In addition, CI estimation diverges from bootstrap resampling with respect to the number of bootstrap samples employed. Since there are a total of N^N possible distinct bootstrap samples for a given sample D (taking order into account), in a conventional bootstrap implementation a Monte Carlo approximation of size M is employed, and the larger M is, the closer the distribution approaches the true bootstrap distribution (Chernick and LaBudde, 2014). In Fomicheva and Specia (2016), CIs are computed via only 50 bootstrap samples, however.[4] Figure 1(c) shows the change in location of CIs for a typical M =1,000, as opposed to M =50 (Figure 1(b)).

[2] We provide a re-analysis of experiment data specifically with respect to Cohen's Kappa. All errors outlined for Cohen's Kappa also lead to the same inaccuracies for weighted Kappa in Fomicheva and Specia (2016), however.

[3] CIs correspond closely to those of the original (Table 1) but differ by a tiny amount due to the randomness involved in regeneration from the code.

[4] We note that M is described as 100 in the publication, but 50 in the released code. Our question raised about the methodology also stands for M =100.

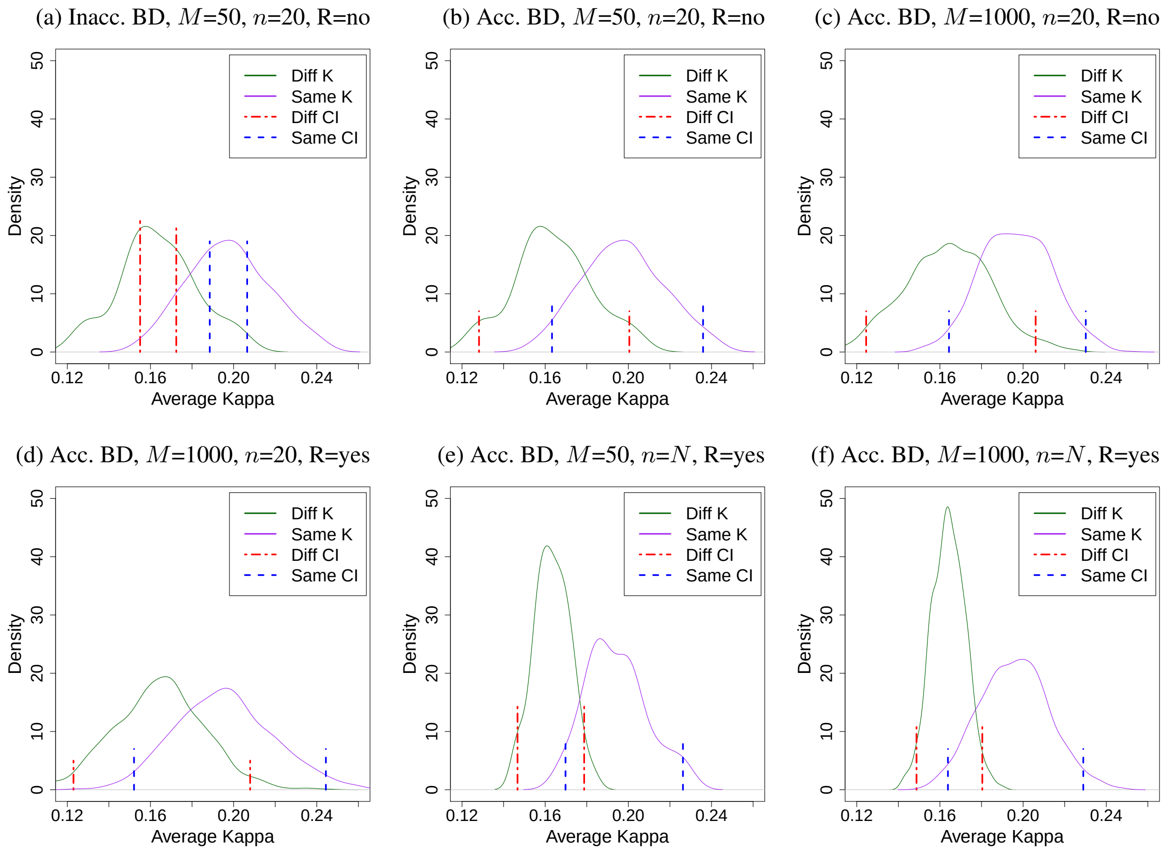

Figure 1: (a) Original bootstrap distribution (BD) and confidence intervals (CI) for average Kappa coefficients when human annotators employ the same reference translation (Same K) or a different reference translation (Diff K) in Fomicheva and Specia (2016) ("Inacc. BD"=inaccurate BD proportion; "Acc. BD"=accurate BD proportion; "M"=number of bootstrap samples; "n"=bootstrap sample size; "R=yes": sampled with replacement; "R=no": sampled without replacement); (b) is (a) with accurate BD proportion; (c) is (b) with conventional M; (d) is (c) with R=yes; (f) is (d) with N=n (N is the full sample size); (e) is (f) with M=50; (f) corresponds to correct BD with all CI errors corrected.

Furthermore, bootstrap distributions in Fomicheva and Specia (2016) are computed by random sampling *without* replacement, and the size of each bootstrap does not equal the original sample size N.[5] Figure 1(d) shows bootstrap distributions of Figure 1(c) when the sampling without replacement error is corrected, and Figure 1(f) shows bootstrap distributions of Figure 1(d) when the sample size error is corrected.

In summary, Figure 1(f) shows all errors with respect to CI estimate in Fomicheva and Specia (2016) corrected, and subsequently CIs for a standard implementation of bootstrap, which can be contrasted to those that led to the original conclusion of strong reference bias in Figure 1(a). CIs in Figure 1(f) for SAME and DIFF now overlap revealing that experiments in Fomicheva and Specia (2016), thus far do not show any evidence of reference bias.

2.1 Measures of Central Tendency

Even if the correct implementation of bootstrap resampling, shown in Figure 1(f), had shown non-overlapping confidence intervals, it would still unfortunately not have been appropriate to draw a conclusion from this of reference bias, however, due to the fact that significant differences are not investigated for the statistic of interest, the Kappa coefficient, but only for a measure of central tendency of two Kappa coefficient distributions, the *average* Kappa of each Kappa distribution. One reason for avoiding a comparison based on significant differences in average Kappa, as opposed to the Kappa point estimates themselves, is that it is

[5] A variant of bootstrap does exist where N is intentionally lowered to appropriately reduce the variance estimate but is only applicable when that of standard bootstrap is known to be over-estimated (Chernick and LaBudde, 2014).

possible for the average of two distributions to be equal, or indeed have a small but non-significant difference, while the underlying distributions differing considerably in several other respects.

Figure 2 shows Kappa coefficient distributions for all pairs of judges in SAME (40 pairs), DIFF (150 pairs) and SOURCE (10 pairs), revealing all distributions to have very similar Kappa coefficient distributions, with the one exception arising for SOURCE, where two of the human annotator pairs had an unusually high agreement level.[6]

A more informative comparison about levels of agreement in SAME and DIFF examines significant differences in Kappa point estimates, as opposed to comparison based on a measure of central tendency. For this reason, despite there being no significant difference in *average Kappa* for SAME and DIFF, we also examine the *proportion of Kappa point estimates of judge pairs in* SAME *that are significantly different from agreement levels of judge pairs in* DIFF, which will provide genuine insight into differences in levels of agreement between the two groups.

Table 2 shows proportions of all judge pairs with significant differences in Kappa point estimates (non-overlapping confidence intervals) for each combination of settings (Revelle, 2014).[7] The number of significant differences in Kappa point estimates for pairs of judges in SAME and DIFF is only 13%, or, in other words, 87% of judge pairs across SAME and DIFF have no significant difference in agreement levels. Table 2 also includes proportions of significant differences for Kappa point estimates resulting from judges belonging to a single setting (significance testing all Kappa of SAME with respect to all *other* Kappa belonging to SAME, for example), revealing that the proportion of significant differences within SAME (12%) to be very similar to that of SAME × DIFF (13%), and similarly for DIFF (12%), with only a single percentage point difference in both cases in proportions of significant differences. Subsequently, even after correcting the measure of central tendency error in Fomicheva and Specia (2016), evidence of reference bias can still not be concluded.

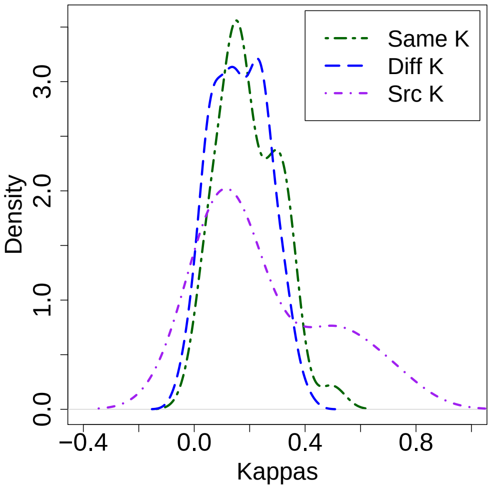

Figure 2: Distribution of Kappa coefficients for translations assessed with the same reference translation ("Same K"), different reference translations ("Diff K") and source sentences ("Src K") (Fomicheva and Specia (2016) data set).

	SOURCE	SAME	DIFF
SOURCE	47% (45)	29% (400)	27% (1,500)
SAME	–	12% (780)	13% (6,000)
DIFF	–	–	12% (11,175)

Table 2: Percentage of human annotator pairs in Fomicheva and Specia (2016) with significant differences in Kappa coefficients for pairs of annotators shown the same reference translation (SAME), different reference translations (DIFF) or the source language input only (SOURCE), total numbers of annotator comparisons in each case are provided within parentheses, numbers of annotator pairs was 10 for SOURCE, 40 for SAME and 150 for DIFF.

2.2 Differences in Ratings

The effect that reference bias may or may not have on actual 1–5 ratings attributed to translations, is again only reported in terms of a measure of central tendency, i.e. average ratings, in Fomicheva and Specia (2016). The average rating of each group shown a distinct reference translation is reported, showing distinct average scores for assessors employing a distinct set of reference translations. Due to the fact that each group had a distinct average rating, the conclusion is drawn that *MT quality is perceived differently depending on the human translation used as gold-standard.* It is however, entirely possible that, the difference in average ratings is in part or even fully caused by

[6] The difference in distributions for SOURCE is exaggerated to some degree due to the total number of annotator pairs in SOURCE being substantially lower than the other two settings (only 10 pairs).

[7] Our re-analysis code is available at https://github.com/qingsongma/percentage-refBias

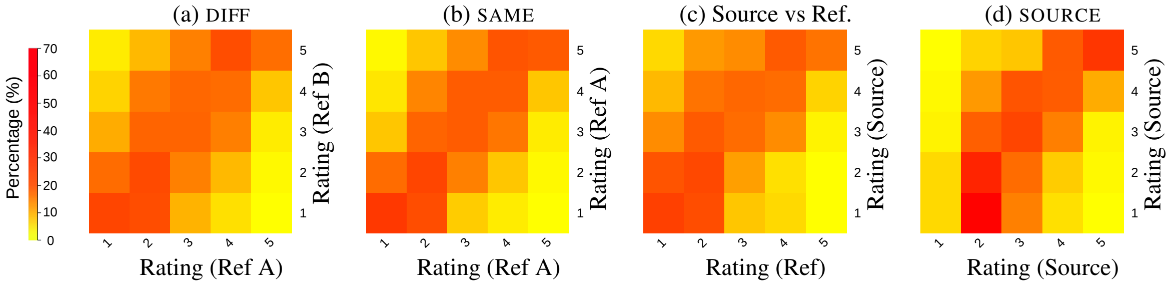

Figure 4: Proportions of 1–5 ratings (1=lowest; 5=highest) for translations when human assessors are shown different reference translations (DIFF), the same reference translation (SAME), the source input versus a reference translation (Source vs Ref.) or the source input (SOURCE) for data in Fomicheva and Specia (2016).

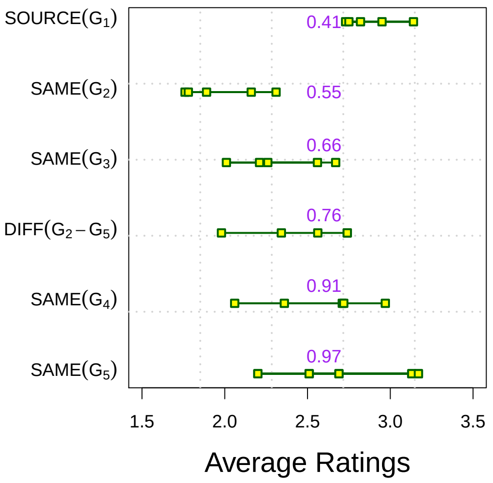

Figure 3: Average rating of human assessors shown the source input (SOURCE), the same reference translation (SAME), or a distinct reference translation (DIFF); range of average ratings provided adjacent to each setting.

the known lack of consistency across human annotators in general.

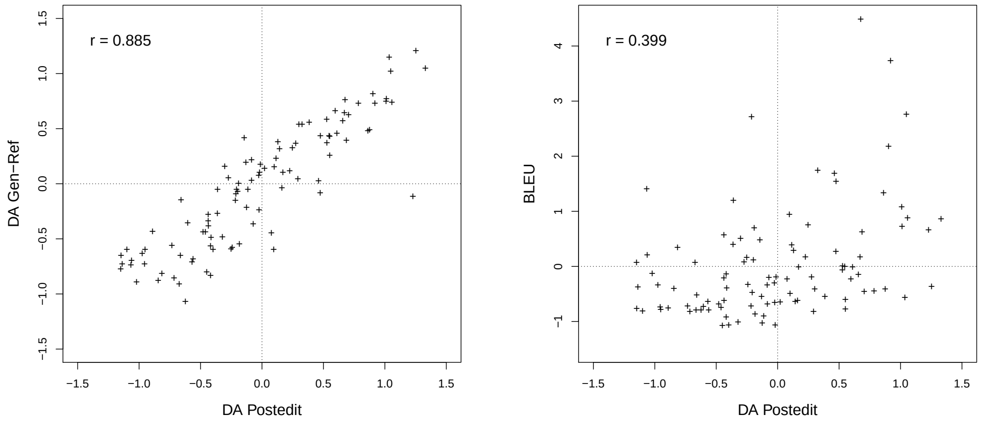
Quite a substantial leap is made therefore between the difference in average ratings and the cause of that difference. To investigate this further, we reproduce the average ratings for assessors shown a distinct reference translation, each represented by a green square along the line labeled “DIFF(G_2–G_5)” in Figure 3, where the overall range in average ratings is 0.76. The extremity of this range is better put into context by comparison with the average rating of human assessors shown the same reference translation, each labeled SAME in Figure 3, where the range of average ratings attributed to human assessors shown *the same reference* can be as large as 0.97 (G5). Thus, it *cannot* be concluded from a difference in average ratings for annotators shown distinct reference translations that the cause of this difference is the reference translation.

However, comparison of ratings based only on averages, again hides detail that an analysis could otherwise benefit from. We therefore examine the distribution of individual ratings attributed to translations, and how well ratings for the same translation correspond when pairs of annotators employ the same or distinct reference translation (or indeed the source input) in Figure 4.[8] The rating pattern in Figure 4 (a) of judge pairs employing a distinct reference translation compared to those in Figure 4 (b), where assessors employ the same reference translation, shows agreement at the level of individual ratings to be almost indistinguishable, showing no evidence of reference bias.

3 Alternate Reference Bias Investigation

Although we can now say that experiments in Fomicheva and Specia (2016) showed no evidence of reference bias, a further issue lies in the fact that low IAA was incurred throughout the study, and low IAA unfortunately provides no assurance with respect to the reliability of conclusions, even when corrected for analytical errors. In addition, the fact that IAA was itself the measure by which bias was investigated is also likely to exacerbate any problems with respect to reliability of conclusions. We therefore provide our own additional investigation into reference bias in monolingual evaluation of MT. Instead of investigating via IAA, we explore the degree to which unfairly high or low ratings might be assigned to translations with respect to

[8] The sum of percentages in a given row equals 100% in each heat map.



(a)

(b)

Figure 5: (a) Scatter plot of direct assessment (DA) scores for 100 Chinese to English translations carried out by comparison with a generic reference translation (DA Gen-Ref) or DA with the reference replaced by a human post-edit of the MT output (DA Postedit); (b) sentence-level (smoothed) BLEU scores for the same translations also plotted against DA POST-EDIT; translations and references of (a) and (b) data set of Fomicheva and Specia (2016); post-edits provided by professional translators with access to the source and MT output only. BLEU and DA scores are standardized for ease of comparison in all plots.

surface similarity or dissimilarity with the reference translation.

Reference-similarity bias is the attribution of unfairly high scores to translations due to high surface-similarity with the reference translation even though the translation is not high quality. A converse kind of reference bias can also occur, which we call *reference-dissimilarity bias*, where unfairly low scores are attributed to translations that are superficially dissimilar to the reference translation but are in fact high quality translations. The challenge in investigating reference bias lies in the ability to accurately distinguish between translations that receive *unfair* scores due to surface-similarity or dissimilarity from those that achieved a *fair* score due to the translation being genuinely high or low quality.

To separate genuine high quality translations from those that score *unfairly* high, we carry out two separate assessments of the same set of translations. Firstly, we carry out a standard monolingual MT evaluation that employs a generic reference translation (GEN-REF setting), the scores that potentially encounter reference bias. Secondly, we carry out an additional human evaluation of the same translations, where, instead of the generic reference, the human assessor compares the MT output with a human post-edit of it (POST-EDIT setting). The latter human assessment is highly unlikely to encounter any form of reference bias because the assessment employs a post-edit of the MT output, which itself will only differ the MT output with respect to the parts of it that are genuinely incorrect. Translations encountering reference-similarity bias can then be identified by a high GEN-REF score combined with a low POST-EDIT score, and vice-versa for reference-dissimilarity, a low GEN-REF score combined with a high POST-EDIT score.

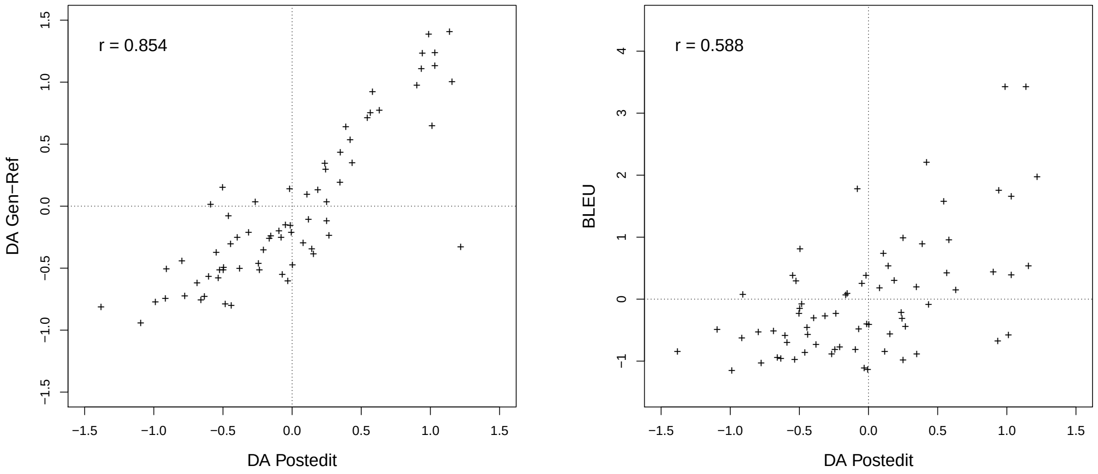
3.1 Reference Bias Experiments

Experiments were carried out using the original 100 Chinese to English translations released by Fomicheva and Specia (2016), in addition to 70 English to Spanish MT translations (WMT-13 Quality Estimation Task 1.1).[9] Professional translators, entirely blind to the purpose of the study, were employed to post-edit the MT outputs used in the POST-EDIT setting, and were shown the source input document and the MT output document only (no reference translations).[10]

Once post-edits had been created, DA was employed in two separate runs on Amazon Mechani-

[9] A single generic reference translation was chosen at random from the Chinese to English data set; only a single reference is available for each translation in the English to Spanish data set.

[10] Post-editors were paid at the standard rate.



(a)

(b)

Figure 6: (a) Scatter plot of direct assessment (DA) scores for 70 English to Spanish translations carried out by comparison with a generic reference translation (DA Gen-Ref) or DA with the reference replaced by a human post-edit of the MT output (DA Postedit); (b) sentence-level (smoothed) BLEU scores for the same translations also plotted against DA POST-EDIT; translations and generic references for (a) and (b) WMT-13 Quality Estimation Task 1.1 (Bojar et al., 2013) data set; post-edits provided by professional translators with access to the source and MT output only. DA and BLEU scores are standardized for ease of comparison in all plots.

cal Turk,[11] once for GEN-REF and once for POST-EDIT. Besides employing distinct reference translations in the assessment, all other set-up criteria were identical for both evaluation settings, including the conventional segment-level DA setting, where a minimum of 15 human assessments are combined into a mean DA score for a given translation, after strict quality control measures and score standardization have been applied.

3.2 Results and Discussion

Figure 5(a) shows a scatter-plot of DA scores attributed to translations for GEN-REF compared to POST-EDIT in the Chinese to English experiment. Translations that encounter reference-dissimilarity bias are expected to appear in the lower-right quadrant of Figure 5(a), receiving an unfairly low GEN-REF score combined with a high POST-EDIT score. As can be seen from Figure 5(a) only a very small number of translations fall into this quadrant, all of which are very closely located to adjacent upper-right and lower-left quadrants. A single translation in Figure 5(a) is an outlier in this respect, receiving a high POST-EDIT score in combination with a lower than average GEN-REF score, possibly indicating reference bias. On closer inspection, however, the score combination is in fact the result of a mistake in the reference translation. Although the low GEN-REF score was the result of an error in the reference translation, a single translation having this score combination is not sufficient evidence to conclude strong reference bias. In future work we would like to investigate the frequency of erroneous reference translations in existing MT test sets, although we expect them to be few, accurate statistics would provide a better indication of the degree to which they could negatively impact the accuracy of DA evaluations.

Figure 5(a) is also void of evidence of reference-similarity bias, as only a small number of translations lie in the upper-left quadrant and are all very close to the origin and/or adjacent quadrants.

Contrasting Figure 5(a), the correspondence of GEN-REF scores to POST-EDIT scores, with Figure 5(b), the correspondence of known reference-biased BLEU scores, in contrast a large number of BLEU scores for translations do encounter reference bias, as seen by the spread of translations appearing across both the bottom-right and upper-left quadrants.

[11] https://www.mturk.com

Similarly for English to Spanish, the correspondence between GEN-REF and POST-EDIT scores for translations are shown in Figure 6(a), where, again, only a small number of translations appear in the bottom-right and upper-left quadrants, all lying very close to adjacent quadrants, again, showing no significant indication of reference bias. A single translation appears to break the trend again, however, receiving a low GEN-REF score combined with a high POST-EDIT score, located in the lower-right quadrant of Figure 6(a). On closer inspection, the low GEN-REF score is the result of something unexpected, as the MT output is in fact an accurate translation while at the same time the generic reference is also correct, but unusually the meaning of the two diverge from each other.[12] Again, a single translation receiving this score combination is not sufficient evidence to conclude reference bias to be a significant problem for monolingual evaluation. The lack of reference bias in Figure 6(a) can again be contrasted to known reference-biased BLEU scores in Figure 6(b) for English to Spanish.

4 Conclusions

In this paper, we provided an investigation into reference bias in monolingual evaluation of MT. Our review of past investigations reveals potential analytical errors and raises questions about the reliability of past conclusions of strong reference bias. This motivates our further investigation for Chinese to English and English to Spanish MT employing direct human assessment in a monolingual MT evaluation setting. Results showed no significant evidence of reference bias, contrary to prior reports and intuition.

A Challenge Set Approach to Evaluating Machine Translation

Abstract

Neural machine translation represents an exciting leap forward in translation quality. But what longstanding weaknesses does it resolve, and which remain? We address these questions with a challenge set approach to translation evaluation and error analysis. A challenge set consists of a small set of sentences, each hand-designed to probe a system's capacity to bridge a particular structural divergence between languages. To exemplify this approach, we present an English–French challenge set, and use it to analyze phrase-based and neural systems. The resulting analysis provides not only a more fine-grained picture of the strengths of neural systems, but also insight into which linguistic phenomena remain out of reach.

1 Introduction

The advent of neural techniques in machine translation (MT) (Kalchbrenner and Blunsom, 2013; Cho et al., 2014; Sutskever et al., 2014) has led to profound improvements in MT quality. For "easy" language pairs such as English/French or English/Spanish in particular, neural (NMT) systems are much closer to human performance than previous statistical techniques (Wu et al., 2016). This puts pressure on automatic evaluation metrics such as BLEU (Papineni et al., 2002), which exploit surface-matching heuristics that are relatively insensitive to subtle differences. As NMT continues to improve, these metrics will inevitably lose their effectiveness. Another challenge posed by NMT systems is their opacity: while it was usually clear which phenomena were ill-handled by previous statistical systems—and why—these questions are more difficult to answer for NMT.

Is the subject-verb agreement correct (y/n)? **Yes**	

Figure 1: Example challenge set question.

We propose a new evaluation methodology centered around a *challenge set* of difficult examples that are designed using expert linguistic knowledge to probe an MT system's capabilities. This methodology is complementary to the standard practice of randomly selecting a test set from "real text," which remains necessary in order to predict performance on new text. By concentrating on difficult examples, a challenge set is intended to provide a stronger signal to developers. Although we believe that the general approach is compatible with automatic metrics, we used manual evaluation for the work presented here. Our challenge set consists of short sentences that each focus on one particular phenomenon, which makes it easy to collect reliable manual assessments of MT output by asking direct yes-no questions. An example is shown in Figure 1.

We generated a challenge set for English to French translation by canvassing areas of linguistic divergence between the two language pairs, especially those where errors would be made visible by French morphology. Example choice was also partly motivated by extensive knowledge of the weaknesses of phrase-based MT (PBMT). Neither of these characteristics is essential to our method, however, which we envisage evolving as NMT progresses. We used our challenge set to evalu-

ate in-house PBMT and NMT systems as well as Google's GNMT system.

In addition to proposing the novel idea of a challenge set evaluation, our contribution includes our annotated English–French challenge set, which we provide in both formatted text and machine-readable formats (see supplemental materials). We also supply further evidence that NMT is systematically better than PBMT, even when BLEU score differences are small. Finally, we give an analysis of the challenges that remain to be solved in NMT, an area that has received little attention thus far.

2 Related Work

A number of recent papers have evaluated NMT using broad performance metrics. The WMT 2016 News Translation Task (Bojar et al., 2016) evaluated submitted systems according to both BLEU and human judgments. NMT systems were submitted to 9 of the 12 translation directions, winning 4 of these and tying for first or second in the other 5, according to the official human ranking. Since then, controlled comparisons have used BLEU to show that NMT outperforms strong PBMT systems on 30 translation directions from the United Nations Parallel Corpus (Junczys-Dowmunt et al., 2016a), and on the IWSLT English-Arabic tasks (Durrani et al., 2016). These evaluations indicate that NMT performs better on average than previous technologies, but they do not help us understand what aspects of the translation have improved.

Some groups have conducted more detailed error analyses. Bentivogli et al. (2016) carried out a number of experiments on IWSLT 2015 English-German evaluation data, where they compare machine outputs to professional post-edits in order to automatically detect a number of error categories. Compared to PBMT, NMT required less post-editing effort overall, with substantial improvements in lexical, morphological and word order errors. NMT consistently out-performed PBMT, but its performance degraded faster as sentence length increased. Later, Toral and Sánchez-Cartagena (2017) conducted a similar study, examining the outputs of competition-grade systems for the 9 WMT 2016 directions that included NMT competitors. They reached similar conclusions regarding morphological inflection and word order, but found an even greater degradation in NMT performance as sentence length increased, perhaps due to these systems' use of subword units.

Most recently, Sennrich (2016) proposed an approach to perform targeted evaluations of NMT through the use of contrastive translation pairs. This method introduces a particular type of error automatically in reference sentences, and then checks whether the NMT system's conditional probability model prefers the original reference or the corrupted version. Using this technique, they are able to determine that a recently-proposed character-based model improves generalization on unseen words, but at the cost of introducing new grammatical errors.

Our approach differs from these studies in a number of ways. First, whereas others have analyzed sentences drawn from an existing bitext, we conduct our study on sentences that are manually constructed to exhibit canonical examples of specific linguistic phenomena. We focus on phenomena that we expect to be more difficult than average, resulting in a particularly challenging MT test suite (King and Falkedal, 1990). These sentences are designed to dive deep into linguistic phenomena of interest, and to provide a much finer-grained analysis of the strengths and weaknesses of existing technologies, including NMT systems.

However, this strategy also necessitates that we work on fewer sentences. We leverage the small size of our challenge set to manually evaluate whether the system's actual output correctly handles our phenomena of interest. Manual evaluation side-steps some of the pitfalls that can come with Sennrich (2016)'s contrastive pairs, as a ranking of two contrastive sentences may not necessarily reflect whether the error in question will occur in the system's actual output.

3 Challenge Set Evaluation

Our challenge set is meant to measure the ability of MT systems to deal with some of the more difficult problems that arise in translating English into French. This particular language pair happened to be most convenient for us, but similar sets can be built for any language pair.

One aspect of MT performance excluded from our evaluation is robustness to sparse data. To control for this, when crafting source and reference sentences, we chose words that occurred at least 100 times in our training corpus (section 4.1).[1]

[1] With two exceptions: *spilt* (58 occurrences), which is

The challenging aspect of the test set we are presenting stems from the fact that the source English sentences have been chosen so that their closest French equivalent will be *structurally divergent* from the source in some crucial way. Translational divergences have been extensively studied in the past—see for example (Vinay and Darbelnet, 1958; Dorr, 1994). We expect the level of difficulty of an MT test set to correlate well with its density in divergence phenomena, which we classify into three main types: morpho-syntactic, lexico-syntactic and purely syntactic divergences.

3.1 Morpho-syntactic divergences

In some languages, word morphology (e.g. inflections) carries more grammatical information than in others. When translating a word towards the richer language, there is a need to recover additional grammatically-relevant information from the context of the target language word. Note that we only include in our set cases where the relevant information is available in the *linguistic* context.[2]

One particularly important case of morpho-syntactic divergence is that of *subject–verb agreement*. French verbs typically have more than 30 different inflected forms, while English verbs typically have 4 or 5. As a result, English verb forms strongly underspecify their French counterparts. Much of the missing information must be filled in through forced agreement in person, number and gender with the grammatical subject of the verb. But extracting these parameters can prove difficult. For example, the agreement features of a coordinated noun phrase are a complex function of the coordinated elements: a) the gender is feminine if all conjuncts are feminine, otherwise masculine wins; b) the conjunct with the smallest person (p1<p2<p3) wins; and c) the number is always plural when the coordination is "et" ("and") but the case is more complex with "ou" ("or").

A second example of morpho-syntactic divergence between English and French is the more explicit marking of the *subjunctive mood* in French subordinate clauses. In the following example, the verb "partiez", unlike its English counterpart, is marked as subjunctive:

> He demanded that you leave immediately. → Il a exigé que vous *partiez* immédiatement.

When translating an English verb within a subordinate clause, the context must be examined for possible subjunctive triggers. Typically these are specific lexical items found in a governing position with respect to the subordinate clause: verbs such as "exiger que", adjectives such as "regrettable que" or subordinate conjunctions such as "à condition que".

3.2 Lexico-syntactic divergences

Syntactically governing words such as verbs tend to impose specific requirements on their complements: they *subcategorize* for complements of a certain syntactic type. But a source language governor and its target language counterpart can diverge on their respective requirements. The translation of such words must then trigger adjustments in the target language complement pattern. We can only examine here a few of the types instantiated in our challenge set.

A good example is *argument switching*. This refers to the situation where the translation of a source verb V_s as V_t is correct but only provided the arguments (usually the subject and the object) are flipped around. The translation of "to miss" as "manquer à" is such a case:

> John misses Mary → Mary *manque à* John.

Failing to perform the switch results in a severe case of mistranslation.

A second example of lexico-syntactic divergence is that of "crossing movement" verbs. Consider the following example:

> Terry swam across the river → Terry *a traversé* la rivière *à la nage*.

The French translation could be glossed as, "Terry crossed the river by swimming." A literal translation such as "Terry a nagé à travers la rivière," is ruled out.

part of an idiomatic phrase, and *guitared* (0 occurrences), which is meant to test the ability to deal with "nonce words" as discussed in section 5.

[2] The so-called Winograd Schema Challenges (en.wikipedia.org/wiki/Winograd_Schema_Challenge) often involve cases where common-sense reasoning is required to correctly choose between two potential antecedent phrases for a pronoun. Such cases become En → Fr translation challenges if the relevant English pronoun is *they* and its alternative antecedents happen to have different grammatical genders in French: *they* → *ils/elles*.

3.3 Syntactic divergences

Some syntactic divergences are not relative to the presence of a particular lexical item but rather stem from differences in the set of available syntactic patterns. Source-language instances of structures missing from the target language must be mapped onto equivalent structures. Here are some of the types appearing in our challenge set.

The position of French pronouns is a major case of divergence from English. French is basically an SVO language like English but it departs from that canonical order when post-verbal complements are pronominalized: the pronouns must then be rendered as *proclitics*, that is phonetically attached to the verb on its left side.

> He gave Mary a book. → Il a donné un livre à Marie.
>
> He gave$_i$ it$_j$ to her$_k$. → Il *le*$_j$ *lui*$_k$ a donné$_i$.

Another example of syntactic divergence between English and French is that of *stranded prepositions*. In both languages, an operation known as "WH-movement" will move a relativized or questioned element to the front of the clause containing it. When this element happens to be a prepositional phrase, English offers the option to leave the preposition in its normal place, fronting only its pronominalized object. In French, the preposition is always fronted alongside its object:

> The girl whom$_i$ he was dancing with$_j$ is rich. → La fille *avec*$_j$ *qui*$_i$ il dansait est riche.

A final example of syntactic divergence is the use of the so-called *middle voice*. While English uses the passive voice in agentless generic statements, French tends to prefer the use of a special pronominal construction where the pronoun "se" has no real referent:

> Caviar is eaten with bread. → Le caviar *se mange* avec du pain.

This completes our exemplification of morphosyntactic, lexico-syntactic and purely syntactic divergences. Our actual test set includes several more subcategories of each type. The ability of MT systems to deal with each such subcategory is then tested using at least three different test sentences. We use short test sentences so as to keep the targeted divergence in focus. The 108 sentences that constitute our current challenge set can be found in Appendix 7.

3.4 Evaluation Methodology

Given the very small size of our challenge set, it is easy to perform a human evaluation of the respective outputs of a handful of different systems. The obvious advantage is that the assessment is then absolute instead of relative to one or a few reference translations.

The intent of each challenge sentence is to test one and only one system capability, namely that of coping correctly with the particular associated divergence subtype. As illustrated in Figure 1, we provide annotators with a question that specifies the divergence phenomenon currently being tested, along with a reference translation with the areas of divergence highlighted. As a result, judgments become straightforward: was the targeted divergence correctly bridged, yes or no?[3] There is no need to mentally average over a number of different aspects of the test sentence as one does when rating the global translation quality of a sentence, e.g. on a 5-point scale. However, we acknowledge that measuring translation performance on complex sentences exhibiting many different phenomena remains crucial. We see our approach as being complementary to evaluations of overall translation quality.

One consequence of our divergence-focused approach is that faulty translations will be judged as successes when the faults lie outside of the targeted divergence zone. However, this problem is mitigated by our use of short test sentences.

4 Machine Translation Systems

We trained state-of-the-art neural and phrase-based systems for English-French translation on data from the WMT 2014 evaluation.

4.1 Data

We used the LIUM shared-task subset of the WMT 2014 corpora,[4] retaining the provided tokenization

[3] Sometimes the system produces a translation that circumvents the divergence issue. For example, it may dodge a divergence involving adverbs by reformulating the translation to use an adjective instead. In these rare cases, we instruct our annotators to abstain from making a judgment, regardless of whether the translation is correct or not.

and corpus organization, but mapping characters to lowercase. Table 1 gives corpus statistics.

4.2 Phrase-based systems

To ensure a competitive PBMT baseline, we performed phrase extraction using both IBM4 and HMM alignments with a phrase-length limit of 7; after frequency pruning, the resulting phrase table contained 516M entries. For each extracted phrase pair, we collected statistics for the hierarchical reordering model of Galley and Manning (2008).

We trained an NNJM model (Devlin et al., 2014) on the HMM-aligned training corpus, with input and output vocabulary sizes of 64k and 32k. Words not in the vocabulary were mapped to one of 100 mkcls classes. We trained for 60 epochs of 20k × 128 minibatches, yielding a final dev-set perplexity of 6.88.

Our set of log-linear features consisted of forward and backward Kneser-Ney smoothed phrase probabilities and HMM lexical probabilities (4 features); hierarchical reordering probabilities (6); the NNJM probability (1); a set of sparse features as described by Cherry (2013) (10,386); word-count and distortion penalties (2); and 5-gram language models trained on the French half of the training corpus and the French monolingual corpus (2). Tuning was carried out using batch lattice MIRA (Cherry and Foster, 2012). Decoding used the cube-pruning algorithm of Huang and Chiang (2007), with a distortion limit of 7.

We include two phrase-based systems in our comparison: PBMT-1 has data conditions that exactly match those of the NMT system, in that it does not use the language model trained on the French monolingual corpus, while PBMT-2 uses both language models.

4.3 Neural systems

To build our NMT system, we used the Nematus toolkit,[5] which implements a single-layer neural sequence-to-sequence architecture with attention (Bahdanau et al., 2015) and gated recurrent units (Cho et al., 2014). We used 512-dimensional word embeddings with source and target vocabulary sizes of 90k, and 1024-dimensional state vectors. The model contains 172M parameters.

We preprocessed the data using a BPE model learned from source and target corpora (Sennrich et al., 2016). Sentences longer than 50 words were discarded. Training used the Adadelta algorithm (Zeiler, 2012), with a minibatch size of 100 and gradients clipped to 1.0. It ran for 5 epochs, writing a checkpoint model every 30k minibatches. Following Junczys-Dowmunt et al. (2016b), we averaged the parameters from the last 8 checkpoints. To decode, we used the AmuNMT decoder (Junczys-Dowmunt et al., 2016a) with a beam size of 4.

While our primary results will focus on the above PBMT and NMT systems, where we can describe replicable configurations, we have also evaluated Google's production system,[6] which has recently moved to NMT (Wu et al., 2016). Notably, the "GNMT" system uses (at least) 8 encoder and 8 decoder layers, compared to our 1 layer for each, and it is trained on corpora that are "two to three decimal orders of magnitudes bigger than the WMT." The evaluated outputs were downloaded in December 2016.

5 Experiments

The 108-sentence English–French challenge set presented in Appendix 7 was submitted to the four MT systems described in section 4: PBMT-1, PBMT-2, NMT, and GNMT. Three bilingual native speakers of French rated each translated sentence as either a success or a failure according to the protocol described in section 3.4. For example, the 26 sentences of the subcategories S1–S5 of Appendix 7 are all about different cases of subject-verb agreement. The corresponding translations were judged successful if and only if the translated verb correctly agrees with the translated subject.

The different system outputs for each source sentence were grouped together to reduce the burden on the annotators. That is, in figure 1, anno-

[5] https://github.com/rsennrich/nematus

[6] https://translate.google.com

tators were asked to answer the question for each of four outputs, rather than just one as shown. The outputs were listed in random order, without identification. Questions were also presented in random order to each annotator. Appendix A in the supplemental materials contains the instructions shown to the annotators.

5.1 Quantitative comparison

Table 2 summarizes our results in terms of percentage of successful translations, globally and over each main type of divergence. For comparison with traditional metrics, we also include BLEU scores measured on the WMT 2014 test set.

As we can see, the two PBMT systems fare very poorly on our challenge set, especially in the morpho-syntactic and purely syntactic types. Their somewhat better handling of lexico-syntactic issues probably reflects the fact that PBMT systems are naturally more attuned to lexical cues than to morphology or syntax. The two NMT systems are clear winners in all three categories. The GNMT system is best overall with a success rate of 68%, likely due to the data and architectural factors mentioned in section 4.3.[7]

WMT BLEU scores correlate poorly with challenge-set performance. The large gap of 2.3 BLEU points between PBMT-1 and PBMT-2 corresponds to only a 1% gain on the challenge set, while the small gap of 0.4 BLEU between PBMT-2 and NMT corresponds to a 21% gain.

Inter-annotator agreement (final column in table 2) is excellent overall, with all three annotators agreeing on almost 90% of system outputs. Syntactic divergences appear to be somewhat harder to judge than other categories.

5.2 Qualitative assessment of NMT

We now turn to an analysis of the strengths and weaknesses of neural MT through the microscope of our divergence categorization system, hoping that this may help focus future research on key issues. In this discussion we ignore the results obtained by PBMT-2 and compare: a) the results obtained by PBMT-1 to those of NMT, both systems having been trained on the same dataset; and b) the results of these two systems with those of Google NMT which was trained on a much larger dataset.

In the remainder of the present section we will refer to the sentences of our challenge set using the subcategory-based numbering scheme S1-S26 as assigned in Appendix 7. A summary of the category-wise performance of PBMT-1, NMT and Google NMT is provided in Table 3.

Strengths of neural MT

Overall, both neural MT systems do much better than PBMT-1 at bridging divergences. In the case of morpho-syntactic divergences, we observe a jump from 16% to 72% in the case of our two local systems. This is mostly due to the NMT system's ability to deal with many of the more complex cases of subject-verb agrement:

- *Distractors.* The subject's head noun agreement features get correctly passed to the verb phrase across intervening noun phrase complements (sentences S1a–c).
- *Coordinated verb phrases.* Subject agreement marks are correctly distributed across the elements of such verb phrases (S3a–c).
- *Coordinated subjects.* Much of the logic that is at stake in determining the agreement features of coordinated noun phrases (cf. our relevant description in section 3.1) appears to be correctly captured in the NMT translations of S4.
- *Past participles.* Even though the rules governing French past participle agreement are notoriously difficult (especially after the "avoir" auxiliary), they are fairly well captured in the NMT translations of (S5b–e).

The NMT systems are also better at handling lexico-syntactic divergences. For example:

- *Double-object verbs.* There are no such verbs in French and the NMT systems perform the required adjustments flawlessly (sentences S8a–S8c).
- *Overlapping subcat frames.* NMT systems manage to discriminate between an NP complement and a sentential complement starting with an NP: cf. *to know NP* versus *to know NP is VP* (S11b–e)
- *NP-to-VP complements.* These English infinitival complements often need to be rendered as finite clauses in French and the NMT systems are better at this task (S12a–c).

[7] We cannot offer a full comparison with the pre-NMT Google system. However, in October 2016 we ran a smaller 35-sentence version of our challenge set on both the Google system and our PBMT-1 system. The Google system only got 4 of those examples right (11.4%) while our PBMT-1 got 6 right (17.1%).

Divergence type	PBMT-1	PBMT-2	NMT	Google NMT	Agreement
Morpho-syntactic	16%	16%	72%	65%	94%
Lexico-syntactic	42%	46%	52%	62%	94%
Syntactic	33%	33%	40%	75%	81%
Overall	31%	32%	53%	68%	89%
WMT BLEU	34.2	36.5	36.9	—	—

Table 2: Summary performance statistics for each system under study, including challenge set success rate grouped by linguistic category (aggregating all positive judgments and dividing by total judgments), as well as BLEU scores on the WMT 2014 test set. The final column gives the proportion of system outputs on which all three annotators agreed.

Finally, NMT systems also turn out to better handle purely syntactic divergences. For example:

- *Yes-no question syntax.* The differences between English and French yes-no question syntax are correctly bridged by the two NMT systems (S17a–c).
- *French proclitics.* NMT systems are significantly better at transforming English pronouns into French proclitics, i.e. moving them before the main verb and case-inflecting them correctly (S23a–e).
- Finally, we note that the Google system manages to overcome several additional challenges. It correctly translates *tag questions* (S18a–c), constructions with *stranded prepositions* (S19a–f), most cases of the *inalienable possession* construction (S25a–e) as well as *zero relative pronouns* (S26a–c).

The large gap observed between the results of the in-house and Google NMT systems indicates that current neural MT systems are extremely data hungry. But given enough data, they can successfully tackle some challenges that are often thought of as extremely difficult. A case in point here is that of stranded prepositions (see discussion in section 3.3), in which we see the NMT model capture some instances of WH-movement, the textbook example of long-distance dependencies.

Weaknesses of neural MT

In spite of its clear edge over PBMT, NMT is not without some serious shortcomings. We already mentioned the degradation issue with long sentence which, by design, could not be observed with our challenge set. But an analysis of our results will reveal many other problems. Globally, we note that even using a staggering quantity of data and a highly sophisticated NMT model, the Google system fails to reach the 70% mark on our challenge set. The fine-grained error categorization associated with the challenge set will help us single out precise areas where more research is needed. Here are some relevant observations.

Incomplete generalizations. In several cases where partial results might suggest that NMT has correctly captured some basic generalization about linguistic data, further instances reveals that this is not fully the case.

- *Agreement logic.* The logic governing the agreement features of coordinated noun phrases (see section 3.1) has been mostly captured by the NMT systems (cf. the 12 sentences of S4), but there are some gaps. For example, the Google system runs into trouble with mixed-person subjects (sentences S4d1–3).
- *Subjunctive mood triggers.* While some subjunctive mood triggers are correctly registered (e.g. "demander que" and "malheureux que"), the case of such a highly frequent subordinate conjunction as *provided that* → *à condition que* is somehow being missed (sentence S6a–c).
- *Noun compounds.* The French translation of an English compound N_1 N_2 is usually of the form N_2 *Prep* N_1. For any given headnoun N_2 the correct preposition *Prep* depends on the semantic class of N_1. For example *steel/ceramic/plastic knife* → *couteau **en** acier/céramique/plastique* but *butter/meat/steak knife* → *couteau **à** beurre/viande/steak*. Given that neural models are known to perform some semantic generalizations, we find their performance disappointing on our compound noun examples (S14a–i).

Category	Subcategory	#	PBMT-1	NMT	Google NMT
Morpho-syntactic	Agreement across distractors	3	0%	100%	100%
	through control verbs	4	25%	25%	25%
	with coordinated target	3	0%	100%	100%
	with coordinated source	12	17%	92%	75%
	of past participles	4	25%	75%	75%
	Subjunctive mood	3	33%	33%	67%
Lexico-syntactic	Argument switch	3	0%	0%	0%
	Double-object verbs	3	33%	67%	100%
	Fail-to	3	67%	100%	67%
	Manner-of-movement verbs	4	0%	0%	0%
	Overlapping subcat frames	5	60%	100%	100%
	NP-to-VP	3	33%	67%	67%
	Factitives	3	0%	33%	67%
	Noun compounds	9	67%	67%	78%
	Common idioms	6	50%	0%	33%
	Syntactically flexible idioms	2	0%	0%	0%
Syntactic	Yes-no question syntax	3	33%	100%	100%
	Tag questions	3	0%	0%	100%
	Stranded preps	6	0%	0%	100%
	Adv-triggered inversion	3	0%	0%	33%
	Middle voice	3	0%	0%	0%
	Fronted should	3	67%	33%	33%
	Clitic pronouns	5	40%	80%	60%
	Ordinal placement	3	100%	100%	100%
	Inalienable possession	6	50%	17%	83%
	Zero REL PRO	3	0%	33%	100%

Table 3: Summary of scores by fine-grained categories. "#" reports number of questions in each category, while the reported score is the percentage of questions for which the divergence was correctly bridged. For each question, the three human judgments were transformed into a single judgment by taking system outputs with two positive judgments as positive, and all others as negative.

- The so-called French "inalienable possession" construction arises when an agent performs an action on one of her body parts, e.g. *I brushed my teeth*. The French translation will normally replace the possessive article with a definite one and introduce a reflexive pronoun, e.g. *Je me suis brossé les dents* ('I brushed myself the teeth'). In our dataset, the Google system gets this right for examples in the first and third persons (sentences S25a,b) but fails to do the same with the example in the second person (sentence S25c).

Then there are also phenomena that current NMT systems, even with massive amounts of data, appear to be completely missing:

- *Common and syntactically flexible idioms.* While PBMT-1 produces an acceptable translation for half of the idiomatic expressions of S15 and S16, the local NMT system misses them all and the Google system does barely better. NMT systems appear to be short on raw memorization capabilities.
- *Control verbs.* Two different classes of verbs can govern a subject NP, an object NP plus an infinitival complement. With verbs of the "object-control" class (e.g. "persuade"), the object of the verb is understood as the semantic subject of the infinitive. But with those of the "subject-control" class (e.g. "promise"), it is rather the subject of the verb which plays that semantic role. None of the systems tested here appear to get a grip on subject control cases, as evidenced by the lack of correct feminine agreement on the French adjectives in sentences S2b–d.
- *Argument switching verbs.* All systems tested

here mistranslate sentences S7a–c by failing to perform the required argument switch: *NP_1 misses NP_2 → NP_2 manque à NP_1.*

- *Crossing movement verbs.* None of the systems managed to correctly restructure the regular manner-of-movement verbs e.g. *swim across X → traverser X à la nage* in sentences S10a-c. Unsurprisingly, all systems also fail on the even harder example S10d, in which the "nonce verb" *guitared* is a spontaneous derivation from the noun *guitar* being cast as an ad hoc manner-of-movement verb. [8]
- *Middle voice.* None of the systems tested here were able to recast the English "generic passive" of S21a–c into the expected French "middle voice" pronominal construction.

6 Conclusions

We have presented a radically different kind of evaluation for MT systems: the use of challenge sets designed to stress-test MT systems on "hard" linguistic material, while providing a fine-grained linguistic classification of their successes and failures. This approach is not meant to replace our community's traditional evaluation tools but to supplement them.

Our proposed error categorization scheme makes it possible to bring to light different strengths and weaknesses of PBMT and neural MT. With the exception of idiom processing, in all cases where a clear difference was observed it turned out to be in favor of neural MT. A key factor in NMT's superiority appears to be its ability to overcome many limitations of n-gram language modeling. This is clearly at play in dealing with subject-verb agreement, double-object verbs, overlapping subcategorization frames and last but not least, the pinnacle of Chomskyan linguistics, WH-movement (in this case, stranded prepositions).

But our challenge set also brings to light some important shortcomings of current neural MT, regardless of the massive amounts of training data it may have been fed. As may have been already known or suspected, NMT systems struggle with the translation of idiomatic phrases. Perhaps more interestingly, we notice that neural MT's impressive generalizations still seem somewhat brittle. For example, the NMT system can appear to have mastered the rules governing subject-verb agreement or inalienable possession in French, only to trip over a rather obvious instantiation of those rules. Probing where these boundaries are, and how they relate to the neural system's training data and architecture is an obvious next step.

7 Future Work

It is our hope that the insights derived from our challenge set evaluation will help inspire future MT research, and call attention to the fact that even "easy" language pairs like English–French still have many linguistic issues left to be resolved. But there are also several ways to improve and expand upon our challenge set approach itself.

First, though our human judgments of output sentences allowed us to precisely assess the phenomena of interest, this approach is not scalable to large sets, and requires access to native speakers in order to replicate the evaluation. It would be interesting to see whether similar scores could be achieved through automatic means. The existence of human judgments for this set provides a gold-standard by which proposed automatic judgments may be meta-evaluated.

Second, the construction of such a challenge set requires in-depth knowledge of the structural divergences between the two languages of interest. A method to automatically create such a challenge set for a new language pair would be extremely useful. One could imagine approaches that search for divergences, indicated by atypical output configurations, or perhaps by a system's inability to reproduce a reference from its own training data. Localizing a divergence within a difficult sentence pair would be another useful subtask.

Finally, we would like to explore how to train an MT system to improve its performance on these divergence phenomena. This could take the form of designing a curriculum to demonstrate a particular divergence to the machine, or altering the network structure to capture such generalizations.

Acknowledgments

We would like to thank Cyril Goutte, Eric Joanis and Michel Simard, who graciously spent the time required to rate the output of four different MT systems on our challenge sentences. We also thank Roland Kuhn for valuable discussions, and comments on an earlier version of the paper.

Knowledge Distillation for Bilingual Dictionary Induction

Abstract

Leveraging zero-shot learning to learn mapping functions between vector spaces of different languages is a promising approach to bilingual dictionary induction. However, methods using this approach have not yet achieved high accuracy on the task. In this paper, we propose a bridging approach, where our main contribution is a knowledge distillation training objective. As teachers, rich resource translation paths are exploited in this role. And as learners, translation paths involving low resource languages learn from the teachers. Our training objective allows seamless addition of teacher translation paths for any given low resource pair. Since our approach relies on the quality of monolingual word embeddings, we also propose to enhance vector representations of both the source and target language with linguistic information. Our experiments on various languages show large performance gains from our distillation training objective, obtaining as high as 17% accuracy improvements.

1 Introduction

In traditional supervised learning, a classifier is trained on a labeled dataset of the form $(\mathbf{X}, \mathbf{Y})$. Each $x_i \in X$ is a feature vector representing a single training instance and $y_i \in Y$ is the label associated with x_i. In zero-shot learning (Mitchell et al., 2008), at test time we can encounter a test instance x_j whose corresponding label was not seen at training time. This setting occurs in domains where $\mathbf{Y}$ can take on many values, and obtaining labeled examples for all possible Y values is expensive. Computer vision is one such domain, where there are thousands of objects a system needs to recognize yet at training time we may only see examples of some of the objects. In zero-shot learning, instead of learning parameters associated with each possible label in Y, the learning task is cast as a problem of learning a single mapping function from the vector space of input instances to the vector space of the output labels. The resulting induced function can then be applied to test instances x_j whose labels may not have been seen at training time, producing a projected vector, $\hat{y}_j$, in the label space. The nearest neighbor of the mapped vector in the label space is then considered to be the label of x_j.

In this paper, we study zero-shot learning in the context of bilingual dictionary induction, which is the problem of mapping words from a source language to equivalent words in a target language. The label space is the full vocabulary of the target language which can be on the order of millions of tokens. First, word embeddings are learned separately for each language, and second, using a given seed dictionary, we train a mapping function to connect the two monolingual vector spaces, thereby facilitating bilingual dictionary induction. The advantage of zero-shot learning is that it can help reduce the amount of labeled data for applications with many possible labels, such as the application we study in this paper, bilingual dictionary induction. However, the state-of-the-art accuracy on zero-shot bilingual dictionary induction is still low. On the task of English to Italian $(en \rightarrow it)$, top-1 and top-10 accuracies are around 40% and 60%, respectively (Lazaridou et al., 2015; Dinu et al., 2014).

An important aspect of zero-shot learning for bilingual dictionary induction is that, it relies on availability of a large seed dictionary[1]. Such large

[1] 5000 seed pairs for the $(en \rightarrow it)$ dataset.

\end{tikzcd}$$

Figure 1: Trilingual paths for Portuguese(pt) to English(en) via Spanish (es), Afrikaans(af) to (en) via Dutch (nl), and Danish(da) to (en) via Swedish(sv).

training dictionaries might not be available for all languages. However, for a given language with only a small seed dictionary, there could be a highly related language with a much larger seed dictionary. For example, we might have a small seed dictionary for translating Portuguese to English ($pt \rightarrow en$), but a large seed dictionary for translating Spanish to English language ($es \rightarrow en$). At training time, we can train the ($pt \rightarrow en$) mapping function not only using the small seed dictionary, but also make use of the trilingual path going through Spanish, ($pt \rightarrow es \rightarrow en$). Since pt and es are highly related, a small amount of data may be sufficient to learn the projection ($pt \rightarrow es$). This is the idea of using a bridge or pivot language in machine translation (Utiyama and Isahara, 2007). Our contribution is a knowledge distillation training objective function that encourages the mapping function ($pt \rightarrow en$) to predict the true English target words as well as to match the predictions of the trilingual path ($pt \rightarrow es \rightarrow en$) within a margin. This is approach allows seamless Example trilingual paths are shown in Figure 1.

By setting up our objective function in this way, we are distilling knowledge (Bucilu et al., 2006; Hinton et al., 2015) from the trilingual paths to train a single mapping function for ($pt \rightarrow en$). In our experiments, we show performance gains for several language pairs, 17% for top-10 precision for ($pt \rightarrow en$). We also show that, for a given language pair, our objective seamlessly allows us to distill from several related languages. Moreover, we learn weights for each of the distillation paths, thereby automatically learning indicative weights of how useful each distillation path is. Finally, we show that even when we only use unlabeled data to distill knowledge from trilingual paths, we still obtain performance gains over a model trained on a small seed dictionary.

Since our approach relies on the quality of monolingual word embeddings, we also propose to enhance vector representations of both the source and target language with linguistic information. In particular, we augment word vectors with additional dimensions capturing corpus statistics of part-of-speech tags of words. Second, we model sub-word information in the vector representations of words.

2 Related Work

Cross Vector Space Mapping with Seed Dictionaries. Our work is most related to models that do zero-shot learning for bilingual dictionary induction, using maps between vector spaces with seed dictionaries as training data. Examples include the models of (Mikolov et al., 2013; Dinu et al., 2014; Lazaridou et al., 2015; Vulic and Korhonen, 2016). Like these approaches, we first learn word embeddings for each language, then use a seed dictionary to train a mapping function between the two vector spaces. In a departure from these prior methods, we propose to distill knowledge from trilingual paths of nearby languages for languages with small seed dictionaries using a distillation training objective. Additionally, we model linguistic information in the vector space of the source and target languages. Another line of research in this vein is the work of (Vulic and Korhonen, 2016), who analyze how properties of the seed dictionary affect bilingual dictionary induction across different dimensions (i.e., lexicon source, lexicon size, translation method, translation pair reliability). However, methodologically, their approach is based on prior work (Mikolov et al., 2013; Dinu et al., 2014).

Bilingual word embeddings. There is a rich body of work on bilingual embeddings. Bilingual word embedding learning methods produce a shared bilingual word embedding space where words from two languages are represented in the new space so that similar words, which may be in different languages, have similar representations. Such bilingual word embeddings have been used in a number of tasks including semantic word similarity (Faruqui and Dyer, 2014; Ammar et al., 2016) learning bilingual word lexicons (Mikolov et al., 2013; Gouws et al., 2015; Vulic and Korhonen, 2016), parsing (Guo et al., 2015; Täckström et al., 2012), information retrieval (Vulic and Moens, 2015), and cross-lingual document classification (Klementiev et al., 2012; Kočiskỳ et al., 2014).

Some bilingual word embedding methods such as (Blunsom and Hermann, 2014; Gouws et al., 2015) require sentence or word aligned data, which our approach does not require. We compare our approach to the bilingual embeddings produced by the recent method of (Ammar et al., 2016). Like our approach, this work does not require availability of parallel corpora but only a seed dictionary.

On the aspect of enriching word embeddings with linguistic knowledge for the purpose of machine translation, Sennrich and Barry (Sennrich and Haddow, 2016) introduce linguistic features in sequence to sequence neural machine translation. Like our work, they also represent such features in the embedding layer. In addition to part-of-speech tags and morphological features, they also use syntactic dependency labels which are not applicable to our model since we work at the word level while their model is at the sentence level.

Knowledge Distillation. Knowledge distillation was introduced for model compression to learn small models from larger models (Bucilu et al., 2006; Hinton et al., 2015). For example, from a large neural network model a smaller model can be distilled such that it generalizes in the same way as the large model (Romero et al., 2014). Knowledge distillation was also used by (Hu et al., 2016) to distill knowledge from logical rules in the tasks of named entity recognition and sentiment analysis, thereby enforcing constraints on the trained model. Our approach is different from this prior work on knowledge distillation in that we distill knowledge from mapping functions of related languages into mapping functions of languages with only small seed dictionaries.

Domain adaptation, for which there is a long history, is also related to our work (Ben-David et al., 2007; Daumé III, 2007; Pan et al., 2010; Long and Wang, 2015). (Daumé III, 2007) proposed feature augmentation, suggesting that a model should have features that are general across domains, as well as features that are domain-specific. Thus the model learns from all domains while preserving domain-specific information. These kinds of models have to be retrained when a new domain is added. Our work however only has to train mapping functions that involve a new language, all others can be distilled without retraining them.

3 Embedding Linguistic Information

Since our approach relies on the quality of monolingual word embeddings, we would like to work with high quality word embeddings. We therefore, first seek to enhance the vector representations of words in the source and target languages so that they can capture useful linguistic information. The intuition is that such information can help narrow down the words in the target language that are considered valid translations for a given source language word. To that end, we model both part of speech (POS) tag distributions of words and subword information in the vector representations.

3.1 Part of Speech Distributions

The idea behind modeling POS tags is that words should have the same part of speech tag in different languages. For example, if we are translating the noun *Katze* from German to English, in English we expect the singular noun *cat* and not the plural *cats*. While this information may be monolithically represented in word vectors generated by embedding methods such as Skip-gram and CBOW, here we seek to explicitly model POS tags. Since each word can have multiple POS tags, we model a word's part of speech information as a distribution over all the possible POS tags that it can take on. We learn POS tag statistics by first tagging a large corpus of each language, we then use tag counts to generate distributions. For example, if the English word, *bark* appears tagged as a verb 30 times in our corpus, and tagged as a noun 10 times, we generate a vector which puts 2/3 in the verb direction, and 1/3 in the noun direction, and 0 in the directions of all other POS tags. While these statistics can be noisy, we hope they can still provide useful signals. We use the universal POS tags, there are 12 tags in the universal POS tags (Petrov et al., 2011).

For a given word w, we compute a vector representation $w_i \in \mathbb{R}^d$ using a word embedding method. For now, let's assume we use the Skip-gram model. In the next section, we describe an enhanced word embedding method. We compute a POS corpus statistics vector $v_i \in \mathbb{R}^{12}$ for the word using the 12 universal POS tags. With this new information, the representation for word i is given by

$$x_i = (w_i, v_i) \in \mathbb{R}^{d+12}\,. \tag{1}$$

3.2 Word Internal Structure

Morphology carries information that is useful for capturing the identity of a word. It represents information such as tense. When doing cross-lingual zero-shot projection of a word in a source language, we wish to translate to words that have the same linguistic properties. For example, the German word *gewinnen* should be translated to the present tense win, not the past tense won which in German is *gewonnen*. We approximate morphology by incorporating sub-word information into the vector representations. There are several ways of doing this, one approach is to work on the level of characters. We go for the middle-ground, in which a word is represented as a combination of a vector for the word itself with vectors of sub-word units that comprise it. In particular, for a given a word we learn a vector representation for the word itself, and also for each n-gram of $>=$ 3 and $<$ 6 in the word (Bojanowski et al., 2017). Each word is thus represented by the sum of the vector representations of its n-grams, including the word itself. This representation is then used to replace w_i in equation 1.

4 Training Objective

A common objective function used in prior work (Mikolov et al., 2013; Dinu et al., 2014) for learning cross vector space mapping functions is the regularized least squares error:

$$\hat{\mathbf{W}} = \underset{\mathbf{W}\in\mathbb{R}^{s\times t}}{\arg\min} ||\mathbf{XW} - \mathbf{Y}||_F + \lambda||\mathbf{W}|| \qquad (2)$$

where matrix $\hat{\mathbf{W}}$ is the learned mapping function, $\mathbf{X}$ and $\mathbf{Y}$ represent the matrices containing the vectors for the source language words and vectors for the target language words, respectively. Instead of the least squares loss shown in equation 2, we use a ranking loss, as in (Lazaridou et al., 2015), which aims to rank correct training data pairs (x_i, y_i) higher than incorrect pairs (x_i, y_j) with a margin of at least γ. The margin γ is a hyper-parameter which is application specific, and the incorrect labels, y_j can be selected randomly such that $j \neq i$ or in a more application specific manner[2].

Given a seed dictionary training data of the form $D^{tr} = \{x_i, y_i\}_{i=1}^{m}$, the margin-based ranking loss is defined as:

$$J_{\text{single}} = \sum_{i=1}^{m}\sum_{j\neq i}^{k} \max\Big(0, \gamma + d(y_i, \hat{y}_i) - d(y_j, \hat{y}_i)\Big) \qquad (3)$$

where $\hat{y}_i = \mathbf{W}x_i$ is the prediction, k is the number of incorrect examples per training instance, and $d(x, y) = (x - y)^2$ is the distance measure.

For a given correct pair and incorrect pair, substituting $\hat{y}_i = \mathbf{W}x_i$. The loss is given by:

$$\max\Big(0, \gamma + (y_i - \hat{y}_i)^2 - (y_j - \hat{y}_i)^2\Big) : j \neq i. \qquad (4)$$

To evaluate the derivative analytically, we can write:

$$\begin{aligned} &\max\left(0, \gamma + (y_i - \hat{y}_i)^2 - (y_j - \hat{y}_i)^2\right) \\ &= \theta\left(\gamma + (y_i - \hat{y}_i)^2 - (y_j - \hat{y}_i)^2\right) \times \\ &\qquad \left[\gamma + (y_i - \hat{y}_i)^2 - (y_j - \hat{y}_i)^2\right] \end{aligned} \qquad (5)$$

where $\theta(x)$ denotes the Heaviside θ-function. The derivative with respect to the elements of the matrix $\mathbf{W}$ is then approximated by, after neglecting a term that would only contribute if the difference $(y_j - \hat{y}_i)^2 - (y_i - \hat{y}_i)^2$ were exactly γ

$$\begin{aligned} &\frac{\partial}{\partial W_{ab}}(\theta\left(\gamma + (y_i - \hat{y}_i)^2 - (y_j - \hat{y}_i)^2\right) \times \\ &\qquad \left[\gamma + (y_i - \hat{y}_i)^2 - (y_j - \hat{y}_i)^2\right] \\ &\simeq 2\theta\left(\gamma + (y_i - \hat{y}_i)^2 - (y_j - \hat{y}_i)^2\right) \times \\ &\qquad x_{i\,b}\,(y_{j\,a} - y_{i\,a}) \end{aligned} \qquad (6)$$

5 Model Distillation

In zero-shot learning for bilingual dictionary induction a large seed dictionary is used to train a mapping function. Such large training dictionaries might not be available for all languages. However, for a given language with only a small seed dictionary, there could be a highly related language with a much larger seed dictionary. We propose a method for leveraging mapping functions of nearby languages to train mapping functions for languages where large seed dictionaries may not be available. Our method is related to notion of having a bridge or pivot language as done in sentence level translation (Utiyama and Isahara, 2007). We develop a distillation training objective that allows us to seamlessly leverage several bridge languages for word level translation.

[2] In our experiments, we explored several application specific approaches for choosing negative examples, including one that picks negative examples among words whose part of speech class is different from the positive example. However, these approaches did produce significant improvement, and we resorted back to randomly selected negative examples.

5.1 Trilingual Paths for distillation

Let us consider the problem of translating from a given source language to English. As a running example, we use Portuguese(pt) as the source language. We wish to learn a mapping function from word vectors in Portuguese to word vectors in English. We can set up a learning task, using a training dataset $D = \{x_i, y_i\}_{i=1}^m$ and the loss defined in Equation 3. This gives us the projection function in the form of a matrix: $\mathbf{W}^{(pt\rightarrow en)}$. We can thus translate Portuguese words to English as follows:

$$\hat{y_i}^{(en)\hookleftarrow(pt)} = \mathbf{W}^{(pt\rightarrow en)} x_i^{(pt)} \tag{7}$$

If the seed dictionary for Portuguese to English is small, $\mathbf{W}^{(pt\rightarrow en)}$ might generalize poorly, producing many wrong translations when using Equation 7. Suppose, a related language, for example, Spanish has a lot of training data available, and we have independently trained its mapping function, which can make predictions from Spanish to English as follows:

$$\hat{y_i}^{(en)\hookleftarrow(es)} = \mathbf{W}^{(es\rightarrow en)} x_i^{(es)} \tag{8}$$

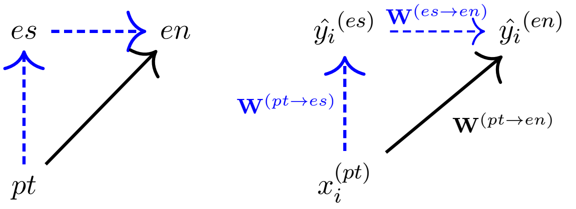
Since $\mathbf{W}^{(es\rightarrow en)}$ is trained with a lot of data, we expect it to generalize better and make more accurate predictions than $\mathbf{W}^{(pt\rightarrow en)}$. One insight here is that since the languages es and pt are highly related, we need much less data to train an accurate mapping matrix $\mathbf{W}^{(pt\rightarrow es)}$ than we to need to learn an accurate $\mathbf{W}^{(pt\rightarrow en)}$. Therefore we train a mapping function from Portuguese to Spanish, which makes predictions as follows.

$$\hat{y_i}^{(es)\hookleftarrow(pt)} = \mathbf{W}^{(pt\rightarrow es)} x_i^{(pt)} \tag{9}$$

We now have a second path that goes from Portuguese to English much like Equation 7 but this path goes via Spanish as follows:

$$\begin{aligned} \hat{y_i}^{(es)\hookleftarrow(pt)} &= \mathbf{W}^{(pt\rightarrow es)} x_i^{(pt)} \\ \hat{y_i}^{(en)\hookleftarrow(es)\hookleftarrow(pt)} &= \mathbf{W}^{(es\rightarrow en)} \hat{y_i}^{(es)\hookleftarrow(pt)} \end{aligned} \tag{10}$$

Figure 2 illustrates the two paths from Portuguese to English. Our main insight is to use knowledge distillation, to improve the accuracy of the mapping matrix $\mathbf{W}^{(pt\rightarrow en)}$ through $\hat{y_i}^{(en)\hookleftarrow(es)\hookleftarrow(pt)}$. This distillation is done by modifying our learning objective.



es
en
pt
$\hat{y_i}^{(es)}$
$\mathbf{W}^{(es\rightarrow en)}$
$\hat{y_i}^{(en)}$
$\mathbf{W}^{(pt\rightarrow es)}$
$\mathbf{W}^{(pt\rightarrow en)}$
$x_i^{(pt)}$

(a)

$$\hat{y_i}^{(es)\hookleftarrow(pt)} = \mathbf{W}^{(pt\rightarrow es)} x_i^{(pt)}$$
$$\hat{y_i}^{(en)\hookleftarrow(es)\hookleftarrow(pt)} = \mathbf{W}^{(es\rightarrow en)} \hat{y_i}^{(es)\hookleftarrow(pt)}$$

(b)

$$\hat{y_i}^{(en)\hookleftarrow(pt)} = \mathbf{W}^{(pt\rightarrow en)} x_i^{(pt)}$$

Figure 2: Translating with both a trilingual path (dotted lines, and equation (a)) , and a bilingual path (solid line, and equation (b))

5.2 Distillation Objective

For a given Portuguese word $x_i^{(pt)}$, Equation 7 makes the prediction $\hat{y_i}^{(en)\hookleftarrow(pt)}$ and Equation 10 makes the trilingual prediction $\hat{y_i}^{(en)\hookleftarrow(es)\hookleftarrow(pt)}$ which involves three languages. We would like to improve predictions made by Equation 7 by improving the mapping matrix $\mathbf{W}^{(en\rightarrow pt)}$. Therefore when training using the Portuguese to English training data, we want our objective to both minimize the loss defined in Equation 3 and simultaneously to let $\mathbf{W}^{(en\rightarrow pt)}$ mimic predictions made through the path $\hat{y_i}^{(en)\hookleftarrow(es)\hookleftarrow(pt)}$ as "soft targets" within a margin. The distillation objective is as follows:

$$\begin{aligned} J_d = \sum_{i=1}^{m} \max \Big(0, \\ \big(\hat{y_i}^{(en)\hookleftarrow(pt)} - \hat{y_i}^{(en)\hookleftarrow(es)\hookleftarrow(pt)} \big)^2 - \phi \Big), \end{aligned} \tag{11}$$

where ϕ is the margin. We combine J_{single} and J_d through a weighted average of the two different objective functions. Notice that J_d can be computed without having labeled training data. In our experiments, we show that even in this case of unlabeled data, which gets rid of J_{single} since it requires labeled data, J_d outperforms models trained using only J_{single} when the training data is small.

5.3 Multiple Trilingual Paths

We are not restricted to distilling Portuguese through Spanish only. Our model can, in addition, for example distill through German, French, and other languages. We can modify the distillation loss as follows:

$$J_{d-multi} = \sum_{i=1}^{m} \sum_{j=1}^{n} \psi_j \max \Big(0, \Big(\hat{y_i}^{(en) \hookleftarrow (pt)} - \hat{y_i}^{(en) \hookleftarrow (j) \hookleftarrow (pt)}\Big)^2 - \phi\Big), \quad (12)$$

where j labels the distillation language. With the objective $J_{d-multi}$ combined with J_{single}, we are training a mapping function which mimics the behavior of many trilingual paths, as “soft targets” within a margin ψ. We keep ϕ the same in our experiments across all trilingual paths. The ψ_i are weights that reflect how much we penalize our model if it diverges from the predictions of a particular trilingual path. Intuitively, if a language is similar to our source language, (pt) in this case, its corresponding ψ value should be high. For example, if Spanish is considered more related to Portuguese than any other language in the trilingual paths in Equation 12, than we expect $\forall i \neq 1, \psi_1 > \phi_i$. This is assuming that the second parts of the trilingual paths have similar accuracies, ie. $\mathbf{W}^{(es \rightarrow en)}$, $\mathbf{W}^{(fr \rightarrow en)}$, and $\mathbf{W}^{(\ldots \rightarrow en)}$ have similar projection accuracies. The most similar language is expected to be the easiest to project into from Portuguese. For example we might expect $\mathbf{W}^{(pt \rightarrow es)}$ to be more accurate than $\mathbf{W}^{(pt \rightarrow de)}$, if we have similar amounts of training data for learning both of these. We next present how we learn the ψ_i values for the multiple paths.

5.4 Weighted Trilingual Paths

Going back to the example, we first learn the weights using the Portuguese to English training set, $D = \{x_i^{pt}, y_i^{en}\}_{i=1}^{m}$, and then input the weights into the model before training with $J_{d-multi}$ and J_{single}. Suppose we want to compute ψ_1 which corresponds to Spanish in Equation 12. For a given Portuguese word $x_i^{pt} \in D$, whose English translation is y_i^{en}, we can compute:

$$\psi_{1i}^{dot} = (y_i^{en})^T \hat{y_i}^{(en) \hookleftarrow (es) \hookleftarrow (pt)} \quad (13)$$

We also experimented with a bilinear term:

$$\psi_{1i}^{bilinear} = (y_i^{en})^T H \hat{y_i}^{(en) \hookleftarrow (es) \hookleftarrow (pt)} \quad (14)$$

We found a better performing approach to be:

$$V = \Big(\hat{y_i}^{(en) \hookleftarrow (pt)} - \hat{y_i}^{(en) \hookleftarrow (es) \hookleftarrow (pt)}\Big)^2$$

$$\psi_{1i}^{euclid} = \exp(\frac{1}{V}). \quad (15)$$

6 Experimental Evaluation

In this section, we study the following questions:

- What is the effect of modeling linguistic information in the vector representations of the source and target languages on accuracy of bilingual dictionary induction?

- Can our knowledge distillation objective from trilingual paths involving related languages improve accuracy of mapping functions of languages with small seed dictionaries?

6.1 Data and Experimental Setup

In most of our experiments, we use the training data that was used to train the multi-lingual embeddings in (Ammar et al., 2016). We indicate when this is not the training data used. This data was obtained automatically by using Google Translate. For test data, we use manual translations either from prior work or from searching the Web, including genealogical word lists [3].

For word vector representations, we use Wikipedia to train 300 dimensional vectors for all languages we evaluate on. Based on a validation set, we set the margin γ in Equation 3 through Equation 6 to be $\gamma = 0.4$, ϕ in Equations 11, 12, and 15 to be $\phi = 0.01$. We estimate model parameters using stochastic gradient descent.

6.2 Methods Under Comparison

In our experiments, we compare performance of the following methods.

- The method **THIS** refers to our model which uses a max-margin loss function as defined

[3] For example: https://familysearch.org/wiki/en/Afrikaans_Word_List

in Equation 3. It uses sub-word information in the vector representations of words. One variation of our method is, **THIS w/pos**, which includes POS tag statistics as additional dimensions. The distilled variations of our method explicitly indicate the languages involved, for example $(pt \rightarrow es \rightarrow en)$.

- The method **Ridge** is used in a number of prior work (Mikolov et al., 2013; Dinu et al., 2014; Vulic and Korhonen, 2016). These approaches use an L2-regularized least-squares error objective as shown in Equation 2.
- The method **Lazaridou et al.** was proposed by (Lazaridou et al., 2015). It uses a max-margin ranking function and introduces a way of picking negative examples in computing the loss.
- The methods **MultiCluster** and **MultiCCA** refer to the multilingual word embeddings introduced by (Ammar et al., 2016). They extend canonical correlation analysis (CCA) based methods (Haghighi et al., 2008; Faruqui and Dyer, 2014) to a multi-lingual setting where they treat English as the common vector space. For these methods, we use their pre-trained word embeddings.

6.3 Linguistic Information Evaluation

To address the first of our evaluation questions, we performed experiments on the dataset introduced by (Dinu et al., 2014), where the state-of-the art is the work of (Lazaridou et al., 2015). This is an Italian to English dataset, which consists of $5K$ translation pairs as training data, and $1.5K$ pairs as test data. In both (Dinu et al., 2014) and (Lazaridou et al., 2015), the embeddings were trained on Wikipedia and additional corpora, we only train on Wikipedia.

The results for this experiment are shown in Table 1. Our method, THIS, performs well above the previous state of the art (Lazaridou et al., 2015). For top-1 precision, as can been seen in Table 1, we obtained an 11% gain. From Table 1, we can also see that the POS statistics are only marginally helpful. The word embeddings generated with MultiCluster and MultiCCA perform poorly, with MultiCluster doing better than MultiCCA.

	de ↓ en	es ↓ en	fr ↓ en	it ↓ en	nl ↓ en	sv ↓ en
Train	400k*	400k*	100k*	5k	1,392	110k*

MultiCCA	6.7	4.3	2.9	5.6	-	10.1

Table 3: Top-10 precision for eight languages translated to English. The high accuracy on Italian can be explained by the fact that, unlike other language pairs, for Italian we do not use Google Translate training data, but the data of (Dinu et al., 2014), as shown in Table 2.

We additionally carried out experiments on 8 other language pairs, further showing our method outperforming prior work. The results are shown in Table 3, and the corresponding data is shown in Table 2. For these language pairs, we do not show results for our method, THIS w/pos, since POS taggers are not available for some of the languages. We also do not show (Lazaridou et al., 2015), as they did not do experiments on these data sets, and we did not have an implementation of their approach. Additionally, (Ammar et al., 2016) did not have trained embeddings for Dutch (nl).

6.4 Trilingual Paths for Distillation

To address our second evaluation question, we carried out experiments with languages for which we only had small seed dictionaries. The training and test datasets for this setup are shown in Table 4. We gathered these datasets by searching for manually created datasets. In the cases were we could not find any, we used Google Translate, which, however produces some noisy translations. This is partly due to the fact that the translations are done out of context.

We begin with thorough experiments on the

	pt ↓ en	pt ↓ es	pt ↓ fr	pt ↓ de	da ↓ en	da ↓ sv	af ↓ en	af ↓ nl

6	Ridge	60.8

Table 5: Trilingual path distillation results for Portuguese to English.

Portuguese-English language pair. The results are shown in Table 5. First, we see that if we distill through the Spanish trilingual path ($pt \rightarrow es \rightarrow en$), without using any labeled data from $pt \rightarrow en$, we already obtain a 9% gain in accuracy, line 2 in Table 5. If, in addition to distilling through Spanish, we use the available training data $pt \rightarrow en$, 573 translation pairs, line 3 in Table 5, we obtain a 17% gain in accuracy. We see however that adding the distillation paths via French, and German did not improve performance, line 4 in Table 5. This can be attributed to the fact that with multiple distillation paths, the model has to optimize a more difficult function. On the other hand, we see that our trilingual weighting mechanism is effective. Without path weights, top-10 accuracy is 78.4% vs 81.8% with weights, lines 4 and 5 in Table 5. The learned weights for the three languages involved in the trilingual paths for Portuguese are shown in Figure 3. Spanish is the highest weighted, followed by French, and German has the lowest weight. By definition, the learned weights add up to 1. In Figure 4, we show accuracy while varying the size of the seed dictionary. We can see that, given the small size of the training data, distillation provides a strong advantage.

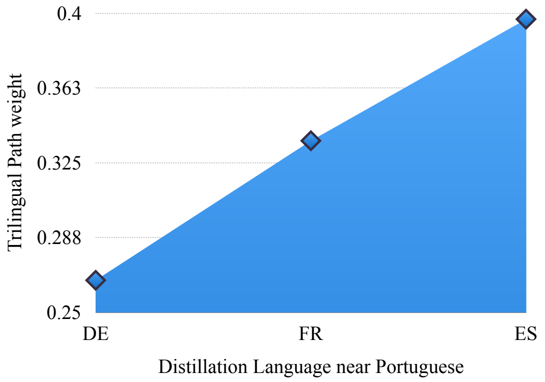

Figure 3: Learned weights for languages involved in trilingual paths for translating Portuguese to English. Spanish is the highest weighted and German is the lowest.

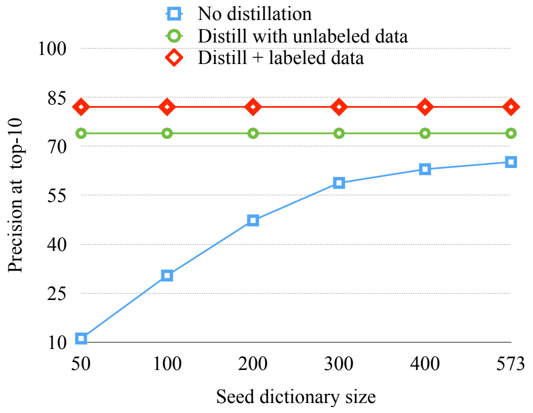

Figure 4: Varying the size of the seed dictionary for ($pt \rightarrow en$).

Finally, we applied our distillation method to Afrikaans and Danish. Afrikaans distills from Dutch, and Danish distills from Swedish. As shown in Table 6, in both cases, we obtained performance gains. However, in both of these cases, performance gains are modest. Unlike Portuguese to English, the seed dictionaries involved in training these language pairs were obtained automatically using Google Translate and contain noisy translations.

7 Conclusion

We have presented a knowledge distillation training objective that leverages trilingual paths of related languages to improve mapping functions of languages with small seed dictionaries. The model produces substantial gains in accuracy for several language pairs.

There are several future directions. First, due

to advances in methods for extracting general purpose knowledge (Mitchell et al., 2015; Nakashole et al., 2013; Wijaya et al., 2014), the use of semantic knowledge has been explored for several natural language tasks (Nakashole and Mitchell, 2015; Yang and Mitchell, 2017). However, for bilingual dictionary induction, and more generally, machine translation, the role of semantic knowledge has not been fully explored. We consider this to be a promising line of future work. Second, although we focus on bilingual dictionary induction, our knowledge distillation training objective that enables seamless use of paths of rich resource languages as teachers of low resource languages is general and can be applied to problems such as multilingual tagging and parsing.

Machine Translation, it's a question of style, innit?
The case of English tag questions

Rachel Bawden
LIMSI, CNRS, Univ. Paris-Sud, Université Paris-Saclay, F-91405 Orsay, France
rachel.bawden@limsi.fr

Abstract

In this paper, we address the problem of generating English tag questions (TQs) (e.g. *it is, **isn't it?***) in Machine Translation (MT). We propose a post-edition solution, formulating the problem as a multi-class classification task. We present (i) the automatic annotation of English TQs in a parallel corpus of subtitles and (ii) an approach using a series of classifiers to predict TQ forms, which we use to post-edit state-of-the-art MT outputs. Our method provides significant improvements in English TQ translation when translating from Czech, French and German, in turn improving the fluidity, naturalness, grammatical correctness and pragmatic coherence of MT output.

1 Introduction

When it comes to the machine translation (MT) of discourse, revisiting the question of what constitutes a high quality translation is essential; which aspects of language should be tackled and how to evaluate them. A first step is to identify the many stylistic aspects of speech that pose a problem for current MT techniques and to study how they could be taken into account and evaluated.

We take a step in this direction by addressing a new aspect of discourse in MT, related to speaker attitude and style: the English tag question (hereafter TQ), i.e. utterances such as *catchy, **ain't it?*** and *it wasn't him, **was it?***. When translating into English, TQs present two main challenges. The first is knowing when to generate one. Similar to the translation of discourse connectives, TQ use is a question of style and speaker attitude, and importantly, there is not often a direct, lexical correspondence across languages. TQs are common in English and far less so in other languages, which means that other contextual cues are necessary to determine whether a TQ should appear in the English translation. The second, in particular for canonical TQs (*e.g. was it?, isn't it?*), is that the overall grammaticality of the utterance is determined by the correct choice of tag, which, in a similar way to anaphor translation, is grammatically dependent on the rest of the MT output.

Our aim in this paper is to improve the generation of English TQs in an MT setting with English as the target language. We formulate this as a multi-class classification task, using features from both source sentences and machine translated outputs. The prediction of the appropriate question tag to use in the English translation (if any) is then used to post-edit MT outputs. Our results, when translating from Czech (CS), French (FR) and German (DE) into English (EN), display significant improvements, as shown by automatic and manual evaluations (Sec. 5).[1]

2 English tag questions (TQs)

TQs are interrogative constructions, common in spoken English, formed of a main clause (typically declarative), followed by a peripheral interrogative element, the *question tag*:

(1) *You do believe in happy endings*, **don't you?**

(2) *He can't do that*, **can he?**

In its canonical form, the English question tag (in bold) is formed of an auxiliary verb, which can be negated, followed by a pronoun. It parallels the verb and subject (underlined) of the preceding host clause (in italics). The grammatical structure of TQs and agreement between the host and the tag gives them the name of *grammatical TQs*.[2]

[1] All scripts and annotations are freely available at http://diamt.limsi.fr.

[2] Although in theory their form is relatively systematic, their attested usage is more complex.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2507–2512
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

There exists a second type of TQ, *lexical TQs*, formed of a word or phrase that is invariant to the subject and verb of the host clause. For example:

(7) *He's a proper bad man*, **innit?**

(8) *There's got to be a cure*, **right?**

TQs' functions are complex and communicate information about speaker attitude, tone, the relationship between dialogue participants, common ground and dialogue flow (McGregor, 1995). Yet few languages have such a systematic use of TQs, in particular of grammatical TQs, as English (Axelsson, 2011). When translating into English, the first difficulty is appropriately generating English TQs from a source sentence that does not have a TQ; the complex and often ambiguous functions of TQs (e.g. expressing doubt or surprise) can be expressed differently, and subtly, in the source language. The second difficulty is ensuring grammatical coherence of canonical TQs. Consider the German sentence *Sie lebt noch, nicht wahr?* and its English translation *She's alive, isn't she?*. The choice of the question tag *isn't she?* is dependent on the subject and verb of the anchor clause. Had the translation been *She still lives*, the correct question tag would have been *doesn't she?*.

3 Related work

Discourse is a growing field in MT (Le Nagard and Koehn, 2010; Hardmeier, 2012, 2014). To our knowledge, there has been no previous work on TQs in MT, but the two main challenges described above are similar to those associated with two previously studied discursive aspects: the translation of discourse connectives and of anaphoric pronouns. As with TQs, their frequency is relatively low, but their mistranslation has a high impact on coherence, naturalness and therefore human understanding of translations (Meyer and Popescu-Belis, 2012).

Discourse connectives (e.g. *since*, *because*) indicate the relation between discursive units and are linked to the overall coherence of a text in a similar way to TQs. They often have no direct mapping when translated (Meyer and Webber, 2013) and it is often necessary to generate a discourse connective or a TQ where one is not present in the source sentence. Previous work by Meyer and Webber (2013) consists in the disambiguation of discourse connectives in source sentences prior to translation, using automatic sense classification, which guides the MT system's choice of how a discourse connective should be translated (if at all). However they do not handle the case of generating discourse relations from a source sentences in which they do not appear lexically, as is our aim for TQs.

The difficulty of anaphoric pronoun translation is ensuring grammatical agreement between a pronoun and its coreferent, when the information relevant to grammatical agreement in the target language is not present in the source language. For example, the French translation of the pronoun *it* in *I hear an owl but I can't see it* is translated as *le* or *la*, depending on whether *owl* is translated as masc. *hibou* or fem. *chouette*. The position of the coreferent, as with the subject and verb for TQs, is not pre-determined, and identifying which words the translated pronoun or TQ must agree with is not always easy. The majority of works perform classification of pronominal forms in view to post-editing MT output (Guillou, 2016), encouraged by the shared task on cross-lingual pronoun prediction at DiscoMT15 (Hardmeier et al., 2015) and WMT16 (Guillou et al., 2016). We use the same strategy here, since the coherent use of TQs, like anaphors, is dependent on the MT translation.

4 Our post-edition approach

Our method to improve the generation of English TQs in MT is the automatic post-edition of state-of-the-art MT outputs. We formulate the problem as a supervised, multi-class classification task, exploiting lexical features from source sentences and their machine translations (Sec. 4.2). Possible labels are the different question tag forms (e.g. *isn't it*, *ok*). Predicted tags are either used to replace the question tag already present in the MT output or appended to it otherwise. We test our method for three source languages (CS, DE and FR) into EN.

4.1 Corpus annotation for English TQs

The first step is to produce annotated data. The corpora used cover three language pairs: CS-EN, DE-EN and FR-EN, and are large subsets of the most recent films of the OpenSubtitles[3] parallel corpus (Lison and Tiedemann, 2016). The subtitles were automatically cleaned using heuristics and processed with the MElt tokeniser (Denis and Sagot, 2012) and the Moses truecaser (Koehn et al., 2007). We then developed robust, manually defined lexical rules to identify English TQs. We

[3] www.opensubtitles.org

identify both the presence of TQs and the question tags themselves (e.g. *is it?*, *right?*).

A manual evaluation on a random subset of 500 grammatical TQs and 500 lexical TQs shows that annotations are near perfect (accuracy of ≈98% and recall of 100% on sentence-final grammatical TQs whose host clause is in the same subtitle).[4]

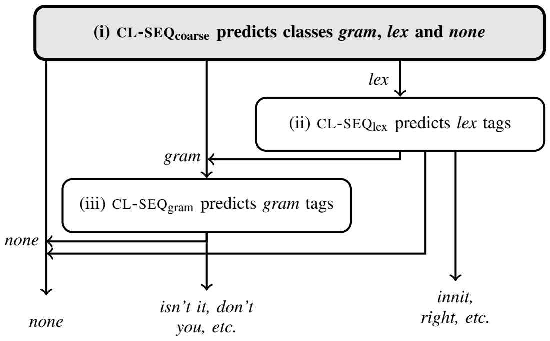
Each corpus was divided into three sets: TRAIN ($\frac{2}{3}$), DEV ($\frac{1}{6}$) and TEST ($\frac{1}{6}$). The distribution of TQs is shown in Tab. 1. TQs make up approximately 1% of subtitles, but are common among questions (≈20%). There are between 238 and 285 distinct English question tags, depending on the language pair (including a label *none* for non-TQs). The most frequent question tag is *right?* (≈20%), followed by *ok?* (≈16%). The majority of labels are grammatical question tags, but the most frequent (*isn't it?*) represents only ≈3% of all TQs, revealing a huge class imbalance.

		#English TQs			#labels	
	#sents	all	gram.	lex.	gram.	lex.
CS-EN	15.1M	146,782	44,572	102,210	269	15
DE-EN	6.2M	57,435	18,396	39,039	221	16
FR-EN	15.1M	149,847	44,651	105,196	254	16

Table 1: TQ distribution for each language pair.

4.2 Question tag classification

Given the class imbalance (Sec. 4.1) and the different nature of lexical and grammatical TQs, we hypothesise that first predicting the presence of an English TQ before selecting tag forms is preferable to directly predicting tags in a single, direct pass. We compare a single statistical classifier (hereafter CL-ONE), which directly predicts the question tag (including the label *none*), to a more complex system using a sequence of classifiers (hereafter CL-SEQ, see Fig. 1). In CL-SEQ, a first classifier (CL-SEQ$_{\text{coarse}}$) predicts a coarse-grained label *gram* (grammatical TQ), *lex* (lexical TQ) or *none* (non-TQ), which determines which classifier (CL-SEQ$_{\text{lex}}$ or CL-SEQ$_{\text{gram}}$) is used to predict the tag form. Both CL-SEQ$_{\text{coarse}}$ and CL-SEQ$_{\text{lex}}$ are statistical classifiers. CL-SEQ$_{\text{lex}}$ is trained on the TRAIN examples assigned the label *lex* by CL-SEQ$_{\text{coarse}}$, which explains why it provides a second chance to predict grammatical or non-TQs. CL-SEQ$_{\text{gram}}$ is a rule-based system, a choice that is better adapted to the sparse labels of grammatical TQs. Where there is no rule available, this system too can predict the label *none*.



(i) CL-SEQ$_{\text{coarse}}$ predicts classes *gram*, *lex* and *none*
lex
(ii) CL-SEQ$_{\text{lex}}$ predicts *lex* tags
gram
(iii) CL-SEQ$_{\text{gram}}$ predicts *gram* tags
none
none
isn't it, don't you, etc.
innit, right, etc.

Figure 1: CL-SEQ classification: (i) into coarse-grained classes, (ii–iii) prediction of forms

Experimental setup All statistical classifiers are linear classifiers trained using Vowpal Wabbit (Langford et al., 2009).[5,6] To account for class imbalance, examples are weighted according to their relative frequency in the TRAIN set, and the degree of weighting is optimised on the DEV set.[7] Features used for all statistical classifiers are described just below. The rule-based CL-SEQ$_{\text{gram}}$ system relies on the MT output alone.

Features We use automatically and manually defined lexical feature templates. Unless indicated the features apply to both the source sentence and the MT output. The first set of features are automatically identified bag-of-word features, which represent the 500 uni-, bi- and tri-grams most associated with a TQ, as measured by a G^2 test. The second set of features are manually defined, based on language-specific question-response patterns and recognisable lexical clues. They include (i) the presence of a question tag (and its form), (ii) the presence of a final question mark, (iii) (CS and DE only) whether the following subtitle contains a verb that appears in the current subtitle (and if so, we include as a feature the verb type and the preceding word in both the current and following subtitles)[8], (iv) the following subtitle contains a specific response (from a predefined list of replies

[4] Recall for lexical TQs cannot be accurately measured, as identification relies on a closed list of forms found in the literature and observed in the data.

[5] http://hunch.net/~vw/

[6] We use "OAA", FTRL-proximal optimisation, L2 regularisation ($\lambda = 1e - 6$) and quadratic features.

[7] We vary weights from equal for all examples to weights that fully counterbalance the class distribution.

[8] In German and Czech, it is common for a reply to a yes/no question to repeat the verb of the question, e.g. *Poslala jsi mu to?* 'Did you send it to him?' — *Poslala jsem* 'Yes, I did' (lit. 'send (I)_did') (Gruet-Skrabalova, 2013).

		Gram TQs				Lex TQs				Non-TQs			Overall

Table 2: Precision (P), Recall (R), F-score (F) and fine-grained labelling precision (P*) for the TEST set on each language pair. Results are given for each coarse-grained TQ class (*gram*, *lex* and *non-TQ*). Labelling precision is calculated on the subtitles with the corresponding predicted coarse-grained label. Marked in grey are the cells containing the best F-scores for coarse-grained label groupings and the overall labelling precision (for fine-grained classes).

such as *OK*, *yes*, *no*, etc.), and (v) the first words of the MT output (1-4 gram), the last auxiliary, the last pronoun and the last pronoun-auxiliary pair.

Rule-based grammatical TQ prediction Our rule-based approach is designed to predict which grammatical tag should be appended to a given translation. The rules consist in the identification of certain lexical cues from the translation. For instance, utterance-initial words can be a good indicator of the use of a particular question tag: imperatives such as *let's ...* (indicative of the tag *shall we*), and claims about the interlocutor's perception such as *you think...* or *you know...* (indicative of the tag *don't you*). When there is a single auxiliary and subject, these are directly used to construct a question tag, using, as a simplification, the opposite polarity to that of the anchor clause, which is the most common polarity pattern in TQs. We include several rules to account for complex clauses and perform grammatical checking between the subject and auxiliary of the question tag. The complete set of rules is available at the address cited in Footnote 1.

"Baseline" MT outputs For Czech and German, we use the top systems at WMT16, both attentional encoder-decoder NMT models (Sennrich et al., 2016). For French, we trained a phrase-based model with Moses (Koehn et al., 2007).[9] Baseline predictions are automatically extracted from the MT outputs using our English TQ identification rules (Sec. 4.1).

5 Results and analysis

As mentioned by Hardmeier (2012), evaluating coherence-related MT phenomena is problematic. A question tag can be the correct choice without matching the question tag form in the reference translation (Sec. 2), making traditional metrics involving lexical comparison (including all standard MT evaluation metrics) ill-adapted to the task.

Despite this, we provide in Tab. 2 results using traditional metrics. To get a better view of the scores, we group final predicted question tags into their coarse-grained classes (*gram*, *lex*, *none*) and calculate the precision (P), recall (R) and F-score (F) for these three classes. Within each coarse-grained class, we also provide labelling precision (P*), corresponding to the number of question tags within that coarse-grained class assigned the correct question tag form according to the gold label. Labelling precision is also given overall for all test sentences (in the final column).

Overall labelling precision is significantly improved for all language pairs with both classification systems, but in particular for CL-SEQ. This is partly due to a better prediction of non-TQs, represented by the high corresponding F-scores for CL-SEQ for all three language pairs. However it is also linked to a better labelling of grammatical and lexical TQs, which can be seen by the high labelling precision (P*) in the context of high recall (R). The higher scores of CL-SEQ over CL-ONE, particularly in terms of recall, which are most likely a result of question tag label sparsity, show that our two-tier strategy of predicting grammatical and lexical tags separately is better adapted than a single classifier.

There is a notable drop in recall between CL-

[9] We use a combination of three phrase tables and three 4-gram KenLM language models (Heafield et al., 2013), trained on Europarl, Ted Talks and 3M-sentence subtitles, tuned using `kbmira` on a disjoint 2.5K-sentence subset.

Source	Reference	Baseline	CL-SEQ	Judgement
Du hast das gemacht, nicht wahr?	You did this , **didn't you?**	You've done that, **don't you?**	haven't you?	Improved
Das Gehirn zerstören, wisst ihr?	Kill the brain, **you know?**	Destroying the brain, **you know?**	none	Degraded
Das stimmt, oder?	I know, **right?**	That's true, **right?**	isn't it	Equal (correct)
Das ist merkwürdig, oder?	It's weird, **isn't it?**	That 's odd, **does it?**	none	Equal (incorrect)

Table 3: Some examples from the manual comparison of the baseline translation and CL-SEQ predictions. An example is given for each of the possibilities: the prediction is better, worse or the translation and the prediction are equally good or poor with respect to tag question prediction.

SEQ and CL-SEQ when it comes to grammatical TQ prediction, which is not as marked for lexical TQ prediction. This is most likely due to the huge class imbalance in the different question tags (221 grammatical tags vs. 16 lexical tags), which causes the purely statistical one-pass system to favour the more frequent lexical tags and struggle to predict the wide range of much rarer grammatical tags.

		baseline			
		gram	lex	none	Total
gold	gram	871	180	1986	3037
	lex	429	2878	3066	6373
	none	605	1109	1019408	1021122

		predicted			
		gram	lex	none	Total
gold	gram	1298	367	1372	3037
	lex	418	3391	2564	6373
	none	474	1178	1019470	1021122

Table 4: Confusion matrix of for baseline and predicted versus gold tags (when question tags are grouped into their three coarse-grained classes) for DE→EN.

Tab. 4 shows a comparison of baseline and predicted tags for the DE→EN test set. For ease of illustration, the question tags are again regrouped into their three coarse-grained classes (*gram*, *lex* and *none*). The matrix reveals that for predicted lexical tags and non-TQs, the majority were correctly classed into these coarse-grained classes. However, grammatical tags proved more difficult to predict, the majority being classed as non-TQs, most likely a result of the fact that no such tag question was present on the German source side. The most common errors on this test set were predicting a non-TQ when a lexical tag was expected. For example, CL-SEQ predicted *none* 1112 times when the gold tag *right?* was expected. However the number of correct predictions of *right* exceeded this number (1371 cases) and compared to baseline predictions, all coarse-grained categories show an improvement in recall.

Manual analysis Given the drawbacks of automatic metrics, we manually evaluated a set of final translations post-edited with the predictions produced by the CL-SEQ system for DE→EN. We randomly selected 100 examples for which the baseline translation was modified and, comparing the baseline and CL-SEQ prediction, we labelled the example as *improved* (baseline incorrect and prediction correct) or *degraded* (baseline correct and prediction incorrect) or *equal* (both baseline and prediction (in)correct). Examples of these choices are provided in Tab. 3. We found that post-edition made an improved choice of tag in 59/100 examples (compared to 13 worse choices). Only 25 of the 59 improved examples exactly matched the reference tag, confirming the problem of relying solely on traditional metrics. We notice in particular an improvement in the choice of grammatical TQs (33 out of the 59 improvements).

6 Discussion and perspectives

Improvements in the generation of English TQs in MT outputs, as seen by our manual analysis, result in improved grammatical coherence, particularly for grammatical TQs. However, TQ translation is far from solved. As a stylistic aspect, its prediction and evaluation are complex and should be further explored. Possible improvements include improving the choice of linguistic information used and using this work to explore how TQs' functions are portrayed in languages other than English.

Interesting future work would be to compare the opposite approach to the task; augmenting source sentences with disambiguating information prior to translation, particularly within an NMT framework, which has good potential for handling non-local context and integrating extra features.

Deciphering Related Languages

Abstract

We present a method for translating texts between close language pairs. The method does not require parallel data, and it does not require the languages to be written in the same script. We show results for six language pairs: Afrikaans/Dutch, Bosnian/Serbian, Danish/Swedish, Macedonian/Bulgarian, Malaysian/Indonesian, and Polish/Belorussian. We report BLEU scores showing our method to outperform others that do not use parallel data.

1 Introduction

Statistical Natural Language Processing (NLP) tools often need large amounts of training data in order to achieve good performance. This limits the use of current NLP tools to a few resource-rich languages. Assume an incident happens in an area with a low-resource language, known as the Incident Language (IL). For a quick response, we need to build NLP tools with available data, as finding or annotating new data is expensive and time consuming. For many languages this means that we only have a small amount of often out-of-domain parallel data (e.g. a Bible or Ubuntu manual), some monolingual data and almost no annotation such as part of speech tags.

Fortunately, many low-resource languages have one or more higher-resource, closely Related Languages (RL). Examples of such IL/RL pairs are Afrikaans/Dutch and Bosnian/Serbian. A natural idea is to use RL resources to improve the task for IL. But this requires some kind of conversion between RL and IL. Assume the required NLP capability is named entity tagging. If we can convert RL to IL, we can convert all RL training data along with annotations into IL and train the tagger for IL. Or, if we can convert IL to RL we can use the potentially existing RL named entity tagger on converted IL data and project back the tags.

Following this idea, Currey et al. (2016) use a rule-based translation system to convert Italian and Portuguese into Spanish, to improve Spanish (here, IL) language modeling, Nakov and Ng (2009) convert RL/English parallel data to IL/English where both RL and IL have Latin orthography to improve IL/English machine translation. Hana et al. (2006) use cognates to adapt Spanish resources to Brazilian Portuguese to train a part-of-speech tagger. Mann and Yarowsky (2001) use Spanish/Portuguese cognates to convert an English/Spanish lexicon to English/Portuguese. These works prove the usefulness of RL data to improve NLP for IL, but they are designed for specific tasks and IL/RL pairs.

In this paper we propose a universal method for translating texts between closely related languages. We assume that IL and RL are mostly cognates, having roughly the same word order. Our method is orthography-agnostic for alphabetic systems, and crucially, it does not need any parallel data. From now on, we talk about converting RL to IL, but the method does not distinguish between RL and IL; as mentioned above, each direction of translation can have its own potential uses.

To translate RL to IL, we train a character-based cipher model and connect it to a word-based language model. The cipher model is trained in a noisy channel model where a character language model produces IL characters and the model converts them to RL. Expectation Maximization is used to train the model parameters to maximize the likelihood of a set of RL monolingual data. At decoding time, the cipher model reads the RL text character by character in which words are separated by a special character, and produces a weighted lattice of characters representing all the possible translations for each of the input tokens.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2513–2518
Copenhagen, Denmark, September 7–11, 2017.

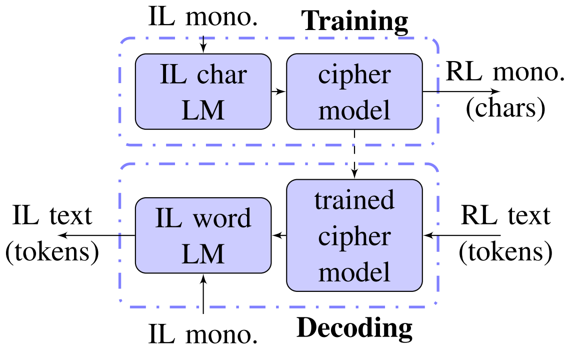

Figure 1: The process used for training the cipher model and decoding RL text to IL

The word-based language model takes this lattice and produces a sequence of output words that maximize the language model score times the cipher model score. Figure 1 depicts this process.

Our cipher models one-to-one, one-to-two and two-to-one character mappings. This allows us to handle cases like Cyrillic 'ч' and Latin 'ch', and also subtle differences in pronunciation between RL and IL like Portuguese 'justiça' and Spanish 'justicia'. Using a character-based cipher model provides the flexibility to generate unseen words. In other words, the vocabulary is limited by the decoding LM, not the cipher model. Separation of training and decoding language models enables us to train the decoding LM on as much data as is available without worrying about training speed or memory issues. We can also transliterate out of vocabulary words by spelling out the best path produced by cipher model in case no good match is found for a token in the decoding LM.

2 Related Work

Previous work on translation between related languages can be categorized into three groups:

Systems for specific language pairs such as Czech-Slovak (Haji et al., 2000), Turkish-Crimean Tatar (Cicekli, 2002), Irish-Scottish Gaelic (Scannell, 2006), and Indonesian-Malaysian (Larasati and Kubo, 2010). Another similar trend is translation between dialects of the same language like Arabic dialects to standard Arabic (Hitham et al., 2008; Sawaf, 2010; Salloum and Habash, 2010). Also, work has been done on translating back the Romanized version of languages like Greeklish to Greek (Chalamandaris et al., 2006) and Arabizi to Arabic (May et al., 2014). These methods cannot be applied to our problem because time and resources are limited to build a translation system for the specific language pair.

Machine learning systems that use parallel data: These methods cover a broader range of languages but require parallel text between related languages. They include character-level machine translation (Vilar et al., 2007; Tiedemann, 2009) or combination of word-level and character-level machine translation (Nakov and Tiedemann, 2012) between related languages.

Use of non-parallel data: Cognates can be extracted from monolingual data and used as a parallel lexicon (Hana et al., 2006; Mann and Yarowsky, 2001; Kondrak et al., 2003). However, our task is whole-text transformation, not just cognate extraction.

Unsupervised deciphering methods, which require no parallel data, have been used for bilingual lexicon extraction and machine translation. Word-based deciphering systems ignore sub-word similarities between related languages (Koehn and Knight, 2002; Ravi and Knight, 2011b; Nuhn et al., 2012; Dou and Knight, 2012; Ravi, 2013). Haghighi et al. (2008) and Naim and Gildea (2015) propose models that can use orthographic similarities. However, the model proposed by (Naim and Gildea, 2015) is only capable of producing a parallel lexicon and not translation. Furthermore, both systems require the languages to have the same orthography and their vocabulary is limited to what they see during training.

Character-based decipherment is the model we use for solving this problem. Character-based decipherment has been previously applied to problems like solving letter substitution ciphers (Knight et al., 2006; Ravi and Knight, 2011a) or transliterating Japanese katakana into English (Ravi and Knight, 2009), but not for translating full texts between related languages.

3 Translating RL to IL

We learn a character-based cipher model for translating RL to IL. At decoding, this model is combined with a word based IL language model to produce IL text from RL.

3.1 Cipher Model

Our noisy-channel cipher model converts a sequence of IL characters $s_1, ..., s_n$ to a sequence of RL characters $t_1, ..., t_m$. It is a WFST composed of three components (Figure 2):

WFST1 is a one-to-one letter substitution model. For each IL character s it writes one RL character t with probability $p_1(t|s)$.

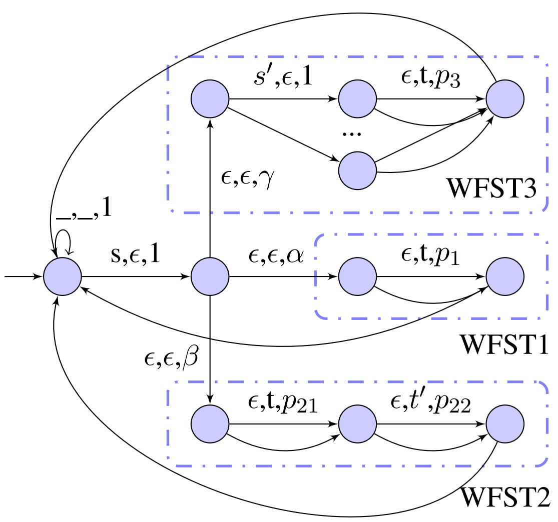

Figure 2: Part of the cipher model corresponding to reading IL character s from start state. The same pattern repeats for any IL character. After reading s, the model goes to WFST1, WFST2, or WFST3 with respective probability $\alpha(s)$, $\beta(s)$, or $\gamma(s)$. In WFST1, the model produces each RL character t with probability $p_1(t|s)$. In WFST2, the model produces each two RL characters t and t' with probability $p_{21}(t|s)$ and $p_{22}(t'|s)$. In WFST3, the model reads each IL character s' and produces each RL character t with probability $p_3(t|ss')$. From the last state of WFST1, WFST2, and WFST3, the model returns to the start state without reading or writing.The model has a loop on start state that reads and writes space.

WFST2 is a one-to-two letter substitution model. For each IL character s, it writes two RL characters t and t' with respective probabilities $p_{21}(t|s)$ and $p_{22}(t'|s)$.

We assume $p_{22}(t'|s)$ is independent of t. As a result we can estimate $p(tt'|s) = p(t|s)p(t'|t, s) \simeq p_{21}(t|s)p_{22}(t'|s)$ as modeled in WFST2. This simplification is required to make the model practicable. Otherwise, the size of the cipher model would become cubic in the number of RL and IL characters, and combining it with a language model would make the system unfeasibly large for training.

WFST3 is a two-to-one letter substitution cipher. For each IL character s, it reads another IL character s' with probability 1, and then writes one RL character t with probability $p_3(t|ss')$. As we will discuss in Section 3.2 we train p_3 directly from p_{21} and p_{22}, hence the cubic number of parameters does not cause a problem.

The start state reads each IL character s and goes to WFST1, WFST2, or WFST3 with respective probability $\alpha(s)$, $\beta(s)$, or $\gamma(s)$. The last state of each component returns to start without reading or writing anything. The start state also reads and writes space with probability one.

3.2 Training the Model

The cipher model described in Section 3.1 is much more flexible than a one-to-one letter substitution cipher. A few thousand sentences of RL monolingual data is not enough to train the model as a whole, and more training data makes the process too slow to be practical. Hence, we break the full model into WFST1, WFST2, and WFST3 and train the parameters of each component, i.e. p_1, p_{21} and p_{22}, and p_3 in separate steps. A final step trains the probability of moving into each of the components, i.e. α, β, and γ.

Each step of the training uses EM algorithm to maximize the likelihood of 500 sentences of RL text in a noisy channel model where a fixed 5-gram character based IL language model (trained on 5000 IL sentences) produces an IL text character by character and the cipher model converts RL characters into RL (top section of Figure 1).

Step one: We set $\alpha(s) = 1$ and $\beta(s) = \gamma(s) = 0$ and train $p_{1IL\to RL}(t|s)$ for each IL character s and each RL character t. In parallel we reverse RL and IL and train $p_{1RL\to IL}(s|t)$ for each RL character t and each IL character s. We use $p_1(t|s) = \frac{1}{2}(p_{1IL\to RL}(t|s) + p_{1RL\to IL}(s|t))$ to set WFST1 parameters in the next steps.

Step two: We set $\alpha(s) = \beta(s) = \frac{1}{2}$ and $\gamma(s) = 0$, fix p_1 and train $p_{21IL\to RL}(t|s)$ and $p_{22IL\to RL}(t'|s)$ for each IL character s and each pair of RL characters t and t'. In parallel we reverse RL and IL and train $p_{21RL\to IL}(s|t)$ and $p_{22RL\to IL}(s'|t)$ for each RL character t and each pair of IL characters s and s'.

Step three: Our cipher model has to decide after reading one IL character if it will perform a one-to-one, one-to-two or two-to-one mapping. In the first two scenarios the model has enough information to decide, but for the two-to-one mapping the model has to decide before reading the second IL character. For instance, consider converting Bosnian to Serbian. When the model reads the character “c” it has to decide between one-to-one, one-to-two and two-to-one mappings. A good decision will be two-to-one mapping because “ch” maps to ч, hence the system learns a large γ for character “c” but the same γ applies to any other

	afr	dut	bel	pol	bos	srb	dan	swe	mkd	bul	mal	ind

#tok.	19M	74M	26M	58M	17M	29M	71M	70M	16M	33M	8M	75M

Table 1: Size of monolingual data available for each language. IL and RL are presented in pairs, IL first.

character that follows “c” which is not desirable.

One way to overcome this problem is to change the model to make the decision after reading two IL characters, but this will over-complicate the model. We use a simpler trick instead. We compute $p_{3IL \rightarrow RL}(t|ss')$ from $p_{21RL \rightarrow IL}(s|t)$ and $p_{22RL \rightarrow IL}(s'|t)$ using Bayes rule:

$$p_3(t|ss') = \frac{p(ss'|t)p(t)}{p(ss')} \simeq \frac{p_{21}(s|t)p_{22}(s'|t)p(t)}{p(ss')} \quad (1)$$

The estimate is based on our assumption from the previous step that $p_{22}(s'|t)$ is independent of s. For each RL character t we compute the empirical probability $p(t)$ from monolingual data and $p(ss')$ is the normalization factor.

We set p_3 parameters using equation (1), but before normalizing we manually prune the probabilities. If for IL characters s and s' there exists no RL character t such that $p_{21}(s|t)p_{22}(s'|t)p(t) > 0.01$ we assume that ss' does not map to any RL character. Otherwise, we only keep RL characters for which $p_{21}(s|t)p_{22}(s'|t)p(t) > 0.01$ and then apply the normalization.

Step four: In the final step we fix p_1, p_{21}, p_{22}, and p_3 to the trained values and train $\alpha(s)$, $\beta(s)$, and $\gamma(s)$ for each IL character s.

3.3 Decoding

In the decoding step we compose the cipher WFST with an IL word based language model WFST and find the best path for the input sentence in the resulting WFST (bottom section of Figure 1). If the best path has a high enough score the model outputs the corresponding IL token. Otherwise it outputs the highest scored character sequence produced by the cipher model as and OOV. In our experiments we use 1-gram and 2-gram language models trained on all the existing IL monolingual data (Table 1).

4 Data

We collect data for six pairs of related languages: Afrikaans(afr) / Dutch(dut), Bosnian(bos) / Serbian(srb), Danish(dan) / Swedish(swe), Macedonian(mkd) / Bulgarian(bul), Malaysian(mal) / Indonesian(ind), and Polish(pol) / Belorussian(bel). For each language, we download the monolingual data from Leipzig corpora (Goldhahn et al., 2012). The domain of the data is news, web, and Wikipedia. We consider the language with more data as RL and the one with less data as IL. Table 1 shows the size of available data for each language.

We also extract the list of alphabets for each language from Wikipedia, and collect the Universal Declaration of Human Rights (UDHR) for each IL and RL. We manually sentence align these documents and get 104 sentences and about 1.5K tokens per language. We use these documents for testing the conversion accuracy.

We tokenize and lowercase all the monolingual, parallel and UDHR data with Moses scripts. We remove all non-alphabetic characters from each text according to the alphabet extracted from Wikipedia. This includes numbers, punctuations, and rare/old characters that are not considered as official characters of the language. We keep all the accented variations of characters.

5 Experiments

We translate the UDHR between the related languages using the following methods:

Copy: Copying the text. This is not applicable for languages with different orthography.

LS: One-to-one Letter Substitution cipher. This is equivalent to using WFST1 without a decoding language model.

LS+1g LM: One-to-one letter substitution cipher with a 1-gram word language model at decoding.

PM+1g LM, **PM+2g LM:** The Proposed Method with respectively 1-gram and 2-gram word language model at decoding.

Results are reported for both directions of translation in Tables 2, and 3. For all the language pairs except Malaysian(mal) / Indonesian(ind), the proposed method is the best model with a large margin. Malaysian/Indonesian is a special case where, although the languages have a different vocabulary and a slightly different grammar, they have a common alphabet, and almost all of their cognates are exactly the same. See Figure 3 for an example. As a result the proposed method cannot learn much more than copying.

	afr→dut	bel→pol	bos→srb	dan→swe	mkd→bul	mal→ind
Copy	1.9 / 29.1	- / -	- / -	1.2 / 17.6	5.6 / 34.2	10.0 / 42.7

PM+2g LM	5.2 / 31.2	1.9 / 25.2	42.3 / 67.8	7.6 / 41.2	10.2 / 41.3	10.0 / 41.7

Table 3: BLEU scores for RL-to-IL translation of UDHR text. Format is BLEU4/BLEU1. Polish / Belorussian and Serbian / Bosnian have different orthographies hence copying is not applicable.

mal:	**semua**	manusia	**dilahirkan**	bebas	**dan**	samarata	dari	segi	kemuliaan	**dan**	**hakhak**
ind:	**semua**	orang	**dilahirkan**	merdeka	**dan**	mempunyai	martabat	**dan**	**hakhak**	yang	sama

Figure 3: First sentence of the first article of UDHR in Malaysian (mal) and Indonesian (ind). These languages have a different vocabulary, but their cognates (shown in bold) are exact matches.

afr:	alle	menslike	wesens	word	vry	met	gelyke	--	waardigheid	en	regte
a2d:	**alle**	menslike	wezens	werd	**vrij**	met	gelijke	--	**waardigheid**	**en**	rechte
dut:	**alle**	mensen	------	worden	**vrij**	en	gelijk	in	**waardigheid**	**en**	rechten
afr2en:	all	human	beings	are	free	with	equal	--	dignity	and	rights
a2d2en:	all	human	beings	were	free	with	equal	--	dignity	and	straight
dut2en:	all	people	------	are	free	and	equal	in	dignity	and	rights

Figure 4: First sentence of the first article of UDHR in Afrikaans (afr), Dutch (dut) and its conversion from Afrikaans to Dutch using PM+2-gram LM (a2d), along with their translations to English.

The proposed method translates between Serbian (srb) and Bosnian (bos) almost perfectly. For other pairs, we translate between a quarter and half of the words correctly, but we get few of the higher n-grams. Figure 4 visualizes the conversion of the first sentence of the first article of UDHR from Afrikaans (afr) to Dutch (dut) using PM+2g LM (4.3 BLEU4, 36.2 BLEU1). Observe that 4 out of 10 tokens are translated correctly, close to the 36.2 BLEU1 score, and there is no 3 or 4-gram match. For other tokens except "menslike" the translation is either correct but non-existent in the dutch sentence (wezens = beings, met = with) or has a meaning similar enough that can be useful in the downstream applications (werd = were v.s. worden = are, gelijke = equal(noun) v.s. gelijk = equal(adjective), rechte = straight/right v.s. rechten = rights). The token "menslike" in a2d is an OOV. The model is not able to convert "menslike" (afr) to "mensen" (dut). The language model does not accept other potential conversions and passes out "menslike" (a2d) as the best output of the cipher model.

6 Conclusion

In this paper we present a method for translating texts between closely related languages with potentially different orthography, without needing any parallel data. The only requirement is a few thousand lines of monolingual data for each language and a word language model for the target. Our experiments on six language pairs show the proposed method outperforms others that do not use parallel data.

Abstract

We present a system for identifying cognate sets across dictionaries of related languages. The likelihood of a cognate relationship is calculated on the basis of a rich set of features that capture both phonetic and semantic similarity, as well as the presence of regular sound correspondences. The similarity scores are used to cluster words from different languages that may originate from a common protoword. When tested on the Algonquian language family, our system detects 63% of cognate sets while maintaining cluster purity of 70%.

1 Introduction

Cognates are words in related languages that have originated from the same word in an ancestor language; for example English *earth* and German *Erde*. On average, cognates display higher phonetic and semantic similarity than random word pairs between languages that are indisputably related (Kondrak, 2013). The term *cognate* is sometimes used within computational linguistics to denote orthographically similar words that have the same meaning (Nakov and Tiedemann, 2012). In this work, however, we adhere to the strict linguistic definition of cognates and aim to distinguish them from lexical borrowings by detecting regular sound correspondences.

Cognate information between languages is critical to the field of historical and comparative linguistics, where it plays a central role in determining the relations and structures of language families (Trask, 1996). Automated phylogenetic reconstructions often rely on cognate information as input (Bouchard-Côté et al., 2013). The percentage of shared cognates can also be used to estimate the time of pre-historic language splits (Dyen et al., 1992). While cognates are valuable to linguists, their identification is a time-consuming process, even for experts, who have to sift through hundreds or even thousands of words in related languages. The languages that are the least well studied, and therefore the ones in which historical linguists are most interested, often lack cognate information.

A number of computational methods have been proposed to automate the process of cognate identification. Many of the systems focus on identifying cognates within classes of semantically equivalent words, such as Swadesh lists of basic concepts. Those systems, which typically consider only the phonetic or orthographic forms of words, can be further divided into the ones that operate on language pairs (*pairwise*) vs. multilingual approaches. However, because of semantic drift, many cognates are no longer exact synonyms, which severely limits the effectiveness of such systems. For example, a cognate pair like English *bite* and French *fendre* "to split" cannot be detected because these words are listed under different basic meanings in the Comparative Indoeuropean Database (Dyen et al., 1992). In addition, the number of basic concepts is typically small.

In this paper, we address the challenging task of identifying cognate sets across multiple languages directly from dictionary lists representing related languages, by taking into account both the forms of words and their dictionary definitions (c.f. Figure 1). Our methods are designed for less-studied languages — we assume only the existence of basic dictionaries containing a substantial number of word forms in a semi-phonetic notation, with the meaning of words conveyed using one of the major languages. Such dictionaries are typically created before Bible translations, which have been accomplished for most of the world's languages.

While our approach is unsupervised, assuming no cognate sets from the analyzed language fam-

ily to start with, it incorporates supervised machine learning models that either leverage cognate data from unrelated families, or use self-training on subsets of likely cognate pairs. We derive two types of models to classify pairs of words across languages as either cognate or not. The language-independent *general model* employs a number of features defined on both word forms and definitions, including word vector representations. The additional *specific models* exploit regular sound correspondences between specific pairs of languages. The scores from the general and specific models inform a clustering algorithm that constructs the proposed cognate sets.

We evaluate our system on dictionary lists that represent four indigenous North American languages from the Algonquian family. On the task of pairwise classification, we achieve a 42% error reduction with respect to the state of the art. On the task of multilingual clustering, our system detects 63% of gold sets, while maintaining a cluster purity score of 70%. The system code is publicly available.[1]

2 Related Work

Most previous work in automatic cognate identification only consider words as cognates if they have identical definitions. As such, they make limited or no use of semantic information. The simplest variant of this task is to make pairwise cognate classifications based on orthographic or phonetic forms. Turchin et al. (2010) apply a heuristic based on consonant classes to identify the ratio of cognate pairs to non-cognate pairs between languages in an effort to determine the likelihood that they are related. Ciobanu and Dinu (2013) find cognate pairs by referring to dictionaries containing etymological information. Rama (2015) experiments with features motivated by string kernels for pairwise cognate classification.

A more challenging version of the task is to cluster cognates within lists of words that have identical definitions. Hauer and Kondrak (2011) use confidence scores from a binary classifier that incorporates a variety of string similarity features to guide an average score clustering algorithm. Hall and Klein (2010, 2011) define generative models that model the evolution of words along a phylogeny according to automatically learned sound laws in the form of parametric edit distances. List and Moran (2013) propose an approach based on sound class alignments and an average score clustering algorithm. List et al. (2016) extend the approach to include partial cognates within word lists.

Cognate identification that considers semantic information is a less-studied problem. Again, the task can be framed as either a pairwise classification or multi-lingual clustering. In a pairwise context, Kondrak (2004) describes a system for identifying cognates between language dictionaries which is based on phonetic similarity, complex multi-phoneme correspondences, and seman-

[1] *https://github.com/ajstarna/SemaPhoR*

tic information. The method of Wang and Sitbon (2014) employs word sense disambiguation combined with classic string similarity measures for finding cognate pairs in parallel texts to aid language learners.

Finally, very little has been published on creating cognate sets based on both phonetic and semantic information, which is the task that we focus on in this paper. Kondrak et al. (2007) combine phonetic and sound correspondence scores with a simple semantic heuristic, and create cognate sets by using graph-based algorithms on connected components. Steiner et al. (2011) aim at a fully automated approach to the comparative method, including cognate set identification and language phylogeny construction. Neither of those systems and datasets are publicly available for the purpose of direct comparison to our method.

3 Methods

In this section, we describe the design of our language-independent general model, as well as the language-specific models. Given a pair of words from related languages, the models produce a score that reflects the likelihood of the words being cognate. The models are implemented as Support Vector Machine (SVM) classifiers via the software package SVM-Light (Joachims, 1999). The scores from both types of models are used to cluster words from different languages into cognate sets.

3.1 Features of the General Model

The general model is a supervised classifier that makes cognate judgments on pairs of words accompanied by their semantic definitions. The model is intended to be language-independent, so that it can be trained on cognate annotations from well-studied languages, and applied to completely unrelated families. The features of the general model are of two kinds: phonetic, which pertain to the analyzed word forms, and semantic, which refer to their definitions.

The **phonetic features** are defined on the word forms, represented in ASJP format (Brown et al., 2008), which is a simplified phonetic representation.

- *Normalized edit distance* is calculated at the character level, and normalized by the length of the longer word.
- *LCSR* is the longest common subsequence ratio of the words.
- *Alignment score* reflects an overall phonetic similarity, provided by the ALINE phonetic aligner (Kondrak, 2009).
- *Consonant match* returns the number of aligned consonants normalized by the number of consonants in the longer word.

For example, consider the words *meškweːkenwi* and *mæhkiːkan* (meSkwekenwi and mEhkikan in ASJP notation) from cognate set 1725 in Figure 1. The corresponding values for the above four features are 0.364, 0.364, 0.523, and 0.714, respectively.

The **semantic features** refer to the dictionary definitions of words. We assume that the definitions are provided in a single meta-language, such as English or Spanish. We consider not only a definition in its entirety, but also its *sub-definitions*, which are separated by commas and semicolons. We distinguish between a closed class of about 300 *stop words*, which express grammatical relationships, and an open class of *content words*, which carry a meaning. Filtering out stopwords reduces the likelihood of spurious matches between dictionary definitions.

Our semantic features can be divided into those that focus on surface definition resemblance, and those that attempt to detect the affinity of meaning. The features of the first type are the following:

- *Sub-definition match* denotes an exact match between any of the word sub-definitions (c.f. set 42 of Figure 1).
- *Sub-definition content match* is performed after removing stop words from definitions.
- *Normalized word-level edit distance* calculates the minimum distance between sub-definitions at the level of words, normalized by the length of the longer sub-definition.
- *Content overlap* fires if any sub-definitions have at least one content word in common.

The second type of semantic features are aimed at detecting deeper meaning connections between definitions. We use WordNet (Fellbaum, 1998) to identify the relations of synonymy and hypernymy, and to associate different inflectional forms of words. The WordNet-based features are as follows:

- *Synonym overlap* indicates a WordNet synonymy relation between content words across sub-definitions (e.g. "ease" and "repose").
- *Hypernym overlap* indicates a WordNet hypernymy relation between content words across sub-definitions (e.g. "flannel" and "cloth").
- *Inflection overlap* is a feature that associates inflectional variants of content words (e.g. "scrape" and "scraping").
- *Inflection synonym overlap* indicates a synonymy relation between lemmas of content words (e.g. "scratches" and "scraping").
- *Inflection hypernym overlap* is defined analogously to the inflection synonym overlap feature.

In order to detect subtle definition similarity that goes beyond inflectional variants and simple semantic relations, we add two features designed to take advantage of recent advances in word vector representations. The two vector-based features are:

- *Vector cosine similarity* is the cosine similarity between the two vectors that represent the average of each vector within a sub-definition.
- *Content vector cosine similarity* is analogous, but only includes content words.

As an example, consider the definitions "he is in mourning" and "she is widowed," from Table 5, which do not fire any of the WordNet-based features. Using the entire definitions yields a vector cosine similarity of 0.566, while considering only the content words "mourning" and "widowed" produces a feature value of 0.146.

3.2 Regular Correspondences

The features described in the previous section are language-independent, but we would also like to take into account cognate information that is specific to pairs of languages, namely regular sound correspondences. For example, *th/d* is a sound correspondence between English and German, occurring in words such as *think/denken* and *leather/Leder*. A model trained on another language family would not be able to learn that a corresponding *th* and *d* is an important indicator of cognation in English/German pairs.

For each language pair, we derive a specific model by implementing the approach of Bergsma and Kondrak (2007). As features, we extract pairs of substrings, up to length 3, that are consistent with the alignment induced by the minimum edit distance algorithm. The models are able to learn when a certain substring in one language corresponds to a certain substring in another language.

In order to train the specific models, we need a substantial number of cognate pairs, which are not initially available in our unsupervised setting. We use a heuristic method to overcome this limitation. We create sets of words that satisfy the following two constraints: (1) identical dictionary definition, and (2) identical first letter. For example, this heuristic will correctly cluster the two words defined as "red cloth" in Figure 1, but will miss the two other cognates from Set 1725. We ensure that every set contains words from at least two languages. The resulting word sets are mutually exclusive, and contain mostly cognates. (In fact, we use this method as our baseline in the Experiments section.) We extract positive training examples from these high-precision sets, and create negative examples by sampling random entries from the language dictionaries. A separate specific model is learned for each language pair in order to capture regular sound correspondences. Note that the specific models include no semantic features. We combine the specific models with the general model by simply averaging their respective scores.

3.3 Cognate Clustering

We apply our general and specific models to score pairs of words across languages. Featurizing all possible pairs of words from all languages is very time consuming, so we first filter out dissimilar word pairs that obtain a normalized score below 0.35 from ALINE. In development experiments, we observed that over 95% of cognate pairs exceed this threshold.

Once pairwise scores have been computed, we cluster words into putative cognate sets using a variant of the UPGMA clustering algorithm (Sokal and Michener, 1958), which has been used in previous work on cognate clustering (Hauer and Kondrak, 2011; List et al., 2016). Initially, all words are placed into their own cluster. The score between clusters is computed as the average of all pairwise scores between the words within those clusters. In each iteration, the two clusters with the highest average score are merged. For efficiency reasons, only positive scores are included in the pairwise similarity matrix, which implies that merges are only performed if all pairwise scores between two clusters are positive. The algorithm terminates when no pair of clusters have a positive average score.

4 Experiments

In this section, we discuss two evaluation experiments. After describing the datasets, we compare our cognate classifier to the current state of the art in pairwise classification. We then consider the evaluation metrics for our main task of cognate set recovery from raw language dictionaries, which is followed by the results on the Algonquian dataset. We refer to our system as SemaPhoR, to reflect the fact that it exploits three kinds of evidence: **Sema**ntic, **Pho**netic, and **R**egular Sound Correspondences.

4.1 Data Sets

Our experiments involve three different language families: Algonquian, Polynesian, and Totonacan.

The Algonquian dataset consists of four dictionary lists (c.f. Figure 1) compiled by Hewson (1993) and normalized by Kondrak (2004). We convert the phonetic forms into a Unicode encoding. The gold-standard annotation consists of 3661 cognate sets, which were established by Hewson on the basis of the regular correspondences identified by Bloomfield (1946). The dataset contains as many as 22,747 unique definitions, which highlights the difference between our task and previous work in cognate identification within word lists, where cognate relationships are restricted to a limited set of basic concepts.

The second dataset corresponds to a version of POLLEX, a large-scale comparative dictionary of over 60 Polynesian languages (Greenhill and Clark, 2011). Table 1 shows that nearly 99% of words in the POLLEX dataset belong to a cognate set, meaning that it is composed almost entirely of cognate sets rather than language dictionaries. This makes the POLLEX dataset unsuitable for system evaluation; however, we use it to train our general classifier, by randomly selecting 25,000 cognate and 250,000 non-cognate word pairs. For calculating our word vector based features, we use the Python package *gensim* (Řehůřek and Sojka, 2010) applied to word vectors pre-trained on approximately 100 billion English words using the approach of Mikolov et al. (2013).[2] The positive training instances are constrained to involve languages that belong to different Polynesian subfamilies.

Family	Lang.	Entries	Sets	Cognates
Algonquian	4	26,985	3,661	8,675
Polynesian	62	27,049	3,690	26,699
Totonacan	10	43,073	?	?

Table 1: The number of languages, total dictionary entries, cognate sets, and cognate words for each language family.

The final dataset consists of 10 dictionaries of the Totonacan language family spoken in Mexico. Since the definitions of the Totonacan dictionaries are in Spanish, we use the Spanish WordNet, a list of 200 stop words, and approximately 1 billion pre-trained Spanish word vectors (Cardellino, 2016) for this dataset.[3] The Totonacan data is yet to be fully analyzed by historical linguists, and as such provides an important motivation for developing our system.

Although the Totonacan dataset includes no cognate information, we manually evaluated a number of candidate cognate sets generated by our system in the development stage. From these annotations, we created a pairwise development set, including all possible 6755 cognate pairs and 67,550 randomly selected non-cognate pairs, and used it for testing our general model that was trained on the Polynesian dataset. The resulting pairwise F-Score of 88.0% shows that our cognate classification model need not be trained on the same language family that it is applied to. Moreover, it confirms that our system can function on datasets where definitions are written in a meta-language that is different from the one used in the training set.

4.2 Pairwise Classification Results

Although our main objective is multilingual clustering, the goal of the first experiment is to compare the effectiveness of our pairwise classifiers against the system of Kondrak (2004), which was designed to process one language pair at a time. As much as possible, we try to follow the original evaluation methodology, which reports 11-point interpolated precision (Manning et al., 2008, page

158) on lists of positively classified word pairs that have been sorted according to their confidence scores. We also use the same dataset, which is limited to the nouns in the Algonquian data. As the original system contained no machine-learning component, it required no training data, but the Cree-Ojibwa language pair served as the development and tuning set.

We evaluate two variants of our general model: one trained on the Cree-Ojibwa (CO) noun subset, and another on the POLLEX dataset. The language-specific models are trained on each respective language pair, using the unsupervised heuristic approach described in Section 3.2.

Table 2 shows the results on each language pair. K-2004 denotes the results reported in Kondrak (2004). The increase in the average 11-point precision on the five test sets (except Cree-Ojibwa) from 66.1% to 80.3% represents an error reduction of 42%. This improvement demonstrates the superiority of a machine learning approach with a rich feature set over a categorical approach with manually-tuned parameters. When our classifier is trained instead on cognate data from an unrelated Polynesian language family, the average 11-point precision on the test sets drops only slightly to 80.0%, which confirms its generality.

The correspondence-based specific models contribute towards the high accuracy of our system. Without them, the average results on the test sets decrease by 0.9% to 79.4% for the CO-trained model, and by 3.0% to 77.0% for the POLLEX-trained model. We conjecture that the language-specific models are less helpful in the former case because the general model already incorporates much of the information that is particular to the Algonquian family.

4.3 Evaluation Metrics for Clustering

The choice of evaluation metrics for multilingual cognate clustering, which is our main task, requires careful consideration. Pairwise F-score works well for pairwise cognate classification, but in the context of clustering, the number of word pairs grows quadratically with the size of a set, which creates a bias against smaller sets. For example, a set containing 10 words may contribute as much to the pairwise recall as 45 two-word sets.

For the task of clustering words with identical definitions, Hauer and Kondrak (2011) propose to use B-Cubed F-score (Bagga and Baldwin, 1998). However, we found that B-Cubed F-score assigns counter-intuitive scores to clusterings involving datasets of dictionary size, in which many words are outside of any cognate set in the reference annotation. For example, on the Algonquian dataset, a trivial strategy of placing each word into its own cluster (*MaxPrecision*) would achieve a B-Cubed F-Score of 89.6%.

In search for a better metric, we considered MUC (Vilain et al., 1995), which is designed to score co-reference algorithms. MUC assigns precision, recall and F-Score based on the number of *missing links* in the proposed clusters. However, as pointed out by Bagga and Baldwin (1998), when penalizing incorrectly placed elements, MUC is insensitive to the size of the cluster in question. For example, a completely useless clustering of all Algonquian words into one giant set (*MaxRecall*) yields a higher MUC F-Score than most of the reasonably effective approaches.

We believe that an appropriate measure of *recall* for a cognate clustering system is the total number of *found sets*. A set that exists in the gold annotation is considered found if any of the words that belong to the set are clustered together by the system. We report both partially and completely found sets. Arguably, the number of partially found sets may be more important, as it is easier for a linguist to extend a found set to other languages than to discover the set in the first place. In fact, a discovery of a single pair of cross-lingual cognates implies the existence of a corresponding proto-word in their ancestor language, which is likely to have reflexes in the other languages of the family.

As a corresponding measure of *precision*, we report *cluster purity*, which has previously been used to evaluate cognate clusterings by Hall and

Klein (2011) and Bouchard-Côté et al. (2013). In order to calculate purity, each output set is first matched to a gold set with which it has the most words in common. Then purity is calculated as the fraction of total words that are matched to the correct gold set. More formally, let $G = \{G_1, G_2, ..., G_n\}$ be a gold clustering and $C = \{C_1, C_2, ..., C_m\}$ be a proposed clustering. Then

$$purity(C, G) = \frac{1}{N} \sum_{i=1}^{m} max_j |G_j \cap C_i|$$

where N is the total number of words. The tradeoff between the number of found sets and cluster purity gives a good idea of the performance of a cognate clustering. For example, both of the *MaxRecall* and *MaxPrecision* strategies mentioned above would obtain 100% scores according to one of the measures, but close to 0% according to the other.

4.4 Cognate Clustering Results

In our main experiment, we apply our system to the task of creating cognate sets from the Algonquian dataset. The general classification model is trained on the POLLEX dataset, as described in Section 4.2, while the language-specific models are derived following the procedure described in Section 3.2. The scores from both models are then used to guide the clustering process. Only one word from each language is allowed per cluster.

Since most work done in the area of cognate clustering starts from semantically aligned word lists, it is difficult to make a direct comparison. We report the results obtained with LEXSTAT (List and Moran, 2013).[4] The system has no capability to consider the degree of semantic similarity between words, so we first group together the words that have identical definitions and provide these as its input. As a baseline, we adopt the heuristic described in Section 3.2, which creates sets from words that have identical definitions and start with the same letter.

System	Found Sets	Purity
Heuristic Baseline	18.9 (9.9)	96.4
LEXSTAT	19.6 (10.5)	97.1
SemaPhoR	**63.1 (48.2)**	**70.3**

Table 3: Cognate clustering results on the Algonquian dataset (in %). The absolute percentage of fully found sets is given in parentheses.

Table 3 shows the results. LEXSTAT performs slightly better than the heuristic baseline, but both are limited by their inability to relate words that have non-identical definitions. In fact, only 21.4% of all gold cognate sets in the Algonquian dataset contain at least two words with the same definition, which establishes an upper bound on the number of found sets for systems that are designed to operate on word lists, rather than dictionaries. For example, most of the cognates in Figure 1 cannot be captured by such systems.

Our system, SemaPhoR, finds approximately three times as many cognate sets as LEXSTAT, and over 75% of those sets are complete with respect to the gold annotation. In practical terms, our system is able to provide concrete evidence for the existence of most of the proto-words that have reflexes in the recorded languages, and identifies the majority of those reflexes in the process. The purity of the produced clusters indicates that there are many more hits than misses in the system output. In addition, the clusters can be sorted according to their confidence scores, in order to facilitate the analysis of the results by an expert linguist.

5 Discussion

In this section, we interpret the results of our feature ablation experiments, and analyze several types of errors made by our system.

5.1 Feature Ablation

In order to determine the relative effect of the features described in Section 3.1, we test four variants of the general model, which employ increasingly complex subsets of features. The simplest variant uses only the phonetic features that are defined on the word forms. The next variant adds the features that consider surface definition resemblance. The third variant also includes WordNet-based semantic features. The final variant is the full system configuration that incorporates the features defined on word vector representations, but without language-specific models.

Table 4 shows the results. The phonetic features alone are sufficient to detect just over half of the cognate sets. Each successive variant substantially improves the recall at a cost of slightly lower precision. The full feature set yields a 27% relative increase in the number of found sets over

[4] *http://lingpy.org*

Features	Found Sets	Purity
Phonetic only	52.0 (36.3)	70.2
+ Definitions	57.4 (41.7)	68.4
+ WordNet	61.9 (46.9)	68.1
+ Word Vectors	66.2 (51.3)	66.5

Table 4: Cognate clustering results on the Algonquian dataset (in %) with subsets of features.

the phonetic-only variant, with only a 5% drop in cluster purity.

In comparison with our full system, which incorporates the language-specific models, the final variant finds a greater number of the cognate sets, but with a trade-off in overall precision (c.f. *SemaPhoR* in Table 3). This shows that our system is able to exploit regular sound correspondences to filter out a substantial number of false cognates, such as lexical borrowings or chance resemblances. However, the overall contribution of the specific models is relatively small. One possible explanation is that the Algonquian languages are relatively closely related, which enables the general model to discern most of the cognate relationships on the basis of phonetic and semantic similarity. For example, many of the regular correspondences detected by the specific models, such as *s:s* and *hk:kk*, involve identical phonemes. The impact of the specific models could be greater for a more distantly-related language family.

5.2 Error Analysis

A number of omission errors can be traced to the imperfect heuristic that constrains the positive training instances for the language-specific models to begin with the same letter. Indeed, 88.1% of Algonquian cognate sets are composed of words that share the initial phoneme. While this constraint yields high-precision training sets that satisfy the transitivity condition, it also introduces a bias against cognates that differ in the first letter.

The second type of errors made by our system are caused by semantic drift that has altered the meaning of the original proto-word. For example, “sickness” is difficult for our general model to associate with “bitterness, pain.” On the other hand, there are many instances where our system is successful in identifying non-obvious semantic similarity, often thanks to the word vector features of our model. Table 5 provides examples of cognates found by our system that would have been very difficult to identify without word vector technology.

C	maːyaːčiteːheːw	he is angry
M	mianaːčetæhæːw	he is nauseated
C	piːsisiw	he is in bits
O	piːssisi	he is ground up
C	ayiwiskaweːw	he is taller than someone else
O	aniwiškaw	precede, surpass someone
C	siːkaːwiw	he is in mourning
M	seːkawew	she is widowed

Table 5: Examples of cognates found with the assistance of word vector features.

A substantial number of apparent errors made by our system are due to the complex polysynthetic morphology of Algonquian, in which a single Algonquian word can express a meaning of several English words. A number of distinct cognate sets are highly similar in their definitions and phonetic forms. For example, our system erroneously places the Menominee word *aːkuaqtæːhsen* into a cluster with two similar Cree and Ojibwa words, instead of associating it with the Ojibwa word *aːkawaːtteːššin* (Table 6). Although it could be argued that such closely-related forms are all cognate, we refrain from modifying any gold annotations, even if this negatively impacts the overall accuracy of our system.

C	aːkawaːsteːsimoːw	he lies down in the shade
O	aːkawaːtteːššimoːn	be in the shadow
M	**aːkuaqtæːhsen**	**he is in the shade**
O	aːkawaːtteːššin	make shadow

Table 6: A clustering error due to morphology.

Finally, some apparent errors made by our system may not be errors at all, but rather reflect the incompleteness of the gold annotation. For example, consider the two false positive pairs in Table 7. Even though they are not listed in Hewson’s (1993) etymological dictionary, the exact definition match, coupled with striking phonetic similarity and the presence of regular sound correspondences strongly suggest that they are actually cognates.

M	pekuač	growing wild
O	pekwači	growing wild
C	nisoːteːw	twin
O	niːšoːteːnq	twin

Table 7: Examples of proposed cognate sets that are not found in the gold data.

6 Conclusion

We have presented a comprehensive system for the novel task of identifying cognate sets directly from dictionaries of related languages by leveraging both word forms and word definitions. To the best of our knowledge, it is the first system to use word vector representations for cognate identification. The main insight from our work is that a cognate classification model can be trained on one language family, and achieve impressive results when classifying a completely unrelated language family. This allows cognate information from a high-resource language family to guide cognate identification between languages that little is known about.

There are aspects of cognate identification that can only be detected by human experts, such as cognates that have undergone extensive phonetic and semantic changes, or large-scale lexical borrowing between languages. However, we believe that our system represents a step towards automated cognate identification, and will prove a useful tool for historical linguists.

Acknowledgments

We thank the following students that contributed to our cognate-related projects over the last few years (in alphabetical order): Matthew Darling, Jacob Denson, Philip Dilts, Bradley Hauer, Mildred Lau, Tyler Lazar, Garrett Nicolai, Dylan Stankievech, Nicholas Tam, and Cindy Xiao. Learning Language Representations for Typology Prediction

Chaitanya Malaviya and **Graham Neubig** and **Patrick Littell**

Abstract

One central mystery of neural NLP is what neural models "know" about their subject matter. When a neural machine translation system learns to translate from one language to another, does it learn the syntax or semantics of the languages? Can this knowledge be extracted from the system to fill holes in human scientific knowledge? Existing typological databases contain relatively full feature specifications for only a few hundred languages. Exploiting the existence of parallel texts in more than a thousand languages, we build a massive many-to-one neural machine translation (NMT) system from 1017 languages into English, and use this to predict information missing from typological databases. Experiments show that the proposed method is able to infer not only syntactic, but also phonological and phonetic inventory features, and improves over a baseline that has access to information about the languages' geographic and phylogenetic neighbors.[1]

1 Introduction

Linguistic typology is the classification of human languages according to syntactic, phonological, and other classes of features, and the investigation of the relationships and correlations between these classes/features. This study has been a scientific pursuit in its own right since the 19th century (Greenberg, 1963; Comrie, 1989; Nichols, 1992), but recently typology has borne practical fruit within various subfields of NLP, particularly on problems involving lower-resource languages.

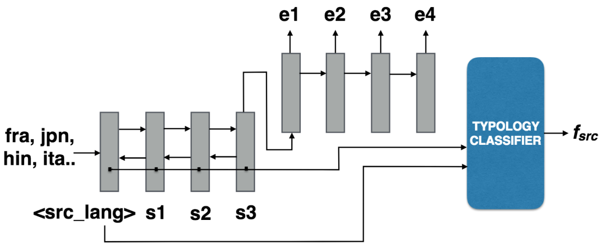

Figure 1: Learning representations from multilingual neural MT for typology classification. (Model MTBOTH)

Typological information from sources like the World Atlas of Language Structures (WALS) (Dryer and Haspelmath, 2013), has proven useful in many NLP tasks (O'Horan et al., 2016), such as multilingual dependency parsing (Ammar et al., 2016), generative parsing in low-resource settings (Naseem et al., 2012; Täckström et al., 2013), phonological language modeling and loanword prediction (Tsvetkov et al., 2016), POS-tagging (Zhang et al., 2012), and machine translation (Daiber et al., 2016).

However, the needs of NLP tasks differ in many ways from the needs of scientific typology, and typological databases are often only sparsely populated, by necessity or by design.[2] In NLP, on the other hand, what is important is having a relatively full set of features for the particular group of languages you are working on. This mismatch of needs has motivated various proposals to reconstruct missing entries, in WALS and other databases, from known entries (Daumé III and Campbell, 2007; Daumé III, 2009; Coke et al., 2016; Littell et al., 2017).

In this study, we examine whether we can

[1] Code and learned vectors are available at http://github.com/chaitanyamalaviya/lang-reps

[2] For example, each chapter of WALS aims to provide a statistically balanced set of languages over language families and geographical areas, and so many languages are left out in order to maintain balance.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2529–2535

tackle the problem of inferring linguistic typology from parallel corpora, specifically by training a massively multi-lingual neural machine translation (NMT) system and using the learned representations to infer typological features for each language. This is motivated both by prior work in linguistics (Bugarski, 1991; García, 2002) demonstrating strong links between translation studies and tools for contrastive linguistic analysis, work in inferring typology from bilingual data (Östling, 2015) and English as Second Language texts (Berzak et al., 2014), as well as work in NLP (Shi et al., 2016; Kuncoro et al., 2017; Belinkov et al., 2017) showing that syntactic knowledge can be extracted from neural nets on the word-by-word or sentence-by-sentence level. This work presents a more holistic analysis of whether we can discover what neural networks learn about the linguistic concepts of an entire language by aggregating their representations over a large number of the sentences in the language.

We examine several methods for discovering feature vectors for typology prediction, including those learning a language vector specifying the language while training multilingual neural language models (Östling and Tiedemann, 2017) or neural machine translation (Johnson et al., 2016) systems. We further propose a novel method for aggregating the values of the latent state of the encoder neural network to a single vector representing the entire language. We calculate these feature vectors using an NMT model trained on 1017 languages, and use them for typlogy prediction both on their own and in composite with feature vectors from previous work based on the genetic and geographic distance between languages (Littell et al., 2017). Results show that the extracted representations do in fact allow us to learn about the typology of languages, with particular gains for syntactic features like word order and the presence of case markers.

2 Dataset and Experimental Setup

Typology Database: To perform our analysis, we use the URIEL language typology database (Littell et al., 2017), which is a collection of binary features extracted from multiple typological, phylogenetic, and geographical databases such as WALS (World Atlas of Language Structures) (Collins and Kayne, 2011), PHOIBLE (Moran et al., 2014), Ethnologue (Lewis et al., 2015), and Glottolog (Hammarström et al., 2015). These features are divided into separate classes regarding syntax (e.g. whether a language has prepositions or postpositions), phonology (e.g. whether a language has complex syllabic onset clusters), and phonetic inventory (e.g. whether a language has interdental fricatives). There are 103 syntactical features, 28 phonology features and 158 phonetic inventory features in the database.

Baseline Feature Vectors: Several previous methods take advantage of typological implicature, the fact that some typological traits correlate strongly with others, to use known features of a language to help infer other unknown features of the language (Daumé III and Campbell, 2007; Takamura et al., 2016; Coke et al., 2016). As an alternative that does not necessarily require pre-existing knowledge of the typological features in the language at hand, Littell et al. (2017) have proposed a method for inferring typological features directly from the language's k nearest neighbors (k-NN) according to geodesic distance (distance on the Earth's surface) and genetic distance (distance according to a phylogenetic family tree). In our experiments, our baseline uses this method by taking the 3-NN for each language according to normalized geodesic+genetic distance, and calculating an average feature vector of these three neighbors.

Typology Prediction: To perform prediction, we trained a logistic regression classifier[3] with the baseline k-NN feature vectors described above and the proposed NMT feature vectors described in the next section. We train individual classifiers for predicting each typological feature in a class (syntax etc). We performed 10-fold cross-validation over the URIEL database, where we train on 9/10 of the languages to predict 1/10 of the languages for 10 folds over the data.

3 Learning Representations for Typology Prediction

In this section we describe three methods for learning representations for typology prediction with multilingual neural models.

LM Language Vector Several methods have been proposed to learn multilingual language

[3] We experimented with a non-linear classifier as well, but the logistic regression classifier performed better.

models (LMs) that utilize vector representations of languages (Tsvetkov et al., 2016; Östling and Tiedemann, 2017). Specifically, these models train a recurrent neural network LM (RNNLM; Mikolov et al. (2010)) using long short-term memory (LSTM; Hochreiter and Schmidhuber (1997)) with an additional vector representing the current language as an input. The expectation is that this vector will be able to capture the features of the language and improve LM accuracy. Östling and Tiedemann (2017) noted that, intriguingly, agglomerative clustering of these language vectors results in something that looks roughly like a phylogenetic tree, but stopped short of performing typological inference. We train this vector by appending a special token representing the source language (e.g. "⟨fra⟩" for French) to the beginning of the source sentence, as shown in Fig. 1, then using the word representation learned for this token as a representation of the language. We will call this first set of feature vectors LMVec, and examine their utility for typology prediction.

NMT Language Vector In our second set of feature vectors, MTVec, we similarly use a language embedding vector, but instead learn a multilingual neural MT model trained to translate from many languages to English, in a similar fashion to Johnson et al. (2016); Ha et al. (2016). In contrast to LMVec, we hypothesize that the alignments to an identical sentence in English, the model will have a stronger signal allowing it to more accurately learn vectors that reflect the syntactic, phonetic, or semantic consistencies of various languages. This has been demonstrated to some extent in previous work that has used specifically engineered alignment-based models (Lewis and Xia, 2008; Östling, 2015; Coke et al., 2016), and we examine whether these results apply to neural network feature extractors and expand beyond word order and syntax to other types of typology as well.

NMT Encoder Mean Cell States Finally, we propose a new vector representation of a language (MTCell) that has not been investigated in previous work: the average hidden cell state of the encoder LSTM for all sentences in the language. Inspired by previous work that has noted that the hidden cells of LSTMs can automatically capture salient and interpretable information such as syntax (Karpathy et al., 2015; Shi et al., 2016) or sentiment (Radford et al., 2017), we expect that the cell states will represent features that may be linked to the typology of the language. To create vectors for each language using LSTM hidden states, we obtain the mean of cell states ($\boldsymbol{c}$ in the standard LSTM equations) for all time steps of all sentences in each language.[4]

	Syntax		Phonology		Inventory	
	-Aux	+Aux	-Aux	+Aux	-Aux	+Aux
None	69.91	83.07	77.92	86.59	85.17	90.68
LMVec	71.32	82.94	80.80	86.74	87.51	89.94
MTVec	74.90	83.31	82.41	87.64	89.62	90.94
MTCell	75.91	85.14	84.33	88.80	90.01	90.85
MTBoth	**77.11**	**86.33**	**85.77**	**89.04**	**90.06**	**91.03**

Table 1: Accuracy of syntactic, phonological, and inventory features using LM language vectors (LMVec), MT language vectors (MTVec), MT encoder cell averages (MTCell) or both MT feature vectors (MTBoth). Aux indicates auxiliary information of geodesic/genetic nearest neighbors; "None -Aux" is the majority class chance rate, while "None +Aux" is a 3-NN classification.

4 Experiments

4.1 Multilingual Data and Training Regimen

To train a multilingual neural machine translation system, we used a corpus of Bible translations that was obtained by scraping a massive online Bible database at `bible.com`.[5] This corpus contains data for 1017 languages. After preprocessing the corpus, we obtained a training set of 20.6 million sentences over all languages.

The implementation of both the LM and NMT models described in §3 was done in the DyNet toolkit (Neubig et al., 2017). In order to obtain a manageable shared vocabulary for all languages, we divided the data into subwords using joint byte-pair encoding of all languages (Sennrich et al., 2016) with 32K merge operations. We

[4] We also tried using the mean of final hidden cell states of the encoder LSTM, but the mean cell state over all words in the sentence gave improved performance. Additionally, we tried using the hidden states $\boldsymbol{h}$, but we found that these had significantly less information and lesser variance, due to being modulated by the output gate at each time step.

[5] A possible concern is that Bible translations may use archaic language not representative of modern usage. However, an inspection of the data did not turn up such archaisms, likely because the bulk of world Bible translation was done in the late 19th and 20th centuries. In addition, languages that do have antique Bibles are also those with many other Bible translations, so the effect of the archaisms is likely limited.

used LSTM cells in a single recurrent layer with 512-dimensional hidden state and input embedding size. The Adam optimizer was used with a learning rate of 0.001 and a dropout of 0.5 was enforced during training.

4.2 Results and Discussion

The results of the experiments can be found in Tab. 1. First, focusing on the “-Aux” results, we can see that all feature vectors obtained by the neural models improve over the chance rate, demonstrating that indeed it is possible to extract information about linguistic typology from unsupervised neural models. Comparing LMVEC to MTVEC, we can see a convincing improvement of 2-3% across the board, indicating that the use of bilingual information does indeed provide a stronger signal, allowing the network to extract more salient features. Next, we can see that MTCELL further outperforms MTVEC, indicating that the proposed method of investigating the hidden cell dynamics is more effective than using a statically learned language vector. Finally, combining both feature vectors as MTBOTH leads to further improvements. To measure statistical significance of the results, we performed a paired bootstrap test to measure the gain between NONE+AUX and MTBOTH+AUX and found that the gains for syntax and inventory were significant (p=0.05), but phonology was not, perhaps because the number of phonological features was fewer than the other classes (only 28).

When further using the geodesic/genetic distance neighbor feature vectors, we can see that these trends largely hold although gains are much smaller, indicating that the proposed method is still useful in the case where we have a-priori knowledge about the environment in which the language exists. It should be noted, however, that the gains of LMVEC evaporate, indicating that access to aligned data may be essential when inferring the typology of a new language. We also noted that the accuracies of certain features decreased from NONE-AUX to MTBOTH-AUX, particularly gender markers, case suffix and negative affix, but these decreases were to a lesser extent in magnitude than the improvements.

Feature	NONE	MT	Gain
S_NUMERAL_AFTER_NOUN	37.40	81.26	43.86
S_NUMERAL_BEFORE_NOUN	46.49	83.22	36.73

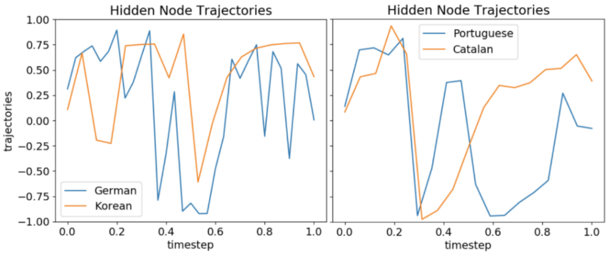
I_VOICELESS_PALATAL_FRICATIVE	82.41	93.66	11.25

Table 2: Top 5 improvements from “NONE -Aux” to “MTBOTH -Aux” in the syntax (“S_”), phonology (“P_”), and inventory (“I_”) classes.



GER: Ich bin das A und das O , der Anfang und das Ende , spricht Gott der HERR , der da ist und der da war und der da kommt , der Allmächtige .

KOR: 지금도 계시고 전에도 계셨고 앞으로 오실 전능하신 주 하나님께서 “ 나는 알파요 오메가다 ” 하고 말씀하십니다 .

POR: Paulo , chamado para ser apóstolo de Cristo Jesus pela vontade de Deus , e o irmão Sóstenes

CAT: Pau , cridat per voler de Déu a ser apòstol de Jesucrist , i el germà Sòstenes

Figure 2: Cell trajectories for sentences in languages where S_OBJ_BEFORE_VERB is either active or inactive.

Interestingly, and in contrast to previous methods for inferring typology from raw text, which have been specifically designed for inducing word order or other syntactic features (Lewis and Xia, 2008; Östling, 2015; Coke et al., 2016), our proposed method is also able to infer information about phonological or phonetic inventory features. This may seem surprising or even counterintuitive, but a look at the most-improved phonology/inventory features (Tab. 2) shows a number of features in which languages with the “non-default” option (e.g. having uvular consonants or initial velar nasals, *not* having lateral consonants, etc.) are concentrated in particular geographical regions. For example, uvular consonants are not common world-wide, but are common in particular geographic regions like the North American Pacific Northwest and the Caucasus (Maddieson, 2013b), while initial velar nasals are common in Southeast Asia (Anderson, 2013), and lateral consonants are *uncommon* in the Amazon Basin (Maddieson, 2013a). Since these are also regions with a particular and sometimes distinct syntactic character, we think the model may be finding regional clusters through syntax, and seeing an improvement in regionally-distinctive phonology/inventory features as a side effect.

Finally, given that MTCELL uses the feature vectors of the latent cell state to predict typology, it is of interest to observe how these latent cells behave for typologically different languages. In Fig. 2 we examine the node that contributed most to the prediction of "S_OBJ_BEFORE_VERB" (the node with maximum weight in the classifier) for German and Korean, where the feature is active, and Portuguese and Catalan, where the feature is inactive. We can see that the node trajectories closely track each other (particularly at the beginning of the sentence) for Portuguese and Catalan, and in general the languages where objects precede verbs have higher average values, which would be expressed by our mean cell state features. The similar trends for languages that share the value for a typological feature (S_OBJ_BEFORE_VERB) indicate that information stored in the selected hidden node is consistent across languages with similar structures.

5 Conclusion and Future Work

Through this study, we have shown that neural models can learn a range of linguistic concepts, and may be used to impute missing features in typological databases. In particular, we have demonstrated the utility of learning representations with parallel text, and results hinted at the importance of modeling the dynamics of the representation as models process sentences. We hope that this study will encourage additional use of typological features in downstream NLP tasks, and inspire further techniques for missing knowledge prediction in under-documented languages.

Cheap Translation for Cross-Lingual Named Entity Recognition

Abstract

Recent work in NLP has attempted to deal with low-resource languages but still assumed a resource level that is not present for most languages, e.g., the availability of Wikipedia in the target language. We propose a simple method for cross-lingual named entity recognition (NER) that works well in settings with *very* minimal resources. Our approach makes use of a lexicon to "translate" annotated data available in one or several high resource language(s) into the target language, and learns a standard monolingual NER model there. Further, when Wikipedia is available in the target language, our method can enhance Wikipedia based methods to yield state-of-the-art NER results; we evaluate on 7 diverse languages, improving the state-of-the-art by an average of 5.5% F1 points. With the minimal resources required, this is an extremely portable cross-lingual NER approach, as illustrated using a truly low-resource language, Uyghur.

1 Introduction

In recent years, interest in the natural language processing (NLP) community has expanded to include multilingual applications. Although this uptick of interest has produced diverse annotated corpora, most languages are still classified as low-resource. In order to build NLP tools for low-resource languages, we either need to annotate data (a costly exercise, especially for languages with few native speakers), or find a way to use annotated data in other languages in service to the cause. We refer to the latter techniques as cross-lingual techniques.

In this paper, we address cross-lingual named entity recognition (NER). Prior methods (described in detail in Section 2) depend heavily on limited and expensive resources such as Wikipedia or large parallel text. Concretely, there are about 3800 written languages in the world.[1] Wikipedia exists in about 280 languages, but most versions are too sparse to be useful. Parallel text may be found on an ad-hoc basis for some languages, but it is hardly a general solution. Religious texts, such as the Bible and the Koran, exist in many languages, but the unique domain makes them hard to use. This leaves the vast majority of the world's languages with no general method for NER.

	German	Spanish	Dutch	Avg
Baseline	22.61	45.77	43.10	37.27
Previous SOA	48.12	60.55	61.56	56.74
Cheap Translation	57.53	65.18	66.50	62.65

Table 1: We show dramatic improvement on 3 European languages in a low-resource setting. More detailed results in Table 2 show that this improvement continues to a wide variety of languages. The baseline is a simple direct transfer model. The previous state-of-the-art (SOA) is Tsai et al. (2016)

We propose a simple solution that requires only minimal resources. We translate annotated data in a high-resource language into a low-resource language, using just a lexicon.[2] We refer to this as *cheap translation*, because in general, lexicons are much cheaper and easier to find than parallel text (Mausam et al., 2010).

One of the biggest efforts at gathering lexicons is Panlex (Kamholz et al., 2014), which has lexicons for 10,000 language varieties available to download today. The quality and size of these dic-

[1] https://www.ethnologue.com/enterprise-faq/how-many-languages-world-are-unwritten-0

[2] We use the terms 'lexicon' and 'dictionary' interchangeably.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2536–2545
Copenhagen, Denmark, September 7–11, 2017.

tionaries may vary, but in Section 5.3 we showed that even small dictionaries can give improvements. If there is no dictionary, or if the quality is poor, then the Uyghur case study outlined in Section 6 suggests that effort is best spent in developing a high-quality dictionary, rather than gathering questionable-quality parallel text.

We show that our approach gives non-trivial scores across several languages, and when combined with orthogonal features from Wikipedia, improves on state-of-the-art scores. Table 1 compares a simple direct transfer baseline, the previous state-of-the-art in cross-lingual NER, and our proposed algorithm. For these languages, we beat the baseline by 25.4 points, and the state-of-the-art by 5.9 points. In addition, we found that translating from a language related to the target language gives a further boost. We conclude with a case study of a truly low-resource language, Uyghur, and show a good score, despite having almost no target language resources.

2 Related Work

There are two main branches of work in cross-lingual NLP: projection across parallel data, and language independent methods.

2.1 Projection

Projection methods take a parallel corpus between source and target languages, annotate the source side, and push annotations across learned alignment edges. Assuming that source side annotations are of high quality, success depends largely on the quality of the alignments, which depends, in turn, on the size of the parallel data.

There is work on projection for POS tagging (Yarowsky et al., 2001; Das and Petrov, 2011; Duong et al., 2014), NER (Wang and Manning, 2014; Kim et al., 2012; Ehrmann et al., 2011; Ni and Florian, 2016), mention detection (Zitouni and Florian, 2008), and parsing (Hwa et al., 2005; McDonald et al., 2011).

For NER, the received wisdom is that parallel projection methods work very well, although there is no consensus on the necessary size of the parallel corpus. Most approaches require millions of sentences, with a few exceptions which require thousands. Accordingly, the drawback to this approach is the difficulty of finding any parallel data, let alone millions of sentences. Religious texts (such as the Bible and the Koran) exist in a large number of languages, but the domain is too far removed from typical target domains (such as newswire) to be useful. As a simple example, the Bible contains almost no entities tagged as 'organization'. We approach the problem with the assumption that little to no parallel data is available.

2.2 Language Independent

The second common tool for cross-lingual NLP is to use language independent features. This is often called direct transfer, in the sense that a model is trained on one language and then applied without modification on a dataset in a different language. Lexical or lexical-derived features are typically not used unless there is significant vocabulary overlap between languages.

Täckström et al. (2012) experiments with direct transfer of dependency parsing and NER, and showed that using word cluster features can help, especially if the clusters are forced to conform across languages. The cross-lingual word clusters were induced using large parallel corpora.

Building on this work, Täckström (2012) focuses solely on NER, and includes experiments on self-training and multi-source transfer for NER.

Tsai and Roth (2016) link words and phrases to entries in Wikipedia and use page categories as features. They showed that these wikifier features are strong language independent features. We build on this work, and use these features in our experiments.

Bharadwaj et al. (2016) build a transfer model using phonetic features instead of lexical features. These features are not strictly language-independent, but can work well when languages share vocabulary but with spelling variations, as in the case of Turkish, Uzbek, and Uyghur.

2.3 Others

In a technique similar to ours, Carreras et al. (2003) use Spanish resources for Catalan NER. They translate the features in the weight vector, which has the flavor of a language independent model with the lexical features of a projection model. Our work is a natural extension of this paper, but explores these techniques on many more languages, showing that with some modifications, it has a broad applicability. Further, we experiment with orthogonal features, and with combining multiple source languages to get state of the art results on standard datasets.

Irvine and Callison-Burch (2016) build a machine translation system for low-resource languages by inducing bilingual dictionaries from monolingual texts.

Koehn and Knight (2001) experiment with varying knowledge levels on the task of translating German nouns in a small parallel German-English corpus. A lexicon along with monolingual text can correctly translate 79% of the nouns in the evaluation set. They reach a score of 89% when a parallel corpus is available along with a lexicon, but also comment on the scarcity of parallel corpora.

The main takeaways from the viewpoint of our work are a) word level translation can be effective, at least for nouns, and b) obtaining the correct word pair is more difficult than choosing between a set of options.

3 Our method: Cheap Translation

We create target language training data by translating source data into the target language. It is effectively the same as standard phrase-based statistical machine translation systems (such as MOSES (Koehn et al., 2007)), except that the translation table is not induced from expensive parallel text, but is built from a lexicon, hence the name *cheap translation*.

The entries in our lexicon contain word-to-word translations, as well as word-to-phrase, phrase-to-word, and phrase-to-phrase translations. Entries typically do not have any further information, such as part of speech or sense disambiguation. The standard problems related to ambiguity in language apply: a source language word may have several translations, and several source language words may have the same translation.

We are mostly concerned with the problem of multiple translations of a source language word. For example, in the English-Spanish lexicon, the English word *woman* translates into about 50 different words, with meanings ranging from *woman*, to *female golfer*, to *youth*. Although all candidates might be technically correct, we are interested in the most prominent translation. To estimate this, we gathered cooccurrence counts of each source-target word pair in the lexicon. For Spanish, in the case of *woman*, the most probable translation is *mujer*, because it shows up in other contexts in the dictionary, such as *farm woman* or *young woman*, whereas translations such as *joven* cooccur infrequently with *woman*. We normalize these cooccurrence counts in each candidate set, and call this the *prominence score*.

Algorithm 1 Our translation algorithm

```
Input
    $D_E$: Annotated data in $E$
    $L$: Lexicon between $E$–$F$
Returns
    $D_F$: Annotated data in $F$
for $\forall w_i \in D_E$ do
    $p = w_i w_{i+1} ... w_{i+j}$        ▷ Window of size $j$
    while $p$ not in $L$ and $j \geq 0$ do
        Decrement $j$
        $p = w_i w_{i+1} ... w_{i+j}$
    end while
    if $p$ in $L$ then
        if $|L[p]| > 1$ then
            resolve with LM and prominence
        end if
        $D_F$ add ($L[p]$, labels of $p$)
    else
        $D_F$ add ($w_i$, label of $w_i$)
    end if
    Increment $i$ by length of $p$
end for
```

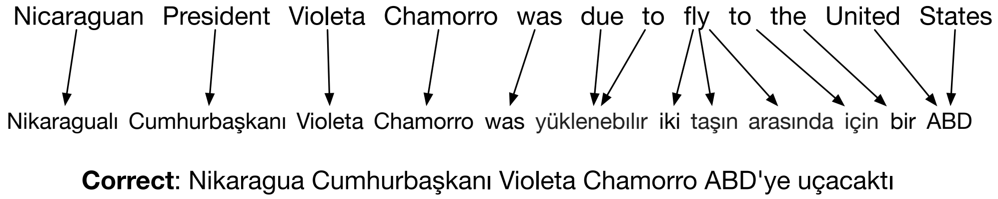
With these probabilities in hand, we have effectively constructed a phrase translation table. We use a simple greedy decoding method (as shown in Algorithm 1) where options from the lexicon are resolved by a language model multiplied by the prominence score of each option. We use SRILM (Stolcke et al., 2002) trained on Wikipedia (although any large monolingual corpus will do).

During decoding, once we have chosen a candidate, we copy all labels from the source phrase to the target phrase. Since the translation is phrase-to-phrase, we can copy gold labels directly,[3] without worrying about getting good alignments. The result is annotated data in the target language.

Notice that the algorithm allows for no reordering beyond what exists in the phrase-to-phrase entries of the lexicon. Compared to phrase-tables learned from massive parallel corpora, our lexicon-based phrase tables are not large enough or expressive enough for robust reordering. We leave explorations of reordering to future work.

See Figure 1 for a representative example of translation from English to Turkish, with a human translation as reference. There are sin-

[3] We use a standard BIO labeling scheme.



Nicaraguan President Violeta Chamorro was due to fly to the United States
Nikaraguali Cumhurbaşkanı Violeta Chamorro was yüklenebılır iki taşın arasında için bir ABD
Correct: Nikaragua Cumhurbaşkanı Violeta Chamorro ABD'ye uçacaktı

Figure 1: Demonstration of word translation. The top is English, the bottom is Turkish. Lines represent dictionary translations (e.g. *the* translates to *bir*). **Correct** is the correct translation. This illustrates congruence in named entity patterns between languages, as well as some errors we are prone to make.

gle words translated into phrases, named entities copied over verbatim, and phrases translated into single words. Some words are translated correctly (*President* into *Cumhurbaşkanı*) and some incorrectly (*fly* into *iki taşın arasında*, which loosely translates to 'between two stones'). We see ignorance of morphology (seen in translation of United States), and confused word order. But in spite of all these mistakes, the context around the entities, which is what matters for NER, is reasonably well-preserved. Notably, the word *President/Cumhurbaşkanı* is a strong context feature for both LOC (Nicaragua) and PER (Violeta Chamorro) in both languages.

4 Experimental Setup

Before we describe our experiments, we describe some of the tools we used.

4.1 Lexicons

We use lexicons provided by (Rolston and Kirchhoff, 2016), which are harvested from PanLex, Wiktionary, and various other sources. There are 103 lexicons, each mapping between English and a target language. These vary in size from 56K entries to 1.36M entries, as shown in the second row of Table 2. There are also noisy translations. Some entries consist of a single English letter, some are morphological endings, others are misspellings, others are obscure translations of metaphors, and still others are just wrong.

4.2 Datasets

We use data from CoNLL2002/2003 shared tasks (Tjong Kim Sang, 2002; Tjong Kim Sang and De Meulder, 2003). The 4 languages represented are English, German, Spanish, and Dutch. All training is on the train set, and testing is on the test set (TestB). The evaluation metric for all experiments is phrase level F1, as explained in Tjong Kim Sang (2002).

In order to experiment on a broader range of languages, we also use data from the REFLEX (Simpson et al., 2008), and LORELEI projects. From LORELEI, we use Turkish and Hausa [4] From REFLEX, we use Bengali, Tamil, and Yoruba.[5] We use the same set of test documents as used in Tsai et al. (2016).

We also use Hindi and Malayalam data from FIRE 2013,[6] pre-processed to contain only PER, ORG, and LOC tags.

While several of these languages are decidedly high-resource, we limit the resources used in order to show that our techniques will work in truly low-resource settings. In practice, this means generating training data where high-quality manually annotated data is already available, and using dictionaries where translation is available.

4.3 NER Model

In all of our work we use the Illinois NER system (Ratinov and Roth, 2009) with standard features (forms, capitalization, affixes, word prior, word after, etc.) as our base model. We train Brown clusters on the entire Wikipedia dump for any given language (again, any monolingual corpus will do), and include the multilingual gazetteers and wikifier features proposed in Tsai et al. (2016).

5 Experiments

We performed two different sets of experiments: first translating only from English, then translating from additional languages selected to be similar to the target language.

5.1 Translation from English

We start by translating from the highest resourced language in the world, English. We first show that

[4] LDC2014E115,LDC2015E70

[5] LDC2015E13,LDC2015E90,LDC2015E83, LDC2015E91

[6] http://au-kbc.org/nlp/NER-FIRE2013/

our technique gives large improvement over a simple baseline, then combine with orthogonal features, then compare against a ceiling obtained with Google Translate.

Baseline Improvement

To get the baseline, we trained a model on English CoNLL data (train set), and applied the model directly to the target language, mismatching lexical features notwithstanding. We did not use gazetteers in this approach. For the non-Latin script languages, Tamil and Bengali, we transliterated the entire English corpus into the target script. These results are in Table 2, row "Baseline".

In our approach ("Cheap Translation"), for each test language, we translated the English CoNLL data (train set) into that language. The first row of Table 2 shows the coverage of each dictionary. For example, in the case of Spanish, 90.94% of the words were translated into Spanish. This gives an average of 14.6 points F1 improvement over the baseline. This shows that simple translation is surprisingly effective across the board. The improvement is most noticeable for Bengali and Tamil, which are languages with non-Latin script. This mostly shows that the trivial baseline doesn't work across scripts, even with transliteration. Spanish shows the least improvement over the baseline, which may be because English and Spanish are so similar that the baseline is already high.

We found that we needed to normalize the Yoruba text (that is, remove all pronunciation symbols on vowels) in order to make the data less sparse. Since the training data for Bengali and Tamil never shares a script with the test data, we omit using the word surface form as a feature. This is indicated by the † in Table 2. Brown clusters, which implicitly use the word form, are still used.

Wikifier Features

Now we show that our approach is also orthogonal to other approaches, and can be combined with great effect. Wikifier features (Tsai et al., 2016) are obtained by grounding words and phrases to English Wikipedia pages, and using the categories of the linked page as NER features for the surface text. Our approach can be naturally combined with wikifier features. We show results in Table 2, in the row marked 'Cheap Translation+Wiki'.

Using wikifier features improves scores for all 7 languages. Further, for all languages we beat Tsai et al. (2016), with an average of 3.92 points F1 improvement. For the three European languages (Dutch, German, and Spanish), we have an average improvement of 4.8 points F1 over Tsai et al. (2016). This may reflect the fact that English is more closely related to European languages than Indian or African languages, in terms of lexical similarities, word order, and spellings and distribution of named entities. This suggests that it is advantageous to select a source language similar to the target language (by some definition of similar). We explore this hypothesis in Section 5.2.

Google Translate

Since we are performing translation, we compared against a high-quality translation system to get a ceiling. We used Google Translate to translate the English CoNLL training data into the target language, sentence by sentence. We aligned the source-target data using fast align (Dyer et al., 2013), and projected labels across alignments.[7] Since this is high-quality translation, we treat it as an upper bound on our technique, but with the caveat that the alignments can be noisy given the relatively small amount of text. This introduces a source of noise that is not present in our technique, but the loss from this noise is small compared to the gain from the high-quality translation. As with the other approaches, we found that Brown cluster features were an important signal.

Surprisingly, Google Translate beats our basic approach with a margin of only 4.3 points. Despite the naïvete of our approach, we are relatively close to the ceiling. Further, Google Translate is limited to 103 languages, whereas our approach is limited only by available dictionaries. In low-resource settings, such as the one presented in Section 6, Google Translate is not available, but dictionaries are available, although perhaps only by pivoting through a high-resource language.

5.2 Translation from Similar Languages

Observing that English as a source works well for European languages, but not as well for non-European languages, we form a key hypothesis: *cheap translation between similar languages should be better than between different languages.* There are several reasons for this. First, similar languages should have similar word orderings. Since we do no reordering in translation, this means the target text has a better chance of a

[7] Google Translate does not output alignments. If we had an in-house translation system, we could avoid this step.

Method	Dutch	German	Spanish	Turkish	Bengali	Tamil	Yoruba	Avg
Lexicon Coverage	88.01	89.97	90.94	83.80	83.34	73.84	74.60	–
E-L Dict size	961K	1.36M	1.25M	578K	217K	182K	334K	–
Baseline	43.10	22.61	45.77	34.63	6.40	4.60	37.70	27.83
Google Translate ceiling	65.71	56.65	53.65	45.63	37.84	29.11	39.18	46.82
Wiki (Tsai et al., 2016)	61.56	48.12	60.55	47.12	43.27	29.64	36.65	46.70
Cheap Translation	53.94	50.96	51.82	46.37	30.47†	25.91†	37.58	42.43
Cheap Translation+Wiki	63.37	57.23	64.10	51.79	46.28†	33.10†	38.52	50.62
Best Combination	64.48	57.53	65.95	48.50	31.70†	27.63†	39.12	47.84
Best Combination+Wiki	66.50	59.11	65.43	53.44	45.70†	34.90†	40.88	52.28

Table 2: Baseline is naive direct transfer, with no gazetteers. 'Cheap Translation' translates from English into the target. Google Translate translates whole sentences, and does not use gazetteers. 'Cheap Translation+Wiki' incorporates wikifier features. 'Best Combination' uses language combinations from Table 3 for source training data. † denotes that this run does not use word features.

Target	Train lang
Dutch	English, German
German	English, Dutch
Spanish	English, Dutch
Turkish	English, Uzbek
Bengali	English, Hindi
Tamil	English, Malayalam
Yoruba	English, Hausa

Table 3: This shows the language selection results. In each row, we see the target language, and the languages used for training. For example, when testing on Dutch, we train on German and English. These scores came from WALS.

coherent ordering. Second, in case of dictionary misses, vocabulary common between languages will be correct in the target language.

This requires two new resources: annotated data in a similar language S, and a lexicon that maps from S to T, the target language.

Data in other languages

For most target languages, English is not the closest language, and it is likely that there exists an annotated dataset in a closer language. There are annotated datasets available in many languages with a diversity of script and family. We have datasets annotated in about 10 different languages, although more exist.

One caveat is that the source dataset must have a matching tagset with the target dataset. At present, we accept this as a limitation, with the understanding that there is a common set of coarse-grained tags that is widely used (PER, ORG, LOC). We leave further exploration to future work.

Pivoting Lexicons

Although we cannot expect to find lexicons between all pairs of languages, we can usually expect that a language will have at least one lexicon with a high-resource language. Often that language is English. We can use this high-resource language as a pivot to transitively create an S–T dictionary, although perhaps with some loss of precision.

Assume we want a Turkish-Bengali lexicon and we have only English-Bengali and English-Turkish lexicons. We collect all English words that appear in both dictionaries. Each such English word has two sets of candidate translations, one set in Turkish, the other in Bengali. To create transitive pairs, we take the Cartesian product of these two sets of candidate translations. This will create too many entries, some of which will be incorrect, but usually the correct entry is there.

Notice also that the resulting dictionary contains only those English words that appear in both original dictionaries. If either of the original dictionaries is small, the result will be smaller still.

Source Selection and Combination

To choose a related source language, we used syntactic features of languages retrieved from the World Atlas of Language Structures (WALS) (Dryer and Haspelmath, 2013). Each language is represented as a binary vector with each index indicating presence or absence of a syntactic feature in that language. We used the feature set called *syntax_knn*, which includes 103 syntactic features, such as *subject before verb*, and *possessive suffix*, and uses k-Nearest Neighbors to predict missing values. We measure similarity as cosine distance between language vectors.

In the absence of criteria for a similarity cutoff, we chose to include only the top most similar language as source for that target language. The results of this similarity calculation are shown in Table 3. For example, when the target language is Dutch, German is the closest. We also included English in the training, as the highest resource language, and with the highest quality dictionaries.

Results

Our results are in Table 2, in the row named 'Best Combination'. The average over all languages surpasses the English-source average by 5.4 points, and also beats (Tsai et al., 2016). We also add wikifier features, and report results in row 'Best Combination+Wiki.' This shows improvement on all but Spanish, with an average improvement of 5.58 points F1 over Tsai et al. (2016). To the best of our knowledge, these are the best cross-language settings scores for all these datasets.

While these scores are lower than those seen on typical NER tasks (70-90% F1), we emphasize first that cross-lingual scores will necessarily be much lower than monolingual scores, and second that these are the best available given the setup.

5.3 Dictionary Ablation

The most expensive resource we require is a lexicon. In this section, we briefly explore what effect the size of the lexicon has on the end result. Using Turkish, we vary the size of the dictionary by randomly removing entries. The sizes vary from no entries to full dictionary (rows 'Baseline' and 'Cheap Translation' in Table 2, respectively), with several gradations in the middle. With each reduced dictionary, we translate from English to generate Turkish training data as in Section 5.1. As before, we train an NER model on the generated data, and test on the Turkish test data. Results are shown in Figure 2.

Interestingly, we see improvement over the baseline even with only 500 entries. This improvement continues until 125K entries. It is important to note that only a small number of dictionary entries – words that typically show up in the contexts of named entities, such as *president*, *university* or *town* – are likely to be useful. The larger the dictionary, the more likely these valuable entries are present. Further, our random removal process may unfairly prioritize less common words, compared to a manually compiled dictionary which would prioritize common words. It is likely that a small but carefully constructed manual dictionary could have a large impact.

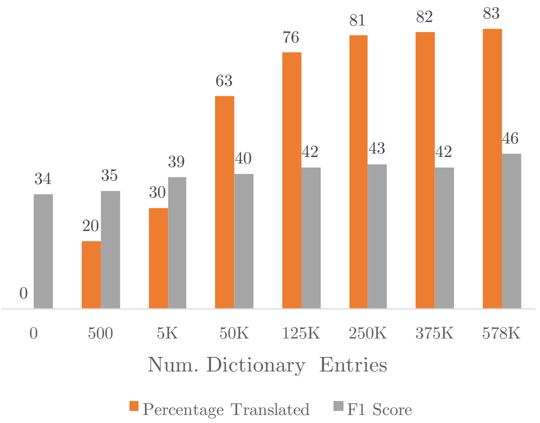


Figure 2: Effect of dictionary size on F1 score for Turkish. Each column is an experiment with a randomly reduced dictionary. The orange bars represent how much of the corpus is translated.

6 Case study: Uyghur

We have shown in the previous sections that our method is effective across a variety of languages. However, all of the tested languages have some resources, most notably, Google Translate and reasonably sized Wikipedias. In this section, we show that our methods hold up on a truly low-resource language, Uyhgur.

Uyghur is a language native to northwest China, with about 25 million speakers.[8] It is a Turkic language, and is related most closely to Uzbek, although it uses an Arabic writing system. Uyghur is not supported by Google Translate, and the Uyghur Wikipedia has less than 3,000 articles. In contrast, the smallest Wikipedia size language in our test set is Yoruba, with 30K articles. Because of the small Wikipedia size, we do not use any wikifier features.

We did this work as part of the NIST LoReHLT evaluation in the summer of 2016. The official evaluation scores were calculated over a set of 4500 Uyghur documents. Each team was given the unannotated version of those documents, with the task being to submit annotations on that set. Our official scores are reported in Table 4, and compared with Bharadwaj et al. (2016).

After the evaluation, NIST released 199 of the annotated evaluation documents, called the *unse-*

Table 5: F1 scores for Uyghur. Monolingual scores are on the 41 document test set. All other scores are on the full unsequestered data. We omit forms or gazetteers but use Brown clusters. 'Standard Translation' uses the same resources as the scores in Table 2 (e.g. without stemming)

questered set. In this section, we will drill into the various methods we used to build the transfer model, and report finer-grained results using the unsequestered set.

The following are some of the language-specific techniques we employed.

- **Dictionary** The dictionary provided for Uyghur from Rolston and Kirchhoff (2016) had only 5K entries, so we augmented this with the dictionary provided in the LORELEI evaluation, which resulted in 116K entries.

- **Name Substitution** As with Bengali and Tamil, very few names were translated. We found transliteration models were too noisy, so instead, we gathered a list of gazetteers from Uyghur Wikipedia, categorized by tag type (PER, LOC, GPE, ORG). Upon encountering an untranslatable NE, we replaced it with a randomly selected NE from the gazetteer list corresponding to the tag. This led to improbable sentences like *John Kerry has joined the Baskin Robbins*, but it meant that NEs were fluent in the target text.

- **Stemming** We created a very simple stemmer for Uyghur. This consists of 45 common suffixes sorted longest first. For each Uyghur word in a corpus, we removed all possible suffixes (Uyghur words can take multiple suffixes). We stemmed all train and test data.

We report results in Table 5. The first row is from a monolingual model trained on 158 documents in the unsequestered set, and tested on the remaining 41. All other rows test on the complete unsequestered set. The next section, 'Standard Translation', refers to the method described above. Notably, we do not use stemming for train or test data here. As with Bengali and Tamil, we omit form features.

We translate from English, Turkish, and Uzbek, which are the closest languages predicted by WALS. Next, we incorporated language specific methods. The scores we get from training on English, Turkish and Uzbek all go up because the stemming makes the features more dense. Next we generated dictionaries using observations over Uyghur and Uzbek, and we used non-native speakers to annotate Uyghur data.

6.1 Language Specific Dictionary Induction

We began by romanizing Uyghur text into the Uyghur Latin alphabet (ULY) so we could read it. We noticed that Uzbek and Uyghur are very similar, sharing a sizable amount of vocabulary, and several morphological rules. However, while there is a shared vocabulary, the words are usually spelled slightly differently. For example, the word for "southern" is "janubiy" in Uzbek and "jenubiy" in Uyghur.

We tried several ideas for gathering a mapping for this shared vocabulary: manual mapping, edit-distance mapping, and cross-lingual CCA with word vectors.

Manual mapping: We manually translated about 100 words often found around entities, such as *president*, and *university*

Edit-distance mapping: We gathered (Uyghur, Uzbek) word pairs with low-edit distance, using a modified edit-distance algorithm that allowed certain substitutions at zero cost. For example, this discovered such pairs as *pokistan-pakistan* and *telegraph-télégraf*.

Cross-lingual CCA with word vectors: We projected Uyghur and Uzbek monolingual vectors into a shared semantic space, using CCA (Faruqui and Dyer, 2014). We used the list of low edit-distance word pairs as the dictionary for the projection. Once all the vectors were in the same space, we found the closest Uyghur word to each Uzbek word.

6.2 Results

Scores are in Table 5. Interestingly, the language specific methods evaluated individually did not improve much over the generic word translation methods. But with all language specific methods combined, 'All Lang. Spec.', the score increased by nearly 10 points, suggesting that the different training data covers many angles.

To the best of our knowledge, there are no published scores on the unsequestered data set. Our best score is comparable to the score of our evaluation submission on the unsequestered dataset.

7 Conclusion

We have shown a novel cross-lingual method for generating NER data that gives significant improvement over state-of-the-art on standard datasets. The method benefits from annotated data in many languages, combines well with orthogonal features, and works even when resources are virtually nil. The simplicity and minimal use of resources makes this approach more portable than all previous approaches.

Abstract

Existing approaches to automatic VerbNet-style verb classification are heavily dependent on feature engineering and therefore limited to languages with mature NLP pipelines. In this work, we propose a novel cross-lingual transfer method for inducing VerbNets for multiple languages. To the best of our knowledge, this is the first study which demonstrates how the architectures for learning word embeddings can be applied to this challenging syntactic-semantic task. Our method uses cross-lingual translation pairs to tie each of the six target languages into a bilingual vector space with English, jointly specialising the representations to encode the relational information from English VerbNet. A standard clustering algorithm is then run on top of the VerbNet-specialised representations, using vector dimensions as features for learning verb classes. Our results show that the proposed cross-lingual transfer approach sets new state-of-the-art verb classification performance across all six target languages explored in this work.

1 Introduction

Playing a key role in conveying the meaning of a sentence, verbs are famously complex. They display a wide range of syntactic-semantic behaviour, expressing the semantics of an event as well as relational information among its participants (Jackendoff, 1972; Gruber, 1976; Levin, 1993, inter alia).

Lexical resources which capture the variability of verbs are instrumental for many Natural Language Processing (NLP) applications. One of the richest verb resources currently available for English is VerbNet (Kipper et al., 2000; Kipper, 2005).[1] Based on the work of Levin (1993), this largely hand-crafted taxonomy organises verbs into classes on the basis of their shared syntactic-semantic behaviour. Providing a useful level of generalisation for many NLP tasks, VerbNet has been used to support semantic role labelling (Swier and Stevenson, 2004; Giuglea and Moschitti, 2006), semantic parsing (Shi and Mihalcea, 2005), word sense disambiguation (Brown et al., 2011), discourse parsing (Subba and Di Eugenio, 2009), information extraction (Mausam et al., 2012), text mining applications (Lippincott et al., 2013; Rimell et al., 2013), research into human language acquisition (Korhonen, 2010), and other tasks.

This benefit for English NLP has motivated the development of VerbNets for languages such as Spanish and Catalan (Aparicio et al., 2008), Czech (Pala and Horák, 2008), and Mandarin (Liu and Chiang, 2008). However, end-to-end manual resource development using Levin's methodology is extremely time consuming, even when supported by translations of English VerbNet classes to other languages (Sun et al., 2010; Scarton et al., 2014). Approaches which aim to learn verb classes automatically offer an attractive alternative. However, existing methods rely on carefully engineered features that are extracted using sophisticated language-specific resources (Joanis et al., 2008; Sun et al., 2010; Falk et al., 2012, i.a.), ranging from accurate parsers to pre-compiled subcategorisation frames (Schulte im Walde, 2006; Li and Brew, 2008; Messiant, 2008). Such methods are limited to a small set of resource-rich languages.

It has been argued that VerbNet-style classification has a strong cross-lingual element (Jackendoff, 1992; Levin, 1993). In support of this argument, Majewska et al. (2017) have shown that English VerbNet has high translatability across different,

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2546–2558
Copenhagen, Denmark, September 7–11, 2017.

even typologically diverse languages. Based on this finding, we propose an automatic approach which exploits readily available annotations for English to facilitate efficient, large-scale development of VerbNets for a wide set of target languages.

Recently, unsupervised methods for inducing distributed word vector space representations or *word embeddings* (Mikolov et al., 2013a) have been successfully applied to a plethora of NLP tasks (Turian et al., 2010; Collobert et al., 2011; Baroni et al., 2014, i.a.). These methods offer an elegant way to learn directly from large corpora, bypassing the feature engineering step and the dependence on mature NLP pipelines (e.g., POS taggers, parsers, extraction of subcategorisation frames). In this work, we demonstrate how these models can be used to support automatic verb class induction. Moreover, we show that these models offer the means to exploit inherent cross-lingual links in VerbNet-style classification in order to guide the development of new classifications for resource-lean languages. To the best of our knowledge, this proposition has not been investigated in previous work.

There has been little work on assessing the suitability of embeddings for capturing rich syntactic-semantic phenomena. One challenge is their reliance on the distributional hypothesis (Harris, 1954), which coalesces fine-grained syntactic-semantic relations between words into a broad relation of semantic relatedness (e.g., *coffee:cup*) (Hill et al., 2015; Kiela et al., 2015). This property has an adverse effect when word embeddings are used in downstream tasks such as spoken language understanding (Kim et al., 2016a,b) or dialogue state tracking (Mrkšić et al., 2016, 2017a). It could have a similar effect on verb classification, which relies on the similarity in syntactic-semantic properties of verbs within a class. In summary, we explore three important questions in this paper:

(Q1) Given their fundamental dependence on the distributional hypothesis, to what extent can unsupervised methods for inducing vector spaces facilitate the automatic induction of VerbNet-style verb classes across different languages?

(Q2) Can one boost verb classification for lower-resource languages by exploiting general-purpose cross-lingual resources such as BabelNet (Navigli and Ponzetto, 2012; Ehrmann et al., 2014) or bilingual dictionaries such as PanLex (Kamholz et al., 2014) to construct better word vector spaces for these languages?

(Q3) Based on the stipulated cross-linguistic validity of VerbNet-style classification, can one exploit rich sets of readily available annotations in one language (e.g., the full English VerbNet) to automatically bootstrap the creation of VerbNets for other languages? In other words, is it possible to exploit a cross-lingual vector space to transfer VerbNet knowledge from a resource-rich to a resource-lean language?

To investigate Q1, we induce standard distributional vector spaces (Mikolov et al., 2013b; Levy and Goldberg, 2014) from large monolingual corpora in English and six target languages. As expected, the results obtained with this straightforward approach show positive trends, but at the same time reveal its limitations for all the languages involved. Therefore, the focus of our work shifts to Q2 and Q3. The problem of inducing VerbNet-oriented embeddings is framed as vector space specialisation using the available external resources: BabelNet or PanLex, and (English) VerbNet. Formalised as an instance of post-processing *semantic specialisation* approaches (Faruqui et al., 2015; Mrkšić et al., 2016), our procedure is steered by two sets of linguistic constraints: **1)** cross-lingual (translation) links between languages extracted from BabelNet (targeting Q2); and **2)** the available VerbNet annotations for a resource-rich language. The two sets of constraints jointly target Q3.

The main goal of vector space specialisation is to pull examples standing in desirable relations, as described by the constraints, closer together in the transformed vector space. The specialisation process can capitalise on the knowledge of VerbNet relations in the *source* language (English) by using translation pairs to transfer that knowledge to each of the *target* languages. By constructing shared bilingual vector spaces, our method facilitates the transfer of semantic relations derived from VerbNet to the vector spaces of resource-lean target languages. This idea is illustrated by Fig. 1.

Our results indicate that cross-lingual connections yield improved verb classes across all six target languages (thus answering Q2). Moreover, a consistent and significant boost in verb classification performance is achieved by propagating the VerbNet-style information from the source language (English) to any other target language (e.g., Italian, Croatian, Polish, Finnish) for which no VerbNet-style information is available during the

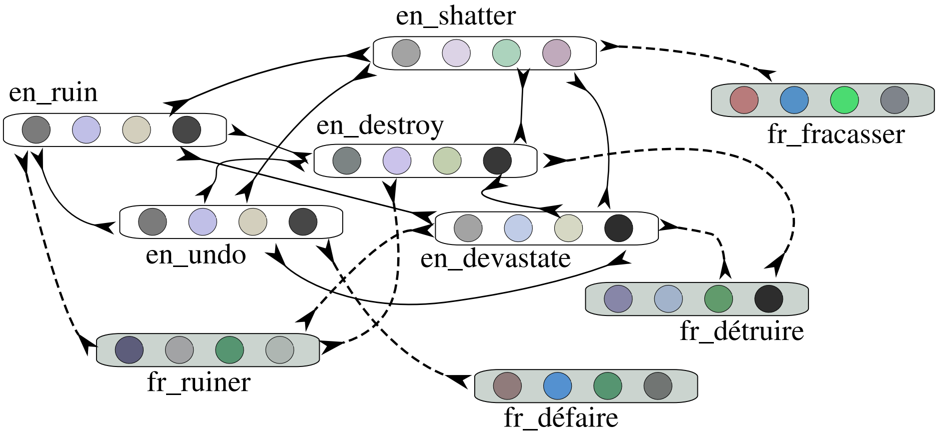

Figure 1: Transferring VerbNet information from a resource-rich to a resource-lean language through a word vector space: an *English*→ *French* toy example. Representations of words described by two types of ATTRACT constraints are pulled closer together in the joint vector space. (1) Monolingual pairwise constraints in English (e.g., *(en_ruin, en_shatter), (en_destroy, en_undo)*) reflect the EN VerbNet structure and are generated from the readily available verb classification in English (solid lines). They are used to specialise the distributional EN vector subspace for the VerbNet relation. (2) Cross-lingual English-French pairwise constraints (extracted from BabelNet) describe cross-lingual synonyms (i.e., translation links) such as *(en_ruin, fr_ruiner) or (en_shatter, fr_fracasser)* (dashed lines). The post-processing fine-tuning specialisation procedure based on (1) and (2) effectively transforms the initial distributional French vector subspace to also emphasise the VerbNet-style structure, facilitating the induction of verb classes in French.

fine-tuning process (thus answering Q3).[2] We report state-of-the-art verb classification performance for all six languages in our experiments. For instance, we improve the state-of-the-art F-1 score from prior work from 0.55 to 0.79 for French, and from 0.43 to 0.74 for Brazilian Portuguese.

2 Methodology: Specialising for VerbNet

Motivation: Verb Classes and VerbNet VerbNet is a hierarchical, domain-independent, broad-coverage verb lexicon based on Levin's classification and taxonomy of English (EN) verbs (Levin, 1993; Kipper, 2005). Verbs are grouped into classes (e.g. the class PUT-9.1 for verbs such as *place*, *position*, *insert*, and *arrange*) based on their shared meaning components and syntactic behaviour, defined in terms of their participation in *diathesis alternations*, i.e., alternating verb frames that are related with the same or similar meaning. VerbNet extends and refines Levin's classification, providing more fine-grained syntactic and semantic information for individual classes. Each VerbNet class is characterised by its member verbs, syntactic frames, semantic predicates and typical verb arguments.[3] The current version of VerbNet (v3.2) contains 8,537 distinct English verbs grouped into 273 VerbNet main classes.

The inter-relatedness of syntactic behaviour and meaning of verbs is not limited to English (Levin, 1993). The basic meaning components underlying verb classes are said to be *cross-linguistically valid* (Jackendoff, 1992; Merlo et al., 2002)[4] and therefore the classification has a strong cross-lingual dimension. A recent investigation of Majewska et al. (2017) show that it is possible to manually translate VerbNet classes and class members to different, typologically diverse languages with high accuracy.

The practical usefulness of VerbNet style classification both within and across languages has been limited by the fact that few languages boast resources similar to the English VerbNet. Some VerbNets have been developed completely manually from scratch, aiming to capture properties specific to the language in question, e.g., the resources for Spanish and Catalan (Aparicio et al., 2008),

[2] On a high level, we demonstrate that a constraints-driven fine-tuning framework can specialise word embeddings to reflect VerbNet-style relations which rely not only on verb sense similarity, but also on similarity in syntax, selectional preferences, and diathesis alternations.

[3] The usefulness of VerbNet is further accentuated by available mappings (Loper et al., 2007) to a number of other verb resources such as WordNet (Fellbaum, 1998), FrameNet (Baker et al., 1998), and PropBank (Palmer et al., 2005).

[4] For example, Levin (1993) notes that verbs in Warlpiri manifest analogous behavior to English with respect to the conative alternation. In another example, Polish verbs have the same patterns as EN verbs in terms of the middle construction.

Czech (Pala and Horák, 2008), and Mandarin (Liu and Chiang, 2008). Other VerbNets were created semi-automatically, with the help of other lexical resources, e.g., for French (Pradet et al., 2014) and Brazilian Portuguese (Scarton and Aluısio, 2012). These approaches involved substantial amounts of specialised linguistic and translation work. Finally, automatic methods have been developed, e.g., for French (Sun et al., 2010; Falk et al., 2012) and Brazilian Portuguese (Scarton et al., 2014), with insufficient accuracy (as emphasised in Sect. 4). Until now, work in this area has been limited to a small number of languages, due to the large requirements in terms of human input and/or the availability of mature NLP pipelines which exist only for a few resource-rich languages (e.g., English, German).

In this work, we propose a novel, fully automated approach for inducing VerbNets for multiple languages - one based on cross-lingual transfer. Unlike earlier approaches, our method does not require any parsed data or manual annotations for the target language. It encodes the cross-linguistic validity of Levin-style verb classifications into the vector-space specialisation framework (Sect. 2.1) driven by linguistic constraints. A standard clustering algorithm is then run on top of the VerbNet-specialised representations using vector dimensions as features to learn verb clusters (Sect. 2.2). Our approach attains state-of-the-art verb classification performance across all six target languages.

2.1 Vector Space Specialisation

Specialisation Model Our departure point is a state-of-the-art specialisation model for fine-tuning vector spaces termed PARAGRAM (Wieting et al., 2015).[5] The PARAGRAM procedure injects similarity constraints between word pairs in order to make their vector space representations more similar; we term these the ATTRACT constraints. Let $V = V_s \sqcup V_t$ be the vocabulary consisting of the source language and target language vocabularies V_s and V_t, respectively. Let C be the set of word pairs standing in desirable lexical relations; these include: **1)** verb pairs from the same VerbNet class (e.g. (*en_transport, en_transfer*) from verb class SEND-11.1); and **2)** the cross-lingual synonymy pairs (e.g. (*en_peace, fi_rauha*)). Given the initial distributional space and collections of such ATTRACT pairs C, the model gradually modifies the space to bring the designated word vectors closer together, working in mini-batches of size k. The method's cost function can be expressed as:

$$O(\mathcal{B}_C) = O_C(\mathcal{B}_C) + R(\mathcal{B}_C) \qquad (1)$$

The first term of the method's cost function (i.e., $\mathcal{O}_C$) pulls the ATTRACT examples $(x_l, x_r) \in C$ closer together (see Fig. 1 for an illustration). B_C refers to the current mini-batch of ATTRACT constraints. This term is expressed as follows:

$$\begin{aligned} O_C(\mathcal{B}_C) \;=\; \sum_{(x_l,x_r)\in\mathcal{B}_C} & \big[\, \tau\left(\delta_{att} + \mathbf{x}_l\mathbf{t}_l - \mathbf{x}_l\mathbf{x}_r\right) \\ & + \tau\left(\delta_{att} + \mathbf{x}_r\mathbf{t}_r - \mathbf{x}_l\mathbf{x}_r\right) \big] \qquad (2) \end{aligned}$$

$\tau(x) = \max(0, x)$ is the standard rectified linear unit or the hinge loss function (Tsochantaridis et al., 2004; Nair and Hinton, 2010). δ_{att} is the "attract" margin: it determines how much vectors of words from ATTRACT constraints should be closer to each other than to their negative examples. The negative example $\mathbf{t}_i$ for each word x_i in any ATTRACT pair is always the vector closest to $\mathbf{x}_i$ taken from the pairs in the current mini-batch, distinct from the other word paired with x_i, and x_i itself.[6]

The second $R(\mathcal{B}_C)$ term is the regularisation which aims to retain the semantic information encoded in the initial distributional space as long as this information does not contradict the used ATTRACT constraints. Let $\mathbf{x}_i^{init}$ refer to the initial distributional vector of the word x_i and let $\mathcal{V}(\mathcal{B}_C)$ be the set of all word vectors present in the given mini-batch. If λ_{reg} denotes the L2 regularisation constant, this term can be expressed as:

$$R(\mathcal{B}_C) = \sum_{\mathbf{x}_i \in \mathcal{V}(\mathcal{B}_C)} \lambda_{reg} \left\| \mathbf{x}_i^{init} - \mathbf{x}_i \right\|_2 \qquad (3)$$

Linguistic Constraints: Transferring VerbNet-Style Knowledge The fine-tuning procedure effectively blends the knowledge from external resources (i.e., the input ATTRACT set of constraints) with distributional information extracted directly from large corpora. We show how to propagate annotations from a knowledge source such as VerbNet from source to target by combining two types of constraints within the specialisation framework:

[5] The original PARAGRAM model as well as other fine-tuning models from prior work inject pairwise linguistic constraints into existing vector spaces in order to improve their ability to capture semantic similarity/paraphrasability. In this work, we demonstrate that the same generic specialisation framework can be used to transform vector spaces to capture other types of lexical relations such as VerbNet relations.

[6] Effectively, this term forces word pairs from the in-batch ATTRACT constraints to be closer to one another than to any other word in the current mini-batch.

LEARN-14	BREAK-45.1	ACCEPT-77
(learn, study)	(break, dissolve)	(accept, understand)
(learn, relearn)	(crash, crush)	(accept, reject)
(read, study)	(shatter, split)	(repent, rue)
(cram, relearn)	(break, rip)	(reject, discourage)
(read, assimilate)	(crack, smash)	(encourage, discourage)
(learn, assimilate)	(shred, splinter)	(reject, discourage)
(read, relearn)	(snap, tear)	(disprefer, understand)

Table 1: Example pairwise ATTRACT constraints extracted from three VerbNet classes in English.

a) cross-lingual (translation) links between languages, and **b)** available VerbNet annotations in a resource-rich language transformed into pairwise constraints. Cross-lingual constraints such as *(pl_wojna, it_guerra)* are extracted from BabelNet (Navigli and Ponzetto, 2012), a large-scale resource which groups words into cross-lingual BABEL synsets (and is currently available for 271 languages). The wide and steadily growing coverage of languages in BabelNet means that our proposed framework promises to support the transfer of VerbNet-style information to numerous target languages (with increasingly high accuracy).

To establish that the proposed transfer approach is in fact independent of the chosen cross-lingual information source, we also experiment with another cross-lingual dictionary: PanLex (Kamholz et al., 2014), which was used in prior work on cross-lingual word vector spaces (Duong et al., 2016; Adams et al., 2017). This dictionary currently covers around 1,300 language varieties with over 12 million expressions, thus offering support also for low-resource transfer settings.[7]

VerbNet constraints are extracted from the English VerbNet class structure in a straightforward manner. For each class VN_i from the 273 VerbNet classes, we simply take the set of all n_i verbs $CL_i = \{v_{1,i}, v_{2,i}, \ldots, v_{n_i,i}\}$ associated with that class, including its subclasses, and generate all unique pairs (v_k, v_l) so that $v_k, v_l \in CL_i$ and $v_k \neq v_l$. Example VerbNet pairwise constraints are shown in Tab. 1. Note that VerbNet classes in practice contain verb instances standing in a variety of lexical relations, including synonyms, antonyms, troponyms, hypernyms, and the class membership is determined on the basis of connections between the syntactic patterns and the underlying semantic relations (Kipper et al., 2006, 2008).

2.2 Clustering Algorithm

Given the initial distributional or specialised collection of target language vectors $\mathbf{V_t}$, we apply an off-the-shelf clustering algorithm on top of these vectors in order to group verbs into classes. Following prior work (Brew and Schulte im Walde, 2002; Sun and Korhonen, 2009; Sun et al., 2010), we employ the MNCut spectral clustering algorithm (Meila and Shi, 2001), which has wide applicability in similar NLP tasks which involve high-dimensional feature spaces (Chen et al., 2006; von Luxburg, 2007; Scarton et al., 2014, i.a.). Again, following prior work (Sun et al., 2010, 2013), we estimate the number of clusters K_{Clust} using the self-tuning method of Zelnik-Manor and Perona (2004). This algorithm finds the optimal number by minimising a cost function based on the eigenvector structure of the word similarity matrix. We refer the reader to the relevant literature for further details.

3 Experimental Setup

Languages We experiment with six target languages: French (FR), Brazilian Portuguese (PT), Italian (IT), Polish (PL), Croatian (HR), and Finnish (FI). All statistics regarding the source and size of training and test data, and linguistic constraints for each target language are summarised in Tab. 2.

Automatic approaches to verb class induction have been tried out in prior work for FR and PT. To the best of our knowledge, our cross-lingual study is the first aiming to generalise an automatic induction method to more languages using an underlying methodology which is language-pair independent.

Initial Vector Space: Training Data and Setup All target language vectors were trained on large monolingual running text using the same setup: 300-dimensional word vectors, the frequency cut-off set to 100, bag-of-words (BOW) contexts, and the window size of 2 (Levy and Goldberg, 2014; Schwartz et al., 2016). All tokens were lowercased, and all numbers were converted to a placeholder symbol <NUM>.[8] FR and IT word vectors were trained on the standard frWaC and itWaC corpora (Baroni et al., 2009), and vectors for other target languages were trained on the corpora of similar style and size: HR vectors were trained on the hrWaC corpus (Ljubešić and Klubička, 2014), PT

[7] Similar to BabelNet, the translations in PanLex were derived from various sources such as glossaries, dictionaries, and automatic inference from other languages. This results in a high-coverage lexicon containing a certain amount of noise.

[8] Other SGNS parameters were also set to standard values (Baroni et al., 2014; Vulić and Korhonen, 2016): 15 epochs, 15 negative samples, global learning rate: .025, subsampling rate: $1e-4$. Similar trends in results persist with $d = 100, 500$.

Table 2: Statistics of the experimental setup for each target language: training/test data and constraints. *Coverage* refers to the percentage of test verbs represented in the target language vocabularies.

vectors on ptWaC (Wagner Filho et al., 2016), FI vectors on fiWaC (Ljubešić et al., 2016), and PL vectors on the Araneum Polonicum Maius Web corpus (Benko, 2014). Note that we do not utilise any VerbNet-specific knowledge in the target language to induce and further specialise these word vectors.

Source EN vectors were taken directly from the work of Levy and Goldberg (2014): they are trained with SGNS on the cleaned and tokenised Polyglot Wikipedia (Al-Rfou et al., 2013) containing $\sim$75M sentences, $\sim$1.7B word tokens and a vocabulary of $\sim$180k words after lowercasing and frequency cut-off. To measure the importance of the starting source language space as well as to test if syntactic knowledge on the source side may be propagated to the target space, we test two variant EN vector spaces: SGNS with (a) BOW contexts and the window size 2 (SGNS-BOW2); and (b) dependency-based contexts (SGNS-DEPS) (Padó and Lapata, 2007; Levy and Goldberg, 2014).

Linguistic Constraints We experiment with the following constraint types: (a) monolingual synonymy constraints in each target language extracted from BabelNet (*Mono-Syn*); (b) cross-lingual EN-TARGET constraints from BabelNet; (c) cross-lingual EN-TARGET constraints plus EN VerbNet constraints (see Sect. 2.1 and Fig. 1). Unless stated otherwise, we use BabelNet as the default source of cross-lingual constraints for (b) and (c).

Vector Space Specialisation The PARAGRAM model's parameters are adopted directly from prior work (Wieting et al., 2015) without any additional fine-tuning: $\delta_{att} = 0.6$, $\lambda_{reg} = 10^{-9}$, $k = 50$. We train for 5 epochs without early stopping using AdaGrad (Duchi et al., 2011). PARAGRAM is in fact a special case of the more general ATTRACT-REPEL specialisation framework (Mrkšić et al., 2017b): we use this more recent and more efficient TensorFlow implementation of the model in all experiments.[9]

Test Data The development of an automatic verb classification approach requires an initial gold standard (Sun et al., 2010): these have been developed for FR (Sun et al., 2010), PT (Scarton et al., 2014), IT, PL, HR, and FI (Majewska et al., 2017). They were created using the methodology of Sun et al. (2010), based on the EN gold standard of Sun et al. (2008) which contains 17 fine-grained Levin classes with 12 member verbs each. For instance, the class PUT-9.1 in French contains verbs such as *accrocher, déposer, mettre, répartir, réintégrer*, etc.

Evaluation Measures We use standard evaluation measures from prior work on verb clustering (Ó Séaghdha and Copestake, 2008; Sun and Korhonen, 2009; Sun et al., 2010; Falk et al., 2012, i.a.). The mean *precision* of induced verb clusters labelled *modified purity* (MPUR) is computed as:

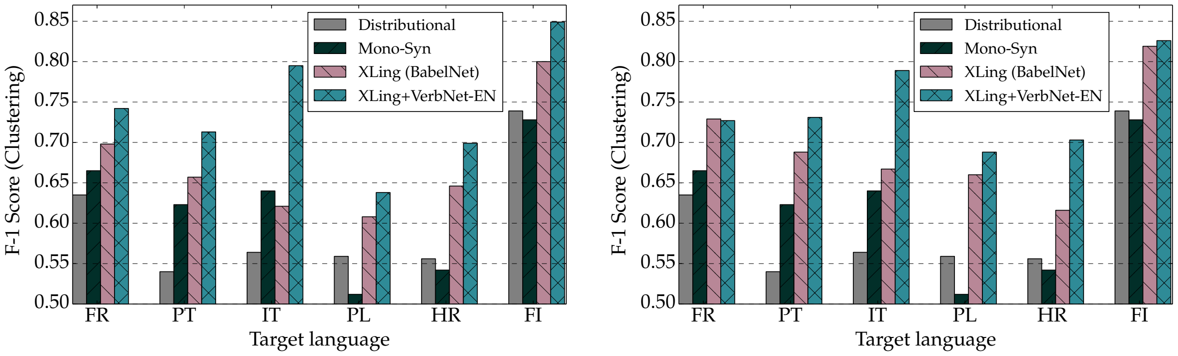
$$\text{MPUR} = \frac{\sum_{C \in \mathbf{Clust}, n_{prev(C)} > 1} n_{prev(C)}}{\#\text{test\_verbs}} \quad (4)$$

Here, each cluster C from the set of all K_{Clust} induced clusters **Clust** is associated with its prevalent class/cluster from the gold standard, and the number of verbs in an induced cluster C taking this prevalent class is labelled $n_{prev(C)}$. All other verbs not taking the prevalent class are considered errors.[10] *#test_verbs* denotes the total number of test verb instances. The second measure targeting *recall* is *weighted class accuracy* (WACC), computed as:

$$\text{WACC} = \frac{\sum_{C \in \mathbf{Gold}} n_{dom(C)}}{\#\text{test\_verbs}} \quad (5)$$

[9] https://github.com/nmrksic/attract-repel

[10] Clusters with $n_{prev(C)} = 1$ are discarded from the count to avoid an undesired bias towards singleton clusters (Sun and Korhonen, 2009; Sun et al., 2010).



(a) EN Vectors: SGNS-BOW2

(b) EN Vectors: SGNS-DEPS

Figure 2: *F-1* scores in six target languages using the post-processing specialisation procedure from Sect. 2.1 and different sets of constraints: *Distributional* refers to the initial vector space in each target language; *Mono-Syn* is the vector space tuned using monolingual synonymy constraints from BabelNet; *XLing* uses cross-lingual EN-TARGET constraints from BabelNet (TARGET refers to any of the six target languages); *XLing+VerbNet-EN* is a fine-tuned vector space which uses both cross-lingual EN-TARGET constraints plus EN VerbNet constraints. Results are provided with (a) SGNS-BOW2 and (b) SGNS-DEPS source vector space in English for the *XLing* and *XLing+VerbNet* variants, see Sect. 3.

For each cluster C from the set of gold standard clusters **Gold**, we have to find the dominant cluster from the set of induced clusters: this cluster has the most verbs in common with the gold cluster C, and that number is $n_{dom(C)}$. As measures of precision and recall, MPUR and WACC may be combined into an F-1 score, computed as the balanced harmonic mean, which we report in this work.[11]

4 Results and Discussion

Cross-Lingual Transfer Model F-1 verb classification scores for the six target languages with different sets of constraints are summarised in Fig. 2. We can draw several interesting conclusions. First, the strongest results on average are obtained with the model which transfers the VerbNet knowledge from English (as a resource-rich language) to the resource-lean target language (providing an answer to question Q3, Sect. 1). These improvements are visible across all target languages, empirically demonstrating the cross-lingual nature of VerbNet-style classifications. Second, using cross-lingual constraints alone (*XLing*) yields strong gains over initial distributional spaces (answering Q1 and Q2). Fig. 2 also shows that cross-lingual similarity constraints are more beneficial than the monolingual ones, despite a larger total number of the monolingual constraints in each language (see Tab. 2). This suggests that such cross-lingual similarity links are strong implicit indicators of class membership. Namely, target language words which map to the same source language word are likely to be synonyms and consequently end up in the same verb class in the target language. However, the cross-lingual links are even more useful as means for transferring the VerbNet knowledge, as evidenced by additional gains with *XLing+VerbNet-EN*.

The absolute classification scores are the lowest for the two Slavic languages: PL and HR. This may be partially explained by the lowest number of cross-lingual constraints for the two languages covering only a subset of their entire vocabularies (see Tab. 2 and compare the total number of constraints for HR and PL to the numbers for e.g. FI or FR). Another reason for weaker performance of these two languages could be their rich morphology, which induces data sparsity both in the initial vector space estimation and in the coverage of constraints.

State-of-the-Art A direct comparison of previous state-of-the-art classification scores available for FR (Sun et al., 2010) and PT (Scarton et al., 2014) on the same test data exemplifies the extent of improvement achieved by our transfer model. F-1 scores improve from 0.55 to 0.75 for FR and from 0.43 to 0.73 for PT. Scarton et al. (2014) explain the low performance by "the lower quality NLP tools". This issue is largely mitigated by our VerbNet transfer model, which exploits the assump-

[11] We have also experimented with V-measure (Rosenberg and Hirschberg, 2007), another standard evaluation measure which balances between homogeneity (precision) and completeness (recall); we do not report these scores for brevity as similar trends in results are observed.

Table 3: The effect of multilingual vector space specialisation. Results are reported for FR and IT using: a) cross-lingual constraints only (*XLing*); and b) the VerbNet transfer model (*XLing+VN*).

tion of cross-linguistic class consistency directly through a specialised vector space, and also avoids any reliance on target-language-specific NLP tools.

Starting Source Vector Space Fig. 2a and Fig. 2b enable a brief analysis of the influence of the starting EN vector space on the results for each target language. We observe small but consistent gains with SGNS-DEPS, which utilises syntactic information stemming from a dependency parser on the source side, over SGNS-BOW for the *XLing* variant. The improvements are +2.1 points on average, visible for 5 out of 6 target languages. We again see an increase in performance with the *XLing+VerbNet* model, but we do not observe any major difference between the two starting source spaces now: average slight score difference of 0.3 is in favour of SGNS-BOW2, which outperforms SGNS-DEPS for 3 out of 6 target languages. This finding indicates that VerbNet-based linguistic constraints are more important for the final classification performance, and mitigate the artefacts of the starting distributional source space.

Bilingual vs. Multilingual The transfer model can operate with more than two languages, effectively inducing a multilingual vector space. We analyse such multilingual training based on the results on FR and IT (Tab. 3). On average, the results with *XLing* improve with more languages (see also the results for EN in Tab. 4), as the model relies on more constraints for the vector space specialisation. Yet additional languages do not lead to clear improvements with *XLing+VerbNet*: we hypothesise that the specialisation procedure becomes dominated by cross-lingual constraints which may diminish the importance of VerbNet-based EN constraints. The language configuration in the multilingual vector space also makes a difference:

	VC:XLing	*Sim*:XLing	*Sim*:XLing+VN
EN-Dist	0.484	0.275	–
+FR	0.608	0.556	0.481
+PT	0.633	0.537	0.466
+IT	0.602	0.524	0.476
+PL	0.597	0.469	0.431
+HR	0.582	0.497	0.446
+FI	0.662	0.598	0.491
+FR+IT	0.633	0.571	0.526
+FI+FR+IT	0.641	0.635	0.558
+FR+IT+PT	0.674	0.596	0.515
EN-VN	**0.956**	–	0.358

Table 4: Comparison of verb classification (*VC*) and verb semantic similarity (*Sim*) for English. *VC* is measured on the EN test set of Sun et al. (2008). *Sim* is measured on SimVerb-3500 (Gerz et al., 2016). The scores are Spearman's ρ correlation scores. EN-Dist is the initial distributional English vector space: SGNS-BOW2; EN-VN is the same space transformed using monolingual EN VerbNet constraints only, an upper bound for the specialisation-based approach in EN.

e.g., combining PL with the Romance languages degrades the performance, while FI surprisingly boosts it slightly. For brevity, we only report the results for FR and IT. Similar trends are observed when making the transition from bilingual to multilingual vector spaces for other target languages.

Clustering Algorithm Since vector space specialisation is detached from the application of the clustering algorithm, our framework allows straightforward experimentation with other algorithms. Following prior work (Brew and Schulte im Walde, 2002; Sun et al., 2010), we also test K-means clustering. Results for the six languages using the EN SGNS-BOW2 source space and *Xling+VerbNet-EN* are on average 3.8 points lower than the ones reported in Fig. 2a. K-Means is outperformed for each target language, confirming the superiority of spectral clustering established in prior work, e.g., (Scarton et al., 2014). On the other hand, we find results with another clustering algorithm, hierarchical agglomerative clustering with Ward's linkage (Ward, 1963), on par with spectral clustering (1.4 points on average in favour of spectral, which is better on 4 out of 6 languages). We believe that further gains in verb class induction could be achieved by additional fine-tuning of the clustering algorithm.

Other Cross-Lingual Sources Replacing BabelNet with PanLex as the alternative source of cross-

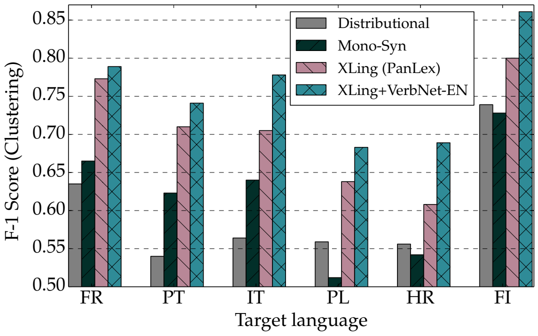

Figure 3: *F-1* scores when PanLex is used as the source of cross-lingual ATTRACT constraints (instead of BabelNet). EN Vectors: SGNS-BOW2.

lingual information again leads to large gains with the cross-lingual transfer model, as is evident from Fig. 3. This suggests that the proposed approach does not depend on a particular source of information - it can be used with any general-purpose bilingual dictionary. We mark slight improvements for 3/6 target languages when comparing the results with the ones from Fig. 2a. The new state-of-the-art F-1 scores are 0.79 for FR and 0.74 for PT.

Verb Classification vs. Semantic Similarity An interesting question originating from prior work on verb representation learning, e.g., (Baker et al., 2014) touches upon the correlation between verb classification and semantic similarity. Due to the availability of VerbNet constraints and a recent similarity evaluation set (SimVerb-3500; it contains human similarity ratings for 3,500 verb pairs) (Gerz et al., 2016), we perform the analysis on English: the results are summarised in Tab. 4. They clearly indicate that cross-lingual synonymy constraints are useful for both relationship types (compare the scores with *XLing*), with strong gains over the non-specialised distributional space. However, the inclusion of VerbNet information, while boosting classification scores for target languages and (trivially) for EN, deteriorates EN similarity scores across the board (compare *XLing+VN* against *XLing* in Tab. 4). This suggests that the VerbNet-style class membership is definitely not equivalent to pure semantic similarity captured by SimVerb.

4.1 Further Discussion and Future Work

This work has proven the potential of transferring lexical resources from resource-rich to resource-poor languages using general-purpose cross-lingual dictionaries and bilingual vector spaces as means of transfer within a semantic specialisation framework. However, we believe that the proposed basic framework may be upgraded and extended across several research paths in future work.

First, in the current work we have operated with standard single-sense/single-prototype representations, thus effectively disregarding the problem of verb polysemy. While several polysemy-aware verb classification models for English were developed recently (Kawahara et al., 2014; Peterson et al., 2016), the current lack of polysemy-aware evaluation sets in other languages impedes this line of research. Evaluation issues aside, one idea for future work is to use the ATTRACT-REPEL specialisation framework for sense-aware cross-lingual transfer relying on recently developed multi-sense/prototype word representations (Neelakantan et al., 2014; Pilehvar and Collier, 2016, inter alia).

Another challenge is to apply the idea from this work to enable cross-lingual transfer of other structured lexical resources available in English such as FrameNet (Baker et al., 1998), PropBank (Palmer et al., 2005), and VerbKB (Wijaya and Mitchell, 2016). Other potential research avenues include porting the approach to other typologically diverse languages and truly low-resource settings (e.g., with only limited amounts of parallel data), as well as experiments with other distributional spaces, e.g. (Melamud et al., 2016). Further refinements of the specialisation and clustering algorithms may also result in improved verb class induction.

5 Conclusion

We have presented a novel cross-lingual transfer model which enables the automatic induction of VerbNet-style verb classifications across multiple languages. The transfer is based on a word vector space specialisation framework, utilised to directly model the assumption of cross-linguistic validity of VerbNet-style classifications. Our results indicate strong improvements in verb classification accuracy across all six target languages explored. All automatically induced VerbNets are available at: `github.com/cambridgeltl/verbnets`.

Abstract

This paper addresses the automatic recognition of telicity, an aspectual notion. A *telic* event includes a natural endpoint (*she walked home*), while an *atelic* event does not (*she walked around*). Recognizing this difference is a prerequisite for temporal natural language understanding. In English, this classification task is difficult, as telicity is a covert linguistic category. In contrast, in Slavic languages, aspect is part of a verb's meaning and even available in machine-readable dictionaries. Our contributions are as follows. We successfully leverage additional silver standard training data in the form of projected annotations from parallel English-Czech data as well as context information, improving automatic telicity classification for English significantly compared to previous work. We also create a new data set of English texts manually annotated with telicity.

1 Introduction

This paper addresses the computational modeling of *telicity*, a linguistic feature which represents whether the event type evoked by a sentence's verb constellation (i.e., the verb and its arguments and modifiers) has a natural endpoint or not (Comrie, 1976; Smith, 1997), see (1a) and (1b).

(1) (a) Mary ate an apple. (*telic*)
(b) I gazed at the sunset. (*atelic*)

Automatic recognition of telicity is a necessary step for natural language understanding tasks that require reasoning about time, e.g., natural language generation, summarization, question answering, information extraction or machine translation (Moens and Steedman, 1988; Siegel and McKeown, 2000). For example, there is an entailment relation between English Progressive and Perfect constructions (as shown in (2)), but only for atelic verb constellations.

(2) (a) He was swimming in the lake. (*atelic*)
$\models$ He has swum in the lake.
(b) He was swimming across the lake. (*telic*)
$\not\models$ He has swum across the lake.

We model telicity at the word-sense level, corresponding to the *fundamental aspectual class* of Siegel and McKeown (2000), i.e., we take into account the verb and its arguments and modifiers, but no additional aspectual markers (such as the Progressive). In (2) we classify whether the event types "swim in the lake" and "swim across the lake" have natural endpoints. This is defined on a linguistic level rather than by world knowledge requiring inference. "Swimming in the lake" has no natural endpoint, as also shown by the linguistic test presented in (2). In contrast, "swimming across the lake" will necessarily be finished once the other side is reached.

In English, the aspectual notion of telicity is a covert category, i.e., a semantic distinction that is not expressed overtly by lexical or morphological means. As illustrated by (2) and (3), the same *verb type* (lemma) can introduce telic and atelic events to the discourse depending on the context in which it occurs.

(3) (a) John drank coffee. (*atelic*)
(b) John drank a cup of coffee. (*telic*)

In Slavic languages, aspect is a component of verb meaning. Most verb types are either *perfective* or *imperfective* (and are marked as such in dictionaries). For example, the two occurrences of "drink" in (3) are translated into Czech using the imperfective verb "pil" and the perfective verb

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2559–2565
Copenhagen, Denmark, September 7–11, 2017.

"vypil," respectively (Filip, 1994):[1]

(4) (a) Pil kávu. (*imperfective*)
He was drinking (some) coffee.
(b) Vypil kávu. (*perfective*)
He drank up (all) the coffee.

Our contributions are as follows: (1) using the English-Czech part of InterCorp (Čermák and Rosen, 2012) and a valency lexicon for Czech verbs (Žabokrtský and Lopatková, 2007), we create a large silver standard with automatically derived annotations and validate our approach by comparing the labels given by humans versus the projected labels; (2) we provide a freely available data set of English texts taken from MASC (Ide et al., 2010) manually annotated for telicity; (3) we show that using contextual features and the silver standard as additional training data improves computational modeling of telicity for English in terms of F_1 compared to previous work.

2 Related work

Siegel and McKeown (2000, henceforth SMK2000) present the first machine-learning based approach to identifying *completedness*, i.e., telicity, determining whether an event reaches a culmination or completion point at which a new state is introduced. Their approach describes each verb occurrence exclusively using features reflecting corpus-based statistics of the corresponding verb type. For each verb type, they collect the co-occurrence frequencies with 14 linguistic markers (e.g., present tense, perfect, combination with temporal adverbs) in an automatically parsed background corpus. They call these features *linguistic indicators* and train a variety of machine learning models based on 300 clauses, of which roughly 2/3 are *culminated*, i.e., telic. Their test set also contains about 300 clauses, corresponding to 204 distinct non-stative verbs. Their data sets are not available, but as this work is the most closely related to ours, we reimplement their approach and compare to it in Section 5.

Samardžić and Merlo (2016) create a model for real-world duration of events (as *short* or *long*) of English verbs as annotated in TimeBank (Pustejovsky et al., 2003). The model is informed by temporal boundedness information collected from parallel English-Serbian data. Their only features are how often the respective verb type was aligned to Serbian verbs carrying certain affixes that indicate perfectiveness or imperfectiveness. Their usage of "verb type" differs from ours as they do not lemmatize, i.e., they always predict that "falling" is a long event, while "fall" is short. Our approach shares the idea of projecting aspectual information from Slavic languages to English, but in contrast to classifying verb types, we classify whether an event type introduced by the verb constellation of a clause is telic or atelic, making use of a machine-readable dictionary for Czech instead of relying on affix information.

Loáiciga and Grisot (2016) create an automatic classifier for boundedness, defined as whether the endpoint of an event has occurred or not, and show that this is useful for picking the correct tense in French translations of the English Simple Past. Their classifier employs a similar but smaller feature set compared to ours. Other related work on predicting aspect include systems aiming at identifying lexical aspect (Siegel and McKeown, 2000; Friedrich and Palmer, 2014) or habituals (Mathew and Katz, 2009; Friedrich and Pinkal, 2015).

Cross-linguistic annotation projection approaches mostly make use of existing manually created annotations in the source language; similar to our approach, Diab and Resnik (2002) and Marasović et al. (2016) leverage properties of the source language to automatically induce annotations on the target side.

3 Data sets and annotation projection

We conduct our experiments based on two data sets: (a) English texts from MASC manually annotated for telicity, on which we train and test our computational models, and (b) a silver standard automatically extracted via annotation projection from the Czech-English part of the parallel corpus InterCorp, which we use as additional training data in order to improve our models.[2]

3.1 Gold standard: MASC (EN)

We create a new data set consisting of 10 English texts taken from MASC (Ide et al., 2010), annotated for telicity. Texts include two essays, a journal article, two blog texts, two history texts from travel guides, and three texts from the fic-

[1] In Czech, aspectual verb pairs may be related by affixes as in this example, but this is not always the case. They may even use different lexemes (Vintr, 2001).

[2] Annotations, guidelines and code available from `https://github.com/annefried/telicity`

	MASC (gold standard)	InterCorp (silver standard)	intersection
clauses (instances)	1863	457,000	-
% telic	82	55	-
% atelic	18	45	-
distinct verb types (lemmas)	567	2262	510
ambiguous verb types	70	1130	69

Table 1: Corpus statistics.

tion genre. Annotation was performed using the web-based SWAN system (Gühring et al., 2016). Annotators were given a short written manual with instructions. We model telicity for *dynamic* (*eventive*) verb occurrences because *stative* verbs (e.g., "like") do not have built-in endpoints by definition. Annotators choose one of the labels *telic* and *atelic* or they skip clauses that they consider to be stative. In a first round, each verb occurrence was labeled by three annotators (the second author of this paper plus two paid student assistants). They unanimously agreed on telicity labels for 1166 verb occurrences; these are directly used for the gold standard. Cases in which only two annotators agreed on a telicity label (the third annotator may have either disagreed or skipped the clause) are labeled by a fourth independent annotator (the first author), who did not have access to the labels of the first rounds. This second annotation round resulted in 697 further cases in which three annotators gave the same telicity label. Statistics for our final gold standard, which consists of all instances for which at least three out of the four annotators agreed, are shown in Table 1; "ambiguous" verb types are those for which the gold standard contains both telic and atelic instances. 510 of the 567 verb types also occur in the InterCorp silver standard, which provides training instances for 69 out of the 70 ambiguous verb types.

Finally, there are 446 cases for which no three annotators supplied the same label. Disagreement and skipping was mainly observed for verbs indicating attributions ("critics claim" or "the film uses"), which can be perceived either as statives or as instances of historic present. Other difficult cases include degree verbs ("increase"), aspectual verbs ("begin"), perception verbs ("hear"), iteratives ("flash") and the verb "do." For these cases, decisions how to treat them may have to be made depending on the concrete application; for now, they are excluded from our gold standard. Another source of error is that despite the training, annotators sometimes conflate their world knowledge (i.e., that some events necessarily come to an end eventually, such as the "swimming in the lake" in (2)) with the annotation task of determining telicity at a linguistic level.

3.2 Silver standard: InterCorp (EN-CZ)

We create a silver standard of approximately 457,000 labeled English verb occurrences (i.e., clauses) extracted from the InterCorp parallel corpus project (Čermák and Rosen, 2012). We leverage the sentence alignments, as well as part-of-speech and lemma information provided by InterCorp. We use the data from 151 sentence-aligned books (novels) of the Czech-English part of the corpus and further align the verbs of all 1:1-aligned sentence pairs to each other using the verbs' lemmas, achieving high precision by making sure that the translation of the verbs is licensed by the free online dictionary Glosbe.[3] We then look up the aspect of the Czech verb in Vallex 2.8.3 (Žabokrtský and Lopatková, 2007), a valency lexicon for Czech verbs, and project the label *telic* to English verb occurrences corresponding to a *perfective* Czech verb and the label *atelic* to instances translated using *imperfective* verbs.

Our annotation projection approach leverages the fact that most perfective Czech verbs will be translated into English using verb constellations that induce a telic event structure, as they describe one-time finished actions. Imperfective verbs, in contrast, are used for actions that are presented as unfinished, repeated or extending in time (Vintr, 2001). They are often, but not always, translated using atelic verb constellations. A notable exception is the English Progressive: "John was reading a book" signals an ongoing event in the past, which is telic at the word-sense level but would require translation using the imperfective Czech verb "četl." The initial corpus contained 4% sentences in the Progressive, out of which 89% were translated using imperfectives.[4] Due to the above

[3] https://glosbe.com

[4] For comparison, in the manually annotated validation

described mismatch, we remove all English Progressive sentences from our silver standard. Statistics for the final automatically created silver standard are shown in Table 1.

For validation, we sample 2402 instances from the above created silver standard and have our three annotators from the first annotation round mark them in the same way as the MASC data. Sampling picked one instance per verb type but was otherwise random. A majority agreement among the three annotators can be reached in 2126 cases (due to allowing skipping).[5] In this sample, 77.8% of the instances received the label telic from the human annotators, 61.5% received the label telic from the projection method. The accuracy of our projection method can be estimated as about 78%; F_1 for the telic class is 0.84, F_1 for atelic is 0.65. Errors made by the projection include for instance habituals, which use the imperfective in Czech but are not necessarily atelic at the event type level as in "John cycles to work every day."

4 Computational modeling

In this section, we describe the computational models for telicity classification, which we test on the MASC data and which we improve by adding the InterCorp silver standard data.

Features. We model each instance by means of a variety of syntactic-semantic features, using the toolkit provided by Friedrich et al. (2016).[6] Preprocessing is done using Stanford CoreNLP (Chen and Manning, 2014) based on dkpro (Eckart de Castilho and Gurevych, 2014). For the verb's lemma, the features include the WordNet (Fellbaum, 1998) sense and supersense and linguistic indicators (Siegel and McKeown, 2000) extracted from GigaWord (Graff et al., 2003). Using *only* the latter as features corresponds to the system by SMK2000 as described in Section 2. The feature set also describes the verb's subject and objects; among others their number, person, countability[7], their most frequent WordNet sense and the respective supersenses, and dependency relations between the argument and its governor(s). In addition, tense, voice and whether the clause is in the Perfect or Progressive aspect is reflected, as well as the presence of clausal (e.g., temporal) modifiers. For replicability we make the configuration files for the feature set available.

Classifier. We train L1-regularized multi-class logistic regression models using LIBLINEAR (Fan et al., 2008) with parameter settings ε=0.01 and bias=1. For each instance described by feature vector $\vec{x}$, the probability of each possible label y (here telic or atelic) is computed according to

$$P(y|\vec{x}) = \frac{1}{Z(\vec{x})} exp\left(\sum_{i=1}^{m} \lambda_i f_i(y, \vec{x})\right),$$

where f_i are the feature functions, λ_i are the weights learned for each feature function, and $Z(\vec{x})$ is a normalization constant (Klinger and Tomanek, 2007). The feature functions f_i indicate whether a particular feature is present, e.g., whether the tense of the verb is "past."

5 Experiments

Experimental settings. We evaluate our models via 10-fold cross validation (CV) on the MASC data set. We split the data into folds by documents in order to make sure that no training data from the same document is available for each instance in order to avoid an unfair bias. We report results in terms of accuracy, F_1 per class and macro-average F_1 (the harmonic mean of macro-average precision and recall). We test significance between differences in F_1 (for each class) using approximate randomization (Yeh, 2000; Padó, 2006) with $p < 0.1$ and significance between differences in accuracy using McNemar's test (McNemar, 1947) with $p < 0.01$. Table 2 shows our results: significantly different scores are marked with the same symbol where relevant (per column).

Results. A simple baseline of labeling each instance with the overall majority class (telic) has a very high accuracy, but the output of this baseline is uninformative and results in a low F_1. Rows titled "verb type" use the verb's lemma as their single feature and thus correspond to the informed baseline of using the training set majority class for each verb type. Rows labeled "+IC" indicate that the full set of instances with projected labels extracted from InterCorp has been added as additional training data in each fold; in rows titled "+ICs," the telic instances in InterCorp have been upsampled to match the 80:20 distribution in MASC. Our model using the full set of features significantly outperforms the verb type baseline

sample only 66% of Progressives received the label atelic.

[5] Of the 2402 cases, annotators completely agreed on 1577 cases (1114 telic, 203 atelic, 260 skipped). 85 cases were 2x atelic + 1x skipped, 219 cases were 2x telic + 1x skipped.

[6] https://github.com/annefried/sitent

[7] http://celex.mpi.nl

as well as SMK2000 (see † ‡ ∗). Using the additional training data from InterCorp results in a large improvement in the case of the difficult (because infrequent) atelic class (see ⋆), leading to the best overall results in terms of F_1. The best results regarding accuracy *and* F_1 are reached using the sampled version of the silver standard; the differences compared to the respective best scores in each column (in bold) are not significant.

Ablation experiments on the MASC data show that features describing the clause's main verb are most important: when ablating part-of-speech tag and tense and aspect (Progressive or Perfect), performance deteriorates by 1.8% in accuracy and 5% F_1, hinting at a correlation between telicity and choice of tense-aspect form. Whether this is due to an actual correlation of how telic and atelic verbs are used in context or merely due to annotation errors remains to be investigated in future work.

In sum, our experiments show that using annotations projected onto English text from parallel Czech text as cheap additional training data is a step forward to creating better models for the task of classifying telicity of verb occurrences.

6 Conclusion

Our model using a diverse set of features representing both verb-type relevant information and the context in which a verb occurs strongly outperformed previous work on predicting telicity (Siegel and McKeown, 2000). We have shown that silver standard data induced from parallel Czech-English data is useful for creating computational models for recognizing telicity in English. Our new manually annotated MASC data set is freely available; the projected annotations for InterCorp are published in a stand-off format due to license restrictions.

7 Future work

Aspectual distinctions made by one language rarely *completely* correspond to a linguistic phenomenon observed in another language. As we have discussed in Section 3.2, telicity in English and perfectiveness in Czech are closely related. As shown by our experiments, the projected labels cover useful information for the telicity classification task. One idea for future work is thus to leverage additional projected annotations from similar phenomena in additional languages, possibly improving overall performance by combining complementary information. Clustering more than two languages may also enable us to induce clusters corresponding to the different usages of imperfective verbs in Czech.

Table 2: Results for telicity classification on MASC data (1863 instances), 10-fold CV.

The presence of endpoints has consequences for the temporal interpretation of a discourse (Smith, 1997; Smith and Erbaugh, 2005), as endpoints introduce new states and therefore signal an advancement of time. In English, boundedness, i.e., whether an endpoint of an event has actually occurred, is primarily signaled by the choice of tense and Progressive or Perfect aspect. In tense-less languages such as Mandarin Chinese, boundedness is a covert category and closely related to telicity. We plan to leverage similar ideas as presented in this paper to create temporal discourse parsing models for such languages.

When translating, telic and atelic constructions also require different lexical choices and appropriate selection of aspectual markers. Hence, telicity recognition is also relevant for machine translation research and could be a useful component in computer aided language learning systems, helping learners to select appropriate aspectual forms.

Acknowledgments

We thank Klára Jágrová, Irina Stenger and Andrea Fischer for their help with Czech-specific questions and with finding appropriate corpora, and Lucie Poláková for pointing us to Vallex. Melissa Peate Sørensen and Christine Bocionek helped with the annotation. Finally, thanks to the anonymous reviewers, Alexis Palmer, Manfred Pinkal, Andrea Horbach, Benjamin Roth, Katharina Kann and Heike Adel for their helpful comments. This research was supported in part by the MMCI Cluster of Excellence of the DFG.

Abstract

The goal of counterfactual learning for statistical machine translation (SMT) is to optimize a target SMT system from logged data that consist of user feedback to translations that were predicted by another, historic SMT system. A challenge arises by the fact that risk-averse commercial SMT systems deterministically log the most probable translation. The lack of sufficient exploration of the SMT output space seemingly contradicts the theoretical requirements for counterfactual learning. We show that counterfactual learning from deterministic bandit logs is possible nevertheless by smoothing out deterministic components in learning. This can be achieved by additive and multiplicative control variates that avoid degenerate behavior in empirical risk minimization. Our simulation experiments show improvements of up to 2 BLEU points by counterfactual learning from deterministic bandit feedback.

1 Introduction

Commercial SMT systems allow to record large amounts of interaction log data at no cost. Such logs typically contain a record of the source, the translation predicted by the system, and the user feedback. The latter can be gathered directly if explicit user quality ratings of translations are supported, or inferred indirectly from the interaction of the user with the translated content. Indirect feedback in form user clicks on displayed ads has been shown to be a valuable feedback signal in response prediction for display advertising (Bottou et al., 2013). Similar to the computational advertising scenario, one could imagine a scenario where SMT systems are optimized from partial information in form of user feedback to predicted translations, instead of from manually created reference translations. This learning scenario has been investigated in the areas of *bandit learning* (Bubeck and Cesa-Bianchi, 2012) or *reinforcement learning* (RL) (Sutton and Barto, 1998). Figure 1 illustrates the learning protocol using the terminology of *bandit structured prediction* (Sokolov et al., 2016; Kreutzer et al., 2017), where at each round, a *system* (corresponding to a *policy* in RL terms) makes a prediction (also called *action* in RL, or pulling an *arm* of a bandit), and receives a *reward*, which is used to update the system.

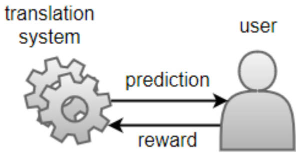

Figure 1: Online learning from partial feedback.

Counterfactual learning attempts to reuse existing interaction data where the predictions have been made by a historic system different from the target system. This enables *offline* or *batch* learning from logged data, and is important if

Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

online experiments that deploy the target system are risky and/or expensive. Counterfactual learning tasks include *policy evaluation*, i.e. estimating how a target policy would have performed if it had been in control of choosing the predictions for which the rewards were logged, and *policy optimization* (also called *policy learning*), i.e. optimizing parameters of a target policy given the logged data from the historic system. Both tasks are called *counterfactual*, or *off-policy* in RL terms, since the target policy was actually not in control during logging. Figure 2 shows the learning protocol for off-policy learning from partial feedback.

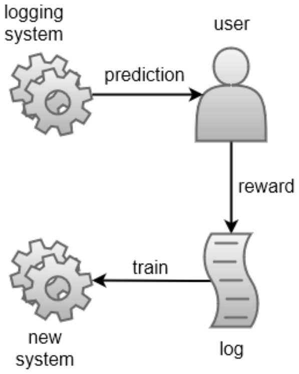

Figure 2: Offline learning from partial feedback.

The crucial trick to obtain unbiased estimators to evaluate and to optimize the off-policy system is to correct the sampling bias of the logging policy. This can be done by importance sampling where the estimate is corrected by the inverse propensity score (Rosenbaum and Rubin, 1983) of the historical algorithm, mitigating the problem that predictions there were favored by the historical system are over-represented in the logs. As shown by Langford et al. (2008) or Strehl et al. (2010), a sufficient exploration of the output space by the logging system is a prerequisite for counterfactual learning. If the logging policy acts stochastically in predicting outputs, this condition is satisfied, and inverse propensity scoring can be applied to correct the sampling bias. However, commercial SMT systems usually try to avoid any risk and only log the most probable translation. This effectively results in deterministic logging policies, making theory and practice of off-policy methods inapplicable to counterfactual learning in SMT.

This paper presents a case study in counterfactual learning for SMT that shows that policy optimization from deterministic bandit logs is possible despite these seemingly contradictory theoretical requirements. We formalize our learning problem as an empirical risk minimization over logged data. While a simple empirical risk minimizer can show degenerate behavior where the objective is minimized by avoiding or over-representing training samples, thus suffering from decreased generalization ability, we show that the use of control variates can remedy this problem. Techniques such as doubly-robust policy evaluation and learning (Dudik et al., 2011) or weighted importance sampling (Jiang and Li, 2016; Thomas and Brunskill, 2016) can be interpreted as additive (Ross, 2013) or multiplicative control variates (Kong, 1992) that serve for variance reduction in estimation. We observe that a further effect of these techniques is that of smoothing out deterministic components by taking the whole output space into account. Furthermore, we conjecture that while outputs are logged deterministically, the stochastic selection of inputs serves as sufficient exploration in parameter optimization over a joint feature representation over inputs and outputs. We present experiments using simulated bandit feedback for two different SMT tasks, showing improvements of up to 2 BLEU in SMT domain adaptation from deterministically logged bandit feedback. This result, together with a comparison to the standard case of policy learning from stochastically logged simulated bandit feedback, confirms the effectiveness our proposed techniques.

2 Related Work

Counterfactual learning has been known under the name of off-policy learning in various fields that deal with partial feedback, namely contextual bandits (Langford et al. (2008); Strehl et al.

(2010); Dudik et al. (2011); Li et al. (2015), *inter alia*), reinforcement learning (Sutton and Barto (1998); Precup et al. (2000); Jiang and Li (2016); Thomas and Brunskill (2016), *inter alia*), and structured prediction (Swaminathan and Joachims (2015a,b), *inter alia*). The idea behind these approaches is to first perform policy evaluation and then policy optimization, under the assumption that better evaluation leads to better optimization. Our work puts a focus on policy optimization in an empirical risk minimization framework for deterministically logged data. Since our experiment is a simulation study, we can compare the deterministic case to the standard scenario of policy optimization and evaluation under stochastic logging.

Variance reduction by additive control variates has implicitly been used in doubly robust techniques (Dudik et al., 2011; Jiang and Li, 2016). However, the connection to Monte Carlo techniques has not been made explicit until Thomas and Brunskill (2016), nor has the control variate technique of optimizing the variance reduction by adjusting a linear interpolation scalar (Ross, 2013) been applied in off-policy learning. Similarly, the technique of weighted importance sampling has been used as variance reduction technique in off-policy learning (Precup et al., 2000; Jiang and Li, 2016; Thomas and Brunskill, 2016). The connection to multiplicative control variates (Kong, 1992) has been made explicit in Swaminathan and Joachims (2015b). To our knowledge, our analysis of both control variate techniques from the perspective of avoiding degenerate behavior in learning from deterministically logged data is novel.

3 Counterfactual Learning from Deterministic Bandit Logs

Problem Definition. The problem of counterfactual learning (in the following used in the sense of counterfactual optimization) for bandit structured prediction can be described as follows: Let $\mathcal{X}$ be a structured input space, let $\mathcal{Y}(x)$ be the set of possible output structures for input x, and let $\Delta : \mathcal{Y} \rightarrow [0,1]$ be a reward function (and $\delta = -\Delta$ be the corresponding task loss function)[1] quantifying the quality of structured outputs. We are given a data log of triples $\mathcal{D} = \{(x_t, y_t, \delta_t)\}_{t=1}^{n}$ where outputs y_t for inputs x_t were generated by a logging system, and loss values δ_t were observed only at the generated data points. In case of stochastic logging with probability π_0, the inverse propensity scoring approach (Rosenbaum and Rubin, 1983) uses importance sampling to achieve an unbiased estimate of the expected loss under the parametric target policy π_w:

$$\begin{aligned}\hat{R}_{\text{IPS}}(\pi_w) &= \frac{1}{n}\sum_{t=1}^{n}\delta_t \frac{\pi_w(y_t|x_t)}{\pi_0(y_t|x_t)} \qquad (1)\\ &\approx \mathbb{E}_{p(x)}\mathbb{E}_{\pi_0(y|x)}[\delta(y)\frac{\pi_w(y|x)}{\pi_0(y|x)}]\\ &= \mathbb{E}_{p(x)}\mathbb{E}_{\pi_w(y|x)}[\delta(y)].\end{aligned}$$

In case of deterministic logging, we are confined to empirical risk minimization:

$$\hat{R}_{\text{DPM}}(\pi_w) = \frac{1}{n}\sum_{t=1}^{n}\delta_t \pi_w(y_t|x_t). \qquad (2)$$

Equation (2) assumes deterministically logged outputs with propensity $\pi_0 = 1, t = 1, \ldots, n$ of the historical system. We call this objective the *deterministic propensity matching (DPM)* objective since it matches deterministic outputs of the logging system to outputs in the n-best list of the target system. For optimization under deterministic logging, a sampling bias is unavoidable since objective (2) does not correct it by importance sampling. Furthermore, the DPM estimator may show a degenerate behavior in learning. This problem can be remedied by the use of control variates, as we will discuss in Section 5.

Learning Principle: Doubly Controlled Empirical Risk Minimization. Our first modification of Equation (2) has been originally motivated by the use of weighted importance sampling in inverse propensity scoring because of

[1] We will use both terms, reward and loss, in order to be consistent with the respective literature.

$\nabla \hat{R}_{\text{DPM}} = \frac{1}{n}\sum_{t=1}^{n} \delta_t \pi_w(y_t \mid x_t)\nabla \log \pi_w(y_t \mid x_t).$
$\nabla \hat{R}_{\text{DPM+R}} = \frac{1}{n}\sum_{t=1}^{n} [\delta_t \bar{\pi}_w(y_t \mid x_t)(\nabla \log \pi_w(y_t \mid x_t) - \sum_{u=1}^{n} \bar{\pi}_w(y_u \mid x_u)\nabla \log \pi_w(y_u \mid x_u))].$
$\nabla \hat{R}_{\hat{c}\text{DC}} = \frac{1}{n}\sum_{t=1}^{n} [(\delta_t - \hat{c}\hat{\delta}_t)\bar{\pi}_w(y_t \mid x_t)(\nabla \log \pi_w(y_t \mid x_t) - \sum_{u=1}^{n} \bar{\pi}_w(y_u \mid x_u)\nabla \log \pi_w(y_u \mid x_u))$ $+\hat{c}\sum_{y\in\mathcal{Y}(x_t)} \hat{\delta}(x_t, y)\pi_w(y \mid x_t)\nabla \log \pi_w(y \mid x_t)].$

Table 1: Gradients of counterfactual objectives.

its observed stability and variance reduction effects (Precup et al., 2000; Jiang and Li, 2016; Thomas and Brunskill, 2016). We call this objective the *reweighted deterministic propensity matching (DPM+R)* objective:

$$\begin{aligned}\hat{R}_{\text{DPM+R}}(\pi_w) &= \frac{1}{n}\sum_{t=1}^{n} \delta_t \bar{\pi}_w(y_t|x_t) \qquad (3)\\ &= \frac{1}{n}\sum_{t=1}^{n} \delta_t \frac{\pi_w(y_t|x_t)}{\sum_{t=1}^{n} \pi_w(y_t|x_t)}.\end{aligned}$$

From the perspective of Monte Carlo simulation, the advantage of this modification can be explained by viewing reweighting as a multiplicative control variate (Swaminathan and Joachims, 2015b). Let $Z = \delta_t \pi_w(y_t|x_t)$ and $W = \pi_w(y_t|x_t)$ be two random variables, then the variance of $r = \frac{\frac{1}{n}\sum_{t=1}^{n} Z}{\frac{1}{n}\sum_{t=1}^{n} W}$ can be approximately written as follows (Kong, 1992): $\text{Var}(r) \approx \frac{1}{n}(r^2\text{Var}(W) + \text{Var}(Z) - 2r\,\text{Cov}(W, Z))$. This shows that a positive correlation between the variable W, representing the target model probability, and the variable Z, representing the target model scaled by the task loss function, will reduce the variance of the estimator. Since there are exponentially many outputs to choose from for each input during logging, variance reduction is useful in counterfactual learning even in the deterministic case. Under a stochastic logging policy, a similar modification can be done to objective (1) by reweighting the ratio $\rho_t = \frac{\pi_w(y_t|x_t)}{\pi_0(y_t|x_t)}$ as $\bar{\rho}_t = \frac{\rho_t}{\sum_t \rho_t}$. We will use this reweighted IPS objective, called IPS+R, in our comparison experiments that use stochastically logged data.

A further modification of Equation (3) is motivated by the incorporation of a direct reward estimation method in the inverse propensity scorer as proposed in the doubly-robust estimator (Dudik et al., 2011; Jiang and Li, 2016; Thomas and Brunskill, 2016). Let $\hat{\delta}(x_t, y_t)$ be a regression-based reward model trained on the logged data, and let $\hat{c}$ be a scalar that allows to optimize the estimator for minimal variance (Ross, 2013). We define a *doubly controlled* empirical risk minimization objective $\hat{R}_{\hat{c}\text{DC}}$ as follows (for $\hat{c} = 1$ we arrive at a similar objective called $\hat{R}_{\text{DC}}$):

$$\begin{aligned}\hat{R}_{\hat{c}\text{DC}}(\pi_w) =& \frac{1}{n}\sum_{t=1}^{n} \Big[(\delta_t - \hat{c}\hat{\delta}_t)\ \bar{\pi}_w(y_t|x_t) \qquad (4)\\ &+ \hat{c} \sum_{y\in\mathcal{Y}(x_t)} \hat{\delta}(x_t, y)\ \pi_w(y|x_t)\Big].\end{aligned}$$

From the perspective of Monte Carlo simulation, the doubly robust estimator can be seen as variance reduction via additive control variates (Ross, 2013). Let $X = \delta_t$ and $Y = \hat{\delta}_t$ be two random variables. Then $\bar{Y} = \sum_{y\in\mathcal{Y}(x_t)} \hat{\delta}(x_t, y)\ \pi_w(y|x_t)$ is the expectation[2] of Y, and Equation (4) can be rewritten as $\mathbb{E}_{\bar{\pi}_w(x)}(X - \hat{c}\,Y) + \hat{c}\,\bar{Y}$. The variance of the term $X - \hat{c}\,Y$ is $\text{Var}(X - \hat{c}\,Y) = \text{Var}(X) + \hat{c}^2\text{Var}(Y) - 2\hat{c}\,\text{Cov}(X, Y)$. (Ross (2013), Chap. 9.2). Again this shows that variance of the estimator can be reduced if the variable X, representing the reward function, and the variable Y, representing the regression-based reward model, are positively correlated. The optimal scalar parameter $\hat{c}$

[2] Note that we introduce a slight bias by using π_w versus $\bar{\pi}_w$ in sampling probability and control variate.

can be derived easily by taking the derivative of variance term, leading to

$$\hat{c} = \frac{\mathrm{Cov}(X,Y)}{\mathrm{Var}(Y)}. \quad (5)$$

In case of stochastic logging the reweighted target probability $\bar{\pi}_w(y_t|x_t)$ is replaced by a reweighted ratio $\bar{\rho}_t$. We will use such reweighted models of the original doubly robust model, with and without optimal $\hat{c}$, called DR and $\hat{c}$DR, in our experiments that use stochastic logging.

Learning Algorithms. Applying a stochastic gradient descent update rule $w_{t+1} = w_t - \eta \nabla \hat{R}(\pi_w)_t$ to the objective functions defined above leads to a variety of algorithms. The gradients of the objectives can be derived by using the score function gradient estimator (Fu, 2006) and are shown in Table 1. Stochastic gradient descent algorithms apply to any differentiable policy π_w, thus our methods can be applied to a variety of systems, including linear and non-linear models. Since previous work on off-policy methods in RL and contextual bandits has been done in the area of linear classification, we start with an adaptation of off-policy methods to linear SMT models in our work. We assume a Gibbs model

$$\pi_w(y_t|x_t) = \frac{e^{\alpha(w^\top \phi(x_t,y_t))}}{\sum_{y \in \mathcal{Y}(x_t)} e^{\alpha(w^\top \phi(x_t,y))}}, \quad (6)$$

based on a feature representation $\phi : \mathcal{X} \times \mathcal{Y} \to \mathbb{R}^d$, a weight vector $w \in \mathbb{R}^d$, and a smoothing parameter $\alpha \in \mathbb{R}^+$, yielding the following simple derivative $\nabla \log \pi_w(y_t|x_t) = \alpha\big(\phi(x_t, y_t) - \sum_{y \in \mathcal{Y}(x_t)} \phi(x_t, y)\pi_w(y_t|x_t)\big)$.

4 Experiments

Setup. In our experiments, we aim to simulate the following scenario: We assume that it is possible to divert a small fraction of the user interaction traffic for the purpose of policy evaluation and to perform stochastic logging on this small data set. The main traffic is assumed to be logged deterministically, following a conservative regime where one-best translations are used for an SMT system that does not change frequently over time. Since our experiments are simulation studies, we will additionally perform stochastic logging, and compare policy learning for the (realistic) case of deterministic logging with the (theoretically motivated) case of stochastic logging.

train	122k	30k
validation	3k	1k
test	3k	2k

Table 2: Number of sentences for in-domain data splits of SMT train, validation, and test data.

In our deterministic-based policy learning experiments, we evaluate the empirical risk minimization algorithms derived from objectives (3) (DPM+R) and (4). For the doubly controlled objective we employ two variants: First, $\hat{c}$ is set to 1 as in (Dudik et al., 2011) (DC). Second, we calculate $\hat{c}$ as described in Equation (5) ($\hat{c}$DC). The algorithms used in policy evaluation and for stochastic-based policy learning are variants of these objectives that replace $\bar{\pi}$ by $\bar{\rho}$ to yield estimators IPS+R, DR, and $\hat{c}$DR of the expected loss.

All objectives will be employed in a domain adaptation scenario for machine translation. A system trained on out-of-domain data will be used to collect feedback on in-domain data. This data will serve as the logged data $\mathcal{D}$ in the learning experiments. We conduct two SMT tasks with hypergraph re-decoding: The first is German-to-English and is trained using a concatenation of the Europarl corpus (Koehn, 2005), the Common Crawl corpus[3] and the News Commentary corpus (Koehn and Schroeder, 2007). The goal is to adapt the trained system to the domain of transcribed TED talks using the TED parallel corpus (Tiedemann, 2012). A second task uses the French-to-English Europarl data

[3] http://www.statmt.org/wmt13/training-parallel-commoncrawl.tgz

with the goal of domain adaptation to news articles with the News Commentary corpus (Koehn and Schroeder, 2007). We split off two parts from the TED corpus to be used as validation and test data for the learning experiments. As validation data for the News Commentary corpus we use the splits provided at the WMT shared task, namely `nc-devtest2007` as validation data and `nc-test2007` as test data. An overview of the data statistics can be seen in Table 2.

As baseline, an out-of-domain system is built using the SCFG framework CDEC (Dyer et al., 2010) with dense features (10 standard features and 2 for the language model). After tokenizing and lowercasing the training data, the data were word aligned using CDEC's `fast_align`. A 4-gram language model is build on the target languages for the out-of-domain data using KENLM (Heafield et al., 2013). For News, we additionally assume access to in-domain target language text and train another in-domain language model on that data, increasing the number of features to 14 for News.

The framework uses a standard linear Gibbs model whose distribution can be peaked using a parameter α (see Equation (6)): Higher value of α will shift the probability of the one-best translation closer to 1 and all others closer to 0. Using $\alpha > 1$ during training will promote to learn models that are optimal when outputting the one-best translation. In our experiments, we found $\alpha = 5$ to work well on validation data.

Additionally, we tune a system using CDEC's MERT implementation (Och, 2003) on the in-domain data with their references. This full-information in-domain system conveys the best possible improvement using the given training data. It can thus be seen as the oracle system for the systems which are learnt using the same input-side training data, but have only bandit feedback available to them as a learning signal. All systems are evaluated using the corpus-level BLEU metric (Papineni et al., 2002).

The logged data $\mathcal{D}$ is created by translating the in-domain training data of the corpora using the original out-of-domain systems, and logging the one-best translation. For the stochastic experiments, the translations are sampled from the model distribution. The feedback to the logged translation is simulated using the reference and sentence-level BLEU (Nakov et al., 2012).

News	avg. estimate	-7.78	+6.63	+0.95
	std. dev.	0.97	4.13	2.33

Table 4: Policy evaluation by macro averaged difference between estimated and ground truth BLEU on 10k stochastically logged data, averaged over 5 runs.

Direct Reward Estimation. When creating the logged data $\mathcal{D}$, we also record the feature vectors of the translations to train the direct reward estimate that is needed for ($\hat{c}$)DC. Using the feature vector as input and the per-sentence BLEU as the output value, we train a regression-based random forest with 10 trees using scikit-learn (Pedregosa et al., 2011). To measure performance, we perform 5-fold cross-validation and measure the macro average between estimated rewards and the true rewards from the log: $|\frac{1}{n}\sum\delta(x_t, y_t) - \frac{1}{n}\sum\hat{\delta}(x_t, y_t)|$. We also report the micro average which quantifies how far off one can expect the model to be for a random sample: $\frac{1}{n}\sum|\delta(x_t, y_t) - \hat{\delta}(x_t, y_t)|$. The final model used in the experiments is trained on the full training data. Cross-validation results for the regression-based direct reward model can be found in Table 3.

Policy Evaluation. Policy evaluation aims to use the logged data $\mathcal{D}$ to estimate the performance of the target system π_w. The small logged data $\mathcal{D}_{eval}$ that is diverted for policy evaluation is created by translating only 10k sentences of the in-domain training data with the out-of-domain system and sample translations according to the model probability. Again we record the sentence-level BLEU as the feedback. The reference translations that also exist for those 10k sentences are used to measure the ground truth BLEU value for translations using the full-information in-domain system. The goal of evaluation is to achieve a value of IPS+R, DR, and $\hat{c}$ DR on $\mathcal{D}_{eval}$ that are as close as possible to the ground truth BLEU value.

To be able to measure variance, we create five folds of $\mathcal{D}_{eval}$, differing in random seeds. We report the average difference between the ground truth BLEU score and the value of the log-based policy evaluation, as well as the standard deviation in Table 4. We see that IPS+R underestimates the BLEU value by 7.78 on News. DR overestimates instead. $\hat{c}$ DR achieves the closest estimate, overestimating the true value by less than 1 BLEU. On TED, all policy evaluation results are overestimates. For the DR variants the overestimation result can be explained by the random forests' tendency to overestimate. Optimal $\hat{c}$ DR can correct for this, but not always in a sufficient way.

Policy Learning. In our learning experiments, learning starts with the weights w_0 from the out-of-domain model. As this was the system that produced the logged data $\mathcal{D}$, the first iteration will have the same translations in the one-best position. After some iterations, however, the translation that was logged may not be in the first position any more. In this case, the n-best list is searched for the correct translation. Due to speed reasons, the scores of the translation system are normalized to probabilities using the first 1,000 unique entries in the n-best list, rather than using the full hypergraph. Our experiments showed that this did not impact the quality of learning.

In order for the multiplicative control variate to be effective, the learning procedure has to utilize mini-batches. If the mini-batch size is chosen too small, the estimates of the control variates may not be reliable. We test mini-batch sizes of 30k and 10k examples, whereas 30k on News means that we perform batch training since the mini-batch spans the entire training set. Mini-batch size β and early stopping point where selected by choosing the setup and iteration that achieved the highest BLEU score on the one-best translations for the validation data. The learning rate η was selected in the same way, whereas the possible values were $1\mathrm{e}{-4}, 1\mathrm{e}{-5}, 1\mathrm{e}{-6}$ or, alternatively, Adadelta (Zeiler, 2012), which sets the learning rate on a per-feature basis. The results on both validation and test set are reported in Table 5. Statistical significance of the out-of-domain system compared to all other systems is measured using Approximate Randomization testing (Noreen, 1989).

For the deterministic case, we see that in general DPM+R shows the lowest increase but can still significantly outperform the baseline. An explanation of why DPM+R cannot improve any further, will be addressed separately below. DC yields improvements of up to 1.5 BLEU points, while $\hat{c}$ DC obtains improvements of up to 2 BLEU points over the out-of-domain baseline. In more detail on the TED data, DC can close the gap of nearly 3 BLEU by half between the out-of-domain and the full-information in-domain system. $\hat{c}$ DC can improve by further 0.6 BLEU which is a significant improvement at $p = 0.0017$. Also note that, while $\hat{c}$ DC takes more iterations to reach its best result on the validation data, $\hat{c}$ DC already outperforms DC at the stopping iteration of DC. At this point $\hat{c}$ DC is better by 0.18 BLEU on the validation set and continues to increase until its own stopping iteration. The final results of $\hat{c}$ DC falls only 0.8 BLEU behind the oracle system that had references available during its learning process. Considering the substantial difference in information that both systems had available, this is remark-

			BLEU	BLEU difference			BLEU

		test	25.27	+0.81	+1.18	+0.95	28.08

Table 5: BLEU increases for learning, over the out-of-domain baseline on validation and test set. Out-of-domain is the baseline and starting system and in-domain is the oracle system tuned on in-domain data with references. For the deterministic case, all results are statistically significant at $p \leq 0.001$ with regards to the baseline. For the stochastic case, all results are statistically significant at $p \leq 0.002$ with regards to the baseline, except for IPS+R on the News corpus.

able. The improvements on the News corpus show similar tendencies. Again there is a gap of nearly 3 BLEU to close and with an improvement of 1.05 BLEU points, DC can achieve a notable result. $\hat{c}$DC was able to further improve on this but not as successfully as was the case for the TED corpus. Analyzing the actual $\hat{c}$ values that were calculated in both experiments allows us to gain an insight as to why this was the case: For TED, $\hat{c}$ is on average 1.35. In the case of News, however, $\hat{c}$ has a maximum value of 1.14 and thus stays quite close to 1, which would equate to using DC. It is thus not surprising that there is no significant difference between DC and $\hat{c}$DC.

Comparison to the Stochastic Case. Even if not realistic for commercial applications of SMT, our simulation study allows us to stochastically log large amounts of data in order to compare learning from deterministic logs to the standard case. As shown in Table 5, the relations between algorithms and even the absolute improvements are similar for stochastic and deterministic logging. Significance tests between each deterministic/stochastic experiment pair show a significant difference only in case of DC/DR on TED data. However, the DR result still does not significantly outperform the best deterministic objective on TED ($\hat{c}$DC). The p values for all other experiment pairs lie above 0.1. From this we can conclude that it is indeed an acceptable practice to log deterministically.

5 Analysis

Langford et al. (2008) show that counterfactual learning is impossible unless the logging system sufficiently explores the output space. This condition is seemingly not satisfied if the logging systems acts according to a deterministic policy. Furthermore, since techniques such as “exploration over time” (Strehl et al., 2010) are not applicable to commercial SMT systems that are not frequently changed over time, the case of counterfactual learning for SMT seems hopeless. However, our experiments present evidence to the contrary. In the following, we present an analysis that aims to explain this apparent contradiction.

Implicit Exploration. In an experimental comparison between stochastic and deterministic logging for bandit learning in computational advertising, Chapelle and Li (2011) observed that varying contexts (representing user and page visited) induces enough exploration into ad selection such that learning becomes possible. A similar implicit exploration can also be attributed to the case of SMT: An identical input word or phrase can lead, depending on the other words and phrases in the input sentence, to different output words and phrases. Moreover, an identical output word or phrase can appear in different output sentences. Across the entire log, this implicitly performs the exploration on phrase translations that seems to be missing at first glance.

Smoothing by Multiplicative Control Variates. The DPM estimator can show a degenerate behavior in that the objective can be minimized simply by setting the probability of every logged data point to 1.0. This over-represents logged data that received low rewards, which is undesired. Furthermore, systems optimized with this objective cannot properly discriminate between the translations in the output space. This can be seen as a case of translation invariance of the objective, as has been previously noted by Swaminathan and Joachims (2015b): Adding a small constant c to the probability of every data point in the log increases the overall value of the objective without improving the discriminative power between high-reward and low-reward translations.

DPM+R solves the degeneracy of DPM by defining a probability distribution over the logged data by reweighting via the multiplicative control variate. After reweighting, the objective value will decrease if the probability of a low-reward translation increased, as it takes away probability mass from other, higher reward samples. Because of this trade-off, balancing the probabilities over low-reward and high-reward samples becomes important, as desired.

Smoothing by Additive Control Variates. Despite reweighting, DPM+R can still show a degenerate behavior by setting the probabilities of only the highest-reward samples to 1.0, while avoiding all other logged data points. This clearly hampers the generalization ability of the model since inputs that have been avoided in training will not receive a proper ranking of their translations.

The use of an additive control variate can solve this problem by using a reward estimate that takes the full output space into account. The objective will now be increased if the probability of translations with high estimated reward is increased, even if they were not seen in training. This will shift probability mass to unseen data with high estimated-reward, and thus improve the generalization ability of the model.

6 Conclusion

In this paper, we showed that off-policy learning from deterministic bandit logs for SMT is possible if smoothing techniques based on control variates are used. These techniques will avoid degenerate behavior in learning and improve generalization of empirical risk minimization over logged data. Furthermore, we showed that standard off-policy evaluation is applicable to SMT under stochastic logging policies.

To our knowledge, this is the first application of counterfactual learning to a complex structured prediction problem like SMT. Since our objectives are agnostic of the choice of the underlying model π_w, it is also possible to transfer our techniques to non-linear models such as neural machine translation. This will be a desideratum for future work.

Abstract

User generated categories (UGCs) are short texts that reflect how people describe and organize entities, expressing rich semantic relations implicitly. While most methods on UGC relation extraction are based on pattern matching in English circumstances, learning relations from Chinese UGCs poses different challenges due to the flexibility of expressions. In this paper, we present a weakly supervised learning framework to harvest relations from Chinese UGCs. We identify is-a relations via word embedding based projection and inference, extract non-taxonomic relations and their category patterns by graph mining. We conduct experiments on Chinese Wikipedia and achieve high accuracy, outperforming state-of-the-art methods.

1 Introduction

UGCs are descriptive phrases related to entities, frequently appearing in online encyclopedias and vertical websites. These texts are concise and informative, reflecting the way people organize and characterize entities (Xu et al., 2016a).

UGCs (especially Wikipedia categories) are important sources for knowledge harvesting. Previous approaches (Flati et al., 2014; Ponzetto and Strube, 2007; Ponzetto and Navigli, 2009) focus on inferring is-a relations between entities and UGCs for taxonomy construction. A few others extract multiple types of relations from Wikipedia categories (Nastase and Strube, 2008; Suchanek et al., 2007). These methods are mostly designed for English language by employing language-specific patterns or linguistic rules.

For Chinese, harvesting semantic relations from texts poses different challenges. There is no distinction between singular and plural forms and no word spaces in Chinese. Word orders can be arranged in multiple ways with very flexible expressions. As illustrated in Qiu and Zhang (2014); Chen et al. (2014), the research of relation extraction from Chinese texts makes less significant process than the research for English. Although several approaches are proposed to construct Chinese taxonomies from Wikipedia categories (Li et al., 2015; Wang et al., 2014), extracting fine-grained and multi-typed relations from UGCs still needs further study. This is because there exist very few high-quality lexical patterns for relation identification in Chinese UGCs (in contrast to Nastase and Strube (2008); Suchanek et al. (2007)). Hence this problem is similar to "open relation extraction" (Etzioni et al., 2011) from Chinese short texts, without pre-defined relation types.

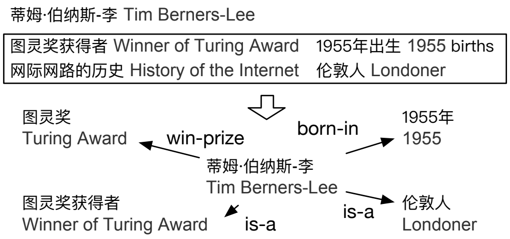

Figure 1: An illustrative example with respect to "Tim Berners-Lee" in Chinese Wikipedia.

In this paper, we propose a weakly supervised learning framework to mine fine-grained and multiple-typed relations from Chinese UGCs. A simple example is illustrated in Figure 1[1]. Inspired by Fu et al. (2014); Wang et al. (2017), is-a relations are extracted based on word embedding

[*] Corresponding author.

[1] The category "Winner of Turing Award" can serve as a class of "Tim Berners-Lee" (similar to Wu et al. (2012)) and be treated as a relational category (similar to Suchanek et al. (2007)). We regard both are valid and extract two relations.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2577–2587
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

based projection models. We further refine prediction results by collective inference and hypernym expansion. For non-taxonomic relations, relation types and corresponding category patterns are identified jointly based on graph clique mining. Finally, these mined "raw" relations are mapped to canonicalized relation triples. In our work, except for a set of heuristic rules, the proposed approach is weakly supervised without manual labeling.

In the experiments, given only 0.6M entities and their respective 2.4M categories in Chinese Wikipedia, our method extracts 1.52M relations with an overall accuracy of 93.6%. The experiments also show that our approach outperforms previous methods for both is-a and non-taxonomic relation extraction from Chinese UGCs. The extracted relations and the labeled test set are publicly available[2].

The rest of this paper is as follows. Section 2 summarizes related work. Details of our approach are described in Section 3 to Section 5, with experiments in Section 6. Finally, we conclude our paper and discuss the future work in Section 7.

2 Related Work

In this section, we overview the related work on relation extraction from UGCs.

2.1 Is-a Relation Extraction

Is-a relations are backbones in taxonomies. In YAGO (Suchanek et al., 2007), a Wikipedia category is regarded as conceptual if it matches the pattern "pre-modifier + head word + post-modifier". WikiTaxonomy (Ponzetto and Strube, 2007) constructs a taxonomy from Wikipedia categories using multiple types of features. The taxonomy is reconstructed and improved in Ponzetto and Navigli (2009). Other similar projects use classifiers and rule based inference to predict is-a relations for taxonomy learning (Flati et al., 2014; Mahdisoltani et al., 2015; Nastase et al., 2010; Alfarone and Davis, 2015; Shwartz et al., 2016; Gupta et al., 2016). Since harvesting English is-a relations is not our focus, we do not elaborate here.

For Chinese, this task is more challenging because there are few category patterns that can be used to extract is-a relations from UGCs. Based on the word formation of Wikipedia categories, Li et al. (2015) propose a classification method to build a large Chinese taxonomy from Wikipedia. A similar approach is presented in Lu et al. (2015). Besides encyclopedias, Fu et al. (2013) generate candidate hypernyms and employ an SVM-based ranking model to detect the most likely hypernym of an entity. These methods have relatively high precision but require careful feature engineering and a large amount of human work.

Another thread of related work is cross-lingual approaches, which use larger English knowledge sources to supervise Chinese is-a relations extraction. For example, Wang et al. (2014) propose a dynamic adaptive boosting model to learn taxonomic prediction functions for English and Chinese. Xu et al. (2016b) link Chinese entities with DBpedia types based on cross-lingual links between Chinese and English entities. Other approaches can be found in Wu et al. (2016); Mahdisoltani et al. (2015). These methods take advantages of languages with richer resources but are constrained by cross-lingual links.

To capture linguistic regularities of is-a relations, deep learning approaches map the vectors of entities to the vectors of their hypernyms. Fu et al. (2014) design piecewise linear projection models to learn Chinese semantic hierarchies based on word embeddings (Mikolov et al., 2013). Wang and He (2016) improve this approach by adding an iterative update strategy and a pattern-based validation mechanism. Wang et al. (2017) design a transductive learning approach by considering the semantics of both is-a and not-is-a relations, linguistic rules and the unlabeled data jointly. In this work, we further propose a word embedding based model that consider the word formation of UGCs to improve the prediction results.

2.2 Non-taxonomic Relation Extraction

Unlike the case of is-a relations, the task of extracting non-taxonomic relations from UGCs has rarely been addressed. A possible cause is that harvesting relations from short texts is more challenging. The pioneer work Nastase and Strube (2008) extracts relations by lexical pattern matching and inference. Pasca (2017) studies how to decompose Wikipedia categories into attribute-value pairs. YAGO (Suchanek et al., 2007) uses regular expression based matching to harvest relations. While patterns in English are more regular, enumerating patterns for Chinese requires a large amount of human labor. In our work, we solve this problem by graph mining, which has high pre-

[2] https://chywang.github.io/data/emnlp17.zip

cision and requires minimal human intervention. Note that our work is also similar to open relation extraction (Etzioni et al., 2011) due to the unknown number of relation types. The difference is that our work focuses on UGCs which are very short phrases rather than sentences.

3 General Framework

In Wikipedia, each entity e is associated with a collection of UGCs $Cat(e)$. We first learn a prediction model $f(e, c)$ to distinguish is-a relations from not-is-a relations where $c \in Cat(e)$, and extract all is-a relations (Section 4). For example, we can obtain is-a relations "(Tim Berners-Lee, is-a, Londoner)" and "(Tim Berners-Lee, is-a, Winner of Turing Award)", as shown in Figure 1.

After that, we mine non-taxonomic relations from Wikipedia UGCs (Section 5). Our algorithm first makes a single pass over all categories to mine significant category patterns (Section 5.1). For example, the pattern "[E]获得者(Winner of [E])" is extracted, which frequently appears in UGCs and may refers to a type of relation where "[E]" is a placeholder for entities. Candidate relation instances for such patterns are obtained by a graph clique mining algorithm (Section 5.2). The instances extracted based on the previous pattern are "(Tim Berners-Lee, Turing Award)", "(Albert Einstein, Nobel Prize for Physics)", etc. Finally, the extracted "raw" instances are mapped to canonicalized triples (Section 5.3). In this step, a relation predicate "win-prize" is defined for the pattern and these pairs are mapped to "win-prize" relations.

4 Mining Is-a Relations

In this section, we introduce how to learn $f(e, c)$ and extract is-a relations from UGCs.

4.1 Training Data Generation

The training of $f(e, c)$ requires positive and negative entity-category pairs. To avoid the time-consuming labeling process, we generate the training set automatically. The first part is borrowed from Fu et al. (2014), containing 1,391 positive pairs and 4,294 negative pairs. However, the number of positive pairs is not sufficient for our propose. We design a heuristic rule to generate more positive pairs from Wikipedia categories. We treat a pair (e, c) as positive if the following two conditions hold:

- The category c matches the pattern "premodifier + 的+ head word" or the head words of e and c are the same[3].
- The head word of a category name is a noun and is *not* in a Chinese thematic lexicon extended from the dictionary used in Li et al. (2015), containing 184 thematic words (e.g., "军事(Military)", "娱乐(Entertainment)".

In total, we sample 5,000 pairs to add to our training set. The TP rate is 98.7%, estimated over 300 pairs, indicating the effectiveness of rules.

4.2 Projection-based Model Prediction

Except for the previous pattern, other Chinese is-a relations can not be directly extracted by lexical matching. Inspired by Wang et al. (2017), we employ projection models to learn the semantics of is-a and not-is-a relations.

A projection model is a linear model that maps the embedding vector of a word to the vector of another where the two words satisfy a particular relation (Fu et al., 2014). In Wikipedia, most category names are relatively long and fine-grained, making it difficult to learn the embeddings precisely. We find that given a pair (e, c), if the head word of category c is a valid hypernym of e, so it is for c itself, e.g., "英格兰计算机科学家(CS scientist in England)" for "Tim Berners-Lee". Denote $\vec{v}(e)$ as the embedding vector of entity e, with the dimensionality as n. Let c_h be the head word of c. For each pair in the positive training set $(e, c) \in D^+$, assume there is a positive projection model such that $\mathbf{M}^+\vec{v}(e) + \mathbf{B}^+ \approx \vec{v}(c_h)$ where $\mathbf{M}^+$ is an $n \times n$ projection matrix and $\mathbf{B}^+$ is an $n \times 1$ bias vector. Similarly, for pairs in negative training set $(e', c') \in D^-$, we learn a negative model $\mathbf{M}^-\vec{v}(e') + \mathbf{B}^- \approx \vec{v}(c'_h)$. Note that we do not impose explicit connections between two models because the semantics of Chinese is-a and not-is-a relations are very complicated and difficult to model (Fu et al., 2014; Wang and He, 2016). In our work, we let the algorithms to learn representations of is-a/not-is-a relations.

This approach learns is-a and not-is-a relation representations implicitly and does not require deep NLP analysis on UGCs, which is suitable to deal with the flexible expressions in Chinese. In

[3] The head word of a category name is the root word in the dependency parsing tree. "的" is an auxiliary word in Chinese, usually appearing between adjectives and nouns.

the training phase, we aim to minimize the objective function for positive projection learning:

$$J(\mathbf{M}^+, \mathbf{B}^+) = \sum_{(e,c)\in D^+} \|\mathbf{M}^+\vec{v}(e) + \mathbf{B}^+ - \vec{v}(c_h)\|_F^2 + \frac{\lambda}{2}\|\mathbf{M}^+\|_F^2 + \frac{\lambda}{2}\|\mathbf{B}^+\|_F^2$$

where $\lambda > 0$ gives an additional Tikhonov smoothness effect on the projection matrices (Golub et al., 1999). For negative model, we have

$$J(\mathbf{M}^-, \mathbf{B}^-) = \sum_{(e,c)\in D^-} \|\mathbf{M}^-\vec{v}(e) + \mathbf{B}^- - \vec{v}(c_h)\|_F^2 + \frac{\lambda}{2}\|\mathbf{M}^-\|_F^2 + \frac{\lambda}{2}\|\mathbf{B}^-\|_F^2$$

After model training, for an unlabeled pair (e, c), if the category c is the correct hypernym of the entity e, the vector $\vec{v}(c_h)$ will be close to $\mathbf{M}^+\vec{v}(e) + \mathbf{B}^+$ and far away from $\mathbf{M}^-\vec{v}(e) + \mathbf{B}^-$. Denote $d^+(e, c)$ and $d^-(e, c)$ as:

$$d^+(e,c) = \|\mathbf{M}^+\vec{v}(e) + \mathbf{B}^+ - \vec{v}(c_h)\|_2$$

$$d^-(e,c) = \|\mathbf{M}^-\vec{v}(e) + \mathbf{B}^- - \vec{v}(c_h)\|_2$$

The prediction score is calculated as follows:

$$s(e,c) = \tanh(d^-(e,c) - d^+(e,c))$$

where $s(e, c) \in (-1, 1)$. High prediction score means a large probability of the existence of an is-a relation between e and c.

4.3 Collective Prediction Refinement

As indicated in Fu et al. (2013); Levy et al. (2015), some categories naturally serve as “prototypical hypernyms”, regardless of the entities. To encode this assumption into our method, we refine the previous prediction results by collective inference.

Consider the category “伦敦人(Londoner)” in Figure 1, which can be literally translated as “伦敦(London)人(person)”. “人(person)” is the “prototypical hypernym” here. Other categories whose head words are “人(person)” such as “哥本哈根人(Copenhagen person[4], people from Copenhagen)” are likely to be conceptual categories, too.

Denote H as the head word set of all Wikipedia UGCs. For each $h \in H$, let $D_h = \{(e, c)\}$ be the collection of unlabeled pairs (i.e., pairs not in the training set) where the head word of category c is h. D_h^+ is the collection of positive pairs with h as the head word of c in the training set (generated based on Section 4.1). We define the unnormalized global prediction score $\tilde{g}(h)$ for each $h \in H$:

$$\tilde{g}(h) = \ln(1 + |D_h| + |D_h^+|)\frac{|D_h^+| + \sum_{(e,c)\in D_h} s(e,c)}{|D_h| + |D_h^+|}$$

In this formula, each unlabeled data instance $(e, c) \in D_h$ has the weight of $s(e, c)$ and each training data instance $(e, c) \in D_h^+$ has the weight of 1. $\frac{|D_h^+|+\sum_{(e,c)\in D_h} s(e,c)}{|D_h|+|D_h^+|}$ is the average prediction score for categories with the head word h. $\ln(1 + |D_h| + |D_h^*|)$ gives a larger impact to $\tilde{g}(h)$ when the head word h appears more frequently in Wikipedia categories. This heuristic setting is inspired by transductive learning which takes both training and unlabeled data into consideration (Chapelle et al., 2006). It is also similar to the prior probability feature (Fu et al., 2013).

We normalize the global prediction score $g(h)$ as follows:

$$g(h) = \frac{\tilde{g}(h)}{\max_{h' \in H} |\tilde{g}(h')|}$$

The prediction function $f(e, c)$ for the entity e and the category c with the head word h is defined in a combination of $s(e, c)$ and $g(h)$:

$$f(e,c) = \beta s(e,c) + (1 - \beta) g(h)$$

where $\beta \in (0, 1)$ is a tuning parameter that controls the relative importance of the two scores.

We predict there is an is-a relation between entity e and category $c \in Cat(e)$ if at least one of the two conditions holds:

- (e, c) meets the two conditions in Section 4.1.
- $f(e, c) > \theta$ where θ is a threshold.

Finally, we regard c_h as a valid hypernym of e if c is predicted as a hypernym of e and c_h is also a Wikipedia concept. This step (called hypernym expansion) increases the number of hypernyms and hence the number of is-a relations.[5]

5 Mining Non-taxonomic Relations

In this section, we present our approach to extract non-taxonomic relations from Wikipedia UGCs.

[4] Literal translation.

[5] We do not extract all the entity-head word pairs (e, c_h) as is-a relations because word segmentation, tagging and parsing errors may occur when we extract head words by NLP tools. We observe that if c_h is also a Wikipedia concept, the head word extraction process is most probably correct.

5.1 Single-pass Category Pattern Miner

This module automatically learns important category patterns that appear frequently in Wikipedia and have a probability to represent certain semantic relations. Formally, a category pattern p is an ordered sequence of common words and entity tags. For example, the pattern of the category "图灵奖获得者(Winner of Turing Award)" is "[E]获得者(Winner of [E])". Define $R_p = \{(e_p, c_p)\}$ as the collection of entity pairs such that in Wikipedia page e_p, a category containing c_p matches the pattern p[6]. c_p is in the place of "[E]". Consider the previous example. In Wikipedia page "Tim Berners-Lee", there is a category "Winner of Turing Award" that matches the pattern "Winner of [E]". "Turing Award" is the "[E]" here. Thus we have e_p ="Tim Berners-Lee" and c_p ="Turing Award" as an entity pair in R_p. We can see that R_p is the collection of all candidate relation instances that may have the relation that p represents.

Let L_p be the number of common words in pattern p. We define the support of the pattern $supp(p)$ as follows:

$$supp(p) = |R_p| \cdot \ln(1 + L_p)$$

where $\ln(1 + L_p)$ gives larger support values to longer patterns because longer patterns tend to be more specific and may contain richer semantics.

In the implementation, we employ a CRF-based Chinese NER tagger (Qiu et al., 2013) and a dictionary consisting of all Wikipedia entities to recognize the entities and obtain these patterns. This step processes all the categories within a single pass and calculates their support values. It keeps top-k highest support patterns as the input of the next step, together with the matched entity pairs.

5.2 Graph-based Raw Relation Extractor

In this part, for each top-k highest support pattern p, we select a subset of pairs R_p^* from R_p as seed relation instances for an underlying relation that the pattern p may represent. After that, we filter out low quality patterns and extract relation instances $R_p^{'}$ from R_p as the final result.

5.2.1 Seed Relation Instance Extraction

To select seed relation instances R_p^*, we propose an unsupervised graph mining approach. Let $G_p = (C_p, L_p, W_p)$ be a weighted, undirected graph where C_p, L_p and W_p denote vertices, edges and edge weights, respectively. The vertices correspond to the matched entities in categories for pattern p, i.e., $C_p = \{c_p | (e_p, c_p) \in R_p\}$. The edge weights reflect the semantic similarities among entities in C_p. Because the link structure in Chinese Wikipedia is relatively sparse (Wang et al., 2016), we estimate the similarity between entities c_p and $c_p^{'}$ semantically as follows:

$$sim(c_p, c_p^{'}) = \frac{\sum_{c \in Cat(c_p)} \sum_{c^{'} \in Cat(c_p^{'})} \cos(\vec{v}(c_h), \vec{v}(c_h^{'}))}{|Cat(c_p)| \cdot |Cat(c_p^{'})|}$$

where $\cos(\cdot)$ is a cosine function to compute the similarity of two words in the embedding space.

Given a similarity threshold τ, iff $sim(c_p, c_p^{'}) > \tau$, we have $(c_p, c_p^{'}) \in L_p$ and $w(c_p, c_p^{'}) = sim(c_p, c_p^{'})$. In this way, entities in C_p are interconnected if they are similar in semantics.

In this paper, we model the problem of mining R_p^* from R_p as a Maximum Edge Weight Clique Problem (MEWCP) (Alidaee et al., 2007), which detects a maximum edge weight clique C_p^* from C_p in R_p to form R_p^*. Recall that in an undirected graph with edge weights, a maximum edge weight clique is a clique in which the sum of edge weights in the clique is the largest among all the cliques.

To produce a solution for MEWCP, several algorithms have been proposed in the optimization research community, e.g., unconstrained quadratic programming (Alidaee et al., 2007) and the branch-and-cut algorithm (Sørensen, 2004). However, they suffer from high computational complexity due to the NP-Hardness of the problem (Alidaee et al., 2007). In this paper, we introduce an approximate algorithm based on Monte Carlo methods. The general procedure is shown in Algorithm 1. It starts with an empty graph G_p^* to store the clique. In each iteration, it selects an edge $(c_p, c_p^{'})$ from G_p with the probability proportional to its weight $w(c_p, c_p^{'})$. After a particular edge $(c_p, c_p^{'})$ is chosen, the algorithm adds the edge to G_p^*, and removes the edge and other edges that do not connect with any nodes in C_p^* from G_p. This process iterates until no more edges in G_p can be added to G_p^*. Thus, the vertices in G_p^* form the desired clique C_p^*.

Because it is a random, approximate algorithm, the average runtime complexity depends on the input graph structure. We can see that the worst-case runtime complexity is $O(|L_p|^2)$. We run it k

[6] Without ambiguity, we use e_p to represent both the Wikipedia page with the title as e_p and the entity e_p itself.

Algorithm 1 Algorithm for MEWCP

```
Input: Graph $G_p = (C_p, L_p, W_p)$.
Output: Maximum edge weight clique $C_p^*$.
  Initialize temp graph $G_p^* = (C_p^*, L_p^*)$ with $C_p^* = \emptyset$ and $L_p^* = \emptyset$;
  while $L_p \neq \emptyset$ do
    Sample $(c_p, c_p^{'})$ from $L_p$ with prob $\propto w(c_p, c_p^{'})$;
    $C_p = C_p \setminus \{c_p, c_p^{'}\}$, $C_p^* = C_p^* \cup \{c_p, c_p^{'}\}$;
    $L_p = L_p \setminus \{(c_p, c_p^{'})\}$, $L_p^* = L_p^* \cup \{(c_p, c_p^{'})\}$;
    for each $(\tilde{c}_p, \tilde{c}_p^{'}) \in L_p$ do
      if $\tilde{c}_p \notin C_p^*$ and $\tilde{c}_p^{'} \notin C_p^*$ then
        $C_p = C_p \setminus \{\tilde{c}_p, \tilde{c}_p^{'}\}$;
        $L_p = L_p \setminus \{(\tilde{c}_p, \tilde{c}_p^{'})\}$;
      end if
    end for
  end while
  return Maximum edge weight clique $C_p^*$;
```

times and produce multiple results. We select the clique with largest edge weights as the maximum edge weight clique for G_p. The seed relation instance collection is defined as $R_p^* = \{(e_p, c_p) | c_p \in C_p^*, (e_p, c_p) \in R_p\}$. Thus the total runtime complexity is $O(k|L_p|^2)$. In this way, the NP-hard problem is effectively solved in quadratic time.

5.2.2 Relation Extraction and Filtering

After the seed relation instances R_p^* are detected, we employ a confidence score to quantify the quality of pattern p. Intuitively, if pattern p represents entity pairs with the same clear semantic relation, the size of R_p^* and the sum of edge weights in C_p^* will be sufficiently large. Here, we define the confidence score of pattern p as follows:

$$conf(p) = \frac{\ln(1 + |R_p^*|)}{|R_p^*| \cdot (|R_p^*| - 1)} \sum_{c_p, c_p^{'} \in C_p^*, c_p \neq c_p^{'}} sim(c_p, c_p^{'})$$

Based on the formula, patterns with low confidence scores can be filtered. For the remaining patterns, given each $(e_p, c_p) \in R_p$, we add it to the final extracted relation instance collection $R_p^{'}$ if $(e_p, c_p) \in R_p^*$ or it is similar enough to entity pairs in R_p^*. Denote γ as a parameter that controls the precision-recall trade-off. The criteria is:

$$\frac{\sum_{c_p^{'} \in C_p^*} sim(c_p, c_p^{'})}{|C_p^*|} > \frac{\gamma \sum_{c_p^{'}, c_p^{''} \in C_p^*, c_p^{'} \neq c_p^{''}} sim(c_p^{'}, c_p^{''})}{|R_p^*| \cdot (|R_p^*| - 1)}$$

In general, our method detects most probably correct pairs as "seeds" and extract other pairs that are similar enough to seeds. Because it is difficult to ensure high precision for short text relation extraction, we do not use iterative extraction method to avoid "semantic drift" (Carlson et al., 2010).

5.3 Relation Mapping

The final step is to map $R_p^{'}$ to relation triples with a proper relation predicate. Based on category patterns, we have three types of mappings:

Direct Verbal Mapping If the head word of the pattern is a verb, we can use it as the relation predicate. For example, in "[E]出生([E] births)", "出生(born in)" is expressed as a verb in Chinese and is taken as a predicate.

Direct Non-verbal Mapping If the category pattern does not contain a verb but expresses a semantic relation by one/many non-verbs, we define the relation predicate and map the entity pairs to relation triples by logical rules. For example, in the pattern "[E]获得者(Winner of [E])", "获得者(winner)" is a noun that indicates the "得奖(win-prize)" relation.

Indirect Mapping Similar to Suchanek et al. (2007), a few patterns do not describe relations between entity pairs, but should be mapped to other relations indirectly[7]. In "[E]军事([E] military)", it indicates that the entity is related to the topic "军事(military)". Thus, we define a new relation predicate "话题(topic-of)" and establish the relations between entities and "军事(military)".

As seen, the only manual work in our approach is to define relation predicates for direct non-verbal mappings and indirect mappings. In our work, such logical mapping rules are required for only a couple of relation types. Therefore, the proposed approach needs very minimal human work.

6 Experiments

In this section, we conduct experiments to evaluate our method and compare it with state-of-the-art approaches. We also present the overall extraction performance to make the convincing conclusion.

[7] There are also a few is-a relations that are generated by indirect mapping. For example, the pattern "[E]单曲([E] digital single)" infers that the entity that is associated with the category is a song. However, most of the cases are related to non-taxonomic relations.

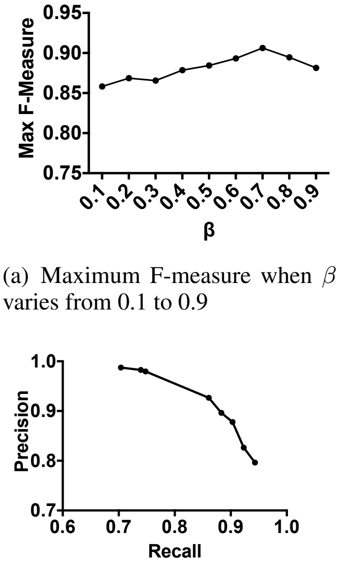
6.1 Data Source and Experimental Settings

The data source is downloaded from the Chinese Wikipedia dump of the version January 20th, 2017[8]. Because some Wikipedia pages are not related to entities, we use heuristic rules to filter out disambiguation, redirect, template and list pages. Finally, we obtain 0.6M entities and 2.4M entity-category pairs. The open-source toolkit FudanNLP (Qiu et al., 2013) is employed for Chinese NLP analysis. The word embeddings are trained via a Skip-gram model using a large corpus from Wang and He (2016) and set to 100 dimensions.

6.2 Is-a Relation Extraction

Test Set Generation We randomly select 2,000 entity-category pairs and ask multiple human annotators to label the relations (i.e., is-a and not-is-a). We discard all the pairs that have inconsistent labels across different annotators and obtain a dataset of 1,788 pairs. 30% of the data are used for parameter tuning and the rest for testing. The dataset is publicly available for research.[9]

Parameter Analysis Two parameters are required to be tuned in our method, i.e., β and θ. We vary the value of β from 0.1 to 0.9. With a fixed value of β, we change the value of θ to achieve the best performance over the development set. Figure 2(a) illustrates the maximum F-measure. Experimental results show our method is generally not very sensitive to the selection of β. When $\beta = 0.7$, it has the highest performance, indicating a good balance between the local and global prediction scores. Additionally, Figure 2(b) illustrates the precision-recall curve with respect to the change of θ when $\beta = 0.7$. The highest F-measure is achieved when we set $\theta = 0.05$.



(a) Maximum F-measure when β varies from 0.1 to 0.9

(b) Precision-recall curve when θ varies from -1 to 1

Figure 2: Parameter analysis.

Method	Precision	Recall	F1
Concat Model	79.5%	64.2%	67.2%
Sum Model	80.9%	70.1%	72.6%
Diff Model	78.3%	69.0%	71.5%
Piecewise Projection	78.9%	72.3%	75.5%
Our Method (w/o Exp)	89.2%	88.1%	88.7%
Our Method	**89.8%**	**88.3%**	**89.0%**

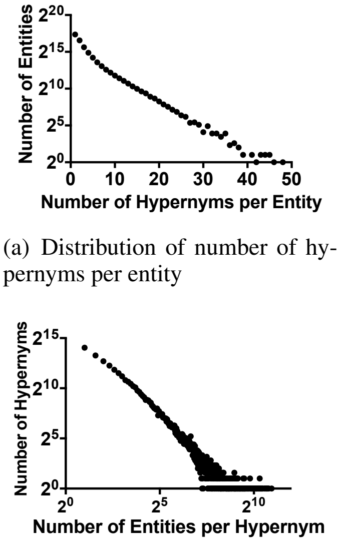
Table 1: Performance comparison over test set.

Comparative Study We set up the following strong baselines to compare our method with state-of-the-art approaches. The experimental results are shown in Table 1. To represent entity-category pairs with word embedding based features, we implement several state-of-the-art methods: the *concat* model $\vec{v}(e) \oplus \vec{v}(c_h)$, the *sum* model $\vec{v}(e) + \vec{v}(c_h)$ and the *diff* model $\vec{v}(e) - \vec{v}(c_h)$ (Baroni et al., 2012; Roller et al., 2014; Mirza and Tonelli, 2016). l_2-regularized logistic regression is trained to make the prediction due to the high performance in previous research. This approach achieves the highest F-measure of 72.6%. We also test the *piecewise projection* model proposed in Wang and He (2016) over Chinese Wikipedia, which is state-of-the-art for predicting is-a relations between Chinese words. It has a slight improvement in performance. As seen, our method without the hypernym expansion step (i.e., "Our Method (w/o Exp)" in Table 1) increases the F-measure by 13.2% (with $p < 0.01$) compared to Wang and He (2016). The full implementation of our method has the F-measure of 89.0%, which shows the effectiveness of our approach.

Overall Results In total, we extract 1.17M is-a relations from Chinese Wikipedia categories, consisting 412K entities and 113K distinct categories. In Figure 3(a), we present how many entities have a particular number of hypernyms. In average, each entity has 2.84 hypernyms. We can see that this distribution fits in a semi-log line, defined by

[8] http://download.wikipedia.com/zhwiki/20170120/

[9] There exist a few public datasets for Chinese is-a relations (Fu et al., 2013, 2014). But they aim to learn is-a relations between short concepts/terms and are not suitable for evaluating our work. We focus on understanding (relatively long) categories for entities.



(a) Distribution of number of hypernyms per entity

(b) Distribution of number of entities per hypernym

Figure 3: Distributional analysis on is-a relations.

Category Pattern	Relation Predicate
[E]校友(Alumni)	毕业(graduated-from)
[E]队教练(Coach)	执教(coach-team)
[E]省市镇 (City/Town in Province)	位于(located-in)
[E]获得者(Winner)	获奖(win-prize)

a log scale on the y-axis and a linear scale on the x-axis. Similarly, each hypernym has 10.35 entities in average, with the distribution illustrated in Figure 3(b). The number of entities per hypernym follows the power-law distribution with a long tail.

6.3 Non-taxonomic Relation Extraction

Detailed Steps We first run the single-pass pattern miner and extract the category patterns with top-500 highest support values. This is because only fewer than 20 entities are matched for the rest of the patterns. For each of these patterns, we fix $\tau = 0.7$ and run the MEWCP algorithm three times to ensure the high reliability of the seed relation instances, and select top-250 most confident category patterns. To determine the value of γ, we carry out a preliminary experiment, which samples 200 entity pairs to estimate the accuracy. It shows that even we set γ to a relatively low value (i.e., 0.2), the accuracy is over 90%. Finally, 26 relation types are created automatically based on direct verb mapping. We design the mapping rules and relation predicates for the remaining 16 relation types manually, with examples in Table 2.

Evaluation To evaluate the correctness of extracted relations, we carry out two experimental tests: accuracy test and coverage test. Following Suchanek et al. (2007), in the accuracy test, we randomly sample 200 relation instances for each relation type and ask human annotators to label. We discard the results if human annotators disagree. The coverage test is to determine whether the extracted relations already exist in Chinese knowledge bases. Low coverage score means these relations are not present in existing Chinese knowledge bases. In the experiments, we take CN-DBpedia V2.0 (Xu et al., 2017) as the ground truth knowledge base. Up till February 2017, it contains 41M explicit semantic relations of 9M entities, excluding entity summaries, synonyms, etc. We use the CN-DBpedia API[10] to obtain relations for each entity and report the coverage of relation r as:

$$cov(r) = \frac{\#\text{Matched extractions in CN-DBpedia}}{\#\text{Correct extractions generated by our approach}}$$

For fair comparison, because relations in different knowledge base systems may express differently, we ask human annotators to determine whether the relations extracted by our approach and CN-DBpedia match or not. In Table 3, we present the size, accuracy and coverage values of eight non-taxonomic relations, each with over three thousand relation instances.

From the experimental results, we can see that the accuracy is over 90% for all the eight relations. Especially the accuracy values of some relations are over 98% or even equal to 100%. This means it is reliable to extract relations from Chinese UGCs based category pattern mining. The results of the coverage tests present a large variance among different relations. While some relations such as “born-in” have a relatively high coverage in CN-DBpedia, other relation instances that we extract are rarely present in the knowledge base. Overall, the average coverage is approximately 21.1%. This means although the Chinese knowledge base is relatively large in size, it is far from complete. Furthermore, most relations in Chinese knowledge bases are extracted from infoboxes, in the form of attribute-value pairs (Fang et al., 2016; Niu et al., 2011; Wang et al., 2013). Thus, the knowledge harvested from UGCs can be an important supplementary for these systems.

Relation	Size	Accu.	Cov.	Relation	Size	Accu.	Cov.
毕业(graduated-from)	44,118	98.0%	22.9%	位于(located-in)	29,460	97.2%	8.5%
建立(established-in)	20,154	95.0%	31.5%	出生(born-in)	11,671	98.3%	41.4%
成员(member-of)	8,445	96.0%	4.2%	启用(open-in)	8,956	98.2%	21.6%
逝世(died-in)	5,597	100.0%	18.4%	得奖(win-prize)	3,262	90.0%	27.3%

Table 3: Size, accuracy and coverage values of eight extracted relation types.

Type	Category Pattern	Example
Member pattern	[E]成员/总统 Member/President of [E]	中国科学院成员 Member of Chinese Academy of Sciences
Verb-NP pattern	[E]+Verb+(的)+Noun Phrase	1990年建立的组织 Organization founded in 1990
Verb pattern	[E]+Verb	1980年出生1980 births

Table 4: Category patterns that we design for CN-WikiRe.

Currently, we only focus on Chinese Wikipedia categories. We will study how to extend our approach to UGCs for other knowledge sources, especially domain-specific sources in the future.

Overall Results In summary, our approach extracts 1.52M relations, including 1.17M is-a relations and 0.36M others. The estimated accuracy values of is-a, other and all relations are 92.2%, 97.4% and 93.6% respectively. The accuracy values are estimated over random samples of 500 relations.

Comparison Harvesting non-taxonomic relations from UGCs is non-trivial with no standard evaluation frameworks available. Furthermore, the significant difference between English and Chinese makes it difficult to compare our method with similar research. Pasca (2017) focuses on modifier in categories and is not directly comparable to our work. In YAGO (Suchanek et al., 2007), relations in categories are extracted by handcrafting regular expressions. They extract nine non-taxonomic relations, with accuracy values of around 90%-98%. Our approach avoids the manual work to a large extent and harvests more types of relations with a comparable accuracy.

Next we compare our work with Nastase and Strube (2008), which heavily relies on prepositions in patterns such as “Verb in/of” and “Member/CEO/President of” to discover relations. In Chinese, prepositions are usually expressed implicitly and hence these patterns are not directly applicable. We implement a variant for Chinese (denoted as CN-WikiRe). The patterns that we used in CN-WikiRe are shown in Table 4. In the experiments, we extract 165,048 non-taxonomic relation instances using CN-WikiRe, containing 631 relation types. Although the number of relation types may seem large at the first glance, only 14% of them are actual relation predicates, with the rest being either incorrect or uninformative. The reasons are twofold: i) word segmentation and POS tagging for Chinese short texts still suffer from low accuracy and ii) not all verbs extracted by CN-WikiRe can serve as relation predicates (e.g., “传导(transmit)”, “缩小(shrink)”). We sample 500 relations from the collection where the extracted verbs are labeled as real relation predicates. The accuracy is 58.6%, much lower than our method. Furthermore, the partially explicit and implicit patterns (see (Nastase and Strube, 2008)) do not have their counterparts in Chinese. Therefore, our method is superior to existing systems.

7 Conclusion and Future Work

We propose a weakly supervised framework to extract relations from Chinese UGCs. For is-a relations, we introduce a word embedding based method and refine prediction results using collective inference. To extract non-taxonomic relations, we design a graph mining technique to harvest relation types and category patterns with minimal human supervision. Future work includes: i) improving our work for short text knowledge extraction and ii) designing a general framework for cross-lingual UGC relation extraction.

Abstract

Slot Filling (SF) aims to extract the values of certain types of attributes (or slots, such as person:cities_of_residence) for a given entity from a large collection of source documents. In this paper we propose an effective DNN architecture for SF with the following new strategies: (1). Take a regularized dependency graph instead of a raw sentence as input to DNN, to compress the wide contexts between query and candidate filler; (2). Incorporate two attention mechanisms: local attention learned from query and candidate filler, and global attention learned from external knowledge bases, to guide the model to better select indicative contexts to determine slot type. Experiments show that this framework outperforms state-of-the-art on both relation extraction (16% absolute F-score gain) and slot filling validation for each individual system (up to 8.5% absolute F-score gain).

1 Introduction

The goal of Slot Filling (SF) is to extract pre-defined types of attributes or slots (e.g., *per:cities_of_residence*) for a given query entity from a large collection of documents. The slot filler (attribute value) can be an entity, time expression or value (e.g., *per:charges*). The TAC-KBP slot filling task (Ji et al., 2011a; Surdeanu and Ji, 2014) defined 41 slot types, including 25 types for person and 16 types for organization.

One critical component of slot filling is relation extraction, namely to classify the relation between a pair of query entity and candidate slot filler into one of the 41 types or none. Most previous studies have treated SF in the same way as within-sentence relation extraction tasks in ACE [1] or SemEval (Hendrickx et al., 2009). They created training data based on crowd-sourcing or distant supervision, and then trained a multi-class classifier or multiple binary classifiers for each slot type based on a set of hand-crafted features.

Although Deep Neural Networks (DNN) such as Convolutional Neural Networks (CNN) and Recurrent Neural Networks (RNN) have achieved state-of-the-art results on within-sentence relation extraction (Zeng et al., 2014; Liu et al., 2015; Santos et al., 2015; Nguyen and Grishman, 2015; Yang et al., 2016; Wang et al., 2016), there are limited studies on SF using DNN. Adel and Schütze (2015) and Adel et al. (2016) exploited DNN for SF but did not achieve comparable results as traditional methods. In this paper we aim to answer the following questions: What is the difference between SF and ACE/SemEval relation extraction task? How can we make DNN work for SF?

We argue that SF is different and more challenging than traditional relation extraction. First, a query and its candidate filler are usually separated by much wider contexts than the entity pairs in traditional relation extraction. As Figure 1 shows, in ACE data, for 70% of relations, two mentions are embedded in each other or separated by at most one word. In contrast, in SF, more than 46% of ⟨*query, filler*⟩ entity pairs are separated by at least 7 words. For example, in the following sentence:

E1. "**Arcandor**$_{query}$ owns a 52-percent stake in Europe's second biggest tourism group Thomas Cook, the Karstadt chain of department stores and iconic shops such as the **KaDeWe**$_{filler}$ in what used to be the commercial heart of West Berlin.",

[*] This work was carried out during an internship at IBM Research.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2588–2597
Copenhagen, Denmark, September 7–11, 2017.

Here, **Arcandor** and **KaDeWe** are far separated and it's difficult to determine the slot type as *org:subsidiaries* based on the raw wide contexts.

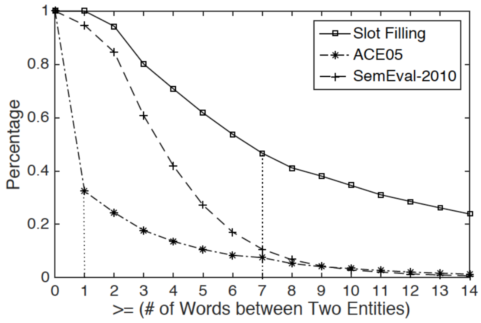

Figure 1: Comparison of the Percentage by the # of Words between two entity mentions in ACE05 and SemEval-2010 Task 8 relations, and between query and slot filler in KBP2013 Slot Filling.

In addition, compared with relations defined in ACE (18 types) and SemEval (9 types), slot types are more fine-grained and heavily rely on indicative contextual words for disambiguation. Yu et al. (2015) and Yu and Ji (2016) demonstrate that many slot types can be specified by contextual *trigger* words. Here, a *trigger* is defined as the word which is related to both the query and candidate filler, and can indicate the type of the target slot. Considering E1 again, *owns* is a trigger word between **Arcandor** and **KaDeWe**, which can indicate the slot type as *org:subsidiaries*. Most previous work manually constructed trigger lists for each slot type. However, for some slot types, the triggers can be implicit and ambiguous.

To address the above challenges, we propose the following new solutions:

- To compress wide contexts, we model the connection of query and candidate filler using dependency structures, and feed dependency graph to DNN. To our knowledge, we are the first to directly take dependency graphs as input to CNN.

- Motivated by the definition of *trigger*, we design two attention mechanisms: a local attention and a global attention using large external knowledge bases (KBs), to better capture implicit clues that indicate slot types.

2 Architecture Overview

Figure 2 illustrates the pipeline of a SF system. Given a query and a source corpus, the system retrieves related documents, identifies candidate fillers (including entities, time, values, and titles), extracts the relation between query and each candidate filler occurring in the same sentence, and finally determines the filler for each slot. Relation extraction plays a vital role in such a SF pipeline. In this work, we focus on relation extraction component and design a neural architecture.

Given a query, a candidate filler, and a sentence, we first construct a regularized dependency graph and take all $\langle$*governor, dependent*$\rangle$ word pairs as input to Convolutional Neural Networks (CNN).

Moreover, We design two attention mechanisms: **(1) Local Attention**, which utilizes the concatenation of *Query* and *Candidate Filler* vectors to measure the relatedness of each input bigram (we set filter width as 2) to the specific query and filler. **(2) Global attention**: We use prelearned slot type representations to measure the relatedness of each input bigram with each slot type via a transformation matrix. These two attention mechanisms will guide the pooling step to select the information which is related to query and filler and can indicate slot type.

3 Regularized Dependency Graph based CNN

3.1 Regularized Dependency Graph

Dependency parsing based features, especially the shortest dependency path between two entities, have been proved to be effective to extract the most important information for identifying the relation between two entities (Bunescu and Mooney, 2005; Zhao and Grishman, 2005; GuoDong et al., 2005; Jiang and Zhai, 2007). Several recent studies also explored transforming a dependency path into a sequence and applied Neural Networks to the sequence for relation classification (Liu et al., 2015; Cai et al., 2016; Xu et al., 2015).

However, for SF, the shortest dependency path between query and candidate filler is not always sufficient to infer the slot type due to two reasons. First, the most indicative words may not be included in the path. For example, in the following sentence:

E2. Survivors include two *sons* and *daughters*-in-law, **Troy**$_{filler}$ and Phyllis Perry, **Kenny**$_{query}$ and Donna Perry, all of Bluff City.

the shortest dependency path between **Kenny** and **Troy** is: "Troy $\xleftarrow{conj}$ Perry $\xleftarrow{conj}$ Kenny", which

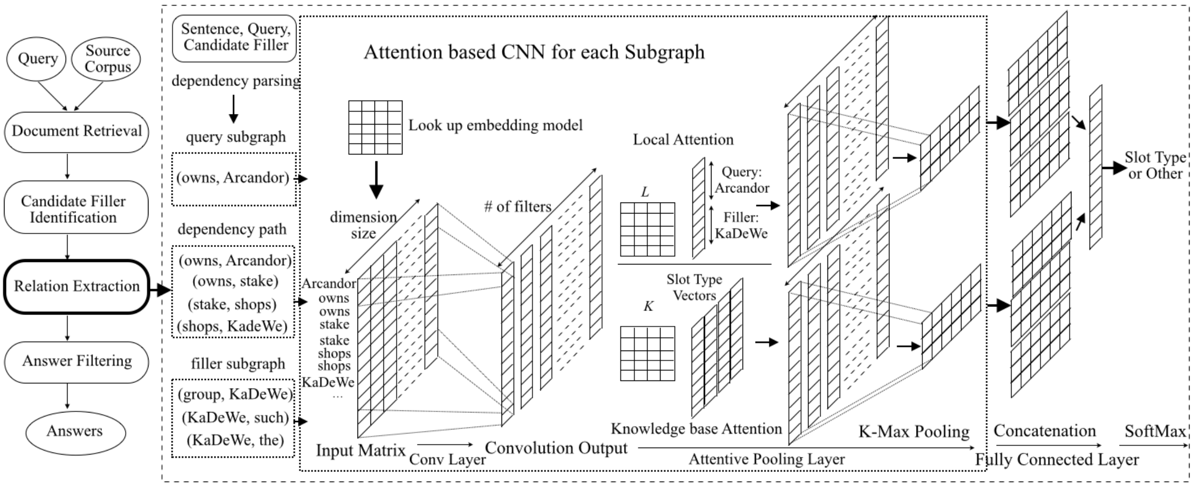

Figure 2: Overview of the Architecture.

does not include the most indicative words: *sons* and *daughters* for their *per:siblings* relation. In addition, the relation between query and candidate filler is also highly related to their entity types, especially for disambiguating slot types such as *per:country_of_birth* *per:state_of_birth* and *per:city_of_birth*. Entity types can be inferred by enriching query and filler related contexts. For example, in the following sentence:

E3. **Merkel**$_{query}$ died in the southern German city of **Passau**$_{filler}$ in 1967.

we can determine the slot type as *city* related by incorporating rich contexts (e.g., "*city*").

To tackle these problems, we propose to regularize the dependency graph, incorporating the shortest dependency path between query and candidate filler, as well as their rich contextual words.

Given a sentence s including a query q and candidate filler f, we first apply the Stanford Dependency Parser (Manning et al., 2014) to generate all dependent word pairs: ⟨*governor, dependent*⟩, then discover the shortest dependency path between query and candidate filler based on Breadth-First-Search (BFS) algorithm. The regularized dependency graph includes words on the shortest dependency path, as well as words which can be connected to query and filler within n hops. In our experiments, we set $n = 1$. Figure 3 shows the dependency parsing output for E1 mentioned in Section 1, and the regularized dependency graph with the bold circled nodes. We can see that, the most indicative trigger *owns* can be found in both the shortest dependency path of **Arcandor** and **KaDeWe**, and the context words of **Arcandor**. In addition, the context words, such as *shops*, can also infer the type of candidate filler **KaDeWe** as an Organization.

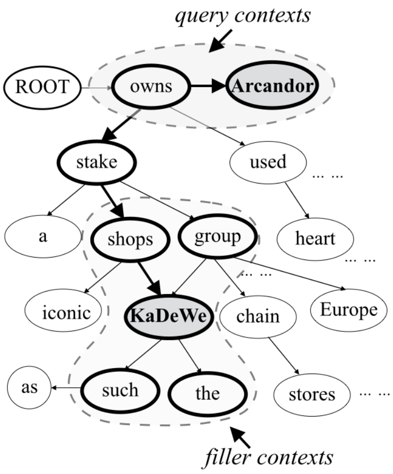

Figure 3: Regularized Dependency Graph for Query *Arcandor* and Filler *KaDeWe* in E1.

3.2 Graph based CNN

Previous work (Adel et al., 2016) split an input sentence into three parts based on the positions of the query and candidate filler and generate a feature vector for each part using a shared CNN. To compress the wide contexts, instead of taking the raw sentence directly as input, we split the regularized dependency graph into three parts: query related subgraph, candidate filler related subgraph, and the dependency path between query and filler. Each subgraph will be taken as input to a CNN, as illustrated in Figure 2. We now describe the details of each part as follows.

Input layer: Each subgraph or path G in the regularized dependency graph is represented as a set of dependent word pairs $G = \{\langle g_1, d_1\rangle, \langle g_2, d_2\rangle, ...\langle g_n, d_n\rangle\}$. Here, g_i, d_i denote the *governor* and *dependent* respectively. Each word is represented as a d-dimensional pre-trained vector. For the word which does not exist in the pre-trained embedding model, we assign a random vector for it. Each word pair $\langle g_i, d_i\rangle$ is converted to a $\mathbb{R}^{2\times d}$ matrix. We concatenate the matrices of all word pairs and get the input matrix $M \in \mathbb{R}^{2n\times d}$.

Convolution layer: For each subgraph, $M \in \mathbb{R}^{2n\times d}$ is the input of the convolution layer, which is a list of linear layers with parameters shared by filtering windows with various size. We set the stride as 2 to obtain all word pairs from the input matrix M. For each word pair $p_{in} = \langle v_{g_i}, v_{d_i}\rangle$, we compute the output vector p_{out} of a convolution layer as:

$$p_{out} = tanh(W \cdot p_{in} + b)$$

where p_{in} is the concatenation of vectors for the words v_{g_i} and v_{d_i}, W denotes the convolution weights, and b is the bias. In our work all three convolution layers share the same W and b.

K-Max Pooling Layer: we follow Adel et al. (2016) and use K-max pooling to select K values for each convolution layer. Later we will incorporate attention mechanisms into K-max pooling.

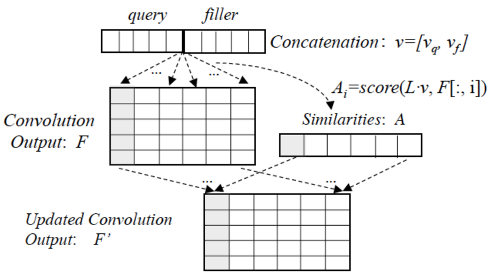
Fully Connected Layer: After getting the high-level features based on the (attentive) pooling layer for each input subgraph, we flatten and concatenate these three outputs as input to a fully connected layer. This layer connects each input to every single neuron it contains, and learns non-linear combinations based on the whole input.

Output Layer: It takes the output of the fully connected layer as input to a softmax regression function to predict the type. We use negative log-likelihood as loss function to train the parameters.

4 Attention Strategies for SF

4.1 Local Attention

The basic idea of attention mechanism is to assign a weight to each position of a lower layer when computing the representations for an upper layer, so that the model can be attentive to specific regions (Bahdanau et al., 2014). In SF, the indicative words are the most meaningful information that the model should pay attention to. Wang et al. (2016) applied attention from the entities directly to determine the most influential parts in the input sentence. Following the same intuition, we apply the attention from the query and candidate filler to the convolution output instead of the input, to avoid information vanishing during convolution process (Yin et al., 2016).



query
filler
Concatenation: $v=[v_q, v_f]$
A_i=score($L\cdot v$, F[:, i])
Convolution Output: F
Similarities: A
Updated Convolution Output: F'

Figure 4: Local Attention.

Figure 4 illustrates our approach to incorporate local attention. We first concatenate the vector of query q and candidate filler f using pre-trained embeddings $v = [v_q, v_f], \in \mathbb{R}^{2d}$. For q or f that includes multiple words, we average the vectors of all individual words. For each convolution output F, which is a feature map $\in \mathbb{R}^{\widehat{K}\times N}$, where N is the number of word pairs from the input, and $\widehat{K}$ is the number of filters, we define the attention similarity matrix $A \in R^{N\times 1}$ as:

$$A_i = cosine(L \cdot v, F[:, i])$$

where $L \in \mathbb{R}^{\widehat{K}\times 2d}$ is the transformation matrix between the concatenated vector v and convolution output. $F[:, i]$ denotes the vector of column i in F. Then we use the attention matrix A to update each column of the feature map F, and generate an updated attention feature map $F^{'}$ as follows:

$$F^{'}[:, i] = F[:, i] \cdot A[i]$$

4.2 Global Attention

Considering E1 in Section 1 again, the most discriminating word *owns* is not only related to the query and filler, but more specific to the type *org:subsidiaries*. Local attention aims to identify the query and filler related contexts. In order to detect type-indicative parts, we design global attention, using pre-learned slot type representations.

Wang et al. (2016) explored relation type attention with automatically learned type vectors from training data. However, in most cases, the training data is not balanced and some relation types cannot be assigned high-quality vectors with limited data. Thus, we designed two methods to generate pre-learned slot type representations.

First, we compose pre-trained lexical word embeddings of each slot type name to directly generate type representations. For example, for the type *per:date_of_birth*, we average the vectors of all single tokens (*person*, *birth*, *date*) within the type name as its representation.

Another new method is to take advantage of the large size of facts from external knowledge base (KB) to represent slot types. We use DBPedia as the target KB and manually map KB relations to slot types. For example, *per:alternate_names* can be mapped to *alternativeNames*, *birthName* and *nickName* in DBPedia. Thus for each slot type, we collect many triples: ⟨*query, slot, filler*⟩ and use TransE (Bordes et al., 2013), which models slot types as translations operating on the embeddings of query and filler, to derive a representation for each slot type. Compared with the first lexical based slot type representation induction approach, TransE jointly learns entity and relation representations and can better capture the correlation and differentiation among various slot types. Later, we will show the impact of these two types of slot type representations in Section 5.2.

Next we use the pre-learned slot type representations to guide the pooling process. Formally, let $R \in \mathbb{R}^{d \times r}$ be the matrix of all slot type vectors, where d is the vector dimension size and r is the number of slot types. Let $F \in \mathbb{R}^{\widehat{K} \times N}$ be a convolution output, which is the same as Section 4.1. We define the attention weight matrix S as:

$$S_{i,j} = cosine(F[:,i], W \cdot R[:,j])$$

where $W \in \mathbb{R}^{\widehat{K} \times d}$ is the transformation matrix for pre-learned slot type representations and convolution output. Given the weight matrix S, we generate the attention feature map $F^{''}$ as follows:

$$F^{''}[:,i] = F[:,i] \cdot \max_{j}\{S[i,j]\}$$

where $S[i,:]$ denotes the similarity scores between column i in F with all slot type vectors, and $\max\{S[i,:]\}$ is the max value among all similarity scores for column i in F.

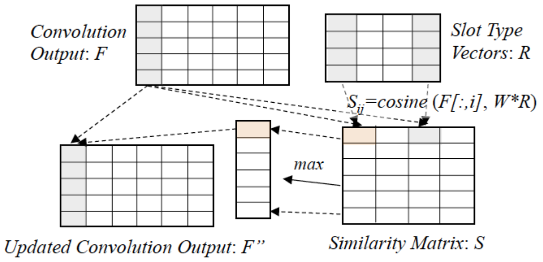


Figure 5: Global Attention.

We apply local attention to each convolution output of each subgraph, then take the concatenation of three flattened attentive pooling outputs to a fully connected layer and generate a robust feature representation. Similarly, another feature representation is generated based on global attention. We concatenate these two features to the softmax layer to get the predicted types.

5 Experiments

5.1 Data

For model training, Angeli et al. (2014) created some high-quality clean annotations for SF based on crowd-sourcing[2]. In addition, Adel et al. (2016) automatically created a larger size of noisy training data based on distant supervision, including about 1,725,891 positive training instances for 41 slot types. We manually assessed the correctness of candidate filler identification and their slot type annotation, and extracted a subset of their noisy annotations and combined it with the clean annotations. Ultimately, we obtain 23,993 positive and 3,000 negative training instances for all slot types.

We evaluate our approach in two settings: (1) relation extraction for all slot types, given the boundaries of query and candidate fillers. We use a script[3] to generate a test set (4892 instances) from KBP 2012/2013 slot filling evaluation data sets with manual assessment. (2) apply our approach to re-classify and validate the results of slot filling systems. We use the data from the KBP 2013 Slot Filling Validation (SFV) shared task, which consists of merged responses returned by 52 runs from 18 teams submitted to the Slot Filling task.

We used the May-2014 English Wikipedia dump to learn word embeddings based on the Continuous Skip-gram model (Mikolov et al., 2013).

h	Hidden Unit Size in Fully Connected Layer	1000
k^p	Max Pooling Size	3

Table 1: Hyper-parameters.

5.2 Relation Extraction

We compare with several existing state-of-the-art slot filling and relation extraction methods on slot filling data sets. Besides, we also design several variants to demonstrate the effectiveness of each component in our approach. Table 2 presents the detailed approaches and the features used by these methods.

We report scores with Macro F_1 and Micro F_1. Macro F_1 is computed from the average precision and recall of all types while Micro F_1 is computed from the overall precision and recall, which is more useful when the size of each category varies. Table 3 shows the comparison results on relation extraction.

We can see that by incorporating the shortest dependency path or regularized dependency graph into neural networks, the model can achieve more than 13% micro F-score gain over the previously widely adopted methods by state-of-the-art systems for SemEval relation classification. It confirms our claim that SF is a different and more challenging task than traditional relation classification and also demonstrates the effectiveness of dependency knowledge for SF.

In addition, by incorporating local or global attention mechanism into the GraphCNN, the performance can be further improved, which proves the effectiveness of these two attention mechanisms. Our method finally achieves absolute 16% F-score gain by incorporating the regularized dependency graph and two attention mechanisms.

To better quantify the contribution of different attention mechanisms on each slot type, we further compared the performances on each single slot type. Table 4 shows the gain/loss percentage of the Micro F1 by adding local attention or global attention into GraphCNN for each slot type. We can see that both attentions yield improvement for most slot types.

5.3 Slot Filling Validation

In TAC-KBP 2013 Slot Filling Validation (SFV) (Ji et al., 2011b) task, there are 100 queries. We first retrieve the sentences from the source corpus (about 2,099,319 documents) and identify the query and candidate filler using the offsets generated by each response, then apply our approach to re-predict the slot type. Figure 6 shows the F-scores based on our approach and the original system. For a system which has multiple runs, we select one for comparison. We can see that our approach consistently improves the performance of almost all SF systems in an absolute gain range of [-0.18%, 8.48%]. With analysis of each system run, we find that our approach can provide more gains to the SF systems which have lower precision.

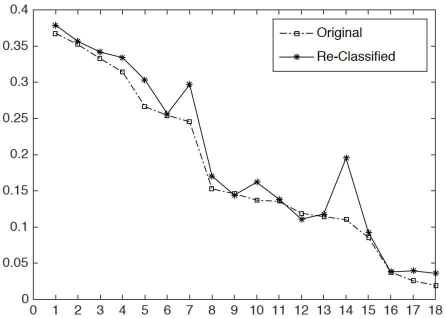

Figure 6: Comparison on Individual System

Previous studies (Tamang and Ji, 2011; Rodriguez et al., 2015; Zhi et al., 2015; Viswanathan et al., 2015; Rajani and Mooney, 2016a; Yu et al., 2014a; Rajani and Mooney, 2016b) for SFV trained supervised classifiers based on features such as confidence score of each response and system credibility. For comparison, we developed a new SFV approach: a new SVM classifier based on a set of features (docId, filler string, original predicted slot type and confidence score, new predicted slot type confidence score based on our neural architecture) for each response to take advantage of the redundant information from various system runs. Table 5 compares our SFV performance against previous reported scores on judging each response as true or false. We can see that our approach advances state-of-the-art methods.

Our Method	GraphCNN+L+G^2	**57.39**	**38.26**

Table 3: Relation Extraction Component Performance on **Slot Filling Data Set** (%).

approaches are not random, we randomly sample 10 subsets (each contains 500 instances) from the testing dataset, and conduct paired t-test between each of these two approaches over these 10 data sets to check whether the average difference in their performances is significantly different or not. Table 6 shows the two-tailed P values. The differences are all considered to be statistically significant while all p-values are less than 0.05.

Impact of Training Data Size: We examine the impact of the size of training data on the performance for each slot type. Table 4 shows the distribution of training data and the F-score of each single type. We can see that, for some slot types, such as *per:date_of_birth* and *per:age*, the entity types of their candidate fillers are easy to learn and differentiate from other slot types, and their indicative words are usually explicit, thus our approach can get high f-score with limited training data (less than 507 instances). In contrast, for some slots, such as *org:location_of_headquarters*, their clues are implicit and the entity types of candidate fillers are difficult to be inferred. Although the size of training data is larger (more than 1,433 instances), the f-score remains quite low. One possible solution is to incorporate fine-grained entity types from existing tools into the neural architecture.

Impact of Wide Context Distribution: We further compared the performance and distribution of instances with wide contexts across all slot types. A context is considered as wide if the query and candidate filler are separated with more than 7 words. The last column of Table 4 shows the performance by incorporating regularized dependency graph (ContextCNN *v.s.* GraphCNN). We can see that, for most slot types with wide contexts, such as *per:states_of_residence* and *per:employee_of*, the f-scores are improved significantly while for some slots such as *per:date_of_birth*, the f-scores decrease because most date phrases do not exist in our pre-trained embedding model.

Error Analysis: Both of the relation extraction and SFV results showed that, more than 58% classification errors are spurious. Besides, we also observed many misclassifications that are caused by conflicting clues. There may be several indicative words within the contexts, but only one slot type is labeled, especially between *per:location_of_death* and *per:location_of_residence*. For example, in the following sentence:

E4. ***Billy Mays***$_{query}$*, a beloved and parodied pitchman who became a pop-culture figure through his commercials for cleaning prod-*

> *ucts like Orange Glo, OxiClean and Kaboom, died Sunday at his home in* ***Tampa***$_{filler}$*, Fla.,*

the correct slot type is *per:city_of_death* while our approach mistakenly labeled it as *per:city_of_residence* with clue words like *home*. In addition, as we mentioned before, slot typing heavily relies on the fine-grained entity type of candidate filler, especially for the *location* (including *city, state, country*) related slot types. When the context is not specified enough, we can only rely on the pre-trained embeddings of candidate fillers, which may not be as informative as we hope. Such cases will benefit from introducing additional gazetteers such as *Geonames* [4].

6 Related Work

One major challenge of SF is the lack of labeled data to generalize a wide range of features and patterns, especially for slot types that are in the long-tail of the quite skewed distribution of slot fills (Ji et al., 2011a). Previous work has mostly focused on compensating the data needs by constructing patterns (Sun et al., 2011; Roth et al., 2014b), automatic annotation by distant supervision (Surdeanu et al., 2011; Roth et al., 2014a; Adel et al., 2016), and constructing trigger lists for unsupervised dependency graph mining (Yu and Ji, 2016; Yu et al., 2016). Some work (Rodriguez et al., 2015; Zhi et al., 2015; Viswanathan et al., 2015; Hong et al., 2015; Rajani and Mooney, 2016a; Yu et al., 2014a; Rajani and Mooney, 2016b; Ma et al., 2015) also attempted to validate slot types by combining results from multiple systems.

Our work is also related to dependency path based relation extraction. The effectiveness of dependency features for relation classification has been reported in some previous work (Bunescu and Mooney, 2005; Zhao and Grishman, 2005; GuoDong et al., 2005; Jiang and Zhai, 2007; Neville and Jensen, 2003; Ebrahimi and Dou, 2015; Xu et al., 2015; Ji et al., 2014). Liu et al. (2015), Cai et al. (2016) and Xu et al. (2015) applied CNN, bidirectional recurrent CNN and LSTM to CONLL relation extraction and demonstrated that the most important information has been included within the shortest paths between entities. Considering that the indicative words may not be included by the shortest dependency path between query and candidate filler, we enrich it to a regularized dependency graph by adding more contexts.

7 Conclusions and Future Work

In this work, we discussed the unique challenges of slot filling compared with tradition relation extraction tasks. We designed a regularized dependency graph based neural architecture for slot filling. By incorporating local and global attention mechanisms, this approach can better capture indicative contexts. Experiments on relation extraction and Slot Filling Validation data sets demonstrate the effectiveness of our neural architecture. In the future, we will combine additional rules, patterns, and constraints with DNN techniques to further improve slot filling.

Abstract

One weakness of machine-learned NLP models is that they typically perform poorly on out-of-domain data. In this work, we study the task of identifying products being bought and sold in online cybercrime forums, which exhibits particularly challenging cross-domain effects. We formulate a task that represents a hybrid of slot-filling information extraction and named entity recognition and annotate data from four different forums. Each of these forums constitutes its own "fine-grained domain" in that the forums cover different market sectors with different properties, even though all forums are in the broad domain of cybercrime. We characterize these domain differences in the context of a learning-based system: supervised models see decreased accuracy when applied to new forums, and standard techniques for semi-supervised learning and domain adaptation have limited effectiveness on this data, which suggests the need to improve these techniques. We release a dataset of 1,938 annotated posts from across the four forums.[1]

1 Introduction

NLP can be extremely useful for enabling scientific inquiry, helping us to quickly and efficiently understand large corpora, gather evidence, and test hypotheses (Bamman et al., 2013; O'Connor et al., 2013). One domain for which automated analysis is particularly useful is Internet security: researchers obtain large amounts of text data pertinent to active threats or ongoing cybercriminal activity, for which the ability to rapidly characterize that text and draw conclusions can reap major benefits (Krebs, 2013a,b). However, conducting automatic analysis is difficult because this data is out-of-domain for conventional NLP models, which harms the performance of both discrete models (McClosky et al., 2010) and deep models (Zhang et al., 2017). Not only that, we show that data from one cybercrime forum is even out of domain with respect to *another* cybercrime forum, making this data especially challenging.

TITLE: [buy] Backconnect bot
BODY: Looking for a solid backconnect bot .
If you know of anyone who codes them please let me know

(a) File 0-initiator4856

TITLE: Exploit cleaning ?
BODY: Have some Exploits i need fud .

(b) File 0-initiator10815

Figure 1: Example posts and annotations from Darkode, with annotated product tokens underlined. The second example exhibits jargon (*fud* means "fully undetectable"), nouns that could be a product in other contexts (*Exploit*), and multiple lexically-distinct descriptions of a single service. Note that these posts are much shorter than the average Darkode post (61.5 words).

In this work, we present the task of identifying products being bought and sold in the marketplace sections of these online cybercrime forums.

Forum	Posts	Words per post	Products per post	Annotated posts	Annotators per post	Inter-annotator agreement 3-annotated	 all-annotated
Darkode	3,368	61.5	3.2	660/100/100	3/8/8	0.62	0.66
Hack Forums	51,271	58.9	2.2	758/140	3/4	0.58	0.65
Blackhat	167	174	3.2	80	3	0.66	0.67
Nulled	39,118	157	2.3	100	3	0.77	-

Table 1: Forum statistics. The left columns (posts and words per post) are calculated over all data, while the right columns are based on annotated data only. Note that products per post indicate product mentions per post, not product types. Slashes indicate the train/development/test split for Darkode and train/test split for Hack Forums. Agreement is measured using Fleiss' Kappa; the two columns cover data where three annotators labeled each post and a subset labeled by all annotators.

We define a token-level annotation task where, for each post, we annotate references to the product or products being bought or sold in that post. Having the ability to automatically tag posts in this way lets us characterize the composition of a forum in terms of what products it deals with, identify trends over time, associate users with particular activity profiles, and connect to price information to better understand the marketplace. Some of these analyses only require post-level information (what is the product being bought or sold in this post?) whereas other analyses might require token-level references; we annotate at the token level to make our annotation as general as possible. Our dataset has already proven enabling for case studies on these particular forums (Portnoff et al., 2017), including a study of marketplace activity on bulk hacked accounts versus users selling their own accounts.

Our task has similarities to both slot-filling information extraction (with provenance information) as well as standard named-entity recognition (NER). Compared to NER, our task features a higher dependence on context: we only care about the specific product being bought or sold in a post, not other products that might be mentioned. Moreover, because we are operating over forums, the data is substantially messier than classical NER corpora like CoNLL (Tjong Kim Sang and De Meulder, 2003). While prior work has dealt with these messy characteristics for syntax (Kaljahi et al., 2015) and for discourse (Lui and Baldwin, 2010; Kim et al., 2010; Wang et al., 2011), our work is the first to tackle forum data (and marketplace forums specifically) from an information extraction perspective.

Having annotated a dataset, we examine supervised and semi-supervised learning approaches to the product extraction problem. Binary or CRF classification of tokens as products is effective, but performance drops off precipitously when a system trained on one forum is applied to a different forum: in this sense, even two different cybercrime forums seem to represent different "fine-grained domains." Since we want to avoid having to annotate data for every new forum that might need to be analyzed, we explore several methods for adaptation, mixing type-level annotation (Garrette and Baldridge, 2013; Garrette et al., 2013), token-level annotation (Daume III, 2007), and semi-supervised approaches (Turian et al., 2010; Kshirsagar et al., 2015). We find little improvement from these methods and discuss why they fail to have a larger impact.

Overall, our results characterize the challenges of our fine-grained domain adaptation problem in online marketplace data. We believe that this new dataset provides a useful testbed for additional inquiry and investigation into modeling of fine-grained domain differences.

2 Dataset and Annotation

We consider several forums that vary in the nature of products being traded:

- Darkode: Cybercriminal wares, including exploit kits, spam services, ransomware programs, and stealthy botnets.
- Hack Forums: A mixture of cyber-security and computer gaming blackhat and non-cybercrime products.
- Blackhat: Blackhat Search Engine Optimization techniques.
- Nulled: Data stealing tools and services.

Table 1 gives some statistics of these forums. These are the same forums used to study product activity in Portnoff et al. (2017). We collected all available posts and annotated a subset of them. In total, we annotated 130,336 tokens; accounting for multiple annotators, our annotators considered 478,176 tokens in the process of labeling the data.

Figure 1 shows two examples of posts from Darkode. In addition to aspects of the annotation, which we describe below, we see that the text exhibits common features of web text: abbreviations, ungrammaticality, spelling errors, and visual formatting, particularly in thread titles. Also, note how some words that are not products here might be in other contexts (e.g., *Exploits*).

2.1 Annotation Process

We developed our annotation guidelines through six preliminary rounds of annotation, covering 560 posts. Each round was followed by discussion and resolution of every post with disagreements. We benefited from members of our team who brought extensive domain expertise to the task. As well as refining the annotation guidelines, the development process trained annotators who were not security experts. The data annotated during this process is not included in Table 1.

Once we had defined the annotation standard, we annotated datasets from Darkode, Hack Forums, Blackhat, and Nulled as described in Table 1.[2] Three people annotated every post in the Darkode training, Hack Forums training, Blackhat test, and Nulled test sets; these annotations were then merged into a final annotation by majority vote. The development and test sets for Darkode and Hack Forums were annotated by additional team members (five for Darkode, one for Hack Forums), and then every disagreement was discussed and resolved to produce a final annotation. The authors, who are researchers in either NLP or computer security, did all of the annotation.

We preprocessed the data using the tokenizer and sentence-splitter from the Stanford CoreNLP toolkit (Manning et al., 2014). Note that many sentences in the data are already delimited by line breaks, making the sentence-splitting task much easier. We performed annotation on the tokenized data so that annotations would be consistent with surrounding punctuation and hyphenated words.

Our full annotation guide is available with our data release.[3] Our basic annotation principle is to annotate tokens when they are either the product that will be delivered or are an integral part of the method leading to the delivery of that product. Figure 1 shows examples of this for a deliverable product (*bot*) as well as a service (*cleaning*). Both a product and service may be annotated in a single example: for a post asking to *hack an account*, *hack* is the method and the deliverable is the *account*, so both are annotated. In general, methods expressed as verbs may be annotated in addition to nominal references.

When the product is a multiword expression (e.g., *Backconnect bot*), it is almost exclusively a noun phrase, in which case we annotate the head word of the noun phrase (*bot*). Annotating single tokens instead of spans meant that we avoided having to agree on an exact parse of each post, since even the boundaries of base noun phrases can be quite difficult to agree on in ungrammatical text.

If multiple different products are being bought or sold, we annotate them all. We do not annotate:

- Features of products
- Generic product references, e.g., *this*, *them*
- Product mentions inside "vouches" (reviews from other users)
- Product mentions outside of the first and last 10 lines of each post[4]

Table 1 shows inter-annotator agreement according to our annotation scheme. We use the Fleiss' Kappa measurement (Fleiss, 1971), treating our task as a token-level annotation where every token is annotated as either a product or not. We chose this measure as we are interested in agreement between more than two annotators (ruling out Cohen's kappa), have a binary assignment (ruling out correlation coefficients) and have datasets large enough that the biases Krippendorff's Alpha addresses are not a concern. The values indicate reasonable agreement.

2.2 Discussion

Because we annotate entities in a context-sensitive way (i.e., only annotating those in product context), our task resembles a post-level information

[2] The table does not include additional posts that were labeled by all annotators in order to check agreement.

[3] `https://evidencebasedsecurity.org/forums/annotation-guide.pdf`

[4] In preliminary annotation we found that content in the middle of the post typically described features or gave instructions without explicitly mentioning the product. Most posts are unaffected by this rule: 96% of Darkode, 77% of Hack Forums, 84% of Blackhat, and 93% of Nulled posts are less than 20 lines. However, the cutoff still substantially reduced annotator effort on the tail of very long posts.

extraction task. The product information in a post can be thought of as a list-valued slot to be filled in the style of TAC KBP (Surdeanu, 2013; Surdeanu and Ji, 2014), with the token-level annotations constituting provenance information. However, we chose to anchor the task fully at the token level to simplify the annotation task: at the post level, we would have to decide whether two distinct product mentions were actually distinct products or not, which requires heavier domain knowledge. Our approach also resembles the fully token-level annotations of entity and event information in the ACE dataset (NIST, 2005).

3 Evaluation Metrics

In light of the various views on this task and its different requirements for different potential applications, we describe and motivate a few distinct evaluation metrics below. The choice of metric will impact system design, as we discuss in the following sections.

Token-level accuracy We can follow the approach used in token-level tasks like NER and compute precision, recall, and F_1 over the set of tokens labeled as products. This most closely mimics our annotation process.

Type-level product extraction (per post) For many applications, the primary goal of the extraction task is more in line with KBP-style slot filling, where we care about the set of products extracted from a particular post. Without a domain-specific lexicon containing full synsets of products (e.g., something that could recognize that *hack* and *access* are synonymous), it is difficult to evaluate this in a fully satisfying way. However, we approximate this evaluation by comparing the set of product *types*[5] in a post with the set of product types predicted by the system. Again, we consider precision, recall, and F_1 over these two sets. This metric favors systems that consistently make correct post-level predictions even if they do not retrieve every token-level occurrence of the product.

Post-level accuracy Most posts contain only one product, but our type-level extraction will naturally be a conservative estimate of performance simply because there may seem to be multiple "products" that are actually just different ways of referring to one core product. Roughly 60% of posts in the two forums contain multiple annotated tokens that are distinct beyond stemming and lowercasing. However, we analyzed 100 of these multiple product posts across Darkode and Hack Forums, and found that only 6 of them were actually selling multiple products, indicating that posts selling multiple types of products are actually quite rare (roughly 3% of cases overall). In the rest of the cases, the variations were due to slightly different ways of describing the same product.

In light of this, we also might consider asking the system to extract *some* product reference from the post, rather than all of them. Specifically, we compute accuracy on a post-level by checking whether the first product type extracted by the system is contained in the annotated set of product types.[6] Because most posts feature one product, this metric is sufficient to evaluate whether we understood what the core product of the post was.

3.1 Phrase-level Evaluation

Another axis of variation in metrics comes from whether we consider token-level or phrase-level outputs. As noted in the previous section, we did not annotate noun phrases, but we may actually be interested in identifying them. In Figure 1, for example, extracting *Backconnect bot* is more useful than extracting *bot* in isolation, since *bot* is a less specific characterization of the product.

We can convert our token-level annotations to phrase-level annotations by projecting our annotations to the noun phrase level based on the output of an automatic parser. We used the parser of Chen and Manning (2014) to parse all sentences of each post. For each annotated token that was given a nominal tag (N*), we projected that token to the largest NP containing it of length less than or equal to 7; most product NPs are shorter than this, and when the parser predicts a longer NP, our analysis found that it typically reflects a mistake. In Figure 1, the entire noun phrase *Backconnect bot* would be labeled as a product. For products realized as verbs (e.g., *hack*), we leave the annotation as the single token.

Throughout the rest of this work, we will evaluate sometimes at the token-level and sometimes at

[5] Two product tokens are considered the same type if after lowercasing and stemming they have a sufficiently small edit distance: 0 if the tokens are length 4 or less, 1 if the lengths are between 5 and 7, and 2 for lengths of 8 or more

[6] For this metric we exclude posts containing no products. These are usually posts that have had their content deleted or are about forum administration.

the NP-level[7] (including for the product type evaluation and post-level accuracy); we will specify which evaluation is used where.

4 Models

We consider several baselines for product extraction, two supervised learning-based methods (here), and semi-supervised methods (Section 5).

Baselines One approach takes the most **frequent** noun or verb in a post and classifies all occurrences of that word type as products. A more sophisticated lexical baseline is based on a product **dictionary** extracted from our training data: we tag the most frequent noun or verb in a post that also appears in this dictionary. This method fails primarily in that it prefers to extract common words like *account* and *website* even when they do not occur as products. The most relevant off-the-shelf system is an **NER** tagging model; we retrain the Stanford NER system on our data (Finkel et al., 2005). Finally, we can tag the **first** noun phrase of the post as a product, which will often capture the product if it is mentioned in the title of the post.[8]

We also include human performance results. We averaged the results for annotators compared with the consensus annotations. For the phrase level evaluation, we apply the projection method described in Section 3.1.

Binary classifier/CRF One learning-based approach to this task is to employ a binary SVM classifier for each token in isolation. We also experimented with a token-level CRF with a binary tagset, and found identical performance, so we describe the binary classifier version.[9] Our features look at both the token under consideration as well as neighboring tokens, as described in the next paragraph. A vector of "base features" is extracted for each of these target tokens: these include 1) sentence position in the document and word position in the current sentence as bucketed indices; 2) word identity (for common words), POS tag, and dependency relation to parent for each word in a window of size 3 surrounding the current word; 3) character 3-grams of the current word. The same base feature set is used for every token.

Our token-classifying SVM extracts base features on the token under consideration as well as its syntactic parent. Before inclusion in the final classifier, these features are conjoined with an indicator of their source (i.e., the current token or the parent token). Our NP-classifying SVM extracts base features on first, last, head, and syntactic parent tokens of the noun phrase, again with each feature conjoined with its token source.

We weight false positives and false negatives differently to adjust the precision/recall curve (tuned on development data for each forum), and we also empirically found better performance by upweighting the contribution to the objective of singleton products (product types that occur only once in the training set).

Post-level classifier As discussed in Section 3, one metric we are interested in is whether we can find *any* occurrence of a product in a post. This task is easier than the general tagging problem: if we can effectively identify the product in, e.g., the title of a post, then we do not need to identify additional references to that product in the body of the post. Therefore, we also consider a post-level model, which directly tries to select one token (or NP) out of a post as the most likely product. Structuring the prediction problem in this way naturally lets the model be more conservative in its extractions, since highly ambiguous product mentions can be ignored if a clear product mention is present. Put another way, it supplies a useful form of prior knowledge, namely that each post has exactly one product in almost all cases.

Our post-level system is formulated as an instance of a latent SVM (Yu and Joachims, 2009). The output space is the set of all tokens (or noun phrases, in the NP case) in the post. The latent variable is the choice of token/NP to select, since there may be multiple correct choices of product tokens. The features used on each token/NP are the same as in the token classifier.

We trained all of the learned models by subgradient descent on the primal form of the objective (Ratliff et al., 2007; Kummerfeld et al., 2015). We use AdaGrad (Duchi et al., 2011) to speed convergence in the presence of a large weight vector with heterogeneous feature types. All product extractors in this section are trained for 5 iterations with ℓ_1-regularization tuned on the development set.

[7] Where NP-level means "noun phrases and verbs" as described in Section 3.1.

[8] Since this baseline fundamentally relies on noun phrases, we only evaluate it in the noun phrase setting.

[9] We further experimented with a bidirectional LSTM tagger and found similar performance as well.

Token Prediction							
	Tokens			Products			Posts

Table 2: Development set results on Darkode. Bolded F$_1$ values represent statistically-significant improvements over all other system values in the column with $p < 0.05$ according to a bootstrap resampling test. Our post-level system outperforms our binary classifier at whole-post accuracy and on type-level product extraction, even though it is less good on the token-level metric. All systems consistently identify product NPs better than they identify product tokens. However, there is a substantial gap between our systems and human performance.

4.1 Basic Results

Table 2 shows development set results on Darkode for each of the four systems for each metric described in Section 3. Our learning-based systems substantially outperform the baselines on the metrics they are optimized for. The post-level system underperforms the binary classifier on the token evaluation, but is superior at not only post-level accuracy but also product type F$_1$. This lends credence to our hypothesis that picking one product suffices to characterize a large fraction of posts. Comparing the automatic systems with human annotator performance we see a substantial gap. Note that our best annotator's token F$_1$ was 89.8, and NP post accuracy was 100%; a careful, well-trained annotator can achieve very high performance, indicating a high skyline.

The noun phrase metric appears to be generally more forgiving, since token distinctions within noun phrases are erased. The post-level NP system achieves an F-score of 78 on product type identification, and post-level accuracy is around 88%. While there is room for improvement, this system is accurate enough to enable analysis of Darkode with automatic annotation.

Throughout the rest of this work, we focus on NP-level evaluation and post-level NP accuracy.

5 Domain Adaptation

Table 2 only showed results for training and evaluating within the same forum (Darkode). However, we wish to apply our system to extract product occurrences from a wide variety of forums, so we are interested in how well the system will generalize to a new forum. Tables 3 and 4 show full results of several systems in within-forum and cross-forum evaluation settings. Performance is severely degraded in the cross-forum setting compared to the within-forum setting, e.g., on NP-level F$_1$, a Hack Forums-trained model is 14.6 F$_1$ worse at the Darkode task than a Darkode-trained model (61.2 vs. 75.8). Differences in how the systems adapt between different forums will be explored more thoroughly in Section 5.4.

In the next few sections, we explore several possible methods for improving results in the cross-forum settings and attempting to build a more domain-general system. These techniques generally reflect two possible hypotheses about the source of the cross-domain challenges:

Hypothesis 1: Product inventories are the primary difference across domains; context-based features will transfer, but the main challenge is not being able to recognize unknown products.

Hypothesis 2: Product inventories **and** stylistic conventions both differ across domains; we need to capture both to adapt models successfully.

5.1 Brown Clusters

To test Hypothesis 1, we investigate whether additional lexical information helps identify product-like words in new domains. A classic semi-supervised technique for exploiting unlabeled target data is to fire features over word clusters or word vectors (Turian et al., 2010). These features should generalize well across domains that the clusters are formed on: if product nouns occur in similar contexts across domains and therefore wind up in the same cluster, then a model trained on domain-limited data should be able to learn that that cluster identity is indicative of products.

We form Brown clusters on our unlabeled data from both Darkode and Hack Forums (see Table 1

Brown clusters and gazetteers give similarly mixed results as in the token-level evaluation; † indicates statistically significant gains over the post-level system with $p < 0.05$ according to a bootstrap resampling test.

for sizes). We use Liang (2005)'s implementation to learn 50 clusters.[10] Upon inspection, these clusters do indeed capture some of the semantics relevant to the problem: for example, the cluster 110 has as its most frequent members *service*, *account*, *price*, *time*, *crypter*, and *server*, many of which are product-associated nouns. We incorporate these as features into our model by characterizing each token with prefixes of the Brown cluster ID; we used prefixes of length 2, 4, and 6.

Tables 3 and 4 show the results of incorporating Brown cluster features into our trained models. These features do not lead to statistically-significant gains in either NP-level F_1 or post-level accuracy, despite small improvements in some cases. This indicates that Brown clusters might be a useful feature sometimes, but do not solve the domain adaptation problem in this context.[11]

5.2 Type-level Annotation

Another approach following Hypothesis 1 is to use small amounts of supervised data, One cheap approach for annotating data in a new domain is to exploit type-level annotation (Garrette and Baldridge, 2013; Garrette et al., 2013). Our token-level annotation standard is relatively complex to learn, but a researcher could quite easily provide a few exemplar products for a new forum based on just a few minutes of reading posts and analyzing the forum.

Given the data that we've already annotated, we can simulate this process by iterating through our labeled data and collecting annotated product names that are sufficiently common. Specifically, we take all (lowercased, stemmed) product tokens and keep those occurring at least 4 times in the training dataset (recall that these datasets are ≈ 700 posts). This gives us a list of 121 products in Darkode and 105 products in Hack Forums.

To incorporate this information into our system, we add a new feature on each token indicating whether or not it occurs in the gazetteer. At training time, we use the gazetteer scraped from the training set. At test time, we use the gazetteer from the target domain as a form of partial type-level supervision. Tables 3 and 4 shows the results of incorporating the gazetteer into the system. Gazetteers seem to provide somewhat consistent gains in cross-domain settings, though many of these individual improvements are not statistically significant, and the gazetteers can sometimes hurt performance when testing on the same domain the system was trained on.

[10] This value was chosen based on dev set experiments.

[11] We could also use vector representations of words here, but in initial experiments, these did not outperform Brown clusters. That is consistent with the results of Turian et al. (2010) who showed similar performance between Brown clusters and word vectors for chunking and NER.

Test	Darkode			Hack Forums			Blackhat			Nulled		
System	% OOV	R_{seen}	R_{OOV}	% OOV	R_{seen}	R_{OOV}	% OOV	R_{seen}	R_{OOV}	% OOV	R_{seen}	R_{OOV}
Binary (Darkode)	20	78	62	41	64	47	42	69	46	30	72	45
Binary (HF)	50	76	40	35	75	42	51	70	38	33	83	32

Table 5: Product token out-of-vocabulary rates on development sets (test set for Blackhat and Nulled) of various forums with respect to training on Darkode and Hack Forums. We also show the recall of an NP-level system on seen (R_{seen}) and OOV (R_{OOV}) tokens. Darkode seems to be more "general" than Hack Forums: the Darkode system generally has lower OOV rates and provides more consistent performance on OOV tokens than the Hack Forums system.

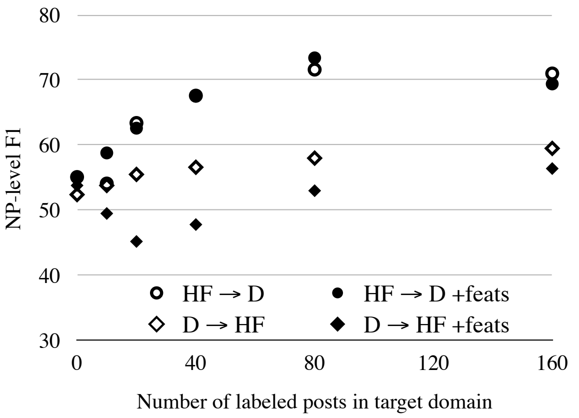

Figure 2: Token-supervised domain adaptation results for two settings. As our system is trained on an increasing amount of target-domain data (x-axis), its performance generally improves. However, adaptation from Hack Forums to Darkode is much more effective than the other way around, and using domain features as in Daume III (2007) gives little benefit over naïve use of the new data.

5.3 Token-level Annotation

We now turn our attention to methods that might address Hypothesis 2. If we assume the domain transfer problem is more complex, we really want to leverage labeled data in the target domain rather than attempting to transfer features based only on type-level information. Specifically, we are interested in cases where a relatively small number of labeled posts (less than 100) might provide substantial benefit to the adaptation; a researcher could plausibly do this annotation in a few hours.

We consider two ways of exploiting labeled target-domain data. The first is to simply take these posts as additional training data. The second is to also employ the "frustratingly easy" domain adaptation method of Daume III (2007). In this framework, each feature fired in our model is actually fired twice: one copy is domain-general and one is conjoined with the domain label (here, the name of the forum).[12] In doing so, the model should gain some ability to separate domain-general from domain-specific feature values, with regularization encouraging the domain-general feature to explain as much of the phenomenon as possible. For both training methods, we upweight the contribution of the target-domain posts in the objective by a factor of 5.

Figure 2 shows learning curves for both of these methods in two adaptation settings as we vary the amount of labeled target-domain data. The system trained on Hack Forums is able to make good use of labeled data from Darkode: having access to 20 labeled posts leads to gains of roughly 7 F_1. Interestingly, the system trained on Darkode is not able to make good use of labeled data from Hack Forums, and the domain-specific features actually cause a drop in performance until we include a substantial amount of data from Hack Forums (at least 80 posts). We are likely overfitting the small Hack Forums training set with the domain-specific features.

5.4 Analysis

In order to understand the variable performance and shortcomings of the domain adaptation approaches we explored, it is useful to examine our two initial hypotheses and characterize the datasets a bit further. To do so, we break down system performance on products seen in the training set versus novel products. Because our systems depend on lexical and character n-gram features, we expect that they will do better at predicting products we have seen before.

Table 5 confirms this intuition: it shows product out-of-vocabulary rates in each of the four forums relative to training on both Darkode and Hack Forums, along with recall of an NP-level system on both previously seen and OOV products. As expected, performance is substantially higher on in-

[12] If we are training on data from k domains, this gives rise to up to $k + 1$ total versions of each feature.

vocabulary products. OOV rates of a Darkode-trained system are generally lower on new forums, indicating that that forum has better all-around product coverage. A system trained on Darkode is therefore in some sense more domain-general than one trained on Hack Forums.

This would seem to support Hypothesis 1. Moreover, Table 3 shows that the Hack Forums-trained system achieves a 21% error reduction on Hack Forums compared to a Darkode-trained system, while a Darkode-trained system obtains a 38% error reduction on Darkode relative to a Hack Forums-trained system; this greater error reduction means that Darkode has better coverage of Hack Forums than vice versa. Darkode's better product coverage also helps explain why Section 5.3 showed better performance of adapting Hack Forums to Darkode than the other way around: augmenting Hack Forums data with a few posts from Darkode can give critical knowledge about new products, but this is less true if the forums are reversed. Duplicating features and adding parameters to the learner also has less of a clear benefit when adapting from Darkode, when the types of knowledge that need to be added are less concrete.

Note, however, that these results do not tell the full story. Table 5 reports recall values, but not all systems have the same precision/recall tradeoff: although they were tuned to balance precision and recall on their respective development sets, the Hack Forums-trained system is slightly more precision-oriented on Nulled than the Darkode-trained system.[13] In fact, Table 3 shows that the Hack Forums-trained system actually performs better on Nulled, largely due to better performance on previously-seen products. This indicates that there is some truth to Hypothesis 2: product coverage is not the only important factor determining performance.

6 Conclusion

We present a new dataset of posts from cybercrime marketplaces annotated with product references, a task which blends IE and NER. Learning-based methods degrade in performance when applied to new forums, and while we explore methods for fine-grained domain adaption in this data, effective methods for this task are still an open question.

Our datasets used in this work are available at https://evidencebasedsecurity.org/forums/ Code for the product extractor can be found at https://github.com/ccied/ugforum-analysis/tree/master/extract-product

Labeling Gaps Between Words: Recognizing Overlapping Mentions with Mention Separators

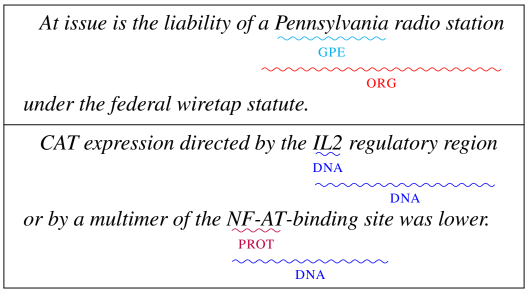
Aldrian Obaja Muis and **Wei Lu**
Singapore University of Technology and Design
{aldrian_muis,luwei}@sutd.edu.sg

Abstract

In this paper, we propose a new model that is capable of recognizing overlapping mentions. We introduce a novel notion of *mention separators* that can be effectively used to capture how mentions overlap with one another. On top of a novel multigraph representation that we introduce, we show that efficient and exact inference can still be performed. We present some theoretical analysis on the differences between our model and a recently proposed model for recognizing overlapping mentions, and discuss the possible implications of the differences. Through extensive empirical analysis on standard datasets, we demonstrate the effectiveness of our approach.

1 Introduction

Named entity recognition (NER), or in general the task of recognizing entity mentions[1] in a text, has been a research topic for many years (McCallum and Li, 2003; Nadeau and Sekine, 2007; Ratinov and Roth, 2009; Ling and Weld, 2012). However, as noted by Finkel and Manning (2009), many previous works ignored overlapping mentions, although they are quite common. Figure 1 illustrates some examples of overlapping mentions adapted from existing datasets. For example, the location mention *Pennsylvania* appears within the mention of type organization *a Pennsylvania radio station*. In practice, overlapping mentions have been found in many existing datasets across different domains (Doddington et al., 2004; Kim et al., 2003; Suominen et al., 2013). Developing algorithms that can effectively and efficiently extract overlapping mentions can be crucial for the performance of many downstream tasks such as relation extraction (Mintz et al., 2009; Gupta and Andrassy, 2016), event extraction (Lu and Roth, 2012; Li et al., 2013; Nguyen et al., 2016), coreference resolution (Chang et al., 2013; Lu et al., 2016), question answering (Mollá et al., 2007), and equation parsing (Roy et al., 2016).



At issue is the liability of a Pennsylvania radio station under the federal wiretap statute.

CAT expression directed by the IL2 regulatory region or by a multimer of the NF-AT-binding site was lower.

Figure 1: Examples of overlapping mentions.

Overlapping mention recognition is non-trivial, as existing methods that model mention recognition as a sequence prediction problem – e.g., using linear-chain conditional random fields (CRF) (Lafferty et al., 2001) – have difficulties in handling overlapping mentions (Alex et al., 2007). Finkel and Manning (2009) proposed to use a tree-based constituency parsing model to handle nested entities.[2] Due to the tree structured representation used, the resulting algorithm has a time complexity that is cubic in n for its inference procedure with n being the number of words in the sentence. This effectively makes the algorithm less scalable compared to models such as linear-chain CRF where the complexity is linear in n. Lu and Roth (2015) proposed an alternative approach which shows a time complexity that is linear in n. Their method differs from the conven-

[1] As noted in (Florian et al., 2004), mention recognition is more general than NER, where a mention can be either named, nominal, or pronominal.

[2] We note that nested entities are only one of the two kinds of overlapping entities, the other kind being crossing entities, where two entities overlap but neither is contained in another. However, it is extremely rare, and there is only one occurrence of crossing entity in our datasets.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2608–2618
Copenhagen, Denmark, September 7–11, 2017.

tional sequence labeling approach, in that a hypergraph representation was used in their model.

In this work, we make an observation that there exists an efficient model for recognizing overlapping mentions while still regarding the problem as a sequence labeling problem. As opposed to the conventional approach where we assign labels to natural language words, in our new approach we assign labels to the *gaps* between words, modeling the mention boundaries instead of modeling the role of words in forming mentions. Furthermore, while these gap-based labels can be modeled using conventional graphical models like linear-chain CRFs, we also propose a novel multigraph representation to utilize such gap-based labels efficiently. To the best of our knowledge, this is the first structured prediction model utilizing a gap-based annotation scheme to predict overlapping structures.

In this paper we make the following major contributions:

- We propose a set of *mention separators* which can be collectively used to define all possible mention combinations together with a novel multigraph representation, on top of which efficient and exact inference can be performed.
- Theoretically, we show that unlike a recently proposed state-of-the-art model that we compare against, our model does not exhibit the *spurious structures* issue in its learning procedure. On the other hand, it still maintains the same inference time complexity as the previous model.
- Empirically, we show that our model is able to achieve higher F_1-scores compared to previous models in multiple datasets.

We believe our proposed approach and the novel representations can be applied in other research problems involving predicting overlapping structures, and we hope this work can inspire further research along such a direction.

2 Related Work

NER or mention detection is normally regarded as a chunking task similar to base noun phrase chunking (Kudo and Matsumoto, 2001; Shen and Sarkar, 2005), and hence the entities or mentions are usually represented in a similar way, using BILOU (Beginning, Inside, Last, Outside, Unit-length mention) or the simpler BIO annotation scheme (Ratinov and Roth, 2009). As a chunking task, it is commonly modeled using sequence labeling models, such as the linear-chain CRF (Lafferty et al., 2001), which has time complexity $O(nT^2)$ with n being the number of words in the sentence and T the number of mention types.

On the task of recognizing mentions that may overlap with one another, one of the earliest works that attempted to regard this task as a structured prediction task was by McDonald et al. (2005). They represented entity mentions as top-k predictions with positive score from a structured multilabel classification model. Their model has a time complexity of $O(n^3T)$.

Alex et al. (2007) proposed a cascading approach using multiple linear-chain CRF models, each handling a subset of all the possible mention types, where the models which come later in the pipeline have access to the predictions of the models earlier in the pipeline. This results in the time complexity of roughly $O(nT)$ depending on how the pipeline was designed.

Finkel and Manning (2009) later proposed a constituency parser to handle nested entities by converting each sentence into a tree, and each mention is represented as one of the subtrees. Their model has the standard time complexity for a constituency parser with binary grammar: $O(n^3\,|G|)$, where $|G|$ is the size of the grammar, which in this case is proportional to T in the best case, and T^3 in the worst case. They showed that their model outperforms a semi-CRF baseline (Sarawagi and Cohen, 2004) in terms of F_1-score.

Recently, Lu and Roth (2015) proposed a hypergraph-based model called *mention hypergraph* that is able to handle overlapping mentions with a linear time complexity $O(nT)$. The model was shown to achieve competitive results compared to previous models on standard datasets. As we will be making extensive comparisons against this previous state-of-the-art model, we will describe this approach in the next section.

3 Mention Hypergraph

In the mention hypergraph model of Lu and Roth (2015), nodes and directed hyperedges[3] are used together to encode mentions and their combinations. The following five types of nodes are used at the position k of a sentence:

- $\mathbf{A}^k$ denotes all mentions starting at k or later,

[3] For brevity, in this paper we may also use *edge* to refer to *hyperedge* in some discussions.

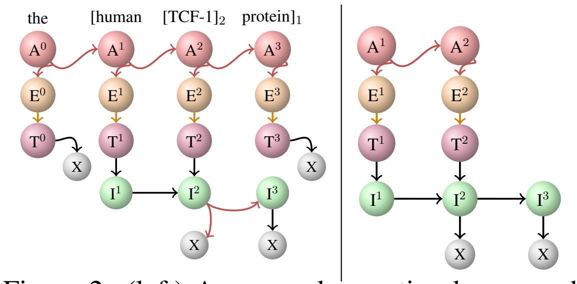


Figure 2: (left) An example mention hypergraph encoding two overlapping mentions. (right) An example of spurious structure.

- $\mathbf{E}^k$ denotes all mentions starting at k,
- $\mathbf{T}_t^k$ denotes all mentions (type t) starting at k,
- $\mathbf{I}_t^k$ denotes all mentions (type t) covering k,
- $\mathbf{X}$ denotes the end of a mention (leaf node).

Different hyperedges connecting these nodes are used to represent how the semantics of a node is composed from those of its child nodes.

Specifically, each $\mathbf{A}^k$ is connected to $\mathbf{A}^{k+1}$ and $\mathbf{E}^k$ through the hyperedge $\mathbf{A}^k \rightarrow (\mathbf{A}^{k+1}, \mathbf{E}^k)$, denoting the fact that the set of mentions that start at k or later is the union of the set of mentions that start at $k+1$ or later and the set of mentions that start at k. Each $\mathbf{E}^k$ is connected to $\mathbf{T}_1^k, \mathbf{T}_2^k, \ldots, \mathbf{T}_T^k$ through a hyperedge, denoting the fact that the mentions that start at k must be one of the T types. Each $\mathbf{T}_t^k$ can be connected to $\mathbf{I}_t^k$ through an edge (denoting there is a mention of type t that starts at the k-th token) or to $\mathbf{X}$ through another edge (denoting there are no mentions of type t that start at the k-th token). Each $\mathbf{I}_t^k$ can be connected to $\mathbf{I}_t^{k+1}$ (denoting there is a mention continuing to the next token), to $\mathbf{X}$ (denoting there is a mention ending here), or to both (with a single hyperedge, denoting the two cases above occur at the same time, a case of overlapping mentions).

In this mention hypergraph, each possible mention is represented as a path from a $\mathbf{T}$-node to the $\mathbf{X}$-node through a sequence of $\mathbf{I}$-nodes (each denoting the words which are part of the mention), and the set of all mentions present in a given sentence forms a hyperpath from the root node $\mathbf{A}_0$ to the leaf node $\mathbf{X}$. Figure 2 shows how the mention hypergraph represents the two mentions in the phrase "*the human TCF-1 protein*", which are "*TCF-1*" and "*human TCF-1 protein*". The edges $\mathbf{T}^1 - \mathbf{I}^1$ and $\mathbf{T}^2 - \mathbf{I}^2$ respectively denote that the words "*human*" and "*TCF-1*" are the beginning of a mention, and the edges from the $\mathbf{I}$-nodes to the $\mathbf{X}$-node define the end of the mentions. We remark that any mention hypergraph which encodes the mentions in a sentence, like this example, forms a hyperpath from the root node $\mathbf{A}^0$ to the leaf node $\mathbf{X}$, where a hyperpath is defined as a subgraph of a hypergraph with the property that each node has exactly one outgoing (hyper)edge except the last node, and the root node is connected to all nodes.

We refer the readers to Lu and Roth (2015) for more details on the model.

3.1 Spurious Structures

Mention hypergraph is trained by maximizing the likelihood of the training data, similar to training a linear-chain CRF. Recall that the likelihood of the training data can be calculated by taking the score of the correct structures and divide it by the normalization term, which is the total score of all possible structures. Lu and Roth (2015) used a dynamic programming algorithm to calculate the normalization term. However, the normalization term calculated this way contains additional terms, which we call the *spurious structures*. This leads to the following:

Theorem 3.1. *Let Z' be the normalization term as calculated using forward-backward algorithm on mention hypergraph, and let Z be the true normalization term. Then we have $Z' > Z$.*

Due to space limitation, we provide a proof sketch here. We refer the reader to the supplemental material for the details on spurious structures.

Proof sketch. First note that Z' includes all possible hyperpaths, so $Z' \geq Z$. Next, due to the presence of a node with multiple parents (e.g., node $\mathbf{I}^2$ in Figure 2 (left)), Z' includes the score of that node multiple times with different children, which results in a subgraph which is not a hyperpath. For example, Z' includes the score[4] of the structure shown in Figure 2 (right), where node $\mathbf{I}^2$ has two children, and so it is not a hyperpath. Since Z is the sum of all hyperpaths, this structure is not part of Z, but it is included in Z', so $Z' > Z$. □

Later we will see how this issue may affect the model's performance in predicting mentions.

4 Mention Separators

We now describe the mention separators which can be used to encode overlapping mentions in a sentence. Traditional encoding schemes that associate labels to words, such as BIO scheme, attach the semantics of the labels to the role of the words

[4] Note that structure scores $\exp(\mathbf{w} \cdot \mathbf{f})$ are always positive.

$w\ \ w$ X	$w\ [w$ S	$w]\ w$ E	$w]\ [w$ ES
w - w C	w -$[w$ CS	$w]$- w EC	$w]$-$[w$ ECS

Figure 3: An illustration of the 8 mention separators. The opening bracket ([), closing bracket (]), and dash (-) respectively refer to S, E, and C.

in forming mentions. For example, the label **B** in BIO scheme denotes the role of the word it is attached to, which is the first word of a mention.

This BIO scheme cannot be used directly to encode overlapping mentions, since they only encode whether a word is part of a mention and possibly their position in the mention. We notice that by encoding the mention boundaries instead, we can represent overlapping mentions. This can be accomplished by assigning what we call *mention separators* to the gaps between two words.

At each gap, we consider eight possible types of mention separators based on the combination of the following three cases:

1. A mention is starting at the next word (S)
2. A mention is ending at the previous word (E)
3. A mention is continuing to the next word (C)

Therefore, for each token, the possible combinations of cases are as follows: ECS, EC, CS, C, ES, E, S, and X, where X means none of the three cases applies. For example, the separator EC means there is a mention ending at the current token and another mention (overlapping) continuing to the next token. Note that there might be more than just two mentions involved here. Figure 3 shows an illustration of these separators, and Figure 4a shows how they can be used to encode the example in Figure 2.

Now we prove that the following theorem holds:

Theorem 4.1. *For any combination of mentions in a sentence, there is exactly one sequence of mention separators that encodes it.*

Proof. Consider the gap between any two adjacent words in the sentence. The combination of mentions present in the sentence uniquely defines what mention separator is associated with this gap. If there is a mention starting at the next word, then case S applies. Similarly, if there is a mention ending at the previous word, case E applies. And finally, if there is a mention covering both words, case C applies. By combining the cases, we get the corresponding mention separator for this gap. In this way, each gap in the sentence has a unique mention separator, which in turn defines the unique sequence of mention separators. □

Note that the converse of Theorem 4.1 is not true, as multiple mention combinations might encode to the same sequence of mention separators.

Now we describe two ways the mention separators can be used to encode overlapping mentions.

STATE-based The first is by directly using these mention separators to replace the standard mention encoding scheme (e.g., BIO encoding) in standard linear-chain CRF. So we assign each mention separator to a state in a linear-chain CRF model. Since this model encodes the gap between words and also the gap before the first word and after the last word, a sentence with n words is modeled by a sequence of $n + 1$ mention separators. Since each sequence of mention separators can only encode mentions of the same type, we support multiple types by using multiple sequences, one for each mention type.

EDGE-based Now, we propose a novel way of utilizing these mention separators. Since the mention separators encode the gaps between words, it is more intuitive to assign the mention separators to the edges of a graphical model, as opposed to the states, as described in the previous paragraph. To do this, we need to define the states of the models in such a way that all possible sequences of mention separators are accounted for. For this purpose we assign two states to each word at position k:

- $\mathbf{I}_k$: word at k is part of a mention,
- $\mathbf{O}_k$: word at k is not part of any mentions.

Next we define the edges between the states according to the eight possible mention separators between adjacent words. More specifically, each mention separator is mapped to an edge connecting one state in the current position to another state in the next position depending on whether the separator defines current and next word as part of an mention, so in total we have eight edges between two positions in the model. Some mention separators may connect the same two states, for example, the ES and C separator both connect $\mathbf{I}_k$ to $\mathbf{I}_{k+1}$ since in both cases the current word and the next word are part of a mention. In those cases, we simply define multiple edges between the pair of states. The resulting graph, where there can be multiple edges between two states, is known in graph theory literature as a **multigraph**[5].

(a) (b)

Figure 4: Our mention separator model with the EDGE representation encoding two phrases.

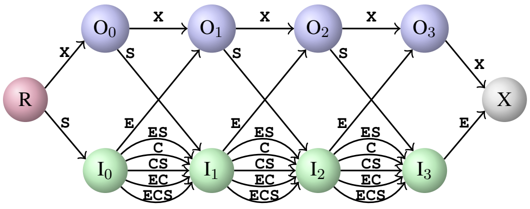

Figure 5: The full graph in EDGE-based model.

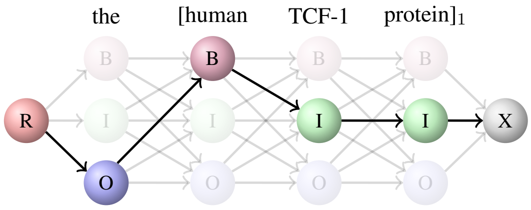

Figure 6: A linear-chain CRF model encoding a mention in BIO scheme.

The first **I**- and **O**-nodes in the sentence are connected to the root node, and the last **I**- and **O**-nodes are connected to the unique leaf node **X**.

Figure 4a shows how the EDGE-based model encodes the two mentions "*human TCF-1 protein*" and "*TCF-1*" in the phrase "*the human TCF-1 protein*", and Figure 4b shows the encoding of the phrase found in the second example in Figure 1. Note how each edge maps to a distinct mention separator visualized in the text in red.

Figure 5 shows the full graph of our EDGE-based model, in a format similar to the trellis graph for linear-chain CRFs in Figure 6. We remark that the EDGE-based model can be seen as an extension of linear-chain CRFs, with additional semantics attached to the edges. Also note that this graph encodes only one mention type. To support multiple types, similar to the STATE-based approach we can use multiple chains, one for each type.

Note that the edges in our EDGE-based representations are directed, with nodes on the left serving as parents to the nodes on the right. Such directed edges will be helpful when performing inference, to be discussed in the next section.

We remark that the way we utilize multigraph in the EDGE-based model can also be applied to the discontiguous mention model (DMM) by Muis and Lu (2016). In fact, it can be shown that the number of canonical structures as calculated in the supplementary material of DMM paper matches the number of possible paths in our multigraph-based model, as the transition matrix in DMM corresponds to the number of possible transitions from one position to the next position, which is encoded in our multigraph-based model as edges between adjacent positions. See the supplemental material for more discussion on this.

4.1 Training, Inference and Decoding

We follow the log-linear approach to define our model, using regularized log-likelihood in training data $\mathcal{D}$ as our objective function, as follows:

$$\mathcal{L}_{\mathcal{D}}(\mathbf{w}) = \sum_{(\mathbf{x},\mathbf{y})\in\mathcal{D}} \left[\sum_{\mathbf{e}\in\mathbf{y}} \mathbf{w}\cdot\mathbf{f}(\mathbf{e}) - \log Z_{\mathbf{w}}(\mathbf{x}) \right] - \lambda||\mathbf{w}||^2 \tag{1}$$

Here, $(\mathbf{x}, \mathbf{y})$ is a training instance consisting of the sentence $\mathbf{x}$ and the correct output $\mathbf{y}$, $\mathbf{w}$ is the weight vector, $\mathbf{f}(\mathbf{e})$ is the feature vector defined over the edge $\mathbf{e}$, $Z_{\mathbf{w}}(\mathbf{x})$ is the normalization term, and λ is the l_2-regularization parameter. The objective function is then optimized until convergence using L-BFGS (Liu and Nocedal, 1989).

We note the mention hypergraph model also defines the objective in a similar manner. For both of our models, the inference is done based on a generalized inside-outside algorithm. Both models involve directed structures, on top of which the inference algorithm first calculates the inside score for each node from the leaf node to root, and then the outside score from the root to the leaf node, in very much the same way as how inference is done in a classic graphical model. Specifically, for our EDGE-based model, the inside scores are calculated using a bottom-up (right-to-left) dynamic programming procedure, where we calculate the inside score at each node by summing up the scores associated with each path connecting the current node to one of its child nodes. Each

regarded as a *lattice* where edges are associated with labels.

such path score is defined as the product of the inside score stored in that child node and the score defined over the edge connecting them. The computation of the outside scores can be done in an analogous manner from left to right. It can be verified that the time complexity of this inference procedure for our model is $O(nT)$, which is the same as the mention hypergraph model. Note that, however, both of our models do not have the spurious structures issue, as for any *path* in these models there are no nodes with multiple incoming edges.

During decoding, we perform MAP inference using a max-product procedure that is analogous to how the Viterbi decoding algorithm is used in conventional tree-structured graphical models to find out the highest-scoring subgraph, from which we extract mentions through the process that we call the *interpretation process*. As noted in previous section, there could be multiple mention combinations that correspond to the same sequence of mention separators, which presents an ambiguity during the interpretation process. For these ambiguous cases, we implemented the same interpretation process as that was done in the mention hypergraph model, which is by resolving ambiguous structures as nested mentions. For other cases, there is exactly one way to interpret the structure. For example, in Figure 4b, although there is only one gap marked as starting position (`S`) and two gaps marked as ending position (`EC` and `E`), the interpretation is clear that the two mentions here are "*IL2*" and "*IL2 regulatory region*".

5 Experiments

5.1 Datasets

To assess our model's capability in recognizing overlapping mentions and make comparisons with previous models, we looked at datasets where overlapping mentions are explicitly annotated. Following the previous work (Lu and Roth, 2015), our main results are based on the standard ACE-2004 and ACE-2005 datasets (Doddington et al., 2004). We also additionally looked at the GENIA dataset (Kim et al., 2003), which was used in the previous works (Finkel and Manning, 2009; Lu and Roth, 2015).

For ACE datasets, we used the same splits as used in our previous work (Lu and Roth, 2015), published on our website[6]. For GENIA, we used GENIAcorpus3.02p[7] that comes with POS tags for each word (Tateisi and Tsujii, 2004). Following previous works (Finkel and Manning, 2009; Lu and Roth, 2015), we first split the last 10% of the data as the test set. Next we used the first 80% and the subsequent 10% for training and development, respectively. We made the same modifications as described by Finkel and Manning (2009) by collapsing all *DNA*, *RNA*, and *protein* subtypes into *DNA*, *RNA*, and *protein*, keeping *cell line* and *cell type*, and removing other mention types, resulting in 5 mention types. The statistics of each dataset are shown in Table 1. We can see overlapping mentions are common in such datasets.

For more details on the dataset preprocessing, please refer to the supplemental material.

5.2 Features

For models that fall under the edge-based paradigm (mention hypergraph and our model), we define features over the edges in the models. Features are defined as string concatenations of input features – information extracted over the inputs (such as current word and POS tags of surrounding words) and output features – structured information extracted over the output structure. We carefully defined the input and output features in a way that allows us to make use of the identical set of features for both our mention separator model and the baseline mention hypergraph model, in order to make a proper comparison. We also followed Lu and Roth (2015) to add the additional *mention penalty* feature for our model and all baseline approaches so that we are able to tune F_1-scores on the development set. Roughly speak-

Table 2: Main results (on ACE).

ing, the weight of this feature controls how confident the model should be in predicting more mentions. In other words, this is a way to balance the precision and recall of the model.

When defining the input features for both our model and the mention hypergraph model, we implemented the features used by previous works in each dataset based on the descriptions in their papers: we followed Lu and Roth (2015) for the features used in ACE datasets, and Finkel and Manning (2009) for features used in GENIA dataset. In general, they include surrounding words, surrounding POS tags, bag-of-words, Brown clusters (for GENIA only), and orthographic features. See the supplemental material for more details.

5.3 Experimental Setup

We trained each model in the training set, then tuned the l_2-regularization parameter based on the development set. For GENIA experiments, we also tuned the number of Brown clusters. Following Lu and Roth (2015), we also used each development set to tune the mention penalty to optimize the F_1-score and report the scores on the corresponding test sets separately. Similar to Finkel and Manning (2009), as another baseline model we also trained a standard linear-chain CRF using the BILOU scheme. Although this model does not support overlapping mentions, it gives us a baseline to see the extent to which our model's ability to recognize overlapping mentions can help the overall performance. There is also a simple extension[8] of this linear-chain CRF model that can support overlapping mentions of *different types* by considering each type separately using multiple chains, one for each type. We call this multiple-chain variant *LCRF (multiple)* and the earlier standard approach *LCRF (single)*. In all models, we also implement the mention penalty feature, adapted accordingly so that increasing the feature weight will increase the number of mentions predicted by the model. See supplemental material for more details.

We implemented all models using Java, and also made additional comparisons on running time by running them under the same machine. In addition, we also analyzed the convergence rate for different models.

6 Results and Discussion

6.1 Results on ACE

Table 2 shows the results on the ACE datasets, and these are our main results. Following previous works (Finkel and Manning, 2009; Lu and Roth, 2015), we report standard precision (P), recall (R) and F_1-score percentage scores. The highest results (F_1-score) and those results that are not significantly different from the highest results are highlighted in bold (based on bootstrap resampling test (Koehn, 2004), where $p > 0.01$). For ACE datasets, we make comparisons with the two versions of the linear-chain CRF baseline: LCRF (single) which does not support overlapping mentions at all and LCRF (multiple) which does not support overlapping mentions of the same type, as well as our implementation of the mention hypergraph baseline (Lu and Roth, 2015).

From such empirical results we can see that our proposed model using mention separators consistently yields significantly better results ($p < 0.01$) than the mention hypergraph model across these two datasets, under two setups (whether to optimize F_1-score or not). Specifically, when the state-based approach is used (STATE), our approach is able to obtain a much higher recall, resulting in improved F_1-score. Empirically, we found this approach was also faster than the LCRF baseline approach in terms of the number of words processed each second (w/s) during decoding, which is expected, since STATE uses fewer num-

[8] We also tried a more elaborate encoding scheme based on BIO scheme Tang et al. (2013), originally designed for discontiguous mentions, but is supposed to be able to also recognize overlapping mentions of the same type. However, the result is very similar to LCRF (multiple), perhaps due to the invalid structures issue noted by Muis and Lu (2016).

	P	R	F_1	w/s
LCRF (single)	77.1	63.3	69.5	81.6
LCRF (multiple)	75.9	66.1	**70.6**	175.8

Lu and Roth (2015)	74.2	66.7	70.3	931.9
This work (STATE)	74.0	67.7	**70.7**	110.8
This work (EDGE)	75.4	66.8	**70.8**	389.2

Table 3: Results on GENIA.

ber of tags.[9] The edge-based approach (EDGE) using our proposed multigraph representation is able to achieve a significant speedup in comparison with the state-based approach. Although this model is still about 50% slower than the mention hypergraph model[10], but it yielded a significantly higher F_1-score (up to 3.6 points higher on ACE-2004 before optimizing F_1-score). These results largely confirm the effectiveness of our proposed mention separator model and the usefulness of the multigraph representation for learning the model.

And as expected, the LCRF baselines yields relatively lower results compared to the other models, since it cannot predict overlapping mentions.[11] However, such results give us some idea on how much performance increase we can gain by properly recognizing overlapping mentions by looking at the results of LCRF (single), which in this case can be up to 9.7 points in F_1-score in ACE-2004. We can also see the gain from recognizing overlapping mentions of the same type by looking at the results of LCRF (multiple), which can be up to 5.3 points in F_1-score in ACE-2004.

6.2 Results on GENIA

Table 3 shows the results of running the models with F_1-score tuning on GENIA dataset. All models include Brown clustering features learned from PubMed abstracts. Besides the mention hypergraph baseline, we also make comparisons with the system of Finkel and Manning (2009) that can also support overlapping mentions.

We see that the mention hypergraph model matches the performance of the constituency parser-based model of Finkel and Manning (2009), while our models based on mention separators yield significantly higher scores ($p < 0.05$) than all other baselines (except LCRF (multiple), which we will discuss shortly). There are two observations worth mentioning: (1) the absolute difference of F_1-scores of our models and the baseline models in GENIA is much smaller compared to that in ACE datasets, and (2) the LCRF (multiple) model in GENIA dataset can achieve higher scores compared to other more complex baseline models, although LCRF (multiple) does not support overlapping mentions of the same type. We suspect that these two observations are due to the small proportion of overlapping mentions in GENIA (18%, as compared to >40% in ACE datasets, see Table 1). To investigate this, we conduct a few more sets of experiments.

6.3 Further Experiments

On different types of sentences: As these datasets consist of both overlapping and non-overlapping mentions, to further understand the model's effectiveness in recognizing overlapping mentions (and non-overlapping mentions), we performed some additional experiments on the mention hypergraph model and our model.[12] Specifically, we split the test data into two portions, one that consists of only sentences that contain overlapping mentions (O) and those which do not (Ø). The results are shown in Table 4.

We can see that in ACE datasets, our model achieves higher F_1-scores compared to the mention hypergraph for both portions, but it achieves slightly lower results in GENIA dataset for the portion that contains overlapping mentions. We believe that our models learn parameters so as to obtain an optimal overall performance, and since the proportion of the overlapping mentions in GENIA is much smaller compared to that in ACE datasets, it learns to focus more on the non-overlapping mentions. This is supported by the fact that the difference of F_1-score between the mention hypergraph model and our model in GENIA is larger compared to the difference in ACE

[9] There are eight tags in STATE and nine in LCRF.

[10] Though both models have the same time complexity, they differ by a constant factor.

[11] LCRF (single) cannot predict any overlapping mentions, while LCRF (multiple) cannot predict overlapping mentions of the same type.

[12] We also performed this on other models. Due to space constraint, we do not include the results here. See the supplemental material for more details.

Table 5: Results on CoNLL-2003 (without optimizing F_1-score).

datasets (1.1 points in GENIA, compared to 0.9 and 0.6 points in ACE).

These results also lead to the interesting empirical finding that our model appears to be able to do well also on recognizing non-overlapping mentions. This motivates us to conduct the next set of experiments.

On data without overlapping mentions: We also performed one additional set of experiments, on the standard CoNLL-2003 dataset (Tjong Kim Sang and De Meulder, 2003), which has no overlapping mentions.

The results (without optimizing F_1-score) are shown in Table 5. We see that our models based on mention separators outperform baseline models such as the Illinois NER system where external resources are not used (Ratinov and Roth, 2009), and a linear-chain CRF model, although the linear-chain CRF baseline models some interactions between distinct mention types and our models do not. Such results also suggest that modeling the interactions between distinct mention types may not be crucial to get a good performance in mention recognition. This is further corroborated by the result of LCRF (multiple), which is higher than the result of LCRF (single) by about 0.5 points.

When comparing our model against the mention hypergraph model, we note that our model consistently yields a higher recall. We speculate this is due to the fact that as our model does not exhibit the issue of spurious structures we discussed in Section 3.1, it is more confident in making its predictions.

On convergence: We also empirically analyzed the convergence properties of the two models. Empirically, as illustrated in Figure 7 which shows how the objective improves when the training progresses on ACE-2004, GENIA, and CoNLL-2003, we found that our EDGE-based model requires significantly less iterations to converge than the mention hypergraph on the former two datasets which contain overlapping mentions. We believe it is possible that this slower convergence is due to the spurious structures issue in mention hypergraphs, which causes the objective function to be more complex to optimize. However, some further analyses on the convergence issue and the impact of different ways of exploiting features (over different hyperedges) for the hypergraph-based models are needed.

7 Conclusion and Future Work

We proposed the novel *mention separators* for mention recognition where mentions may overlap with one another. We also proposed two ways these mention separators can be utilized to encode overlapping mentions, where one of them utilizes a novel multigraph-based representation. We showed that by utilizing mention separators, we can get better recognition results compared to previous models, and by utilizing the multigraph representation, we can maintain a good inference speed, albeit still slower than the mention hypergraph model. We also performed theoretical analysis on the model and showed that our model does not present the *spurious structures* issue associated with a previous state-of-the-art model, while still keeping the same inference time complexity.

Future work includes further investigations on how to apply the multigraph approach to other structured prediction tasks, as well as applications of the proposed model in other related NLP tasks that involve the prediction of overlapping structures, such as equation parsing (Roy et al., 2016).

Deep Joint Entity Disambiguation with Local Neural Attention

Octavian-Eugen Ganea and **Thomas Hofmann**
Department of Computer Science
ETH Zurich
{octavian.ganea,thomas.hofmann}@inf.ethz.ch

Abstract

We propose a novel deep learning model for joint document-level entity disambiguation, which leverages learned neural representations. Key components are entity embeddings, a neural attention mechanism over local context windows, and a differentiable joint inference stage for disambiguation. Our approach thereby combines benefits of deep learning with more traditional approaches such as graphical models and probabilistic mention-entity maps. Extensive experiments show that we are able to obtain competitive or state-of-the-art accuracy at moderate computational costs.

1 Introduction

Entity disambiguation (ED) is an important stage in text understanding which automatically resolves references to entities in a given knowledge base (KB). This task is challenging due to the inherent ambiguity between surface form mentions such as names and the entities they refer to. This many-to-many ambiguity can often be captured partially by name-entity co-occurrence counts extracted from entity-linked corpora.

ED research has largely focused on two types of contextual information for disambiguation: *local* information based on words that occur in a context window around an entity mention, and, *global* information, exploiting document-level coherence of the referenced entities. Many state-of-the-art methods aim to combine the benefits of both, which is also the philosophy we follow in this paper. What is specific to our approach is that we use embeddings of entities as a common representation to assess local as well as global evidence.

In recent years, many text and language understanding tasks have been advanced by neural network architectures. However, despite recent work, competitive ED systems still largely employ manually designed features. Such features often rely on domain knowledge and may fail to capture all relevant statistical dependencies and interactions. The explicit goal of our work is to use deep learning in order to learn basic features and their combinations from scratch. To the best of our knowledge, our approach is the first to carry out this program with full rigor.

2 Contributions and Related Work

There is a vast prior research on entity disambiguation, highlighted by (Ji, 2016). We will focus here on a discussion of our main contributions in relation to prior work.

Entity Embeddings. We have developed a simple, yet effective method to embed entities and words in a common vector space. This follows the popular line of work on word embeddings, e.g. (Mikolov et al., 2013; Pennington et al., 2014), which was recently extended to entities and ED by (Yamada et al., 2016; Fang et al., 2016; Zwicklbauer et al., 2016; Huang et al., 2015). In contrast to the above methods that require data about entity-entity co-occurrences which often suffers from sparsity, we rather bootstrap entity embeddings from their canonical entity pages and local context of their hyperlink annotations. This allows for more efficient training and alleviates the need to compile co-linking statistics. These vector representations are a key component to avoid hand-engineered features, multiple disambiguation steps, or the need for additional *ad hoc* heuristics when solving the ED task.

Context Attention. We present a novel attention mechanism for local ED. Inspired by mem-

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2619–2629
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

ory networks of (Sukhbaatar et al., 2015) and insights of (Lazic et al., 2015), our model deploys attention to select words that are informative for the disambiguation decision. A learned combination of the resulting context-based entity scores and a mention–entity prior yields the final local scores. Our local model achieves better accuracy than the local probabilistic model of (Ganea et al., 2016), as well as the feature-engineered local model of (Globerson et al., 2016). As an added benefit, our model has a smaller memory footprint and it's very fast for both training and testing.

There have been other deep learning approaches to define local context models for ED. For instance (Francis-Landau et al., 2016; He et al., 2013) use convolutional neural networks (CNNs) and stacked denoising auto-encoders, respectively, to learn representations of textual documents and canonical entity pages. Entities for each mention are locally scored based on cosine similarity with the respective document embedding. In a similar local setting, (Sun et al., 2015) embed mentions, their immediate contexts and their candidate entities using word embeddings and CNNs. However, their entity representations are restrictively built from entity titles and entity categories only. Unfortunately, the above models are rather 'black-box' (as opposed to ours which reveals the attention focus) and were never extended to perform joint document disambiguation.

Collective Disambiguation. Last, a novel deep learning architecture for global ED is proposed. Mentions in a document are resolved jointly, using a conditional random field (Lafferty et al., 2001) with parametrized potentials. We suggest to learn the latter by casting loopy belief propagation (LBP) (Murphy et al., 1999) as a rolled-out deep network. This is inspired by similar approaches in computer vision, e.g. (Domke, 2013), and allows us to backpropagate through the (truncated) message passing, thereby optimizing the CRF potentials to work well in conjunction with the inference scheme. Our model is thus trained end-to-end with the exception of the pre-trained word and entity embeddings. Previous work has investigated different approximation techniques, including: random graph walks (Guo and Barbosa, 2016), personalized PageRank (Pershina et al., 2015), intermention voting (Ferragina and Scaiella, 2010), graph pruning (Hoffart et al., 2011), integer linear programming (Cheng and Roth, 2013), or ranking SVMs (Ratinov et al., 2011). Mostly connected to our approach is (Ganea et al., 2016) where LBP is used for inference (but not learning) in a probabilistic graphical model and (Globerson et al., 2016) where a single round of message passing with attention is performed. To our knowledge, we are one of the first to investigate differentiable message passing for NLP problems.

3 Learning Entity Embeddings

In a first step, we propose to train entity vectors that can be used for the ED task (and potentially for other tasks). These embeddings compress the semantic meaning of entities and drastically reduce the need for manually designed features or co-occurrence statistics.

Entity embeddings are bootstrapped from word embeddings and are trained independently for each entity. A few arguments motivate this decision: (i) there is no need for entity co-occurrence statistics that suffer from sparsity issues and/or large memory footprints; (ii) vectors of entities in a subset domain of interest can be trained separately, obtaining potentially significant speed-ups and memory savings that would otherwise be prohibitive for large entity KBs;[1] (iii) entities can be easily added in an incremental manner, which is important in practice; (iv) the approach extends well into the tail of rare entities with few linked occurrences; (v) empirically, we achieve better quality compared to methods that use entity co-occurrence statistics.

Our model embeds words and entities in the same low-dimensional vector space in order to exploit geometric similarity between them. We start with a pre-trained word embedding map $\mathbf{x} : \mathcal{W} \to \mathbb{R}^d$ that is known to encode semantic meaning of words $w \in \mathcal{W}$; specifically we use word2vec pretrained vectors (Mikolov et al., 2013). We extend this map to entities $\mathcal{E}$, i.e. $\mathbf{x} : \mathcal{E} \to \mathbb{R}^d$, as described below.

We assume a generative model in which words that co-occur with an entity e are sampled from a conditional distribution $p(w|e)$ when they are generated. Empirically, we collect word-entity co-occurrence counts $\#(w, e)$ from two sources: (i) the canonical KB description page of the entity (e.g. entity's Wikipedia page in our case), and (ii) the windows of fixed size surrounding mentions of the entity in an annotated corpus (e.g. Wikipedia

[1] Notably useful with (limited memory) GPU hardware.

hyperlinks in our case). These counts define a practical approximation of the above word-entity conditional distribution, i.e. $\hat{p}(w|e) \propto \#(w,e)$. We call this the ”positive” distribution of words related to the entity. Next, let $q(w)$ be a generic word probability distribution which we use for sampling ”negative” words unrelated to a specific entity. As in (Mikolov et al., 2013), we choose a smoothed unigram distribution $q(w) = \hat{p}(w)^\alpha$ for some $\alpha \in (0,1)$. The desired outcome is that vectors of positive words are closer (in terms of dot product) to the embedding of entity e compared to vectors of random words. Let $w^+ \sim \hat{p}(w|e)$ and $w^- \sim q(w)$. Then, we use a max-margin objective to infer the optimal embedding for entity e:

$$\begin{aligned} J(\mathbf{z}; e) &:= \mathbb{E}_{w^+|e}\, \mathbb{E}_{w^-} \left[h\left(\mathbf{z}; w^+, w^-\right)\right] \\ h(\mathbf{z}; w, v) &:= [\gamma - \langle \mathbf{z}, \mathbf{x}_w - \mathbf{x}_v \rangle]_+ \\ \mathbf{x}_e &:= \underset{\mathbf{z}:\|\mathbf{z}\|=1}{\arg\min}\, J(\mathbf{z}; e) \end{aligned} \quad (1)$$

where $\gamma > 0$ is a margin parameter and $[\cdot]_+$ is the ReLU function. The above loss is optimized using stochastic gradient descent with projection over sampled pairs (w^+, w^-). Note that the entity vector is directly optimized on the unit sphere which is important in order to obtain qualitative embeddings.

We empirically assess the quality of our entity embeddings on entity similarity and ED tasks as detailed in Section 7 and Appendix A. The technique described in this section can also be applied, in principle, for computing embeddings of general text documents, but a comparison with such methods is left as future work.

4 Local Model with Neural Attention

We now explain our local ED approach that uses word and entity embeddings to steer a neural attention mechanism. We build on the insight that only a few context words are informative for resolving an ambiguous mention, something that has been exploited before in (Lazic et al., 2015). Focusing only on those words helps reducing noise and improves disambiguation. (Yamada et al., 2016) observe the same problem and adopt the restrictive strategy of removing all non-nouns. Here, we assume that a context word may be relevant, if it is strongly related to at least one of the entity candidates of a given mention.

Context Scores.

Let us assume that we have computed a mention–entity prior $\hat{p}(e|m)$ (procedure detailed in Section 6). In addition, for each mention m, a pruned candidate set $\Gamma(m)$ of at most S entities has been identified. Our model, depicted in Figure 1, computes a score for each $e \in \Gamma(m)$ based on the K-word local context $c = \{w_1, \ldots, w_K\}$ surrounding m, as well as on the prior. It is a composition of differentiable functions, thus it is smooth from input to output, allowing us to easily compute gradients and backpropagate through it.

Each word $w \in c$ and entity $e \in \Gamma(m)$ is mapped to its embedding via the pre-trained map $\mathbf{x}$ (cf. Section 3). We then compute an unnormalized support score for each word in the context as follows:

$$u(w) = \max_{e \in \Gamma(m)} \mathbf{x}_e^\top \mathbf{A} \mathbf{x}_w \quad (2)$$

where $\mathbf{A}$ is a parameterized diagonal matrix. The weight is high if the word is strongly related to at least one candidate entity. We often observe that uninformative words (e.g. similar to stop words) receive non-negligible scores which add undesired noise to our local context model. As a consequence, we (hard) prune to the top $R \leq K$ words with the highest scores[2] and apply a softmax function on these weights. Define the reduced context:

$$\bar{c} = \{w \in c | u(w) \in \text{topR}(\mathbf{u})\} \quad (3)$$

Then, the final attention weights are explicitly

$$\beta(w) = \begin{cases} \frac{\exp[u(w)]}{\sum_{v \in \bar{c}} \exp[u(v)]}. & \text{if } w \in \bar{c} \\ 0 & \text{otherwise.} \end{cases} \quad (4)$$

Finally, we define a β-weighted context-based entity-mention score via

$$\Psi(e, c) = \sum_{w \in \bar{c}} \beta(w)\, \mathbf{x}_e^\top \mathbf{B}\, \mathbf{x}_w \quad (5)$$

where $\mathbf{B}$ is another trainable diagonal matrix. We will later use the same architecture for the *unary* scores of our global ED model.

Local Score Combination.

We integrate these context scores with the context-independent scores encoded in $\hat{p}(e|m)$.

[2] We implement this in a differentiable way by setting the lowest K-R attention weights in $\mathbf{u}$ to $-\infty$ and applying a vanila softmax on top of them. We used the layers Threshold and TemporalDynamicKMaxPooling from Torch nn package, which allow subgradient computation.

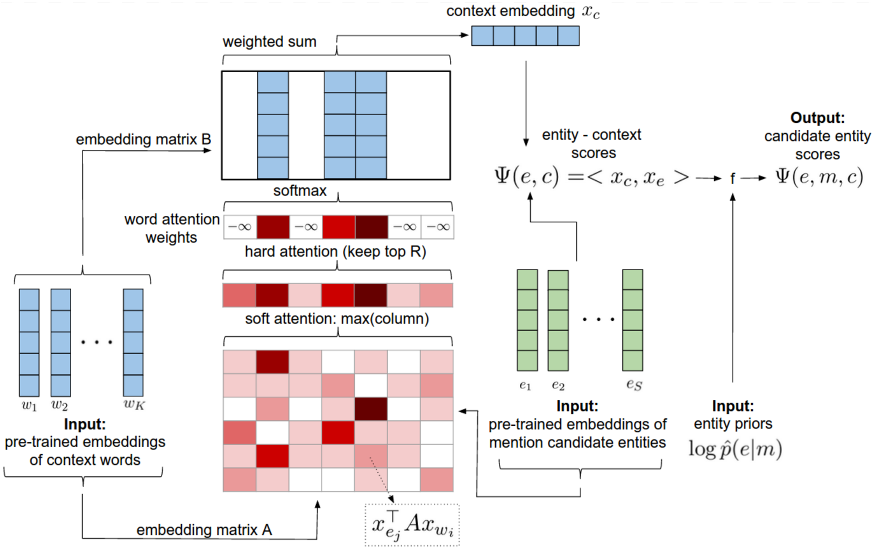

Figure 1: Local model with neural attention. Inputs: context word vectors, candidate entity priors and embeddings. Outputs: entity scores. All parts are differentiable and trainable with backpropagation.

Our final (unnormalized) local model is a combination of both $\Psi(e,c)$ and $\log \hat{p}(e|m)$:

$$\Psi(e,m,c) = f(\Psi(e,c), \log \hat{p}(e|m)) \qquad (6)$$

We find a flexible choice for f to be important and superior to a naïve weighted average combination model. We therefore use a neural network with two fully connected layers of 100 hidden units and ReLU non-linearities, which we regularize as suggested in (Denton et al., 2015) by constraining the sum of squares of all weights in the linear layer. We use standard projected SGD for training. The same network is also used in Section 5.

Prediction is done independently for each mention m_i and context c_i by maximizing the $\Psi(e, m_i, c_i)$ score.

Learning the Local Model.

Entity and word embeddings are pre-trained as discussed in Section 3. Thus, the only learnable parameters are the diagonal matrices $\mathbf{A}$ and $\mathbf{B}$, plus the parameters of f. Having few parameters helps to avoid overfitting and to be able to train with little annotated data. We assume that a set of known mention-entity pairs $\{(m, e^*)\}$ with their respective context windows have been extracted from a corpus. For model fitting, we then utilize a max-margin loss that ranks ground truth entities higher than other candidate entities. This leads us to the objective:

$$\theta^* = \arg\min_{\theta} \sum_{D\in\mathcal{D}} \sum_{m\in D} \sum_{e\in\Gamma(m)} g(e,m), \qquad (7)$$

$$g(e,m) := [\gamma - \Psi(e^*, m, c) + \Psi(e,m,c)]_+$$

where $\gamma > 0$ is a margin parameter and $\mathcal{D}$ is a training set of entity annotated documents. We aim to find a Ψ (i.e. parameterized by θ) such that the score of the correct entity e^* referenced by m is at least a margin γ higher than that of any other candidate entity e. Whenever this is not the case, the margin violation becomes the experienced loss.

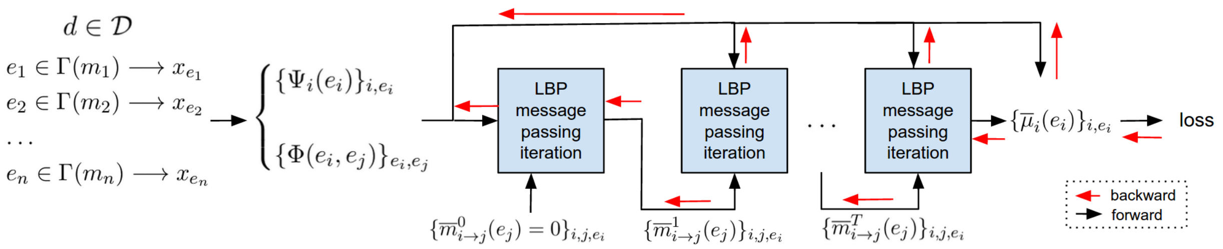
5 Document-Level Deep Model

Next, we address global ED assuming document coherence among entities. We therefore introduce the notion of a document as consisting of a set of mentions $\mathbf{m} = m_1, \ldots, m_n$, along with their context windows $\mathbf{c} = c_1, \ldots c_n$. Our goal is to define a joint probability distribution over $\Gamma(m_1) \times \ldots \times \Gamma(m_n) \ni \mathbf{e}$. Each such $\mathbf{e}$ selects one candidate entity for each mention in the document. Obviously, the state space of $\mathbf{e}$ grows exponentially in the number of mentions n.

CRF Model.

Our model is a fully-connected pairwise conditional random field, defined on the log scale as

$$g(\mathbf{e},\mathbf{m},\mathbf{c}) = \sum_{i=1}^{n} \Psi_i(e_i) + \sum_{i<j} \Phi(e_i, e_j) \qquad (8)$$



$d \in \mathcal{D}$
$e_1 \in \Gamma(m_1) \longrightarrow x_{e_1}$
$e_2 \in \Gamma(m_2) \longrightarrow x_{e_2}$
$\dots$
$e_n \in \Gamma(m_n) \longrightarrow x_{e_n}$
$\{\Psi_i(e_i)\}_{i,e_i}$
$\{\Phi(e_i,e_j)\}_{e_i,e_j}$
LBP message passing iteration
LBP message passing iteration
$\dots$
LBP message passing iteration
$\{\overline{\mu}_i(e_i)\}_{i,e_i}$
loss
$\{\overline{m}^0_{i\to j}(e_j)=0\}_{i,j,e_i}$
$\{\overline{m}^1_{i\to j}(e_j)\}_{i,j,e_i}$
$\{\overline{m}^T_{i\to j}(e_j)\}_{i,j,e_i}$
backward
forward

Figure 2: Global model: unrolled LBP deep network that is end-to-end differentiable and trainable.

The unary factors are the local scores $\Psi_i(e_i) = \Psi(e_i, c_i)$ described in Eq. (5). The pairwise factors are bilinear forms of the entity embeddings

$$\Phi(e, e') = \frac{2}{n-1}\, \mathbf{x}_e^\top \mathbf{C}\, \mathbf{x}_{e'}\,, \tag{9}$$

where $\mathbf{C}$ is a diagonal matrix. Similar to (Ganea et al., 2016), the above normalization helps balancing the unary and pairwise terms across documents with different numbers of mentions.

The function value $g(\mathbf{e}, \mathbf{m}, \mathbf{c})$ is supposedly high for semantically related sets of entities that also have local support. The goal of a global ED prediction method is to perform maximum-a-posteriori on this CRF to find the set of entities $\mathbf{e}$ that maximize $g(\mathbf{e}, \mathbf{m}, \mathbf{c})$.

Differentiable Inference.

Training and prediction in binary CRF models as the one above is NP-hard. Therefore, in learning one usually maximizes a likelihood approximation and during operations (i.e. in prediction) one may use an approximate inference procedure, often based on message-passing. Among many challenges of these approaches, it is worth pointing out that weaknesses of the approximate inference procedure are generally not captured during learning. Inspired by (Domke, 2011, 2013), we use *truncated fitting* of loopy belief propagation (LBP) to a fixed number of message passing iterations. Our model directly optimizes the marginal likelihoods, using the same networks for learning and prediction. As noted by (Domke, 2013), this method is robust to model mis-specification, avoids inherent difficulties of partition functions and is faster compared to double-loop likelihood training (where, for each stochastic update, inference is run until convergence is achieved).

Our architecture is shown in Figure 2. A neural network with T layers encodes T message passing iterations of synchronous max-product LBP[3] which is designed to find the most likely (MAP) entity assignments that maximize $g(\mathbf{e}, \mathbf{m}, \mathbf{c})$. We also use message damping, which is known to speed-up and stabilize convergence of message passing. Formally, in iteration t, mention m_i votes for entity candidate $e \in \Gamma(m_j)$ of mention m_j using the normalized log-message $\overline{m}^t_{i\to j}(e)$ computed as:

$$m^{t+1}_{i\to j}(e) = \max_{e' \in \Gamma(m_i)} \Big\{\Psi_i(e') + \Phi(e, e') + \sum_{k \neq j} \overline{m}^t_{k\to i}(e')\Big\}\,. \tag{10}$$

Herein the first part just reflects the CRF potentials, whereas the second part is defined as

$$\overline{m}^t_{i\to j}(e) = \log[\delta \cdot \mathrm{softmax}(m^t_{i\to j}(e)) + (1-\delta)\cdot \exp(\overline{m}^{t-1}_{i\to j}(e))] \tag{11}$$

where $\delta \in (0, 1]$ is a damping factor. Note that, without loss of generality, we simplify the LBP procedure by dropping the factor nodes. The messages at first iteration (layer) are set to zero.

After T iterations (network layers), the beliefs (marginals) are computed as:

$$\mu_i(e) = \Psi_i(e) + \sum_{k \neq i} \overline{m}^T_{k\to i}(e) \tag{12}$$

$$\overline{\mu}_i(e) = \frac{\exp[\mu_i(e)]}{\sum_{e' \in \Gamma(m_i)} \exp[\mu_i(e')]} \tag{13}$$

Similar to the local case, we obtain accuracy improvement when combining the mention-entity prior $\hat{p}(e|m)$ with marginal $\mu_i(e)$ using the same non-linear combination function f from Equation 6 as follows:

$$\rho_i(e) := f(\overline{\mu}_i(e), \log \hat{p}(e|m_i)) \tag{14}$$

The learned function f for global ED is non-trivial (see Figure 3), showing that the influence of the prior tends to weaken for larger $\mu(e)$,

[3] Sum-product and mean-field performed worse in our experiments.

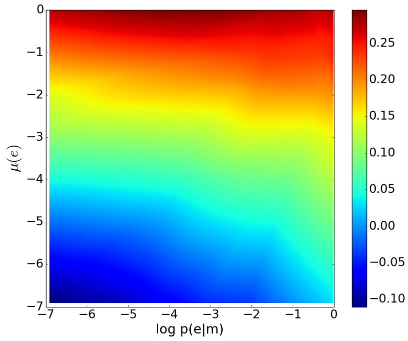


Figure 3: Non-linear scoring function of the belief and mention prior learned with a neural network. Achieves a 1.7% improvement on AIDA-B dataset compared to a weighted average scheme.

whereas it has a dominating influence whenever the document-level evidence is weak. We also experimented with the prior integrated directly inside the unary factors $\Psi_i(e_i)$, but results were worse because, in some cases, the global entity interaction is not able to recover from strong incorrect priors (e.g. country names have a strong prior towards the respective countries as opposed to national sports teams).

Parameters of our global model are the diagonal matrices $\mathbf{A}, \mathbf{B}, \mathbf{C}$ and the weights of the f network. As before, we find a margin based objective to be the most effective and we suggest to fit parameters by minimizing a ranking loss[4] defined as:

$$L(\theta) = \sum_{D \in \mathcal{D}} \sum_{m_i \in D} \sum_{e \in \Gamma(m_i)} h(m_i, e) \qquad (15)$$

$$h(m_i, e) = [\gamma - \rho_i(e_i^*) + \rho_i(e)]_+ \qquad (16)$$

Computing this objective is trivial by running T times the steps described by Eqs. (10), (11), followed in the end by the step in Eq. (13). Each step is differentiable and the gradient of the model parameters can be computed on the resulting marginals and back-propagated over messages using chain rule.

At test time, marginals $\rho_i(e)$ are computed jointly per document using this network, but prediction is done independently for each mention m_i by maximizing its respective marginal score.

6 Candidate Selection

We use a mention-entity prior $\hat{p}(e|m)$ both as a feature and for entity candidate selection. It is computed by averaging probabilities from two indexes build from mention entity hyperlink count statistics from Wikipedia and a large Web corpus (Spitkovsky and Chang, 2012). Moreover, we add the YAGO dictionary of (Hoffart et al., 2011), where each candidate receives a uniform prior.

Metric Method	NDCG@1	NDCG@5	NDCG@10	MAP
WikiLinkMeasure (WLM)	0.54	0.52	0.55	0.48
(Yamada et al., 2016) d = 500	0.59	0.56	0.59	0.52
our (canonical pages) d = 300	0.624	0.589	0.615	0.549
our (canonical&hyperlinks) d = 300	**0.632**	**0.609**	**0.641**	**0.578**

Table 1: Entity relatedness results on the test set of (Ceccarelli et al., 2013). WLM is a well-known similarity method of (Milne and Witten, 2008).

Dataset	**Number mentions**	**Number docs**	**Mentions per doc**	**Gold recall**
AIDA-train	18448	946	19.5	-
AIDA-A (valid)	4791	216	22.1	96.9%
AIDA-B (test)	4485	231	19.4	98.2%
MSNBC	656	20	32.8	98.5%
AQUAINT	727	50	14.5	94.2%
ACE2004	257	36	7.1	90.6%
WNED-CWEB	11154	320	34.8	91.1%
WNED-WIKI	6821	320	21.3	92%

Table 2: Statistics of ED datasets. *Gold recall* is the percentage of mentions for which the entity candidate set contains the ground truth entity. We only train on mentions with at least one candidate.

Candidate selection, i.e. construction of $\Gamma(e)$, is done for each input mention as follows: first, the top 30 candidates are selected based on the prior $\hat{p}(e|m)$. Then, in order to optimize for memory and run time (LBP has complexity quadratic in S), we keep only 7 of these entities based on the following heuristic: (i) the top 4 entities based on $\hat{p}(e|m)$ are selected, (ii) the top 3 entities based on the local context-entity similarity measured using the function from Eq. 5 are selected.[5]. We refrain from annotating mentions without any candidate entity, implying that precision and recall can be different in our case.

In a few cases, generic mentions of persons (e.g. ”Peter”) are coreferences of more specific mentions (e.g. ”Peter Such”) from the same document. We employ a simple heuristic to address this issue: for each mention m, if there exist mentions of persons that contain m as a continuous subse-

[4] Optimizing a marginal log-likelihood loss function performed worse.

[5] We have used a simpler context vector here computed by simply averaging all its constituent word vectors.

Methods	AIDA-B

quence of words, then we consider the merged set of the candidate sets of these specific mentions as the candidate set for the mention m. We decide that a mention refers to a person if its most probable candidate by $\hat{p}(e|m)$ is a person.

7 Experiments

7.1 ED Datasets

We validate our ED models on some of the most popular available datasets used by our predecessors[6]. We provide statistics in Table 2.

- AIDA-CoNLL dataset (Hoffart et al., 2011) is one of the biggest manually annotated ED datasets. It contains training (AIDA-train), validation (AIDA-A) and test (AIDA-B) sets.
- MSNBC (MSB), AQUAINT (AQ) and ACE2004 (ACE) datasets cleaned and updated by (Guo and Barbosa, 2016)[7]
- WNED-WIKI (WW) and WNED-CWEB (CWEB): are larger, but automatically extracted, thus less reliable. Are built from the ClueWeb and Wikipedia corpora by (Guo and Barbosa, 2016; Gabrilovich et al., 2013).

7.2 Training Details and (Hyper)Parameters

We explain training details of our approach. All models are implemented in the Torch framework.

Entity Vectors Training & Relatedness Evaluation. For entity embeddings only, we use Wikipedia (Feb 2014) corpus for training. Entity vectors are initialized randomly from a 0-mean normal distribution with standard deviation 1. We first train each entity vector on the entity's Wikipedia canonical description page (title words included) for 400 iterations. Subsequently, Wikipedia hyperlinks of the respective entities are used for learning until validation score (described below) stops improving. In each iteration, 20 positive words, each with 5 negative words, are sampled and used for optimization as explained in Section 3. We use Adagrad (Duchi et al., 2011) with a learning rate of 0.3. We choose embedding size $d = 300$, pre-trained (fixed) Word2Vec word vectors[8], $\alpha = 0.6$, $\gamma = 0.1$ and window size of 20 for the hyperlinks. We remove stop words before training. Since our method allows to train the embedding of each entity independently of other entities, we decide for efficiency reasons (and without loss of generality) to learn only the vectors of all entities appearing as mention candidates in all the test datasets described in Sec. 7.1, a total of 270000 entities. Training of those takes 20 hours on a single TitanX GPU with 12GB of memory.

Global methods	MSB	AQ	ACE	CWEB	WW
prior $\hat{p}(e\|m)$	89.3	83.2	84.4	69.8	64.2
(Fang et al., 2016)	81.2	88.8	85.3	-	-
(Ganea et al., 2016)	91	89.2	**88.7**	-	-
(Milne and Witten, 2008)	78	85	81	64.1	81.7
(Hoffart et al., 2011)	79	56	80	58.6	63
(Ratinov et al., 2011)	75	83	82	56.2	67.2
(Cheng and Roth, 2013)	90	**90**	86	67.5	73.4
(Guo and Barbosa, 2016)	92	87	88	77	**84.5**
our (global)	**93.7** ± **0.1**	88.5 ± 0.4	**88.5** ± **0.3**	**77.9** ± **0.1**	77.5 ± 0.1

Table 4: Micro F1 results for other datasets.

We test and validate our entity embeddings on the entity relatedness dataset of (Ceccarelli et al., 2013). It contains 3319 and 3673 queries for the test and validation sets. Each query consist of one target entity and up to 100 candidate entities with gold standard binary labels indicating if the two entities are related. The associated task requires ranking of related candidate entities higher than the others. Following previous work, we use different evaluation metrics: normalized discounted cumulative gain (NDCG) and mean average precision (MAP). The validation score used during learning is then the sum of the four metrics showed in Table 1. We perform candidate ranking based on cosine similarity of entity pairs.

[6] TAC-KBP datasets used by (Yamada et al., 2016; Globerson et al., 2016; Sun et al., 2015) are no longer available.

Table 5: Effects of two of the hyper-parameters. Left: A low T (e.g.5) is already sufficient for accurate approximate marginals. Right: Hard attention improves accuracy of a local model with K=100.

Local and Global Model Training. Our local and global ED models are trained on AIDA-train (multiple epochs), validated on AIDA-A and tested on AIDA-B and other datasets mentioned in Section 7.1. We use Adam (Kingma and Ba, 2014) with learning rate of 1e-4 until validation accuracy exceeds 90%, afterwards setting it to 1e-5. Variable size mini-batches consisting of all mentions in a document are used during training. We remove stop words. Hyper-parameters of the best validated global model are: $\gamma = 0.01, K = 100, R = 25, S = 7, \delta = 0.5, T = 10$. For the local model, $R = 50$ was best. Validation accuracy is computed after each 5 epochs. To regularize, we use early stopping, i.e. we stop learning if the validation accuracy does not increase after 500 epochs. Training on a single GPU takes, on average, 2ms per mention, or 16 hours for 1250 epochs over AIDA-train.

By using diagonal matrices $\mathbf{A}, \mathbf{B}, \mathbf{C}$, we keep the number of parameters very low (approx. 1.2K parameters). This is necessary to avoid overfitting when learning from a very small training set. We also experimented with diagonal plus low-rank matrices, but encountered quality degradation.

7.3 Entity Similarity Results

Results for the entity similarity task are shown in Table 1. Our method outperforms the well established Wikipedia link measure and the method of (Yamada et al., 2016) using less information (only word - entity statistics). We note that the best result on this dataset was reported in the unpublished work of (Huang et al., 2015). Their entity embeddings are trained on many more sources of information (e.g. KG links, relations, entity types). However, our focus was to prove that lightweight trained embeddings useful for the ED task can also perform decently for the entity similarity task. We emphasize that our global ED model outperforms Huang's ED model (Table 3), likely due to the power of our local and joint neural network architectures. For example, our attention mechanism clearly benefits from explicitly embedding words and entities in the same space.

Freq gold entity	Number mentions	Solved correctly	$\hat{p}(e\|m)$ **gold entity**	Number mentions	Solved correctly
0	5	80.0 %	≤ 0.01	36	89.19%
1-10	0	-	0.01 - 0.03	249	88.76%
11-20	4	100.0%	0.03 - 0.1	306	82.03%
21-50	50	90.0%	0.1 - 0.3	381	86.61%
> 50	4345	94.2%	> 0.3	3431	96.53%

Table 6: ED accuracy on AIDA-B for our best system splitted by Wikipedia hyperlink frequency and mention prior of the ground truth entity, in cases where the gold entity appears in the candidate set.

7.4 ED Baselines & Results

We compare with systems that report state-of-the-art results on the datasets. Some baseline scores from Table 4 are taken from (Guo and Barbosa, 2016). The best results for the AIDA datasets are reported by (Yamada et al., 2016) and (Globerson et al., 2016). We do not compare against (Pershina et al., 2015) since, as noted also by (Globerson et al., 2016), their mention index artificially includes the gold entity (guaranteed gold recall), which is not a realistic setting.

For a fair comparison with prior work, we use in-KB accuracy and micro F1 (averaged per mention) metrics to evaluate our approach. Results are shown in Tables 3 and 4. We run our system 5 times, each time we pick the best model on the validation set, and report results on the test set for these models. We obtain state of the art accuracy on AIDA which is the largest and hardest (by the accuracy of the $\hat{p}(e|m)$ baseline) manually created ED dataset . We are also competitive on the other datasets. It should be noted that all the other methods use, at least partially, engineered features. The merit of our proposed method is to show that, with the exception of the $\hat{p}(e|m)$ feature, a neural network is able to learn the best features for ED without requiring expert input.

To gain further insight, we analyzed the accuracy on the AIDA-B dataset for situations where gold entities have low frequency or mention prior. Table 6 shows that our method performs well in these harder cases.

Mention	Gold entity	$\hat{p}(e\|m)$ **of gold entity**	**Attended contextual words**
Scotland	Scotland national rugby union team	0.034	England Rugby team squad Murrayfield Twickenham national play Cup Saturday World game George following Italy week Friday selection dropped row month
Wolverhampton	Wolverhampton Wanderers F.C.	0.103	matches League Oxford Hull league Charlton Oldham Cambridge Sunderland Blackburn Sheffield Southampton Huddersfield Leeds Middlesbrough Reading Coventry Darlington Bradford Birmingham Enfield Barnsley
Montreal	Montreal Canadiens	0.021	League team Hockey Toronto Ottawa games Anaheim Edmonton Rangers Philadelphia Caps Buffalo Pittsburgh Chicago Louis National home Friday York Dallas Washington Ice
Santander	Santander Group	0.192	Carlos Telmex Mexico Mexican group firm market week Ponce debt shares buying Televisa earlier pesos share stepped Friday analysts ended
World Cup	FIS Alpine Ski World Cup	0.063	Alpine ski national slalom World Skiing Whistler downhill Cup events race consecutive weekend Mountain Canadian racing

Table 7: Examples of context words selected by our local attention mechanism. Distinct words are sorted decreasingly by attention weights and only words with non-zero weights are shown.

7.5 Hyperparameter Studies

In Table 5, we analyze the effect of two hyperparameters. First, we see that hard attention (i.e. $R < K$) helps reducing the noise from uninformative context words (as opposed to keeping all words when $R = K$).

Second, we see that a small number of LBP iterations (hard-coded in our network) is enough to obtain good accuracy. This speeds up training and testing compared to traditional methods that run LBP until convergence. An explanation is that a truncated version of LBP can perform well enough if used at both training and test time.

7.6 Qualitative Analysis of Local Model

In Table 7 we show some examples of context words attended by our local model for correctly solved hard cases (where the mention prior of the correct entity is low). One can notice that words relevant for at least one entity candidate are chosen by our model in most of the cases.

7.7 Error Analysis

We analyse some of the errors made by our model on the AIDA-B dataset. We mostly observe three situations: i) annotation errors, ii) gold entities that do not appear in mentions' candidate sets, or iii) gold entities with very low $p(e|m)$ prior whose mentions have an incorrect entity candidate with high prior. For example, the mention ”Italians” refers in some specific context to the entity ”Italy national football team” rather than the entity representing the country. The contextual information is not strong enough in this case to avoid an incorrect prediction. On the other hand, there are situations where the context can be misleading, e.g. a document heavily discussing about cricket will favor resolving the mention ”Australia” to the entity ”Australia national cricket team” instead of the gold entity ”Australia” (naming a location of cricket games in the given context).

8 Conclusion

We have proposed a novel deep learning architecture for entity disambiguation that combines entity embeddings, a contextual attention mechanism, an adaptive local score combination, as well as unrolled differentiable message passing for global inference. Compared to many other methods, we do not rely on hand-engineered features, nor on an extensive corpus for entity co-occurrences or relatedness. Our system is fully differentiable, although we chose to pre-train word and entity embeddings. Extensive experiments show the competitiveness of our approach across a wide range of corpora. In the future, we would like to extend this system to perform nil detection, coreference resolution and mention detection.

Abstract

The goal of Open Information Extraction (OIE) is to extract surface relations and their arguments from natural-language text in an unsupervised, domain-independent manner. In this paper, we propose MinIE, an OIE system that aims to provide useful, compact extractions with high precision and recall. MinIE approaches these goals by (1) representing information about polarity, modality, attribution, and quantities with semantic annotations instead of in the actual extraction, and (2) identifying and removing parts that are considered overly specific. We conducted an experimental study with several real-world datasets and found that MinIE achieves competitive or higher precision and recall than most prior systems, while at the same time producing shorter, semantically enriched extractions.

1 Introduction

Open Information Extraction (OIE) (Banko et al., 2007) is the task of generating a structured, machine-readable representation of information expressed in natural language text in an unsupervised, domain-independent manner. In contrast to traditional IE systems, OIE systems do not require an upfront specification of the target schema (e.g., target relations) or access to background knowledge (e.g., a knowledge base). Instead, extractions are (usually) represented in the form of surface subject-relation-object triples. OIE serves as input for deeper understanding tasks such as relation extraction (Riedel et al., 2013; Petroni et al., 2015), knowledge base construction (Dong et al., 2014), question answering (Fader et al., 2014), word analogy (Stanovsky et al., 2015), or information retrieval (Löser et al., 2012).

Consider, for example, the sentence *"Superman was born on Krypton."* An OIE system aims to extract the triple *(Superman, was born on, Krypton)*, which most of the available systems will correctly produce. As another example, consider the more involved sentence *"Pinocchio believes that the hero Superman was not actually born on beautiful Krypton"*, and the corresponding extractions of various systems in Table 1, extractions 1–6. Although most of the extractions are correct, they are often overly specific in that their constituents contain specific modifiers or even complete clauses. Such extractions severely limit the usefulness of OIE results (e.g., they are often pruned in relation extraction tasks). The main goals of OIE should be (i) to provide useful, compact extractions and (ii) to produce extractions with high precision and recall. The key challenge in OIE is how to achieve both goals simultaneously. In fact, most of the available systems (often implicitly) focus on either compactness (e.g., ReVerb (Fader et al., 2011)) or precision/recall (e.g., ClausIE (Del Corro and Gemulla, 2013)).

We propose MinIE, an OIE system that aims to address and trade-off both goals. MinIE is built on top of ClausIE, a state-of-the-art OIE system that achieves high precision and recall, but often produces overly-specific extractions. To generate more useful and semantically richer extractions, MinIE (i) provides semantic annotations for each extraction, (ii) minimizes overly-specific constituents, and (iii) produces additional extractions that capture implicit relations. Table 1 shows the output of (variants of) MinIE for the example sentence. Note that MinIE's extractions are significantly more compact but retain correctness.

MinIE's semantic annotations represent information about polarity, modality, attribution, and quantities. The idea of using annotations has al-

Table 1: Example extractions and annotations from various OIE systems

ready been explored by OLLIE (Mausam et al., 2012) for capturing the context of an extraction. MinIE follows OLLIE, but adds semantic annotations that make the extraction *itself* more compact and useful (as opposed to capturing context). For example, MinIE detects negations in the relation, removes them from the extraction, and adds a "negative polarity" (-) annotation. In fact, MinIE treats surface relations such as *was born on* and *was not born on* as equivalent up to polarity. The absence of negative evidence is a major concern for relation extraction and knowledge base construction tasks—e.g., addressed by using a local closed world assumption (Dong et al., 2014) or negative sampling (Riedel et al., 2013; Petroni et al., 2015)—and MinIE's annotations can help to alleviate this problem.

In addition to the semantic annotations, MinIE minimizes its extractions by identifying and removing parts that are considered overly specific. In general, such minimization is inherently limited in scope due to the absence of domain knowledge. Thus MinIE does not and cannot correctly minimize all its extractions in all cases. Instead, MinIE supports multiple minimization modes, which differ in their aggressiveness and effectively control the usefulness-precision trade-off. In particular, MinIE's complete mode (C) does not perform any minimizations. MinIE's safe mode (S) only performs minimizations that are considered universally safe. MinIE's dictionary mode (D) makes use of corpus-level statistics to inform the minimization process. Finally, MinIE's aggressive mode (A) only keeps parts that are considered universally necessary. The use of corpus-level statistics by MinIE-D is inspired by the pruning techniques of ReVerb, although we use these statistics for minimization instead of pruning (see Sec. 2). Tab. 1 shows the output of MinIE's various modes.

We conducted an experimental study with several real-world datasets and found that the various modes of MinIE produced much shorter extractions than most prior systems, while simultaneously achieving competitive or higher precision (depending on the mode being used). MinIE sometimes fell behind prior systems in terms of the total number of extractions. We found that in almost all of these cases, MinIE became competitive once redundant extractions were removed.

2 Related work

OIE was introduced by Banko et al. (2007). Since then, many different OIE systems have been proposed. Earlier systems—e.g., Fader et al.

(2011)—relied mostly on shallower NLP techniques such as POS tagging and chunking, while later systems often use dependency parsing in addition (Gamallo et al., 2012; Wu and Weld, 2010). Most OIE systems represent extractions in the form of triples, although some also produce n-ary extractions (Akbik and Löser, 2012; Del Corro and Gemulla, 2013) or nested representations (Bast and Haussmann, 2013; Bhutani et al., 2016). Some systems focus on non-verb-mediated relations (Yahya et al., 2014). MinIE is based on the state-of-the-art OIE system ClausIE (Del Corro and Gemulla, 2013).

A general challenge in OIE is to avoid both uninformative and overly-specific extractions. ReVerb (Fader et al., 2011) proposed to avoid overly-specific relations by making use of *lexical constraints*: relations that occur infrequently in a large corpus were considered overly-specific and pruned. MinIE's dictionary mode also makes use of the corpus frequency of constituents. In contrast to ReVerb, MinIE uses frequency to inform minimization (instead of to prune) and applies it to subjects and arguments as well. Perhaps the closest system in spirit to MinIE is Stanford OIE (Angeli et al., 2015), which uses aggressive minimization. Stanford OIE deletes all subconstituents connected by certain typed dependencies (e.g., *amod*). For some dependencies (e.g., *prep* or *dobj*), it uses a frequency constraint along the lines of ReVerb. MinIE differs from Stanford OIE in that it (i) separates out polarity, modality, attribution, and quantities; (ii) uses a different, more principled (and more precise) approach to minimization.

Annotated OIE extractions were introduced by OLLIE (Mausam et al., 2012), which uses two types of annotations: *attribution* (the supplier of information) and *clause modifier* (a clause modifying the triple). MinIE extends OLLIE's attribution by additional semantic annotations for polarity, modality, and quantities. Such annotations are not provided by prior OIE systems. CSD-IE (Bast and Haussmann, 2013) introduced the notion of nested facts (termed "minimal" in their paper) and produce extractions with "pointers" to other extractions. NestIE (Bhutani et al., 2016) takes up this idea. OLLIE's clause modifier has a similar purpose. MinIE currently does not handle nested extractions.

Another line of research explores the integration of background knowledge into OIE (Nakashole et al., 2012; Moro and Navigli, 2012, 2013). In general, OIE systems should use background knowledge when available, but remain open when not. MinIE currently does not use background knowledge, although it allows providing domain-dependent dictionaries.

3 Overview

The goal of MinIE is to provide minimized, semantically annotated OIE extractions. While the techniques employed here can potentially be integrated into any OIE system, we built MinIE on top of ClausIE. We chose ClausIE because (i) it separates the identification of the extractions from the generation of propositions, (ii) it detects clause types, which are also useful for MinIE, and (iii) it is a state-of-the-art OIE system with high precision and recall.

As ClausIE, MinIE focuses on extractions obtained from individual clauses (with the exception of attribution; Sec. 5.3). Each clause consists of one subject (S), one verb (V) and alternatively an indirect object (O_i), a direct object (O), a complement (C) and one or more adverbials (A). ClausIE identifies the clause type, which indicates which constituents are obligatory or optional from a syntactic point of view. Quirk et al. (1985) identified seven clause types for English: SV, SVA, SVC, SVO, SVOO, SVOA, and SVOC, where letters refer to obligatory constituents and each clause can be accompanied by additional optional adverbials.

MinIE consists of three phases. (1) Each input sentence is run through ClausIE and a separate extractor for implicit facts (Sec. 4.2). We rewrite ClausIE's extractions to make relations more informative (Sec. 4.1). We refer to the resulting extractions as *input extractions*. (2) MinIE then detects information about polarity (Sec. 5.1), modality (Sec. 5.2), attribution (Sec. 5.3), and quantities (Sec. 5.4) and represents it with semantic annotations. (3) To further minimize the resulting *annotated extractions*, MinIE provides various minimization modes (Sec. 6) with increasing levels of aggressiveness: MinIE-C(omplete), MinIE-S(afe), MinIE-D(ictionary), and MinIE-A(ggressive). The modes differ in the amount of minimizations being applied. The result of this phase is a *minimized extraction*.

Finally, MinIE outputs each minimized extraction along with its annotations. Semantic annotations (such as polarity) are crucial to correctly represent the extraction, whereas other annotations (such as original relation) provide additional information about the minimization process.

4 Input Extractions

We first describe how MinIE obtains meaningful input extractions.

4.1 Enriching Relations

As mentioned before, MinIE uses ClausIE as its underlying OIE system. The relations extracted by ClausIE consist of only verbs and negation particles (cf. Tab. 1). Fader et al. (2011) argue that such an approach can lead to uninformative relations. For example, from the sentence *"Faust made a deal with the Devil"*, ClausIE extracts triple *(Faust, made, a deal with the Devil)*, whereas the extraction *(Faust, made a deal with, the Devil)* has a more informative relation and a shorter argument. Indeed, the relation *made* is highly polysemous (49 synsets in WordNet), whereas *made a deal with* is not. MinIE aims to produce informative relations by deciding which constituents of the input sentence should be pushed into the relation. Our goal is to retain only one of the constituents of the input clause in the argument of the extraction whenever possible, while simultaneously retaining coherence. In particular, our approach uses the clause types detected by ClausIE to ensure that MinIE never removes obligatory constituents from a clause (which would lead to incoherent extractions); it instead may opt to move such constituents to the relation. Our approach is inspired by the syntactic patterns of ReVerb—which is similar to our handling of the SVA and SVO clause types—but, in contrast, applies to all clause types. Note that the relations produced in this step may sometimes be considered overly specific; they will be minimized further in subsequent steps.

SVA. If the adverbial is a prepositional complement, we push the preposition into the relation. For example, we rewrite *(Superman, lives, in Metropolis)* to *(Superman, lives in, Metropolis)*. This allows us to distinguish *live in* from relations such as *live during*, *live until*, *live through*, and so on.

SVO$_i$O, SVOC. We generally push the indirect object (SVO$_i$O) or direct object (SVOC) into the relation. In both cases, the verb requires two additional constituents: we use the first one to enrich the relation and the second one as an argument. For example, we rewrite *(Superman, declared, the city safe)* to *(Superman, declared the city, safe)*. As this example indicates, this rewrite is somewhat unsatisfying; further exploration is an interesting direction for future work.

SVOA. If the adverbial consists of a single adverb, we push it to the relation and use the object as an argument. This approach retains coherence because such adverbials are "fluent", i.e., they do not have a fixed position. Otherwise, we proceed as in SVOC, but additionally push the starting preposition (if present) of the adverbial to the relation. For example, *(Ana, turned, the light off)* becomes *(Ana, turned off, the light)*, and *(The doorman, leads, visitors to their destination)* becomes *(The doorman, leads visitors to, their destination)*.

Optional adverbials. If the clause contains optional adverbials, ClausIE creates one extraction without any optional adverbial and one additional extraction per optional adverbial. The former extractions are processed as above. The latter extractions are treated as if the adverbial were obligatory. For example, the extraction *(Faust, made, a deal with the Devil)* becomes *(Faust, made a deal with, the Devil)*. Here the actual clause type is SVO, but we process it as if it were SVOA.

Infinitive forms. If the argument starts with a to-infinitive verb, we move it to the relation. For example, *(Superman, needs, to defeat Lex)* becomes *(Superman, needs to defeat, Lex)*.

4.2 Implicit Extractions

ClausIE produces non-verb-mediated extractions from appositions and possessives. We refer to these extractions as *implicit extractions*. MinIE makes use of additional implicit extractors. In particular, we use the patterns of FINET (Del Corro et al., 2015) to detect explicit type mentions. For example, if the sentence contains "*president Barack Obama*", we obtain *(Barack Obama, is, president)*. We also include certain patterns involving named entities: pattern *ORG IN LOC* for extraction *(ORG, is IN, LOC)*; pattern *"Mr." PER* for *(PER, is, male)* (similarly, Ms. or Mrs.); and pattern *ORG POS? NP PER* for *(PER, is NP of, ORG)* from RelNoun (Pal and Mausam, 2016). Apart from providing additional high-quality extractions, we use implicit extractions as a signal for minimization (Sec. 6.2). The extractors above have thus been included both to increase recall and to be able to provide more effective minimizations.

Sentence	Factuality
S. does live in Metropolis.	(+, CT)
S. does not live in M.	(– [not], CT)
S. does probably live in M.	(+, PS [probably])
S. probably does not live in M.	(– [not], PS [probably])

Table 2: Factuality examples. MinIE extracts triple *(Superman; does live in; Metropolis)* from each sentence but the factuality annotations differ.

5 Semantic Annotations

Once input extractions have been created, MinIE detects information about polarity (Sec. 5.1), modality (Sec. 5.2), attribution (Sec. 5.3), and quantities (Sec. 5.4) and represents it using semantic annotations. Our focus is on simple, rule-based methods that are both domain-independent and (considered) safe to use in that they do not harm the accuracy of the extraction.

5.1 Polarity

MinIE annotates each extraction with information about its *factuality*. Following Saurí and Pustejovsky (2012), we represent the factuality of an extraction with two pieces of information: polarity (+ or -) and modality (CT or PS; for certainty or possibility, resp.). Tab. 2 lists some examples.

The *polarity* indicates whether or not a triple occurred in negated form. In order to assign a polarity value to a triple, we aim to detect whether the relation indicates a negative polarity. If so, we assign negative polarity to the whole triple. We detect negations using a small lexicon of negation words (e.g., *no, not, never, none*). If a word from the lexicon is detected, it is dropped from the relation and the triple is annotated with negative polarity (-) and the negation word. In Tab. 2, the extractions from sentences 2 and 4 are annotated as negative.

We found that this simple approach successfully spots many negations present in the input relations. Note that whenever a negation is present but not detected, MinIE still produces correct results because such negations are retained in the triple. For example, if a negations occurs in the subject or argument of the extraction, MinIE does not detect it. E.g., from sentence *"No people were hurt in the fire"*, MinIE extracts *(Q_1 people, were hurt in; fire)* with quantity Q_1=*no* (see Sec. 5.4). This extraction is correct, but can be further minimized to *(people; were hurt in; fire)* with a negative polarity annotation. We consider such advanced minimizations too dangerous to use.

Generally, negation detection is a hard problem and involves questions such as negation scope resolution, focus detection, and double negation (Blanco and Moldovan, 2011). MinIE does not address these problems, but restricts attention to the simple, safe cases.

5.2 Modality

The *modality* indicates whether the triple is a *certainty* (CT) or a *possibility* (PS) according to the clause in which it occurs. We proceed similarly as for the detection of negations and consider a triple certain unless we find evidence of possibility.

To find such evidence, MinIE searches the relation for (1) modal verbs such as *may* or *can*, (2) possibility-indicating words, and (3) certain infinitive verb phrases. For (2) and (3), we make use of a small domain-independent lexicon. Our lexicon is based on the lexicon of Saurí and Pustejovsky (2012) and the words in the corresponding WordNet synsets. It mainly contains adverbs such as *probably, possibly, maybe, likely* and infinitive verb phrases such as *is going to*, *is planning to*, or *intends to*. Whenever words indicating possibility are detected, we remove these words from the triple and annotate the triple as possible (PS) along with the words just removed. For example, sentences 3 and 4 in Tab. 2 are annotated PS with the possibility-indicating word *probably*.

5.3 Attribution

The *attribution* of a triple is the supplier of information given in the input sentence, if any. We adapt our attribution annotation from the notion of *source* of Saurí and Pustejovsky (2012), i.e., the attribution consists of a supplier of information (as in OLLIE) and an additional factuality (polarity and modality). The factuality is independent from the factuality of the extracted triple; it indicates whether the supplier expresses a negation or a possibility. Tab. 1 shows some examples.

We extract attributions from subordinate clauses and from "according to" patterns.

Subordinate clauses. MinIE searches for extractions that contain entire clauses as arguments. We then compare the relation against a domain-independent dictionary of relations indicating attributions (e.g., *say* or *believe*).[1] If we find a

[1] As with modality, the dictionary is based on Saurí and

match, we create an attribution annotation and use the subject of the extraction as the supplier of information. Each entry in the attribution dictionary is annotated with a modality. For example, relations such as *know*, *say*, or *write* express certainty, whereas relations such as *believe* or *guess* express possibility. If the relation is modified by a negation word, we mark the attribution with negative polarity (e.g., *never said that*). After the attribution has been established, we run ClausIE on the main clause and add the attribution to each extracted triple.

***"according to"* adverbial patterns.** We search for adverbials that start with *according to* and take whatever follows as the supplier with factuality (+, CT). The remaining part of the clause is processed as before.

5.4 Quantities

A *quantity* is a phrase that expresses an amount (or the absence) of something. It either modifies a noun phrase (e.g., *9 cats*) or is an independent complement (e.g., *I have 3*). Quantities include cardinals (*9*), determiners (*all*) or phrases (*almost 10*). If we detect a quantity, we replace it by a placeholder *Q* and add an annotation with the original quantity. The goal of this step is to unify extractions that only differ in quantities. For example, the phrases *9 cats*, *all cats* and *almost about 100 cats* are all rewritten to *Q cats*, only the quantity annotation differs.

We detect quantities by looking for numbers (NER types such as NUMBER or PERCENT) or words expressing quantities (such as *all, some, many*). We then extend these words via relevant typed dependencies, such as quantity modifiers (*quantmod*) and adverbial modifiers (*advmod*).

6 Minimization

After adding semantic annotations, MinIE minimizes extractions by dropping additional words. Since such minimization is risky, MinIE employs various minimization modes with different levels of aggressiveness, which effectively control the minimality-precision trade-off.

MinIE represents each constituent of an annotated extraction by its words, its dependency structure, its POS tags, and its named entities (detected by a named-entity recognizer). In general, each mode defines a set of *stable subconstituents*, which will always be fully retained, and subsequently searches for candidate words to drop outside of the stable subconstituents. Whenever a word is dropped from a constituent, we add an annotation with the original, unmodified constituent.

In all of MinIE's modes, noun sequences (which include the head) and named entities (from NER) are considered stable subconstituents. MinIE's minimization can be augmented with domain knowledge by providing information about additional stable subconstituents (e.g., collocations).

6.1 Complete Mode (MinIE-C)

MinIE's *complete mode* (MinIE-C) prunes all the extractions that contain subordinate clauses but does not otherwise modify the annotated extractions. The rationale is that extractions containing subordinate clauses are almost always overly specific. MinIE-C serves as a baseline.

6.2 Safe Mode (MinIE-S)

MinIE's *safe mode* only drops words which we consider universally safe to drop. We first drop all constituents that are covered by the implicit extractions discussed in Sec. 4.2 (e.g., *"Mr."* before persons). We then drop all determiners, possessive pronouns, adverbs modifying the verb in the relation, as well as adjectives and adverbs modifying words tagged as PERSON by the NER. An exception to these rules is given by named entities, which we consider as stable subconstituents (e.g., we do not drop *"Mr."* in (*Joe*, *cleans with*, *Mr. Muscle*)).

Note that this procedure cannot be considered safe when used on input extractions. We consider it safe, however, when applied to annotated extractions. In particular, all determiners, pronouns, and adverbs indicating negation, modality, or quantities are already processed and captured in annotations. The safe mode thus only performs simple rewrites such as *the great city* to *great city*, *his car* to *car*, *had also* to *had*, and *the eloquent president Mr. Barack Obama* to *Barack Obama*.

6.3 Dictionary Mode (MinIE-D)

Our dictionary mode uses a *dictionary $\mathcal{D}$ of stable constituents*. We first discuss how the dictionary is being used and subsequently how we construct it. An example is given in Fig. 1.

MinIE-D first performs all the minimizations of the safe mode and then searches for maximal noun phrases of the form $P \equiv$ *[adverbial|adjective]*$^+$

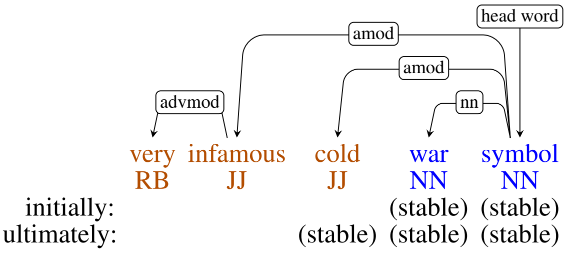
Pustejovsky (2012) plus WordNet synonyms.

[noun$^+$*|ner]*. For each instance of P, we drop a certain subset of its words. For example, a suitable minimization for *very infamous cold war symbol* (i.e., the Berlin wall) is *cold war symbol*, i.e., we consider *cold* as essential to the meaning of the constituent and *very infamous* as overly specific. The decision of what is considered essential and what overly specific is informed by dictionary $\mathcal{D}$. Note that in order to minimize mistakes, we consider for dropping only words in instances of pattern P. In particular, we do not touch subconstituents that contain prepositions because these are notoriously difficult to handle (e.g., we do not want to minimize *Bill of Rights* to *Bill*).

Our goal is to retain phrases occurring in $\mathcal{D}$, even if they occur in different order or with additional modifiers. We proceed as follows for each instance I of P. We first mark all nouns modifying the root (or the named entity) as *stable*. Afterwards, we create a set of *potentially stable subconstituents* (PSS). Each PSS is queried against dictionary $\mathcal{D}$. If it occurs in $\mathcal{D}$, all of its words are marked as stable. Once all PSS have been processed, we drop all words from I that are not marked stable. In our example, if $\{$*cold war*$\} \in \mathcal{D}$, we obtain *cold war symbol*.

To generate the set of PSS, we enumerate all syntactically valid subconstituents of I. For example, *infamous symbol* or *cold infamous war* are syntactically valid, whereas *very symbol* or *very cold war* are not. Conceptually,[2] we enumerate all subsequences of I and check whether (1) at least one noun (or named entity) is retained, and (2) whenever an adverb or adjective is not retained, neither are its modifiers. For each such subsequence, we generate all permutations of adverbial and adjective modifiers originating from the same dependency node, and each result as a PSS. This step ensures that the order of modifiers in I does influence whether or not a word is marked stable. The set of PSS for *very infamous cold war symbol* contains 22 entries.

The construction of dictionary $\mathcal{D}$ is inspired by the lexical constraint of Fader et al. (2011): Our assumption is that everything sufficiently frequent in a large corpus is not overly specific. To obtain $\mathcal{D}$, we process the entire corpus using the safe mode and include all frequent (e.g., frequency $\geq$ 10) subjects, relations, and arguments into $\mathcal{D}$. Applications can extend the dictionary using suitable collocations, either from domain-dependent dictionaries or by using methods to automatically extract collocations from a corpus (Gries, 2013).



PSS include: cold war symbol, cold symbol, **cold war**, infamous war symbol, infamous symbol, . . .

Figure 1: Illustration of PSS generation in MinIE-D. Initially stable words are marked blue. Entries in dictionary $\mathcal{D}$ are printed in bold face.

6.4 Aggressive Mode (MinIE-A)

All previous modes aimed to be conservative. MinIE-A proceeds the other way around: all words for which we are not sure if they need to be retained are dropped. For every word in a constituent of an annotated extraction, we drop all adverbial, adjective, possessive, and temporal modifiers (along with their modifiers). We also drop prepositional attachments (e.g., *man with apples* becomes *man*), quantities modifying nouns, auxiliary modifiers to the main verb (e.g., *have escalated* becomes *escalated*), and all compound nouns that have a different named-entity type than their head word (e.g., *European Union official* becomes *official*). In most cases, after applying these steps, only a single word, named entity, or a sequence of nouns remains for subject and argument constituents.

7 Experimental Study

The goal of our experimental study was to investigate the differences in the various modes of MinIE w.r.t. precision, recall, and extraction length as well as to compare it with popular prior methods.

7.1 Experimental Setup

Source code, dictionaries, datasets, extractions, labels, and labeling guidelines are made available.[3]

Datasets. We used (1) 10,000 random sentences from the New York Times Corpus (NYT-

[2] We generate both instances of P as well as the set of PSS directly from the dependency structure of the constituent.

[3] http://dws.informatik.uni-mannheim.de/en/resources/software/minie/

10k) (Sandhaus, 2008), (2) a random sample of 200 sentences from the same corpus (NYT), and (3) a random sample of 200 sentences from Wikipedia (Wiki). NYT and Wiki were used in the evaluation of ClausIE and NestIE.[4]

Methods. We used ClausIE, OLLIE, and Stanford OIE as baseline systems. We adapted the publicly available version of ClausIE to Stanford CoreNLP 3.8.0 and implemented MinIE on top. For MinIE-D, we built dictionary $\mathcal{D}$ from the entire NYT and Wikipedia corpus, respectively.

Labeling. Labelers provided two labels per extraction of NYT and Wiki: one for the triple (without attribution) and one for the attribution. A triple is labeled as correct if it is entailed by its corresponding clause; here factuality annotations are taken into account but attribution errors are ignored. For example, all triples except #3 of Tab. 1 are considered correct. An attribution is incorrect if there is an attribution in the sentence which is neither present in the triple nor in the attribution annotation. In Tab. 1, the attribution is incorrect for extractions #2, #3, #5, and #6. Attribution is labeled only when the fact triple is labeled correct. See the labeling guidelines for further details.

Overall, there were more than 9,400 distinct extractions on NYT and Wiki. Each extraction was labeled by two independent labelers. We treat an extraction as *correct* if both labelers labeled it as *correct*. The inter-annotator agreement was moderate (NYT: Cohen's $\kappa = 0.53$, 78% of labels agree; Wiki: $\kappa = 0.5$, 79% of labels agree).

Measures. For each system, we measured the total number of extractions, the total number of correct triples (*recall*), the fraction of correct triples out of all extractions (*factual precision*), and the fraction of correct triples that have correct attributions (*attribution precision*). We also determined the mean word count per triple (μ) and its standard deviation (σ) as a proxy for minimality. Finally, as some systems produced a large number of redundant extractions, we also report the number of non-redundant extractions. For simplicity, we consider a triple t_1 redundant if it appears as subsequence in some other triple t_2 produced by the same extractor from the same sentence (e.g., extraction #5 in Tab. 1 is redundant given extraction #6).

7.2 Extraction Statistics

In our first experiment, we used the larger but unlabeled NYT-10k dataset. The goal of this experiment was to investigate the total number of redundant and non-redundant extractions produced by each system and how frequently semantic annotations were produced (Tab. 3). For MinIE, we show the fraction of negative polarity and possibility annotations for triples only (i.e., we exclude the attribution polarity annotations).

In terms of number of extractions, MinIE (all modes) and Stanford OIE were roughly on par; OLLIE fell behind and ClausIE went ahead. The reason why ClausIE has more extractions than MinIE is that different (partly redundant) extractions from ClausIE may lead to the same minimized extraction. This is also also the reason why extraction numbers drop in the more aggressive modes of MinIE. We also determined the number of non-redundant extractions produced by each system and found that most systems produced only a moderate number of redundant extractions. A notable exception is Stanford OIE, which produced many extraction variants by dropping different subsets of words.

We observed that all modes of MinIE achieved significantly smaller extractions than ClausIE (its underlying OIE system), and that the average extraction length indeed dropped as we used more aggressive modes. Only MinIE-A produced shorter extractions than Stanford OIE. The main reason for the short extraction length of Stanford OIE is its aggressive creation of short redundant extractions (at the cost of precision; see below). We also found that to further minimize the extractions of MinIE-D, it is often necessary to minimize subjects and objects with prepositional modifiers (which MinIE currently avoids).

Only OLLIE and MinIE make use of annotations. The fraction of extracted attribution annotations was significantly smaller for OLLIE than for MinIE, mainly because OLLIE's attribution detection is limited to the *ccomp* dependency relation. Our results also indicate that MinIE frequently provides semantic annotations (with the notable exception of negative polarity).

7.3 Precision

In our second experiment, we compared the precision and recall of the various systems on the

[4] We did not use the OIE benchmark of Stanovsky and Dagan (2016) because it treats an extraction as correct if the heads of each constituent match the ones of a gold extraction. This is not suitable for us because it does not account for minimization (which does not change grammatical heads).

	OLLIE	ClausIE	Stanford	MinIE-C	MinIE-S	MinIE-D	MinIE-A
# non-redundant extr.	20,557	36,173	16,350	**37,465**	37,093	36,921	36,474

Table 4: Results on the labeled NYT and Wiki datasets

smaller NYT and Wiki datasets. Our results are summarized in Tab. 4.

We found that Stanford OIE had the lowest factual precision and recall for non-redundant extractions throughout; it produced many incorrect and many redundant extractions (e.g., Stanford OIE produced 400 extractions from five sentences on NYT). For MinIE, the factual precision dropped as expected when we use more aggressive modes. Interestingly, the drop in precision between MinIE-C and MinIE-D was quite low, even though extractions get shorter. The aggressive minimization of MinIE-A led to a more severe drop in precision. Surprisingly to us, even MinIE's aggressive mode achieved precision comparable to ClausIE and higher than Stanford OIE. Note that MinIE-C, MinIE-S, and MinIE-D had higher precision than ClausIE. Reasons include that MinIE produces additional high-precision implicit extractions and breaks up very long and thus error-prone extractions.We also tried enriching the dictionary of MinIE-D with WordNet and Wiktionary collocations; the precision was almost the same.

As for attribution precision, most of the sentences in our samples did not contain attributions; these numbers thus have low accuracy. OLLIE and MinIE achieved similar results, even though MinIE additionally annotated attributions with factuality information.

Errors. For all modes, errors in dependency parsing transfer over to errors in MinIE, which we believe was the main source of error in MinIE-C and MinIE-S. For MinIE-D, we sometimes drop adjectives which in fact form collocations (e.g., "*assistant* director") with the noun they are modifying. This happens when the collocation is not present in the dictionary; better collocation dictionaries may address this problem. Another source of error stems from the NER (e.g., the first word of the entity *Personal Ensign* was not recognized).

8 Conclusions

We believe that the use of minimized extractions with semantic annotations are a promising direction for OIE. The techniques presented here can be seen as a step towards this goal, but there are still many open questions. Important directions include additional annotation types (e.g., temporal/spatial), use of background knowledge, better handling of collocations, the use of nested representations, and multilingual OIE.

Scientific Information Extraction with Semi-supervised Neural Tagging

Yi Luan   Mari Ostendorf   Hannaneh Hajishirzi

Abstract

This paper addresses the problem of extracting keyphrases from scientific articles and categorizing them as corresponding to a task, process, or material. We cast the problem as sequence tagging and introduce semi-supervised methods to a neural tagging model, which builds on recent advances in named entity recognition. Since annotated training data is scarce in this domain, we introduce a graph-based semi-supervised algorithm together with a data selection scheme to leverage unannotated articles. Both inductive and transductive semi-supervised learning strategies outperform state-of-the-art information extraction performance on the 2017 SemEval Task 10 ScienceIE task.

1 Introduction

As a research community grows, more and more papers are published each year. As a result there is increasing demand for improved methods for finding relevant papers and automatically understanding the key ideas in those papers. However, due to the large variety of domains and extremely limited annotated resources, there has been relatively little work on scientific information extraction. Previous research has focused on unsupervised approaches such as bootstrapping (Gupta and Manning, 2011; Tsai et al., 2013), where hand-designed templates are used to extract scientific keyphrases, and more templates are added through bootstrapping.

Very recently a new challenge on Scientific Information Extraction (ScienceIE) (Augenstein et al., 2017)[1] provides a dataset consisting of 500 scientific paragraphs with keyphrase annotations for three categories: TASK, PROCESS, MATERIAL across three scientific domains, Computer Science (CS), Material Science (MS), and Physics (Phy), as in Figure 1. This dataset enables the use of more advanced approaches such as neural network (NN) models. To that end, we cast the keyphrase extraction task as a sequence tagging problem, and build on recent progress in another information extraction task: Named Entity Recognition (NER) (Lample et al., 2016; Peng and Dredze, 2015). Like named entities, keyphrases can be identified by their linguistic context, e.g. researchers ”use” methods. In addition, keyphrases can be associated with different categories in different contexts. For example, ‘semantic parsing’ can be labeled as a TASK in one article and as a PROCESS in another. Scientific keyphrases differ in that they can include both noun phrases and verb phrases and in that non-standard “words” (equations, chemical compounds, references) can provide important cues.

Since the scale of the data is still small for supervised training of neural systems, we introduce semi-supervised methods to the neural tagging

model in order to take advantage of the large quantity of unlabeled scientific articles. This is particularly important because of the differences in keyphrases across domains. Our semi-supervised learning algorithm uses a graph-based label propagation scheme to estimate the posterior probabilities of unlabeled data. It additionally extends the training objective to leverage the confidence of the estimated posteriors. The new training treats low confidence tokens as missing labels and computes the sentence-level score by marginalizing over them.

Our experiments show that our neural tagging model achieves state-of-the-art results in the SemEval Science IE task. We further show that both inductive and transductive semi-supervised strategies significantly improve the performance. Finally, we provide in-depth analysis of domain differences as well as analysis of failure cases.

The key contributions of our work include: i) achieving state of the art in scientific information extraction SEMEVAL Task 10 by extending recent advances in neural tagging models; ii) introducing a semi-supervised learning algorithm that uses graph-based label propagation and confidence-aware data selection, iii) exploring different alternatives for taking advantage of large, multi-domain unannotated data including both unsupervised embedding initialization and semi-supervised model training.

2 Related Work

There has been growing interest in research on automatic methods to help researchers search and extract useful information from scientific literature. Past research has addressed citation sentiment (Athar and Teufel, 2012b,a), citation networks (Kas, 2011; Gabor et al., 2016; Sim et al., 2012; Do et al., 2013; Jaidka et al., 2014), summarization (Abu-Jbara and Radev, 2011) and some analysis of research community (Vogel and Jurafsky, 2012; Anderson et al., 2012; Luan et al., 2012, 2014b; Levow et al., 2014). However, due to scarce hand-annotated data resources, previous work on information extraction (IE) for scientific literature is very limited. Gupta and Manning (2011) first proposed a task that defines scientific terms for 474 abstracts from the ACL anthologhy (Bird et al., 2008) into three aspects: *domain*, *technique* and *focus* and apply template-based bootstrapping to tackle the problem. Based on this study, Tsai et al. (2013) improve the performance by introducing hand-designed features from NER (Collins and Singer, 1999) to the bootstrapping framework. QasemiZadeh and Schumann (2012) compile a dataset of scientific terms into 7 fine-grained categories for 171 abstracts of ACL anothology. Similar to our work, very recently Augenstein and Søgaard (2017) also evaluated on ScienceIE dataset, but use multi-task learning to improve the performance of a supervised neural approach. Instead, we introduce a semi-supervised neural tagging approach that leverages unlabeled data.

Neural tagging models have been recently introduced to tagging problems such as NER. For example, Collobert et al. (2011) use a CNN over a sequence of word embeddings and apply a CRF layer on top. Huang et al. (2015) use hand-crafted features with LSTMs to improve performance. There is currently great interest in using character-based embeddings in neural models. (Chiu and Nichols, 2016; Lample et al., 2016; Ballesteros et al., 2015; Ma and Hovy, 2016). Our approach also takes advantage of neural tagging models and character-based embeddings for IE in scientific articles.

Previous work on semi-supervised learning for neural models has mainly focused on transfer learning (Dai and Le, 2015; Luan et al., 2014a; Harsham et al., 2015) or initializing the model with pre-trained word embeddings (Mikolov et al., 2013; Pennington et al., 2014; Levy and Goldberg, 2014; Luan et al., 2016b, 2015, 2016a). In our work, we use pre-training but also use more powerful methods including graph-based semi-supervision (Subramanya and Bilmes, 2011; Liu and Kirchhoff, 2013, 2015, 2016a,b) and a method for leveraging partially labeled data (Kim et al., 2015). We show that the combination of these techniques gives better results than any one alone.

3 Problem Definition and Data

The purpose of this work is to extract phrases that can answer questions that researchers usually face when reading a paper: What TASK has the paper addressed? What PROCESS or method has the paper used or compared to? What MATERIALS has the paper utilized in experiments? While these fundamental concepts are important in a wide variety of scientific disciplines, the terms that are used in specific disciplines can be substantially different. For example, MATERIALS in computer science might be a text corpus, while they would be physical materials in physics or materials science.

Data We use the SemEval 2017 Task 10 ScienceIE dataset. Fig. 1 provides examples that illustrate the variation in domains, but also show that there are common cues such as "the task of", "using", "technique," etc. A challenge with this dataset is that the size of the training data is very small. It is built from ScienceDirect open access publications and consists of 500 journal articles, but only one paragraph of each article is manually labeled. Therefore, we use a large amount of external data to leverage the continuous-space representation of language in neural network model. We explore the effect of pre-training word embedding with two different external resources: i) a data set of Wikipedia articles as a general English resource, and ii) a data set of 50k Computer Science papers from ACM.[2]

Tagging Problem Formulation The task requires detecting the exact span of a keyphrase. In order to be able to distinguish spans of two consecutive keyphrases of the same type, we assign labels to every word in a sentence, indicating position in the phrase and the type of phrase. We formulate the problem as an IOBES (Inside, Outside, Beginning, End and Singleton) tagging problem where every token is labeled either as: B, if it is at the beginning of a keyphrase; E, if it ends the phrase; I, if it is inside a keyphrase but not the first or last token; S, if it is a single-word keyphrase; or O, otherwise. For example, "named entity recognition" in first sentence of Fig. 1 is labeled as "*B-Task I-task E-task*".

4 Neural Architecture Model

We introduce an end-to-end model to categorize scientific keyphrases, building on a neural named entity recognition model (Lample et al., 2016) and adding a feature-based embedding.

4.1 Model

We develop a 3-layer hierarchical neural model to tag tokens of the documents (details of the tokenization is in Sec. 6). (1) The token representation layer concatenates three components for each token: a bi-directional character-based embedding, a word embedding, and an embedding associated with orthographic and part-of-speech features. (2) The token LSTM layer uses a bidirectional LSTM to incorporate contextual cues from surrounding tokens to derive intermediate token embeddings. (3) The CRF tagging layer models token-level tagging decisions jointly using a CRF objective function to incorporate dependencies between tags.

Character-Based Embedding. The embedding for a token is derived from its characters as the concatenation of forward and backward representations from a bidirectional LSTM. The character lookup table is initialized at random. The advantage of building a character-based embedding layer is that it can handle out-of-vocabulary words and equations, which are frequent in this data, all of which are mapped to "UNK" tokens in the Word Embedding Layer.

Word Embedding. Words from a fixed vocabulary (plus the unknown word token) are mapped to a vector space, initialized using Word2vec pretraining with different combinations of corpora.

Feature Embedding. We map features to a vector space: capitalization (all capital, first capital, all lower, any capital but first letter) and Part-of-Speech tags.[3] We randomly initialize feature vectors and train them together as other parameters.

Token LSTM Layer We apply a bidirectional LSTM at the token level taking the concatenated character-word-feature embedding as input. The token representation obtained by stacking the forward and backward LSTM hidden states is passed as input to a linear layer that project the dimension to the size of label type space and is used as input to CRF layer.

CRF Layer Keyphrase categorization is a task where there is strong dependencies across output labels (e.g., I-TASK cannot follow B-Process). Therefore, instead of making independent tagging decisions for each output, we model them jointly using conditional random field (Lafferty et al., 2001). For an input sentence $\boldsymbol{x} = (x_1, x_2, x_3, \ldots, x_n)$, we consider P to be the matrix of scores output by the bidirectional LSTM network. P is of size $n \times m$, where n is the number of tokens in a sentence, and m is the number of distinct tags. $P_{t,i}$ corresponds to the score of

[2] Due to the difficulty of data collection, experiments with external data from the other two domains is left to future work.

[3] Dependency features were investigated but did not lead to performance gains.

the i-th tag of the t-th word in a sentence. We use a first-order Markov Model and define a transition matrix $\boldsymbol{T}$ where $\boldsymbol{T}_{i,j}$ represents the score from tag i to tag j. We also add y_0 and y_n as the *start* and *end* tags of a sentence. Therefore $\boldsymbol{T}$ becomes a square matrix of dimension $m + 2$.

Given one possible output $\boldsymbol{y}$, and neural network parameters θ we define the score as

$$\phi(\boldsymbol{y}; \boldsymbol{x}, \theta) = \sum_{t=0}^{n} T_{y_t, y_{t+1}} + \sum_{t=1}^{n} P_{t, y_t} \tag{1}$$

The probability of sequence $\boldsymbol{y}$ is obtained by applying a softmax over all possible tag sequences

$$p_\theta(\boldsymbol{y}|\boldsymbol{x}) = \frac{\exp(\phi(\boldsymbol{y}; \boldsymbol{x}, \theta))}{\sum_{\boldsymbol{y}' \in Y} \exp(\phi(\boldsymbol{y}'; \boldsymbol{x}, \theta))} \tag{2}$$

where Y denotes all possible tag sequences. The normalization term is efficiently computed using the forward algorithm.

Supervised Training During training, we maximize the log-probability $\mathcal{L}(\boldsymbol{Y}; \boldsymbol{X}, \theta)$ of the correct tag sequence given the corpus $\{\boldsymbol{X}, \boldsymbol{Y}\}$. Backpropagation is done based on a gradient computed using sentence-level scores.

5 Semi-supervised Learning

We develop a semi-supervised algorithm that extends self-training by estimating the labels of unlabeled data and then using those labels for retraining. Specifically, we use a graph-based algorithm to estimate the posterior probabilities of unlabeled data and develop a new CRF training to take the uncertainty of the estimated labels into account while optimizing the objective function.

5.1 Graph-based Posterior Estimates

Our semi-supervised algorithm uses the following steps to estimate the posterior. It first constructs a graph of tokens based on their semantic similarity, then uses the CRF marginal as a regularization term to do label propagation on the graph. The smoothed posterior is then used to either interpolate with the CRF marginal or as an additional feature to the neural network.

Graph Construction Vertices in the graph correspond to tokens, and edges are distance between token features which capture semantic similarity. The total size of the graph is equal to the number of tokens in both labeled data V_l and unlabeled data V_u. The tokens are modelled with a concatenation of pre-trained word embeddings (with dimension d) of 5-gram centered by the current token, the word embedding of the closest verb, and a set of discrete features including part-of-speech tags and capitalization (43 and 4 dimension one-hot features). The resulting feature vector with dimension of $5d + d + 43 + 4$ is then projected down to 100 dimensions using PCA. We define the weight w_{uv} of the edge between nodes u and v as follows: $w_{uv} = d_e(u, v)$ if $v \in \mathcal{K}(u)$ or $u \in \mathcal{K}(v)$, where $\mathcal{K}(u)$ is the set of k-nearest neighbors of u and $d_e(u, v)$ is the Euclidean distance between any two nodes u and v in the graph. An example of our graph is in Fig. 2.

For every node i in the graph, we compute the marginal probabilities $\{\boldsymbol{q}_i\}$ using the forward-backward algorithm. Let θ^i represent the estimate of the CRF parameters after the n-th iteration, we compute the marginal probabilities $\tilde{\boldsymbol{p}}_{(j,t)} = p(y_t^j | \boldsymbol{x}; \theta^i)$ over IOBES tags for every token position t in sentence j in labeled and unlabeled data.

Label Propagation We use prior-regularized measure propagation (Liu and Kirchhoff, 2014; Subramanya and Bilmes, 2011) to propagate labels from the annotated data to their neighbors in the graph. The algorithm aims for the label distribution between neighboring nodes to be as similar to each other as possible by optimizing an objective function that minimizes the Kullback-Leibler distances between: i) the empirical distribution $\boldsymbol{r}_u$ of labeled data and the predicted label distribution $\boldsymbol{q}_u$ for all labeled nodes in the graph; ii) the distributions $\boldsymbol{q}_u$ and $\boldsymbol{q}_v$ for all nodes u in the graph and their neighbors v; iii) the distributions $\boldsymbol{q}_u$ and the CRF marginals $\tilde{\boldsymbol{p}}_u$ for all nodes. The third term regularizes the predicted distribution toward the

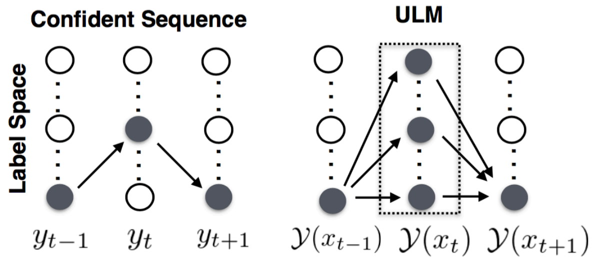

Figure 3: Lattice representation of ULM. Dashed box is the uncertain token which is going to be marginalized over. Arrows and grey nodes are paths to be summed over during training. When all tokens are confident, the score of only one path is calculated.

CRF prediction if the node is not connected to a labeled vertex, ensuring the algorithm performs at least as well as standard self-training.

Posterior Estimates We develop two strategies to estimate the new posteriors $\hat{p}(y_t|\boldsymbol{x};\theta)$, which can then be used in the CRF training.

The first strategy (called GRAPHINTERP) is the commonly used approach (Subramanya et al., 2010; Aliannejadi et al., 2014) that interpolates the smoothed posterior $\{\boldsymbol{q}\}$ with CRF marginals p:

$$\hat{p}(y_t|\boldsymbol{x};\theta) = \alpha p(y_t|\boldsymbol{x};\theta) + (1-\alpha)q(y) \qquad (3)$$

where α is a mixing coefficient.

A second strategy introduced here (called GRAPHFEAT) uses the smoothed posterior $\{\boldsymbol{q}\}$ as features and learns it with other parameters in the neural network. Given a sentence $\{x_1, \ldots, x_n\}$, let $Q = \{\boldsymbol{q}_1, \ldots, \boldsymbol{q}_n\}$ be the predicted label distribution from the graph. We then use Q as a feature input to neural network as $\tilde{P} = P + MQ$ where P is the $n \times m$ matrix output by the bidirectional LSTM network as in Eq. 1, and M is $m \times m$ matrix and is learned together with other parameters of neural network. We modify Eq. 1 by replacing P_{t,y_t} with $\tilde{P}_{t,y_t}$. Note that GRAPHFEAT can only be done in a transductive way since it requires output Q from the graph at test time.

5.2 CRF training with Uncertain Labels

A standard approach to self-training is to make hard decisions for labeling tokens based on the estimated posteriors and retrain the model. However, the estimated posteriors in our task are noisy due to the difficulty and variety of the ScienceIE task. Instead, we extend the CRF training to leverage the confidence of the estimated posteriors. The new CRF training (called Uncertain Label Marginalizing (ULM)) treats low confidence tokens as missing labels and computes the sentence-level score by marginalizing over them. A similar idea has been previously used in treating partially labeled data (Kim et al., 2015).

Specifically, given a sentence $\boldsymbol{x}$ we define a constrained *lattice* $\mathcal{Y}(\boldsymbol{x})$, where at each position t the allowed label types $\mathcal{Y}(x_t)$ are:

$$\mathcal{Y}(x_t) = \begin{cases} \{y_t\}, & \text{if} \quad p(y_t|\boldsymbol{x};\theta) > \eta \\ \text{All label types}, & \text{otherwise} \end{cases} \qquad (4)$$

where η is the confidence threshold, y_t is the prediction of posterior decoding and $p(y_t|\boldsymbol{x};\theta)$ is its CRF token marginal. The new neural network parameters θ are estimated by maximizing the log-likelihood of $p_\theta(\mathcal{Y}(\boldsymbol{x}^k)|\boldsymbol{x}^k)$ for every input sentence $\boldsymbol{x}^k$, where

$$p_\theta(\mathcal{Y}(\boldsymbol{x}^k)|\boldsymbol{x}^k) = \frac{\sum_{\boldsymbol{y}^k \in \mathcal{Y}(\boldsymbol{x}^k)} \exp(\phi(\boldsymbol{y}^k; \boldsymbol{x}^k, \theta))}{\sum_{\boldsymbol{y}' \in Y} \exp(\phi(\boldsymbol{y}'; \boldsymbol{x}, \theta))}$$

where $\boldsymbol{y}^k$ is an instance sequence of lattice $\mathcal{Y}(\boldsymbol{x})$, and k is the sentence index in the training set. Extreme cases are when all tokens are uncertain then the likelihood would be equal to 1, when all tokens of a sequence are confident, it would be equal to Eq. 2 where only one possible sequence, as in Fig. 3.

Inductive and Transductive Learning The semi-supervised training process is summarized as follow: It first computes marginals over the unlabeled data given a set of CRF parameters. It then uses the marginals as a regularization term for label propagation. The smoothed posteriors from the graph are then interpolated with the CRF marginal in GRAPHINTERP or used as an additional feature in GRAPHFEAT. It then uses the estimated labels for the unlabeled data combined with the labeled data to retrain the CRF using either the hard decision CRF training objective as Eq. 2 or the ULM data selection objective.

In the inductive setting, we only use the unlabeled data from the development set for the semi-supervision. In the transductive setting we also use the unlabeled data of the test set to construct the graph. In both cases, the parameters are tuned only on the dev set.

6 Experimental Setup

Data The SemEval ScienceIE (SE) corpus consists of 500 journal articles; one paragraph of each

article is randomly selected and annotated. The complete unlabeled articles and their metadata are provided together with the labeled data. The training data consists of 350 documents; 50 are kept for development and 100 for testing. The 500 articles come from 82 different journals evenly distributed in three domains. We manually labeled 82 journal names in the dataset into the three domains and do analysis based on the domain partitions. The 500 full articles contains 2M words and is 30 times the size of the annotated data.

Additionally, we use two external resources for pretraining word embeddings: i) WIKI, as for Wikipedia articles, specifically a full Wikipedia dump from 2012 containing 46M words, and ii) ACM, a collection of CS papers, containing 108M words.

Comparisons We compare our system with two template matching baselines and the state-of-the-art on the SemEval Science IE task. The first baseline (Gupta and Manning, 2011) is an unsupervised method to extract keyphrases by initially using seed patterns in a dependency tree, and then adding to seed patterns through bootstrapping. The second baseline (Tsai et al., 2013) improves the work of Gupta and Manning (2011) by adding Named Entity Features and use different set of seed patterns.

Implementation details All parameters are tuned on the dev set performance, the best parameters are selected and fixed for model switching and semi-supervised systems. The word embedding dimension is 250; the token-level hidden dimension is 100; the character-level hidden dimension is 25; and the optimization algorithm is SGD with a learning rate of 0.05. For building the graph, the best pre-trained embeddings for the supervised system (Sec. 7.2) are used in each domain. Two special tokens *BOS* and *EOS* are added when pre-training, indicating the begin and end of a sentence. The number of the graph vertices is 2M in tranductive setting and 1.4M in inductive setting. The ULM parameter η in Eq. 4 is tuned from 0.1 to 0.9, the best η is 0.4. The best parameters of label propagation are $\mu = 10^{-6}$ and $\nu = 10^{-5}$. The interpolation parameter α in Eq. 3 is tuned from 0.1 to 0.9, the best α is 0.3. We do iteration of semi-supervised learning until we obtain the best result on the dev set, which is mostly achieved in the second round.

We use Stanford CoreNLP (Manning et al., 2014) tokenizer to tokenize words. The tokenizer is augmented with a few hand-designed rules to handle equations (e.g. “fs(B,t)=Spel(t)S” is a single token) and other non-standard word phenomena (Cu40Zn, 20MW/m2) in scientific literature. We use Approximate Nearest Neighbor Searching (ANN)[4] to calculate the k-nearest neighbors. For all experiments in this paper, $k = 10$.

Setup We evaluate our system in both inductive and transductive settings. The systems with a * superscript in the table are transductive. The inductive setting uses 400 full articles in ScienceIE training and dev sets, while the transductive setting uses 500 full articles including the test set. In both settings parameters are tuned over the dev set.

7 Experimental Results

We evaluate our NN-CRF model in both supervised and semi-supervised settings. We also perform ablations and try different variants to best understand our model.

7.1 Best Case System Performance

Table 1 reports the results of our neural sequence tagging model NN-CRF in both supervised and semi-supervised learning (ULM and graph-based), and compares them with the baselines and the state-of-the-art (best SemEval System (Augenstein et al., 2017)).

Augenstein and Søgaard (2017) use a multi-task learning strategy to improve the performance of supervised keyphrase classification, but they only report dev set performance on SemEval Task 10, we also include their result here and refer it as MULTITASK. We report results for both span identification (SemEval SubTask A) and span classification into TASK, PROCESS and MATERIAL (SemEval Subtask B).[5]

The results show that our neural sequence tagging models significantly outperforms the state of the art and both baselines. It confirms that our neural tagging model outperforms other non-neural and neural models for the SemEval ScienceIE challenge[6]. It further shows that our system achieves significant boost from semi-supervised learning using unlabeled data. Table 5 shows the detailed analysis of the system across different categories.

7.2 Supervised Learning

Impact of Neural Model Components Table 2 provides the results of an ablation study on the dev set showing the impact of different components of our NN-CRF on the Scientific IE task. For the basic model, the word embeddings are initialized by word2vec trained on the 350 full journal articles in the SE training set together with Wikipedia and ScienceIE data. The feature layer, character layer, and bi-LSTM word layers all improves the performance. Moreover, we observe a large improvement (20.6% relative) in the scientific IE task by adding the CRF layer.

Initialization Table 3 reports our NN-CRF performance when pretrained on different domains. We explore different word embedding pretraining with ScienceIE training set alone (SE), and adding other external resources including Wikipedia (wiki) and Computer Science articles (ACM). All alternatives use word2vec. Compared with using SE alone, introduction of all external data sources improve performance. Moreover, we observe that with the introduction of the ACM dataset, the performance on the CS domain is increased significantly in both the dev and test sets. Adding Wikipedia data benefits all three domains, with more significant improvement on the MS and Physics domains.

	Dev			Test		
Initialization	MS	Phy	CS	MS	Phy	CS
SE	49.4	39.4	45.0	42.9	33.0	30.5
+wiki	**52.9**	**40.5**	47.9	**46.1**	**39.2**	31.0
+ACM	50.3	39.8	**49.5**	42.2	37.8	34.2
+wiki+ACM	50.5	40.3	48.9	43.1	37.9	**34.4**

Table 3: F1 score on the dev and test sets for using different sources of data for pretraining.

Based on these observations, we select the best model on each domain according to the dev set and use the combined result as our best supervised system (called NN-CRF(supervised)). The F1 score improves from 39.4 to 40.2 when applying model switching strategy. The best model on the dev set is used for each domain: for MS and physics domain, we pretrain word embeddings with the SE and Wiki, and for the CS domain, we pretrain with the SE and ACM.

7.3 Semi-Supervision Learning

Table 4 reports the results of the semi-supervised learning algorithms in different settings. In particular we ablate incorporating the graph-based methods of computing the posterior and CRF training (ULM vs. hard decision). The table shows incorporating graph-based methods for computing posterior and ULM for CRF training outperforms their counterparts.

For computing the posterior, we explore two different strategies of the graph-based methods: i) GRAPHINTERP that interpolates the smoothed posterior from label propagation with CRF marginals; For inductive setting, GRAPHINTERP only uses un-annotated data from the dev set and uses the best model for decoding at test time. For transductive setting, GRAPHINTERP* uses unannoated data from test set to build the graph as

[5] The evaluation script is provided by the challenge, with a modification to report 3 decimal precision results.

[6] Best SemEval Numbers from https://scienceie.github.io/

Posterior	Training	Dev	Test
-	-	50.2	42.9
-	ULM	51.3	44.4
GraphInterp	-	50.9	43.3
GraphInterp	ULM	**51.9**	**45.3**
GraphInterp*	-	50.7	44.0
GraphInterp*	ULM	51.8	45.7
GraphFeat*	-	51.4	44.9
GraphFeat*	ULM	**52.1**	**46.6**

Table 4: F1 scores of semi-supervised Learning approaches; * shows transductive models.

Span Level	T	P	M	K
Best SemEval	19	44	48	55
supervised	13.3	40.5	43.7	52.1
ULM+GraphInterp	17.0	45.4	49.4	56.9
ULM+GraphFeat*	17.2	46.5	50.7	57.6
Token Level	T	P	M	K
supervised	29.6	56.0	59.3	70.8
ULM+GraphInterp	40.0	60.7	61.2	77.0
ULM+GraphFeat*	40.1	62.8	63.4	78.1

Table 5: F1 score results on the test set for different categories: T indicates Task, P indicates Process, M is Material and K is Keyword identification (SubTask A). * is transductive model.

well, and tune the parameters on the dev set. ii) GraphFeat uses the smoothed posterior from label propagation as additional feature to neural network and only has transductive setting.

As expected, the transductive approaches consistently outperform inductive approaches on the test set. With around the same performance on dev set, GraphInterp* seems to generalize better on test set with 1.6% relative improvement over GraphInterp. We observe higher improvement with GraphFeat* compared to GraphInterp. This is mainly because automatically learning the weight matrix M between neural network scores and graph outputs adds more flexibility compared to tuning an interpolation weight α. The performance is further improved by applying data selection through modifying the objective to ULM. The best inductive system is ULM+GraphInterp with 5.6% relative improvement over pure Self-Training that makes hard decisions, and the best transductive system is ULM+GraphFeat* with 8.6% relative improvement.

7.4 Category and Span Analysis

Table 5 details the performance of our method on the three categories at the span and token level. We observe significant improvement by using ULM+GraphInterp and ULM+GraphFeat over best SemEval and our best supervised system on all three categories at both token and span levels. We further observe that systems' performance on Task classification is much lower than Process and Material. This is in part because Task is much less frequent than the other types. In addition, Task keyphrases often include verb phrases while the other two domains mainly consists of noun phrases. An analysis of confusion patterns show that the most frequent type confusions are between Process and Material. However, we observe that ULM+GraphFeat* can greatly reduce the confusion, with 3.5% relative improvement of Process and 3.6% relative improvement of Process over ULM+GraphInterp on token level.

7.5 Error Analysis

We provide examples of typical errors that our system makes in Table 6. As described in the previous subsection, Task is the hardest type to identify with our system. Row 1 shows a failure to detect the verb phrase following 'to' as part of the Task, but detect 'enantiopure products' as Material. The system prefers to predict Process or Material since those classes have more samples than Task. Row 2 illustrates the problem of identifying general terms as keyphrases due to similar context, such as 'receptors' and 'drug action'. A third common error involves incorrectly labeling adjectives, such as 'neighbouring' in Row 3, which leads to span errors. Another common cause of error is insufficient context: in the last example, a larger context is needed to determine whether 'SWE' is a Process or Material.

8 Conclusion

This paper casts the scientific information extraction task as a sequence tagging problem and introduces a hierarchical LSTM-CRF neural tagging model for this task, building on recent results in NER. We introduced a semi-supervised learning algorithm that incorporates graph-based label propagation and confidence-aware data selection. We show the introduction of semi-supervision significantly outperforms the performance of the supervised LSTM-CRF tagging model. We additionally show that external resources are useful for initializing word embeddings. Both inductive and transductive semi-supervised strategies

Error types	Annotation and System Output
Verb phrases	A key requirement in aiming to [achieve [enantiopure products]$_{\text{Material}}$]$_{\text{Task}}$ is therefore a means to [quantitate [the enantiometric excess]$_{\text{Process}}$]$_{\text{Task}}$.
General terms	Since the [receptors]$_{\text{Material}}$ in human biology mostly consist of [chiral molecules]$_{\text{Material}}$, [drug action]$_{\text{Process}}$ mostly involves a specified enantiometric form.
Falsely predicted adjectives	It has been shown that the most efficient forms of energy transfer between the two occurs when there is a [neighbouring carotenoid species]$_{\text{Material}}$.
Lack of context	Other models use [SWEs]$^{\text{Material}}_{\text{Process}}$ but focus on the use of multi resolution grids or irregular mesh.

Table 6: Common errors, where blue means golden label our system misses, red means falsely predicted results, and green means correctly predicted spans.

achieve state-of-the-art performance in SemEval 2017 ScienceIE task. We also conducted a detailed analysis of the system and point out common error cases.

In our experiments, we observe that including in-domain data only for semi-supervised learning has slightly better performance than using cross-domain data. Reducing the amount of in-domain data hurts performance. Therefore, adding more in-domain unlabeled data may help when combined with selection schemes such as the ULM algorithms proposed here. It would be useful to assess the impact of matched unlabeled data for the physics and material science domain. Other future work includes leveraging global context, information of citation network.

NITE: A Neural Inductive Teaching Framework for Domain-Specific NER

Siliang Tang, Ning Zhang, Jinjian Zhang, Fei Wu and **Yueting Zhuang**
College of Computer Science, Zhejiang University, China
{siliang, aning, jibjianzhang, wufei, yzhuang}@zju.edu.cn

Abstract

In domain-specific NER, due to insufficient labeled training data, deep models usually fail to behave normally. In this paper, we proposed a novel Neural Inductive TEaching framework (NITE) to transfer knowledge from existing domain-specific NER models into an arbitrary deep neural network in a teacher-student training manner. NITE is a general framework that builds upon transfer learning and multiple instance learning, which collaboratively not only transfers knowledge to a deep student network but also reduces the noise from teachers. NITE can help deep learning methods to effectively utilize existing resources (i.e., models, labeled and unlabeled data) in a small domain. The experiment resulted on Disease NER proved that without using any labeled data, NITE can significantly boost the performance of a CNN-bidirectional LSTM-CRF NER neural network nearly over 30% in terms of F1-score.

1 Introduction

Domain-specific Named Entity Recognition (DNER), which aims to identify domain specific entity mentions and their categories, plays an important role in domain document classification, retrieval and content analysis. It is also a foundation for further level of complex information extraction tasks, serves as cornerstone in the knowledge computing process of transforming data into machine readable knowledge (Zhuang et al., 2017). Domain-specific NER is a challenging problem. For example, in biomedical domain, the number of unseen biomedical entity mentions (such as disease names, chemical names), their abbreviations or acronyms, as well as multiple names of the same entity is growing fast with the rapid increase of biomedical literatures and clinical records. However, the performance of a learning based NER system relies heavily on data annotation, which is quite expensive. The situation is even worse in domain-specific NER systems, since their data annotation requires the engage of domain experts. Therefore, in many special domains, only trained models or APIs are available, while their training data are private and inaccessible. On the other hand, due to insufficient labeled training data, deep models usually fail to behave normally in such domain, and state-of-the-art methods in these domains are usually dominated by rule based deductive methods or shallow model with hand-crafted features. However, the way of pre-defining useful domain specific hand-crafted features or rules are usually unavailable to the public.

In this paper, we proposed a novel Neural Inductive TEaching framework (NITE) to transfer knowledge from existing models into an arbitrary deep neural network. The idea of NITE is mainly borrowed from Transfer learning (Pan and Yang, 2010) where previously learned knowledge can aid current situation and solve problems with better solutions. In NITE, existing NER models behave like inefficient teachers to teach a deep neural network (we called student network) to identify named entities by giving it concrete examples. The knowledge transferred from these models is their posterior distributions on unlabeled data. These teachers are inefficient because they transfer not only useful information, but also errors to the student. The inputs of student network can be twofold, one is a small proportion from human labeled ground truth data (optional, like text book), and another is a large proportion from teachers, which is always noisy and less trustable.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2652–2657
Copenhagen, Denmark, September 7–11, 2017.

In such case, a student is overwhelmed and often inferior to the teachers, therefore in NITE, we introduced Multiple Instance Learning (MIL) trick (Dietterich et al., 1997; Babenko, 2008) to reduce the input noise during the model training.

In summary, NITE is a general framework that can help deep learning methods to make the best use of existing resources (i.e., models, labeled and unlabeled data). The experiment results on Disease NER (DNER) proved that without using any labeled data, NITE can significantly boost the performance of a CNN-bidirectional LSTM-CRF NER neural network (Ma and Hovy, 2016), which trained on NCBI training dataset nearly over 30% in terms of F1-score. It also outperformed the teacher model, which proved the correctness of our hypothesis.

2 Neural Inductive Teaching Framework

In this section we will define our NITE framework step by step, and apply it to Disease NER.

2.1 Inductive Teaching

Inductive teaching means teaching student by examples, our inductive teaching method builds upon teacher-student models (Ba and Caruana, 2014) and knowledge distillation (Hinton et al., 2015). The main idea of our method is to transfer discriminative knowledge from well-trained existing models (teachers) to a new and more capable model (student). The student learns by imitating the teachers' behaviors, and the teaching process can be defined as follows:

Let $x = \{w_1, w_2, \ldots, w_{|x|}\}$ be an input sentence of $|x|$ words, where w_k is the kth word in x. If l_k is the corresponding 3-dimensional one hot IOB (In-Out-Begin) vector for w_k, then the NER labeling sequence of x can be defined as $y = \{l_1, l_2, \ldots, l_{|x|}\}$.

For a given sentence x_i, we further define the posterior distribution of a teacher as $y_i^{f_t} = f_t(y_i|x_i)$, while the posterior distribution of a student network can be defined as $y_i^{f_s} = f_s(y_i|x_i;\theta)$, where θ is the parameters of the student network. During training, we measure the similarity between y^{f_t} and y^{f_s} with KL-divergence, and minimize their difference. Therefore, for a given x_i, we optimize:

$$\min_{\theta} \sum_{i=1}^{n} D_{KL}(f_t(y_i|x_i)||f_s(y_i|x_i;\theta)) \quad (1)$$

, where $D_{KL}(P||Q) = \sum_j P_j \log \frac{P_j}{Q_j}$ is the KL-divergence. This equation can be optimized through stochastic gradient descent over shuffled mini-batches with the Adadelta (Zeiler, 2012) update rule.

2.2 Multiple Instance Learning

Multiple Instance Learning is an effective training method that can help to train a supervised model to alleviate the wrong label problem (Riedel et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012). Instead of predicting labels for each individual training sample, the objective of MIL is to predict the labels (positive or negative) of the unseen bags, where each bag contains a fixed number of instances (samples). The standard MIL assumption assumes that a bag is positively labeled if at least one instance in a bag is positive, and is negatively labeled if all instances in a bag are negative. MIL is generally used in training a binary classifier, to apply MIL in NITE, we redefine the label of a bag as the quality (correctness) of its containing samples. Thus, in NITE, a bag is positively labeled if at least one instance in it is labeled correctly. Furthermore, it is inappropriate to evaluate the correctness of IOB label (i.e., l_k) of each word (i.e., w_k), since the IOB sequence y_i of a sentence x_i is generated dependently. Therefore, we choose sentence x_i as our MIL instance, and the correctness of x_i is evaluated by the likelihood probability of all words with correct BIO tags. In general, our MIL can be formally defined as follows:

Randomly allocate training samples in a mini-batch $\mathcal{B}$ into M bags, i.e., $\mathcal{B} = \{B_1, B_2, \ldots, B_M\}$ with their corresponding labels $\{z_1, z_2, \ldots, z_M\}$, where $z_m \in \{-1, 1\}$. For bag B_m, it contains K instances, i.e., $B_m = \{x_1, x_2, \ldots, x_K\}$, where x_i is a sentence with its posterior evaluation $y_i^{f_s}$.

During the training, given a bag B_m, if $z_m = 1$, which means B_m is a positive bag. In order to reduce the noise, our MIL learner will select the most correct instance $y_{i*}^{f_s}$, which has the maximum likelihood among all other instances (i.e., sentence) in the bag B_m. That is $P(z_m = 1|B_m) = P(y_{i*}^{f_s}) = \arg\max_i\{P(y_i^{f_s}|x_i)\}$, where $1 \leq i \leq K, x_i \in B_m$. If $z_m = -1$, which means B_m is a negative bag, in order to better detect such negative bags, our MIL learner should select the most violated instance for learning, which is also the instance with maximum likelihood. Thus, the bag label z (which indicates the sentence is labeled correctly or incorrectly) is actually integrated out, since no matter what the value z is, MIL in NITE will always select the instance with the highest likelihood probability. Finally the MIL in NITE can be summarized as:

$$P(z_m|B_m) = P(y_{i*}^{f_s}) = \arg\max_{i=1:K}\{P(y_i^{f_s}|x_i)\} \tag{2}$$

In summary, MIL in NITE can be regarded as a mechanism for posterior selection, or regularization on posterior distribution of a student network. Therefore, MIL only affects the model training, and it will not affect the testing process.

2.3 Teacher Model & Student Network

Theoretically, the teacher model of NITE can be any existing well-trained model, while the student network can be an arbitrary deep neural network. In this paper, we focus on domain-specific NER, and more specifically on Disease NER, which is a small but typical domain that is suffering from insufficient labeled training data.

There are many existing DNER systems, and the most well-known systems are BANNER (Leaman et al., 2008), and DNorm (Leaman et al., 2013). BANNER is an open-source biomedical NER system implemented using conditional random fields (CRFs) (Lafferty et al., 2001). While, DNorm uses supervised semantic indexing, is trained with pairwise learning to rank, to score the mentions returned by BANNER. Therefore, DNorm can be regarded as an extension of BANNER, and the whole system depends on handcrafted features such as word spelling features and orthographic features. DNorm is the state-of-the-art DNER system, and therefore we adopt DNorm as our teacher model.

For the student network, we are looking for state-of-the-art solutions in general NER. There are many studies on applying complex deep learning models on general NER or other sequence labeling tasks. Without any feature engineering trick, deep models have achieved comparable or better performances than many other traditional methods. More recently, Ma and Hovy (2016) proposed a method that concatenated CNN, bidirectional LSTM, and CRF successively to form an end to end deep NER model (CLC for short). CLC achieved state-of-the-art performance in general NER, and therefore we take the CLC as our student network, Fig. 1 shows the overall architecture of our student network.

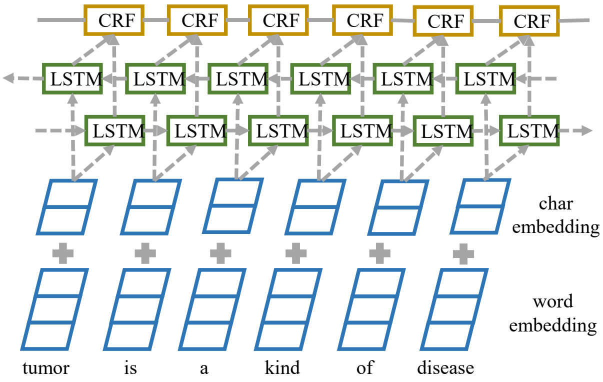

Figure 1: the Flowchart of the Student Network

As shown in Fig. 1, the character-level embeddings are generated by CNN layers, then are concatenated with pre-trained word embeddings, and finally fed into the bidirectional LSTM layer. The bidirectional LSTM is efficient to capture syntactic and semantic information both preceding and following simultaneously. Its output vectors are fed into the CRFs layer for IOB sequence labeling. It uses maximum conditional likelihood estimation to choose parameters during the finally CRFs training process, and its likelihood can be given as follows:

$$P(y_i^{f_s}|x_i) = \arg\max_{y\in\mathcal{Y}(x_i)} P(y|x_i) \tag{3}$$

, where $\mathcal{Y}(x_i)$ denotes the set of possible label sequences for x_i. Eq. 3 can be solved efficiently by adopting the Viterbi algorithm.

Fig. 2 shows the whole NITE-NER training process. For each training iteration, training samples in a mini-batch are randomly allocated into M bags, and then fed into the student network f_s. For bag B_m, the student network will generate posterior evaluation $y_i^{f_s}$ for each input instance $x_i \in B_m$ respectively. Then the MIL module will select the best sample $y_{i*}^{f_t}$ from all K instances according to Eq. 3 and 2. Finally, NITE will retrieve posterior evaluation $y_{i*}^{f_t}$ from the teacher, and update θ based on Eq. 1.

3 Experiments

In this section we designed several experiments to testify our hypothesis of inductive teaching as well as evaluate our NITE framework.

work is learned indirectly from the teacher models, therefore NITE can be trained without any labeled data.

To evaluate the efficiency of the NITE framework, we trained two DNER models on NCBI disease corpus (Doğan et al., 2014; Islamaj Dogan and Lu, 2012). One is the well-known DNorm model, which is the state-of-the-art method in disease NER. Another one is the bi-directional LSTM-CNN-CRF NER neural network i.e., CLC (Ma and Hovy, 2016), which has the state-of-the-art performance in general NER task. The CLC architecture also serves as our student network.

The NCBI disease corpus is a widely used data corpus with disease name and related concept annotations in biomedical research field. The corpus is an extension of the AZDC corpus (Leaman et al., 2009) which was annotated only with disease mentions. The detailed characteristics of the NCBI disease corpus as well as how we partition the data are shown in Table 1.

NCBI	Train	Validate	Test
# of documents	593	100	100
# of sentences	5661	791	961
# of disease	5148	791	961
Specific Disease	2959	409	556
Disease Class	781	127	121
Modifier	1292	218	264
Composite Mention	116	37	20

Table 1: The description of the NCBI corpus as training, validating and testing sets for the recognition of disease named entity

3.2 Experiment Setup

The experiment's setup is as follows:

Our NITE-DNER is trained without any labeled data, we randomly sampled 2,000 unlabeled abstracts of biomedical literature from PubMed as our training data. The DNorm model is served as the teacher model in the NITE framework.

In student network, we initialized character embeddings with uniform samples from $[-\sqrt{\frac{3}{d}}, +\sqrt{\frac{3}{d}}]$, where we set the dimension $d = 30$. We use 30 filters with window length 3 in CNN and 200 hidden states in bi-directional LSTM. In training procedure we set initial learning rate $\eta_0 = 0.015$ with decay rate $\rho = 0.05$, the learning rate is updated as $\eta_t = \eta_0/(1.0 + \rho n)$, where n is the number of epochs. We use a fixed dropout rate 0.5 at CNN and both input and output vectors of bi-directional LSTM to mitigate overfitting. For MIL we set the bag size $K = 5$ with mini-batch size 30. We implemented neural networks on a GeForce GTX 1080 using Theano.

3.3 Results and Discussion

We evaluated all three DNER methods on the NCBI test set in terms of precision, recall and F1-score. All the measurements are based on exact location of extracted disease mentions in the given test sentences.

Method	**CLC-DNER**	**DNorm**	**NITE**
Labels	NCBI	NCBI	-
Remark	Student only	Teacher only	S+T+MIL
Precision	79.20	80.50	85.40
Recall	51.73	75.70	75.07
F1-score	62.58	78.06	**79.91**

Table 2: Performance comparisons.

The experiment results are presented in Table 2. As shown in Table 2, although the complex CLC network is the state-of-the-art method in general NER, it behaves poorly in domain-specific NER task due to insufficient labeled training data. However, with the help of our NITE framework, its performance is significantly boosted, and reached the comparable level of DNorm. This proved that knowledge transfer in NITE is efficient and important in training a deep model of domain-specific NER.

3.4 Conclusion

In this paper, we proposed a general framework, NITE, and demonstrated its efficiency in transferring DNER knowledge into an end to end deep NER model. Although we only proposed a solution for DNER, it could be easily applied to other domain-specific NER problems (e.g., chemical, gene, and protein) or even applications other than NER. The experiment results suggested that NITE can be very helpful on training a deep model when other resources are available. For future work, a NITE architecture with more than one teacher could be considered. Moreover, as mentioned in (Zhou et al., 2017), crowd knowledge can be used to reshape deep learning features. Our framework can also incorporate crowd knowledge easily, in which the teachers can be human crowds, and then the NITE can employs active learning (Olsson, 2009) or lifelong machine learning (Chen and Liu, 2016) to progressively polishing the student model.

Abstract

RLIE-DQN is a recently proposed Reinforcement Learning-based Information Extraction (IE) technique which is able to incorporate external evidence during the extraction process. RLIE-DQN trains a single agent *sequentially*, training on one instance at a time. This results in significant training slowdown which is undesirable. We leverage recent advances in parallel RL training using asynchronous methods and propose RLIE-A3C. RLIE-A3C trains multiple agents in *parallel* and is able to achieve upto 6x training speedup over RLIE-DQN, while suffering no loss in average accuracy.

1 Introduction

Extracting information about an event (or entity) involves multiple decisions, as one first needs to identify documents relevant to the event, extract relevant information from those documents, and finally reconcile various values obtained for the same relation of the event from different sources (Ahn, 2006). Search based methods for Information Extraction have been increasingly investigated (West et al., 2014); (Hegde and Talukdar, 2015); (Zhang et al., 2016); (Bing et al., 2017).

(Kanani and McCallum, 2012) combine search and Information Extraction (IE) using Reinforcement Learning (RL), with the goal of selecting good actions while staying within resource constraints, but don't optimze for extraction accuracy. More recently, (Narasimhan et al., 2016) proposed a RL-based approach to model the IE process outlined above. We shall refer to this approach as RLIE-DQN in this paper. RLIE-DQN trains an RL agent using Deep Q-Network (DQN) (Mnih et al., 2015) to select optimal actions to query for documents and also reconcile extracted values.

DQN trains a single agent *sequentially*, updating parameters based on one instance at a time. Each such instance is sampled from the entire training data, also called the *experience replay*. Such sequential experience replay-based training results in slow learning, while requiring high memory and computation resources. In order to overcome this challenge, A3C (Asynchronous Advantage Actor-Critic), an asynchronous deep RL training algorithm, has been proposed recently (Mnih et al., 2016). A3C trains multiple RL agents in *parallel*, each of which estimates gradients locally, and asynchronously updates globally shared parameters. Recent work has explored applications for A3C in varied domains (Fernando et al., 2017), (Mirowski et al., 2016).

In this paper, we propose RLIE-A3C which uses A3C-based parallel asynchronous agents for training. This is in contrast to the sequential DQN training in RLIE-DQN. Differences between the training regimes of the two methods are shown in Figure 1. Through experiments on multiple real-world datasets, we find that RLIE-A3C achieves upto 6x training speedup compared to RLIE-DQN, while suffering no loss in accuracy. To the best of our knowledge, this is the first application of asynchronous deep RL methods in IE (and also in NLP), and we hope this paper will foster further adoption and research into such methods in the NLP community. RLIE-A3C code is available at https://github.com/adi-sharma/RLIE_A3C

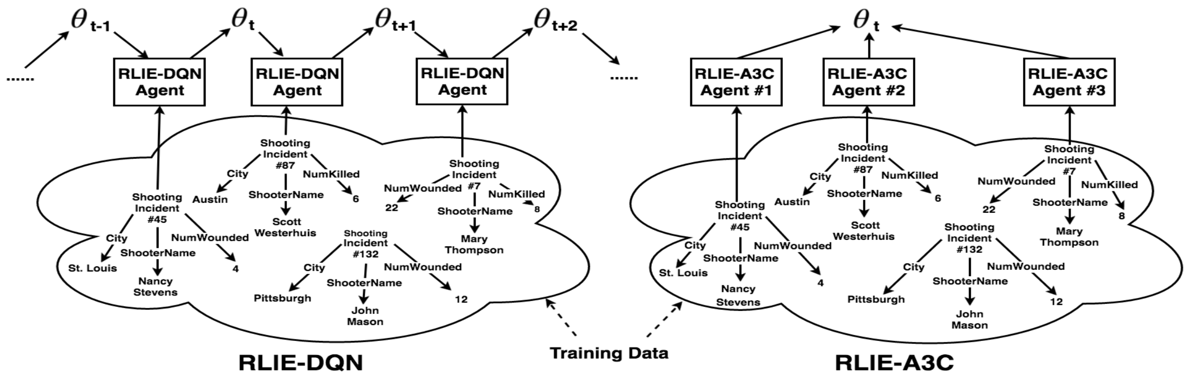

Figure 1: **Left:** DQN-based *sequential* learning framework used in RLIE-DQN (Narasimhan et al., 2016), as discussed in Section 2. At each time step, the agent looks at a specific instance from the training data. **Right:** A3C-based *parallel* learning framework in RLIE-A3C (proposed approach). The parallel agents look at different parts of the training data, estimate parameter update statistics locally, and then perform *asynchronous* updates on the globally shared parameters (θ_t) at time step t. See Section 3 for details. Due to the asynchronous parallel updates, RLIE-A3C achieves significant training speedup without loss in accuracy, as we shall see in Section 4.

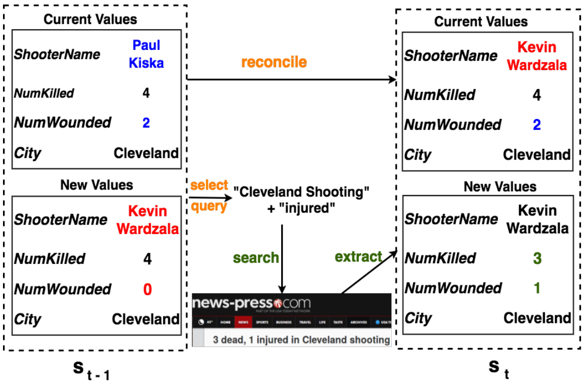

Figure 2: Sample state transition in the MDP of RLIE-DQN (and also RLIE-A3C). In each transition, two actions are carried out: (1) reconcile new values with current values,; and (2) issue query to retrieve other relevant documents and extract values from those documents. Please see Section 2 for details.

2 RLIE-DQN: Information Extraction using Reinforcement Learning

We first present a brief overview of RLIE-DQN (Narasimhan et al., 2016). Given a document to extract information about an event, RLIE-DQN issues a search query to retrieve other documents related to the event, extracts event information from those documents, and finally reconciles values extracted from the documents. If confidence in the extracted values are low, then RLIE-DQN repeats this process with additional queries. This way, RLIE-DQN incorporates evidences from external sources to improve information extraction (IE) from a given source document.

RLIE-DQN models the task as a Markov Decision Process (MDP) in order to reconcile newly extracted information selectively and dynamically. The MDP describes the environment in which the RL agent learns to make decisions. The MDP is represented using a tuple $\langle S, A, R, T\rangle$, where S is the set of states, $A = \{a_d, a_q\}$ is the set of actions, $R(s, a)$ is the reward for taking action $a \in A$ from state $s \in S$, and $T(s^{'}|s, (a_d, a_q))$ is the state transition function. Here, a_d is the reconciliation action, while a_q is the query action. Based on a_d, the agent may accept extracted values for one or all relations, reject all newly extracted values or stop (episode ends).

A sample state transition in RLIE-DQN's MDP is shown in Figure 2. State representation consists of many details such as confidence scores of current and newly extracted relation values, context statistics from which the extractions are performed, etc. But for better readability, only the set of current and new values are shown for the states in this figure. Each transition consists of two actions: reconcile decision and query. The RL agent uses the reconcile action (a_d) to update value of the *ShooterName* relation from *Paul Kiska* to *Kevin Wardzala*. The agent uses the query action (a_q) to issue a new query (*"Cleveland shooting"* + *"injured"*) to retrieve other relevant documents and extract new values 3 and 1 for relations *NumKilled* and *NumWounded*, respectively. The transitions stop whenever a_d is a stop decision.

The reward function at each state, is the cumulative difference of current and previous extracted accuracies, summed over all relations. Also, a negative reward per step is added to the reward in order to penalize the agent for longer episodes, since issuing queries to a search engine is expensive.

Deep Q-Learning (DQN): Let $Q(s, a)$ be the measure of long-term cumulative reward obtained by taking action a from state s. The RL agent makes use of $Q(s, a)$ to select the next action from a from state s. Q-learning (Watkins and Dayan, 1992) is a popular technique to estimate this function, in which the function for optimal Q-value is estimated using the Bellman equation (Sutton and Barto, 1998) $Q_{i+1}(s, a) = \mathbb{E}_{(s,a)}[R(s, a) + \gamma \max_{a'} Q_i(s', a')|s, a]$. Here, $R(s, a)$ is the immediate reward and γ is the discount factor for the value of future rewards.

For high dimensional state spaces, Deep Q-Network (DQN) (Mnih et al., 2013) approximates $Q(s, a)$ as $Q(s, a; \theta)$ using parameters θ of a deep network. RLIE-DQN used such a DQN-based agent to learn optimal policy, as shown in Figure 1.

3 Proposed Approach: RLIE-A3C

The DQN-based agent used in RLIE-DQN is sequential, as it moves from one instance to another to update parameters. This can result in significant training time slowdown, especially in large data settings. Instead of using experience replay of the DQN algorithm for stabilizing updates, we consider a framework with multiple asynchronous agents, each of which explore different areas of the environment in parallel.

Asynchronous Advantage Actor-critic (A3C) (Mnih et al., 2016) is a recently proposed deep RL algorithm which makes use of parallel agents for parameter estimation. We replace DQN with A3C in RLIE-DQN and call the resulting method RLIE-A3C – our proposed approach (See Figure 1).

At time instant t, RLIE-A3C poses decision policy $\pi_d(a_d|s_t)$, and query policy $\pi_q(a_q|s_t)$ as probability distributions over candidate actions a_d and a_q, respectively. RLIE-A3C also calculates the state value function $V(s_t)$, as an estimate of the cumulative long-term reward obtained starting from state s_t. Owing to the large continuous state space of the problem, RLIE-A3C approximates each of these three functions using three separate deep neural networks, which are parametrized by θ_d, θ_q, and θ_v, as $\pi_d(a_d|s_t) \approx \pi_d(a_d|s_t; \theta_d)$, $\pi_q(a_q|s_t) \approx \pi_q(a_q|s_t; \theta_d)$ and $V(s_t) \approx V(s_t; \theta_v)$. These parameters are updated by agents working in parallel. Based on the policies, each agent selects the query and decision actions to be performed and updates it's state accordingly. This is repeated up to t_{max} steps or until a terminal state is reached.

Local Gradient Calculation: The agents estimate parameter gradients using a local copy of the network parameters, and then perform *asynchronous* updates on the globally shared parameters θ_d, θ_q, and θ_v. Hence, the policy and value functions are jointly estimated. The policy gradient update equations calculated over the local copy of network parameters of each parallel RLIE-A3C agent p are as follows:

$$\begin{aligned} d\theta_x^p \leftarrow d\theta_x^p + \nabla_{\theta_x^p} \log \pi_d(a_{x_i}, s_;\theta_x^p) A(s_i, a_{x_t}; \theta_v^p) \\ + \beta_x \nabla_{\theta_x^p} H(\pi_x(s_t; \theta_x^p)) \end{aligned} \tag{1}$$

where, x $\in$ {d, q} for decision and query. The advantage function $A(s_t, a_t; \theta_v) = \sum_{i=0}^{k-1} \gamma^i R_{t+i} + \gamma^k V(s_{t+k}; \theta_v) - V(s_t; \theta_v)$ above significantly reduces the variance of the policy gradient, where γ is the discount factor and k can vary from state to state and is upper-bounded by t_{max}. Since the gradient updates are accumulated, training stability increases. Further, exploration is encouraged by introducing the entropy regularization term $\beta_x \nabla_{\theta_x^p} H(\pi_x(s_t; \theta_x^p))$ in the equation above. Here, H is the entropy function and β_x controls dominance of the entropy term.

The gradient update for the parameters of value function V is calculated locally by every parallel agent p as follows:

$$d\theta_v^p \leftarrow d\theta_v^p + \partial(G_t - V(s_t; \theta_v^p))^2 / \partial\theta_v^p$$

where $G_t = \mathbb{E}_{(s)}[\sum_{k=0}^{\infty} \gamma^k R_{t+k+1}]$ is the return.

Global Parameter Update: The parameters θ_d, θ_q and θ_v are learnt using stochastic gradient descent with RMSprop (Tieleman and Hinton, 2012). The standard non-centered RMSProp update is used by the parallel agents p to update the shared parameters asynchronously using the gradients obtained from Equation (1), as follows:

$$g = \alpha g + (1 - \alpha)(d\theta_x^p)^2 \;\; ; \;\; \theta_x \leftarrow \theta_x - \eta \frac{d\theta_x^p}{\sqrt{g + \epsilon}}$$

where x $\in$ {d, q, v}, α is the decay factor, η is the learning rate, ϵ is the smoothing constant and

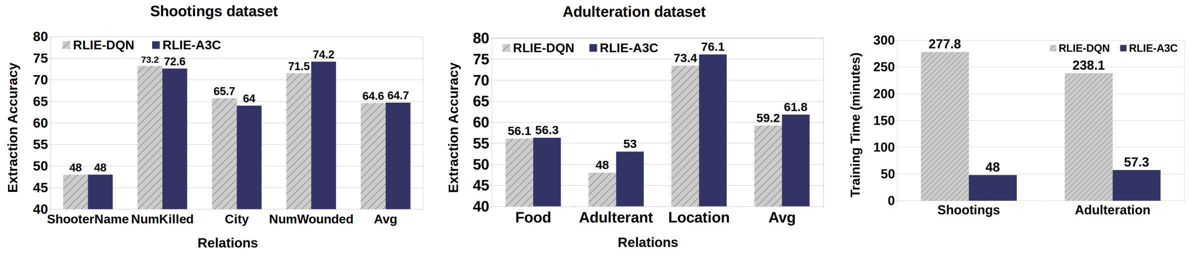

Figure 3: **Left, Middle Panels**: Extraction accuracy of the baseline (RLIE-DQN) and our system (RLIE-A3C) on the Shooting Incidents and Food Adulteration datasets. **Right Panel**: Training time comparison between RLIE-DQN and RLIE-A3C. Overall, we observe that RLIE-A3C results in upto 6x speedup over RLIE-DQN, without any loss in average extraction accuracy. This is our main result. Please see Section 4.1 for details.

g is the moving average of element-wise squared gradients. The pseudo-code for RLIE-A3C can be found in the Appendix.

4 Experiments and Results

Setup: We compare RLIE-A3C against RLIE-DQN using the same protocol and hyperparameters as reported in (Narasimhan et al., 2016). Also, we experiment with the same two datasets used in that paper: the Gun Violence Archive[1] and the Foodshield EMA database[2]. The train, dev and test datasets contain 372, 146 and 146 source articles respectively for the Shooting incident cases and 292, 42 and 148 source articles respectively for the food adulteration cases. We used the implementation of RLIE-DQN provided by the authors of that system. For more details on the dataset and other parameters, we refer the reader to (Narasimhan et al., 2016).

RLIE-A3C: This is our proposed method which is described in Section 3. For the sake of fair comparison, the network, base classifier, and evaluation metrics are same as that of RLIE-DQN. Each of the three deep networks in RLIE-A3C, one each for $\pi(a_d|s)$, $\pi(a_q|s)$ and $V(s)$, is built using two linear layers with 20 hidden units, followed by ReLUs. MaxEnt classifier is used as the base extractor, and the model is evaluated on the entire *test* set for 1.6 million steps. The *dev* set is used to tune all hyperparameters, which can be found in the Appendix. For RLIE-A3C, the evaluation is carried out 50 times after training and the average accuracy values are taken over the top 5 evaluations, as done in (Mnih et al., 2016).

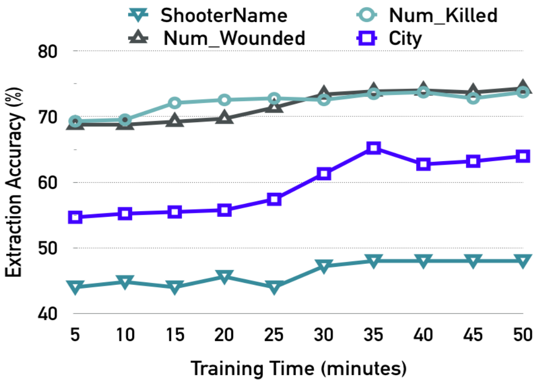

Figure 4: Evolution of accuracy of RLIE-A3C for the four relations on *test* set of the *Shooting Incidents* dataset. Please see Section 4.1 for details.

4.1 Results and Discussion

Extraction Accuracy: Experimental results comparing extraction accuracies of RLIE-DQN and RLIE-A3C are presented in Figure 3[3] (left and middle panels). From this figure, we observe that there is no loss in average accuracy in transitioning from RLIE-DQN to RLIE-A3C (in fact there is a slight gain in case of the Adulteration dataset). Please note that, improvement in accuracy is not our primary goal in the paper – it is the training time speedup, as discussed next.

Speedup: Training times of RLIE-DQN and RLIE-A3C over both datasets are compared in the right panel of Figure 3[4]. From Figure 3, we find that RLIE-A3C is able to achieve upto 6x training

[1] http://www.shootingtracker.com/Main_Page

[2] http://www.foodshield.org/member/login/

[3] The tolerance for all the relation accuracy values for RLIE-A3C is within ± 1%

[4] During test, policies learned by RLIE-DQN and RLIE-A3C are executed. Since this is an identical process for both, we don't compare test runtimes in this paper.

speedup over RLIE-DQN. In other words, RLIE-A3C is able to achieve significant speedup in training time over RLIE-DQN, without any loss in average accuracy. This is our main result.

While RLIE-DQN was implemented in Torch, RLIE-A3C was implemented in Python using TensorFlow framework. We note that Torch is known to be faster than TensorFlow (Bahrampour et al., 2015). This makes the speedup gains above even more impressive, and outlines the possibility that further gains may be possible with a Torch-based implementation of RLIE-A3C.

Figure 4 shows evolution of test accuracy of RLIE-A3C for the four relations of the *Shooting Incidents* dataset. For this dataset, state value function of RLIE-A3C converged at 48 minutes. However, from Figure 4, we observe that accuracies converge to the final values much before that.

Why do Asynchronous Methods work? An asynchronous approach fits more naturally with the training data, since different parallel agents look at different events at the same time (see Figure 1), and the model is able to exploit the regularities between events in the dataset. The gradient updates to the global network are less biased and the model is not easily distracted by noise in the data. The asynchronous parallel model is able to converge much faster as compared to replay memory based methods like DQN, as also seen in (Mnih et al., 2016).

5 Conclusion

In this paper, we proposed RLIE-A3C, an asynchronous deep Reinforcement Learning (RL) algorithm for Information Extraction (IE). In contrast to *sequential* training in previously proposed RLIE-DQN (Narasimhan et al., 2016), RLIE-A3C employs *asynchronous parallel* training. This results in upto 6x training speedup, without suffering any loss in average accuracy. We hope that this first application of asynchronous deep RL algorithms will open up more adoption of such techniques in the NLP community.

Abstract

In this paper, we utilize the linguistic structures of texts to improve named entity recognition by BRNN-CNN, a special bidirectional recursive network attached with a convolutional network. Motivated by the observation that named entities are highly related to linguistic constituents, we propose a constituent-based BRNN-CNN for named entity recognition. In contrast to classical sequential labeling methods, the system first identifies which text chunks are possible named entities by whether they are linguistic constituents. Then it classifies these chunks with a constituency tree structure by recursively propagating syntactic and semantic information to each constituent node. This method surpasses current state-of-the-art on OntoNotes 5.0 with automatically generated parses.

1 Introduction

Named Entity Recognition (NER) can be seen as a combined task of locating named entity chunks of texts and classifying which named entity category a chunk falls into. Traditional approaches label each token in texts as a part of a named entity chunk, e.g. "person_begin", and achieve high performances in several benchmark datasets (Ratinov and Roth, 2009; Passos et al., 2014; Chiu and Nichols, 2016).

Being formulated as a sequential labeling problem, NER systems could be naturally implemented by recurrent neural networks. These networks process a token at a time, taking, for each token, the hidden features of its previous token as well as its raw features to compute its own hidden features. Then they classify each token by these hidden features. With both forward and backward directions, networks learn how to propagate the information of a token sequence to each token. Chiu and Nichols (2016) utilize a variation of recurrent networks, bidirectional LSTM, attached with a CNN, which learns character-level features instead of handcrafting. They accomplish state-of-the-art results on both CoNLL-2003 (Tjong Kim Sang and De Meulder, 2003) and OntoNotes 5.0 (Hovy et al., 2006; Pradhan et al., 2013) datasets.

Classical sequential labeling approaches take little information about phrase structures of sentences. However, according to our analysis, most named entity chunks are actually linguistic constituents, e.g. noun phrases. This motivates us to focus on a constituent-based approach for NER where the NER problem is transformed into a named entity classification task on every node of a

constituency structure.

To classify constituents and take into account their structures, we propose BRNN-CNN, a special bidirectional recursive neural network attached with a convolutional network. For each sentence, a constituency parse where every node represents a meaningful chunk of the sentence, i.e. a constituent, is first generated. Then BRNN-CNN recursively computes hidden state features of every node and classifies each node by these hidden features. To capture structural linguistic information, bidirectional passes are applied so that each constituent sees what it is composed of as well as what is containing it, both in a near-to-far fashion.

Our main contribution is the introduction of a novel constituent-based BRNN-CNN for named entity recognition, which successfully utilizes the linguistic structures of texts by recursive neural networks. We show that it achieves better scores than current state-of-the-art on OntoNotes 5.0, where good parses can be automatically generated. Additionally, we analyze the effects of only considering constituents and the effects of constituency parses.

2 Related Work

Collobert et al. (2011) achieved near state-of-the-art performance on CoNLL-2003 NER with an end-to-end neural network which had minimal feature engineering and external data. Chiu and Nichols (2016) achieved the current state-of-the-art on both CoNLL-2003 and OntoNotes 5.0 NER with a sequential bidirectional LSTM-CNN. They also did extensive studies of additional features such as character type, capitalization, and Senna and DBpedia lexicons.

Finkel and Manning (2009) explored training a parser for an NER-suffixed grammar, jointly tackling parsing and NER. They achieved competitive results on OntoNotes with a CRF-CFG parser.

Recursive neural networks have been successfully applied for parsing and sentiment analysis on Stanford sentiment treebank (Socher et al., 2010, 2013a,b; Tai et al., 2015). Their recursive networks, such as RNTN and Tree-LSTM, do sentiment combinations on phrase structures in a bottom-up fashion, showing the potential of such models in computing semantic compositions.

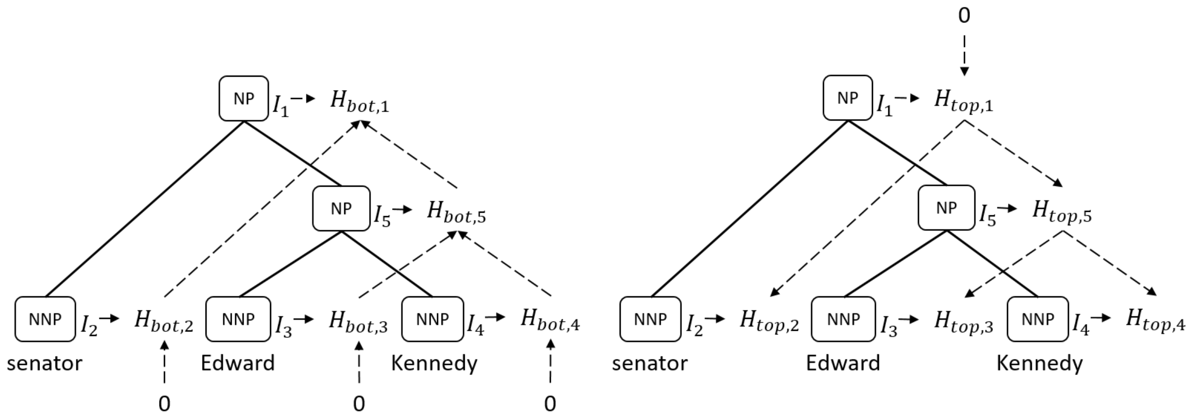

Figure 2: The bottom-up and top-down hidden layers applied to the binarized tree in Figure 1.

3 Method

For each input sentence, our constituent-based BRNN-CNN first extracts features from its constituency parse, then recursively classifies each constituent, and finally resolves conflicting predictions.

3.1 Preparing Constituency Structures

For a sentence and its associated constituency parse, our system first sets three features for each node: a POS, a word, and a head. While constituency tags and words should come readily, semantic head words are determined by a rule-based head finder (Collins, 1999). Additionally, a fourth feature vector is added to each node to utilize lexicon knowledge. The 3-bit vector records if the constituent of a node matches some phrases in each of the three SENNA (Collobert et al., 2011) lexicons of persons, organizations, and locations.

The system then tries to generate more plausible constituents while preserving linguistic structures by applying a binarization process which groups excessive child nodes around the head children. The heuristic is that a head constituent is usually modified by its siblings in a near to far fashion. Algorithm 1 shows the recursive procedure called for the root node of a parse. Figure 1 shows the application of the algorithm to the parse of *senator Edward Kennedy*. With the heuristic that *Edward* modifies the head node *Kennedy* before *senator*. The binarization process successfully adds a new node *Edward Kennedy* that corresponds to a person name.

3.2 Computing Word Embeddings

For each word, our network retrieves one embedding from a trainable lookup table initialized by GloVe (Pennington et al., 2014). However, to capture the morphology information of a word and help dealing with unseen words, the network computes another character-level embedding. Inspired by Kim et al. (2016), the network passes one-hot character vectors through a series of convolutional and highway layers to generate the embedding. These two embeddings are concatenated as the final embedding of a word.

3.3 Computing Hidden Features

Given a constituency parse tree, where every node represents a constituent, our network recursively computes two hidden state features for every node.

First, for each node i with left sibling l and right sibling r, the raw feature vector I_i is formed by concatenating the one-hot POS vectors of i, l, r, the head embeddings of i, l, r, the word embedding of i, the lexicon vector of i, and the mean of word embeddings in the sentence. Then, with the the set of child nodes C and the parent node p, the hidden feature vectors $H_{bot,i}$ and $H_{top,i}$ are computed by 2 hidden layers:

$$H_{bot,i} = ReLU((I_i \| \sum_{c \in C} H_{bot,c}) W_{bot} + b_{bot}) \quad (1)$$

$$H_{top,i} = ReLU((I_i \| H_{top,p}) W_{top} + b_{top}) \quad (2)$$

where Ws are weight matrices, bs are bias vectors, and $ReLU(x) = max(0, x)$. In cases when some needed neighboring nodes do not exist, or when i is a nonterminal and does not have a word, zero

vectors are used as the missing parts of raw or hidden features.

Figure 2 shows the applications of the equations to the binarized tree in Figure 1. The computations are done recursively in two directions. The bottom-up direction computes the semantic composition of the subtree of each node, and the top-down counterpart propagates to that node the linguistic structures which contain the subtree. Together, hidden features of a constituent capture its structural linguistic information.

In addition, each hidden layer can be extended to a deep hidden network. For example, a 2-layer top-down hidden network is given by

$$H_{t\alpha,i} = ReLU((I_i \| H_{t\alpha,p})W_{t\alpha} + b_{t\alpha})$$

$$H_{t\beta,i} = ReLU((H_{t\alpha,i} \| H_{t\beta,p})W_{t\beta} + b_{t\beta})$$

where $t\alpha$ represents the first top-down hidden layer and $t\beta$ represents the second. Our best model is tuned to have 3 layers for both directions.

3.4 Forming Consistent Predictions

Given hidden features for every node, our network computes a probability distribution of named entity classes plus a special non-entity class by an output layer. For each node i with left sibling l and right sibling r, the probability distribution O_i is computed by an output layer:

$$O_i = \sigma((H_i \| H_l \| H_r)W_{out} + b_{out}) \qquad (3)$$

where $H_x = H_{bot,x} + H_{top,x}$, $x \in \{i, l, r\}$, and $\sigma(x) = (1 + e^{-x})^{-1}$. If a sibling does not exist, zero vectors are used as its hidden states. Should deep hidden layers be deployed, the last hidden layer is used.

Finally, the system makes predictions for a sentence by collecting the constituents whose most probable classes are named entity classes. However, nodes whose ancestors are already predicted as named entities are ignored to prevent predicting overlapping named entities.

4 Evaluation

We evaluate our system on OntoNotes 5.0 NER (Hovy et al., 2006; Pradhan et al., 2013) and analyze it with several ablation studies. The project sources are publicly available on `https://github.com/jacobvsdanniel/tf_rnn`.

Split	Token	NE	Constituent
Train	1,088,503	81,828	93.3 → 97.3
Validate	147,724	11,066	92.8 → 97.0
Test	152,728	11,257	92.9 → 97.2

Table 3: Dataset statistics for OntoNotes 5.0.

4.1 Training and Tuning

To train the model, we minimize the cross entropy loss of the softmax class probabilities in Equation 3 by the Adam optimizer (Kingma and Ba, 2014). Other details such as hyperparameters are documented in the supplemental materials as well as the public repository.

4.2 OntoNotes 5.0 NER

OntoNotes 5.0 annotates 18 types of named entities for diverse sources of texts. Like other previous work (Durrett and Klein, 2014; Chiu and Nichols, 2016), we use the format and the train-validate-test split provided by CoNLL-2012. In addition, both gold and auto parses are available.

Table 3 shows the dataset statistics. The last column shows the percentages of named entities that correspond to constituents of auto parses before and after binarization.

Table 1 and Table 2 compare our results with others on the whole dataset and different sources respectively. The sample mean, standard deviation, and sample count of BRNN-auto and Chiu and Nichols' model are 87.10, 0.14, 3 and 86.41, 0.22, 10 respectively. By one-tailed Welch's T-test, the former significantly surpasses the latter with 99% confidence level (0.000489 p-value).

4.3 Analysis of the Approach

The training and validation sets contain 1,236,227 tokens and 92,894 named entities, of which 90,371 correspond to some constituents of binarized auto parses. This backs our motivation that more than 97% named entities are linguistic constituents, and 52,729 of them are noun phrases.

Essentially, the constituent-based approach filters out the other 3% named entities that cross constituent boundaries (Figure 3), i.e. 3% loss of recall. We dig into this problem by analyzing a sequential labeling recurrent network (the sixth model in Table 1). The simple model performs reasonably well, but its non-constituent predictions are mostly false positive. In fact, it slightly improves if all non-constituent predictions are removed in post-processing, i.e., the precision gain of focusing on constituents is more significant than the recall loss. This is one advantage of our system over other sequential models, which try to learn and predict non-constituent named entities but do not perform well.

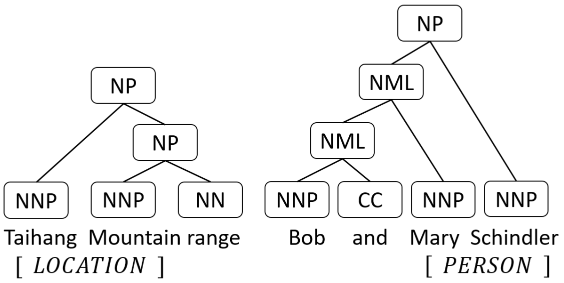

Figure 3: Two sample named entities that cross different branches of syntax parses.

In addition, to analyze the effects of constituency structures, we test our models with different qualities of parses (gold vs. auto in Table 1). The significant F1 differences suggest that structural linguistic information is crucial and can be learned by our model.

5 Conclusion

We have demonstrated a novel constituent-based BRNN-CNN for named entity recognition which successfully utilizes constituency structures and surpasses the current state-of-the-art on OntoNotes 5.0 NER. Instead of propagating information by word orders as normal recurrent networks, the model is able to recursively propagate structural linguistic information to every constituent. Experiments show that when a good parser is available, the approach will be a good alternative to traditional sequential labeling token-based NER.

Named entities that cross constituent boundaries are analyzed and we find out that a naïve sequential labeling model has difficulty predicting them without too many false positives. While avoiding them is one of the strengths of our model, generating more consistent parses to reduce this kind of named entities would be one possible direction for future research.

Fast and Accurate Entity Recognition with Iterated Dilated Convolutions

Abstract

Today when many practitioners run basic NLP on the entire web and large-volume traffic, faster methods are paramount to saving time and energy costs. Recent advances in GPU hardware have led to the emergence of bi-directional LSTMs as a standard method for obtaining per-token vector representations serving as input to labeling tasks such as NER (often followed by prediction in a linear-chain CRF). Though expressive and accurate, these models fail to fully exploit GPU parallelism, limiting their computational efficiency. This paper proposes a faster alternative to Bi-LSTMs for NER: Iterated Dilated Convolutional Neural Networks (ID-CNNs), which have better capacity than traditional CNNs for large context and structured prediction. Unlike LSTMs whose sequential processing on sentences of length N requires $O(N)$ time even in the face of parallelism, ID-CNNs permit fixed-depth convolutions to run in parallel across entire documents. We describe a distinct combination of network structure, parameter sharing and training procedures that enable dramatic 14-20x test-time speedups while retaining accuracy comparable to the Bi-LSTM-CRF. Moreover, ID-CNNs trained to aggregate context from the entire document are even more accurate while maintaining 8x faster test time speeds.

1 Introduction

In order to democratize large-scale NLP and information extraction while minimizing our environmental footprint, we require fast, resource-efficient methods for sequence tagging tasks such as part-of-speech tagging and named entity recognition (NER). Speed is not sufficient of course: they must also be expressive enough to tolerate the tremendous lexical variation in input data.

The massively parallel computation facilitated by GPU hardware has led to a surge of successful neural network architectures for sequence labeling (Ling et al., 2015; Ma and Hovy, 2016; Chiu and Nichols, 2016; Lample et al., 2016). While these models are expressive and accurate, they fail to fully exploit the parallelism opportunities of a GPU, and thus their speed is limited. Specifically, they employ either recurrent neural networks (RNNs) for feature extraction, or Viterbi inference in a structured output model, both of which require sequential computation across the length of the input.

Instead, parallelized runtime independent of the length of the sequence saves time and energy costs, maximizing GPU resource usage and minimizing the amount of time it takes to train and evaluate models. Convolutional neural networks (CNNs) provide exactly this property (Kim, 2014; Kalchbrenner et al., 2014). Rather than composing representations incrementally over each token in a sequence, they apply filters in parallel across the entire sequence at once. Their computational cost grows with the number of layers, but not the input size, up to the memory and threading limitations of the hardware. This provides, for example, audio generation models that can be trained in parallel (van den Oord et al., 2016).

Despite the clear computational advantages of CNNs, RNNs have become the standard method for composing deep representations of text. This is because a token encoded by a bidirectional RNN will incorporate evidence from the entire input sequence, but the CNN's representation is limited by

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2670–2680
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

the effective input width[1] of the network: the size of the input context which is observed, directly or indirectly, by the representation of a token at a given layer in the network. Specifically, in a network composed of a series of stacked convolutional layers of convolution width w, the number r of context tokens incorporated into a token's representation at a given layer l, is given by $r = l(w-1)+1$. The number of layers required to incorporate the entire input context grows linearly with the length of the sequence. To avoid this scaling, one could pool representations across the sequence, but this is not appropriate for sequence labeling, since it reduces the output resolution of the representation.

In response, this paper presents an application of *dilated convolutions* (Yu and Koltun, 2016) for sequence labeling (Figure 1). For dilated convolutions, the effective input width can grow exponentially with the depth, with no loss in resolution at each layer and with a modest number of parameters to estimate. Like typical CNN layers, dilated convolutions operate on a sliding window of context over the sequence, but unlike conventional convolutions, the context need not be consecutive; the dilated window skips over every dilation width d inputs. By stacking layers of dilated convolutions of exponentially increasing dilation width, we can expand the size of the effective input width to cover the entire length of most sequences using only a few layers: The size of the effective input width for a token at layer l is now given by $2^{l+1}-1$. More concretely, just four stacked dilated convolutions of width 3 produces token representations with a n effective input width of 31 tokens – longer than the average sentence length (23) in the Penn TreeBank.

Our overall *iterated dilated CNN* architecture (ID-CNN) repeatedly applies the same block of dilated convolutions to token-wise representations. This parameter sharing prevents overfitting and also provides opportunities to inject supervision on intermediate activations of the network. Similar to models that use logits produced by an RNN, the ID-CNN provides two methods for performing prediction: we can predict each token's label independently, or by running Viterbi inference in a chain structured graphical model.

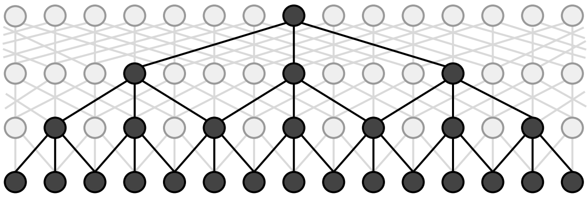

Figure 1: A dilated CNN block with maximum dilation width 4 and filter width 3. Neurons contributing to a single highlighted neuron in the last layer are also highlighted.

In experiments on CoNLL 2003 and OntoNotes 5.0 English NER, we demonstrate significant speed gains of our ID-CNNs over various recurrent models, while maintaining similar F1 performance. When performing prediction using independent classification, the ID-CNN consistently outperforms a bidirectional LSTM (Bi-LSTM), and performs on par with inference in a CRF with logits from a Bi-LSTM (Bi-LSTM-CRF). As an extractor of per-token logits for a CRF, our model out-performs the Bi-LSTM-CRF. We also apply ID-CNNs to entire documents, where independent token classification is as accurate as the Bi-LSTM-CRF while decoding almost 8× faster. The clear accuracy gains resulting from incorporating broader context suggest that these models could similarly benefit many other context-sensitive NLP tasks which have until now been limited by the computational complexity of existing context-rich models.[2]

2 Background

2.1 Conditional Probability Models for Tagging

Let $x = [x_1, \ldots, x_T]$ be our input text and $y = [y_1, \ldots, y_T]$ be per-token output tags. Let D be the domain size of each y_i. We predict the most likely y, given a conditional model $P(y|x)$.

This paper considers two factorizations of the conditional distribution. First, we have

$$P(y|x) = \prod_{t=1}^{T} P(y_t|F(x)), \qquad (1)$$

where the tags are conditionally independent given some features for x. Given these features, $O(D)$ prediction is simple and parallelizable across the

[1] What we call *effective input width* here is known as the *receptive field* in the vision literature, drawing an analogy to the visual receptive field of a neuron in the retina.

[2] Our implementation in TensorFlow (Abadi et al., 2015) is available at: https://github.com/iesl/dilated-cnn-ner

length of the sequence. However, feature extraction may not necessarily be parallelizable. For example, RNN-based features require iterative passes along the length of x.

We also consider a linear-chain CRF model that couples all of y together:

$$P(y|x) = \frac{1}{Z_x} \prod_{t=1}^{T} \psi_t(y_t|F(x))\psi_p(y_t, y_{t-1}), \quad (2)$$

where ψ_t is a local factor, ψ_p is a pairwise factor that scores consecutive tags, and Z_x is the partition function (Lafferty et al., 2001). To avoid overfitting, ψ_p does not depend on the timestep t or the input x in our experiments. Prediction in this model requires global search using the $O(D^2T)$ Viterbi algorithm.

CRF prediction explicitly reasons about interactions among neighboring output tags, whereas prediction in the first model compiles this reasoning into the feature extraction step (Liang et al., 2008). The suitability of such compilation depends on the properties and quantity of the data. While CRF prediction requires non-trivial search in output space, it can guarantee that certain output constraints, such as for IOB tagging (Ramshaw and Marcus, 1999), will always be satisfied. It may also have better sample complexity, as it imposes more prior knowledge about the structure of the interactions among the tags (London et al., 2016). However, it has worse computational complexity than independent prediction.

3 Dilated Convolutions

CNNs in NLP are typically one-dimensional, applied to a sequence of vectors representing tokens rather than to a two-dimensional grid of vectors representing pixels. In this setting, a convolutional neural network layer is equivalent to applying an affine transformation, W_c to a sliding window of width r tokens on either side of each token in the sequence. Here, and throughout the paper, we do not explicitly write the bias terms in affine transformations. The convolutional operator applied to each token x_t with output c_t is defined as:

$$c_t = W_c \bigoplus_{k=0}^{r} x_{t \pm k}, \quad (3)$$

where $\oplus$ is vector concatenation.

Dilated convolutions perform the same operation, except rather than transforming adjacent inputs, the convolution is defined over a wider effective input width by skipping over δ inputs at a time, where δ is the dilation width. We define the dilated convolution operator:

$$c_t = W_c \bigoplus_{k=0}^{r} x_{t \pm k\delta}. \quad (4)$$

A dilated convolution of width 1 is equivalent to a simple convolution. Using the same number of parameters as a simple convolution with the same radius (i.e. W_c has the same dimensionality), the $\delta > 1$ dilated convolution incorporates broader context into the representation of a token than a simple convolution.

3.1 Multi-Scale Context Aggregation

We can leverage the ability of dilated convolutions to incorporate global context without losing important local information by stacking dilated convolutions of increasing width. First described for pixel classification in computer vision, Yu and Koltun (2016) achieve state-of-the-art results on image segmentation benchmarks by stacking dilated convolutions with exponentially increasing rates of dilation, a technique they refer to as *multi-scale context aggregation*. By feeding the outputs of each dilated convolution as the input to the next, increasingly non-local information is incorporated into each pixel's representation. Performing a dilation-1 convolution in the first layer ensures that no pixels within the effective input width of any pixel are excluded. By doubling the dilation width at each layer, the size of the effective input width grows exponentially while the number of parameters grows only linearly with the number of layers, so a pixel representation quickly incorporates rich global evidence from the entire image.

4 Iterated Dilated CNNs

Stacked dilated CNNs can easily incorporate global information from a whole sentence or document. For example, with a radius of 1 and 4 layers of dilated convolutions, the effective input width of each token is width 31, which exceeds the average sentence length (23) in the Penn TreeBank corpus. With a radius of size 2 and 8 layers of dilated convolutions, the effective input width exceeds 1,000 tokens, long enough to encode a full newswire document.

Unfortunately, simply increasing the depth of stacked dilated CNNs causes considerable over-fitting in our experiments. In response, we present Iterated Dilated CNNs (ID-CNNs), which instead apply the same small stack of dilated convolutions multiple times, each iterate taking as input the result of the last application. Repeatedly employing the same parameters in a recurrent fashion provides both broad effective input width and desirable generalization capabilities. We also obtain significant accuracy gains with a training objective that strives for accurate labeling after each iterate, allowing follow-on iterations to observe and resolve dependency violations.

4.1 Model Architecture

The network takes as input a sequence of T vectors $\mathbf{x_t}$, and outputs a sequence of per-class scores $\mathbf{h_t}$, which serve either as the local conditional distributions of Eqn. (1) or the local factors ψ_t of Eqn. (2).

We denote the jth dilated convolutional layer of dilation width δ as $D_\delta^{(j)}$. The first layer in the network is a dilation-1 convolution $D_1^{(0)}$ that transforms the input to a representation $\mathbf{i_t}$:

$$\mathbf{i_t} = D_1^{(0)}\mathbf{x_t} \tag{5}$$

Next, L_c layers of dilated convolutions of exponentially increasing dilation width are applied to $\mathbf{i_t}$, folding in increasingly broader context into the embedded representation of $\mathbf{x_t}$ at each layer. Let $r()$ denote the ReLU activation function (Glorot et al., 2011). Beginning with $\mathbf{c_t}^{(0)} = \mathbf{i_t}$ we define the stack of layers with the following recurrence:

$$\mathbf{c_t}^{(j)} = r\left(D_{2^{L_c-1}}^{(j-1)}\mathbf{c_t}^{(j-1)}\right) \tag{6}$$

and add a final dilation-1 layer to the stack:

$$\mathbf{c_t}^{(L_c+1)} = r\left(D_1^{(L_c)}\mathbf{c_t}^{(L_c)}\right) \tag{7}$$

We refer to this stack of dilated convolutions as a *block* $B(\cdot)$, which has output resolution equal to its input resolution. To incorporate even broader context without over-fitting, we avoid making B deeper, and instead iteratively apply B L_b times, introducing no extra parameters. Starting with $\mathbf{b_t}^{(1)} = B(\mathbf{i_t})$:

$$\mathbf{b_t}^{(k)} = B\left(\mathbf{b_t}^{(k-1)}\right) \tag{8}$$

We apply a simple affine transformation W_o to this final representation to obtain per-class scores for each token $\mathbf{x_t}$:

$$\mathbf{h_t}^{(L_b)} = W_o\mathbf{b_t}^{(L_b)} \tag{9}$$

4.2 Training

Our main focus is to apply the ID-CNN an encoder to produce per-token logits for the first conditional model described in Sec. 2.1, where tags are conditionally independent given deep features, since this will enable prediction that is parallelizable across the length of the input sequence. Here, maximum likelihood training is straightforward because the likelihood decouples into the sum of the likelihoods of independent logistic regression problems for every tag, with natural parameters given by Eqn. (9):

$$\frac{1}{T}\sum_{t=1}^{T}\log P(y_t \mid \mathbf{h_t}^{(L_b)}) \tag{10}$$

We can also use the ID-CNN as logits for the CRF model (Eqn. (2)), where the partition function and its gradient are computed using the forward-backward algorithm.

We next present an alternative training method that helps bridge the gap between these two techniques. Sec. 2.1 identifies that the CRF has preferable sample complexity and accuracy since prediction directly reasons in the space of structured outputs. In response, we compile some of this reasoning in output space into ID-CNN feature extraction. Instead of explicit reasoning over output labels during inference, we train the network such that each block is predictive of output labels. Subsequent blocks learn to correct dependency violations of their predecessors, refining the final sequence prediction.

To do so, we first define predictions of the model after each of the L_b applications of the block. Let $\mathbf{h_t}^{(k)}$ be the result of applying the matrix W_o from (9) to $\mathbf{b_t}^{(k)}$, the output of block k. We minimize the average of the losses for each application of the block:

$$\frac{1}{L_b}\sum_{k=1}^{L_b}\frac{1}{T}\sum_{t=1}^{T}\log P(y_t \mid \mathbf{h_t}^{(k)}). \tag{11}$$

By rewarding accurate predictions after each application of the block, we learn a model where later blocks are used to refine initial predictions.

The loss also helps reduce the vanishing gradient problem (Hochreiter, 1998) for deep architectures. Such an approach has been applied in a variety of contexts for training very deep networks in computer vision (Romero et al., 2014; Szegedy et al., 2015; Lee et al., 2015; Gülçehre and Bengio, 2016), but not to our knowledge in NLP.

We apply dropout (Srivastava et al., 2014) to the raw inputs $\mathbf{x_t}$ and to each block's output $\mathbf{b_t}^{(b)}$ to help prevent overfitting. The version of dropout typically used in practice has the undesirable property that the randomized predictor used at train time differs from the fixed one used at test time. Ma et al. (2017) present *dropout with expectation-linear regularization*, which explicitly regularizes these two predictors to behave similarly. All of our best reported results include such regularization. This is the first investigation of the technique's effectiveness for NLP, including for RNNs. We encourage its further application.

5 Related work

The state-of-the art models for sequence labeling include an inference step that searches the space of possible output sequences of a chain-structured graphical model, or approximates this search with a beam (Collobert et al., 2011; Weiss et al., 2015; Lample et al., 2016; Ma and Hovy, 2016; Chiu and Nichols, 2016). These outperform similar systems that use the same features, but independent local predictions. On the other hand, the greedy *sequential prediction* (Daumé III et al., 2009) approach of Ratinov and Roth (2009), which employs lexicalized features, gazetteers, and word clusters, outperforms CRFs with similar features.

LSTMs (Hochreiter and Schmidhuber, 1997) were used for NER as early as the CoNLL shared task in 2003 (Hammerton, 2003; Tjong Kim Sang and De Meulder, 2003). More recently, a wide variety of neural network architectures for NER have been proposed. Collobert et al. (2011) employ a one-layer CNN with pre-trained word embeddings, capitalization and lexicon features, and CRF-based prediction. Huang et al. (2015) achieved state-of-the-art accuracy on part-of-speech, chunking and NER using a Bi-LSTM-CRF. Lample et al. (2016) proposed two models which incorporated Bi-LSTM-composed character embeddings alongside words: a Bi-LSTM-CRF, and a greedy stack LSTM which uses a simple shift-reduce grammar to compose words into labeled entities. Their Bi-LSTM-CRF obtained the state-of-the-art on four languages without word shape or lexicon features. Ma and Hovy (2016) use CNNs rather than LSTMs to compose characters in a Bi-LSTM-CRF, achieving state-of-the-art performance on part-of-speech tagging and CoNLL NER without lexicons. Chiu and Nichols (2016) evaluate a similar network but propose a novel method for encoding lexicon matches, presenting results on CoNLL and OntoNotes NER. Yang et al. (2016) use GRU-CRFs with GRU-composed character embeddings of words to train a single network on many tasks and languages.

In general, distributed representations for text can provide useful generalization capabilities for NER systems, since they can leverage unsupervised pre-training of distributed word representations (Turian et al., 2010; Collobert et al., 2011; Passos et al., 2014). Though our models would also likely benefit from additional features such as character representations and lexicons, we focus on simpler models which use word-embeddings alone, leaving more elaborate input representations to future work.

In these NER approaches, CNNs were used for low-level feature extraction that feeds into alternative architectures. Overall, end-to-end CNNs have mainly been used in NLP for sentence classification, where the output representation is lower resolution than that of the input Kim (2014); Kalchbrenner et al. (2014); Zhang et al. (2015); Toutanova et al. (2015). Lei et al. (2015) present a CNN variant where convolutions adaptively skip neighboring words. While the flexibility of this model is powerful, its adaptive behavior is not well-suited to GPU acceleration.

Our work draws on the use of dilated convolutions for image segmentation in the computer vision community (Yu and Koltun, 2016; Chen et al., 2015). Similar to our block, Yu and Koltun (2016) employ a *context-module* of stacked dilated convolutions of exponentially increasing dilation width. Dilated convolutions were recently applied to the task of speech generation (van den Oord et al., 2016), and concurrent with this work, Kalchbrenner et al. (2016) posted a pre-print describing the similar ByteNet network for machine translation that uses dilated convolutions in the encoder and decoder components. Our basic model architecture is similar to that of the ByteNet encoder, except that the inputs to our model are tokens and not bytes. Additionally, we present a novel loss and parameter sharing scheme to facilitate training models on much smaller datasets than those used by Kalchbrenner et al. (2016). We are the first to use dilated convolutions for sequence labeling.

The broad effective input width of the ID-CNN helps aggregate document-level context. Ratinov and Roth (2009) incorporate document context in their greedy model by adding features based on tagged entities within a large, fixed window of tokens. Prior work has also posed a structured model that couples predictions across the whole document (Bunescu and Mooney, 2004; Sutton and McCallum, 2004; Finkel et al., 2005).

6 Experimental Results

We describe experiments on two benchmark English named entity recognition datasets. On CoNLL-2003 English NER, our ID-CNN performs on par with a Bi-LSTM not only when used to produce per-token logits for structured inference, but the ID-CNN with greedy decoding also performs on-par with the Bi-LSTM-CRF while running at more than 14 times the speed. We also observe a performance boost in almost all models when broadening the context to incorporate entire documents, achieving an average F1 of 90.65 on CoNLL-2003, out-performing the sentence-level model while still decoding at nearly 8 times the speed of the Bi-LSTM-CRF.

6.1 Data and Evaluation

We evaluate using labeled data from the CoNLL-2003 shared task (Tjong Kim Sang and De Meulder, 2003) and OntoNotes 5.0 (Hovy et al., 2006; Pradhan et al., 2006). Following previous work, we use the same OntoNotes data split used for co-reference resolution in the CoNLL-2012 shared task (Pradhan et al., 2012). For both datasets, we convert the IOB boundary encoding to BILOU as previous work found this encoding to result in improved performance (Ratinov and Roth, 2009). As in previous work we evaluate the performance of our models using segment-level micro-averaged F1 score. Hyperparameters that resulted in the best performance on the validation set were selected via grid search. A more detailed description of the data, evaluation, optimization and data pre-processing can be found in the Appendix.

6.2 Baselines

We compare our **ID-CNN** against strong LSTM and CNN baselines: a **Bi-LSTM** with local decoding, and one with CRF decoding (**Bi-LSTM-CRF**). We also compare against a non-dilated CNN architecture with the same number of convolutional layers as our dilated network (**4-layer CNN**) and one with enough layers to incorporate an effective input width of the same size as that of the dilated network (**5-layer CNN**) to demonstrate that the dilated convolutions more effectively aggregate contextual information than simple convolutions (i.e. using fewer parameters). We also compare our document-level ID-CNNs to a baseline which does not share parameters between blocks (**noshare**) and one that computes loss only at the last block, rather than after every iterated block of dilated convolutions (**1-loss**).

We do not compare with deeper or more elaborate CNN architectures for a number of reasons: 1) Fast train and test performance are highly desirable for NLP practitioners, and deeper models require more computation time 2) more complicated models tend to over-fit on this relatively small dataset and 3) most accurate deep CNN architectures repeatedly up-sample and down-sample the inputs. We do not compare to stacked LSTMs for similar reasons — a single LSTM is already slower than a 4-layer CNN. Since our task is sequence labeling, we desire a model that maintains the token-level resolution of the input, making dilated convolutions an elegant solution.

6.3 CoNLL-2003 English NER

6.3.1 Sentence-level prediction

Table 1 lists F1 scores of models predicting with sentence-level context on CoNLL-2003. For models that we trained, we report F1 and standard deviation obtained by averaging over 10 random restarts. The Viterbi-decoding Bi-LSTM-CRF and ID-CNN-CRF and greedy ID-CNN obtain the highest average scores, with the ID-CNN-CRF outperforming the Bi-LSTM-CRF by 0.11 points of F1 on average, and the Bi-LSTM-CRF out-performing the greedy ID-CNN by 0.11 as well. Our greedy ID-CNN outperforms the Bi-LSTM and the 4-layer CNN, which uses the same number of parameters as the ID-CNN, and performs similarly to the 5-layer CNN which uses more parameters but covers the same effective input width. All CNN models out-perform the Bi-

4-layer ID-CNN	89.65 ± 0.30	**90.32** ± 0.26

Table 3: Comparison of models trained with and without expectation-linear dropout regularization (DR). DR improves all models.

LSTM when paired with greedy decoding, suggesting that CNNs are better token encoders than Bi-LSTMs for independent logistic regression. When paired with Viterbi decoding, our ID-CNN performs on par with the Bi-LSTM, showing that the ID-CNN is also an effective token encoder for structured inference.

Our ID-CNN is not only a better token encoder than the Bi-LSTM but it is also faster. Table 2 lists relative decoding times on the CoNLL development set, compared to the Bi-LSTM-CRF. We report decoding times using the fastest batch size for each method.[3]

The ID-CNN model decodes nearly 50% faster than the Bi-LSTM. With Viterbi decoding, the gap closes somewhat but the ID-CNN-CRF still comes out ahead, about 30% faster than the Bi-LSTM-CRF. The most vast speed improvements come when comparing the greedy ID-CNN to the Bi-LSTM-CRF – our ID-CNN is more than 14 times faster than the Bi-LSTM-CRF at test time, with comparable accuracy. The 5-layer CNN, which observes the same effective input width as the ID-CNN but with more parameters, performs at about the same speed as the ID-CNN in our experiments. With a better implementation of dilated convolutions than currently included in TensorFlow, we would expect the ID-CNN to be notably faster than the 5-layer CNN.

We emphasize the importance of the dropout regularizer of Ma et al. (2017) in Table 3, where we observe increased F1 for every model trained with expectation-linear dropout regularization. Dropout is important for training neural network models that generalize well, especially on relatively small NLP datasets such as CoNLL-2003. We recommend this regularizer as a simple and helpful tool for practitioners training neural networks for NLP.

6.3.2 Document-level prediction

In Table 4 we show that adding document-level context improves every model on CoNLL-2003. Incorporating document-level context further improves our greedy ID-CNN model, attaining 90.65 average F1. We believe this model sees greater improvement with the addition of document-level context than the Bi-LSTM-CRF due to the ID-CNN learning a feature function better suited for representing broad context, in contrast with the Bi-LSTM which, though better than a simple RNN at encoding long memories of sequences, may reach its limit when provided with sequences more than 1,000 tokens long such as entire documents.

We also note that our combination of training objective (Eqn. 11) and tied parameters (Eqn.

[3] For each model, we tried batch sizes $b = 2^i$ with $i = 0...11$. At scale, speed should increase with batch size, as we could compose each batch of as many sentences of the same length as would fit in GPU memory, requiring no padding and giving CNNs and ID-CNNs even more of a speed advantage.

[5] Our ID-CNN could see up to 18× speed-up with a less naive implementation than is included in TensorFlow as of this writing.

8) more effectively learns to aggregate this broad context than a vanilla cross-entropy loss or deep CNN back-propagated from the final neural network layer. Table 5 compares models trained to incorporate entire document context using the document baselines described in Section 6.2.

In Table 6 we show that, in addition to being more accurate, our ID-CNN model is also much faster than the Bi-LSTM-CRF when incorporating context from entire documents, decoding at almost 8 times the speed. On these long sequences, it also tags at more than 4.5 times the speed of the greedy Bi-LSTM, demonstrative of the benefit of our ID-CNNs context-aggregating computation that does not depend on the length of the sequence.

6.4 OntoNotes 5.0 English NER

We observe similar patterns on OntoNotes as we do on CoNLL. Table 7 lists overall F1 scores of our models compared to those in the existing literature. The greedy Bi-LSTM out-performs the lexicalized greedy model of Ratinov and Roth (2009), and our ID-CNN out-performs the Bi-LSTM as well as the more complex model of Durrett and Klein (2014) which leverages the parallel co-reference annotation available in the OntoNotes corpus to predict named entities jointly with entity linking and co-reference. Our greedy model is out-performed by the Bi-LSTM-CRF reported in Chiu and Nichols (2016) as well as our own re-implementation, which appears to be the new state-of-the-art on this dataset.

Model	Speed
Bi-LSTM-CRF	1×
Bi-LSTM	4.60×
ID-CNN	7.96×

Table 6: Relative test-time speed of document models (fastest batch size for each model).

Model	F1	Speed
Ratinov and Roth (2009)[6]	83.45	
Durrett and Klein (2014)	84.04	
Chiu and Nichols (2016)	86.19 ± 0.25	
Bi-LSTM-CRF	86.99 ± 0.22	1×

ID-CNN-CRF (1 block)	86.84 ± 0.19	1.83×
ID-CNN-Doc (3 blocks)	85.76 ± 0.13	21.19×
ID-CNN (3 blocks)	85.27 ± 0.24	13.21×
ID-CNN (1 block)	84.28 ± 0.10	26.01×

Table 7: F1 score of sentence and document models on OntoNotes.

The gap between our greedy model and those using Viterbi decoding is wider than on CoNLL. We believe this is due to the more diverse set of entities in OntoNotes, which also tend to be much longer – the average length of a multi-token named entity segment in CoNLL is about one token shorter than in OntoNotes. These long entities benefit more from explicit structured constraints enforced in Viterbi decoding. Still, our ID-CNN outperforms all other greedy methods, achieving our goal of learning a better token encoder for structured prediction.

Incorporating greater context significantly boosts the score of our greedy model on OntoNotes, whereas the Bi-LSTM-CRF performs more poorly. In Table 7, we also list the F1 of our ID-CNN model and the Bi-LSTM-CRF model trained on entire document context. For the first time, we see the score decrease when more context is added to the Bi-LSTM-CRF model, though the ID-CNN, whose sentence model a lower score than that of the Bi-LSTM-CRF, sees an increase. We believe the decrease in the Bi-LSTM-CRF model occurs because of the

[6] Results as reported in Durrett and Klein (2014) as this data split did not exist at the time of publication.

nature of the OntoNotes dataset compared to CoNLL-2003: CoNLL-2003 contains a particularly high proportion of ambiguous entities,[7] perhaps leading to more benefit from document context that helps with disambiguation. In this scenario, adding the wider context may just add noise to the high-scoring Bi-LSTM-CRF model, whereas the less accurate dilated model can still benefit from the refined predictions of the iterated dilated convolutions.

7 Conclusion

We present iterated dilated convolutional neural networks, fast token encoders that efficiently aggregate broad context without losing resolution. These provide impressive speed improvements for sequence labeling, particularly when processing entire documents at a time. In the future we hope to extend this work to NLP tasks with richer structured output, such as parsing.

Acknowledgments

We thank Subhransu Maji and Luke Vilnis for helpful discussions, and Brendan O'Connor, Yoav Goldberg, the UMass NLP reading group and many anonymous reviewers for constructive comments on various drafts of the paper. We are also grateful to Guillaume Lample for sharing his pretrained word embeddings. Abstract

For accurate entity linking, we need to capture various information aspects of an entity, such as its description in a KB, contexts in which it is mentioned, and structured knowledge. Additionally, a linking system should work on texts from different domains without requiring domain-specific training data or hand-engineered features.

In this work we present a neural, modular entity linking system that learns a unified dense representation for each entity using multiple sources of information, such as its description, contexts around its mentions, and its fine-grained types. We show that the resulting entity linking system is effective at combining these sources, and performs competitively, sometimes out-performing current state-of-the-art systems across datasets, without requiring any domain-specific training data or hand-engineered features. We also show that our model can effectively "embed" entities that are new to the KB, and is able to link its mentions accurately.

1 Introduction

Entity linking, the task of identifying the real-world entity a mention in text refers to, provides the ability to ground text to existing knowledge bases, and thus supports multiple natural language understanding, and knowledge acquisition tasks.

A key challenge for successful entity linking is the need to capture semantic and background information at various levels of granularity. For example, to resolve the mention "India" in "**India** plays a match in England today" to the correct entity, `India_cricket_team`, one needs to use mention-level context to identify that the sentence refers to a sports team (using *plays* and *match*), use document-level context to identify the sport, and information about the entity to realize that `India_cricket_team` is a sports team and the string "India" may refer to it. The problem has been studied extensively by employing a variety of machine learning, and inference methods, including a pipeline of deterministic modules (Ling et al., 2015), simple classifiers (Cucerzan, 2007; Ratinov et al., 2011), graphical models (Durrett and Klein, 2014), classifiers augmented with ILP inference (Cheng and Roth, 2013), and more recently, neural approaches (He et al., 2013; Sun et al., 2015; Francis-Landau et al., 2016).

We present a neural approach to linking[1] that learns a dense unified representation of entities by encoding the semantic and background information from multiple sources – encyclopedic entity descriptions, entity-type information, and the contexts the entity occurs in – thus capturing different aspects of the "meaning" of an entity. Hence, we overcome the shortcomings of several existing models that do not capture all these aspects. For example, methods, such as Vinculum (Ling et al., 2015), do not make use of the local context of the mention ("plays" and "match") while others, such as Berkeley-CNN (Francis-Landau et al., 2016), do not take entity-types into account. Our proposed model uses compositional training to ensure that the learned entity representation captures the various information sources available to it, making it quite modular. Specifically, we introduce encoders for the different sources of information about the entity, and encourage the entity embedding to be similar to all of the encoded representations.

A key requirement for information extraction systems is their ability to work across texts from

various domains. Some methods (Francis-Landau et al., 2016; Nguyen et al., 2016; Hoffart et al., 2011) train parameters on domain-specific linked data, thus hampering their ability to generalize to new domains. By only making use of indirect supervision that is available in Wikipedia/Freebase, we refrain from using domain specific training data, and produce a domain-independent linking system. Our comprehensive evaluation on recent entity linking benchmarks reveals that the resulting entity linker compares favorably to state-of-the-art systems across datasets, even those that have hand-engineered features or use dataset-specific training. We hence show that our model not only leverages all the available information for each entity effectively, but is also robust to missing information, such as entities without links/description in Wikipedia or with incomplete entity types.

In the real-world, new entities are regularly added to the knowledge bases, thus, it is important for any entity linking system to be extendable to such entities, especially the ones that do not have any existing linked mentions. By the virtue of our model's modular nature, it can easily incorporate new entities not present during training. Specifically, we show that our model can perform accurate linking for new entities, without having to re-train the existing entity representations, only using their description and types.

2 Related Work

Existing approaches for entity linking differ in several ways, including the machine learning models, the types of training data, and the kinds of information used about the entities.

Many existing approaches use links and information from Wikipedia as the only source of supervision to build the entity linking system. These approaches use sparse entity and mention-context representations, such as, based on the Wikipedia categories (Cucerzan, 2007), weighted bag of words in the entity description and mention context (Kulkarni et al., 2009; Ratinov et al., 2011), hand crafted features based on partial string matches, punctuations in entity name (McNamee et al., 2009), etc. Heuristics (Mihalcea and Csomai, 2007) or linear classifiers (Bunescu and Pasca, 2006; Cucerzan, 2007; Ratinov et al., 2011; McNamee et al., 2009) are used over these features to rank entity candidates for linking. Recently, neural models have been proposed as a way to support better generalization over the sparse features; e.g., using feed-forward networks on bag-of-words of the entity context (He et al., 2013), or using entity-class information from KB (Sun et al., 2015).

Some models ignore the entity's description on Wikipedia, but rather, only rely on the context from links to learn entity representations (Lazic et al., 2015), or use a pipeline of existing annotators to filter entity candidates (Ling et al., 2015). Our model is similar to these approaches by only using information from Wikipedia; however, we do not use hand-crafted features, and use multiple sources of information such as local and document-level entity context, KB descriptions, and entity types, to learn explicit entity representation.

Few recent entity linking approaches (Hoffart et al., 2011; Durrett and Klein, 2014; Nguyen et al., 2016; Francis-Landau et al., 2016) use manually-annotated domain specific training data to learn the linking system. AIDA (Hoffart et al., 2011), for example, evaluate their system on test set from CoNLL-YAGO dataset but also train on the training data from the same dataset. Berkeley-CNN (Francis-Landau et al., 2016), that uses CNNs operating over different granularity of entity and mention contexts, also follows this training regime and trains separate models for each dataset. Such approaches can be prohibitive in many applications as it encourages the model to over-fit to the peculiarities of different datasets and domains.

Other forms of information, apart from descriptions, and context from linked data, are also utilized for linking. Many approaches perform joint inference over the linking decisions in a document (Milne and Witten, 2008; Ratinov et al., 2011; Hoffart et al., 2011; Globerson et al., 2016), identify mentions that do not link to any existing entity (`NIL`) (Bunescu and Pasca, 2006; Ratinov et al., 2011), and cluster `NIL`-mentions (Wick et al., 2013; Lazic et al., 2015) to discover new entities. Few approaches jointly model entity linking, and other related NLP tasks to improve linking, such as, coreference resolution (Hajishirzi et al., 2013), relational inference (Cheng and Roth, 2013), and joint coreference with typing (Durrett and Klein, 2014). In our model, we use fine-grained type information of the entity as an auxiliary distant supervision to improve mention-context representation but do not use intermediate typing decisions for linking.

Many approaches that learn entity embeddings for other applications have also been proposed,

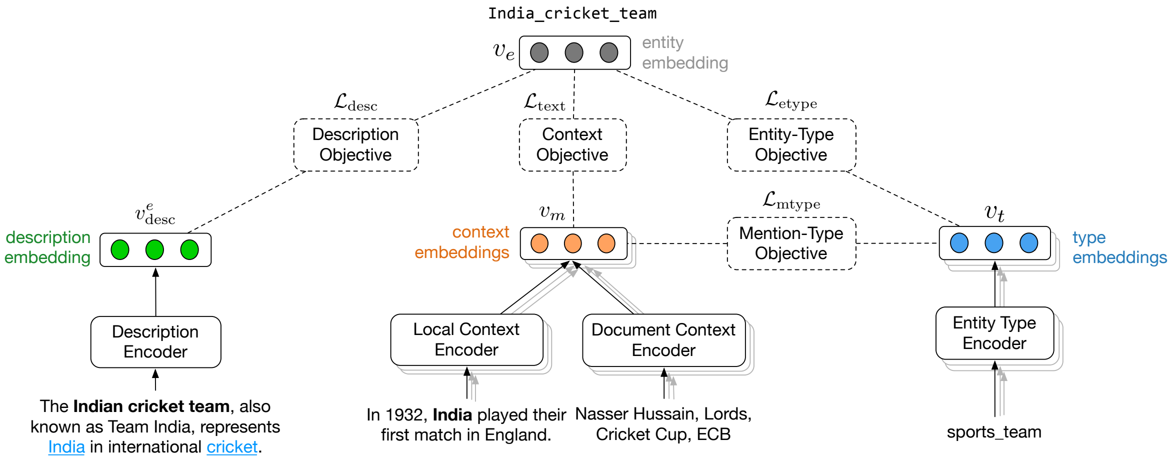

Figure 1: **Overview of the Model** (§ 3): Each entity has a Wikipedia description, linked mentions in Wikipedia (only one shown), and fine-grained types from Freebase (only one shown). We encode local and document-level mention contexts (§ 3.1), entity-description (§ 3.2), and fine-grained entity-types (§ 3.3 & § 3.4). Joint optimization (§ 3.5) over these provides the unified entity representations $\{v_e\}$.

such as, from the structured KB for KB completion (Bordes et al., 2011, 2013; Yang et al., 2014; Lin et al., 2015), or from both structured KBs, and text for relation extraction (Toutanova et al., 2016; Verga et al., 2016a). However, since it is not trivial for these models to incorporate new entities to the KB, few recent approaches alleviate this issue by representing entities as a composition of words in their names (Socher et al., 2013), relations they participate in (Verga et al., 2016b), or their types (Das et al., 2017), but do not use multiple sources of information jointly. In our work, we use structured knowledge (types) as well as unstructured knowledge (description and context) to learn entity embeddings for entity linking, and show that it extends to new entities.

3 Jointly Embedding Entity Information

Knowledge bases contain different kinds of information about entities such as textual description, linked mentions (in Wikipedia), and types (in Freebase). For accurate linking, it is often necessary to combine information from these various sources. Here, we describe our model that encodes information about the set of entities $\mathcal{E}$ using dense unified representation for linking ($v_e \in \mathbb{R}^d, \forall e \in \mathcal{E}$). In particular, we use existing mentions in Wikipedia to encode the context (§ 3.1), textual descriptions from Wikipedia to encode background information (§ 3.2), and fine-grained types from Freebase as structured topical knowledge (§ 3.3). Figure 1 provides an overview of our model.

3.1 Encoding the Mention Context, C

Consider the example mention in Figure 1 that contains two mentions, "India" and "England". In order to disambiguate "India" to the correct entity, a linking system would need to utilize both the local context (*played* and *match*), and the document context (to identify the sport). However, the model needs to represent context such that the semantics are preserved, e.g. "England" should not be linked to a sports team even though it shares the context with "India". In this section, we describe how we encode these two types of context, using a LSTM-based encoder to capture the lexical and syntactical local-context of a mention (v_m^{local}), and a feed-forward network to encode the document-level topical knowledge (v_m^{doc}), and combine them in a single representation for each mention (v_m).

Local-Context Encoder Given a mention m in the sentence $s = w_1, \ldots, m, \ldots, w_N$, we use LSTM encoders on the left ($w_1, \ldots, m$) and right ($m, \ldots, w_N$) contexts of the mention separately, and then combine it to form the local context representation of the mention (Fig. 2). More precisely, we formulate an LSTM as $h_i, s_i = \text{LSTM}(u_i, h_{i-1}, s_{i-1})$, $u_i \in \mathbb{R}^{d_w}$ is the input embedding of the i-th token in the sequence, and $h_{i-1}, s_{i-1} \in \mathbb{R}^l$ is the previous output and the cell state of the LSTM, respectively. The left-LSTM is applied to the sequence ($w_1, \ldots, m$) with the last output $\overrightarrow{h^l_m}$, while a different right-LSTM is ap-

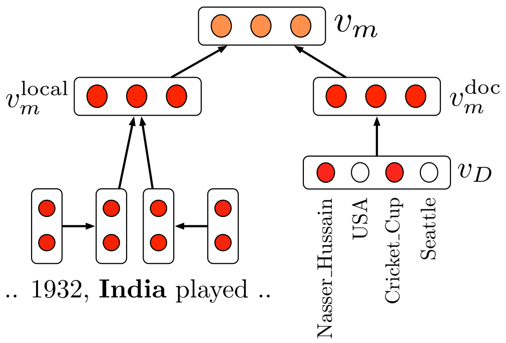

Figure 2: Overview of the mention context encoder

plied to the sequence $(w_N, \ldots, m)$[2] to produce $\overleftarrow{h^r_m}$. We concatenate these output $[\overrightarrow{h^l_m}, \overleftarrow{h^r_m}]$ and pass it through a single layer feed-forward network[3] to produce the local context representation of the mention (v_m^{local}), where $v_m^{\text{local}} \in \mathbb{R}^{D_m}$. Note that this encoder will produce different representations for different mentions in the same sentence.

Document-Context Encoder To represent the document context of a mention m, we use a bag-of-mention surfaces representation, $v_D \in \{0,1\}^{|V_G|}$, of the document, similar to Lazic et al. (2015). The vocabulary V_G consists of all mention surfaces seen in our training data, e.g. *USA*, *Nasser_Hussain*, *Pearl_Jam* etc. Such a representation helps capture the topical and entity coherence information in the document by utilizing co-occurrence between entity surface forms. This sparse vector v_D of bag-of-mention surfaces is compressed to a low-dimensional representation $v_m^{\text{doc}} \in \mathbb{R}^{D_m}$ using a single layer feed-forward network.

Mention-Context Encoder We combine the local (v_m^{local}) and document (v_m^{doc}) level context vectors by concatenating them, and passing them through a single-layer feed-forward network to obtain the mention context embedding $v_m \in \mathbb{R}^d$. In order to learn the entity representation v_e such that it encodes all of its mentions' contexts, we introduce an objective that encourages the context representation v_m to be similar to v_e (where mention m is a link to entity e), and dissimilar to other candidates[4]. Precisely, we maximize the probability of predicting the correct entity from the mention-context vector as $P_{\text{text}}(e|m) = \frac{\exp(v_m \cdot v_e)}{\sum\limits_{c_k \in C_m} \exp(v_m \cdot v_{c_k})}$, where C_m is the set of candidate entities. Given all the mentions in Wikipedia, we jointly optimize the entity representations, and the context encoders by maximizing the following log-likelihood:

$$\mathcal{L}_{\text{text}} = \frac{1}{M} \sum_{i=1}^{M} \log P_{\text{text}}(e_{m^{(i)}} | m^{(i)}) \qquad (1)$$

where $m^{(i)}$ is the i^{th} mention in the linked data, and $e_{m^{(i)}}$ is the entity the mention refers to.

3.2 Encoding Entity Description, D

The textual description about entities in Wikipedia can provide a useful source of background information about the entity, and thus has been used in many existing linking systems. Given the description as a sequence of words, we first embed each word to a d_w-dimensional vector resulting in a sequence of vectors $w_1, \ldots, w_n$. To encode this description as a fixed size vector, we use a Convolution Neural Network (CNN), similar to Francis-Landau et al. (2016), with global average pooling, to obtain $v^e_{\text{desc}} \in \mathbb{R}^d$.

In order for the entity representation v_e to encode its description, we use a similar objective as in the previous section § 3.1, i.e. we maximize the probability $P_{\text{desc}}(e|v^e_{\text{desc}})$, and learn the parameters by maximizing the log-likelihood $\mathcal{L}_{\text{desc}}$, defined similarly as (1).

3.3 Encoding Fine-Grained Types, E

Fine-grained types provide a source of structured information that is quite readily available, often more easily than the description or linked data (e.g. Freebase contains tens of millions of entities with types but Wikipedia only contains descriptions for a few million). These types have been shown to be quite useful for linking (Ling et al., 2015), since an accurate prediction of types from the mention, and its match with the entity types can often resolve many challenging ambiguities.

Here, we focus on being able to represent the different types at the entity level, leaving mention-level type information to the next section. Each entity has multiple types $T_e \subset \mathcal{T}$ from the type set $\mathcal{T}$ introduced by Ling and Weld (2012). We compute the probability $P(t|e)$ of type t being relevant to entity e as $\sigma(v_t \cdot v_e)$, where σ is the sigmoid function, $v_e \in \mathbb{R}^d$ is the entity representation, and $v_t \in \mathbb{R}^d$ is the embedding of type t in $\mathcal{T}$. We maximize the log-likelihood of the type information to

[2] We reverse the token sequence in the right context so that right-LSTM starts at the last token and ends at the mention.

[3] We use rectified linear unit (ReLU) as the non-linear activation throughout this paper.

[4] Details on candidate generation in Sec 4

jointly learn entity and type representations:

$$\mathcal{L}_{\text{etype}} = \frac{1}{|\mathcal{E}|} \sum_{e \in \mathcal{E}} \log \prod_{t \in T_e} P(t|e) \prod_{t' \notin T_e} (1 - P(t'|e))$$

3.4 Type-Aware Context Representation, T

Apart from being able to represent the types of the entities, it is also important for our linker to be able to represent the type information at the mention level. In the example in Fig. 1, although the mention “India” is prominently used to refer to the *country*, it is evident from the sentence that it refers to a *Sports Team*. The context-encoder captures this information in an unstructured manner, thus it will be useful for the encoder to directly utilize this supervision. This is a similar setup as Ling et al. (2015) and Shimaoka et al. (2017) that use noisy distant supervision to train a fine-grained type predictor for mentions.

In order for the context encoders, and type embeddings to directly inform each other, we introduce an objective $\mathcal{L}_{\text{mtype}}$ between every v_m and v_t if type t belongs to T_e for the entity e that m refers to. This objective is similar to $\mathcal{L}_{\text{etype}}$ from § 3.3.

3.5 Learning Unified Entity Representations

In the sections above we described different encoder models to capture entity-context information (local- and document-level), entity-description from a KB, and fine-grained types in a single entity representation vector. To learn the entity representations, and parameters of the encoders, we jointly maximize the total objective:

$$\{v_e\}, \Theta = \underset{\{v_e\},\Theta}{\operatorname{argmax}} \mathcal{L}_{\text{text}} + \mathcal{L}_{\text{desc}} + \mathcal{L}_{\text{etype}} + \mathcal{L}_{\text{mtype}}$$

where $\{v_e\}$ is the set of entity representations, and Θ is set of parameters for the different encoders. One advantage of having such a joint, modular objective is that it is robust to missing information, i.e. entities with missing mentions, types, or descriptions will still obtain accurate representations learned using other sources of information.

4 Entity Linking

Given a document, and mentions marked in it for disambiguation, we perform a two-step procedure to link them to an entity. First, we find a set of candidate entities, and their *prior* scores using a pre-computed dictionary. We then use our mention-context encoder to estimate the semantic similarity of each mention with the vector representations of each entity candidate, and combine the results from the two sources for making linking decisions.

A typical KB contains millions of entities, which makes it prohibitively expensive to compute a similarity score between each mention and all entities in the KB. Prior work has shown that, for a given mention, aggressively pruning the set of possible entities to a small subset hurts performance only negligibly, while making the linker extremely efficient. For each mention m, we generate a set of candidate entities $C_m = \{c_j\} \subset \mathcal{E}$ using CrossWikis (Spitkovsky and Chang, 2012), a dictionary computed from a Google crawl of the web that stores the frequency with which a mention links to a particular entity. To generate C_m we choose the top-30 entities for each mention string, and normalize this frequency across the chosen candidates to compute $P_{\text{prior}}(e|m)$. In the literature, such a dictionary is often built from the anchor links in Wikipedia (Ratinov et al., 2011; Hoffart et al., 2011) but Ling et al. (2015) show using CrossWikis gives improved prior scores and candidate recall.

For each mention m, we use our learned mention-context encoder from § 3.1 to encode the mention's context as v_m, and estimate the distribution over the candidates using $P_{\text{text}}(e|m)$. We treat these two pieces of evidence; pre-computed prior probability, and the context-based probability, as independent, disjunctive sources of signal, and thus combine them to compute $P(e|m)$ as:

$$\begin{aligned} P(e|m) &= P_{\text{prior}}(e|m) + P_{\text{text}}(e|m) \\ &\quad - (P_{\text{prior}}(e|m) * P_{\text{text}}(e|m)) \qquad (2) \\ \hat{e}_m &= \underset{e \in C_m}{\operatorname{argmax}}\ P(e|m) \qquad (3) \end{aligned}$$

where $\hat{e}_m$ is the predicted entity that the mention m should be disambiguated to.

5 Evaluation Setup

Here we provide a detailed description of how we train our models, benchmark datasets, linking systems we compare to, and the evaluation metrics.

Training Data Our primary source of information about the entities is Wikipedia (dump dated 2016/09/20). We use existing links in Wikipedia, with the anchors as mentions, and links as the true entity, as input to the context encoder (see § 3.1). As the description of each entity (§ 3.2), we use the first 100 tokens of the entity's Wikipedia page (same as Francis-Landau et al. (2016)). To obtain entity types (see § 3.3), we extract the types for each entity from Freebase and map them to the 112 fine-grained types introduced by Ling and Weld (2012). For context and description encoders, we use pre-trained 300-dimensional case-sensitive word embeddings by Pennington et al. (2014) as the first layer that is not updated during training.

Hyper-parameters We perform coarse-grained tuning of the hyper-parameters using a fraction of the training data. The vectors for the entities, types, contexts, and descriptions are of size $d = 200$. The size of the local context encoder LSTM hidden layer l, local context output, and the document-context encoder output D_m is set to $100 (= l = D_m)$. The document context vocabulary contains $|V_G| = 1.5$ million strings. We use dropout (Srivastava et al., 2014) with a probability of 0.4. Additionally, we use word-dropout where we replace a random subset of tokens (mention-strings) in the local (document) context with "unk" (rate of 0.4 and 0.6 for local and document context respectively). We use Adam (Kingma and Ba, 2014) for optimization, with learning rate 0.005 and mini-batches of size 1000.

Existing Approaches We compare our approach to the following five entity-linking models: (1) **Plato** (Lazic et al., 2015), an unsupervised generative model that uses indirect-supervision from Wikipedia and an additional corpus of 50 million unlabeled webpages, (2) **Wikifier** (Ratinov et al., 2011), an unsupervised linker that uses hand-crafted features to rank candidates, (3) **Vinculum** (Ling et al., 2015), a modular, unsupervised pipeline system, (4) **AIDA** (Hoffart et al., 2011), a supervised linker trained on CoNLL data and uses hand-crafted features, and (5) **BerkCNN** (Francis-Landau et al., 2016), a recent neural supervised approach that has variants that use hand-crafted features.

Evaluation Setup We evaluate our approach on the following four datasets: CoNLL-YAGO (Hoffart et al., 2011), ACE 2004 (NIST, 2004; Ratinov et al., 2011), ACE 2005 (NIST, 2005; Bentivogli et al., 2010), and Wikipedia (Ratinov et al., 2011). For each of these datasets, we use the standard test/development splits, but do not use any information from the training splits. End-to-end entity linking systems such as Vinculum and Wikifier perform an NER-style F1 evaluation where a prediction is only considered correct if the system mention boundaries match the gold annotation, and the predicted link is correct (we compare against these by extracting mentions with Stanford-NER). On the other hand, systems like Plato, AIDA, and Berkeley-CNN assume mentions are provided, and evaluate using the linking accuracy for gold-mentions. Further, the approaches we compare here (including ours) do not predict NIL entities for the datasets evaluated on.

	CoNLL		**ACE05**	**Wiki**
	Test	**Dev**		
Plato (Sup)	79.7	-	-	-
Plato (Semi-Sup)	86.4	-	-	-
*AIDA**	*81.8*	-	-	-
*BerkCNN:Sparse**	*74.9*	-	*83.6*	*81.5*
*BerkCNN:CNN**	*81.2*	*86.91*	*84.5*	*75.7*
*BerkCNN:Full**	*85.5*	-	*89.9*	*82.2*
Priors	68.5	70.9	81.1	78.1
Model C	81.4	83.4	83.7	86.1
Model CD	81.0	83.2	85.8	86.1
Model CT	82.3	83.9	86.5	88.2
Model CDT	82.5	85.6	86.8	88.0
Model CDTE	82.9	84.9	85.6	89.0

Table 1: **Entity Linking Performance:** Accuracy of existing systems, and variations of our model on gold mentions. The model using context information is labeled C, entity-description as D, context-typing as T, and entity-type encoding as E. Existing models marked in *Italics** train domain-specific linkers for each dataset. Our system performs competitively to these systems, and outperforms Plato (Sup) that uses the same indirect supervision.

6 Results

In this section we present various experiments to evaluate the performance of our proposed entity-linking system. Specifically, we focus on the following questions: (1) how effective is our model in combining different information on standard linking benchmarks, without requiring domain specific information (§ 6.1), (2) is our model able to accommodate unseen entities by using their types, or description, without re-training the entity representations (§ 6.2), and (3) how does the model perform on fine-grained mention typing, a task it is not directly trained for, compared to approaches designed for the task (§ 6.3). Further, Sec 6.4 presents examples to show the effect of encoding different kinds of information in a unified entity representation.

	F1	Accuracy
AIDA	77.8	-
Wikifier	85.1	-
Vinculum	88.5	-
Model C	88.9	93.1
Model CDT	89.8	93.9
Model CDTE	90.7	94.3

Table 2: **Results for ACE-2004**: F1 is calculated for predicted mentions, and accuracy on gold-mentions. Results for Wikifier and AIDA are from (Ling et al., 2015). All systems use the same mention extraction protocol showing the difference in F1 is due to linking performance.

6.1 Entity Linking

In Table 1 we present linking accuracy for our models that vary in the information they use. We see that the model that only encodes the context-information, Model C ($\mathcal{L} = \mathcal{L}_{\text{text}}$) consistently performs better than picking the entity with the highest prior probability from CrossWikis, indicating that the model is able to utilize the context across datasets. On incorporating the description with context (Model CD) we see improvement in the performance on ACE-2005, but slight decrease in CoNLL, suggesting the entity descriptions are not extremely useful for the latter (it contains rare entities, many short and incomplete sentences, and specific entities as annotations for metonymic mentions, as also observed by Ling et al. (2015)). On introducing the entity type-aware loss in Model CT to the context-only model, we see significantly improved results for all datasets, demonstrating that explicitly modeling fine-grained types helps learning a better context encoder and, in turn, type-aware entity representations. Combining descriptions with this model (Model CDT) shows further gains in accuracy indicating that our model is able to exploit complementary information from the two sources. Finally, on introducing explicit entity-type encoding, Model CDTE performs the best on two of the four datasets. As we will see in § 6.2, encoding entity-type information also allows our models to easily generalize to new entities.

On comparison to existing systems we see that all our variants outperform Plato's indirectly-supervised model trained on Wikipedia, which is the same information our Model C and CD use. Their semi-supervised model, that is additionally trained on 50 million web-pages, performs much better. In comparison to AIDA and Berkeley-CNN, that train separate models on respective datasets, we perform better than AIDA and Berkeley-CNN's *sparse* and neural model. On combining features from CNN to the *sparse* model, the Berkeley-CNN models for each dataset outperform our model, but are unlikely to generalize across the datasets[5].

Method	Accuracy
Random Guessing	16.7
Random Embeddings	34.0
Entity Description	65.1
Fine-Grained Types	73.7
Description + Types	79.5

Table 3: **Cold-Start Entities:** Linking new entities by using different information to learn their embeddings. Our model is able to jointly utilize description and type information better.

In Table 2 we present results for our models on ACE-2004. Our model outperforms the Wikifier and Vinculum systems that only use information from Wikipedia, and AIDA, by a significant margin, indicating its possible over-fitting to the CoNLL domain. Hence, it shows our model's ability to perform accurate linking across different datasets without using domain-specific information.

6.2 Cold-Start Entities

In realistic situations, new entities are regularly added to the knowledge base with little or no linked data for them. Hence, it is important for any information extraction system that learns entity representations to be easily extendable for such entities without needing to be re-trained. In this section, we consider the use of our approach to this setting.

In particular, for each such new entity, we need to determine their embedding using only their description and/or type information. For a new entity for which only the description is available, we directly set its embedding to be the output of the entity-description encoder without any need for learning. If only fine-grained types are available, we learn the new entity-embedding by optimizing the objective $\mathcal{L}_{\text{etype}}$. In case both description and types are available, we jointly maximize the similarity of the entity embedding with the output of the entity-description, and the type encoders (i.e. optimize $\mathcal{L}_{\text{desc}}$ and $\mathcal{L}_{\text{etype}}$). Note that we only learn the embeddings of each new entity, keeping all other

[5] Ling et al. (2015) show that AIDA is unable to perform well on datasets it has not been trained on.

Models	Acc.	Macro F1	Micro F1
FIGER	47.4	69.2	65.5
SSIR-LSTM	55.6	75.1	71.7
SSIR-Full	59.6	78.9	75.3
Our Model	57.7	72.8	72.1

Table 4: **Typing Prediction:** Performance on the FIGER (GOLD) dataset. Our performance is competitive with FIGER (Ling and Weld, 2012) and neural-LSTM model of Shimaoka et al. (2017). Their SSIR-Full model that uses a biLSTM layer, an attention layer, combined with hand-crafted features is state-of-art for this task.

parameters of our model (Model CDTE) fixed.

To evaluate this setting of new entities, we randomly select 1000 rare entities from Wikipedia that are not used during training. Among all mentions of these entities in Wikipedia, we only keep the mentions for which our candidate generation generates more than one candidate, resulting in 3791 mentions. On average, each mention had 6 candidate entities, and further, as priors are not available in this setting, we only rely on the context probability for linking, making this a challenging task.

We present the results of using different types of information about the entity for this data in Table 3. It is surprising that randomly initialized embeddings for these new entities perform better than random guessing, suggesting our model is sometimes able to eliminate the wrong candidates purely based on their learned embedding, i.e. an entity with a random embedding has a higher likelihood of being the correct entity. More importantly, we see that our model variants that utilize the available entity information are able to link much more accurately (47-60% error reduction). Further, using both description and types results in the best embeddings for these new entities ($\sim$ 80% accuracy).

6.3 Fine-Grained Typing

Since entity embeddings are trained to be both, context and type-aware, we evaluate whether they can be used to predict fine-grained types for mentions from context (using v_m and v_t). Compared to existing systems trained specifically for this task, embeddings from our approach (Model CDTE) performs competitively (see Table 4). In particular, our model performs better than the neural-LSTM model of Shimaoka et al. (2017), suggesting that our multi-task linking, and typing loss facilitates effective encoding of mention contexts.

12th Asian Nations Cup finals are hosted by **Lebanon** until this October 29. **Model CD:** Lebanon_football_team **Model CT:** Lebanon *(correct)* **Model CDTE:** Lebanon *(correct)*
Yugoslav midfielder **Petrovic** scored twice as PSV Eindhoven romped to a 6-0 win. **Model CD:** Zeljko_Petrovic *(correct)* **Model CT:** Vladimir_Petrovic **Model CDTE:** Zeljko_Petrovic *(correct)*
Ince was clambering over a wall at the Republican stadium during an under-21 clash. **Model CD:** Ince **Model CT:** Tom_Ince **Model CDTE:** Paul_Ince *(correct)*

Table 5: **Example predictions by our models:** Model CT (Ex.1) and CD (Ex.2) predict correctly when correct type prediction or background knowledge is sufficient, respectively. Only Model CDTE (Ex.3) predicts correctly when combination of context, types, and background knowledge is required.

6.4 Example Predictions

In Table 5 we show the prediction from different variants of our model for a few example mentions. In the first example, detecting the type of the mention is crucial, and thus we see both Model CT and CDTE are able to predict accurately. On the other hand, predicting the type of the mention is not especially useful in Example 2, and background factual knowledge from the entity description is needed (which models CD and CDTE are able to encode). Example 3 shows a challenging example where the appropriate combination of context, type prediction, and background knowledge is needed, that our Model CDTE is able to combine.

7 Conclusion

Motivated by the need to provide accurate entity-linking systems that are able to incorporate multiple sources of information, and do not require domain-specific datasets or hand-crafted features, we presented a novel neural approach to linking. We proposed a compositional training objective to learn unified entity embeddings that encode the variety of information available for each entity: its unstructured textual description, local and document contexts for its mentions, and sets of fine-grained types attached to it. The joint formulation allows the model to fruitfully combine the various sources of information, providing accurate linking on multiple datasets, generalization to new entities with missing linked data, and the use of entity embeddings for related tasks such as type prediction.

There are a number of avenues for future work. Further research will include encoding more structured knowledge about the entities, such as their relations to other entities, to make their representations semantically richer. We will investigate how we can use unstructured resources, such as the corpus of unlabeled webpages used by Plato, and noisy supervision from the Wikilinks corpus (Singh et al., 2012) in order to further improve the model. We will also evaluate our approach on substantially varied domains, such as discussion forums, and social media posts.

Abstract

Mining biomedical text offers an opportunity to automatically discover important facts and infer associations among them. As new scientific findings appear across a large collection of biomedical publications, our aim is to tap into this literature to automate biomedical knowledge extraction and identify important insights from them. Towards that goal, we develop a system with novel deep neural networks to extract insights on biomedical literature. Evaluation shows our system is able to provide insights with competitive accuracy of human acceptance and its relation extraction component outperforms previous work.

1 Introduction

Biomedical literature offers a rich set of knowledge sources to discover important facts and find associations among them. For instance, MEDLINE contains over 18 million references to articles published since 1946 and sourced from over 5500 journals worldwide (Simpson and Demner-Fushman, 2012). Two major processing tasks performed on the biomedical text are: (1) identify and classify biomedical entities (NER) into predefined categories such as proteins, genes, or diseases, and (2) infer pair-wise relationships among named entities e.g., protein-protein interaction (Poon et al., 2014), gene-protein, and medical problem-treatment.

This paper presents a system that processes biomedical text to extract two specific types of relationships among biomedical entities: (a) cause-effect and (b) correlation.

This system is motivated by the need to better automate biomedical knowledge extraction and identify important information from them, as new scientific findings appear across a large collection of publications. For instance, given user sleep patterns, existing biomedical research can be better utilized to provide *insights*: inform about potential *effect* (e.g., "*diabetes*", "*obesity*") due to the *cause* (e.g., "*sleep disorder*") and suggest appropriate treatment.

Since biomedical articles usually have title and abstract summarizing the contents of the full-text article, we focus on extracting the two relationship types from them. Unfortunately, mining this summary data still poses several key challenges. Similar to full-text, this data comprises unstructured text with domain-specific vocabulary, issues of synonymy (e.g., *"heart attack"* vs. *"myocardial infarction"*), acronyms, abbreviations and rapidly evolving terminology due to new scientific discoveries. While the titles are short and informative, they do not contain the key information that would be contained in the abstract.

Many of these challenges are also applicable for biomedical relation extraction. Further, identifying particular relation types is challenging because relations are expressed as discontinuous spans of text , and the relation types are typically application-specific. Finally, there is often little consensus on how to best annotate relation types resulting in lack of high quality annotated corpora for training.

In this study, we develop neural networks with novel similarity modeling for better causality/correlation relation extraction, as we map the extraction task into a representational similarity measurement task in the vector space. Our approach innovates in that it explicitly measures both relational and contextual similarity among representations of named entities, entity relations and contexts. Our system also provides a novel combination of recognizing named entities, predicting

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2691–2701
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

relationships (insights) between extracted entities, and ranking the output. We conduct human evaluations of the system to show it is able to extract insights with high human acceptance accuracy, and on a SemEval task evaluation its causality/correlation relation extraction compares favorably against previous state-of-the-art work.

1.1 Contributions

1. We build an end-to-end system to extract insights from biomedical literature.
2. We innovate in similarity measurement modeling with deep neural networks for better causality/correlation relation extraction.
3. Our human evaluation show our system can achieve competitive acceptance accuracy.

2 Related Work

Most previous work in BioNLP focused on extraction of biomedical concepts (Craven, 1999; Finkel et al., 2005; Poon and Vanderwende, 2010; Simpson and Demner-Fushman, 2012; Liu, 2016), such as drug or protein names. We also conduct relation extraction on general named entities, such as "*smoking*" or "*sleep quality*". Kabiljo et al. (2009) compared pattern-matching techniques against a baseline regular expression approach for gene/protein entity extraction. But existing tools for relation extraction are not as comprehensive as entity recognition tools.

Medical dictionaries and resources are heavily utilized by previous work. For instance, Chen et al. (2008) extracted disease-drug relation pairs with MedLEE (Friedman et al., 2004) system for clinical information extraction of EHR records. Liu et al. (2015) developed a text-mining system to search for associations among human diseases, genes, drugs, metabolites and toxins against large collections of text-rich biological databases. Previous research efforts also lead to semantic representation program SemRep (Rindflesh and Fiszman, 2003), which exploits biomedical domain knowledge and linguistic analysis of biomedical text. Other unconventional resource such as web query logs are also utilized (Paparrizos et al., 2016) to provide early warnings about the presence of devastating diseases.

Feature engineering was the dominant approach in most biomedical relation extraction work with machine learning techniques (Dogan et al., 2011; Yala et al., 2016); different sparse features were explored. For example, word n-gram features, knowledge-based features from medical dictionaries and word position features. Our work instead propose neural network models that do not require sparse features as in most previous work.

Algorithm 1 System Overview

```
 1: Input: Biomedical article title and abstract
 2: Preprocess the input texts
 3: for each sentence of the input do
 4:     Identify all possible named entities
 5:     for each named entity pair $(\vec{A}, \vec{B})$ do
 6:         if causality/correlation holds then
 7:             Extract and Score $(\vec{A}, \vec{B})$
 8:         end if
 9:     end for
10: end for
11: Rank all extracted $(\vec{A}, \vec{B})$ pairs
12: return top ranked entity pairs
```

Recent shift from feature engineering to model engineering with neural networks has significantly improved accuracy on many NLP tasks. Jagannatha and Yu (2016) adopted an LSTM model for medical entity detection given patient EHR records. There are recent work with the use of deep reinforcement learning on healthcare study (Li, 2017). Our approach is inspired by recent embedding learning work to jointly represent texts and knowledge base (Toutanova et al., 2015, 2016), previous work on embedding transfer learning (Bordes et al., 2013) and noise-contrastive estimation (Rao et al., 2016). Lastly our work models insight extraction as a similarity measurement problem, and is inspired by similarity measurement work (He et al., 2016; He and Lin, 2016) on pairwise word interaction modeling with deep neural networks.

3 System Overview

We provide a recipe to build a system for biomedical insight extraction and use it as a guide for the remainder of this paper (Algorithm 1).

To make our discussion concrete, we will use a sample biomedical article in Example 1. Given the text, at line 4 of Algorithm 1 we firstly look for all named entities using a shallow parser and public medical dictionaries (see details in Section 4). Many named entities could be found, for example, *"clinical study"*, *"sleep disturbances in middle-aged men"* and *"diabetes"*. Next given any pair of previously extracted entities within a sentence,

RESEARCH METHODS: *A group of 6,599 initially healthy, nondiabetic middle-aged men took part in a prospective, population-based study. The incidence of diabetes during a mean follow-up of 14.8 years was examined in relation to self-reported difficulties in falling asleep.*
RESULTS: *A total of 615 subjects reported either difficulties in falling asleep or use of hypnotics (seen as makers of sleep disturbances). Among those, 281 of the men developed diabetes during the follow-up period. The clinical study suggests sleep disturbances in middle-aged men are likely associated with diabetes.*

Example 1: Sample Text

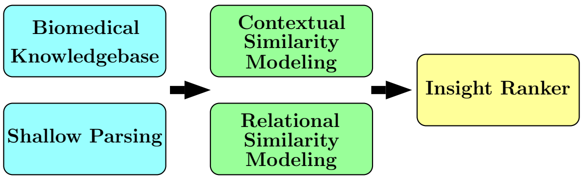
at line 6 our neural network-based relation extractor checks if a valid causality/correlation relationship exists (Section 5). For example, our models can identify that the entity *"sleep disturbances in middle-aged men"* has a correlation relationship with *"diabetes"* but not with *"clinical study"*. Later each valid entity pair is scored via the ranking component at line 7 (Section 6). In the final step, the system returns top ranked insight(s) to users: "*sleep disturbances in middle-aged men* → *diabetes*" given this example.

Figure 1 presents the system which consists of three major neural network-based components: (1) a named entity extractor, (2) a causality/correlation relation extractor, and (3) an insight ranker. Our system reads in biomedical texts, then provides insights in the end. We primarily innovate in the relation extraction component. Next, we describe each of these components in detail.

4 Named Entity Extraction

Named entity extraction in biomedical domain is challenging due to the domain-specific and rapidly evolving terminology. For example, *"Diabetes mellitus type 1"*, *"Type 1 diabetes"*, *"IDDM"*, or *"juvenile diabetes"* all express the same concept. Given frequent evolution of entity naming for new drugs, diseases or abbreviations, this task becomes more complicated.

Most existing off-the-shelf biomedical entity recognizers narrowly focus on specific biomedical terms. Instead we aim to improve the system recall by extracting both specific biomedical concepts such as *"gene tmem230"* or *"prostate cancer"* as well as general noun phrases such as *"sleep quality"*, *"daily exercises"*, or *"men with diabetes"*. Thus the scope of the system is broader.



Biomedical Knowledgebase
Shallow Parsing
Contextual Similarity Modeling
Relational Similarity Modeling
Insight Ranker

Figure 1: Three major components of the system.

We design an entity extractor by using both an in-domain medical knowledge base for keyword matching, and a domain-independent neural network-based shallow parser for entity boundary detection. We present the procedure below:

1. We firstly use a large public dictionary, *Metathesaurus* of the Unified Medical Language System (UMLS) (Bodenreider, 2004) to obtain in-domain biomedical terms. UMLS *Metathesaurus* is a set of dictionaries providing large collections of biomedical vocabularies. We extract over 3.3 million of biomedical terms from UMLS, then utilize the *Aho Corasick* pattern matching algorithm to create a dictionary lookup tool. Our tool can efficiently locate all UMLS terms given input texts, since it has a linear complexity due to its trie tree data structure.
2. We also use a neural network-based shallow parser (Collobert et al., 2011) to identify boundaries of general noun phrases, which are not limited to biomedical terms. Usage of shallow parser is to improve system recall on named entity recognition.
3. Our named entity extraction component aims to locate all entities of input texts. The result list is an output concatenation of both step 2 and 3, and is later provided to the causality/correlation relation extraction component for further processing. If entity overlaps exist, only phrases with longest matching sequence are extracted.

Our insight extraction system adopts a coarse-to-fine design approach. First, we focus on improving recall for the entity extraction task. Then we show how the causality/correlation relation extraction component (Sec. 5) processes extracted named entities to achieve high precision.

5 Relation Extraction as Similarity Measurement

We first provide our model design intuition: if a causality/correlation relationship holds between two named entities, then representations of the two entities should be semantically similar and close to the representation of the relation in a low-dimensional vector space. Therefore we map the causality/correlation relation extraction into a similarity measurement task in the vector space.

Our novel approach learns representations of named entities $(\vec{A}, \vec{B})$, context words and the relation vector $\vec{R}$, then explicitly measures two aspects of the similarity: 1) **relational similarity** between entities and relation (Sec. 5.2); plus, 2) **contextual similarity** between entities and sentence context (Sec. 5.3).

The intent of our approach is to enforce such structure of the vector space: as the similarity among entities, relation and contexts gets stronger, a fit of all should be observed for better causality/correlation relation extraction. We develop two neural network models with such property; both are utilized in the relation extraction component of the system.

We define input sentence representation $S \in \mathbb{R}^{\ell \times d}$ to be a sequence of ℓ words, each with a d-dimensional word embedding vector. $x_t \in \mathbb{R}^d$ denotes the embedding vector of the t-th word $(t \in [1, l])$ in S. Model details are described in the following sections.

5.1 Context Modeling

Different words occurring in similar contexts should have a higher chance to contribute to similarity measurement and relation extraction. We use bidirectional LSTMs (BiLSTM) for context modeling as a basis for all following models.

LSTM (Hochreiter and Schmidhuber, 1997) is a special variant of Recurrent Neural Networks (Williams and Zipser, 1989). At time step t, given an input word x_t and previous LSTM hidden state h_{t-1}, $LSTM(x_t, h_{t-1})$ outputs current hidden state $h_t \in \mathbb{R}^{dim}$. BiLSTM consists of two LSTMs that run in parallel in opposite directions. The BiLSTM hidden state $h_t^{bi} \in \mathbb{R}^{2dim}$ is a concatenation of forward LSTM's h_t^{for} and backward LSTM's h_t^{back}, representing contexts of input word x_t in the sentence. We define *concat* operation and output sentence context representation $H^S \in \mathbb{R}^{\ell \times 2dim}$ below:

$$h_t = LSTM(x_t, h_{t-1}) \tag{1}$$

$$h_t^{bi} = concat(h_t^{for}, h_t^{back}) \tag{2}$$

$$H^S[t] = h_t^{bi} \tag{3}$$

Function 1 $SimiScore(\vec{A}, \vec{B}, \vec{R})$

```
$conC = concat(\vec{A}, \vec{B})$
$entityC = W^C \cdot conC$
$relationT = W^D \cdot \vec{R}$
$dist = W^{di} \cdot tanh(entityC + relationT)$
return $dist$
```

Context modeling with BiLSTM allows our following model components to be built over contexts rather than over individual words. Given named entity positions of the sentence, we get $\vec{A}$ and $\vec{B}$ from context H^S.

5.2 Relational Similarity Modeling

Relational similarity modeling focuses on interactions between named entities and relations in the vector space. When the named entity $\vec{A}$ goes through a transformation process induced by the relation $\vec{R}$, our intent of relational similarity modeling is to force the transformed entity to be translated to the other named entity $\vec{B}$ in the same vector space so that the relation $\vec{R}$ holds between the two named entities.

We show the following objective function of our relational similarity modeling:

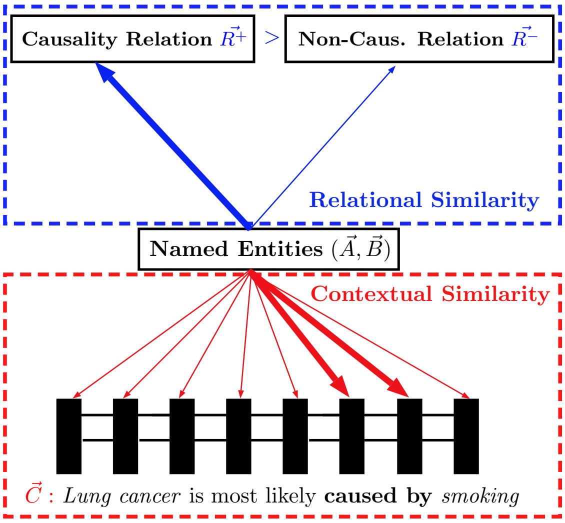
$$\vec{A} + \vec{B} - \vec{R} \simeq 0 \tag{4}$$

To model the transformation process in Equation 4, we need to know how to measure the similarity of the triplet $(\vec{A}, \vec{B}, \vec{R})$. Therefore we develop a similarity measurement function $SimiScore(\vec{A}, \vec{B}, \vec{R})$ with learnable weights (W^*), the similarity function takes an input named entity pair of $(\vec{A}, \vec{B})$ and a relation $\vec{R}$, returns a similarity score $dist \in R^1$ representing how semantically close $(\vec{A}, \vec{B}, \vec{R})$ are, as in Function 1.

We utilize a ranking approach during training to incorporate the constraint of Equation 4 into the relational similarity model. Our goal is to learn a function $SimiScore(\cdot)$ so that the positive triplet $(\vec{A}, \vec{B}, \vec{R^+})$ is assigned a larger score than that of the negative triplet $(\vec{A}, \vec{B}, \vec{R^-})$:

$$SimiScore(\vec{A}, \vec{B}, \vec{R^+}) > SimiScore(\vec{A}, \vec{B}, \vec{R^-}) \tag{5}$$

where R^+ denotes the positive causality/correlation relation, R^- denotes a non-causality/non-correlation relation. The ranking approach maximizes the similarity score between the entity pair $(\vec{A}, \vec{B})$ and a positive relation $\vec{R}^+$ while minimizing the score with the negative $\vec{R}^-$,



Causality Relation $\vec{R}^{+}$
>
Non-Caus. Relation $\vec{R}^{-}$
Relational Similarity
Named Entities $(\vec{A}, \vec{B})$
Contextual Similarity
$\vec{C}$: *Lung cancer* is most likely **caused by** *smoking*

Figure 2: Our causality/correlation relation extraction component models both relational similarity (blue) and contextual similarity (red). Thicker arrows indicate stronger similarity between named entities $(\vec{A}, \vec{B})$ and relation $\vec{R}$/sentence context.

thus ensuring that the positive connection is larger than the negative one as in Figure 2.

Our relational similarity model and the ranking training approach facilitate the transformation process of ($\vec{A}$, $\vec{B}$) and $\vec{R}$ in the vector space, which in the end leads to better constraint satisfaction of objective Equation 4.

The relational similarity model is placed on top of BiLSTM (Sec 5.1) as part of the system. We initialize named entities $\vec{A}/\vec{B}$ as h_A^{bi}/h_B^{bi} from the BiLSTM model, then initialize relation representations $\vec{R^+}/\vec{R^-}$ as random vectors. During training both $\vec{R^+}/\vec{R^-}$ are updated.

5.3 Contextual Similarity Modeling

Since not all words of a given title/abstract are created equal, important context words around named entities that can better contribute to the causality/correlation relation extraction deserve more model focus. We develop a contextual similarity model that can increase model weights onto important context words to better utilizing contextual information.

For example, given a sentence, *lung cancer is most likely caused by smoking*, the context words *caused by* are important clues to suggest there exists a causality/correlation relationship between the two named entities. Clue words that require model attentions usually include, e.g. *lead to, is associated with, because of*, while others are not obvious, such as *promote, reflect, reduce, make*.

Our system does not require a manually prepared list of clue words, but an attention mechanism (Bahdanau et al., 2014) is utilized to better identify them by conducting similarity measurement between context word representation h_t^{bi} (not including entity words) and extracted named entities $(\vec{A}, \vec{B})$ (from Sec. 4). Resulting similarity scores of words are accumulated in $atten \in \mathbb{R}^{\ell}$.

$$mix = W^a \cdot concat(\vec{A}, \vec{B}) \tag{6}$$

$$E[t] = dotProd(mix, h_t^{bi}), \forall t \in [1, l] \tag{7}$$

$$atten = softmax(E) \tag{8}$$

where we concatenate both entity representations $(\vec{A}, \vec{B})$, apply linear transformation with weights W^a to obtain a representation mix of both entities. We then use dot product $dotProd$ to measure the similarity between mix and each context word, finally normalize the attention weights $atten[:]$ with $softmax$. The weights of $atten$ indicate the importance of each context word with respect to both named entities.

The attention weights should better guide the focus of the model onto important context words of the sentence. That is, context words that are closer to entity representation mix should have better chances to be clue words. We define the attention re-weighted sentence representation $attenSen \in \mathbb{R}^{2dim}$:

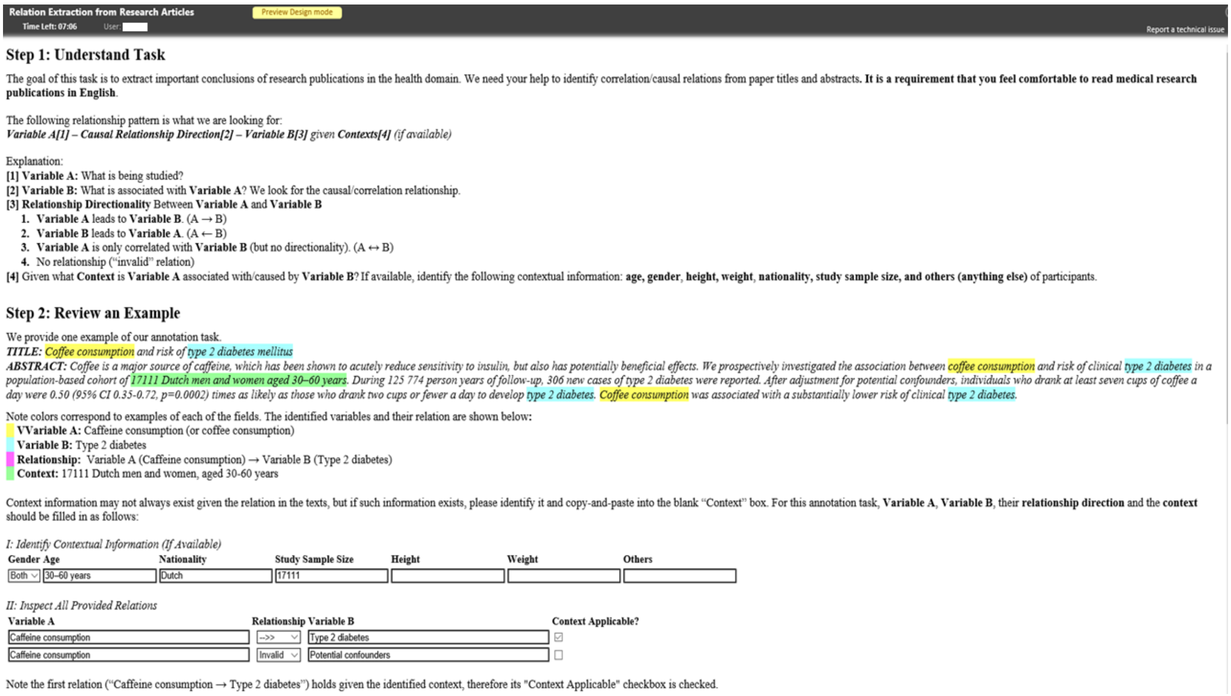
$$attenSen = atten \odot H^S \tag{9}$$

where $\odot$ represents element-wise multiplication.

Figure 2 illustrates an example where representation mix of named entities attends to context words one at a time. Important context clue words "*caused by*" should receive higher attention weights than irrelevant neighbor words.

The re-weighted sentence representation $attenSen$ is used together with entity representations $(\vec{A}, \vec{B})$ for final prediction.

In summary, both models described in this section focus on different aspects of similarity measurement in relation extraction: the contextual similarity model utilizes context information around named entities, while the relational similarity model focuses on enforcing a transformation constraint between entities and relation in the vector space. We adopt both models for better relation extraction, in the end only pairs of named entities that are recognized positively by either one of the models are passed to the next stage of the system.



Step 1: Understand Task

The goal of this task is to extract important conclusions of research publications in the health domain. We need your help to identify correlation/causal relations from paper titles and abstracts. **It is a requirement that you feel comfortable to read medical research publications in English**.

The following relationship pattern is what we are looking for:
Variable A[1] – Causal Relationship Direction[2] – Variable B[3] *given* ***Contexts[4]*** *(if available)*

Explanation:
[1] Variable A: What is being studied?
[2] Variable B: What is associated with **Variable A**? We look for the causal/correlation relationship.
[3] Relationship Directionality Between **Variable A** and **Variable B**

1. **Variable A** leads to **Variable B**. (A → B)
2. **Variable B** leads to **Variable A**. (A ← B)
3. **Variable A** is only correlated with **Variable B** (but no directionality). (A ↔ B)
4. No relationship (“invalid” relation)

[4] Given what **Context** is **Variable A** associated with/caused by **Variable B**? If available, identify the following contextual information: **age, gender**, **height, weight**, **nationality, study sample size, and others (anything else)** of participants.

Step 2: Review an Example

We provide one example of our annotation task.
TITLE: *Coffee consumption and risk of type 2 diabetes mellitus*
ABSTRACT: *Coffee is a major source of caffeine, which has been shown to acutely reduce sensitivity to insulin, but also has potentially beneficial effects. We prospectively investigated the association between coffee consumption and risk of clinical type 2 diabetes in a population-based cohort of 17111 Dutch men and women aged 30–60 years. During 125 774 person years of follow-up, 306 new cases of type 2 diabetes were reported. After adjustment for potential confounders, individuals who drank at least seven cups of coffee a day were 0.50 (95% CI 0.35-0.72, p=0.0002) times as likely as those who drank two cups or fewer a day to develop type 2 diabetes. Coffee consumption was associated with a substantially lower risk of clinical type 2 diabetes.*

Note colors correspond to examples of each of the fields. The identified variables and their relation are shown below:
🟨 **VVariable A:** Caffeine consumption (or coffee consumption)
🟦 **Variable B:** Type 2 diabetes
🟪 **Relationship:** Variable A (Caffeine consumption) → Variable B (Type 2 diabetes)
🟩 **Context:** 17111 Dutch men and women, aged 30-60 years

Context information may not always exist given the relation in the texts, but if such information exists, please identify it and copy-and-paste into the blank “Context” box. For this annotation task, **Variable A**, **Variable B**, their **relationship direction** and the **context** should be filled in as follows:

I: Identify Contextual Information (If Available)

Gender	Age	Nationality	Study Sample Size	Height	Weight	Others
Both	30–60 years	Dutch	17111			

II: Inspect All Provided Relations

Variable A	Relationship	Variable B	Context Applicable?
Caffeine consumption	-->>	Type 2 diabetes	☑
Caffeine consumption	Invalid	Potential confounders	☐

Note the first relation (“Caffeine consumption → Type 2 diabetes”) holds given the identified context, therefore its "Context Applicable" checkbox is checked.

Figure 3: Human annotation interface on UHRS platform. Annotators are required to identify and verify extracted entities and correlation/causality relations from the output of our system for evaluation.

6 Ranking of Extracted Insights

The last major component of our system is to rank extracted relations $(\vec{A}, \vec{B}, \vec{R})$ from the output of the relation extraction component, as there could be many extracted relations but not all of them are important enough as insights of the article. Importance scores of extracted relations are obtained by following a set of rules below:

1. We utilize the output classification probability $(\in [0, 1])$ of the relational similarity model as the base ranking score.
2. We use a multi-perspective convolutional neural network model (MPCNN) (He et al., 2015) to measure the similarity $(\in [0, 1])$ between the title of the article and extracted relation, since the MPCNN model has competitive performance on multiple benchmarks for textual similarity measurement. We compare title text with “$\vec{A}$ leads to $\vec{B}$” of an extracted relation, if the similarity score is over a threshold of 0.75, we increase the extracted relation’s ranking score by 15%. If the extracted relation is from the title text, we also boost its ranking score by 15% because of its location importance.

Once all extracted relations are scored, our system only returns the top ranked insights to users.

7 Experiment Setup

Datasets. Experiments are conducted on two datasets: our own dataset of medical/health publications annotated on Universal Human Relevance System (UHRS), a crowdsourcing platform for end-to-end system evaluation; and SemEval-2010 task 8 dataset for training and evaluation of our relation extraction component:

1. The first dataset consists of 100 publications from recent biomedical/health journals, which are then annotated on UHRS to evaluate our system. In order to ensure high-quality human annotations, Figure 3 provides an annotation interface on UHRS, which displays instructions, title/abstract texts of publications and a list of top ranked extracted insights from the system output. For fair evaluation the order of extracted insights is randomized then we ask expert annotators with suitable background to verify the correctness of each.
2. SemEval-2010 Task 8 (Hendrickx et al., 2009) defines 9 relation types between named entities: *Cause-Effect, Instrument-Agency, Product-Producer, Content-Container, Entity-Origin, Entity-Destination, Component-Whole, Member-Collection and Message-Topic*, and a tenth relation type *Other* when two named enti-

ties do not have the first 9 relations. SemEval-2010 dataset consists of $10,717$ sentences, with $8,000$ for training and $2,717$ for test. The dataset is human annotated, and each instance provides one sentence which includes two named entities and a relation type between the two entities.

Since our system focuses on extracting insights, we only use *Cause-Effect* subset of SemEval-2010 dataset as the positive training/testing examples and treat the remaining 9 categories data such as *Content-Container, Message-Topic* as negatives. We use this dataset for training and evaluating our relation extraction component (Sec. 5) only.

Training. Two loss functions are adopted to train relation extraction neural network models.

For contextual similarity model (Sec. 5.3), a hinge loss is used. The training objective is to minimize the following loss, summed over examples $\langle x, y_{gold} \rangle$:

$$loss_{contextSim}(w, x, y_{gold}) = \sum_{y' \neq y_{gold}} \max(0, 1 + f_w(x, y') - f_w(x, y_{gold})) \quad (10)$$

where input x represents an entity pair $(\vec{A}, \vec{B})$ plus its sentence context, y_{gold} is the ground truth label and y' is the model predicted label. Both y' and y_{gold} indicate the relation type with directionality (e.g. directional causality). w represents weights of contextual similarity model with BiLSTM, function $f_w(x, y')$ outputs the model predicted label value, function $f_w(x, y_{gold})$ outputs the model ground truth label value, and n is the number of training examples.

For relational similarity model (Sec. 5.2), a Bayesian Personalized Ranking (BPR) loss (Rendle et al., 2009) is used. The label of the relational similarity model is binary because the BPR loss ranks positive inputs above negative inputs, thereby requiring the supervision signal to distinguish positives from negatives. Due to BPR loss's ranking nature, each training instance of the relational similarity model include one positive input $(x, \vec{R^+})$ and one negative input $(x, \vec{R^-})$. Given a positive correlation/causality input $(\vec{R^+})$, we generate negative training examples by matching the input x with each of the negative relation labels $(\vec{R^-})$. BPR loss is shown to be better tailored for ranking tasks empirically (Verga et al., 2016):

$$loss_{relationSim}(w, x, \vec{R^+}, \vec{R^-}) = \sum_{\vec{R^-}} - \log(\sigma(f'_w(x, \vec{R^+}) - f'_w(x, \vec{R^-}))) \quad (11)$$

where σ is the sigmoid function, function $f'_w(x, \vec{R})$ represents the relational similarity model with BiLSTM, and outputs a similarity score for ranking purpose (Sec. 5.2).

In all experiments, we perform optimization using RMSProp (Tieleman and Hinton, 2012) with backpropagation (Bottou, 1998) and a learning rate fixed to 10^{-4} and a momentum parameter 0.9.

Settings and Preprocessing. We preprocess both datasets with Stanford CoreNLP toolkit (Manning et al., 2014). We tokenize, lowercase, sentence split and dependency parse all words of both datasets. We set LSTM hidden state $dim = 500$.

Two sets of $d = 300$-dimension word embeddings are utilized. The first one is 300-dimension GloVe word embeddings (Pennington et al., 2014) trained on 840 billion tokens; for better biomedical/health domain adaptation, we also train second word embeddings using the GloVe toolkit on biomedical research articles with over 1 billion tokens. We do not update word embeddings in all experiments.

During system deployment, we only initialize input words with the medical word embeddings if they do not exist in GloVe embeddings' vocabulary. We also concatenate embeddings of both input words and their head words on dependency trees as input for relation extraction models. We follow the task settings and compute F1-score with the official evaluation script only on *Cause-Effect* subset of SemEval-2010 data, then the best model based on F1 is selected for final system deployment. We set a distance limit and do not extract relations between two named entities if the distance is larger than 15.

8 Evaluation and Results

Human Evaluation of the Entire System. We firstly provide a full end-to-end evaluation of the system on UHRS with human annotators.

For each biomedical publication, top 10 candidate insights from the system are listed for further inspection. The annotators are required to understand the texts, carefully inspect each insight, finally either accept it if it is one of the article insights or simply reject it. The annotation

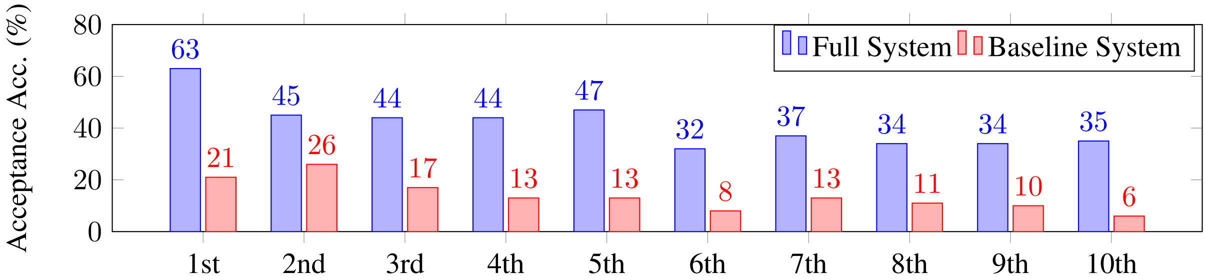


Figure 4: Human evaluation results of the full system and a baseline system on UHRS. We show the acceptance accuracy for each of the top ten positions given both systems' output lists. We primarily focus on the first 1 and 3 positions, namely *Precision*@1 and *Precision*@3.

System Ablation Study	*Precision*@1
Full System	63%
- Remove ReRanker (Sec. 6)	-5%
- Replace with BiGRU (Sec. 5)	-42%

Table 1: Ablation studies on the full system.

task requires understanding of biomedical/health publications and is non-trivial, therefore the system evaluation is completed by five expert annotators, who all hold postgraduate degrees and/or have biomedical background.

We also provide a baseline system, of which its relation extraction component is a bidirectional gated RNN model (BiGRU) (Cho et al., 2014). BiGRU model and the ranking component are major differences between our full and baseline system. Since typically only a limited number of key findings is presented in one article, we evaluate the system with an averaged acceptance accuracy at top 1 (*Precision*@1) and top 3 (*Precision*@3) positions of the output rank list, which represent on average the number of extracted insights accepted by annotators among the first 1 and 3 output.

Figure 4 shows annotation results with acceptance accuracies for each of the ten output positions given biomedical titles and articles. The *Precision*@3 of our full system is 50.6%, which is significantly better than the baseline system's 21.3%. For top 3 extracted insights on the list, our full system on average have 1.5 insights accepted by annotators. Furthermore, the acceptance accuracy *Precision*@1 of our system is 63% in comparison to that of the baseline system's 21%.

Table 1 shows the ablation study on the removal of the ranking component (Sec. 6) and the replacement of BiGRU model for causality/correlation relation extraction. We observe significant performance difference.

Model	F1 score⋆
Tymoshenko and Giuliano (2010)	82.30%
Tratz and Hovy (2010)	87.63%
Rink and Harabagiu (2010)	89.63%
BiGRU	89.89%
Miwa and Bansal (2016)	91.57%
Contextual similarity modeling	90.77%
Relational similarity modeling	**92.28%**

Table 2: Test results (F1 score) on the *Cause-Effect* subset(⋆) of SemEval-2010 dataset. Results are grouped as 1) Top 3 participating teams in SemEval-2010 competition; 2) Baseline BiGRU model; 3) Recent state-of-the-art treeLSTM model (Miwa and Bansal, 2016); 4) Our work.

Evaluation of Relation Extraction Component. We also evaluate the relation extraction component (Sec. 5) on *Cause-Effect* subset of SemEval-2010 dataset. Note our causality/correlation relation extraction component is *not* supposed to be a general purpose one, since our system only focuses on insight extraction of biomedical/health literature. We compare our relation extraction models against previous work on the *Cause-Effect* subset of the data, Table 2 shows our relational similarity model, without the use of sparse features or external resources such as WordNet, outperforms recent state-of-the-art treeLSTM model (Miwa and Bansal, 2016). It also shows BiGRU model is reasonably competitive on this dataset, which is why we use it in our baseline system for comparison purpose.

9 Result Analysis and Case Study

Visualization of Contextual Similarity Model. We show values of attention weights, *atten* of

Table 3: Visualization of model attention weights $atten$ given four SemEval-2010 test sentences.

Equation 8 and 9 from within the contextual similarity model (Sec. 5.3). Given four sentences in the test set of SemEval-2010 data, the model predicts that all provided entity pairs (in bold) have the causality/correlation relation. From Table 3 we observe the model is able to do its expected job: it can recognize important clues words, such as "*result in*", "*produce*", "*generated by*" and "*cause*"; the model produces attention weights (each $\in [0, 1]$) to tell the importance of clue words for causality/correlation relation extraction. We also observe the model tends to focus more on prepositions of clue words, such as "*by*" of "*generated by*" and "*in*" of "*result in*", this is probably because we use head words as extra inputs (Sec. 7) to the model.

Case Study. We lastly provide case study of our system. We show two biomedical articles' titles and abstracts as examples, with only necessary omissions to remove irrelevant texts due to the space limit.

Given **Case 1**, our system outputs the top insight "*the slow negative shift of the DC potential → increased cortical excitability*" with a score of 0.71. Given **Case 2**, our system outputs top 3 insights: "*excessive drinking → skin cancer*" with a score of 0.55, "*excessive drinking → alcohol*" with a score of 0.43, and "*excessive drinking → sunburn*" with a score of 0.31. The above examples show that our system can provide reasonable insights from biomedical text.

10 Conclusion

We build an end-to-end system for insight extraction on biomedical literature. We develop novel similarity measurement modeling with deep neural networks to extract causation/correlation relations. Our evaluation shows the system is able to extract insights with competitive human acceptance accuracy and its relation extraction component compares favorably against previous work.

Case 1: *Scalp recorded direct current potential shifts associated with the transition to sleep in man.* ***Abstract:*** *Cortical direct current (DC) potentials are considered to reflect the state of cortical excitability which may change characteristically from wakefulness to sleep. The present experiments examined changes in the scalp recorded DC potential in 10 healthy humans ... It is reasonable to assume that the slow negative shift of the DC potential at the transition from wakefulness to sleep reflects increased cortical excitability.*

Case 2: *Alcohol consumption and self-reported sunburn: a cross-sectional, population-based survey.* ***Abstract:*** *Heavy drinking has been associated with several cancers, including melanoma and basal cell carcinoma. ... 299,658 adults reported their use of alcohol in the preceding month and a history of sunburn in the preceding year. Approximately 33.5% of respondents reported a sunburn within the past year. ... Excessive drinking is associated with higher rates of sunburn among American adults. The observed relationship typifies the high-risk behavior associated with excessive drinking and suggests one pathway linking alcohol use with skin cancer.*

Word Etymology as Native Language Interference

Vivi Nastase

Abstract

We present experiments that show the influence of native language on lexical choice when producing text in another language – in this particular case English. We start from the premise that non-native English speakers will choose lexical items that are close to words in their native language. This leads us to an etymology-based representation of documents written by people whose mother tongue is an Indo-European language. Based on this representation we grow a language family tree, that matches closely the Indo-European language tree.

1 Introduction

In second-language writing, vestiges of the native language such as pronunciation, vocabulary and grammar are well-attested, and the phenomenon is called native language interference (Odlin, 1989). At the lexical level, the choice as well as the spelling can be indicative of the native language, through the choice of cognates, true or false friends – e.g. a writer with native language German may choose *bloom* cognate with *blume*, while a French one may choose *flower*, cognate with *fleur*. Misspellings – *cuestion* instead of *question* are also indicative, as the writer will tend to spell words close to the form from her original language (Nicolai et al., 2013).

In this paper we also look at native language interference starting from the lexical level, but abstract away from the actual word forms, and focus instead on the language of the etymological ancestors. The hypothesis we investigate is that the collective evidence of etymological ancestor languages are indicative of the language of the native speaker, and that this effect is sufficiently strong to allow us to rebuild an Indo-European language family tree. We use a corpus of essays written by English language learners, whose native language cover the languages from the Indo-European family. Etymological information is provided by an etymological dictionary extracted from Wiktionary.

Eng.: *flower*	Eng.: *bloom*	Eng.: *blossom*
↓	↓	↓
Middle Eng.: *flour*	Middle Eng.: *blome*	Middle Eng.: *blosme*
↓	↓	↓
Anglo Norm.: *flur*	Old Norse: *blōm*	Old Eng.: *blostm*
↓	↓	↓
Latin: *florem*	Proto Ger.: **blōmô*	Proto Ger.: **blōstama*
↓	↓	↓
Proto IE: $*b^hleh_3$	Proto IE: $*bleh_3$	Proto IE: $*b^hleh_3 - s-$

Figure 1: Examples of etymological ancestry from Wiktionary

The fact that word etymologies are included in the native-language interference phenomena could be used in various ways, i.a.: (i) to influence the selection of material for language learning, by focusing on vocabulary closer etymologically to the native language of the student, thus facilitating lexical retention; (ii) to reveal lexical choice errors caused by "etymological interference"; (iii) together with other interference phenomena, for the automatic corrections of language errors.

2 Related Work

English is a widespread common language for communication in a variety of fields – science, news, entertainment, politics, etc. A consequence is that numerous people learn English as a second (or indeed nth language). The study of native language interference with the learning of English can be used in multiple ways, including devising methods to make the learning easier and correcting language errors (Leacock et al., 2014; Gamon, 2010; Dahlmeier and Ng, 2011).

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2702–2707
Copenhagen, Denmark, September 7–11, 2017.

Massung and Zhai (2016) present an overview of approaches to the task of natural language identification (NLI). Various surface indicators hold clues about a speaker's native language, that make their way into language production in a non-native language. Nagata and Whittaker (2013),Nagata (2014) find that grammatical patterns from the native language seep into the production of English texts. Tsur and Rappoport (2007) verify the hypothesis that lexical choice of non-native speakers is influenced by the phonology of their native language, and Wong and Dras (2009) propose the idea that (grammatical) errors are also influenced by the native language. One could draw the inference that character n-grams then could be indicative of the native language, and this was shown to be the case by Ionescu et al. (2014).

The natural language identification task (Tetreault et al., 2013) attracted 29 participating teams, which used a variety of features to accomplish the NLI task as a classification exercise: n-grams of lexical tokens (words and POS tags), skip-grams, grammatical information (dependency parses, parse tree rules, preference for particular grammatical forms, e.g. active or passive voice), spelling errors.

Apart from morphological, lexical, grammatical features, words also have an etymological dimension. The language family tree itself is drawn based on the analysis of the evolution of languages. Language evolution includes, or starts with, word etymologies. Word etymologies have been under-used for tasks related to NLI. They have been used implicitly in work that investigates cognate interference (Nicolai et al., 2013), and explicitly by (Malmasi and Cahill, 2015) who use words with Old English and Latin etymologies as unigram features in building classifiers for the TOEFL11 dataset. Etymological information is obtained from the Etymological WordNet (de Melo and Weikum, 2010).

We also investigate here the impact of etymological information, but unlike previous work, we do not extract unigram/n-gram features for classification, but we look at the collective evidence captured by the etymological "fingerprint" for each document and set of essays.

3 Etymological fingerprints

To investigate the influence of etymological ancestor languages, we represent each essay through etymological features, based on which we also built language vectors for each Indo-European language represented in the corpus. Essay vectors are then used to test native language identification potential, and the language vectors are used to grow a language family tree.

3.1 Word etymologies

Dictionaries customarily include etymological information for their entries. Wikipedia's Wiktionary has amassed a considerable number of entries that joined this trend. The etymological information can, and indeed has been extracted and prepared for machine consumption (de Melo and Weikum, 2010): Etymological WordNet[1] contains 6,031,431 entries for 2,877,036 words (actually, morphemes) in 397 languages. Because we process essays written in English, we use only the entries that give etymological origins for English words – 240,656. Figure 1 shows as an example of the kind of information formalized in the Etymological WordNet the etymological ancestry for the words *flower, blossom, bloom*.

3.2 Document/collection modeling

Essay representation After tokenization, POS tagging and lemmatization, each essay in the dataset is represented as a vector of etymological ancestry proportions obtained through the following processing steps:

1. for each token that has an entry in the etymological dictionary, we replace it with the language of its etymological ancestor – e.g. *sight* will be replaced by *ang* (Old English), *vision* by *lat* (Latin) (Table 1 shows the number of words with etymological ancestors in the subsets corresponding to each language);

2. compute the proportion of each etymological language in the essay, and represent the essay as a vector of language proportions[2]. We experimented with using etymological information going back through several ancestry levels, but using the first level led to the best results.

$$e_i \sim \langle p_{il_1}, ..., p_{il_n} \rangle \quad \textit{where} \quad p_{il_k} = \frac{n_{il_k}}{N_{i,etym}}$$

[1] http://www1.icsi.berkeley.edu/~demelo/etymwn/

[2] Using automatically corrected typos (first option of ispell) did not change the results significantly.

n_{il_k} is the number of words with etymological ancestor l_k in the i-th essay, and $N_{i,etym}$ is the number of words with etymological information in essay i.

Language vectors For each subcollection corresponding to one (student native) language L_j, we build the language vectors by averaging over the essay vectors in the subcollection:

$$V_{L_j} = \langle p_{L_j l_1}, ..., p_{L_j l_m} \rangle$$

$$\textit{where} \quad p_{L_j l_k} = \frac{\sum\limits_{lang(e_i)=L_j} p_{il_k}}{|\{e_i | lang(e_i)=L_j\}|}$$

$p_{L_j l_k}$ is the proportion of etymological ancestor language l_k in all essays whose author has as native language L_j.

The essay and language vectors are filtered by removing etymological languages whose corresponding values in the language vectors are less than 10^{-4}.

4 Experiments

We investigate the strength of the etymological "fingerprint" of individual and collective essays written by non-native speakers of English, through two tasks – native language identification and language family tree construction. Towards this end, we work with a collection of essays written by contributors whose native language is an Indo-European language. The dataset is described in Section 4.1. For etymological information we rely on an etymological dictionary, described briefly in Section 3.1. Data modeling and the experiments conducted are described in Section 3.2.

4.1 Data

We used the ICLE dataset (Granger et al., 2009), consisting of English essays written by non-native English speakers. We filter out those that were written by people whose mother tongue is not from the Indo-European family (i.e. Chinese, Japanese, Turkish and Tswana). Table 1 shows a summary of the data statistics, including the number of words for which we have found ancestors in the etymological dictionary used. The corpus consists entirely of essays written by students. Two types of essay writing are present: argumentative essay writings and literature examination papers. Table 2 displays a list of topics in the corpus. The essays should be at least 500 words long and up to 1,000, and contain all the spelling mistakes made by their authors.

Following Nagata and Whittaker (2013), who also built the Indo-European family tree based on n-grams composed of function words and open-class parts of speech, essays that do not respect one of the following rules are filtered out: (i) the writer has only one native language, (ii) the writer has only one language at home; (iii) the two languages in (i) and (ii) are the same as the native language of the subcorpus to which the essay belongs. Table 1 shows a summary of the data statistics after filtering, including the number of words for which we have found ancestors in the etymological dictionary used.

Native language	*# essays*	*# tokens (with etym)*
Bulgarian	302	226,407 (149,151)
Czech	243	226,895 (148,391)
Dutch	263	264,981 (169,040)
French	347	256,749 (161,136)
German	437	259,967 (170,056)
Italian	392	253,798 (165,500)
Norwegian	317	238,403 (156,764)
Polish	365	263,223 (172,319)
Russian	276	259,510 (167,938)
Spanish	251	225,341 (139,565)
Swedish	355	224,948 (146,143)

Table 1: Statistics on the subset of ICLE dataset used.

1 Crime does not pay.
2 The prison system is outdated. No civilized society should punish its criminals: it should rehabilitate them.
3 Most university degrees are theoretical and do not prepare students for the real world. They are therefore of very little value.
4 A man/woman's financial reward should be commensurate with their contribution to the society they live in.
5 The role of censorship in Western society.
6 Marx once said that religion was the opium of the masses. If he was alive at the end of the 20th century, he would replace religion with television.
7 All armies should consist entirely of professional soldiers : there is no value in a system of military service.
8 The Gulf War has shown us that it is still a great thing to fight for one's country.
9 Feminists have done more harm to the cause of women than good.
10 In his novel Animal Farm, George Orwell wrote "All men are equal: but some are more equal than others". How true is this today?
11 In the words of the old song "Money is the root of all evil".
12 Europe.
13 In the 19th century, Victor Hugo said: ”How sad it is to think that nature is calling out but humanity refuses to pay heed. ”Do you think it is still true nowadays ?
14 Some people say that in our modern world, dominated by science technology and industrialization, there is no longer a place for dreaming and imagination. What is your opinion ?

Table 2: Topics in the ICLE dataset.

The suitability of the dataset above for NLI was questioned by Brooke and Hirst (2012). They have shown that the fact that the corpus consists of sets of essays on a number of topics causes an overestimation of the results of NLI when random splitting, particularly for groups of contributors that were presented with very different topics – e.g. students from Asia vs. students from Europe. We have analyzed the distribution of essays into topics using the essay titles, and observed that contributions from Europe (which are our focus) have similar distributions across the featured topics.

Growing the language tree To grow the language tree from the language vectors built from the English essays, we use a variation of the UPMGA – Unweighted Pair Group Method with Arithmetic Mean – algorithm. Starting with the language vectors V_{L_j}, we compute the distance between each pair of vectors using a distance metric algorithm. At each step we choose the closest pair (L_a, L_b) and combine them in a subtree, then combine their corresponding sub-collection of essays, and build the language vector for the "composite" language $L_{a,b}$, and compute its distance to the other language vectors.

4.2 Results

We test whether etymological information surfaces as native language interference that is detectible through the tasks of native language identification and reconstruction of the language family tree. Table 3 shows results on the multi-class classification of essays according to the native language of the author, in the form of F-score average results using SVM classification in 5-fold cross-validation (using Weka's SMO implementation[3] with polynomial kernel and default parameters). The baseline corresponds to the language distribution in the dataset. We use as additional comparison point another set of features used to reconstruct the language family tree – the (closed-class) word and POS 3grams Nagata and Whittaker (2013), such as *the NN of; a JJ NN; the JJ NN*. We build all such patterns for the data, and keep the top 1000 by overall frequency.

Adding etymological features that capture the distribution of etymological ancestors for each essay led to improved results for all languages, varying from a non-significant improvement of 0.2% point for Russian, to a significant and high 5.3% improvement for German. Using only words, the accuracy is 73.2%, which increases marginally to 73.7 when etymology information is added. Using a full complement of standard features – word, lemma and character ngrams (n=1..3) (built following (Lahiri and Mihalcea, 2013)) – gives an average accuracy (over 5 fold cross-validation) of 85.7%. Adding etymology does not lead to improvements when added to this set.

Language	Baseline	Etym.	Patt.	both
Bulgarian	8.52%	32.4	51.7	54.3
Czech	6.85%	21.9	53.4	54.4
Dutch	7.41%	11.7	50.4	51.1
French	9.78%	30.0	58.8	62.9
German	12.31%	45.4	47.4	52.7
Italian	11.04%	34.3	66.3	67.3
Norwegian	8.93%	35.5	57.0	59.3
Polish	10.28%	42.5	59.9	62.1
Rusian	7.78%	12.7	46.9	47.1
Spanish	7.07%	24.6	57.9	59.6
Swedish	10.00%	23.1	44.8	45.7
Accuracy		31.7	54.2	56.3

Table 3: 5-fold cross-validation F-scores and accuracy for language classification

Despite the rather low results when etymology is used on its own for language identification, the cumulative evidence leads to a language family tree that closely matches the gold standard (Figure 2). The tree on top is the gold standard cf. (Nagata and Whittaker, 2013; Crystal, 1997). The tree is grown by computing the euclidean distance between pairwise vectors, and then iteratively grouping together the closest vectors at each step as described in Section 4.1.

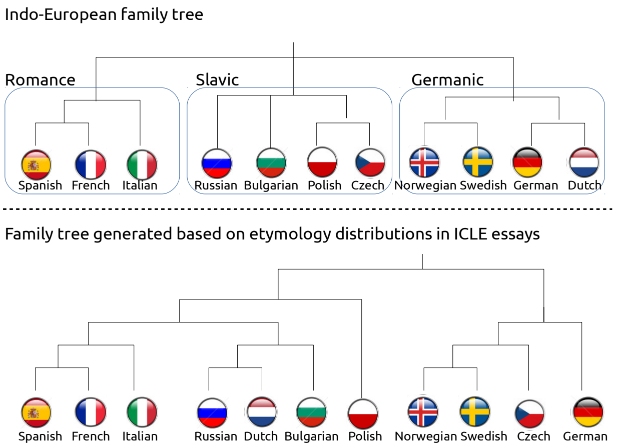

Figure 2: Language family trees – the gold standard and the automatically generated one

The two wrongly placed languages in our language family tree are Czech and Dutch. Czech

[3] http://www.cs.waikato.ac.nz/ml/weka/

is grouped with the Germanic languages. Historically, the country which is now the Czech Republic has been under German occupation for long periods of time. We propose the hypothesis that this has influenced the Czech language at the lexical level, and our etymological fingerprinting characterizes mostly the lexical aspects of language. We plan to verify this theory as etymological information for Czech and German becomes more readily available in sufficient quantities. We have not yet found an explanation for the grouping of Dutch with the Slavic languages. Like mentioned before, the language vectors we built rely exclusively on lexical information, and it is possible that Dutch's grammatical structure is what defines it best as being a part of the Germanic language family, as opposed to the lexical dimension.

5 Conclusion

In this paper we have shown an exploration of a novel indicator of native language interference in second language learning, particularly etymology. While cross-linguistically related words (cognates, false and true friends) have been part of the repertoire of features for native language identification and cross-language studies, we have focused here on the language of etymological ancestors of words, and in particular their distribution in documents. Experiments in recreating the Indo-European family tree have shown that the composition of a document in terms of etymological languages is indicative of the native language of the writer to the extent that fundamental characteristics of languages – typological relatedness between languages – emerge.

Abstract

Story detection is the task of determining whether or not a unit of text contains a story. Prior approaches achieved a maximum performance of 0.66 F_1, and did not generalize well across different corpora. We present a new state-of-the-art detector that achieves a maximum performance of 0.75 F_1 (a 14% improvement), with significantly greater generalizability than previous work. In particular, our detector achieves performance above 0.70 F_1 across a variety of combinations of lexically different corpora for training and testing, as well as dramatic improvements (up to 4,000%) in performance when trained on a small, disfluent data set. The new detector uses two basic types of features–ones related to events, and ones related to characters–totaling 283 specific features overall; previous detectors used tens of thousands of features, and so this detector represents a significant simplification along with increased performance.

1 Motivation

Understanding stories is a long-held goal of both artificial intelligence and natural language processing. Stories can be used for many interesting natural language processing tasks, and much can be learned from them, including concrete facts about specific events, people, and things; commonsense knowledge about the world; and cultural knowledge about the societies in which we live. Applying NLP directly to the large and growing number of stories available electronically, however, has been limited by our inability to efficiently separate story from non-story text. For the most part, studies of stories *per se* has relied on manual curation of story data sets (Mostafazadeh et al., 2016), which is, naturally, time-consuming, expensive, and doesn't scale. These human-driven methods pay no attention to the large number of stories generated daily in news, entertainment, and social media.

The goal of this work is to build and evaluate a high performing story detector that is both simple in design and generalizable across lexically different story corpora. Our definition of story can be found in §1.2, and is based on definitions used in prior work on story detection. Previous approaches to story detection have relied on tens of thousands of features (Ceran et al., 2012; Gordon and Swanson, 2009), and have used complicated pre-processing pipelines (Ceran et al., 2012). Moreover these prior systems, while clearly important advances, did not, arguably, include features that captured the "essence" of stories. Furthermore, these prior efforts had poor generalizability, i.e. when trained on one corpus, the detectors perform poorly when tested on a different corpus. Building on this prior work, we begin to address these shortcomings, presenting a new detector that has many orders of magnitude fewer features than used previously, significantly improved cross corpus performance, and higher F_1 on all training and testing combinations.

1.1 Task

Our goal is to design a system that can automatically decide whether or not a paragraph of text contains a story. We say a paragraph contains a story if any portion of it expresses a significant part of a story, including the characters and events involved in major plot points. Corpora used in prior work included Islamic Extremist texts (Ceran et al., 2012), and personal weblog posts (Gordon and Swanson, 2009), which were both annotated at

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2708–2715
Copenhagen, Denmark, September 7–11, 2017.

this level of granularity. In this paper we test combinations of new features on both of these corpora. Once we determined the best-performing feature set, we ran experiments using those features to evaluate its generalizability across corpora.

1.2 What is a Story?

Author E.M. Forster said "A story is a narrative of events arranged in their time sequence" (Forster, 2010). A more precise definition, of our own coinage, is that a narrative is a discourse presenting a coherent sequence of events which are causally related and purposely related, concern specific characters and times, and overall displays a level of organization beyond the commonsense coherence of the events themselves. In sum, a story is a series of events effected by animate actors. This reflects a general consensus among narratologists that there are at least two key elements to stories, namely, the plot (*fabula*) and the characters (*dramatis personae*) who move the plot forward (Abbott, 2008). While a story is more than just a plot carried out by characters–indeed, critical to 'storyness' is the connective tissue between these elements that can transport an audience to a different time and place–here we focus on these two core elements to effect better story detection.

1.3 Outline of the Paper

We begin by discussing prior work on story detection (§2). Then we introduce our new detector (§3), which relies on simple verb (§3.1) and character (§3.2) features. We test our detector on two corpora (§3.3)—one of blog posts and one of Islamist Extremist texts—using an SVM model to classify each paragraph as to whether or not it contains a story (§3.4). We conduct an array of experiments evaluating different combinations and variants of our features (§4). We also detail our use of undersampling for the majority class (§4.1), as well as our cross validation procedure (§4.2). We present both the results of the single corpus experiments (§4.3) and the cross-corpus and generalizability experiments (§4.4). We conclude with a list of contributions and discussion of future directions (§5).

2 Related Work

There have been three major contributions to the study of automatic story detection. In 2009, Gordan and Swanson developed a bag-of-words-based detector using blog data (Gordon and Swanson, 2009). They annotated a subset of paragraph-sized posts in the Spinn3r Blog corpus for the presence of stories, and used this data to train a confidence weighted linear classifier using all unigrams, bigrams, and trigrams from the data. Their best F_1 was 0.55. This was an important first step in story detection, and the annotated corpus of blog stories is an invaluable resource.

In 2012, Corman *et al.* developed a semantic-triplet-based detector using Islamist Extremist texts (Ceran et al., 2012). They annotated paragraphs of the CSC Islamic Extremist corpus for the presence of stories, and used this data to train an SVM with a variety of features including the top 20,000 *tf-idf* tokens, use of stative verbs, and agent-verb-patient triplets ("semantic triplets," discussed in more detail below in §3.1). Their best performing detector in that study achieved 0.63 F_1. The intent of the semantic triplet features was to encode the plot and the characters. These features were intended to capture the action of stories, but the specifics of the implementation was problematic: each unique agent-verb-patient triplet has its own element in the feature vector, and so this detector was sensitive primarily to the words that appeared in stories, not generalized actions or events.

Although Corman's detector has a higher F_1 than Gordon's, it was not clear which one was actually better; they were tested on different corpora. We compared the two detectors by reimplementing both, confirmed the correctness of the reimplementations, and running experiments where each detector was trained and tested on the corpora (Eisenberg et al., 2016). After these experiments, we showed that Corman's detector had better performance on the majority of experiments. Some of the results of these experiments are shown in Table 2. We also slightly improved the performance of Corman's detector to 0.66 F_1. In addition we reported results investigating the generalizability of the detectors; these results showed that neither the Gordon nor the Corman detectors generalized across corpora. We ascribed this problem to the fact that the features of each detector were closely tied to the literal words used, and did not attempt to generalize beyond those specific lexical items.

In terms of domain independence, we surveyed other discourse related tasks to see how generalization across domains has been achieved. For example, Braud *et al.* achieved domain independence in the identification of implicit relations between discourse units by training their system on both natural and synthetic data, weighting the influence of the two types (Braud and Denis, 2014). Jansen *et al.*, as another example, demonstrated domain independence on the task of non-factoid question answering by using both shallow and deep discourse structure, along with lexical features, to train their classifiers (Jansen et al., 2014). Thus, domain independence is certainly possible for discourse related tasks, but there does not yet seem to be a one-size-fits-all solution.

3 Developing the Detector

In contrast to focusing on specific lexical items, our implementation focuses on features which we believe capture more precisely the essence of stories, namely, features focusing on (a) events involving characters, and (b) the characters themselves.

3.1 Verb Features

Verbs are often used to express events. We use this fact to approximate event detection in a computationally efficient but still relatively accurate manner. The first part of each feature vector for a paragraph comprises 278 dimensions, where each element of this portion of the vector represents one of the 278 verb classes in VerbNet (Schuler, 2005). The value of each element depends on whether a verb from the associated verb class is used in the paragraph. Each element of the vector can have three values: the first value represents when a verb from the element's corresponding verb class is used in the paragraph and also involves a character as an argument of the verb. The second value represents when a verb from the verb class is used, but there are no characters involved. The third value represents the situation where no verbs from the verb class are used in the paragraph.

For clarity, we list the general steps of the verb feature extraction pipeline:

1. Split each paragraph into tokens, assign part of speech tags, and split the text into sentences, all using Stanford CoreNLP (Manning et al., 2014).
2. Parse each sentence with OpenNLP (Apache Foundation, 2017).
3. Label each predicate with its semantic roles using the SRL from the Story Workbench (Finlayson, 2008, 2011).
4. Disambiguate the Wordnet sense (Fellbaum, 1998) for each open-class word using the *It Makes Sense* WSD system (Zhong and Ng, 2010), using the Java WordNet Interface (JWI) to load and interact with WordNet (Finlayson, 2014).
5. Assign one of 278 VerbNet verb classes to each predicate, based on the assigned Wordnet sense, and using the jVerbnet library to interact with VerbNet. (Finlayson, 2012).
6. Determine whether the arguments of each predicate contains characters by using the Stanford Named Entity Recognizer (Finkel et al., 2005) and a gendered pronoun list.

We considered an argument to involve a character if it contained either (1) a gendered pronoun or (2) a named entity of type *Person* or *Organization*. We treated organizations as characters because they often fulfill that role in stories: for example, in the Extremist stories, organizations or groups like the *Islamic Emirate*, *Hamas*, or *the Jews* are agents or patients of important plot events. The verb features were encoded as a vector with length 278, each entry representing a different VerbNet verb class with three possible values: the verb class does not appear in the paragraph; the verb class appears but does not involve characters; or the verb class appears and a character is either an agent, patient, or both.

The verb features represent the types of events that occur in a paragraph, and whether or not characters are involved in those events. This is a generalized version of the semantic triplets that Corman *et al.* used for their story detector (Ceran et al., 2012), where they paired verbs with the specific tokens in the agent and patient arguments. The disadvantage of Corman's approach was that it led to phrases with similar meaning being mapped to different features: for example, the sentences "Bob played a solo" and "Mike improvised a melody" are mapped to different features by the semantic triplet based detector, even though the meaning of the sentences are almost the same: a character is performing music. On the other hand, in our approach, when we extract verb feature vectors from these sentences, both result in the same feature value, because the verbs *played* and *improvised* belong to the *performance* VerbNet class, and both verbs have a character in one of their arguments. This allow a generalized encoding of the types of action that occurs in a text.

3.2 Character Features

Our second focus is on character coreference chains. Characters, as discussed previously, are a key element of stories. A character must be present to drive the action of the story forward. We hypothesize that stories will contain longer coreference chains than non-stories. To encode this as a feature, we calculated the normalized length of the five longest coreference chains, and used those numbers as the character features. We computed these values as follows:

1. Extract coreference chains from each paragraph using Stanford CoreNLP coreference facility (Clark and Manning, 2016).
2. Filter out coreference chains that do not contain a character reference as defined in the Verb section above (a named entity of type *Person* or *Organization*, or a gendered pronoun).
3. Sort the chains within each paragraph with respect to the number of references in the chain.
4. Normalize the chain lengths by dividing the number of referring expression in each chain by the number of sentences in the paragraph.

These normalized chain lengths were used to construct a five-element feature vector for use by the SVM. We experimented with different numbers of longest chains, anywhere from the single longest to the ten longest chains. Testing on a development set of 200 Extremist paragraphs revealed using the five longest chains produced the best result.

3.3 Corpora

As noted, we used two corpora that were annotated by other researchers for the presence of stories at the paragraph level. The CSC Islamic Extremist Corpus comprises 24,009 paragraphs (Ceran et al., 2012), of which 3,300 were labeled as containing a story. These texts recount Afghani and Jihadi activities in the mid-2000's in a variety of location around the world. This corpus was originally used to train and test Corman's semantic-triplet-based story detector. The web blog texts come from the ICWSM 2009 Spinn3r Dataset (Burton et al., 2009). The full data set contains 44 million texts in many languages. Gordon and Swanson (2009) annotated a sample of 4,143 English texts from the full data set, 201 of which were identified as containing stories. This corpus was originally used to train and test Gordon's bag-of-words-based detector. Most of the texts in the blog corpus are no more than 250 characters, roughly a paragraph. The distribution of texts can be seen in Table 1.

Corpus	Story	Non-Story
Extremist	3,300	20,709
Blog	201	3,942

Table 1: Distribution of story paragraphs across the Extremist and blog corpora.

3.4 SVM Machine Learning

We used the Java implementation of LibSVM (Chang and Lin, 2011) to train an SVM classifier with our features. The hyper-parameters for the linear kernel were $\gamma = 0.5$, $\nu = 0.5$, and $c = 20$.

4 Experiments & Results

The results of our new experiments are shown in Table 3. We report precision, recall, and F_1 relative to the story and non-story classes. We performed experiments on three feature sets: the verb features alone (indicated by **Verb** in the table), character features alone (indicated by **Char**), and all features together (**Verb+Char**). We conducted experiments ranging over three corpora: the Extremist corpus (**Ext**), the blog corpus (**Web**), and the union of the two (**Comb**). These results may be compared with the previously best performing detector, namely, Corman's semantic triplet based detector (Ceran et al., 2012), as tested by us in prior work (Eisenberg et al., 2016), and shown in Table 2.

Training	Testing	Prec.	Recall	F_1
Ext	**Ext**	0.77	0.57	**0.66**
Ext	**Web**	0.23	0.37	0.28
Ext	**Comb**	0.43	0.41	0.32
Web	**Web**	0.66	0.31	0.43
Web	**Ext**	0.59	0.003	0.01
Web	**Comb**	0.59	0.01	0.01
Comb	**Ext**	0.62	0.51	0.43
Comb	**Web**	0.36	0.49	0.30
Comb	**Comb**	0.64	0.47	0.46

Table 2: Results for the Corman semantic triplet based detector as reported in (Eisenberg et al., 2016). These results are with respect to the story class.

				Not Story			Story	
Features	**Training**	**Testing**	Prec.	Recall	F_1	Prec.	Recall	F_1
Verb	**Ext**	**Ext**	0.73	0.81	0.77	0.78	0.70	0.74

Verb+Char	**Comb**	**Comb**	0.72	0.81	0.76	0.79	0.68	0.73

Table 3: Results of the new detectors as trained and tested on the Extremist (Ext), weblog (Web), or combined (Comb) corpora. The feature sets tested include the 278 verb class features (Verb), the normalized length of the five longest coreference chains (Char), and the combination of these two feature sets (Verb+Char). Undersampling is utilized in each of these experiments.

4.1 Undersampling

In each of the new experiments, we undersampled the non-story class before training (Japkowicz, 2000). Undersampling is a technique used to help supervised machine learning classifiers learn more about a class that has a significantly smaller number of examples relative to an alternative. In our case, non-story labels outnumbered story labels by a factor of 7 overall. Extremist story paragraphs are only 15.9% of the total annotated paragraphs in that set, and in the blog corpus stories were only 4.9% of the paragraphs. To prevent the detector from being over trained on non-story paragraphs, we thus reduced the size of the non-story training data to that of the story data, by randomly selecting a number of non-story texts equal to the number of story texts for training and testing.

4.2 Cross Validation

We used three versions of cross validation for the new experiments, one for each experimental condition: training and testing on a single corpus; training on a single corpus and testing on the combined corpus; or training on the combined corpus and testing on a single corpus. These procedures are the same as in our previous work (Eisenberg et al., 2016). We performed undersampling before cross validation, so when we are explaining how to divide up the story and non-story texts into cross validation folds, this refers to the full set of story texts and the set of non-story texts that was randomly selected to equal the number of story texts. For all experiments with cross validation, we use ten folds.

Train and Test on a Single Corpus: If the training and testing corpus is the same, divide up the stories into ten subsets of equal size, and the undersampled non-stories into ten subsets of equal size. For each fold of cross validation a different story set and non-story set (of the same index) are used as the testing set and the remaining nine are used for training.

Train on Combined, Test on Single: If the training is done on the combined corpus, and the test corpus is either the weblog or Extremist corpus, which we will refer to as the single test corpus, first divide the stories from the single test corpus into ten equal sized sets, and then divide up that corpus's non-stories into ten equal sets. For each fold of cross validation a different story set and non-story set (of the same index) from the single test corpus are used as the testing set and the remaining nine are used for training. The texts from the other corpus (the corpus that is not the single test corpus), are undersampled and added to all ten folds of training.

Train on Single, Test on Combined: If training is done on a single corpus, and the test corpus is the combined corpus, first divide the stories from the single training corpus into ten equal sized sets, and the undersampled non-stories from the single training corpus into ten equal sized sets. For each fold of cross validation a different story set and non-story set (of the same index) from the single training corpus are used as the testing set and the remaining nine are used for training. The texts from the other corpus (the corpus that is not the single training corpus), are undersampled and added to all ten folds of testing.

4.3 Single Corpus Experiments

For every experiment that used only a single corpus, the best feature set included both the verb and character features, achieving up to 0.74 F_1 when trained and tested on the Extremist corpus. This represents a new state-of-the-art, about 12.6% greater than the performance of Corman's detector when trained and tested on the same corpus (0.66 F_1).

When the detector uses only verb features it achieves an F_1 of 0.74 on the Extremist corpus, only 0.002 lower than the detector using all the features. Interestingly, the detector achieves 0.55 F_1 using only the five character features, which is respectful given such a small feature set. To put this in perspective, the Corman detector (Ceran et al., 2012) uses more than 20,000 features, and achieves an F_1 of 0.66. Thus we were able to achieve 83% of the performance of the Corman detector with 4,000 times fewer features.

When training and testing on the blog corpus, the detector using all the features achieved 0.70 F_1, a 74% increase from the Corman detector's 0.425 F_1. This is the best performing model on the blog corpus, from any experiment to date. The detector using only verb features achieves 0.74 F_1, which is only slightly worse than when both sets of features are used. When we trained using only the character features, the system achieves 0.65 F_1, which is still 54% higher than when the Corman detector is trained and tested on the blog corpus.

In the single corpus experiments, the detectors that we trained and tested on the Extremist paragraphs have higher performance than those trained on the web blogs, except for when we use only the five character features. A possible reason for this is the Stanford NER may not be recognizing the correct named entities in the Extremist texts, which contain many non-Western names, e.g., *Mujahidin*, *Okba ibn Nafi*, or *Wahid*. However, when we include the verb features, the detectors trained on the Extremist texts achieve better performance. We believe this is partially due to the greater number of stories in the Extremist corpus, and their increased grammatical fluency. The Extremist corpus is actually well written compared to the blog corpus, the latter of which contains numerous fragmentary and disjointed posts.

4.4 Cross Corpus Experiments

We show the generalizability of our best-performing detector (that including both verb and character features) by training it on one corpus and testing it on another.

When we trained the detector on the Extremist texts and tested on the blog texts, it scores a 0.68 F_1. This is 142% improvement over Corman's detector in the same setup (0.28 F_1), and is a higher F_1 than the previous state-of-the-art on any single corpus test. When we trained the detector on the Extremist corpus and tested on the combined corpus, it achieved 0.71 F_1, which is an 121% increase from Corman's detector in the equivalent setup.

For the detector trained on the blog corpus and tested on the Extremist corpus, the detector that uses both verbs and character features achieves an 0.27 F_1, which is a 2,600% increase over the Corman detector's 0.01 F_1 in this same setup. While 0.27 F_1 can by no means be called good performance, it is significantly better than the Corman detector's performance on this task, and so demonstrates significantly better generalizability. As seen in our experiments, detectors trained on only the blog corpus do not perform as well as detectors trained on the Extremist corpus. We suspect that this is partially due to the disfluent nature of the blog corpus, which includes many fragmentary sentences, grammatical errors, and slang, all of which are difficult for the NLP pipeline to handle.

Note that we performed no cross validation in the above experiments where we trained the detector on the Extremist corpus and tested on the blog corpus, or vice versa, because in these cases the training and testing sets have no intersection.

The cross corpus experiment with the largest percent increase is for the verb and character detector trained on the blog corpus and tested on the combined corpus. The new detector's F_1 is 0.41, a 4,000% increase from the Corman detector's 0.01 F_1 on this task. Although a 0.41 F_1 is also not good, this is a massive improvement over previous performance. This is further evidence that our verb and character feature based detector is significantly more generalizable than Corman's approach.

The remaining five cross corpus experiments involved the combined corpus. In this case, our detector out-performed Corman's detector. Of special note is the detector trained on the combined corpus and tested on the Extremist corpus. It achieved 0.75 F_1, which is 0.01 points of F_1 higher than our best single corpus detector, which was trained and tested on the Extremist corpus. This isn't a substantial increase in performance, but it suggests that information gleaned from the blog corpus does potentially–albeit marginally–help classification of the Extremist texts.

5 Conclusion

We have introduced a new story detection approach which uses simple verb and character features. This new detector outperforms the prior state-of-the-art in all tasks, sometimes by orders of magnitude. Further, we showed that our detector generalizes significantly better across lexically different corpora. We propose that this increase in performance and generalizability is due to the more general nature of our features, especially those related to verb classes. This approach has additional advantages, for example, the feature vector is fixed in size and does not grow in an unbounded fashion as new texts (with new verbs, agents, and patents) are added to the training data.

In future work we plan to develop richer character-based features. The current approach uses only normalized lengths of the five longest coreference chains, which leaves out important information about characters that could be useful to story detection. Indeed, our experiments showed that these character features only add a small amount of information above and beyond the verb features. However, when used alone, the character features still yield reasonable performance, which suggests that more meaningful character-based features could lead to story detectors with even better performance.

Acknowledgments This work was partially supported by National Institutes of Health (NIH) grant number 5R01GM105033-02. We thank W. Victor H. Yarlott for building a wrapper class to the *It Makes Sense* WSD. We also thank Reid Swanson especially, as well as Andrew Gordon, for working to retrieve, format, and providing their original annotations of the Weblog corpus. Thanks to Steve Corman for facilitating the transmission of the Extremist story data, which is covered by U.S. government FOUO rules.

Multi-modular domain-tailored OCR post-correction

Sarah Schulz and **Jonas Kuhn**

Abstract

One of the main obstacles for many Digital Humanities projects is the low data availability. Texts have to be digitized in an expensive and time consuming process whereas Optical Character Recognition (OCR) post-correction is one of the time-critical factors. At the example of OCR post-correction, we show the adaptation of a generic system to solve a specific problem with little data. The system accounts for a diversity of errors encountered in OCRed texts coming from different time periods in the domain of literature. We show that the combination of different approaches, such as e.g. Statistical Machine Translation and spell checking, with the help of a ranking mechanism tremendously improves over single-handed approaches. Since we consider the accessibility of the resulting tool as a crucial part of Digital Humanities collaborations, we describe the workflow we suggest for efficient text recognition and subsequent automatic and manual post-correction.

1 Introduction

Humanities are no longer just the realm of scholars turning pages of thick books. As the worlds of humanists and computer scientists begin to intertwine, new methods to revisit known ground emerge and options to widen the scope of research questions are available. Moreover, the nature of language encountered in such research attracts the attention of the NLP community (Kao and Jurafsky (2015), Milli and Bamman (2016)). Yet, the basic requirement for the successful implementation of such projects often poses a stumbling block: large digital corpora comprising the textual material of interest are rare. Archives and individual scholars are in the process of improving this situation by applying Optical Character Recognition (OCR) to the physical resources. In the *Google Books*[1] project books are being digitized on a large scale. But even though collections of literary texts like *Project Gutenberg*[2] exist, these collections often lack the texts of interest to a specific question. As an example, we describe the compilation of a corpus of adaptations of Goethe's *Sorrows of the young Werther* which allows for the analysis of character networks throughout the publishing history of this work.

The success of OCR is highly dependent on the quality of the printed source text. Recognition errors, in turn, impact results of computer-aided research (Strange et al., 2014). Especially for older books set in hard-to-read fonts and with stained paper the output of OCR systems is not good enough to serve as a basis for Digital Humanities (DH) research. It needs to be post-corrected in a time-consuming and cost-intensive process.

We describe how we support and facilitate the manual post-correction process with the help of informed automatic post-correction. To account for the problem of relative data sparsity, we illustrate how a generic architecture agnostic to a specific domain can be adjusted to text specificities such as genre and font characteristics by including just small amounts of domain specific data. We suggest a system architecture (cf. Figure 1) with trainable modules which joins general and specific problem solving as required in many applications.

We show that the combination of modules via a ranking algorithm yields results far above the performance of single approaches.

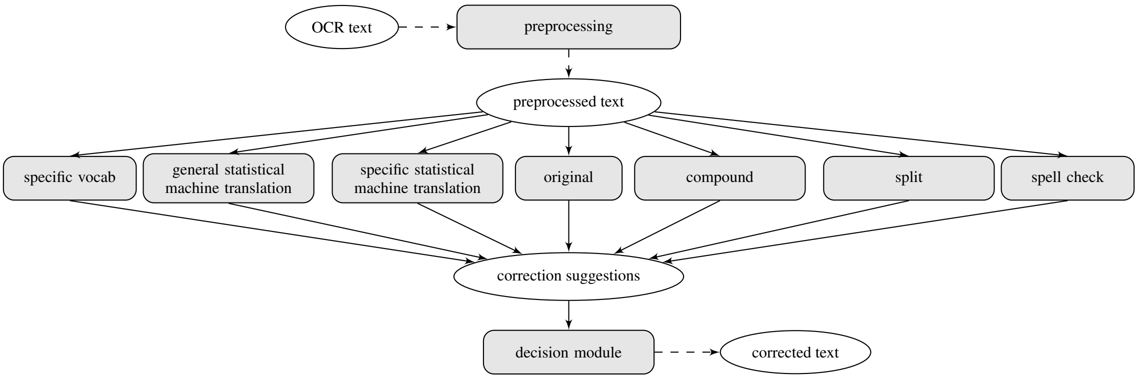

Figure 1: Multi-modular OCR post-correction system.

We discuss the point of departure for our research in Section 2 and introduce the data we base our system on in Section 4. In Section 5, we illustrate the most common errors and motivate our multi-modular, partly customized architecture. Section 6 gives an overview of techniques included in our system and the ranking algorithm. In Section 7, we discuss results, the limitations of automatic post-correction and the influence the amount of training data takes on the performance of such a system. Finally, Section 8 describes a way to efficiently integrate the results of our research into a digitization work-flow as we see the easy accessibility of computer aid as a central point in Digital Humanities collaborations.

2 Related work

There are two obvious ways to automatically improve quality of digitized text: optimization of OCR systems or automatic post-correction. Commonly, OCR utilizes just basic linguistic knowledge like character set of a language or reading direction. The focus lies on the image recognition aspect which is often done with artificial neural networks (cf. Graves et al. (2009), Desai (2010)).
Post-correction is focused on the correction of errors in the linguistic context. It thus allows for the purposeful inclusion of knowledge about the text at hand, e.g. genre-specific vocabulary. Nevertheless, post-correction has predominantly been tackled OCR system agnostic as outlined below. As an advantage, post-correction can also be applied when no scan or physical resource is available.
There have been attempts towards shared datasets for evaluation. Mihov et al. (2005) released a corpus covering four different kinds of OCRed text comprising German and Bulgarian. However, in 2017 the corpus was untraceable and no recent research relating to the data could be found.
OCR post-correction is applied in a diversity of fields in order to compile high-quality datasets. This is not merely reflected in the homogeneity of techniques but in the metric of evaluation as well. While accuracy has been widely used as evaluation measure in OCR post-correction research, Reynaert (2008a) advocates the use of precision and recall in order to improve transparency in evaluations. Dependent on the paradigm of the applied technique even evaluation measures like BLEU score can be found (cf. Afli et al. (2016)).
Since shared tasks are a good opportunity to establish certain standards and facilitate the comparability of techniques, the Competition on Post-OCR Text Correction[3] organized in the context of ICDAR 2017 could mark a milestone for more unified OCR post-correction research efforts.

Regarding techniques used for OCR post-correction, there are two main trends to be mentioned: statistical approaches utilizing error distributions inferred from training data and lexical approaches oriented towards the comparison of source words to a canonical form. Combinations of the two approaches are also available.
Techniques residing in this **statistical** domain have the advantage that they can model specific distributions of the target domain if training data is available. Tong and Evans (1996) approach post-correction as a statistical language modeling problem, taking context into account. Pérez-Cortes et al. (2000) employ stochastic finite-state automaton along with a modified version of the Viterbi Algorithm to perform a stochastic error correcting parsing. Extending the simpler stochastic context-sensitive models, Kolak and

[3] https://sites.google.com/view/icdar2017-postcorrectionocr/home, 3.07.2017.

Resnik (2002) apply the first noisy channel model, using edit distance from noisy to corrected text on character level. In order to train such a model, manually generated training data is required. Reynaert (2008b) suggests a corpus-based correction method, taking spelling variation (especially in historical text) into account. Abdulkader and Casey (2009) introduce an error estimator neural network that learns to assess error probabilities from ground truth data which in turn is then suggested for manual correction. This decreases the time needed for manual post-correction since correct words do not have to be considered as candidates for correction by the human corrector. Llobet et al. (2010) combine information from the OCR system output, the error distribution and the language as weighted finite-state transducers. Reffle and Ringlstetter (2013) use global as well as local error information to be able to fine-tune post-correction systems to historical documents. Related to the approach introduced by Pérez-Cortes et al. (2000), Afli et al. (2016) use statistical machine translation for error correction using the Moses toolkit on character level. Volk et al. (2010) merge the output of two OCR systems with the help of a language model to increase the quality of OCR text. The corpus of yearbooks of the Swiss Alpine Club which has been manually corrected via crowdsourcing (cf. Clematide et al. (2016)) is available from their website.

Lexical approaches often use rather generic distance measures between an erroneous word and a potential canonical lexical item. Strohmaier et al. (2003) investigate the influence of the coverage of a lexicon on the post-correction task. Considering the fact that writing in historical documents is often not standardized, the success of such approaches is limited. Moreover, systems based on lexicons rely on the availability of such resources. Historical stages of a language – which constitute the majority of texts in need for OCR post-correction – often lack such resources or provide incomplete lexicons which would drastically decrease performance of spell-checking-based systems. Ringlstetter et al. (2007) address this problem by suggesting a way to dynamically collect specialized lexicons for this task. Takahashi et al. (1990) apply spelling correction with preceding candidate word detection. Bassil and Alwani (2012) use Google's online spelling suggestions for as they draw on a huge lexicon based on contents gathered from all over the web. The **human component** as final authority has been mentioned in some of these projects. Visual support of the post-correction process has been emphasized by e.g. Vobl et al. (2014) who describe a system of iterative post-correction of OCRed historical text which is evaluated in an application-oriented way. They present the human corrector with an alignment of image and OCRed text and make batch correction of the same error in the entire document possible. They can show that the time needed by human correctors considerably decreases.

3 Evaluation metrics

We describe and evaluate our data by means of word error rate (WER) and character error rate (CER). The error rates are a commonly used metric in speech recognition and machine translation evaluation and can also be referred to as length normalized edit distance. They quantify the number of operations, namely the number of insertions, deletions and substitutions, that are needed to transform the suggested string into the manually corrected string and are computed as follows:

$$\text{WER} = \frac{\text{word insertions} + \text{word substitutions} + \text{word deletions}}{\text{\# words in the reference}}$$

$$\text{CER} = \frac{\text{char insertions} + \text{char substitutions} + \text{char deletions}}{\text{\# characters in the reference}}$$

4 Data

As mentioned in the introduction, errors found in OCRed texts are specific to time of origin, quality of scan and even the characteristics of a specific text. Our multi-modular architecture paves the way for a solution taking this into account by including general as well as specific modules. Thus, we suggest to include domain specific data as well as larger, more generic data sets in order to enhance coverage of vocabulary and possible error classes. The data described hereafter constitutes parallel corpora with OCR output and manually corrected text which we utilize for training statistical models.

4.1 The Werther corpus

Since our system is developed to help in the process of compiling a corpus comprising adaptations of Goethe's *The Sorrows Of Young Werther* throughout different text types and centuries, we

Table 1: Werther texts included in our corpus from different authors and times of origin.

collected texts from this target domain. To be able to train a specialized system, we manually corrected a small corpus of relevant texts (cf. Table 2). We use the output of Abbyy Fine Reader 7 for several Werther adaptations (Table 1) all based on scans of books with German Gothic lettering.

4.2 The Deutsches Textarchive (DTA) corpus

Even though manual OCR post-correction is a vital part of many projects, only very little detailed documentation of this process exists. *Das Deutsche Textarchiv* (The German Text Archive) (DTA) is one of the few projects providing detailed correction guidelines along with the scans and the text corrected within the project (Geyken et al., 2012). This allows the compilation of a comprehensive parallel corpus of OCR output and corrected text spanning a period of four centuries (17th to 20th) in German Gothic lettering. For OCR, we use the open source software *tesseract*[4] (Smith and Inc, 2007) which comes with recognition models for Gothic font.

4.3 Gutenberg data for language modeling

Since the output of our system is supposed to consist of well-formed German sentences, we need a method to assess the quality of the output language. This task is generally tackled by language modeling. We compiled a collection of 500 randomly chosen texts from Project Gutenberg[5] comprising 28,528,078 tokens. With its relative closeness to our target domain it constitutes the best approximation of a target language. The language model is trained with the KenLM toolkit (Heafield, 2011) with an order of 5 on token level and 10 on character level following De Clercq et al. (2013).

5 Why OCR post-correction is hard

In tasks like the normalization of historical text (Bollmann et al., 2012) or social media, one can take advantage of regularities in the deviations from the standard form that appear throughout an entire genre or in case of social media e.g. dialect region (Eisenstein, 2013). Errors in OCR, however, depend on the font and quality of the scan as well as the time of origin which makes each text unique in its composition of features and errors.

In order to exemplify this claim, we analyzed three different samples: *Lorenz Konau* (1776), *Werther der Jude* (1910) and a sample from the DTA data. Figure 2 (a-c) illustrate the point that the quality of scan is crucial for the OCR success. Figure 2a shows a text from the 20th century where the type setting is rather regular and the distances between letters is uniform as opposed to Figure 2b. Figure 2c shows how the writing from the back of the page shines through and makes the script less readable. Thus, we observe a divergence in the frequency of certain character operations between those texts: the percentage of substitutions range between 74% for *Lorenz Konau* and 60% for *Werther der Jude* and 18% and 30% of insertions, respectively. The varying percentage of insertions might be due to the fact that some scans are more "washed out" than others. Successful insertion of missing characters, however, relies on the precondition that a system knows a lot of actual words and sentences in the respective language and cannot be resolved via e.g. character similarity like in the substitution from *l* to *t*.

Another factor that complicates the correction of a specific text is the number of errors per word. Words with an edit distance of one to the correct version are easier to correct those with more than one necessary operation. With respect to errors per word our corpus shows significant differences in error distributions. Especially in our DTA corpus the number of words with two or more character-level errors per word is considerably higher than those with one error. For *Werther*

[4] Considering the open source aspect of our resulting system, we decided to use the open source OCR software tesseract and move away from Abbyy some time after our project started: https://github.com/tesseract-ocr.

(c) DTA: Blumenbach (1791): Handbuch der Naturgeschichte

Figure 2: Scans of three different texts from our corpora. Emphasizes differences in quality of scan and differences in type setting, font and genre (e.g. drama).

der Jude (WER 10.0, CER 2.4) the number of errors in general is much lower than for *Konau* (WER: 34.7, CER: 10.9). These characteristics indicate that subcorpus-specific training of a system is promising.

6 Specialized multi-modular post-correction

In order to account for the nature of errors that can occur in OCR text, we apply a variety of modules for post-correction. The system proceeds in two stages and is largely based on an architecture suggested by Schulz et al. (2016) for normalization of user-generated contents. In the first stage, a set of specialized modules (Section 6.1) suggest corrected versions for the tokenized[6] OCR text lines. Those modules can be context-independent (work on just one word at a time) or context-dependent (an entire text line is processed at a time). The second stage is the decision phase. After the collection of various suggestions per input token, these have to be ranked to enable a decision for the most probable output token given the context. We achieve this by assigning weights the different modules with the help of Minimal Error Rate Training (MERT) (Och, 2003).

6.1 Suggestion modules

In the following, we give an outline of techniques included into our system.

6.1.1 Word level suggestion modules

Schriften ſind insgemein ſo trocken und ſo ernſt;

Figure 3: Irregular type setting in German Gothic lettering. *sind* and *insgemein* are two separate words but yet written closely together.

- **Original**: the majority of words do not contain any kind of error, thus we want to have the initial token available in our suggestion pool
- **Spell checker**: spelling correction suggestion for misspelled words with hunspell[7]
- **Compounder**: merges two tokens into one token if it is evaluated as an existing word by hunspell
- **Word splitter**: splits two tokens into two words using compound-splitter module from the Moses toolkit (Koehn et al., 2007)
- **Text-Internal Vocabulary**: extracts high-frequent words from the input texts and suggests them as correction of words with small adjusted Levenshtein distance[8]

The compound and word split techniques react to the variance in manual typesetting, where the distances between letters vary. This means that the word boundary recognition becomes difficult (cf. Figure 3).

A problem related to the spell-checking approach is the limited coverage of the dictionary since it uses a modern German lexicon. Related to this is the difficulty of out-of-vocabulary words above average for literature text. Archaic words from e.g. the 17th century or named entities cannot be found in a dictionary and can therefore not be covered with any of the approaches mentioned above.

[6] Tokenizer of TreeTagger (Schmid, 1997).

[7] https://github.com/hunspell/hunspell.

[8] OCR-adjusted Levenshtein distance taking frequent substitution, insertion and deletion patterns learned from training data into account.

However, especially named entities are crucial for the automatic or semi-automatic analysis of narratives e.g. with the help of network analysis. Our Text-Internal Vocabulary technique is designed to find frequent words in the input text, following the assumption that errors would not be regular enough to distort those frequencies. We compile a list from those high-frequency words. Subsequently, erroneous words can be corrected calculating an OCR-adjusted Levenshtein distance. In this way misspelled words like *Loveuzo* could be resolved to *Lorenzo* if this name appears frequently. Since the ranking algorithm relies on a language model which will most probable not contain those suggestions, we insert the high-frequency words into the language modeling step.

6.1.2 Sentence level suggestion modules

As has been suggested by Afli et al. (2016), we include Phrase-based **Statistical Machine Translation** (SMT) into our system. We treat the post-correction as a translation problem translating from erroneous to correct text. Like in standard SMT, we train our models on a parallel corpus, the source language being the OCRed text and the target language being manually corrected text. We train models on token level as well as on character-level (unigram). This way, we aim at correcting frequently mis-recognized words along with frequent character-level errors. We train four different systems:

- token level
  - domain specific data (cf. Section 4.1)
  - general data (cf. Section 4.2)
- character level
  - domain specific data (cf. Section 4.1)
  - general data (cf. Section 4.2)

The models are trained with the Moses toolkit (Koehn et al., 2007). Moreover, we use a subsequent approach by forwarding the output of the character-based SMT model to the token-based SMT.

6.1.3 Additional feature

The information whether a word contains an error can help to avoid the incorrect alternation of an initially correct word (overcorrection). In order to deliver this information to the decision module without making a hard choice for each word, we include the information whether a word has been found either in combination with the word before or after in a corpus (cf. Section 4.3) into the decision process in form of a feature that will be weighted along with the other modules. This naive language modeling approach allows for a context-relevant decision of the correctness of a word.

6.2 Decision modules: the ranking mechanism

Since the recognition errors appearing in a text are hard to pre-classify by nature, we run all modules on each sentence of the input, returning suggestions for each word. Since the output of some of our modules are entire sentences, input sentence and output sentence have to be word-aligned in order to be able to make suggestions on word level. The word alignment between input and output sentence is done with the Needleman-Wunsch algorithm (Needleman and Wunsch, 1970), an algorithm originally developed in bioinformatics.

From all corrected suggestions the most probable well-formed combination has to be chosen. To solve the combinatorial problem of deciding which suggestion is the most probable candidate for a word, the decision module makes use of the Moses decoder.

As in general SMT, the decoder makes use of a language model (cf. Section 4.3) and a phrase table. The phrase table is compiled from all input words along with all possible correction suggestions. In order to assign weights to the single modules and the language model, we tune on the phrase tables collected from a run on our dev$_{overall}$ set, following the assumption that suggestions of certain modules are more reliable than others and expect their feature weights to be higher after tuning.

7 Experiments

7.1 Experimental Setup

To guarantee diversity, we split each of texts 1-4 (cf. Table 1) into three parts and combined the respective parts: 80% train (train), 10% development (dev$_{SMT}$) and 10% test (test$_{init}$).

Test setup We introduce two different test scenarios. Even though both test sets are naturally compiled from unseen data, the first test set consists of a self-contained Werther adaptation introducing new named entities, originating from a different source and thus showing a different error

set	# tokens (OCR)	# tokens (corr)	WER	CER
train	70,159	68,608	15.7	5.5
train$_{ext}$	133,457	131,901	12.9	4.0
dev$_{SMT}$	12,464	12,304	13.9	3.5
dev$_{overall}$	13,663	13,396	16.75	4.6
test$_{init}$	17,443	17,367	9.4	2.5
test$_{unk}$	13,286	13,304	31.2	9.2

Table 2: Werther specific parallel corpus of OCR text and corrected text showing the number of tokens before and after post-correction along with WER and CER

set	# tokens (OCR)	# tokens (corr)	WER	CER
train	3,452,922	3,718,712	41.6	13.2
dev	663,376	836,974	30.4	9.1

Table 3: DTA parallel corpus of OCR text and corrected text showing the number of tokens before and after post-correction along with WER and CER

constitution. It constitutes an evaluation in which no initial manual correction as support for the automatic correction is included in the workflow. We henceforth call this unknown set *test$_{unk}$* (text 6).

In contrast, the second set contains parts of the same texts as the training, thus specific vocabulary might have been introduced already. The results for this test set give a first indication of the extent to which pre-informing the system with manually correcting parts of a text could assist the automatic correction process. Since this scenario can be described as a text-specific initiated post-correction, we henceforth refer to this test set as *test$_{init}$*.

We further on experiment with an extended training set train$_{ext}$ (train with texts 7 and 8) to assess the influence of the size of the specific training set on the overall performance. The sizes of the datasets before and after correction along with WER and CER are summarized in Table 2. The sizes for the general dataset before and after correction along with WER and CER are summarized in Table 3.

7.2 Evaluation

In the following we concentrate on the comparison of WER and CER before and after automatic post-correction. As a baseline for our system we chose the strongest single-handed module (SMT on character-level trained on Werther data).

training set	system	test$_{init}$		test$_{unk}$	
		WER	CER	WER	CER
	original text	23.5	15.1	36.7	30.0
train	baseline	22.0	13.2	26.6	26.3
	overall system	**4.7**	**8.0**	**15.4**	**19.6**
train$_{ext}$	baseline	21.1	11.7	24.0	20.4
	overall system	**4.4**	**7.2**	**15.2**	**16.4**

Table 4: WER and CER for both test sets before and after automatic post-correction for the system trained with the small training set (train) and the larger training set (train$_{ext}$). Baselines: the original text coming from the OCR system and the character-level SMT system trained on the Werther data.

Overall performance As indicated previously, our test sets differ with respect to their similarity to the training set. The results for both test scenarios for systems trained on our two training sets are summarized in Table 4. The results from test$_{init}$ and test$_{unk}$ show that our system performs considerably better than the baseline and can improve quality of the OCR output considerably.

For test$_{unk}$, the system improves the quality by almost 20 points of WER from 36.7 to 15.4 and over 10 points in CER from 30.0 to 19.6. For test$_{init}$, our system improves the quality of the text with a reduction of approximately 20 points of WER from 23.5 to 4.7 and 7 points in CER from 15.1 to 8.0. It is not surprising that the decrease in WER is stronger than the decrease in CER. This is due to the fact that many words contain more than one error and require more than one character level operation to get from the incorrect to the correct string.

Just slight improvement can be shown by adding training material to the Werther-specific parts of the system (cf. train$_{ext}$ row of Table 4). Merely the CER can be improved whereas the WER stays about the same. The improvement in test$_{unk}$ is higher than for test$_{init}$.

Module specific analysis Since a WER and CER evaluation is not expedient for all modules as they were designed to correct specific problems and not the entirety of them, we look into the specialized modules in terms of correct suggestions contributed to the suggestion pool and correct suggestions only suggested by one module (unique suggestions). As the system including the extended training set train$_{ext}$ delivered slightly better results, in the following we will describe the contribution of the single modules

	test_{init}			test_{unk}		
module	# overcorrected	# corrected	# unique correct	# overcorrected	# corrected	# unique correct
SMT Werther token	128	364	10	209	1,089	0
SMT Werther character	235	684	0	700	1,919	0
SMT Werther cascaded	273	697	2	728	1,933	4
SMT DTA token	2,179	229	8	1,627	893	19
SMT DTA character	4121	372	22	3,143	1,530	115
text-internal vocab	3,317	131	16	4,142	244	60
word split	594	3	0	720	45	2
spell check	1,329	219	15	2,819	731	40
compound	222	0	0	169	2	2
overall system	238	2171	-	675	2,642	-

Table 5: Number of overcorrected, corrected and uniquely corrected words per module out of 17,367 tokens in test_{init} (2,726 erroneous words) and 13,304 tokens in test_{unk} (4,141 erroneous words)

to the overall performance of this system (cf. Table 5). For test_{unk} the number of corrected tokens along with the number of overcorrections is higher than for test_{init} throughout all modules. Clearly, for test_{init} the Werther-specific modules are strongest. The more general modules prove useful for test_{unk}. The number of corrected words increases for the SMT module trained on DTA data on character-level. The usefulness of the module extracting specific words (text-internal vocab) as well as the general SMT model and the spell checker becomes evident in terms of unique suggestions contributed by those modules.

The analysis of the output of the individual modules and their contribution to the overall system uncovers an issue: those modules that produce a high number of incorrect suggestions, thus overcorrecting actually correct input tokens, are at the same time those modules that are the only ones producing correct suggestions for some of the incorrect input words. Consequently, those uniquely suggested corrections are not chosen in the decision modules due to an overall weak performance of this module. These suggestions are often crucial to the texts like the suggestions by the special vocabulary module which contain named entities or words specific to the time period. For our test_{unk} set, the text-internal vocabulary module yields around 60 unique suggestions, out of which 15 are names (Friedrich, Amalia) or words really specific to the text (*Auftrit* spelled with one t instead of two).

Challenges In the context of literature OCR post-correction is a challenging problem since the texts themselves can be considered *non-standard text*. The aim is not to bring the text at hand to an agreed upon standard form but to digitize exactly what was contained in the print version. This can be far from the standard form of a language. In one of our texts, we find a character speaking German with a strong dialect. Her speech contains a lot of words that are incorrect in standard German, however, the goal is it to preserve this "errors" in the digital version. Thus, correction merely on the basis of the OCR text without consulting the printed version or an image-digitized facsimile, can essentially never be perfect. It follows, that the integration of automatic post-correction techniques into the character recognition process could lead to further improvements.

7.3 Adaptability

Reusability as a key concept in NLP for DH originates in the time limitations given in such projects. Since DH projects do not evolve around the development of tools but the analysis performed with the help this tools in order to answer a specific question, the tools are expected to be delivered in an early phase of collaborative projects. From-scratch development easily exceeds this time limits. We show that our OCR post-correction system is modular enough to be adjusted to correct texts from other languages by training it for two other languages, English and French, with data released in the OCR post-correction competition organized in the context of ICDAR 2017[9]. The texts originate from the the last four centuries and come from different collections and therefore have been digitized using different OCR systems. The data is summarized in Table 6[10].

We adjust our system to the language by retraining the SMT models and including spell-checkers for the respective languages. Due to the modular architecture these adjustments can be made eas-

[9] https://sites.google.com/view/icdar2017-postcorrectionocr/home, 3.07.2017.

[10] The test set does not comply with the official shared task set since the manually corrected data is not yet available for the test set. We test on a combination of periodicals and monographs.

language	$train_{ocr}$	$train_{gold}$	$dev1_{ocr}$	$dev1_{gold}$	$dev2_{ocr}$	$dev2_{gold}$	$test_{ocr}$	$test_{gold}$
English	309,080	282,738	71,049	65,480	13,000	11,966	14,302	12,859
French	805,438	783,371	167,473	163,373	9,566	9,216	12,289	11,780

Table 6: Number of tokens in the English and French corpus provided by the competition on OCR-postcorrection.

ily and with a low expenditure of time. Since the datasets are compilation of a variety of texts, we use all modules but the domain-specific SMT models. We solely include one token-level and character-level SMT module for each language.

language	system	WER	CER
English	original	29.4	28.4
	SMT Cascaded	22.7	23.6
	overall system	22.1	24.5
French	original text	13.3	25.0
	SMT Cascaded	9.9	20.0
	overall system	8.7	21.5

Table 7: The results reported in word error rate (WER) and character error rate (CER) for the English and French test set.

The strongest unique module for these two languages is the subsequent combination of the character-level SMT and the token-level SMT models (Cascaded). For English it performs just slightly worse on WER and even outperforms the overall system on the CER. For French, the overall system is clearly stronger than the Cascaded SMT system with more than 1 percent improvement of WER but also performs worse in terms of CER by 1.5 percent. Generally, the OCR post-correction system achieves about 25% reduction of WER for English and over 30% reduction in WER for French.

8 Digitization workflow

We integrate the automatic OCR process with tesseract and our automatic post-correction system into a workflow which results in an hocr file, an XML format which is readable by PoCoTo (Vobl et al., 2014) a tool for supporting manual post-correction of OCRed text through alignment of image and digitized text. The upload of scans or images is provided online via a webapplication[11]. This shields the user from the technicalities of the correction process and provides them with the input for the PoCoTo tool.

The implementation of an easy-to-handle workflow is an often underemphasized aspect of DH. It needs to be intuitive enough to not absorb the time ion has been saved via automation. Since the final post-correction step requires that the human corrector compares the digitized version with the scan, presenting both next to each other is an ideal scenario. This functionality is one of the main strengths of PoCoTo, a visual correction tool, supporting manually initiated correction operations and batch correction of the same error.

9 Conclusion

We can show that the enhancement of a general, adaptable architecture by including small but specific data sets can improve results within a specific domain. Moreover, the combination of different techniques for of OCR post-correction is significantly superior to single techniques. Especially the integration of SMT models on token level and character level contributes to the overall success of the system. Due to the complexity of OCR post-correction, there cannot be a general solution. Even though the ranking algorithm achieves large improvement, further potential lies in the inclusion of fine-tuned language models since the decision process highly depends upon it. The intrinsic characteristic of literature as being *non-standard* complicates the task. However, techniques that focus on these features like our module that is specialized on extracting text-specific vocabulary show promising results for e.g. named entity correction.

Abstract

The charge prediction task is to determine appropriate charges for a given case, which is helpful for legal assistant systems where the user input is fact description. We argue that relevant law articles play an important role in this task, and therefore propose an attention-based neural network method to jointly model the charge prediction task and the relevant article extraction task in a unified framework. The experimental results show that, besides providing legal basis, the relevant articles can also clearly improve the charge prediction results, and our full model can effectively predict appropriate charges for cases with different expression styles.

1 Introduction

The task of automatic charge prediction is to determine appropriate charges, such as *fraud*, *larceny* or *homicide*, for a case by analyzing its textual fact description. Such techniques are crucial for legal assistant systems, where users could find similar cases or possible penalties by describing a case with their own words. This is helpful for non-legal professionals to get to know the legal basis of their interested cases, e.g., cases they or their friends are involved in, since the massive legal materials and the lack of knowledge of legal jargons make it hard for outsiders to do it on their own.

However, predicting appropriate charges based on fact descriptions is not trivial: (1) The differences between two charges can be subtle, for example, in the context of criminal cases in China, distinguishing *intentional homicide* from *intentional injury* would require to determine, from the fact description, whether the defendant *intended to kill* the victim, or just *intended to hurt the victim, who, unfortunately died of severe injury*. (2) Multiple crimes may be involved in a single case, which means we need to conduct charge prediction in the multi-label classification paradigm. (3) Although we can expect an off-the-shelf classification model to learn to label a case with corresponding charges through massive training data, it is always more convincing to make the prediction with its involved law articles explicitly shown to the users, as legal basis to support the prediction. This issue is crucial in countries using *the civil law system*, e.g., China (except Hong Kong), where judgements are made based on statutory laws only. For example, in Fig. 1, a judgement document in China always includes relevant law articles (in the court view part) to support the decision. Even in countries using *the common law system*, e.g., the United States (except Louisiana), where the judgement is based mainly on decisions of previous cases, there are still some statutory laws that need to be followed when making decisions.

Existing attempts formulate the task of automatic charge prediction as a single-label classification problem, by either adopting a k-Nearest Neighbor (KNN) (Liu et al., 2004; Liu and Hsieh, 2006) as the classifier with shallow textual features, or manually designing key factors for specific charges to help text understanding (Lin et al., 2012), which make those works hard to scale to more types of charges. There are also works addressing a related task, finding the law articles that are involved in a given case. A simple solution is to convert this multi-label problem into a multi-class classification task by only considering a fixed set of article combinations (Liu and Liao, 2005; Liu and Hsieh, 2006), which can only be applied to a small set of articles and does not fit to real applications. Recent improvement takes a two-step approach by performing a preliminary classification first and then re-ranking the results with

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2727–2736
Copenhagen, Denmark, September 7–11, 2017.

word-level and article-level features (Liu et al., 2015). These efforts advance the applications of machine learning and natural language processing methods into legal assistance services, however, they are still in an early stage, e.g., relying on expert knowledge, using relatively simple classification paradigms, and shallow textual analysis. More importantly, related tasks, e.g., charge prediction and relevant article extraction, are treated independently, ignoring the fact that they could benefit from each other.

Recent advances in neural networks enable us to jointly model charge prediction and relevant article extraction in a unified framework, where the latent correspondence from the fact description about a case to its related law articles and further to its charges can be explicitly addressed by a two-stack attention mechanism. Specifically, we use a sentence-level and a document-level Bi-directional Gated Recurrent Units (Bi-GRU) (Bahdanau et al., 2015) with a stack of fact-side attention components to model the correlations among words and sentences, in order to capture the whole story as well as important details of the case. Given the analysis of the fact description, we accordingly learn a stack of article-side attention components to attentively select the most supportive law articles from the statutory laws to support our charge prediction, which is investigated in the multi-label paradigm.

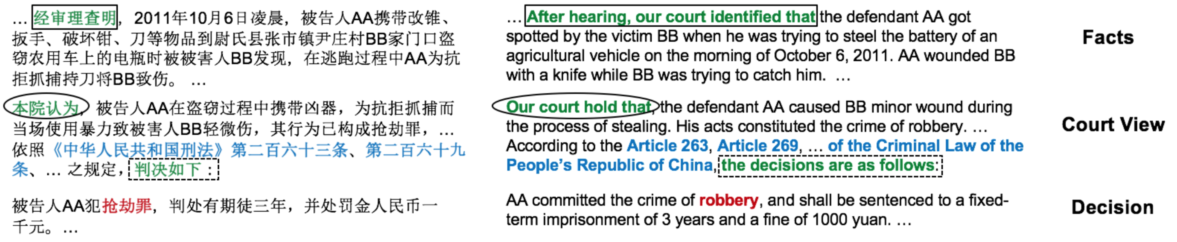
We evaluate our model in the context of predicting charges for criminal cases in China. We collect publicly available judgement documents from China's government website, from which we can automatically extract *fact descriptions*, *relevant law articles* and *the charges* using simple rules, as shown in Figure 1. Experimental results show that our neural network method can effectively predict appropriate charges for a given case, and also provide relevant law articles as legal basis to support the prediction. Our experiments also provide quantitive analysis about the effect of fact-side and article-side information on charge predicion, and confirm that, apart from providing legal basis, relevant articles also contain useful information that can help to improve charge prediction in the civil law system. We also examine our model on the news reports about criminal cases. Although trained on judgement documents, our model can still achieve promising performance on news data, showing a reasonable generalization ability over different expression styles.

2 Related Work

The charge prediction task aims at finding appropriate charges based on the facts of a case. Previous works consider this task in a multi-class classification framework, which takes the fact description as input and outputs a charge label. (Liu et al., 2004; Liu and Hsieh, 2006) use KNN to classify 12 and 6 criminal charges in Taiwan. However, except for the inferior scalability of the KNN method, their word-level and phrase-level features are too shallow to capture sufficient evidence to distinguish similar charges with subtle differences. (Lin et al., 2012) propose to make deeper understanding of a case by identifying charge-specific factors that are manually designed for 2 charges. This method also suffers from the scalability issue due to the human efforts required to design and annotate these factors for each pair of charges. Our method, however, employs Bi-GRU and a two-stack attention mechanism to make comprehensive understanding of a case without relying on explicit human annotations.

Within the civil law system, there are some works focusing on identifying applicable law articles for a given case. (Liu and Liao, 2005; Liu and Hsieh, 2006) convert this multi-label problem into a multi-class classification problem by only considering a fixed set of article combinations, which cannot scale well since the number of possible combinations will grow exponentially when a larger set of law articles are considered. (Liu et al., 2015) instead design a scalable two-step approach by first using Support Vector Machine (SVM) for preliminary article classification, and then re-ranking the results using word level features and co-occurence tendency among articles. We also use SVM to extract top k candidate articles, but further adopt Bi-GRU and article-side attention to better understand the texts and exploring the correlation among articles. More importantly, we optimize the article extraction task within our charge prediction framework, which not only provides another view to understand the facts, but also serves as legal basis to support the final decision.

Another related thread of work is to predict the overall outcome of a case. The target can be which party will the outcome side with (Aletras et al., 2016), or whether the present court will affirm or reverse the decision of a lower court (Katz et al.,



…经审理查明，2011年10月6日凌晨，被告人AA携带改锥、扳手、破坏钳、刀等物品到尉氏县张市镇尹庄村BB家门口盗窃农用车上的电瓶时被被害人BB发现，在逃跑过程中AA为抗拒抓捕持刀将BB致伤。 …	…After hearing, our court identified that the defendant AA got spotted by the victim BB when he was trying to steel the battery of an agricultural vehicle on the morning of October 6, 2011. AA wounded BB with a knife while BB was trying to catch him. …	**Facts**
本院认为，被告人AA在盗窃过程中携带凶器，为抗拒抓捕而当场使用暴力致被害人BB轻微伤，其行为已构成抢劫罪，…依照《中华人民共和国刑法》第二百六十三条、第二百六十九条、… 之规定，判决如下：	Our court hold that the defendant AA caused BB minor wound during the process of stealing. His acts constituted the crime of robbery. … According to the Article 263, Article 269, … of the Criminal Law of the People's Republic of China, the decisions are as follows:	**Court View**
被告人AA犯抢劫罪，判处有期徒三年，并处罚金人民币一千元。…	AA committed the crime of robbery, and shall be sentenced to a fixed-term imprisonment of 3 years and a fine of 1000 yuan. …	**Decision**

Figure 1: An example judgement document excerpt of a criminal case in our dataset. Names are anonymized as AA and BB. Rectangulars, ellipses and dashed rectangulars refer to the clauses that usually indicate the beginning of the facts part, the court view part and the decision part, respectively. Articles and charges are extracted with regular expressions and a charge list.

2016). Our work differs from them in that, instead of binary outcome (the latter one also contains an *other* class), we step further to focus on the detailed results of a case, i.e., the charges, where the output may contain multiple labels.

We also share similar spirit with the legal question answering task (Kim et al., 2014a), which aims at answering the yes/no questions in the Japanese legal bar exams, that we all believe that relevant law articles are important for decisions in the civil law system. Different from ours, this task requires participants to extract relevant Japanese Civil Code articles first, and then use them to answer the yes/no questions. The former phase is often treated as an information retrieval task, and the latter phase is considered as a textual entailment task (Kim et al., 2014b; Carvalho et al., 2016).

In the field of artificial intelligence and law, there are also works trying to find relevant cases given the input query (Raghav et al., 2016; Chen et al., 2013), which is crutial for decision making in the common law system. Rather than finding relevant cases, our work focuses on predicting specific charges, and we also emphasize the importance of law articles in decision making, which is important in the civil law system where the decisions are made based solely on statutory laws.

Our work is also related to the task of document classification, but mainly differs in that we also need to automatically identify applicable law articles to support and improve the charge prediction. Recently, various neural network (NN) architectures such as Convolutional Neural Network (CNN) (Kim, 2014) and Recurrent Neural Network (RNN) have been used for document embedding, which is further used for classification. (Tang et al., 2015) propose a two-layer scheme, RNN or CNN for sentence embedding, and another RNN for document embedding. (Yang et al., 2016) further use global context vectors to attentively distinguish informative words or sentences from non-informative ones during embedding, which we share similar spirit with. But, we take a more flexible and descriptive two-stack attention mechanism, one stack for fact embedding, and the other for article embedding which is dynamically generated for each instance according to the fact-side clues as extra guidance. Another difference is the multi-label nature of our task, where, rather than optimizing as multiple binary classification tasks (Nam et al., 2014), we convert the multi-label target to label distribution during training with cross entropy as loss function (Kurata et al., 2016), and use a threshold tuned on validation set to produce the final prediction, which performs better in our pilot experiments.

3 Data Preparation

Our data are collected from China Judgements Online[1], where the Chinese government has been publishing judgement documents since 2013. We randomly choose 50,000 documents for training, 5,000 for validation and 5,000 for testing. To ensure enough training data for each charge, we only classify the charges that appear more than 80 times in the training data, and treat documents with other charges as negative data. As for law articles, we consider those in the Criminal Law of the People's Republic of China. The resulting dataset contains 50 distinct charges, 321 distinct articles, averagely 383 words per fact description, 3.81 articles per case, and 3.56% cases with more than one charges.

An example judgement document is shown in Figure 1, where we highlight the indicator clauses that we used to divide a document into three pieces

[1] http://wenshu.court.gov.cn

and extract *fact description*, *articles*, and *charges* from each piece, respectively. We use a manually collected charge list to identify all the charges, and law articles are extracted by regular expressions[2]. The extracted charges and articles are considered as gold standard charges and articles for the corresponding fact description. We also masked all the charges in fact descriptions, since although rare, charge names sometimes may appear in the fact description part.

Currently, it is hard and expensive to match the facts related to different defendants with their corresponding charges. We therefore only consider the cases with one defendant, and leave the challenging multi-defendant cases for future work. Although this simplification may change the real-world charge distribution, it enables us to automatically build large scale high quality dataset without relying on annotations from legal practitioners.

4 Our Approach

As depicted in Fig. 2, our approach contains the following steps: (1) The input fact description is fed to a document encoder to generate the fact embedding $\mathbf{d}_f$, where $\mathbf{u}_{fw}$ and $\mathbf{u}_{fs}$ are global word-level and sentence-level context vectors used to attentively select informative words and sentences. (2) Concurrently, the fact description is also passed to an article extractor to find top k relevant law articles. (3) These articles are embedded by another document encoder, and passed to an article aggregator to attentively select supportive articles, and produce the aggregated article embedding $\mathbf{d}_a$. Specifically, three context vectors, i.e., $\mathbf{u}_{aw}$, $\mathbf{u}_{as}$ and $\mathbf{u}_{ad}$, are dynamically generated from $\mathbf{d}_f$, to produce attention values within the article document encoder and the article aggregator. (4) Finally, $\mathbf{d}_f$ and $\mathbf{d}_a$ are concatenated and passed to a softmax classifier to predict the charge distribution for the input case.

4.1 Document Encoder

Intuitively, a sentence is a sequence of words and a document is a sequence of sentences. The document embedding problem, therefore, can be converted to two sequence embedding problems (Tang et al., 2015; Yang et al., 2016). As shown in Fig. 3, we can first embed each sentence using a sentence-level sequence encoder, and then aggregate them with a document-level sequence encoder to produce the document embedding $\mathbf{d}$. While these two encoders can have different architectures, we use the same here for simplicity.

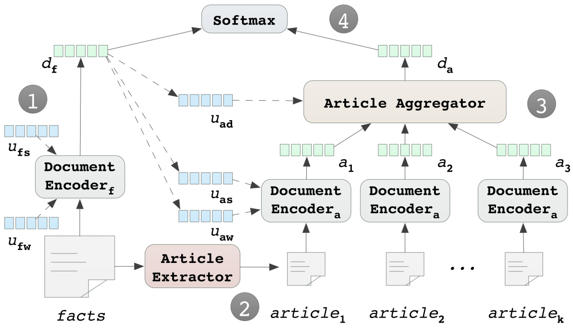


Figure 2: Overview of Our Model

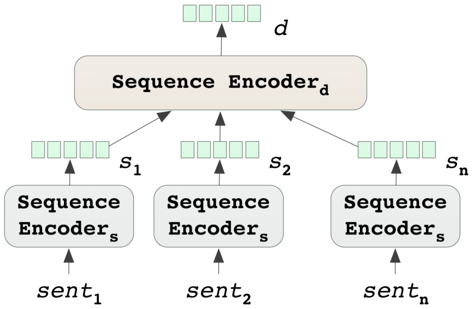

Figure 3: Document Encoder Framework

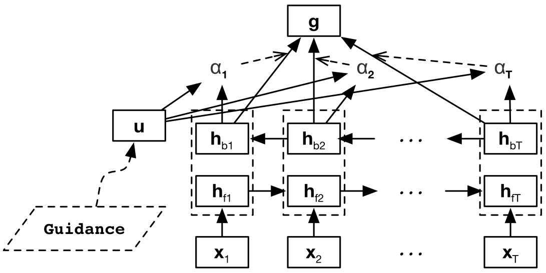

Figure 4: Attentive Sequence Encoder

Bi-GRU Sequence Encoder A challenge in building a sequence encoder is how to take the correlation among different elements into consideration. A promising solution is Bi-directional Gated Recurrent Units (Bi-GRU) (Bahdanau et al., 2015), which encodes the context of each element by using a gating mechanism to track the state of sequence. Specifically, Bi-GRU first uses a forward and a backward GRU (Cho et al., 2014), which is a kind of RNN, to encode the sequence in two opposite directions, and then concatenates the states of both GRUs to form its own states.

Given a sequence $[\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_T]$ where $\mathbf{x}_t$ is

[2] The regular expression used to extract law articles: “第[、零〇一二两三四五六七八九十百千0-9]+条(之[一二两三四五六七八九十])?)”

the input embedding of element t, the state of Bi-GRU at position t is:

$$\mathbf{h}_t = [\mathbf{h}_{ft}, \mathbf{h}_{bt}] \tag{1}$$

where $\mathbf{h}_{ft}$ and $\mathbf{h}_{bt}$ are the states of the forward and backward GRU at position t. The final sequence embedding is either the concatenation of $\mathbf{h}_{fT}$ and $\mathbf{h}_{b1}$ or simply the average of $\mathbf{h}_t$.

Attentive Sequence Encoder However, directly using $[\mathbf{h}_{fT}, \mathbf{h}_{b1}]$ for sequence encoding often fails to capture all the information when the sequence is long, while using the average of $\mathbf{h}_t$ also has the drawback of treating useless elements equally with informative ones. Inspired by (Yang et al., 2016), we use a context vector to attentively aggregate the elements, but instead of using a global context vector, we allow the context vector to be dynamically generated when extra guidance is available (see Sec. 4.2).

As shown in Fig. 4, given the Bi-GRU state sequence $[\mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_T]$, our attentive sequence encoder calculates a sequence of attention values $[\alpha_1, \alpha_2, ..., \alpha_T]$, where $\alpha_t \in [0, 1]$ and $\sum_t \alpha_t = 1$. The final sequence embedding $\mathbf{g}$ is calculated by:

$$\mathbf{g} = \sum_{t=1}^{T} \alpha_t \mathbf{h}_t; \quad \alpha_t = \frac{exp(tanh(\mathbf{W}\mathbf{h}_t)^T\mathbf{u})}{\sum_t exp(tanh(\mathbf{W}\mathbf{h}_t)^T\mathbf{u})} \tag{2}$$

where $\mathbf{W}$ is a weight matrix, and $\mathbf{u}$ is the context vector to distinguish informative elements from non-informative ones.

By using this sequence encoder for fact embedding, the fact-side attention module actually contains two components, i.e., the word-level and sentence-level, using $\mathbf{u}_{fw}$ and $\mathbf{u}_{fs}$ as their global context vectors, respectively.

4.2 Using Law Articles

One of the challenges of using law articles to support charge prediction lies in the fact that statutory laws contain a large number of articles, which makes applying complex models to these articles directly time-consuming, and thus hard to scale. The multi-label nature of relevant article extraction also requires a model that can output multiple articles. We thus adopt a two-step approach, specifically, we first build a fast and easy-to-scale classifier to filter out a large fraction of irrelevant articles, and retain the top k articles. Then, we use neural networks to make comprehensive understanding of the top k articles, and further use the article-side attention module to select the most supportive ones for charge prediction.

Top k Article Extractor We treat the relevant article extraction task as multiple binary classifications. Specifically, we build a binary classifier for each article, focusing on its relevance to the input case, which results in 321 binary classifiers corresponding to the 321 distinct law articles appearing in our dataset. When more articles are considered, we can simply add more binary classifiers accordingly, with the existing classifiers untouched.

Similar to the preliminary classification phase of (Liu et al., 2015), we also use word-based SVM as our binary classifier, which is fast and performs well in text classification (Joachims, 2002; Wang and Manning, 2012). Specifically, we use bag-of-words TF-IDF features, chi-square for feature selection and linear kernel for binary classification.

Article Encoder Since each law article may contain multiple sentences, as shown in Fig. 2, we also use the document encoder described in Sec. 4.1 to produce an embedding $\mathbf{a}_j, j \in [1, k]$, for each article in the top k extracted articles. While using similar architecture, this article encoder differs from the fact encoder that, instead of using global context vectors, its word-level context vector $\mathbf{u}_{aw}$ and sentence-level context vector $\mathbf{u}_{as}$ are dynamically generated for each case according to its corresponding fact embedding $\mathbf{d}_f$:

$$\mathbf{u}_{aw} = \mathbf{W}_w\mathbf{d}_f + \mathbf{b}_w; \quad \mathbf{u}_{as} = \mathbf{W}_s\mathbf{d}_f + \mathbf{b}_s \tag{3}$$

where $\mathbf{W}_*$ is the weight matrix and $\mathbf{b}_*$ is the bias. The context vectors, $\mathbf{u}_{aw}$ and $\mathbf{u}_{as}$, are used to produce the word-level and sentence-level attention values, respectively. Through the dynamic context vectors, the fact embedding $\mathbf{d}_f$ actually guides our model to attend to informative words or sentences with respect to the facts of each case, rather than just selecting generally informative ones.

Attentive Article Aggregator The article aggregator aims to find supportive articles for charge prediction from the top k extractions, and accordingly produce an aggregated article embedding. Although the order of the top k extracted articles is not fully reliable, (Vinyals et al., 2016) suggests that it is still beneficial to use a bi-directional RNN to embed the context of each element even in a set, where the order does not exist. In our task, bi-directional RNN can help to utilize the co-occurrence tendency of relevant articles.

Specifically, we use the attentive sequence encoder in Sec. 4.1 to produce the aggregated article embedding $\mathbf{d}_a$. Again, to guide the attention with fact descriptions, we dynamically generate the article-level context vector $\mathbf{u}_{ad}$ by:

$$\mathbf{u}_{ad} = \mathbf{W}_d \mathbf{d}_f + \mathbf{b}_d \tag{4}$$

The attention values produced by the attentive sequence encoder can be seen as the relevance of each article to the input case, which can be used to rank and filter the top k articles. The results can be shown to users as legal basis for charge prediction.

4.3 The Output

To make the final charge prediction, we first concatenate the document embedding $\mathbf{d}_f$ and the aggregated article embedding $\mathbf{d}_a$, and feed them to two consecutive full connection layers to generate a new vector $\mathbf{d}'$, which is then passed to a softmax classifier to produce the predicted charge distribution. We use the validation set to determine a threshold τ, and consider all the charges with output probability higher than τ as positive predictions. The input to the first full connection layer can also be only $\mathbf{d}_f$ or $\mathbf{d}_a$, which means we use only fact or article to make the prediction.

The loss function for training is cross entropy:

$$Loss = -\sum_{i=1}^{N}\sum_{l=1}^{L} y_{il} log(o_{il}) \tag{5}$$

where N is the number of training data, L is the number of charges, y_{il} and o_{il} are the target and predicted probability of charge l for case i. The target charge distribution $\mathbf{y}_i$ is produced by setting positive labels to $\frac{1}{m_i}$ and negative ones to 0, where m_i is the number of positive labels in case i.

Supervised Article Attention We can also utilize the gold-standard law articles naturally in the judgement documents to supervise the article attention during training. Specifically, given the top k articles, we want the article attention distribution $\boldsymbol{\alpha} \in \mathbb{R}^k$ to simulate the target article distribution $\mathbf{t} \in \mathbb{R}^k$, where $t_j = \frac{1}{k'}$ if article j belongs to the gold-standard articles and $t_j = 0$ otherwise. Here k' is the number of gold-standard articles in the top k extractions. We, again, use cross entropy, and the loss function is:

$$Loss = -\sum_{i=1}^{N}(\sum_{l=1}^{L} y_{il} log(o_{il}) + \beta \sum_{j=1}^{k} t_{ij} log(\alpha_{ij})) \tag{6}$$

where β is the weight of the article attention loss.

5 Experiments

5.1 Experimental Setup

We use HanLP[3] for Chinese word segmentation and POS tagging. Word embeddings are trained using word2vec (Mikolov et al., 2013) on judgement documents, web pages from several legal forums and Baidu Encyclopedia. The resulting word embeddings contain 573,353 words, with 100 dimension. We randomly initialize a 50-d vector for each POS tag, which is concatenated with the word embedding as the final input. Each GRU in the Bi-GRU is of size 75, the two full connection layers are of size 200 and 150. The relevant article extractor generates top 20 articles, the weight of the article attention loss (β in Eq. 6) is 0.1, and prediction threshold τ is 0.4. We use Stochastic Gradient Descent (SGD) for training, with learning rate 0.1, and batch size 8.

We compare our full model with two variations: without article attention supervision and only using facts for charge prediction. The latter one is similar to the state-of-art document classification model (Yang et al., 2016), but adapted to the multi-label nature of our problem. We also implement an SVM model, which is effective and scales well in many fact-description-related tasks in the field of artificial intelligence and law (Liu et al., 2015; Aletras et al., 2016). Specifically, the SVM model takes bag-of-words TF-IDF features as input, and uses chi-square to select top 2,000 features.

5.2 Charge Prediction Results

The charge distribution is imbalanced, and the top 5 charges take more than 60% of the cases. Therefore, we evaluate the charge prediction task using precision, recall and F1, in both micro- and macro-level. The macro-precision/recall are calculated by averaging the precision and recall of each charge, and the micro-precision/recall are averaged over each prediction.

As shown in Table 1, the basic `SVM_fact` model, which only takes fact descriptions as input, indeed proves to be a strong baseline. By

NN_fact_gold_art	98.78/**95.26**	**98.24/95.57**	**98.51/95.42**

Table 1: Charge prediction results. Left and right side of the slash refer to micro and macro statistics, respectively. `gold_art` refers to using gold standard articles mentioned in judgements (marked in blue in Fig. 1), which is the upper bound for article-related modules.

contrast, our corresponding neural network model (`NN_fact`), which also only uses facts for prediction, outperforms `SVM_fact` by about 4% in micro-F1. Since `NN_fact` benefits from the pretrained word embeddings, the two-level Bi-GRU architecture, and the fact-side attention module, it can attentively recognize informative expressions from the description and better capture the underlying correspondence from fact descriptions to appropriate charges, even when there is less overlap in the words used among cases with the same charge, or when there are limited data (i.e., infrequent charges). This may explain that NN models have more balanced performance over different charges, leading to more prominent improvements over SVM ones in macro metrics, which usually have a strong bias towards frequent charges.

When we use both facts and extracted relevant law articles (that are admittedly noisy), the SVM version (`SVM_fact_art`) drops by around 5% than `SVM_fact`, showing that the SVM model cannot benefit from the extracted, thus noisy, relevant articles in such a straightforward way. However, our NN version (`NN_fact_article`) can still learn from the noisy article extractions through attentively aggregating those extracted articles even without direct guidance, thus improves `NN_fact` by around 0.4%. Furthermore, if we use the gold standard articles during training as supervision for the article attention (our full model, `NN_fact_supv_art`), the results can be further improved, achieving 90.21% and 80.48% in micro- and macro-F1, respectively. The improvements made by using relevant law articles actually indicates the nature of the civil law system that judgements are made based on statutory laws.

However, if we only use the extracted relevant articles to make prediction (`SVM_art` and `NN_art`[4]), the performance becomes worse. Even with the proved-helpful attentive aggregator, the model performs worst among all NN variants (though still better than `SVM_fact`). This indicates that it is necessary to consider both facts and relevant law articles for charge prediction, and, the fact that `NN_fact` outperforms `NN_art` also indicates that although the judgments are made based on the statutory laws in the civil law system, the logic employed by the court when making decisions, to some extent, may be implicitly captured through massive fact-charges paris.

Now the question is: *how much improvement can we have if we can make full use of the relevant law articles within the civil law system?* Let us consider an ideal situation where we can access both fact descriptions and gold standard law articles during testing, which could be considered as an upper bound scenario. The SVM version (`SVM_fact_gold_art`) significantly outperforms `SVM_fact_art` by more than 30% in macro-F1. And the NN version (`NN_fact_gold_art`) outperforms `NN_fact_supv_art` by over 8%. These comparisons confirm again that law articles play an important role for automatic judgement prediction, but the extracted relevant articles inevitably contain noise, which should be properly handled, e.g., using an attentively aggregation mechanism to distill valuable evidence to support charge prediction.

Case Study We study the model outputs and find certain star-like confusion patterns among the charges. For example, *intentional injury* is often confused with multiple charges like *intentional homicide* (when the victim is dead, the difference is whether the defendant intends to kill or just hurt the victim) and *picking quarrels and provoking troubles* (there may also exist injuries here). These charges usually share some similar fact descriptions, e.g., how the injuries are caused, and since *intentional injury* appears more frequently than the others, `SVM_fact` thus outputs *intentional injury* in most situations, and fails to distinguish these charges. However, by using Bi-GRU and the attention mechanism, `NN_fact` can at-

[4] `NN_art` uses fact embeddings to attentively aggregate relevant articles, but only use the aggregated article embedding $\mathbf{d}_a$, without fact embedding $\mathbf{d}_f$, for charge prediction.

β	**Prec@1**	**MAP**	**Charge_F1**
0	60.94	61.61	89.59/79.23
0.01	81.06	78.00	89.77/79.48
0.1	87.90	83.39	**90.21/80.48**
0.5	91.44	86.95	89.93/79.67
1	**92.66**	**88.24**	89.83/78.66

Table 2: Refined Article Extraction Performance

tend to important details of the facts and significantly improves the performance on these charges. When the direct supervision for articles is available, NN_fact_supv_art can enhance the interaction between certain pairs of fact descriptions and law articles, which helps to capture the subtle differences among similar charges, and further improves the performance on these situations.

5.3 Article Extraction Results

We also evaluate our SVM article extractor, which achieves 77.60%, 88.96%, 94.21% and 96.53% recall regarding the top 5, 10, 20 and 30 articles, respectively. Although simple, the SVM extractor can obtain over 94% recall for top 20 articles, which is good enough for further refinement. However, the micro-F1 of the extractor is only 61.08% in the test set, which will lead to severe error propagation problem if we use the prediction results of the extractor directly. Therefore, we design the article attention mechanism to handle the noise in the top 20 articles.

Table 2 shows the re-ranking results of our article attention module (column 2-3) and the corresponding charge prediction performances (column 4), under different weights for article attention (β in Eq. 6). Prec@1 refers to top 1 precision, and MAP refers to mean average precision. We can see that, even if there is no supervision over the article attention ($\beta = 0$), our model still has reasonable performance on re-ranking the k articles. When the attention supervision is employed, the extraction quality improves significantly, and keeps increasing as β goes up. However, the charge prediction performance does not always increase with the article extraction quality, and the best performance is achieved when $\beta = 0.1$. This is not surprising, since there exists a tradeoff between the benefits of more accurate article extraction and the less model capacity left for charge classification due to the increased emphasis on the article extraction performance. The promising article extraction results also confirm the ability of our model to provide legal basis for the charge prediction.

Model	**Precision**	**Recall**	**F1**
SVM_fact	**100.00**	40.20	57.34
NN_fact	87.14	59.80	70.93
NN_fact_art	87.18	66.67	75.56
NN_fact_supv_art	90.00	**70.59**	**79.12**

Table 3: Performance (micro statistics) on News

5.4 Performance on News Data

There are usually clear differences between the expressions used by legal practitioners and people without legal background, thus it is important to see how our model will perform on fact descriptions written by non-legal professionals.

We create a news dataset by asking 3 law school students to annotate the appropriate charges for 100 social news reports about criminal cases from two news websites[5], with 262 words on average and 25 distinct charges. The κ value is 0.83, indicating good consistency. The annotators are asked to have a disscussion to achieve an aggreement on inconsistent annotations. The results are shown in Table 3, where we only report micro statistics due to the relatively small size of the dataset compared with the number of distinct charges.

We can see that, SVM_fact suffers a significant drop in F1 on the news data, confirming the gap between the expressions used by legal practitioners and non-legal professionals, given the BOW nature of SVM_fact. Although SVM_fact cannot generalize well, the patterns learned by SVM_fact are reliable in themselves, leading to a high precision. It is not surprising that our NN models also suffer from the expression differences, but due to the effectiveness of our NN architecture, with about 10%∼15% less absolute drop in F1, and NN_fact_supv_art can still achieve 79.12% in F1. For example, the word 暴打 (beat up) is seldom used in judgement documents, making it hard for SVM_fact to correctly utilize 暴打 as an indicator for injury related charges, but, our NN models can associate it with its near-synonymy 殴打 (hit), which is a formal expression in judgement documents. Furthermore, the clear improvements from NN_fact to NN_fact_art, and further to NN_fact_supv_art prove again the importance of relevant law articles in supporting the charge prediction, even in news domain. The reasonable performance on news data also shows that our method do have the ability to help non-legal professionals.

6 Conclusion

In this paper, we propose an attention-based neural network framework that can jointly model the charge prediction task and the relevant article extraction task, where the weighted relevant articles can serve as legal basis to support the charge prediction. The experimental results on judgement documents of criminal cases in China show the effectiveness of our model on both charge prediction and relevant article extraction. The comparison of different variants of our model also indicates the importance of law articles in making judicial decisions in the civil law system. By experimenting on news data, we show that, although trained on judgement documents, our model also has reasonable generalization ability on fact descriptions written by non-legal professionals. While promising, our model still cannot explicitly handle multi-defendant cases, and there is also a clear gap between our model and the upper bound improvement that relevant articles can achieve. We will leave these challenges for future work.

Quantifying the Effects of Text Duplication on Semantic Models

Alexandra Schofield[1] **Laure Thompson**[1] **David Mimno**[2]

Abstract

Duplicate documents are a pervasive problem in text datasets and can have a strong effect on unsupervised models. Methods to remove duplicate texts are typically heuristic or very expensive, so it is vital to know when and why they are needed. We measure the sensitivity of two latent semantic methods to the presence of different levels of document repetition. By artificially creating different forms of duplicate text we confirm several hypotheses about how repeated text impacts models. While a small amount of duplication is tolerable, substantial over-representation of subsets of the text may overwhelm meaningful topical patterns.

1 Introduction

Different discussions of the same subject tend to use similar words. Unsupervised models such as latent semantic analysis (LSA) (Deerwester et al., 1990) and latent Dirichlet allocation (LDA) (Blei et al., 2003) look for these statistical signatures of topicality in the form of repeated word co-occurrences. These methods have become increasingly popular because they are powerful and easy to apply to large unlabeled datasets. The apparent ease-of-use of LSA and LDA, however, makes it easy to overlook potential problems in text corpora. In this work, we focus on measuring the impact of one such issue: duplicate text.

Latent semantic methods look for patterns of repetition. But when text is repeated exactly, statistical methods that look for patterns may be diverted from more meaningful semantic groups: verbatim repetition looks, to the algorithm, more topical than actual topics. If not accounted for, repeated text can change measures of fitness to overvalue fit on repeated texts, or even "leak" held out data that is duplicated in the training data. At best, duplication may cause us to overestimate the expressiveness and reliability of models. At worst, models skewed by text duplication may invalidate any conclusions drawn from them, and, by extension, the method itself.

Text replication is a persistent and difficult problem in natural language corpora. In social media settings, partial duplication due to quotation and threading is ubiquitous. Of the 20k posts in the 20 Newsgroups corpus (Lang, 1995), 1151 are exact duplicates, and 25% of the remaining tokens are quoted text from other newsgroup messages.[1] In literary corpora, different versions of the same document may also conflict: text files for Hamlet may differ slightly due to publisher information, line numbers, editorial changes between Shakespeare's folios, and footnotes. Removing exactly identical duplicates of texts is possible through direct lexicographic matching, but for lexical near-duplicates and partial textual overlap, we may need more careful heuristics to detect duplicates, forcing researchers to make judgments about what text to remove and what to keep.

Evaluating what level of duplication is "safe" can therefore not only reduce the risk of false conclusions but also save great amounts of work spent identifying and removing duplication. In this work, we investigate the effect of text duplication on LSA and LDA by experimentally amplifying the magnitude of text duplication in a variety of corpora. We look both at how models shift to over-represent repeated text and how that shift affects the model representation of documents without repetition. To account for the variety of types of duplication, we look at exact du-

plication of whole documents as well as repetition of a text segment across many documents. Finally, we recommend what aspects of text deduplication one should focus on to successfully reduce negative effects, with different suggestions depending on the chosen model. [2]

2 Previous Work

Text duplication and reuse is a well-established problem in textual corpora. The web is filled with pages of near-duplicate content (Broder et al., 1997; Manku et al., 2007), journalistic reuse is common practice with the dissemination of information from news agencies to newspapers (Clough et al., 2002; Smith et al., 2013), and plagiarism is prevalent in student submissions (Clough et al., 2003). However, past work has focused on the *identification* of reuse instead of the *effects* that duplication has on semantic models.

The detection of text reuse relies on the ability to measure similarity between documents or passages. In general, these techniques measure the similarity of textual content, though other similarity metrics for reuse identification have been proposed (Bär et al., 2012). These measures can fall into two general groups: global and local. Global techniques measure the similarities of entire texts. These techniques are especially used for near-duplicate detection. A common approach of this form is fingerprinting (Potthast and Stein, 2008). This method involves transforming a document into a smaller representation (e.g. a set of n-grams) to measure similarity cheaply. Local techniques measure similarity at a finer granularity (e.g. paragraphs or sentences). In this setting, reuse may be mixed with text derived from other sources. These techniques often involve two steps: one aligning texts with some method (Lee, 2007; Smith et al., 2013)m and one scoring similarity of aligned sequences, e.g. based on cosine similarity of the bag-of-words vector. All of these techniques require choices of hyperparameters such as similarity threshold and n-gram size that affect what the technique considers duplicate text. Our work focuses on understanding what types of document deduplication are important so that practitioners can make better-informed choices about how to calibrate these models.

While it is possible to evaluate semantic models as features in a downstream supervised task, they are harder to evaluate intrinsically as unsupervised models of data exploration. For LDA, it is standard to consider held-out likelihood of a test set as a measure of model fit (Wallach et al., 2009b). One can also use human evaluations to judge the interpretability of topic summaries (Chang et al., 2009), though this measure can also be approximated with automated evaluations based on corpus statistics (Aletras and Stevenson, 2013; Lau et al., 2014; Mimno et al., 2011). One can also evaluate individual topics based on how much they diverge from corpus-wide distributional expectations (Al-Sumait et al., 2009).

Because LSA does not yield semantically meaningful dimensions, intrinsic approaches to evaluation are focused on the spatial aspects of the model's word embedding into the real domain. Word similarity tasks are perhaps the most common evaluation, which compare human "gold standard" judgments of word pair similarity to distances between the corresponding word vectors (Finkelstein et al., 2001; Bruni et al., 2012; Hill et al., 2016). However, the vagueness of definitions of "similarity" and the contextual dependency of similarity have cast doubt on these as gold standards of evaluation (Faruqui et al., 2016). Solving word analogies using vector arithmetic is also sometimes used to evaluate neural word embeddings, but LSA does not tend to produce this structure well (Pennington et al., 2014; Mikolov et al., 2013).

3 Theorized Impact

The fundamental problem with repeated text in a distributional semantic model is the over-representation of specific word co-occurrences to a model. To understand this, we consider the matrix factorization representation of these models. Borrowing notation from Arora et al. (2013), we consider a corpus with M documents and vocabulary size V over which we want to learn a K-dimensional representation of each document and vocabulary term. We can build an $M \times V$ matrix C to represent our corpus, where C_{di} is a function of the frequency of term i in document d. Both LSA and LDA represent factorizations of this matrix into two rank-K matrices, $C = WA^T$, where W is an $M \times K$ matrix and A is a $V \times K$ matrix. In the case of LSA, we apply tf-idf weighting

[2] Code for our experiments can be found at https://github.com/heraldicsandfox/semantic-text-duplication.

to C before producing a truncated singular value decomposition $C = U\Sigma A^T$, with Σ a diagonal matrix of dimension $K \times K$, and U and A column-orthogonal matrices. We can reduce this to the factorization above by multiplying Σ with one of the two outer matrix factors, e.g. $W = U\Sigma$. LDA performs a non-negative matrix factorization on a smoothed stochastic version of C, producing row-stochastic matrices W and A.

Duplicate text implies that more rows in C will contain a particular signature of word frequencies. This implies that a low-rank matrix factorization will increasingly devote representative power to this particular textual signature in order to minimize loss in its representation. We expect to observe two principal effects:

- As text is repeated more, to optimize model fit on the data, one or more topics/dimensions will converge to model the repeated text.
- Text that is not exactly or near-exactly repeated (or *singular* text) will be modeled less effectively both in terms of model fit and interpretability.

These effects are based on the incentive of the model to overfit repeated text: topics and dimensions modeling solely the repeated text will leave less representational power for the remaining text, and combinations of repeated and singular text will likely yield less coherent topics.

4 Evaluation Methods

We quantitatively examine several aspects of models with varying forms and degrees of duplication to determine the magnitude of the change produced by repeated text. It is important to note that our goal is simply to measure the difference between models, and not to make normative statements about the *quality* of topics. Indeed, many measures of topic quality such as word intrusion (Chang et al., 2009) and word co-occurrence (Newman et al., 2010; Mimno et al., 2011; Lau et al., 2014) may improve as a result of degenerate, single-document topics: most documents are internally coherent, so a single document's word distribution may appear to be a sensible topic.

Loss The first aspect is model loss. As stated in Section 3, as a segment of text is repeated more, we anticipate that the fit over documents containing repeated text will improve, while the fit over documents not containing repeated text will worsen. To evaluate this for LSA, we examine the Frobenius norm of the difference between the reconstruction WA^T and C for the rows corresponding to documents with and without repeated text. For LDA, we estimate the perplexity of both the training data and held-out data without repetitions from the same corpus.

Concentration Secondly, we examine component (e.g. topic/dimension) concentration. Repetition of a document amplifies the co-occurrence between the terms contained in the document. As this signal grows stronger, we expect models to begin "memorizing" these words. We anticipate that affected models will develop a simpler latent representation for the repeated document, one concentrated over a small number of components. For example, if a model is devoting topic k to a repeated document, then instances of that document should have a high proportion of topic k. Concentration measurements relate to loss, but focuses specifically on the document-component or document-topic patterns, while loss also includes information about the topic-word dynamics.

The effect of components converging to a single piece of repeated text should be easily observed by examining how close topics are to the unigram language model induced by the repeated text. If we repeat multiple documents independently, however, we may also expect to see distinct components correlated with disjoint subsets of the repeated texts. To account for this, we evaluate component concentration separately for documents with repeated text and without repeated text.

For LDA, we examine the *entropy* of document vectors. Information entropy represents the expectation of the representation length of a given outcome as a function of the probability distribution over outcomes:

$$E_d = \sum_k \theta_{dk} \log \theta_{dk}$$

where θ_{dk} is the probability of a token generated in document d having topic k. Entropy is inverse to concentration: the entropy of text should lower as the text is repeated more, as all of their topical mass would be concentrated in topics converging to modeling duplicate texts. Conversely, documents not containing repeated text may also have their entropy increase as text repetition increases, as topics will less adequately fit to the behavior of the singular documents.

In LSA, entropy is not as directly applicable: vectors in $W = U\Sigma$ can be arbitrarily real-numbered. However, we still want to access a similar basic concept, the amount a vector representation of a document is concentrated in a few dimensions. So, we examine the *absolute dispersion* of each row vector d in W:

$$D_d = \sum_k \frac{|d_k|}{\|d\|_1} \log \frac{|d_k|}{\|d\|_1}$$

where d_k is the kth component of d. Absolute dispersion measures the entropy of the L1-normalized masses of the vectors in W.

Expressivity The final aspect is expressivity of topics. If one topic converges to the unigram language model of repeated documents, the resulting model has effectively lost one topic worth of expressive power by focusing on overly-specific themes. Someone looking to learn generalized semantic corpus patterns from a topic model will therefore have one fewer topic of interest available. The frequency of terms in the repeated text may also overwhelm the most probable terms in many of the topics, again reducing the ability to interpret these topics or to understand their content through a summarized representation. While expressivity in the form of topic summaries makes little sense for LSA, using LDA models, we may examine topic summaries, obtained as the top s most probable terms of a topic where s is a fixed parameter. We may select the same number of terms s from the most probable in a unigram language model of the repeated text, and determine what proportion of the tokens obtained from concatenating topic similarities are the top terms of the repeated text language model.

5 Experimental Setup

Data We use two corpora: a sample of articles from the New York Times Annotated Corpus (Sandhaus, 2008) and a collection of Reuters newswires from the Spanish Language News Text Corpus (REUSL) (Graff, 1995). We choose news corpora because they provide well-curated text with repeated subjects but few exact document-level duplicates, though quotes and templated text may still cause text duplication. We can use these as a testbed for general duplication behaviors we see across a variety of corpora. Text is lower-cased and tokenized to only include tokens of three or more characters, allowing for contractions or hyphenations as single tokens. New York Times articles average 494.5 words in length, while Reuters newswires average 201.5 words.

To ensure our experiments are the only cause of exact duplication of text in our corpora, we use strict methods of text deduplication. When two or more documents have more than 70% unigram overlap, we remove all but the longest document. In addition, we delete 7-grams that appear in more than 10 documents based upon existing thresholds for plagiarism detection (Citron and Ginsparg, 2015). To account for stopwords, we remove all terms appearing in more than 80% of documents. Finally, we remove documents with fewer than 7 tokens after processing. We perform this process on a random sample of 30,000 documents from each corpus to ensure we may obtain a sample of 25,000 curated documents for each of our two corpora. We also produce 10% samples of these corpora, containing 2,500 documents each, to measure the effect of corpus size.

Text Duplication Treatments We use our deduplicated news corpora to construct datasets with artificial text duplication. We examine two different duplication scenarios: exact document duplication and template string duplication.

In *exact document duplication*, we randomly sample $p\%$ of the documents in the dataset and include c copies of each sampled document in our final corpus along with one copy each of the remaining documents, which we refer to as *singular* documents. To test the extremes of this effect, we also perform *single document* tests for large c with only one repeated document. From these synthetically duplicative corpora, we can determine whether effects are triggered by the sheer volume of duplicated text or if they are influenced by the diversity of the copied documents.

In *template string duplication*, rather than duplicating the sampled $p\%$ of documents, we prepend a fixed string to each document in the $p\%$ sample, producing what we refer to as *templated* documents or texts. As repeated text may be lexically similar or different from the non-repeated text of the corpus, we consider two different types of prepended string. The first is a randomly-sampled document from the deduplicated corpus but not included in the training set (*Sampled Template*), simulating repeated text that is lexically similar to the document content. The second is

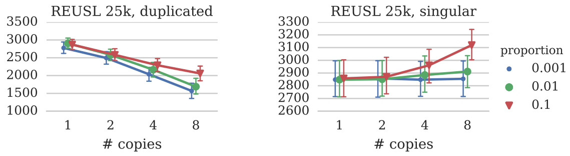

Figure 1: Training perplexity with LDA models trained on the REUSL 25k corpus with 80 topics. Perplexity decreases significantly for the duplicated documents with repetition, but the effect on singular documents is negligible with repeated proportion of the corpus smaller than 0.1.

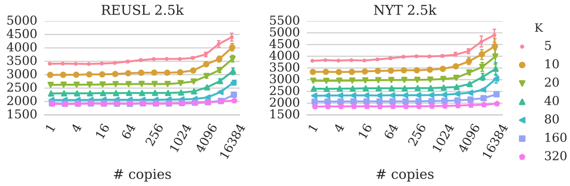

Figure 2: Perplexity from duplicating a single document remains largely unaffected for singular documents until the number of repetitions is $c = 4096$, when duplicate texts outnumber singular texts. There is also a subtle inflection point for smaller numbers of topics K at $c = 256$, approximately 1/10th of the corpus, but this effect is not visible with more topics.

the first 100 words of the classic Lorem Ipsum filler text (*Lorem Template*), simulating repeated text with little lexical overlap with the documents. Because we are investigating bag-of-words models, we do not worry about grammatical errors in the nearly-duplicated text, so the segmentation of this repeated prefix should not be a concern.

Training We analyze two types of semantic models: LSA and LDA. LSA models are trained using tf-idf weighting on word-document matrices using custom Python code.[3] LDA models are trained using Mallet (McCallum, 2002) with fixed hyperparameters $\alpha = 50/K$ and $\beta = 0.01$ for ease of comparison. To compute perplexity, we use log likelihood estimates from Mallet's built-in left-to-right estimation (Wallach et al., 2009a).

6 Results

Because of the exponential combination of different experimental settings available, it would be unfeasible to examine all our metrics for all data. Instead, we focus our analysis on specific examples that we believe demonstrate the effects seen in the rest of the corpus. We use smaller sets of 2.5k documents for examining the effect of heavy duplication and sets of 25k documents otherwise.

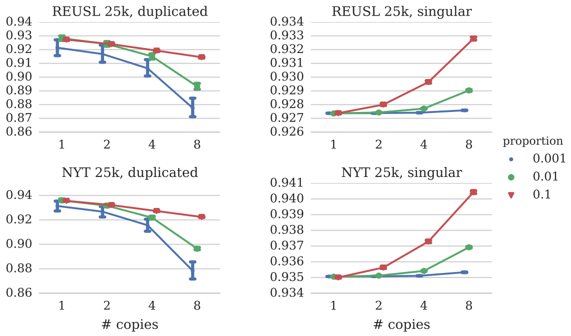

Figure 3: Model loss for LSA models with 80 components. Loss for duplicated documents decreases as the number of repetitions c increases. The frequency of replication affects loss at a much smaller scale for singular documents.

6.1 Loss

We begin with the case of exact document duplication. In Figure 1, the perplexity of LDA decreases substantially as documents are duplicated. This reduction is due to better fit to the duplicated documents. As fit improves in duplicated documents, however, we do not see a meaningfully worse fit for singular documents. These documents increase in perplexity, but the increase is not significant at low levels of duplication, such as when $c = 2$ or $p = 0.001$. In the single document case in Figure 2, this effect is emphasized: likelihood on singular documents remains level even with heavy repetition in short corpora. The sheer volume of duplicated text does not by itself damage model fit, likely because the duplicated text can be easily modeled by a single topic.

This effect is not solely due to LDA's specific probabilistic model. We see a similar pattern in LSA. In Figure 3, we see that loss for duplicated documents decreases as duplication increases. However, the amount of decay depends on the proportion of the corpus replicated: the smaller the proportion size, the more dramatic the decay. In contrast, the loss for singular documents increases only slightly with more copies, though more for higher proportions of duplication.

To gain a better understanding of how duplication affects LSA, we look at the effects of repeating a single document an extreme number of

[3] Code uses `scipy`, `numpy`, and `scikit-learn`.

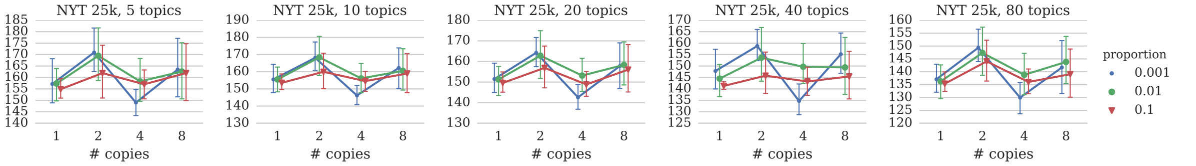

Figure 4: Held-out data perplexity (in thousands) for different the NYT 25k corpus with varying numbers of topics K. Increasing the proportion of repetition for exact duplicate documents does not increase test perplexity. With repeated corpus proportion $p = 0.001$, however, repeating documents exactly 4 times (but not 2 or 8 times) significantly improves perplexity, potentially because it induces a new topic to model it. Held-out data contained no repeated documents.

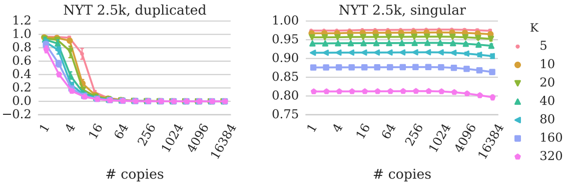

Figure 5: LSA model loss for the NYT 2.5k corpus with one duplicated document. Model loss for singular documents is again unaffected by repetition, while loss for the duplicated document quickly falls to zero as repetition increases. The fall in loss signals the start of model "memorization."

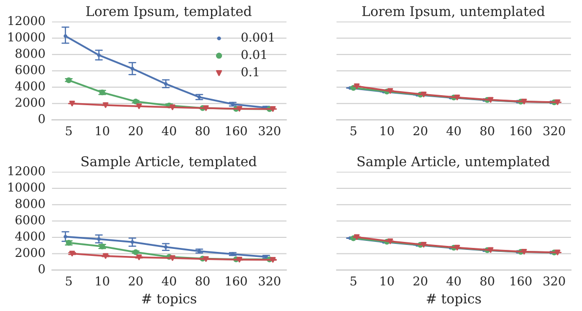

Figure 6: LDA training perplexity for REUSL 2.5k with different types of templated text repetition. The effect of duplication is prominent for small numbers of topics but diminishes with more topics to sufficiently model the missing text. With the fraction of the corpus that contains duplicates $p = 0.1$, the perplexity of template documents is below that of untemplated texts.

times. From Figure 5, we see that the loss of singular documents does not meaningfully change as the number of copies increases. We can observe the steep decline in loss for duplicated documents as the signal of when the top K components begin to "memorize" the duplicated document. The more components K, the fewer repetitions need for the overfitting to begin.

In the LDA case, we may also look at held out perplexity. Figure 4 shows that the fit for held-out test data is not generally significantly affected by increased repetition. There is a pattern within the data, in which repeating documents 4 times seems to produce better perplexity for singular documents than 2 or 8, significantly so for a small fraction of the corpus. A theory for this is that at a sufficient level of repetition, LDA fits the repeated text to its own topic instead of trying to conflate it with other document contents, producing better topics. However, additional repetition further saturates these topics and adds noise to the meaningful co-occurrence signal.

Figure 6 demonstrates that, as before, perplexity is significantly higher as template repetition increases when there is a small number of topics $K = 5$. However, as the number of topics increases, this disparity ceases to be significant. Interestingly, however, with high enough proportion p of documents containing templates, the perplexity drops below that of documents not containing the duplicates at all numbers of topics.

For LSA, templated repetition has no apparent effect on the loss of untemplated texts. However, the effect for templated texts is less straightforward. Figure 7 shows that for proportions $p = 0.1$ and $p = 0.01$ the loss of templated texts is smaller than for untemplated texts for all K component sizes. For proportion $p = 0.001$, though, templated loss is only smaller than untemplated loss when K is large, while templated loss is never significantly lower than untemplated loss for $p = 0.0001$. *Lorem Template* and *Sample Template* also exhibit different behaviors templated texts when $p = 0.001$ and K is large: loss is is significantly smaller for *Lorem Template* and has a larger drop in loss from $K = 80$ to $K = 160$.

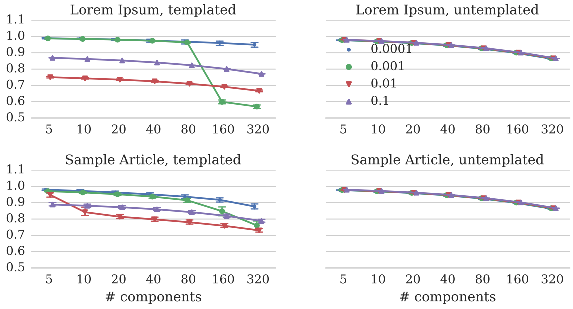

Figure 7: LSA loss of templated text for the REUSL 25k corpus. Higher levels of templating p result in smaller model loss for templated texts than for untemplated texts. For $p = 0.001$, templated loss becomes smaller than untemplated loss for $K = 160$ but more dramatically for the *Lorem Template*.

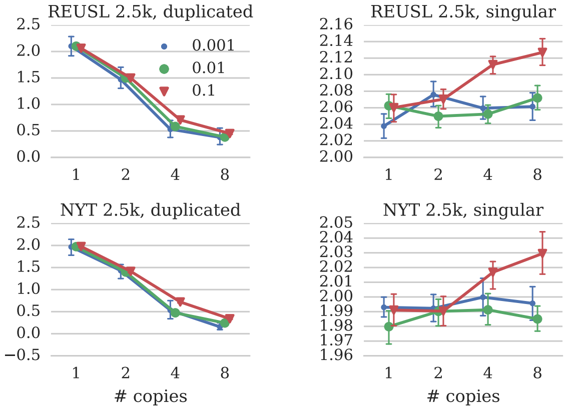

Figure 8: Entropy for LDA with 80 topics decreases for duplicated documents as the frequency of those documents increases, has little initial effect on the entropy of the singular documents.

This may indicate that LSA is able to more effectively model templated text when the templates have a distinctively different language model than the original documents.

6.2 Concentration

We expect the effect of duplication on entropy will be inversely correlated with its effect on model loss. As we increase the proportion of the corpus that is repeated, the model will devote more resources to duplicate text, leaving less modeling power for the remaining text. We therefore expect dispersion to increase with p for duplicate documents and decrease with p for singular documents. In Figure 8, the first effect clearly holds for LDA, but the second does not: there is a negligible change in entropy with the number of repetitions of documents. Figure 9 shows a subtler version of the same effect for LSA. Notably, the decrease in absolute dispersion for repeated documents is only visible in the short corpora.

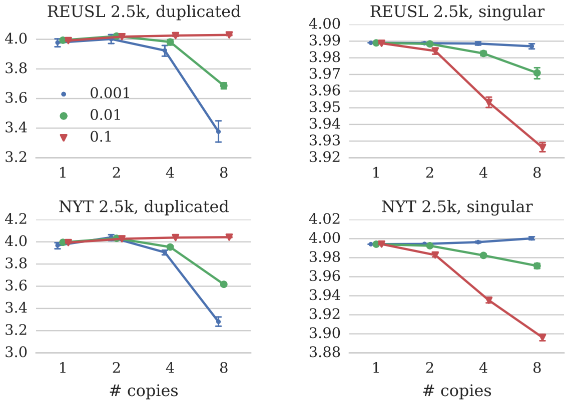

Figure 9: Absolute dispersion for LSA with 80 components increases slightly when first producing duplicates ($c = 2$), but falls off for smaller proportions of repetition $p = 0.01$ and $p = 0.001$ at higher frequencies. Increasing c has a comparatively small effect on the absolute dispersion of singular documents.

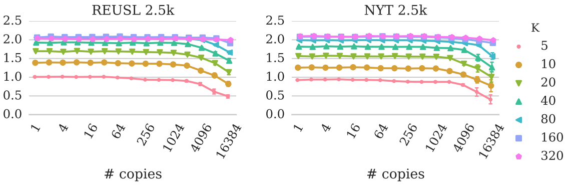

Figure 10: When a single document in the short corpora is repeated enough to comprise the majority of the corpus, the LDA entropy decreases over singular documents.

We can examine the extreme effects of the change in component concentration for singular documents by looking at its behavior in the *single document* treatment. In Figure 10, we see that while entropy remains level for repetitions comprising smaller portions of the corpus, eventually the entropy drops for both repeated and singular documents. This may be because most topics describe the repeated document, leaving few to model the remaining singular documents.

For LSA, absolute dispersion remains level for all repetitions tested for the *single document* treatment. This result highlights a key difference between LDA topics and LSA components: while changing the number of topics in LDA influences

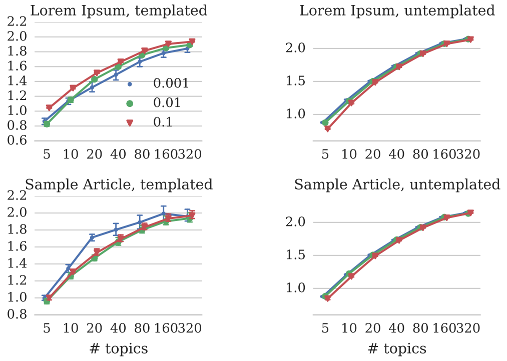

Figure 11: LDA entropy for the REUSL 25k corpus with *Sample Template* and *Lorem Template* treatments. With few topics, templated documents have lower entropy than untemplated documents, but with many topics, their entropy is higher. In the mid range of topics for *Lorem Template*, higher proportions of sampled text p produce higher entropy, but for *Sample Template*, lower p produces higher entropy.

the prior to raise or lower entropy over topics, the components of LSA are fixed. Increasing the number of components increases dimensionality, but never alters preexisting dimensions.

The effect is more subtle when templated text is repeated within documents. Figure 11 shows that with $K = 20$ LDA topics, if we apply the *Sample Template* to a small fraction of documents ($p = 0.001$), it produces a higher entropy than corpora with larger template inclusion proportion p. This is not surprising: though the template text and the original document are similar in style, with high probability they will still have different topics, which the model will have trouble fitting well without more observations. The *Lorem Template* has the reverse effect: the language is sufficiently disjoint from the content of the documents that few topics or even a single topic can model the repeated text fully, leading to low entropy. When the language model of duplicated text is disjoint from that of the text of interest, the template can be modeled by one or a few topics or components without significantly affecting other text.

6.3 Expressivity

Quantitative analyses of model fit and topic uncertainty are helpful in analyzing the effect of different settings, but do not necessarily tell us whether topics from corpora with repeated documents are useful. Analysis of expressivity helps us fill in some of the gaps in our explanations above as to what is happening at the individual topic level. In Figure 12, we see that for a moderate number of topics, increased repetition of documents impacts a substantial portion of the top-ranked words, or most probable terms of topics. The saturation effect has some relation to the number of repeated documents. With a single document repeated, as in Figure 13, as the number of topics increases, the ratio of top-ranked words belonging to the unigram language model drops. We also notice that with few topics, there is a clear "saturation point" where the topic begins to be represented more, which remains level until half the short corpora are represented by the duplicate document. The pattern overwhelmingly shows that single texts are easily fit by single topics.

In the case of the *Lorem Template* input, where little textual overlap exists between the template and original text, a few topics quickly fill in the repeated text, producing a limited effect on most topics. In Table 1, the number of topics containing "lorem" and "ipsum" remains small as the number of topics grows. Regardless of topic count of proportion, topics containing "lorem ipsum" are entirely broken Latin: the top probable terms of an example 320-topic model with $p = 0.1$ are *est justo donec iaculis sit ipsum quam lorem tristique sed amet eget pharetra curabitur fringilla non consequat mattis nec nascetur*, a direct sample of words from the template text.

7 Conclusion

The presence of duplicated strings, either documents or duplicated text within documents, is a serious but not insurmountable problem. Duplicate text can substantially alter the dimensions learned by distributional semantic models. The effect of duplication depends on several factors: the number of distinct repeated strings, the similarity of repeated strings to the rest of the corpus, and the

Proportion	5	10	20	40	80	160	320
0.001	0	0	0	0	0	0.2	0.8
0.01	0	0	0.2	0.56	1	1	1
0.1	1	1	1	1	1.78	2.3	3

Table 1: As the number of total topics increases, the average number of topics fitting the *Lorem Template* duplicate text remains stable, only rising above 1 with repeated proportion of the corpus $p = 0.1$ and at least 80 topics.

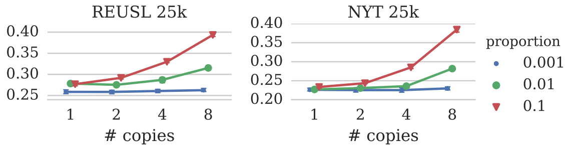

Figure 12: With 80-topic LDA models of our larger datasets, we see that increased repetition leads to significant increases in the amount of representation of repeated text in the top keys of topics.

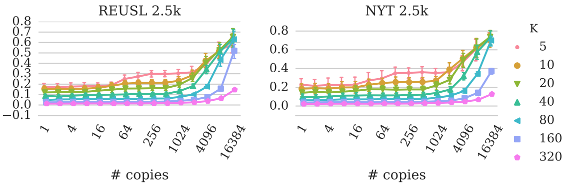

Figure 13: Top keys of LDA topics for only a single repeated document remain concentrated in only a few topics in models with $K > 5$, negligibly impacting the top keys of remaining topics.

number of repetitions. We find that different algorithms are affected in different ways, but that there are methods to alleviate the effect of duplication without exhaustively removing all duplicated documents. We provide the following specific conclusions and recommendations:

LDA accommodates low rates of document duplication for many documents. We find that with more frequent repetition, the algorithm is able to sequester repeated text into small numbers of topics if certain conditions hold. To handle this case, the model must have many topics available relative to the number of repeated strings, and the language of the repeated text must be sufficiently distinct. If these conditions are met, repeated text will affect a small number of topics that can be identified by their similarity to specific documents, or automatically based on lower than expected inter-document variability within a topic (Mimno and Blei, 2011) or distance from specific corpus-word or document-word distributions (AlSumait et al., 2009). We therefore suggest training a model first with slightly more topics than desired, then evaluating if there are any signs of repeated texts overwhelming several topics due to low coherence or corpus statistics. If no such indications occur, or if the duplication remains in one or two topics, then there is no need to modify the corpus or retrain the model, as the duplicate-capturing topic may be ignored.

LSA permits high rates of document duplication so long as few unique texts are repeated. Repeating one document will likely only affect one or a few components regardless of how many repetitions occur. However, if there are many different repeated documents, more components will be used to model them, which worsens the model fit more as the number of unique repeated texts increases. In this case, it may be preferable to look for near-duplicate documents more aggressively and worry less about exact duplicates. Unigram-count-based deduplication may be appropriate in this case, using a simple threshold of cosine similarity between the vectors of unigram counts between two documents to deduplicate.

Repeated text templates for LSA and LDA are sequestered by the model so long as they do not overlap heavily with topics of interest. In a topic model, it may be easy to identify the templated text based upon it appearing in one topic. However, if there is a concern that there is systematic use of text templates in documents (such as page headers or publication information) that may be too close to the language model, the n-gram removal approach inspired by Citron and Ginsparg (2015) is an expensive but straightforward way to ensure these strings are detected and deleted. The combination of unigram deduplication, n-gram deletion, and the inherent ability of semantic models to separate co-occurring text should reduce the negative effects of text duplication.

Abstract

A document outlier is a document that substantially deviates in semantics from the majority ones in a corpus. Automatic identification of document outliers can be valuable in many applications, such as screening health records for medical mistakes. In this paper, we study the problem of mining semantically deviating document outliers in a given corpus. We develop a generative model to identify frequent and characteristic semantic regions in the word embedding space to represent the given corpus, and a robust outlierness measure which is resistant to noisy content in documents. Experiments conducted on two real-world textual data sets show that our method can achieve an up to 135% improvement over baselines in terms of recall at top-1% of the outlier ranking.

1 Introduction

The technology today has made it unprecedentedly easy to collect and store documents in an increasing number of domains. Automatic text analysis (*e.g.* document clustering, summarization, topic modeling) becomes more useful and demanded as the corpus size grows. Some trending domains (*e.g.* health records) call for a new analytical task, *mining outlier documents*: given a corpus, identify a small number of documents which substantially deviate from the semantic focuses of the given corpus. Outlier documents can provide valuable insights or imply potential errors. For example, an outlier health record from records of the same disease could indicate a new variation of the disease if it has an abnormal symptom description, or a medical error if it has an abnormal treatment description. A previous study (Hauskrecht et al., 2013) uses structured data in health records to show the importance of this application, and points out that further improvement should be achieved by leveraging text data.

Existing work has studied a related albeit different task, novel document detection (Kasiviswanathan et al., 2012, 2013; Zhang et al., 2002, 2004), where one aims to identify from a document stream if a newly arriving document is novel or redundant. In other words, this task assumes all the previous documents are known to be "normal", and only checks if a new document is novel. In our task, no document is known to be normal, and there could be multiple outliers in the corpus. Outlier detection (Chandola et al., 2009; Hodge and Austin, 2004) is a popular topic in data mining but few focus on text data. A study (Guthrie, 2008) identifies anomalous text segments in a document, but mainly based on writing styles. We focus on studying semantically deviating documents.

The problem of detecting outlier documents has its unique challenges. First, different words or phrases may be used to indicate the same semantic meaning, which introduces lexical sparsity. Second, finding proper words or phrases to characterize the corpus is non-trivial. Semantically frequent words or phrases can still be too general or too vague. Third, a document can carry extremely

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2748–2757
Copenhagen, Denmark, September 7–11, 2017.

rich and noisy signals, most of which are not helpful to determine whether it is an outlier.

We tackle the problem of mining outlier documents in the following steps. We leverage word embedding (Mikolov et al., 2013) to capture the semantic proximities between words and/or phrases, in order to solve the sparsity issue. Then we propose a generative model to identify semantic regions in the embedded space frequently mentioned by documents in the corpus. The model represents each semantic region with a von Mises-Fisher distribution. We also learn a concentration parameter for each region with our model, and develop a selection method to identify semantically specific regions which can better represent the corpus, and filter regions with largely uninformative words.

As the final step, we design a robust outlierness measure emphasizing only the words or phrases in a document relatively close to the semantic focuses identified, and eliminating the noises and redundant information.

The remaining of the paper is organized as follows. Section 2 introduces the preprocessing of data sets and clarifies the notations. Section 3 proposes the methodology to mine outlier documents. Section 4 describes the experiment setup, Section 5 presents the results and Section 6 concludes the paper.

2 Preliminaries

In this section, we formalize the problem and then briefly describe the preprocessing step.

2.1 Notations

The notations used in this study are introduced here. A *document* is represented as a sequence $d_i = (w_{i1}, w_{i2}, \cdots, w_{in_i})$, where each $w_{ij} \in \mathcal{V}$ represents a word or phrase from a given vocabulary $\mathcal{V}$ and n_i denotes the length of the d_i. We refer to a set of documents as a *corpus*, represented as $D = \{d_i\}_{i=1}^{|D|}$.

Notice that w_{ij} may refer to a unigram word or a multi-gram phrase. Although it is nontrivial to appropriately segment a document into a mixed sequence of words and phrases, it is not the focus of our paper. A recently developed phrase mining technique (Liu et al., 2015) is used to extract quality phrases and segment the documents.

Word embedding provides vectorized representations of words and phrases to capture their semantic proximity. We assume there is an effective word embedding technique (*e.g.* (Mikolov et al., 2013)), $f : \mathcal{V} \mapsto \mathbb{R}^{\nu}$, where f is the transforming function that takes a word or a phrase as input and projects it into a ν-dimensional vector as its distributed representation. The semantic proximity between two words or phrases w and w' can be preserved by the cosine similarity between their embedded vectors:

$$CosSim(f(w), f(w')) = \frac{f(w) \cdot f(w')}{\|f(w)\| \times \|f(w')\|}$$

Problem definition. This work studies how to effectively rank documents in a corpus based on how much they deviate from the semantic focuses of the corpus. Given a set of documents D, our objective is to design an outlierness measure $\Omega : D \mapsto \mathbb{R}$, such that documents with larger outlierness $\Omega(d)$ semantically deviate more from the majority of D.

2.2 Preprocessing

We perform several steps of preprocessing to derive the input representation of each document in a given corpus.

Phrase mining. SegPhrase, a recently developed phrase-mining method (Liu et al., 2015), is utilized to automatically identify quality phrases in a corpus. After being trained in one corpus, SegPhrase is also capable of segmenting unseen documents into chunks of phrases with mixed lengths. We train SegPhrase on an external corpus D_e to obtain the list of quality phrases. Then for each corpus D given for outlier detection, we employ the trained SegPhrase to chunk each document into a sequence of words and quality phrases.

Word embedding. We adopt word embedding as a preprocessing step to capture the semantic proximity between words/phrases. Instead of using the raw text, similar to (Liu et al., 2015), we use the sequence derived from SegPhrase as input to the word embedding algorithm. In particular, *word2vec* (Mikolov et al., 2013) is utilized in our experiments, but can be seamlessly replaced by any other embedding results.

We run the embedding algorithm based on the external corpus D_e, the same corpus used in phrase mining. As D_e is sufficiently large, there are only few words or phrases in D which never appear in D_e, and are simply discarded in the experiments.

Stop words removal. We remove stop words, as well as the words or phrases ranked high within a certain quantile in terms of document frequency[1] (DF) in the external corpus D_e. Such words or phrases usually carry background noise, and obstruct outlier detection.

3 Mining Outlier Documents

Our framework consists of the following steps. First, we leverage a generative model to identify semantic "regions" in the word embedding space frequently mentioned by documents in the given corpus. Second, we develop a selection method to further remove semantics regions that are too general to properly characterize the given corpus, and only keep regions both frequent and semantically specific, denoted as "semantic focuses". Finally, we calculate the outlierness measure for each document based on the mined semantic focuses. We design a robust outlierness measure which is less sensitive to noisy words or phrases in documents.

3.1 Embedded von Mises-Fisher Allocation

We start with a generative model to identify the frequent semantic regions in the word embedding space.

Since we use cosine similarity to capture the semantic proximities between two words or phrases, the magnitude of the embedding vector of each word can be omitted in this part. We use $\mathbf{x}_{ij} = f(w_{ij})/\|f(w_{ij})\|$ to represent the unit vector with the same direction as the embedded vector of w_{ij}, and use $\mathbf{X}$ to represent the collection of all $\mathbf{x}_{ij}$ where $1 \leq i \leq |D|$ and $1 \leq j \leq n_i$.

In order to characterize a semantic region in the embedded space, we introduce von Mises-Fisher (vMF) distribution. The von Mises-Fisher (vMF) distribution is prevalently adopted in directional statistics, which studies the distribution of normalized vectors on a spherical space. The probability density function of the vMF distribution is explicitly instantiated by the cosine similarity. It is an ideal distribution for our task because we use cosine similarity to measure the semantic proximity. Moreover, as we will see later, it empowers us to characterize how specific each semantic region is, which is helpful in further identification of semantic focuses for outlier detection.

We first introduce the formalization of the von Mises-Fisher distribution.

Von Mises-Fisher (vMF) distribution. A ν-dimensional unit random vector $\mathbf{x}$ (*i.e.* $\mathbf{x} \in \mathbb{R}^\nu$ and $\|\mathbf{x}\| = 1$) follows a von Mises-Fisher distribution $\text{vMF}(\cdot|\boldsymbol{\mu}, \kappa)$ if the probability density function follows:

$$p(\mathbf{x}) = C_\nu(\kappa) \exp\big(\kappa \boldsymbol{\mu}^\top \mathbf{x}\big)$$

where $C_\nu(\kappa) = \kappa^{\nu/2-1} \big/ (2\pi)^{\nu/2} I_{\nu/2-1}(\kappa)$; and $I_{\nu/2-1}(\cdot)$ is the modified Bessel function of the first kind; $(\nu/2 - 1)$ is the order.

The two parameters in the vMF distribution are the mean direction $\boldsymbol{\mu}$ and the concentration parameter κ respectively, where $\boldsymbol{\mu} \in \mathbb{R}^\nu$, $\|\boldsymbol{\mu}\| = 1$ and $\kappa > 0$. The distribution concentrated around the mean direction $\boldsymbol{\mu}$, and is more concentrated if the concentration parameter κ is larger.

Embedded von Mises-Fisher allocation. We propose a generative model by regarding each document as a bag of normalized embedded vectors, analogous to the bag-of-word representation of documents utilized in typical topic model (*e.g.*, LDA (Blei et al., 2001)). The major difference is that the data to be generated is now a bag-of-normalized-embedded-vectors for each document, and should be generated from a mixed vMF distribution instead of a mixed multinomial distribution.

A formalized description of the model is summarized as follows:

$$\begin{aligned}
\boldsymbol{\mu}_t &\sim \text{vMF}(\cdot|\boldsymbol{\mu}_0, C_0), && t = 1, 2, \cdots, T \\
\kappa_t &\sim \text{logNormal}(\cdot|m_0, \sigma_0^2), && t = 1, 2, \cdots, T \\
\boldsymbol{\pi}_i &\sim \text{Dirichlet}(\cdot|\boldsymbol{\alpha}), && i = 1, 2, \cdots, |D| \\
z_{ij} &\sim \text{Categorical}(\cdot|\pi_i), && j = 1, 2, \cdots, |d_i| \\
\mathbf{x}_{ij} &\sim \text{vMF}(\cdot|\boldsymbol{\mu}_{z_{ij}}, \kappa_{z_{ij}}), && j = 1, 2, \cdots, |d_i|
\end{aligned}$$

where $T > 0$ is an integer indicating the number of semantic regions, namely the number of vMF distributions in our mixture model.

We regularize the vMF parameters by the following prior distributions. We assume the mean direction $\boldsymbol{\mu}_t$ of each vMF distribution is generated from a prior vMF distribution $\text{vMF}(\cdot|\boldsymbol{\mu}_0, C_0)$, while the concentration parameter κ_t is generated from a log-normal prior $\text{logNormal}(\cdot|m_0, \sigma_0^2)$. A similar design is also adopted in (Gopal and Yang, 2014).

Parameter inference. We infer the parameters by Gibbs sampling. Because both the von Mises-Fisher distribution and the Dirichlet distribution

[1] Document frequency of a word (or phrase) is defined as number of documents where this word or phrase appears.

have conjugate priors, we can integrate out parameters $\boldsymbol{\mu}_t$ and $\boldsymbol{\pi}_i$ and develop a collapsed Gibbs sampler of z_{ij}:

$$
\begin{aligned}
&P(z_{ij} = t|\mathbf{Z}^{-ij}, \mathbf{X}, \boldsymbol{\kappa}; \boldsymbol{\alpha}, m_0, \sigma_0^2, \boldsymbol{\mu}_0, C_0) \\
\propto &\frac{(n_{it}^{-ij} + 1 + \boldsymbol{\alpha}^{(t)}) C_\nu(\kappa_t) C_\nu\big(\|C_0\boldsymbol{\mu}_0 + \kappa_t \mathbf{x}_{\cdot t}^{-ij}\|\big)}{C_\nu\bigg(\bigg\|C_0\boldsymbol{\mu}_0 + \kappa_t\big(\mathbf{x}_{\cdot t}^{-ij} + \mathbf{x}_{ij}\big)\bigg\|\bigg)}
\end{aligned}
$$

where $n_{it}^{-ij} = \sum_{j'}^{|d_i|} \delta(z_{ij'} = t) - \delta(z_{ij} = t)$ is the number of words in the i-th document being assigned to the t-th von Mises-Fisher distribution without taking w_{ij} into account; $\mathbf{x}_{\cdot t}^{-ij} = \sum_{i'}^{|D|} \sum_{j'}^{|d_i|} \mathbf{x}_{i'j'} \delta(z_{i'j'} = t) - \delta(z_{ij} = t)$ is the sum of word vectors assigned to semantic region t without counting w_{ij}. Here $\delta(\cdot)$ is the indicator function.

We can also derive a collapsed Gibbs sampler for concentration parameters κ_t's:

$$
\begin{aligned}
&P(\kappa_t|\mathbf{Z}, \mathbf{X}, \boldsymbol{\kappa}^{-t}; \boldsymbol{\alpha}, m_0, \sigma_0^2, \boldsymbol{\mu}_0, C_0) \\
\propto &\frac{C_\nu^{n_{\cdot t}}(\kappa_t)}{C_\nu\big(\|C_0\boldsymbol{\mu}_0 + \kappa_t \mathbf{x}_{\cdot t}\|\big)} \text{logNormal}(\kappa_t|m_0, \sigma_0^2)
\end{aligned}
$$

where $n_{\cdot t}$ is the number of words in semantic region t.

While sampling z_{ij} is relatively trivial, sampling κ_t is not straightforward. Similar difficulty is also mentioned in (Gopal and Yang, 2014). We employ a Metropolis-Hasting algorithm with another log-normal distribution centered at the current κ_t value as the proposal distribution.

After obtaining a sample from the posterior distribution of z_{ij}'s and κ_t's, we can easily obtain the MAP estimate of mean directions $\boldsymbol{\mu}_t$'s and the mixing distribution of each documents $\boldsymbol{\pi}_i$:

$$
\hat{\boldsymbol{\mu}}_t = \frac{C_0\boldsymbol{\mu}_0 + \kappa_t \mathbf{x}_{\cdot t}}{\|C_0\boldsymbol{\mu}_0 + \kappa_t \mathbf{x}_{\cdot t}\|}, \quad \hat{\boldsymbol{\pi}}_i = \frac{n_{it} + \boldsymbol{\alpha}^{(t)}}{n_{i\cdot} + \sum_t \boldsymbol{\alpha}^{(t)}}
$$

Discussions. We notice that there are some topic models (Das et al., 2015; Batmanghelich et al., 2016) proposed for similar data, where words are represented as embedding vectors. Our model is proposed independently for the purpose of identifying semantic focuses, which serves the task of outlier detection. Existing models may lack signals for the following outlier detection steps and hence cannot be directly plugged in. However, it is possible to adapt certain models to the outlier detection task.

3.2 Identifying Semantic Focuses

The semantic regions learned from the Embedded vMF Allocation model provide a set of candidates frequently mentioned by documents in the corpus. However, not all of them are semantic focuses of the corpus — some are too general to distinguish outlier and normal document.

We notice that uninformative semantic regions (*e.g.* a semantic region containing {"percent", "average", "compare", ...}) tend to have more scattered distribution over embedded vectors, possibly because of the diverse context of their usage. In contrast, corpus-specific semantic regions are more concentrated, (*e.g.* a semantic region containing {"drugs", "antidepressant", "prescription", ...}). Modeling semantic regions by vMF distributions provides us with a parsimonious signal to characterize how concentrated a semantic region is, *i.e.* the concentration parameter κ_t. This allows us to simply filter unqualified semantic regions with too small concentration parameters and obtain high-quality semantic focuses. Let a binary variable ϕ_t ($t = 1, 2, \cdots, T$) indicate whether the t-th vMF distribution is a semantic focus. Suppose a user specifies a threshold parameter $0 \leq \beta \leq 1$. We can determine ϕ_t by estimating the log-normal distribution that generates all κ_t's, $logNormal(\hat{m}, \hat{\sigma}^2)$, where

$$
\hat{m} = \frac{1}{T}\sum_t \log(\kappa_t), \ \hat{\sigma}^2 = \frac{1}{T}\sum_t \Big(\log(\kappa_t) - \hat{m}\Big)^2
$$

Set $\hat{F}_\kappa(\cdot)$ to be its cumulative distribution function. We assign $\phi_t = 1$ for semantic regions with $\kappa_t \geq F_\kappa^{-1}(\beta)$, and filter all the other semantic regions as $\phi_t = 0$.

Although parameter β needs to be set manually, our experiments suggest the performance is not quite sensitive to its value.

3.3 Document Outlierness

In this subsection, we start with a straightforward definition of outlierness based on the mined semantic focuses. Then we present several refinements to improve its robustness.

Baseline outlierness measure. A straightforward intuition is to assume outlier documents averagely have fewer words or phrases drawn from semantic focuses. To estimate this, we first need to calculate the probability of each word being drawn from the semantic focuses.

$$P(\phi_{z_{ij}} = 1 | \mathbf{x}_{ij}, \boldsymbol{\pi}_i) = \frac{\sum_t \phi_t \boldsymbol{\pi}_i^{(t)} \text{vMF}(\mathbf{x}_{ij} | \boldsymbol{\mu}_t, \kappa_t)}{\sum_t \boldsymbol{\pi}_i^{(t)} \text{vMF}(\mathbf{x}_{ij} | \boldsymbol{\mu}_t, \kappa_t)}$$

It is then possible to estimate the expected percentage of words *not* drawn from semantic focuses in each document as the outlierness:

$$\Omega_{\text{sf}}(d_i) = 1 - \frac{1}{|d_i|} \sum_{j=1}^{|d_i|} P(\phi_{z_{ij}} = 1 | \mathbf{x}_{ij}, \boldsymbol{\pi}_i) \quad (1)$$

However, due to the noisiness in text data, this assumption oversimplifies the characterization of outlier documents. In practice, we observe the following two issues: lexically general words/phrases, and noisy content in documents.

Penalizing lexically general words and phrases. Not all words or phrases close to semantic focuses are strong indicators of normal documents. General words (*e.g.* "science") can happen to be semantically close to a semantic focus, but are not as specific as most other words close to it (*e.g.* "medical research"). Therefore, we utilize a background corpus D_{bg} to calculate the specificity of the word. Assuming the actual mention of the word can be chosen from either the general background, or a corpus-specific vocabulary, we write down the probability that a word is corpus-specific to be:

$$P(\lambda_{ij} | w_{ij}) = \frac{nd(w_{ij})/|D|}{nd(w_{ij})/|D| + nd_{bg}(w_{ij})/|D_{bg}|}$$

where $nd(w) = |\{d_i | w \in d_i, d_i \in D\}|$ is the number of documents in D containing word w; $nd_{bg}(w) = |\{d_i | w \in d_i, d_i \in D_{bg}\}|$ is the number of documents containing word w in the background corpus D_{bg}; λ_{ij} is a binary random variable indicating whether w_{ij} is specific enough.

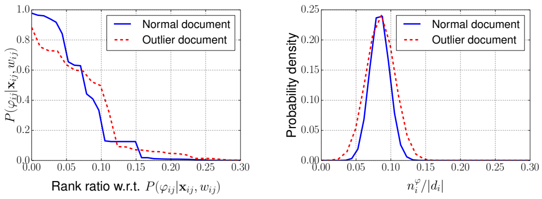
For each word, we define the word is *orthodox* if the word is not only semantically close to a semantic focus of the corpus, but also sufficiently specific. We then define the probability that a word or phrase w_{ij} in document d_i is orthodox as:

$$P(\varphi_{ij} | \mathbf{x}_{ij}, \boldsymbol{\pi}_i w_{ij}) = P(\phi_{z_{ij}} | \mathbf{x}_{ij}, \boldsymbol{\pi}_i) P(\lambda_{ij} | w_{ij})$$

where $\varphi_{ij} = 1$ indicates that w_{ij} (or equivalently $\mathbf{x}_{ij}$) is orthodox.

Now, we can define a second outlierness measure as the expected percentage of words that are *not* orthodox.

$$\Omega_{\text{e}}(d_i) = 1 - \frac{1}{|d_i|} \sum_{j=1}^{|d_i|} P(\varphi_{ij} | \mathbf{x}_{ij}, \boldsymbol{\pi}_i, w_{ij}) \quad (2)$$



(a) Ranked orthodox probability $P(\varphi_{ij} | \mathbf{x}_{ij}, \boldsymbol{\pi}_i, w_{ij})$ (b) Probability distribution of random variable $n_i^{\varphi}/|d_i|$

Figure 1: Comparison of a normal document and an outlier document in a news corpus ("Health" topic).

Noisy content in documents. We present the second issue of normal documents with an example. We compare a normal document in a corpus of New York Times news articles with tag "Health", to another document originally from another corpus, but with its outlierness calculated with regard to the semantic focuses of the "Health" corpus.

In Figure 1(a), we show the distribution of inferred orthodox probability $P(\varphi_{ij} = 1 | \mathbf{x}_{ij}, w_{ij})$ by ranking the words or phrases according to their probability value. We can observe that the outlier document barely has any words or phrases surely orthodox, while the normal document has 5% of words or phrases with a probability no less than 0.8 to be orthodox. However, if we simply take the average, these two documents become indistinguishable as the average is substantially dominated by the "tail" where most words or phrases in either documents are clearly not orthodox. Let n_i^{φ} be a random variable indicating the true number of orthodox words or phrases in document d_i. Since n_i^{φ} follows a Poisson-Binomial distribution, we can plot the probability distribution of n_i^{φ} normalized by the length of the document, as shown in Figure 1(b). It can be observed that the difference between the normalized expectation $\mathbb{E}[n_i^{\varphi}]/d_i$ of two documents is insignificant. Therefore, the measure described in Equation (2) will be unable to tell the difference between these two documents.

This example illustrates why the strategy of taking the average over the whole document can make mistakes, and also provides an important insight. As long as a document has a (potentially small) portion of words or phrases that are highly certain to be orthodox, it should not be considered as an outlier. Based on the above observation, we propose a third outlierness measure.

Orthodox quantile outlierness. We define a *quantile-based outlierness* definition to rank document outliers. Notice that the distribution of random variable n_i^{φ} follows a Poisson-Binomial distribution, which is the total number of success trials when one tosses a coin for each word or phrase in the document to determine whether it is orthodox with probability $P(\varphi_{ij}|\mathbf{x}_{ij}, w_{ij})$.

Moreover, we define the first $\frac{1}{1-\theta}$-quantile of the Poisson-Binomial distribution of n_i^{φ} as:

$$q_\theta(n_i^{\varphi}) = \sup_q \{q : P(n_i^{\varphi} \geq q) \geq \theta\} \qquad (3)$$

where $0 < \theta < 1$ is a given parameter close to 1. Intuitively, it measures the maximum lower bound of n_i^{φ} we can guarantee with confidence θ.

Based on Equation (3), we can give a formalized definition of our proposed outlierness:

$$\Omega_{\theta\text{-q}}(d_i) = 1 - \frac{q_\theta(n_i^{\varphi}) + 1}{|d_i| + 1} \qquad (4)$$

where the $\frac{1}{1-\theta}$-quantile is normalized by the document length with a smoothing constant. The cumulative probability distribution of a Poisson-Binomial distribution can be efficiently calculated by dynamic programming (Chen and Liu, 1997).

The advantage of the last proposed outlierness measure is that it emphasizes more on the highly orthodox words or phrases and eliminates the noise from a number of relatively uncertain ones.

4 Experiment Setup

4.1 Data Sets

New York Times News (NYT). We collected 41,959 news article published in 2013 from The New York Times API[2]. Each article is assigned with a unique label indicating in which section the article is published, such as Arts, Travel, Sports, and Health. There are totally 9 section labels in our collected data set. We treat papers in each section as a corpus D. Thereby we have a set of corpora $\mathcal{D} = \{D_s\}$, without overlapping documents. We also have an external news data set D_e crawled from Google news, with 51,114 news article published in 2015 without any label information.

ArnetMiner Paper Abstracts (ARNET). We employ abstracts of papers published in the field of computer science up to 2013, collected by ArnetMiner (Tang et al., 2008), and assign each paper into a field, according to Wikipedia[3]. We use papers from a set of domains to serve as an external corpus D_e, while papers in other domains form different corpora $\mathcal{D} = \{D_s\}$. Each domain (*e.g.*, data mining, computational biology, and computer graphics) forms a corpus D_s respectively. Again, notice that the corpora do not have overlapping documents with each other.

Table 1: Data set statistics.

Data set	Corpus D		External corpus D_e	
	Avg. $\lvert D \rvert$	Avg. $\lvert d \rvert$	$\lvert D_e \rvert$	Avg. $\lvert d \rvert$
NYT	4,662.11	592.66	52,114	471.63
ARNET	2,930.60	137.21	11,463	152.17

A summary is presented in Table 1.

Benchmark generation. Since we do not have true labels for outliers in a corpus, we use injection method to generate outlier detection benchmark. For each data set, we randomly select a corpus $D_s \in \mathcal{D}$ and mark all of its document as "normal documents". We then randomly select another corpus $D'_s \in \mathcal{D}, D'_s \neq D_s$, to inject ω documents from D'_s into D_s and mark them as outliers. We confine ω to be a small integer less than 1% of the size of $|D_s|$. More concretely, ω is an integer uniformly sampled from $(0, 0.01|D_s|]$.

For each data set, we randomly generate 10 outlier detection benchmarks, and evaluate the overall performance by the average performance on all the benchmarks.

4.2 Methods Evaluated

We compare the performances of the following methods.

Cosine similarity based. We characterize each document as a vector, and use the negative average cosine similarity between each document and the corpus as outlierness. We use two different ways to vectorize documents: TF-IDF weighted, and paragraph2vec (Le and Mikolov, 2014). The two methods are denoted as TFIDF-COS and P2V-COS respectively.

KL divergence based. We represent each document as a probability distribution, and the entire corpus as another probability distribution. Then we use the KL-divergence between each document and the entire corpus as the outlierness. We also

[2] `http://developer.nytimes.com/docs`

[3] `https://en.wikipedia.org/wiki/List_of_computer_science_conferences`

use two different ways to calculate the probability distribution. The first is to estimate the unigram distribution for each document and the entire corpus respectively, denoted as UNI-KL. The other is to first perform LDA on the entire corpus with 10 topics, and then infer topical allocation distribution of each document and the entire corpus. This method is represented as TM-KL.

Our method Our quantile based method is denoted as VMF-Q. We also provide two baselines derived from our own method as an ablation analysis. One method abandons the quantile based outlierness but use the expected orthodox percentage as Equation (2), denoted as VMF-E. The other method further removes the penalty on lexical general words and phrases, using Equation (1), denoted as VMF-SF.

4.3 Evaluation Measures

In most outlier detection applications, people are more concerned with recall. We measure the performance by *recall at a certain percentage*. More specifically, we compute the recall of outlier detection if the user checks a certain percentage r of the top-ranked documents in the output results. Since in our benchmark generation, the percentage of outliers does not exceed 1%. Therefore, the perfect results for any $r \geq 1\%$ should be 1.0.

We choose r to be 1%, 2%, and 5% respectively and evaluate different methods with recall at top-r (percentage). We also report the performance in terms of mean average precision (MAP).

4.4 Parameter Configurations

All benchmark data sets are preprocessed as described in Section 2. In the NYT data set we remove words or phrases within top 20% with respect to document frequency, while in the ARNET data set we remove the top 10%. The document frequency is calculated based on a background corpus D_{bg}, which is the same as the external corpus of NYT. Word embedding are trained on the external data set D_e using code of Mikolov *et al.* (Mikolov et al., 2013) with default parameter configurations, where the embedded vector length is set to 200. For paragraph2vec, we learn the length-100 vectors for each document along with the external data set to guarantee sufficient training data.

Table 2: Performance comparison of different outlier document detection methods. All results are shown as percents.

Data set	Method	MAP	Rcl@1%	Rcl@2%	Rcl@5%
NYT	TFIDF-COS	05.03	04.73	06.72	14.72
	P2V-COS	22.07	23.45	44.64	66.18
	UNI-KL	10.28	11.92	16.32	31.34
	TM-KL	14.51	16.50	16.50	24.67
	VMF-SF	33.70	31.03	44.45	62.60
	VMF-E	36.57	35.91	49.41	67.56
	VMF-Q	**41.88**	**56.99**	**63.29**	**79.23**
ARNET	TFIDF-COS	08.99	15.40	18.75	30.23
	P2V-COS	07.39	10.51	14.78	24.14
	UNI-KL	07.46	14.13	22.26	39.40
	TM-KL	10.09	12.04	15.37	20.24
	VMF-SF	10.69	12.05	22.58	44.51
	VMF-E	10.51	12.67	25.92	45.37
	VMF-Q	**19.74**	**22.40**	**34.40**	**53.87**

For the prior vMF distribution, we set $C_0 = 0.1$, a sufficiently small number so the prior distribution is close to a uniform distribution. $\boldsymbol{\mu}_0$ is set as a normalized all-1 vector. We also set $m_0 = log(100)$, and $\sigma^2 = 0.01$. The total number for Gibbs sampling is set to be 50 times of the total count of z_{ij}'s (*i.e.* $\eta = 50$). The number of vMF distributions T is set to 20 in the NYT data set and 10 in the ARNET data set respectively, due to the smaller sizes of corpora in the ARNET data set.

To determine semantic focuses, we set threshold parameter $\beta = 0.55$ for both data sets. The confidence parameter θ in outlierness calculation is set to 0.95 in both data sets. Our experiments later will show the performance is relatively robust to different configurations of both parameters.

5 Results

We present the experimental results in this section.

Performance comparison. Table 2 shows performance of different outlier document detection methods. It can be observed that our method outperforms all the baselines in both data sets. In both data sets, VMF-Q can achieve a 45% to 135% increase from baselines in terms of recall by examining the top 1% outliers. Generally, performances of most methods are lower in the ARNET data set comparing to NYT, potentially because the relatively short document lengths and more technical terminologies in ARNET.

Ablation analysis. Both refinements of the outlierness measure benefits the performance. Specifically, by changing the average based outlierness to quantile based outlierness, the recall@1% can be improved by 50-75%, and the recall@5% can also be improved by more than 17%.

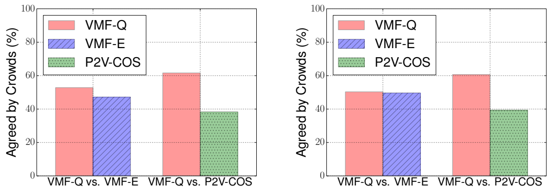
(d) ARNET, varying β

Figure 2: Performance of outlier document detection with different parameter configurations.



(a) Health

(b) Art

Figure 3: Crowd evaluation to compare different outlier detection methods on two corpora in NYT data set.

Sensitivity studies of parameters. We study if our proposed method is sensitive to the confidence parameter θ and filtering threshold parameter β. We compare the performance of VMF-Q by varying each parameter on both data sets. Figure 2(a) and 2(b) show that the performance is not very sensitive to different values of θ, as long as θ is sufficiently large (close to 1). Figure 2(c) and 2(d) show that the performance is relatively stable when β is between 0.5 and 0.7, but drops a little when β is set to larger value.

Human judgments. We compare VMF-Q to VMF-E and P2V-COS respectively by crowdsourcing, *without* artificially inserting "outliers". We conduct this experiments on two corpora in NYT data sets with topic "Health" and "Art" respectively. To compare two methods, we randomly select pairs of documents d_i and d_j such that both are ranked as top-10% outliers by at least one method, but their orders in the two rankings disagree. We conduct the experiments on CrowdFlower. Online crowd workers are given d_i and d_j as well as other documents in the corpus, and are asked to judge which one of d_i and d_j deviates more from the corpus. For each corpus, we select 200 pairs of documents.

Before taking the questions, each crowd worker needs to go through at least 10 "test questions" which we know the correct answer. These questions are constructed by taking one document from the corpus as d_i and another document not from the corpus as d_j. Therefore, the one not from the corpus should be the answer. A crowd worker needs to achieve no less than 80% of accuracy to be eligible to work on actual questions, and the accuracy needs to be maintained over 80% during the work, which is measured by "test questions" hidden in actual questions. Each question is answered by 3 workers. The final answer is determined by majority voting.

Figure 3 presents the results. On both corpora, there are significantly more workers tend to agree with VMF-Q comparing to P2V-COS, with significance level $\alpha = 0.05$. This further verifies that our method VMF-Q can achieve better performance than the P2V-COS baseline. On the other hand, on both data sets we can still observe more workers favoring VMF-Q than VMF-E, but the difference is not as large as the difference between VMF-Q and P2V-COS.

Case study. We also conduct a case study to show how our proposed method outperforms other baselines. Table 3 shows two pairs of documents in "Health" corpus of NYT data set. The left two columns show some comparing methods and their higher ranked outlier documents. The row of "Crowds" shows the outlier document chosen by human workers from the crowdsourcing platform, with a consensus of opinions from multiple workers.

In the first document pair, document A is about gun control policy and is substantially irrelevant to "Health" topic, while document B is about lung infection cases. Document A is a significant outlier, and VMF-Q and VMF-E also agree with our intuition. However, paragraph2vec (P2V) ranks document B higher, probably because it tries to summarize the entire document.

In the second document pair, document B is clearly *not* an outlier as the story is about a new book of AIDS. In comparison, document A dis-

Table 3: Case study of documents in "Health" corpus of NYT data set. We present several pairs of documents and how different methods rank the pair. The "Outlier" column indicates the document ranked higher in the outlier document ranking generated by the corresponding methods, and the row "Crowds" shows the ranking given by human evaluators.

Method	Outlier	Document A	Document B
P2V-COS	Doc B	*CHICAGO (AP) States with the most gun control laws have the fewest gun-related deaths, according to a study that suggests sheer quantity of measures might make a difference ...*	*A prominent Scottish bagpiping school has warned pipers around to world to clean their instruments regularly after one of its longtime members nearly died of a lung infection ...*
VMF-E	Doc A		
VMF-Q	Doc A		
Crowds	Doc A		
P2V-COS	Doc B	*ATLANTA There's more evidence that U.S. births may be leveling off after years of decline. The number of babies born last year only slipped a little, ...*	*Young men in a state prison for juveniles and professors of library science from the University of South Carolina have joined forces to fight AIDS with a graphic novel ...*
VMF-E	Doc B		
VMF-Q	Doc A		
Crowds	Doc A		

cussing U.S. population is an outlier. However, a great part of document B is about the content of the book, which confuses baselines P2V and VMF-E, as both methods tend to summarize the entire document and highly relevant words like "AIDS" are overwhelmed by the majority of the document. The only method that agrees with human annotators is VMF-Q.

6 Conclusion

In this paper, we propose a novel task of detecting document outliers from a given corpus. We propose a generative model to identify semantic focuses of a corpus, each represented as a vMF distribution in the embedded space. We also design a document outlierness measure. We experimentally verify the effectiveness of our methods. We hope this work provides insights for further studies on outlier document texts in specific domains, and in more challenging settings such as detecting outliers from crowdsourced data.

Detecting and Explaining Causes From Text For a Time Series Event

Dongyeop Kang, Varun Gangal, Ang Lu, Zheng Chen, Eduard Hovy

Abstract

Explaining underlying causes or effects about events is a challenging but valuable task. We define a novel problem of generating explanations of a time series event by (1) searching cause and effect relationships of the time series with textual data and (2) constructing a connecting chain between them to generate an explanation. To detect causal features from text, we propose a novel method based on the Granger causality of time series between features extracted from text such as N-grams, topics, sentiments, and their composition. The generation of the sequence of causal entities requires a commonsense causative knowledge base with efficient reasoning. To ensure good interpretability and appropriate lexical usage we combine symbolic and neural representations, using a neural reasoning algorithm trained on commonsense causal tuples to predict the next cause step. Our quantitative and human analysis show empirical evidence that our method successfully extracts meaningful causality relationships between time series with textual features and generates appropriate explanation between them.

1 Introduction

Producing true causal explanations requires deep understanding of the domain. This is beyond the capabilities of modern AI. However, it is possible to collect large amounts of causally related events, and, given powerful enough representational variability, to construct cause-effect chains by selecting individual pairs appropriately and linking them together. Our hypothesis is that chains composed of locally coherent pairs can suggest overall causation.

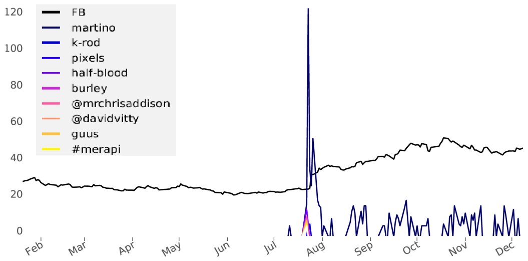

Figure 1: Example of causal features for Facebook's stock change in 2013. The causal features (e.g., *martino*, *k-rod*) rise before the Facebook's rapid stock rise in August.

In this paper, we view *causality* as (commonsense) cause-effect expressions that occur frequently in online text such as news articles or tweets. For example, "*greenhouse gases causes global warming*" is a sentence that provides an 'atomic' link that can be used in a larger chain. By connecting such causal facts in a sequence, the result can be regarded as a *causal explanation* between the two ends of the sequence (see Table 1 for examples).

This paper makes the following contributions:

- we define the problem of causal explanation generation,
- we detect causal features of a time series event (CSpikes) using Granger (Granger, 1988) method with features extracted from text such as N-grams, topics, sentiments, and their composition,
- we produce a large graph called CGraph of local cause-effect units derived from text and develop a method to produce causal explanations by selecting and linking appropriate units, using neural representations to enable unit matching and chaining.

Table 1: Examples of generated causal explanation between some temporal causes and target companies' stock prices.

party $\xmapsto{cut}$ budget_cuts $\xmapsto{lower}$ budget_bill $\xmapsto{decreas}$ republicans $\xmapsto{caus}$ obama $\xmapsto{leadto}$ facebook_polls $\xmapsto{caus}$ **facebook's stock ↓**

The problem of causal explanation generation arises for systems that seek to determine causal factors for events of interest automatically. For given time series events such as companies' stock market prices, our system called CSPIKES detects events that are deemed causally related by time series analysis using Granger Causality regression (Granger, 1988). We consider a large amount of text and tweets related to each company, and produces for each company time series of values for hundreds of thousands of word n-grams, topic labels, sentiment values, etc. Figure 1 shows an example of causal features that temporally causes Facebook's stock rise in August.

However, it is difficult to understand how the statistically verified factors actually cause the changes, and whether there is a latent causal structure relating the two. This paper addresses the challenge of finding such latent causal structures, in the form of *causal explanations* that connect the given cause-effect pair. Table 1 shows example causal explanation that our system found between *party* and *Facebook's stock fall (↓)*.

To construct a general causal graph, we extract all potential causal expressions from a large corpus of text. We refer to this graph as CGRAPH. We use FrameNet (Baker et al., 1998) semantics to provide various causative expressions (verbs, relations, and patterns), which we apply to a resource of $183,253,995$ sentences of text and tweets. These expressions are considerably richer than previous rule-based patterns (Riaz and Girju, 2013; Kozareva, 2012). CGRAPH contains 5,025,636 causal edges.

Our experiment demonstrates that our causality detection algorithm outperforms other baseline methods for forecasting future time series values. Also, we tested the neural reasoner on the inference generation task using the BLEU score. Additionally, our human evaluation shows the relative effectiveness of neural reasoners in generating appropriate lexicons in explanations.

2 CSPIKES: Temporal Causality Detection from Textual Features

The objective of our model is, given a target time series y, to find the best set of textual features $F = \{f_1, ..., f_k\} \subseteq X$, that maximizes sum of causality over the features on y, where X is the set of all features. Note that each feature is itself a time series:

$$\arg\max_F \mathbf{C}(y, \Phi(X, y)) \tag{1}$$

where $\mathbf{C}(y, x)$ is a causality value function between y and x, and Φ is a linear composition function of features f. Φ needs target time series y as well because of our graph based feature selection algorithm described in the next sections.

We first introduce the basic principles of Granger causality in Section 2.1. Section 2.2 describes how to extract good source features $F = \{f_1, ..., f_k\}$ from text. Section 2.3 describes the causality function $\mathbf{C}$ and the feature composition function Φ.

2.1 Granger Causality

The essential assumption behind Granger causality is that a cause must occur before its effect, and can be used to predict the effect. Granger showed that given a target time series y (effect) and a source time series x (cause), *forecasting* future target value y_t with both past target and past source time series $E(y_t|y_{<t}, x_{<t})$ is significantly powerful than with only past target time series $E(y_t|y_{<t})$ (plain auto-regression), if x and y are indeed a cause-effect pair. First, we learn the parameters α and β to maximize the prediction expectation:

$$E(y_t|y_{<t}, x_{t-l}) = \sum_{j=1}^{m} \alpha_j y_{t-j} + \sum_{i=1}^{n} \beta_i x_{t-i} \tag{2}$$

where i and j are size of lags in the past observation. Given a pair of causes x and a target y, if β has magnitude significantly higher than zero (according to a confidence threshold), we can say that x causes y.

2.2 Feature Extraction from Text

Extracting meaningful features is a key component to detect causality. For example, to predict future trend of presidential election poll of *Donald Trump*, we need to consider his past poll data as well as people's reaction about his pledges such as *Immigration*, *Syria* etc. To extract such "good" features crawled from on-line media data, we propose three different types of features: F_{words}, F_{topic}, and F_{senti}.

F_{words} is time series of N-gram words that reflect popularity of the word over time in on-line media. For each word, the number of items (e.g., tweets, blogs and news) that contains the N-gram word is counted to get the day-by-day time series. For example, $x^{Michael\_Jordan} = [12, 51, ..]$ is a time series for a bi-gram word *Michael Jordan*. We filter out stationary words by using simple measures to estimate how dynamically the time series of each word changes over time. Some of the simple measures include Shannon entropy, mean, standard deviation, maximum slope, and number of rise and fall peaks.

F_{topic} is time series of latent topics with respect to the target time series. The latent topic is a group of semantically similar words as identified by a standard topic clustering method such as LDA (Blei et al., 2003). To obtain temporal trend of the latent topics, we choose the top ten frequent words in each topic and count their occurrence in the text to get the day-by-day time series. For example, $x^{healthcare}$ means how popular the topic *healthcare* that consists of *insurance*, *obamacare* etc, is through time.

F_{senti} is time series of sentiments (positive or negative) for each topic. The top ten frequent words in each topic are used as the keywords, and tweets, blogs and news that contain at least one of these keywords are chosen to calculate the sentiment score. The day-by-day sentiment series are then obtained by counting positive and negative words using OpinionFinder (Wilson et al., 2005), and normalized by the total number of the items that day.

2.3 Temporal Causality Detection

We define a causality function $\mathbf{C}$ for calculating causality score between target time series y and source time series x. The causality function $\mathbf{C}$ uses Granger causality (Granger, 1988) by fitting the two time series with a Vector AutoRegressive model with exogenous variables (VARX) (Hamilton, 1994): $y_t = \alpha y_{t-l} + \beta x_{t-l} + \epsilon_t$ where ϵ_t is a white Gaussian random vector at time t and l is a lag term. In our problem, the number of source time series x is not single so the prediction happens in the k multi-variate features $X = (f_1, ...f_k)$ so:

$$y_t = \alpha y_{t-l} + \boldsymbol{\beta}(f_{1,t-l} + ... + f_{k,t-l}) + \epsilon_t \quad (3)$$

where $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ is the coefficient matrix of the target y and source X time series respectively, and ϵ is a residual (prediction error) for each time series. $\boldsymbol{\beta}$ means contributions of each lagged feature $f_{k,t-l}$ to the predicted value y_t. If the variance of $\boldsymbol{\beta_k}$ is reduced by the inclusion of the feature terms $f_{k,t-l} \in X$, then it is said that $f_{k,t-l}$ Granger-causes y.

Our causality function $\mathbf{C}$ is then $\mathbf{C}(y, f, l) = \Delta(\beta_{y,f,l})$ where Δ is change of variance by the feature f with lag l. The total Granger causality of target y is computed by summing the change of variance over all lags and all features:

$$\mathbf{C}(y, X) = \sum_{k,l} \mathbf{C}(y, f_k, l) \quad (4)$$

We compose best set of features Φ by choosing top k features with highest causality scores for each target y. In practice, due to large amount of computation for pairwise Granger calculation, we make a bipartite graph between features and targets, and address two practical problems: *noisiness* and *hidden edges*. We filter out noisy edges based on TFIDF and fill out missing values using non-negative matrix factorization (NMF) (Hoyer, 2004).

3 CGraph Construction

Formally, given source x and target y events that are causally related in time series, if we could find a sequence of cause-effect pairs $(x \mapsto e_1)$, $(e_1 \mapsto e_2)$, ... $(e_t \mapsto y)$, then $e_1 \mapsto e_2, ... \mapsto e_t$ might be a good causal explanation between x and y. Section 3 and 4 describe how to bridge the causal gap between given events (x, y) by (1) constructing a large general cause-effect graph (CGraph) from text, (2) linking the given events to their equivalent entities in the causal graph by finding the internal paths $(x \mapsto e_1, ...e_t \mapsto y)$ as causal explanations, using neural algorithms.

CGraph is a knowledge base graph where edges are directed and causally related between entities. To address less representational variability of rule based methods (Girju, 2003; Blanco et al., 2008; Sharp et al., 2016) in the causal graph construction, we used FrameNet (Baker et al., 1998) semantics. Using a semantic parser such

Table 2: Example (relation, cause, effect) tuples in different categories (manually labeled): *general*, *company*, *country*, and *people*. FrameNet labels related to causation are listed inside parentheses. The number of distinct relation types are 892.

	Relation	**Cause ↦ Effect**	
General	causes (Causation)	the virus (Cause)	aids (Effect)
	cause (Causation)	greenhouse gases (Cause)	global warming (Effect)
	forced (Causation)	the reality of world war ii (Cause)	the cancellation of the olympics (Effect)
Company	heats (Cause_temperature_change)	microsoft vague on windows (Item)	legislation battle (Agent)
	promotes (Cause_change_of_position_on_a_scale)	chrome (Item)	google (Agent)
	makes (Causation)	twitter (Cause)	love people you 've never met facebook (Effect)
Country	developing (Cause_to_make_progress)	north korea (Agent)	nuclear weapons (Project)
	improve (Cause_to_make_progress)	china (Agent)	its human rights record (Project)
	forced (Causation)	war with china (Cause)	the japanese to admit , in july 1938 (Effect)
People	attracts (Cause_motion)	obama (Agent)	more educated voters (Theme)
	draws (Cause_motion)	on america 's economic brains (Goal)	barack obama (Theme)
	made (Causation)	michael jordan (Cause)	about $ 33 million (Effect)

as SEMAFOR (Chen et al., 2010) that produces a FrameNet style analysis of semantic predicate-argument structures, we could obtain lexical tuples of causation in the sentence. Since our goal is to collect only causal relations, we extract total 36 causation related frames[1] from the parsed sentences.

Table 3: Number of sentences parsed, number of entities and tuples, and number of edges (*KB-KB*, *KBcross*) expanded by Freebase in CGRAPH.

# Sentences	# Entities	# Tuples	# *KB-KB*	# *KBcross*
183,253,995	5,623,924	5,025,636	470,250	151,752

To generate meaningful explanations, high coverage of the knowledge is necessary. We collect six years of tweets and NYT news articles from 1989 to 2007 (See Experiment section for details). In total, our corpus has 1.5 billion tweets and 11 million sentences from news articles. The Table 3 has the number of sentences processed and number of entities, relations, and tuples in the final CGRAPH.

Since the tuples extracted from text are very noisy [2], we constructed a large causal graph by linking the tuples with string match and filter out the noisy nodes and edges based on some graph statistics. We filter out nodes with very high degree that are mostly stop-words or auto-generated sentences. Too long or short sentences are also filtered out. Table 2 shows the (case, relation, effect) tuples with manually annotated categories such as *General*, *Company*, *Country*, and *People*.

4 Causal Reasoning

To generate a causal explanation using CGRAPH, we need traversing the graph for finding the path between given source and target events. This section describes how to efficiently traverse the graph by expanding entities with external knowledge base and how to find (or generate) appropriate causal paths to suggest an explanation using symbolic and neural reasoning algorithms.

4.1 Entity Expansion with Knowledge Base

A simple choice for traversing a graph are the traditional graph searching algorithms such as Breadth-First Search (BFS). However, the graph searching procedure is likely to be incomplete (*low recall*), because simple string match is insufficient to match an effect to all its related entities, as it misses out in the case where an entity is semantically related but has a lexically different name.

To address the *low recall* problem and generate better explanations, we propose the use of knowledge base to augment our text-based causal graph with real-world semantic knowledge. We use Freebase (Google, 2016) as the external knowledge base for this purpose. Among 1.9 billion edges in original Freebase dump, we collect its first and second hop neighbours for each target events.

While our CGRAPH is lexical in nature, Freebase entities appear as identifiers (MIDs). For entity linking between two knowledge graphs, we need to annotate Freebase entities with their lexical names by looking at the wiki URLs. We refer to the edges with freebase expansion as *KB-KB* edges, and link the *KB-KB* with our CGRAPH us-

[1] Causation, Cause_change, Causation_scenario, Cause_benefit_or_detriment, Cause_bodily_experience, etc.

[2] SEMAFOR has around 62% of accuracy on held-out set.

ing lexical matching, referring as *KBcross* edges (See Table 3 for the number of the edges).

4.2 Symbolic Reasoning

Simple traversal algorithms such as BFS are infeasible for traversing the CGRAPH due to the large number of nodes and edges. To reduce the search space k in $e_t \mapsto \{e^1_{t+1}, ...e^k_{t+1}\}$, we restricted our search by depth of paths, length of words in entity's name, and edge weight.

Algorithm 1 Backward Causal Inference. y is target event, d is depth of BFS, l is lag size, BFS_{back} is Breadth-First search for one depth in backward direction, and $\sum_l \mathbf{C}$ is sum of Granger causality over the lags.

```
$\mathbb{S} \leftarrow y, d = 0$
while ($\mathbb{S} = \varnothing$) or ($d > D_{max}$) do
    $\{e^1_{-d}, ...e^k_{-d}\} \leftarrow BFS_{back}(\mathbb{S})$
    $d = d + 1, \mathbb{S} \leftarrow \varnothing$
    for $j$ in $\{1, ..., k\}$ do
        if $\sum_l \mathbf{C}(y, e^j_{-d}, l) < \epsilon$ then $\mathbb{S} \leftarrow e^j_{-d}$
```

For more efficient inference, we propose a backward algorithm that searches potential causes (instead of effects) $\{e^1_t, ...e^k_t\} \hookleftarrow e_{t+1}$ starting from the target node $y = e_{t+1}$ using Breadth-first search (BFS). It keeps searching backward until the node e^j_i has less Granger confident causality with the target node y (See Algorithm 4 for causality calculation). This is only possible because our system has temporal causality measure between two time series events. See Algorithm 1 for detail.

4.3 Neural Reasoning

While symbolic inference is fast and straightforward, the sparsity of edges may make our inference semantically poor. To address the *lexical sparseness*, we propose a lexically relaxed reasoning using a neural network.

Inspired by recent success on alignment task such as machine translation (Bahdanau et al., 2014), our model learns the causal alignment between cause phrase and effect phrase for each type of relation between them. Rather than traversing the CGRAPH, our neural reasoner uses CGRAPH as a training resource. The encoder, a recurrent neural network such as LSTM (Hochreiter and Schmidhuber, 1997), takes the causal phrase while the decoder, another LSTM, takes the effectual phrase with their relation specific attention.

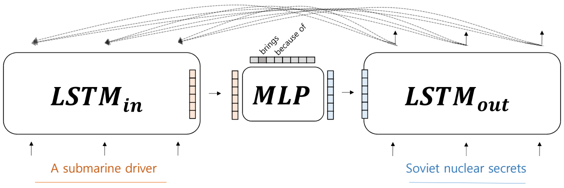

Figure 2: Our neural reasoner. The encoder takes causal phrases and decoder takes effect phrases by learning the causal alignment between them. The MLP layer in the middle takes different types of FrameNet relation and locally attend the cause to the effect w.r.t the relation (e.g., "because of", "led to", etc).

In original attention model (Bahdanau et al., 2014), the contextual vector c is computed by $c_i = a_{ij} * h_j$ where h_j is hidden state of causal sequence at time j and a_{ij} is soft attention weight, trained by feed forward network $a_{ij} = FF(h_j, s_{i-1})$ between input hidden state h_j and output hidden state s_{i-1}. The global attention matrix a, however, is easy to mix up all local alignment patterns of each relation.

For example, a tuple, *(north korea (Agent)* $\xmapsto[(Cause\_to\_make\_progress)]{developing}$ *nuclear weapons (Project))*, is different with another tuple, *(chrome (Item)* $\xmapsto[(Cause\_change\_of\_position)]{promotes}$ *google (Agent))* in terms of local type of causality. To deal with the *local attention*, we decomposed the attention weight a_{ij} by relation specific transformation in feed forward network:

$$a_{ij} = FF(h_j, s_{i-1}, r)$$

where FF has relation specific hidden layer and $r \in R$ is a type of relation in the distinct set of relations R in training corpus (See Figure 2).

Since training only with our causal graph may not be rich enough for dealing various lexical variation in text, we use pre-trained word embedding such as word2vec (Mikolov and Dean, 2013) trained on GoogleNews corpus[3] for initialization. For example, given a cause phrase *weapon equipped*, our model could generate multiple effect phrases with their likelihood: *(*$\xmapsto[0.54]{result}$*war)*, *(*$\xmapsto[0.12]{force}$*army reorganized)*, etc, even though there are no tuples exactly matched in CGRAPH.

[3] https://code.google.com/archive/p/word2vec/

Table 4: Examples of F_{words} with their temporal dynamics: Shannon entropy, mean, standard deviation, slope of peak, and number of peaks.

	entropy	mean	STD	max_slope	#-peaks
#lukewilliamss	0.72	22.01	18.12	6.12	31
happy_thanksgiving	0.40	61.24	945.95	3423.75	414
michael_jackson	0.46	141.93	701.97	389.19	585

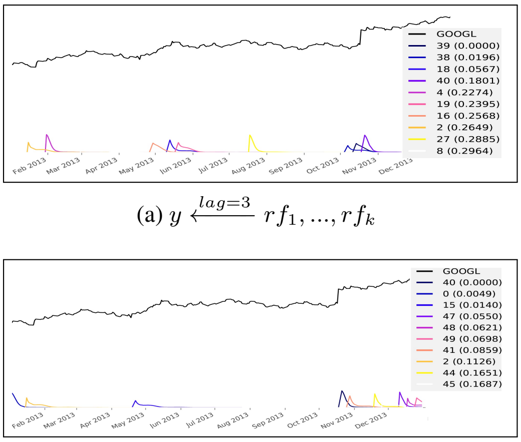
We trained our neural reasoner in either forward or backward direction. In prediction, decoder inferences by predicting effect (or cause) phrase in forward (or backward) direction. As described in the Algorithm 1, the backward inference continue predicting the previous causal phrases until it has high enough Granger confidence with the target event.

5 Experiment

Data. We collect on-line social media from tweets, news articles, and blogs. Our Twitter data has one million tweets per day from 2008 to 2013 that are crawled using Twitter's Garden Hose API. News and Blog dataset have been crawled from 2010 to 2013 using Google's news API. For target time series, we collect companies' stock prices in NASDAQ and NYSE from 2001 until present for 6,200 companies. For presidential election polls, we collect polling data of the 2012 presidential election from 6 different websites, including USA Today , Huffington Post, Reuters, etc.

Features. For N-gram word features F_{word},we choose the spiking words based on their temporal dynamics (See Table 4). For example, if a word is too frequent or the time series is too burst, the word should be filtered out because the trend is too general to be an event. We choose five types of temporal dynamics: Shannon entropy, mean, standard deviation, maximum slope of peak, and number of peaks; and delete words that have too low or high entropy, too low mean and deviation, or the number of peaks and its slope is less than a certain threshold. Also, we filter out words whose frequency is less than five. From the $1,677,583$ original words, we retain $21,120$ words as final candidates for F_{words} including uni-gram and bi-gram words.

For sentiment F_{senti} and topic F_{topic} features, we choose 50 topics generated for both politicians and companies separately using LDA, and then use top 10 words for each topic to calculate sentiment score for this topic. Then we can analyze the causality between sentiment series of a specific topic and collected time series.



(a) $y \xleftarrow{lag=3} rf_1, ..., rf_k$

(b) $y \xrightarrow{lag=3} rf_1, ..., rf_k$

Figure 3: Random causality analysis on **Googles**'s stock price change (y) and randomly generated features (rf) during 2013-01-01 to 2013-12-31. (a) shows how the random features rf cause the target y, while (b) shows how the target y causes the random features rf with lag size of 3 days. The color changes according to causality confidence to the target (blue is the strongest, and yellow is the weakest). The target time series has y scale of prices, while random features have y scale of causality degree $\mathbf{C}(y, rf) \subset [0, 1]$.

Tasks. To show validity of causality detector, first we conduct random analysis between target time series and randomly generated time series. Then, we tested forecasting stock prices and election poll values with or without the detected textual features to check effectiveness of our causal features. We evaluate our reasoning algorithm for generation ability compared to held-out cause-effect tuples using BLEU metric. Then, for some companies' time series, we describe some qualitative result of some interesting causal text features found with Granger causation and explanations generated by our reasoners between the target and the causal features. We also conducted human evaluation on the explanations.

5.1 Random Causality Analysis

To check whether our causality scoring function $\mathbf{C}$ detects the temporal causality well, we conduct a random analysis between target time series and randomly generated time series (See Figure 3). For Google's stock time series, we regularly move window size of 30 over the time and generate five days of time series with a random peak strength using a SpikeM model (Matsubara et al., 2012)[4]. The color of random time series rf changes from blue to yellow according to causality degree with the target $\mathbf{C}(y, rf)$. For example, blue is the strongest causality with target time series, while yellow is the weakest.

We observe that the strong causal (blue) features are detected just before (or after) the rapid rise of Google' stock price on middle October in (a) (or in (b)). With the lag size of three days, we observe that the strength of the random time series gradually decreases as it grows apart from the peak of target event. The random analysis shows that our causality function $\mathbf{C}$ appropriately finds cause or effect relation between two time series in regard of their strength and distance.

5.2 Forecasting with Textual Features

Table 5: Forecasting errors (RMSE) on **Stock** and **Poll** data with time series only (*SpikeM* and *LSTM*) and with time series plus text feature (*random*, *words*, *topics*, *sentiment*, and *composition*).

		Time Series		Time Series + Text				
	Step	SpikeM	LSTM	$\mathbf{C}_{rand}$	$\mathbf{C}_{words}$	$\mathbf{C}_{topics}$	$\mathbf{C}_{senti}$	$\mathbf{C}_{comp}$
Stock	1	102.13	6.80	3.63	2.97	3.01	3.34	$\underline{1.96}$
	3	99.8	7.51	4.47	4.22	4.65	4.87	$\underline{3.78}$
	5	97.99	7.79	5.32	$\underline{5.25}$	5.44	5.95	5.28
Poll	1	10.13	1.46	1.52	1.27	1.59	2.09	$\underline{1.11}$
	3	10.63	1.89	1.84	1.56	1.88	1.94	$\underline{1.49}$
	5	11.13	2.04	2.15	1.84	1.88	1.96	$\underline{1.82}$

We use time series forecasting task as an evaluation metric of whether our textual features are appropriately causing the target time series or not. Our feature composition function Φ is used to extract good causal features for forecasting. We test forecasting on stock price of companies (**Stock**) and predicting poll value for presidential election (**Poll**). For stock data, We collect daily closing stock prices during 2013 for ten IT companies[5]. For poll data, we choose ten candidate politicians [6] in the period of presidential election in 2012.

For each of stock and poll data, the future trend of target is predicted only with target's past time series or with target's past time series and past time series of textual features found by our system. Forecasting only with target's past time series uses *SpikeM* (Matsubara et al., 2012) that models a time series with small number of parameters and simple *LSTM* (Hochreiter and Schmidhuber, 1997; nne, 2015) based time series model. Forecasting with target and textual features' time series use Vector AutoRegressive model with exogenous variables (VARX) (Hamilton, 1994) from different composition function such as $\mathbf{C}_{random}$, $\mathbf{C}_{words}$, $\mathbf{C}_{topics}$, $\mathbf{C}_{senti}$, and $\mathbf{C}_{composition}$. Each composition function except $\mathbf{C}_{random}$ uses top ten textual features that causes each target time series. We also tested LSTM with past time series and textual features but VARX outperforms LSTM.

Table 6: Beam search results in neural reasoning. These examples could be filtered out by graph heuristics before generating final explanation though.

Cause$\mapsto$Effect in CGraph	Beam Predictions
the dollar's $\xmapsto{caus}$ against the yen	[1]$\xmapsto{caus}$ against the yen [2]$\xmapsto{caus}$ against the dollar [3]$\xmapsto{caus}$ against other currencies
without any exercise $\xmapsto{caus}$ news article	[1]$\xmapsto{leadto}$ a difference [2]$\xmapsto{caus}$ the risk [3]$\xmapsto{make}$ their weight

Table 5 shows root mean square error (RMSE) for forecasting with different step size (time steps to predict), different set of features, and different regression algorithms on stock and poll data. The forecasting error is summation of errors over moving a window (30 days) by 10 days over the period. Our $\mathbf{C}_{composition}$ method outperforms other time series only models and time series plus text models in both stock and poll data.

5.3 Generating Causality with Neural Reasoner

The reasoner needs to predict the next effect phrase (or previous cause phrase) so the model should be evaluated in terms of generation task. We used the BLEU (Papineni et al., 2002) metric to evaluate the predicted phrases on held out phrases in our CGraph . Since our CGraph has many edges, there may be many good paths (explanations), possibly making our prediction diverse. To evaluate such diversity in prediction, we used ranking-based BLEU method on the k set of

[4] SpikeM has specific parameters for modeling a time series such as peak strength, length, etc.

[5] Company symbols used: TSLA, MSFT, GOOGL, YHOO, FB, IBM, ORCL, AMZN, AAPL and HPO

[6] Name of politicians used: Santorum, Romney, Pual, Perry, Obama, Huntsman, Gingrich, Cain, Bachmann

Table 7: BLEU ranking. Additional word representation **+WE** and relation specific alignment **+REL** help the model learn the cause and effect generation task especially for diverse patterns.

	B@1	B@3A	B@5A
S2S	10.15	8.80	8.69
S2S + WE	11.86	10.78	10.04
S2S + WE + REL	12.42	12.28	11.53

predicted phrases by beam search. For example, $B@k$ means BLEU scores for generating k number of sentences and $B@kA$ means the average of them.

Table 6 shows some examples of our beam search results when $k = 3$. Given a cause phrase, the neural reasoner sometime predicts semantically similar phrases (e.g., *against the yen*, *against the dollar*), while it sometimes predicts very diverse phrases (e.g., *a different*, *the risk*).

Table 7 shows BLEU ranking results with different reasoning algorithms: **S2S** is a sequence to sequence learning trained on CGraph by default, **S2S+WE** adds word embedding initialization, and **S2S+REL+WE** adds relation specific attention. Initializing with pre-trained word embeddings (**+WE**) helps us improve on prediction. Our relation specific attention model outperforms the others, indicating that different type of relations have different alignment patterns.

5.4 Generating Explanation by Connecting

Evaluating whether a sequence of phrases is reasonable as an explanation is very challenging task. Unfortunately, due to lack of quantitative evaluation measures for the task, we conduct a human annotation experiment.

Table 8 shows example causal chains for the rise (↑) and fall (↓) of companies' stock price, continuously produced by two reasoners: *SYBM* is symbolic reasoner and *NEUR* is neural reasoner.

We also conduct a human assessment on the explanation chains produced by the two reasoners, asking people to choose more convincing explanation chains for each feature-target pair. Table 9 shows their relative preferences.

6 Related Work

Prior works on causality detection (Acharya, 2014; Anand, 2014; Qiu et al., 2012) in time series data (e.g., gene sequence, stock prices, temperature) mainly use Granger (Granger, 1988) ability for predicting future values of a time series using past values of its own and another time series. (Hlaváčková-Schindler et al., 2007) studies more theoretical investigation for measuring causal influence in multivariate time series based on the entropy and mutual information estimation. However, none of them attempts generating explanation on the temporal causality.

Previous works on text causality detection use syntactic patterns such as $X \xmapsto{verb} Y$, where the $verb$ is causative (Girju, 2003; Riaz and Girju, 2013; Kozareva, 2012; Do et al., 2011) with additional features (Blanco et al., 2008). (Kozareva, 2012) extracted cause-effect relations, where the pattern for bootstrapping has a form of $X^* \xmapsto[Z^*]{verb} Y$ from which terms X^* and Z^* was learned. The syntax based approaches, however, are not robust to semantic variation.

As a part of SemEval (Girju et al., 2007), (Mirza and Tonelli, 2016) also uses syntactic causative patterns (Mirza and Tonelli, 2014) and supervised classifier to achieve the state-of-the-art performance. Extracting the cause-effect tuples with such syntactic features or temporality (Bethard et al., 2008) would be our next step for better causal graph construction.

(Grivaz, 2010) conducts very insightful annotation study of what features are used in human reasoning on causation. Beyond the linguistic tests and causal chains for explaining causality in our work, other features such as counterfactuality, temporal order, and ontological asymmetry remain as our future direction to study.

Textual entailment also seeks a directional relation between two given text fragments (Dagan et al., 2006). Recently, (Rocktäschel et al., 2015) developed an attention-based neural network method, trained on large annotated pairs of textual entailment, for classifying the types of relations with decomposable attention (Parikh et al., 2016) or sequential tree structure (Chen et al., 2016). However, the dataset (Bowman et al., 2015) used for training entailment deals with just three categories, *contradiction*, *neutral*, and *entailment*, and focuses on relatively simple lexical and syntactic transformations (Kolesnyk et al., 2016). Our causal explanation generation task is also similar to *future scenario generation* (Hashimoto et al., 2014, 2015). Their scoring

Table 8: Example causal chains for explaining the rise (↑) and fall (↓) of companies' stock price. The temporally causal *feature* and *target* are linked through a sequence of predicted cause-effect tuples by different reasoning algorithms: a symbolic graph traverse algorithm *SYMB* and a neural causality reasoning model *NEUR*.

function uses heuristic filters and is not robust to lexical variation.

7 Conclusion

This paper defines the novel task of detecting and explaining causes from text for a time series. First, we detect causal features from online text. Then, we construct a large cause-effect graph using FrameNet semantics. By training our relation specific neural network on paths from this graph, our model generates causality with richer lexical variation. We could produce a chain of cause and effect pairs as an explanation which shows some appropriateness. Incorporating aspects such as time, location and other event properties remains a point for future work. In our following work, we collect a sequence of causal chains verified by domain experts for more solid evaluation of generating explanations.

Abstract

Recent years have witnessed the proliferation of Massive Open Online Courses (MOOCs). With massive learners being offered MOOCs, there is a demand that the forum contents within MOOCs need to be classified in order to facilitate both learners and instructors. Therefore we investigate a significant application, which is to associate forum threads to subtitles of video clips. This task can be regarded as a document ranking problem, and the key is how to learn a distinguishable text representation from word sequences and learners' behavior sequences. In this paper, we propose a novel cascade model, which can capture both the latent semantics and latent similarity by modeling MOOC data. Experimental results on two real-world datasets demonstrate that our textual representation outperforms state-of-the-art unsupervised counterparts for the application.

1 Introduction

With the rapid development of Massive Open Online Courses (MOOCs), more and more learners participate in MOOCs (Anderson et al., 2014). Due to the lack of effective management, most of the discussion forums within MOOCs are overloaded and in chaos (Huang et al., 2014). Therefore, a key problem is how to manage the forum contents.

To manage the forum contents, threads of forums can be regarded as documents and be classified to groups. There are several straightforward methods, such as defining sub-forums according to weeks and asking learners to tag threads. However their effectiveness is limited (Rossi and Gnawali, 2014), because learners have few incentives to tag threads. Recently, machine learning solutions have been proposed, e.g., content-related thread identification (Wise et al., 2016), confusion classification (Agrawal et al., 2015) and sentiment classification (Ramesh et al., 2015). However they are developed for specific research problems and cannot be applied to our problem. Moreover, they require labeling data which needs domain experts to label data for different courses.

We observe that the video clips of a MOOC would have many well-formed subtitles composed by instructors. Moreover, within MOOC settings, the course contents can be broken down to knowledge points, and each video clip just corresponds to a knowledge point. Consequently, we propose to fulfill the application, which is to associate threads to subtitles of video clips, i.e., thread-subtitle matching. By this way, the relevant videos to the threads can be recommended to learners, and the chaotic threads in discussion forums can also be well grouped.

However, it is challenging to identify the relevant video clips for threads without labeling data. To address this issue, we regard it as a document ranking problem based on the calculation of similarity between documents. The key problem of this task is to learn a textual representation, which can cluster similar documents and meanwhile distinguish irrelevant ones.

Intuitively, Bag-of-words model (BOW) can be utilized to calculate the similarity between threads and subtitles (Salton and Buckley, 1988). However, BOW cannot effectively capture semantics of words and documents. In addition, recently-studied semantic word embeddings, e.g., Word2Vec (Mikolov et al., 2013), can capture the semantics. Para2Vec (Le and Mikolov, 2014) can capture the similarity to some degree, but not explicitly model the latent similarity of documents.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2768–2773
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

Since the latent similarity is crucial to determine whether a document can be associated to the right target, in our task, the document representation is expected to preserve both the latent semantics and similarity.

In this paper, we leverage two kinds of sequential information: 1) word sequence of subtitles and forum contents, and 2) clickstream log of learning behaviors. Specifically, different from conventional representation learning tasks, e.g. Word2Vec and Para2Vec, we consider the clickstream data, which reflects the relationship between thread and video's subtitle. For instance, if a user watches a video and then clicks a thread in forums, the video would be relevant to the thread. In order to learn representations from the two types of data, we propose a novel cascade model.

Our basic idea is to jointly model three components: 1) word-word coherence, 2) document-document coherence, and 3) word-document coherence. The three components are cascaded for learning the low-dimensional word embeddings. Then the learned embeddings are used to calculate similarities between threads and subtitles.

To summarize, our contributions include:

- We study an application-oriented research problem, which is how to capture the latent similarity when learning text representation.
- We propose a novel cascade model to learn the document representation from heterogeneous sequential data: 1) word sequence and 2) learners' clickstream.
- We collect two real-world MOOC datasets and conduct thorough experiments. The results demonstrate that our proposed model outperforms the state-of-the-art unsupervised counterparts on the application.

2 Related Work

MOOC data has attracted extensive research attention and many interesting research problems have been studied. For example, dropout predicting (Qiu et al., 2016), sentiment analysis of learning gains (Ramesh et al., 2015), instructor intervention (Chaturvedi et al., 2014) and answer recommendation (Jenders et al., 2016), etc. Particularly, (Agrawal et al., 2015) considers a similar task as ours, which is to recommend video clips to threads. But its solution is designed for the specific task and needs labeling data. Our solution is an unsupervised learning method and the learned embeddings have other applications, e.g. thread retrieval.

How to represent text is a fundamental research problem in the field of information retrieval. Existing approaches can be generally classified into unsupervised methods and supervised methods (Tang et al., 2015). Although supervised embeddings can obtain good performance in specific tasks, such as using deep neural network (Mikolov et al., 2010; Kim, 2014), they need human efforts to get labels. Unsupervised word embeddings usually leverage various levels of textual information. For example, Word2Vec learns word embeddings based on word coherence. Para2Vec utilizes word and document coherence to learn their embeddings. Particularly, Hierarchical Document Vector (HDV) (Djuric et al., 2015) leverages both streaming documents and their contents to achieve better representation, which is similar to our proposed model. However, HDV regards the documents as the context of words, which cannot learn the latent similarity, since it fails to explicitly reflect the relationship between document and word. In order to model the heterogeneous MOOC data, we develop a cascade representation model. To our knowledge, (Jiang et al., 2017) also proposes an unsupervised learning model (called NOSE) for the task of thread-subtitle matching within MOOC settings. However, NOSE needs to build a heterogeneous textual network beforehand and may suffer from heterogeneous issue, which our model can avoid.

Recently, representation learning has been applied to many tasks, such as network embedding (Grover and Leskovec, 2016) and location embedding (Feng et al., 2017). In this paper, we focus on learning representation of words and documents in MOOCs.

3 Cascade Model

Based on our observation, we utilize two kinds of sequential information: 1) word sequences of subtitles and threads, and 2) clickstream of learning behaviors. In this paper, we regard the subtitles or threads consistently as *documents*. Particularly, we discover that the log of learners' clickstream, i.e., the click records of watching videos, reading threads and posting threads in a chronological order, can reflect the document-level latent semantics. An intuitive explanation is that a learner who jumps from videos to threads may look for further relevant information from forums when s/he is watching a video, or s/he wants to review the relevant videos when s/he reads a thread.

However, learning from the log of clickstream data merely guarantees that similar documents are close enough in the embedding space, while different documents cannot be scattered. To address this issue, we attempt to strengthen the relationship between words and their affiliated documents. Thus, words within the same documents would be gathered and otherwise scattered in the embedding space. Consequently, the latent similarity can be embodied by word embeddings.

Based on the aforementioned idea, we can model the data by three components: 1) latent semantics at word level, 2) latent similarity at document level, and 3) latent similarity between words and documents. To integrate all the three kinds of information into a uniform learning framework, we propose a novel cascade model, as shown in Fig. 1. $\mathcal{L}_1$, $\mathcal{L}_2$ and $\mathcal{L}_3$ correspond to the log-likelihood of three components respectively. Formally, we aim at minimizing the log-likelihood function:

$$\mathcal{L} = \mathcal{L}_1 + \mathcal{L}_2 + \mathcal{L}_3 \quad (1)$$

Note that $\mathcal{L}_3$ not only learns the latent similarity, but also builds a connection between words and documents. In this way, our learned word embeddings can be adopted to our task without learning classifiers by labeling data.

3.1 Word-level Latent Semantics

As to the part of $\mathcal{L}_1$, corresponding to the red/bottom part of Fig. 1, we leverage the Word2Vec model to learn the semantics of words. In this paper, we take the Continuous bag-of-words (CBOW) architecture. The objective function is to minimize the log-likelihood:

$$\mathcal{L}_1 = -\sum_{t=1}^{T} \log \mathbb{P}(w_t | w_{t-c_w} : w_{t+c_w}) \quad (2)$$

where c_w is the context window length used in word sequence, and $w_{t-c_w} : w_{t+c_w}$ is the subsequence $(w_{t-c_w}, \ldots, w_{t+c_w})$ excluding w_t itself. The probability $\mathbb{P}(w_t | w_{t-c_w} : w_{t+c_w})$ is defined by the softmax function $\frac{\exp(\bar{\mathbf{v}}^T \mathbf{v}_{w_t})}{\sum_{w=1}^{W} \exp(\bar{\mathbf{v}}^T \mathbf{v}_w)}$, where $\mathbf{v}_{w_t}$ is the vector representation of word w_t, and $\bar{\mathbf{v}}$ is averaged vector representation of the subsequence. Two methods can be employed to calculating $\mathcal{L}_1$: hierarchical softmax and negative sampling (Mikolov et al., 2013).

$\mathcal{L}_1$: word sequence (word-level coherence)

Figure 1: The architecture of proposed model which is cascaded by three parts: $\mathcal{L}_1$, $\mathcal{L}_2$ and $\mathcal{L}_3$.

3.2 Document-level Latent Similarity

Similar to $\mathcal{L}_1$, we adopt the CBOW architecture for calculating $\mathcal{L}_2$, as shown by the green/top part of Fig. 1. The objective function is to minimize the log-likelihood:

$$\mathcal{L}_2 = -\sum_{m=1}^{M} \log \mathbb{P}(d_m | d_{m-c_d} : d_{m+c_d}) \quad (3)$$

where M is the number of documents, c_d is the context window length used in clickstreams, and $d_{m-c_d} : d_{m+c_d}$ is the sub-sequence $(d_{m-c_d}, \ldots, d_{m+c_d})$ excluding d_m itself. The probability $\mathbb{P}(d_m | d_{m-c_d} : d_{m+c_d})$ is also the softmax function. Methods of hierarchical softmax and negative sampling can be employed to approximate the log-likelihood function.

3.3 Document-Word Latent Similarity

To learn the latent similarity, we make use of the relationship between words and documents, and then similar documents can be clustered, while different documents are scattered. Therefore, we propose the third component, $\mathcal{L}_3$, shown in the middle part of Fig. 1. Different from $\mathcal{L}_1$ and $\mathcal{L}_2$, we employ negative sampling of documents to calculate its approximation, because there are numerous threads in MOOC forums. Given a pair (w_t, d_m), representing that word w_t appears in document d_m, $\mathcal{L}_3$ is denoted as:

$$\mathcal{L}_3 = \sum_{w_t} \left(-\log \sigma(\mathbf{v}_{d_m}^T \mathbf{v}_{w_t}) + \sum_{c=1}^{C} \log \sigma(\mathbf{v}_{d_c}^T \mathbf{v}_{w_t}) \right) \tag{4}$$

where $\sigma(x)$ is the sigmoid function and C is the number of sampled negative documents.

3.4 Model Training

We adopt stochastic gradient descent (SGD) to minimize $\mathcal{L}$. As to the components of $\mathcal{L}_1$ and $\mathcal{L}_2$, we exploit the training methods proposed in (Mikolov et al., 2013) to the two kinds of sequences, i.e., words and documents, respectively. For training $\mathcal{L}_3$, given the pair (w_t, d_m), we calculate the gradients:

$$\frac{\partial \mathcal{L}_3}{\partial \mathbf{v}_{d_j}} = \Big(\sigma(\mathbf{v}_{d_j}^T \mathbf{v}_{w_t}) - \nVdash(j = m) \Big) \mathbf{v}_{w_t}, \tag{5}$$

$$\frac{\partial \mathcal{L}_3}{\partial \mathbf{v}_{w_t}} = \Big(\sigma(\mathbf{v}_{d_j}^T \mathbf{v}_{w_t}) - \nVdash(j = m) \Big) \mathbf{v}_{d_j}, \tag{6}$$

where d_j represents both the positive and negative samples, as $d_j \in \{d_i\} \cup \{d_c \sim P_n(w) | c = 1, \ldots, C\}$. $P_n(w)$ is the noise distribution and we set it as unigram distribution raised to 3/4th power, which is the same as Word2Vec. $\nVdash(x)$ is an indicator function defined as:

$$\nVdash(x) = \begin{cases} 1 & \text{if } x \text{ is true,} \\ 0 & \text{otherwise.} \end{cases} \tag{7}$$

The time complexity of updating $\mathcal{L}$ is $O(T \log T + M \log M + TC)$ when using hierarchical softmax method for $\mathcal{L}_1$ and $\mathcal{L}_2$, or $O((2T + M)C)$ when using negative sampling method. Based on the complexity analysis, our cascade model is efficient enough and can be applied to MOOC datasets.

4 Experiment

Data Sets We collect the sequential data of two MOOCs from Coursera[1] and China University MOOC[2] respectively. The former is an interdiscipline course called *People and Network*, and the second is called *Introduction to MOOC*. From both courses, we collect subtitles of video clips, forum contents and learners' log of clickstream. Table 1 shows the statistical information of the two MOOCs.

For evaluation, we invite the teaching assistants (TAs) of respective courses to label test samples in advance. Note that our model is unsupervised. Therefore, labeled data (thread-subtitle matching pairs) are only used for evaluation, and we do not utilize dev dataset.

Experimental Setting We compare our embeddings with unsupervised rivals and the labels are only used for evaluation. To ensure fair comparison, we represent documents with their averaged word embeddings. Note that in the training phase, we represent each thread/subtitle with a vector, in order to make the words within a document clustered and close to each other. We evaluate the following methods.

- Bag-of-words(BOW): the classical text representation.

- Word2Vec: word embeddings which leverages word-level coherence and we adopt the CBOW architecture.

- Para2Vec: paragraph embeddings which considers document-level context information. We also adopt CBOW framework.

- Hierarchical Document Vector(HDV): the latest word embeddings with a hierarchical architecture for modeling streaming documents and their contents.

- Cascade Document Representation (CDR): our proposed model which captures both the latent semantics and latent similarity.

We use the hype-parameters recommended by previous literatures. For all the evaluated baselines, we use the same parameter setting. Thus it is fair to make comparison. The window size set in all baselines is 5 by default. The number of negative samples is empirically set as 5. The size of hidden layer is set as 100 for all the methods. We utilize the Precision@K (denoted by P@K) as metric. If the retrieved top-K subtitles hit at least one ground-truth label, we regard it as true; otherwise, it is false. In our experiments, we run 10 times and report the average result for each case.

CDR	**0.505**	0.689	0.786	**0.520**	**0.854**	**0.941**

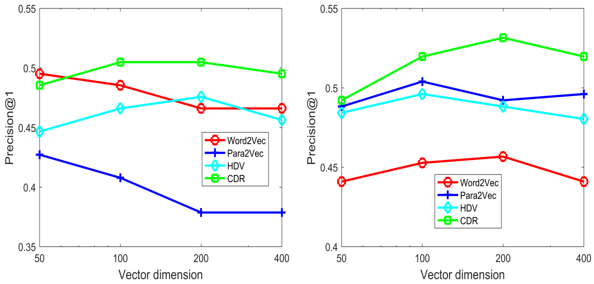
Table 2: Result of thread-subtitle matching.

Result Firstly we use all the data to learn word embeddings by models. Then the learned word vectors are utilized to calculate the similarity between threads and subtitles, and rank the subtitles. Table 2 reports the results of thread-subtitle matching. We can notice that there are some anomalies in P@3 and P@5 results. It may be for the reason of dataset. In the first MOOC (people and network), video subtitles contain relatively less words, and therefore it is hard to get effective representations. Overall, the proposed models can achieve better performance than baselines, and we highlight the Precision@1 results. Compared to HDV which also considers the streaming documents, our model is better at every task. This indicates our model can effectively capture the latent similarity.

We investigate the effect of number of dimensions, i.e., the size of the neural network's hidden layer. From Fig.2, we find that CDR can achieve better performance than baselines with various numbers of dimensions. In addition, the optimal results can be obtained when the dimension is set as 100 or 200 in both datasets.

5 Conclusion

In this paper, we propose an approach to solve a significant problem: how to learn distinguishable representations from word sequences in documents and clickstreams of learners. To model the heterogeneous data, we develop a cascade model which can jointly learn the latent semantics and latent similarity without labeling data. We conduct experiments on two real datasets, and the results demonstrate the effectiveness of our model.



(a) People and Network (b) Introduction to MOOC

Figure 2: P@1 of different dimensions.

Moreover, our model is not limited to MOOC data. For instance, we can adopt the proposed algorithm to streaming documents, e.g. webpage click streams, since our method can model the document-document sequences. We leave this as the future work.

Abstract

Websites' and mobile apps' privacy policies, written in natural language, tend to be long and difficult to understand. Information privacy revolves around the fundamental principle of *notice and choice*, namely the idea that users should be able to make informed decisions about what information about them can be collected and how it can be used. Internet users want control over their privacy, but their choices are often hidden in long and convoluted privacy policy documents. Moreover, little (if any) prior work has been done to detect the provision of choices in text. We address this challenge of enabling user choice by automatically identifying and extracting pertinent choice language in privacy policies. In particular, we present a two-stage architecture of classification models to identify opt-out choices in privacy policy text, labelling common varieties of choices with a mean F1 score of 0.735. Our techniques enable the creation of systems to help Internet users to learn about their choices, thereby effectuating notice and choice and improving Internet privacy.

1 Introduction

Website privacy policies are long, verbose documents that are often difficult to understand. It has been shown that an average Internet user would require an impractical amount of time to read the privacy policies of online services that they use and would not properly understand them (McDonald and Cranor, 2008). Although Internet users are concerned about their privacy and would like to be informed about the privacy controls they can exercise, they are not willing or able to find these choices in policy text. Choices for privacy controls, which are the most actionable pieces of information in these documents, are frequently "hidden in plain sight" among other information. However, the nature of the text and the vocabulary used to present choices provide us with an opportunity to automatically identify choices, a goal that we focus upon in this paper.

We define a *choice instance* as a statement in a privacy policy that indicates that the user has discretion over aspects of their privacy. An example (which notably features a hyperlink) is the following:

> If you would like more information on how to opt out of information collection practices, go to `www.aboutads.info`.[1]

Some examples of choices offered to users include opt-outs or controls for the sharing of personal information with third parties, receiving targeted ads, or receiving promotional emails. Analyzing these choice instances in aggregate will help to understand how notice and choice is implemented in practice, which is of interest to legal scholars, policy makers and regulators. Furthermore, extracted choice options can be presented to users in more concise and usable notice formats (Schaub et al., 2015), such as a browser plug-in or a privacy based question answering system.

For this paper, we treat the identification of choice instances as a binary classification problem, in which we label each sentence in the privacy policy text as containing a choice instance or not. We use the OPP-115 Corpus (Wilson et al., 2016) for training and evaluation of our models.

We further annotate a second dataset[2] and develop a composite model architecture to automatically identify and label different types of opt-out choices offered in privacy policies. We primarily focus on extracting opt-out instances with hyperlinks because these are some the most common and useful choices described in privacy policies. Moreover, these choice expressions are actionable: the first step of the action to be taken (i.e., following a hyperlink) is clearly represented in the text of these instances.

The work presented in this paper has been conducted in the context of the 'Usable Privacy Policy' project, which combines crowdsourcing, machine learning and natural language processing to overcome the limitations of today's approach to 'notice and choice' in privacy (Sadeh et al., 2013).

2 Related Work

The Federal Trade Commission identifies "Notice and Choice" as one of the core principles of information privacy protection under the Fair Information Practice Principles (Federal Trade Commission, 2000). However, privacy policies, being long, complicated documents full of legal jargon, are sub-optimal for communicating information to individuals (Cranor, 2012; Cate, 2010; Schaub et al., 2015; Reidenberg et al., 2015). Antón et al. (2002) conducted a study in which they identified multiple privacy-related goals in accordance with Fair Information Practices, which included 'Choice/Consent' as one of the protection goals.

The potential for the application of NLP and information retrieval techniques to legal documents has been recognized by law practitioners (Mahler, 2015), with multiple efforts applying NLP techniques to legal documents. Bach et al. (2013) use a multi-layer sequence learning model and integer linear programming to learn logical structures of paragraphs in legal articles. Galgani et al. (2012) present a hybrid approach to summarization of legal documents, based on creating rules to combine different types of statistical information about text. Early work on automatically extracting annotations from privacy policies includes that of Ammar et al. (2012). Montemagni et al. (2010) investigate the peculiarities of the language in legal text with respect to that in ordinary text by applying shallow parsing. Ramanath et al. (2014) introduce an unsupervised model for the automatic alignment of privacy policies and show that Hidden Markov Models are more effective than clustering and topic models. Liu et al. (2016a) modelled the language of vagueness in privacy policies using deep neural networks.

Many of these efforts consider legal documents as a whole, and they focus less on identifying specific attributes of data practices such as choices. We focus on choices in the present work because of their potential to present Internet users with engaging, directly actionable information.

3 Approach

We used the OPP-115 Corpus to train and evaluate our models for identifying opt-out choices. The corpus consists of 115 website privacy policies and annotations (created by law students) for *data practices* that appear in them. A data practice is a statement about how a website user's personal information is collected, processed or shared. Each data practice consists of a selection of a category (i.e., a theme associated with the practice, such as "First Party Collection/Use"), a set of values for attributes specific to the category, and text spans from the policy associated with the value selections (Wilson et al., 2016). The attributes representing choice instances are present in multiple categories of data practices, namely "First Party Collection/Use," "Third Party Sharing/Collection," "User Access, Edit and Deletion," "Policy Change," and "User Choice/Control." The dataset contains annotations for different types of user choice instances, namely "opt-in," "opt-out," "opt-out link," "opt-out via contacting company," "deactivate account," "delete account (full)," and "delete account (partial)."

3.1 Dataset Refinement

We treated the problem of extracting choice instances as a binary classification problem where we labeled sentences from a privacy policy as containing a choice instance (positive) or not (negative). We focused specifically on opt-out choices, as they are among the most common choices offered to Internet users and because opting out is notoriously difficult for users (Leon et al., 2012). All sentences that contained an opt-out user choice (as specified by the OPP-115 annotations) were considered positive, and the rest were considered negative. This resulted in a gold standard set of

Test set (30%)
Train weak classifiers using train set
Re-label incorrect instances
Add to dataset

Figure 1: Active learning with relabelling.

labeled sentences with 251 positive instances and approximately 12K negative instances.

Differences between our problem formulation and the OPP-115 annotation scheme led to the need for a few label adjustments. Opt-out text spans which crossed sentence boundaries resulted in positive labels for all involved sentences, although often only one of the sentences in a span was positive. Additionally, during the OPP-115 annotation procedure, the fact that hyperlinks were not shown to annotators meant that some choice instances were not correctly identified. This resulted in noisy labels in our derived dataset.

The unbalanced distribution of the opt-out labels allowed us to manually verify and correct labels in the positive class. However, correcting errors in the much larger negative class (of 12K instances) was a challenge, since comprehensive manual verification was infeasible. Instead, we adopted a semi-automated, iterative relabelling approach with active learning. We randomly divided the dataset into train (70%) and test (30%) sets. We trained a binary logistic regression classifier using bag of n-gram features on the training data, and then used it to classify the test data. This was essentially a weak classifier, since it was trained on noisy (unverified) data. We manually examined the false positives and false negatives as given by this model and relabelled incorrectly labelled instances, thus reducing noise in the dataset. Performing multiple iterations of this approach, each time with a different train and test set, resulted in a much cleaner dataset (Figure 1). Following this refinement, the model F1 scores improved and were also more accurate. For all our experiments thereon, we used this refined version of the dataset for training and evaluation.

3.2 Coarse-Grained Classification

We divided the dataset into train and test sets of 85 and 30 privacy policies, respectively. We experimented with a variety of features for *coarse-grained classification*, to separate positive and negative instances:

Stemmed Unigrams and Bigrams. We removed most stop words from the feature set, although some were retained for the modal verb and opt-out features (described below). Bigrams are important to capture pertinent phrases such as "opt out."

Relative Location in the Document. This was a ratio between the number of sentences appearing before the sentence instance and the total number of sentences in the privacy policy.

Topic Model Features. We represented the OPP-115 segment (roughly, a paragraph) containing the sentence instance as a topic distribution vector using latent Dirichlet allocation (Blei et al., 2003) and non-negative matrix factorization (Xu et al., 2003) with 8 and 10 topics, respectively. Previous work on vocabulary intersections of expert annotations and topic models for data practices in privacy policies (Liu et al., 2016b) inspired us to take this approach.

Modal Verbs and Opt-Out specific phrases. We observed vocabulary cues in positive instances that suggested a domain-independent "vocabulary of choice". Many positive instances were imperative sentences and contained modal words such as *may*, *might*, or *can*. We also identified key phrases in the training set such as *unsubscribe* and *opt-out* that were indicative of opt-out choices.

Syntactic Parse Tree Features. We obtained constituency parse trees for sentences using the Stanford Parser (Manning et al., 2014) and extracted production rules and non-terminals as features. We included the maximum depth and average depth of the parse tree as features, as these are indications of specificity.

We used logistic regression classification for the coarse-grained classification stage. Model hyperparameters were tuned based on 5-fold cross validation on the training set. The final parameters for the best performing model had the inverse L2 regularization constant set at C=1.3 and class-weights of 1.5 and 1 for positive and negative class, respectively.

3.3 Fine-Grained Classification

We also developed a *fine-grained* model to differentiate between varieties of opt-out instances. For training data, we annotated a set of 125 positive instances to assign two additional labels to each of them; these were *Party Offering Choice* and *Purpose*. Party Offering Choice could be one of *First*

Party (FI), *Third Party*, (TH), or *Browser* (BR). Purpose could be one of *Advertisement* (AD), *Data Sharing* (DS), *Communications* (CM), *Analytics* (AN) or *Cookies* (CK). Table 1 shows the distribution of these annotations. To predict these labels, we trained eight binary logistic regression classifiers, one for each of the preceding values. If multiple classifiers in a label set returned positive, we selected the prediction with the higher log likelihood. The features we used for these classifiers were:

Stemmed Unigrams and Bigrams. We collected bags of n-grams from the sentence under consideration and its containing segment.

Anchor Text. The anchor text of the hyperlink in the sentence.

Hyperlink URL Tokens. We split the URL by punctuation (such as '/' and '.') and extracted tokens.

Privacy Policy URL Tokens. We also extracted tokens from the policy URL as features.

URL Similarity Measure. We calculated the Jaccard index between the vocabulary of the policy URL and the hyperlink URL. This feature is used to identify whether the hyperlink was to a first-party page or a third-party page.

Figure 2 illustrates the overall architecture of our system. We first use the coarse-grained step to identify the presence of an opt-out instance, and then use the fine-grained step to ascertain key properties of an opt-out choice if one is present.

4 Results and Discussion

This work is one of the first efforts to automatically detect the provision of choices in text. For the coarse-grained task, we consider a simple baseline that labels sentences as positive if they contain one or more opt-out specific words, which come from a vocabulary set that we identified by examining positive instances in the training set. The F1 of the baseline was 0.554.

We performed ablation tests excluding one feature at a time from the coarse-grained classifier. The results of these tests are presented in Table 2 as precision, recall, and F1 scores for the positive class, i.e., the opt-out class. Using the F1 scores as the primary evaluation metric, it appears that all features help in classification. The unigram, topic distribution, nonterminal, and modal verb and opt-out phrase features contribute the most to performance. Including all the features results in an F1 score of 0.735. Ablation test without unigram features resulted in the lowest F1 score of 0.585, and by analyzing features with higher logistic regression weights, we found n-grams such as *unsubscribe* to have intuitively high weights. We also found the production rule "S→SBAR, VP" to have a high weight, indicating that presence of subordinate clauses (SBARs) help in classification.

For an additional practical evaluation, we created a second dataset of sentences from the privacy policies of the 180 most popular websites (as determined by Alexa rankings. We selected only those sentences that contained hyperlinks, since they are associated with particularly actionable choices in privacy policy text. We used our model (as trained on the OPP-115 Corpus) to label the 3,842 sentences in this set, and then manually verified the 124 positive predictions, observing perfect precision. Although we were unable to measure recall using this method, the high precision suggests the robustness of the model and the practical applicability of this approach to tools for Internet users.

The results for the opt-out type classification are shown in Table 3. Because of data sparsity, we show performance figures for only the top two most frequent label combinations. These results

Features/Models	Precision	Recall	F1

also demonstrate a practical level of performance for Internet user-oriented tools.

5 Conclusion

We presented an approach to the problem of automatically identifying privacy choices in privacy policy text. Our experiments show that a two-stage supervised learning procedure is appropriate for this task. Our approach is to initially identify choices offered by the text and then to determine their properties. Using ablation tests, we showed that a mixture of feature types can improve upon the performance of a baseline bag-of-words model. Planned future work for this project will include the creation of a browser plug-in to present opt-out hyperlinks to Internet users.

Abstract

In this paper, we present a novel approach to infer significance of various textual edits to documents. An author may make several edits to a document; each edit varies in its impact to the content of the document. While some edits are surface changes and introduce negligible change, other edits may change the content/tone of the document significantly. In this paper, we perform an analysis of the human perceptions of edit importance while reviewing documents from one version to the next. We identify linguistic features that influence edit importance and model it in a regression based setting. We show that the predicted importance by our approach is highly correlated with the human perceived importance, established by a Mechanical Turk study.

1 Introduction

In collaborative content authoring, multiple authors make changes to the same document, which results in the final version being significantly different from the base draft. Often there is a need to review the edits made to the original document, which can be a long and arduous task. Tools like Microsoft Word (mic) and Adobe Acrobat (ado) provide reviewers with a list of edits, in the form of insertions and deletions. While helpful, these tools do not differentiate between the different types of edits, or consider the varying impact of edits. For instance, change from numeric '18' to word 'eighteen' may be a minor change and less crucial for the author to review, as compared to an edit that alters the facts of the document. Thus, in our work, we focus on automatically inferring the impact/change introduced by edits, and predict the perceived importance of such edits by authors.

In this paper, we perform a linguistic analysis of how humans evaluate the significance of edits while reviewing documents. Our algorithm assigns scores to edits between two versions of a document, which indicate the significance of the specified edit as perceived by the reviewer. We demonstrate the efficacy of our approach by comparing our algorithm generated edit importance scores with the human perceived ground truth importance, established through a Mechanical Turk survey.

2 Related Work

There has been significant amount of work on defining the importance of a keyword or a sentence in the context of document summarization (Mihalcea and Tarau, 2004). Some prior work has also been done on inferring the type of edits between Wikipedia versions. Bronner et al. (Bronner and Monz, 2012) proposed a supervised approach to classify Wikipedia edits as factual or fluency. Daxenberger et al. (Daxenberger and Gurevych, 2013) propose an approach to classify these edits into a 21-category taxonomy. However, none of the the prior work studies the impact or significance of the edit to the content of the document. They do not take the context of the change into account, neither do they study how edits are perceived by reviewers and the significance associated to each edit type. To the best of our knowledge, there is no prior work that evaluates the importance of an edit between document versions as perceived by human reviewers, which is the novel contribution of our work here.

All authors have equal contribution in this paper.

3 Discussion on types of edits

Before trying to automatically infer the importance of individual edits, we first identified the broad categories of textual edits made by authors. Bronner et al. (Bronner and Monz, 2012) broadly classify text edits into two categories, namely, *Factual Edits* and *Fluency Edits*. Factual edits refer to those that modify, add or delete information in the document while fluency edits mainly deal with changes in writing styles or paraphrasing. To obtain finer granularity edit categories, we subclassified factual edits into *Information Modify, Information Delete* and *Information Insert*. To further classify fluency changes, we looked at linguistic literature (Honeck, 1971) and identified subcategories of paraphrase changes. Based on this, fluency edits were further classified into *Lexical Paraphrase* (change of textual elements by synonymous words/phrases/numbers) and *Transformational Paraphrase* (change in the structure of the sentence, e.g. active to passive voice).
For the purpose of this paper, we assume these edit categories to be exhaustive and consequently classify all changes as belonging to one of these.

4 Data and Annotation

Due to the unavailability of an appropriately annotated dataset, we performed an online survey on Amazon Mechanical Turk[1] to capture people's perception of edit importance. To achieve this, we used an available corpus of news articles[2]. We created newer versions for these articles by manually introducing multiple changes to each article. Fig 1 provides statistics for the types of edits (based on the discussion in the previous section) across this entire corpus of 52 article pairs. There are a total of 523 changed sentence pairs in the document corpus, and an average of 1.2 edits per sentence pair.

For annotation of edit importance, we asked Mechanical Turk workers to assign an importance score to each pair of changed sentences. We first provide each turker with the initial (original) version of a news article. After the turker finishes reading the article, he is presented with a list of sentences that were changed between the initial and the final version, along with the changed sentences. The worker classifies each of these sentence pairs as belonging to one of the following importance classes (a) Very Important, (b) Moderately Important, (c) Important, (d) Neutral, (e) Not necessary for review. To avoid introducing biases based on our own notions of edit importance, we provide only a brief description of the task and encourage annotators to follow their own intuitions of importance. Each sentence pair is annotated by 3 annotators and the final importance score is calculated as the mean of the three scores.

5 Solution Description

This section describes the methodology followed to obtain importance scores for text edits to documents. Fig 2 shows the overall workflow of the proposed approach.

The input to the algorithm is a corpus of documents D, which consists of pairs of documents (d, d') corresponding to the initial and final document versions respectively. We use the sentence alignment module proposed by Zhang et al. (Zhang and Litman, 2014) to obtain the mapped pairs of sentences (s, s'), where s represents a sentence in the first version d and s' is its modified variant in d'.

[1] https://www.mturk.com/mturk/

[2] http://literacynet.org/cnnsf/archives.html

5.1 Classification of Edits

The first step of the algorithm is to determine the number and types of the various edits between each sentence pair (s, s'). In this module, we assign an edit type label, as discussed in Section 3, to all edits between a pair of sentences.

Our analysis of the document corpus revealed that most text edits to sentences do not significantly change the structure of the sentence. Thus, a simple heuristic based approach can be used to identify edit types. We use the Stanford Parser to extract the POS tag sequences of the two sentences, with words backed off to their named entities wherever possible. We identify the longest common subsequence between these to obtain a word to word mapping for the sentence pair. If the ratio of the LCS and the mean of the sentence lengths (original and the modified) is above a threshold, we assume that the sentence structure is preserved. A simple word comparison between the similarly tagged words reveals instances of Information-Modify and Lexical changes; additions and deletions are identified as Information-Insert and Information-Delete respectively. In case the structure of the sentence is not preserved, the above heuristic fails, and we tag the sentence pair as Transformational Paraphrase. For such sentence pairs, we employ the method outlined by Bronner et al. (Bronner and Monz, 2012) and train a supervised classifier to differentiate between factual and fluency edits, without bothering about the subtype.

Following the outlined heuristic, we were able to correctly classify 92% of all edits in the document corpus, without using the supervised classifier.

5.2 Feature Extraction

Next, we extract linguistic features for supervised modeling of edit importance. We hypothesized that the importance of edits would be affected by both the nature of the edits, characterized by the aforementioned categories, as well as the relevance of the sentence to the content of the document. Thus, we chose features that capture both these aspects and have divided them into two groups, namely, change-related features and relevance-related features.

5.2.1 Change-related features

These set of features account for the factual differences between sentence pairs caused due to the edits. The complete list of such features is as follows:

- One-hot feature for type of edits identified in the Edit Classification module. We conjectured that different types of changes will have different perceived importance. For example, factual changes may be more important for the author to review compared to paraphrasing changes.
- One-hot feature for the POS tags and Named Entities whose count changes between the initial and the final version of the sentences. We also include one-hot features for those tags whose corresponding word changes between the two versions. These aim to capture the importance associated with deletion, insertion or modification of specific POS tags and Named Entities.
- One-hot features for the following dependency tuples that change between the two versions, with lexical items backed off to POS tags: (gov,typ, dep), (gov, typ), (typ, dep), (gov, dep).
- Count for the number of edits between the two versions.
- Absolute difference in the Flesch Kinkaid readability scores of the two sentences. We hypothesized that human perception of degree of change may be correlated with the change in ease of readability of content.

5.2.2 Relevance-related features

These features aim to score the sentences where the edit occurred. We conjectured that edit importance must also depend on the relevance of the underlying sentence to the content of the document. For instance, in an article about the monarchy in the United Kingdom, an edit that occurs in a sentence discussing the Queen may potentially be more important than one that provides generic facts about the country. The features we consider are :

- **TextRank Score**: We use the TextRank algorithm (Mihalcea and Tarau, 2004) to extract keywords from the document along with the PageRank score attached to them. Each sentence is scored based on the cumulative scores of all keywords that occur in it. Explicitly, the score of a particular sentence is calculated as:

$$Score(s) = \frac{\sum_{w \in W \cap S} KeywordScore(w)}{|S|} \tag{1}$$

where S is the set of words in the sentence and W is the set of keywords extracted by the TextRank algorithm.

- **Position of the sentence in the document**: The importance of sentence position has been studied in (Edmundson, 1969). We expect more important sentences to have a higher edit importance score attached to them.

We train a ridge regression model with the model parameters tuned using cross validation on the training data. We report the Spearman ρ correlation (Spearman, 1904) of the predicted edit importance scores with the human annotated scores on the test data.

6 Experiments and Results

In this section, we discuss the various experiments performed, and the results obtained. **Baselines**: To the best of our knowledge, our work is the first that attempts to infer importance/impact of text edits between document versions. Thus, we did not have established baselines to compare against. Instead we use the following features as baselines:

- **Sentence Order** - Sentences are ordered according to their position in the document, with the first sentence assigned most importance. This is also the order in which a reviewer would normally view edits.

- **Readability Score** - Sentence edit importance scores are calculated as being proportional to the change in their readability scores.

- **Text Rank** - We expect sentences with higher TextRank score to have higher edit importance attached to them.

Table 1 outlines the Spearman ρ correlation of our model and the above baselines with human judgments. We are able to achieve significant improvement over the baselines using the full set of features. An interesting observation was that sentence position correlates poorly with the human annotated importance scores. This indicates that the order/position of sentences has negligible effect on the perceived significance. Both readability score and TextRank have reasonable influence on edit importance, though neither of them is able to match the performance of the full set of features.

Approach	Spearman ρ
Sentence Position	0.067
Readability Score	0.306
Text Rank	0.208
Proposed Approach	0.979

Table 1: Spearman ρ of the predicted importance score with the human annotated importance scores.

Feature	Spearman ρ
Type of Change	0.47907
Readability Score	0.311989
Change in POS tags	0.978821
Change in NE	0.189176
Change in Dependency Tuples	0.96417
Sentence Position	0.06846
Text Rank	0.209058

Table 2: Performance of each feature group in isolation. Numbers reflect the performance (Spearman ρ) of the model when using only the specified feature group, relative to the performance when using all features.

Contribution of feature groups

In order to gain better insight into individual feature performance, we look more closely at the performance of each feature group in isolation. Table 2 shows the performance of the model when using only a specific feature group, relative to the performance when using all features. This provides us with a number of interesting insights. First, it is evident that change-related features contribute more to edit importance than relevance-related features.

According to our results, humans perceive change in number and types of POS tags to be the most significant indicator of edit importance. For further insight, we looked at the coefficient values of individual POS tags in the ridge regression model trained using only POS tags as features. Our investigations revealed that change in proper nouns, nouns, present participle verbs and modal are most highly correlated with edit importance. Contrary to our expectation, modification of named entities does not significantly influence edit importance. This may be due to the fact that named entity changes occur in only a small subset of sentences, and hence cannot be good predictors of edit importance when used as a feature by themselves.

7 Conclusion and Future Work

In this paper we present a novel approach to infer the importance of text edit between two document versions. We present an empirical analysis of the relevance of various linguistic features for the task of scoring edit importance and model it using a regression model. AMT is used to collect human annotated data for edit importance, and a comparison against those establish the superiority of our proposed approach over several baselines.

Abstract

We model the problem of disfluency detection using a transition-based framework, which incrementally constructs and labels the disfluency chunk of input sentences using a set of transition actions without syntax information. Compared with sequence labeling methods, it can capture non-local chunk-level features; compared with joint parsing and disfluency detection methods, it is free for noise in syntax. Experiments show that our model achieves state-of-the-art F-score on both the commonly used English Switchboard test set and a set of in-house annotated Chinese data.

1 Introduction

Disfluency detection is the task of recognizing non-fluent word sequences in spoken language transcripts (Zayats et al., 2016; Wang et al., 2016; Wu et al., 2015). As shown in Figure 1, standard annotation of disfluency structure (Shriberg, 1994) indicates the reparandum (words that are discarded, or corrected by the following words), the interruption point (+) marking the end of the reparandum, the associated repair, and an optional interregnum after the interruption point (filled pauses, discourse cue words, etc.).

Ignoring the interregnum, disfluencies can be categorized into three types: restarts, repetitions, and corrections, based on whether the repair is empty, the same as the reparandum or different, respectively. Table 1 gives a few examples. Interregnums are easy to detect as they often consist of fixed phrases (e.g. “uh”, “you know”). However, reparandums are more difficult to detect, because they can be in arbitrary form. Most previous disfluency detection work focuses on detecting reparandums.

$$\text{I want a flight [}\underbrace{\textit{to Boston}}_{\text{RM}} + \underbrace{\{\textit{um}\}}_{\text{IM}}\ \underbrace{\text{to Denver}}_{\text{RP}}\text{]}$$

Figure 1: Sentence with disfluencies annotated in English Switchboard corpus. RM=Reparandum, IM=Interregnum, RP=Repair. The preceding RM is corrected by the following RP.

Type	**Annotation**
repair	[I just + I] enjoy working
repair	[we want + {well} in our area we want] to
repetition	[it’s + {uh} it’s] almost like
restart	[we would like +] let’s go to the

Table 1: Different types of disfluencies.

The main challenges of detecting reparandums include that they vary in length, may occur in different locations, and are sometimes nested. For example, the longest reparandum in our training set has fifteen words. Hence, it is very important to capture long-range dependencies for disfluency detection. Since there is large parallelism between the reparandum chunk and the following repair chunk (for example, in Figure 1, the reparandum begins with *to* and ends before another occurrence of *to*), it is also useful to exploit chunk-level representation, which explicitly makes use of resulted infelicity disfluency chunks.

Common approaches take disfluency detection as a sequence labeling problem, where each sentential word is assigned with a label (Zayats et al., 2016; Hough and Schlangen, 2015; Qian and Liu, 2013; Georgila, 2009). These methods achieve good performance, but are not powerful enough to capture complicated disfluencies with longer spans or distances. Another drawback of these approaches is that they are unable to exploit chunk-

[*] Email corresponding.

Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

level features. Semi-CRF (Ferguson et al., 2015) is used to alleviate this issue to some extent. Semi-CRF models still have their inefficiencies because they can only use the local chunk information limited by the markov assumption when decoding.

A different line of work (Rasooli and Tetreault, 2013; Honnibal and Johnson, 2014; Wu et al., 2015) adopts transition-based parsing models for disfluency detection. This line of work can be seen as a joint of disfluency detection and parsing. The main advantage of the joint models is that they can capture long-range dependency of disfluencies as well as chunk-level information. However, they introduce additional annotated syntactic structure, which is very expensive to produce, and can cause noise by significantly enlarging the output search space.

Inspired by the above observations, we investigate a transition-based model without syntactic information. Our model incrementally constructs and labels the disfluency chunks of input sentences using an algorithm similar to transition-based depency parsing. As shown in Figure 2, the model state consists of four components: (i) O, a conventional sequential LSTM (Hochreiter and Schmidhuber, 1997) to store the words that have been labeled as fluency. (ii) S, a stack LSTM to represent partial disfluency chunks, which captures chunk-level information. (iii) A, a conventional sequential LSTM to represent history of actions. (iiii) B, a Bi-LSTM to represent words that have not yet been processed. A sequence of transition actions are used to consume input tokens and construct the output from left to right. To reduce error propagation, we use beam-search (Collins and Roark, 2004) and scheduled sampling (Bengio et al., 2015), respectively.

We evaluate our model on the commonly used English Switchboard test set and a in-house annotated Chinese data set. Results show that our model outperforms previous state-of-the-art systems. The code is released[1].

2 Background

For a background, we briefly introduce transition-based parsing and its extention for joint disfluency detection. An arc-eager transition-based parsing system consists of a stack σ containing words being processed, a buffer β containing words to be processed and a memory A storing dependency

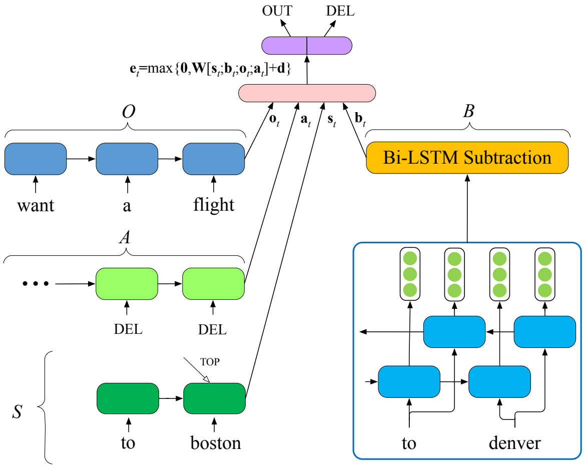

Figure 2: model state when processing the sentence “want a flight to boston to denver”.

arcs which have been generated. There are four types of transition actions (Nivre, 2008)

- *Shift* : Remove the front of the buffer and push it to the stack.
- *Reduce* : Pop the top of the stack.
- *LeftArc* : Pop the top of the stack, and link the popped word to the front of the buffer.
- *RightArc* : Link the front of the buffer to the top of the stack, remove the front of the buffer and push it to the stack.

Many neural network parsers have been constructed under this framework, such as (Dyer et al., 2015), who use different LSTM structure to represent information from σ to β.

For disfluency detection, the input is a sentence with disfluencies from automatic speech recognition (ASR). We denote the word sequence as $w_1^n = (w_1, ..., w_n)$. The output of the task is a sequence of binary tags denoted as $D_1^n = (d_1, ..., d_n)$, where each d_i corresponds to the word w_i, indicating whether w_i is a disfluent word or not. Hence the task can be modeled as searching for the best sequenc D^* given the stream of words w_1^n

$$D^* = argmax_D P(D_1^n | w_1^n)$$

Wu et al. (2015) proposes a statistical transition-based disfluency detection model, which performs disfluency detection and parsing jointly by augmenting the Shift-Reduce algorithm with a binary classifier transition (BCT) action:

[1] https://github.com/hitwsl/transition_disfluency

- *BCT* : Classify whether the current word is disfluent or not. If it is, remove it from the buffer, push it into the stack which is similar to *Shift* and then mark it as disfluent. Otherwise the original parser transition actions will be used.

Disfluency detection and parsing are jointly optimized

$$(D^*, T^*) = argmax_{D,T} \prod_{i=1}^{n} P(d_i|w_1^i, T_1^{i-1}) \\ \times P(T_1^i|w_1^i, T_1^{i-1}, d_i),$$

where T_1^i is the partial tree after word w_i is consumed, d_i is the disfluency tag of w_i. $P(T_1^i|.)$ is the parsing model and $P(d_1^i|.)$ is the disfluency model used to predict the disluency tags on the contexts of partial trees that have been built.

3 Our Transition-Based Model

The BCT model serves as a state-of-the-art transition-based baseline. However, it requires that the training data contains both syntax trees and disfluency annotations, which reduces the practicality of the algorithm. Also, BCT does not explicitly make use of resulting infelicity disfluency chunks. Being a discrete model, the performance relies heavily on manual feature engineering.

To address the constraints above, we apply a transition-based neural model for disfluency detection that does not use any syntax information. Our transition-based method incrementally constructs and labels the disfluency chunk of input sentences by performing a sequence of actions. The task is modeled as

$$(D^*, T^*) = argmax_{D,T} \prod_{i=1}^{n} P(d_i, T_1^i|w_1^i, T_1^{i-1}),$$

where T_1^i is the partial model state after word w_i is consumed. d_i is the disfluency tag of w_i.

3.1 Transition-Based Disfluency Detection

Our model incrementally constructs and labels the disfluency chunks of input sentences, where a state is represented by a tuple (O, S, A, B):

- *output* (O) : the *output* is used to represent the words that have been labeled as fluent.
- *stack* (S) : *stack* is used to represent the partially constructed disfluency chunk.
- *action* (A) : *action* is used to represent the complete history of actions taken by the transition system.
- *buffer* (B) : *buffer* is used to represent the sentences that have not yet been processed.

Given an input disfluent sentence, the *stack*, *output* and *action* are initially empty and the *buffer* contains all words of the sentence, a sequence of transition actions are used to consume words in the *buffer* and build the output sentence:

- OUT: which moves the first word in the *buffer* to the *output* and clears out the *stack* if it is not empty.
- DEL: which moves the first word in the *buffer* to the *stack*.

Search Algorithm

Based on the transition system, the decoder searches for an optimal action sequence for a given sentence. The system is initialized by pushing all the input words and their representations (of § 3.3) onto B in the reverse order, such that the first word is at the top of B, and S, O and A each contains an empty-stack token.

At each step, the system computes a composite representation of the model states (as determined by the current configurations of B, S, O, and A), which is used to predict an action to take. Decoding completes when B is empty (except for the empty-stack symbol), regardless of the state of S. Since each token in B is either moved directly to O or S every step, the total number of actions equals to the length of input sentence. Table 2 shows the sequence of operations required to process the sentence "want a flight to boston to denver".

As shown in Figure 2, the model state representation at time t, which is written as e_t, is defined as:

$$e_t = max\{0, W[s_t; b_t; o_t; a_t] + d\},$$

where W is a learned parameter matrix, s_t is the representation of S, b_t is the representation of B, o_t is the representation of O, a_t is the representation of A, d is a bias term. $(W[s_t; b_t; o_t; a_t] + d)$ is passed through a component-wise rectified linear unit (ReLU) for nonlinearity (Glorot et al., 2011).

Step	Action	Output	Stack	Buffer
0		[]	[]	[a, flight, to, boston, to, denver]
1	OUT	[a]	[]	[flight, to, boston, to, denver]
2	OUT	[a, flight]	[]	[to, boston, to, denver]
3	DEL	[a, flight]	[to]	[boston, to, denver]
4	DEL	[a, flight]	[to, boston]	[to, denver]
5	OUT	[a, flight, to]	[]	[denver]
6	OUT	[a, flight, to, denver]	[]	[]

Table 2: Segmentation process of *a flight to boston to denver*

Finally, the model state e_t is used to compute the probability of the action at time t as:

$$p(z_t|e_t) = \frac{exp(g_{z_t}^{\mathrm{T}} e_t + q_{z_t})}{\sum_{z' \in \mathcal{A}(S,B)} exp(g_{z'}^{\mathrm{T}} e_t + q_{z'})},$$

where g_z is a column vector representing the embedding of the transition action z, and q_z is a bias term for action z. The set $\mathcal{A}(S, B)$ represents the valid actions that may be taken given the current state. Since $e_t = f(s_t, b_t, a_t, o_t)$ encodes information about all previous decisions made by the transition system, the probability of any valid sequence of transition actions z conditioned on the input can be written as:

$$p(z|w) = \prod_{t=1}^{|z|} p(z_t|e_t)$$

We then have

$$\begin{aligned}(D^*, T^*) &= argmax_{D,T} \prod_{i=1}^{|z|} P(d_i, T_1^i | w_1^i, T_1^{i-1}) \\ &= argmax_{D,T} \prod_{t=1}^{|z|} p(z_t|e_t),\end{aligned}$$

where the disfluency detection task is merged into the transition-based system.

Beam Search

The mainly drawback of greedy search is error propagation. An incorrect action will have a negative influence to its subsequent actions, leading to an incorrect output sequence. One way to reduce error propagation is beam-search. Because the number of actions taken always equals to the number of input sentence for every valid path, it is straightforward to use beam search. We use beam-search for both training and testing. The early update strategy from Collins and Roark (2004) is applied for training. In particular, each training sequence is decoded, and we keep track of the location of the gold path in the beam. If the gold path falls out of the beam at step t, decoding process is stopped and parameter update is performed using the gold path as a positive example, and beam items as negative examples. We also use the global optimization method (Andor et al., 2016; Zhou et al., 2015) to train our beam-search model.

Scheduled Sampling

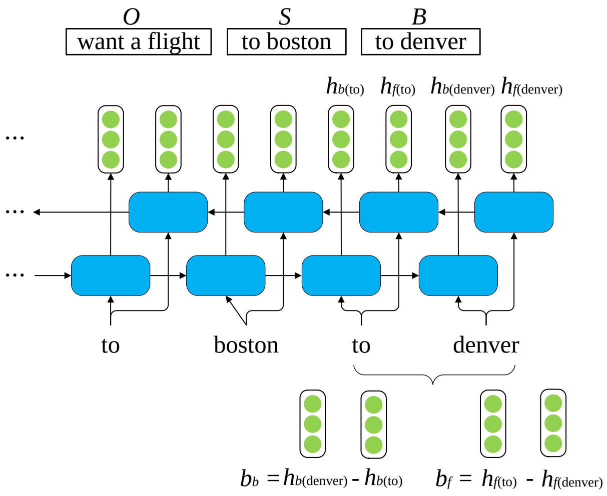
Scheduled sampling (Bengio et al., 2015) can also be used to reduce error propagation. The training goal of the greedy baseline is to maximize the likelihood of each action given the current model state, which means that the correct action is taken at each step. Doing inference, the action predicted by the model itself is taken instead. This discrepancy between training and inference can yield errors that accumulate quickly along the searching process. Scheduled sampling is used to solve the discrepancy by gently changing the training process from a fully guided scheme using the true previous action, towards a less guided scheme which mostly uses the predicting action instead. We take the action gaining higher $p(z_t|e_t)$ with a certain probability p, and a probability $(1-p)$ for the correct action when training.

3.2 State Representation

For better capturing non-local context information, we use LSTM structures to represent different components of each state, including *buffer*, *action*, *stack*, and *output*. In particular, we exploit LSTM-Minus (Wang and Chang, 2016) to model the *buffer* segment, conventional LSTM to model the *action* and *ouptut* segment, and stack LSTM (Dyer et al., 2015) to model the *stack* segments, which demonstrates highly effectively in parsing task.

Buffer Representation

In order to construct more informative representation, we use a Bi-LSTM to represent the *buffer* following the work of Wang and Chang (2016), where the subtraction between a unidirectional



O
want a flight
S
to boston
B
to denver
$h_{b(\text{to})}$ $h_{f(\text{to})}$ $h_{b(\text{denver})}$ $h_{f(\text{denver})}$
...
...
...
to
boston
to
denver
$b_b = h_{b(\text{denver})} - h_{b(\text{to})}$
$b_f = h_{f(\text{to})} - h_{f(\text{denver})}$

Figure 3: Illustration for learning *buffer* representation based on a Bi-LSTM, $h_f(*)$ and $h_b(*)$ indicate the hidden vectors of forward and backward LSTM respectively.

LSTM hidden vectors is utilized to represent a segment's information. We perform a similar method in a Bi-LSTM to obtain the representation of the *buffer*. The forward and backward subtractions for the *buffer* can be described as $b_f = h_f(l) - h_f(f)$ and $b_b = h_b(f) - h_b(l)$, respectively, where $h_f(f)$ and $h_f(l)$ are the hidden vectors of the first and the last words in the forward LSTM, respectively. Similarly, $h_b(f)$ and $h_b(l)$ are the hidden vectors of the first and the last words in the backward LSTM, respectively. Then these subtractions are concatenated as the representation of the *buffer* $b_t = b_f \oplus b_b$. As illustrated in Figure 3, the forward and backward subtractions for *buffer* are $b_f = h_f(to) - h_f(denver)$ and $b_b = h_b(denver) - h_b(to)$, respectively. Here *to* is the first word in *buffer* and *denver* is the last. Then b_f and b_b are concatenated as the representation of *buffer*.

Action Representation

We represent an action a with an embedding $e_a(a)$ from a looking-up table E_a , and apply a conventional LSTM to represent the complete history of actions taken by the transition system. Once an action a is taken, the embedding $e_a(a)$ will be added to the right-most position of the LSTM.

Stack Representation

We use a stack LSTM (Dyer et al., 2015) to represent partial disfluency chunk. The stack LSTM tries to augment the conventional LSTM with a "stack pointer". For a conventional LSTM, new inputs are always added in the right-most position; but in a stack LSTM, the current location of the stack pointer determines which cell in the LSTM provides c_{t-1} and h_{t-1} when computing the new memory cell contents. In addition to adding elements to the end of the sequence, the stack LSTM provides a *pop* operation which moves the stack pointer to the previous element. Thus, the LSTM can be understood as a stack implemented so that contents are never overwritten, When the action OUT is taken, the *stack* is cleared by moving the stack pointer to the initial position. When the action DEL is taken, the representation of the *buffer* will be added directly to the stack LSTM.

Output Representation

We use a conventional LSTM to represent the *output*. When the action OUT is taken, the representation of the *buffer* will be added directly to the right-most position of the LSTM. Because the words in the *output* are a continuous subsequence of the final output sentence with disfluencies removed, the LSTM representation can be seen as a pseudo language model and thus has the ability to keep the generated sentence grammatical, which is very important for disfluency detection.

3.3 Token Embeddings

We use four vectors to represent each input token: a learned word embedding w; a fixed word embedding $\widetilde{w}$; a learned POS-tag embedding p; and a hand-crafted feature representation d. The four vectors are concatenated, transformed by a matrix V and fed to a rectified layer to learn a feature combination:

$$x = max\{0, V[\widetilde{w}; w; p; d] + b\},$$

where V means vector concatenation.

Following the work of Wang et al. (2016), we extract two types of hand-crafted discrete features (as shown in Table 3) for each token in a sentence, and incorporate them into our neural networks by translating them into a 0-1 vector d. The dimension of d is 78, which equals to the number of discrete features. For a token x_t, d_i fires if x_t matches the i-th pattern of the feature templates. The duplicate features indicate whether x_t has a *duplicated* word/POS-tag in certain distance. The *similarity* features indicate whether the surface string of x_t resembles its surrounding words.

duplicate features
$Duplicate(i, w_{i+k}), -15 \leq k \leq +15$ and $k \neq 0$: if w_i equals w_{i+k}, the value is 1, others 0
$Duplicate(p_i, p_{i+k}), -15 \leq k \leq +15$ and $k \neq 0$: if p_i equals p_{i+k}, the value is 1, others 0
$Duplicate(w_i w_{i+1}, w_{i+k} w_{i+k+1}), -4 \leq k \leq +4$ and $k \neq 0$: if $w_i w_{i+1}$ equals $w_{i+k} w_{i+k+1}$, the value is 1, others 0
$Duplicate(p_i p_{i+1}, p_{i+k} p_{i+k+1}), -4 \leq k \leq +4$ and $k \neq 0$: if $p_i p_{i+1}$ equals $p_{i+k} p_{i+k+1}$, the value is 1, others 0
similarity features
$fuzzyMatch(w_i, w_{i+k}), k \in \{-1, +1\}$: $similarity = 2 * num\_same\_letters/(len(w_i) + len(w_{i+k}))$. if $similarity > 0.8$, the value is 1, others 0

Table 3: Discrete features used in our transition-based neural networks. p-POS tag. w-word.

4 Experiments

4.1 Settings

Dataset. Our training data include the Switchboard portion of the English Penn Treebank (Marcus et al., 1993) and a in-house Chinese data set. For English, two annotation layers are provided: one for syntactic bracketing (MRG files), and the other for disfluencies (DPS files). The Switchboard annotation project was not fully completed. Because disfluency annotation is cheaper to produce, many of the DPS training files do not have matching MRG files. Only 619,236 of the 1,482,845 tokens in the DPS disfluency detection training data have gold-standard syntactic parses. To directly compare with transition-based parsing methods (Honnibal and Johnson, 2014; Wu et al., 2015), we also use the subcorpus of PARSED/MRG/SWBD. Following the experiment settings in Charniak and Johnson (2001), the training subcorpus contains directories 2 and 3 in PARSED/MRG/SWBD and directory 4 is split into test, development sets and others. Following Honnibal and Johnson (2014), we lower-case the text and remove all punctuations and partial words[2]. We also discard the ‘um’ and ‘uh’ tokens and merge ‘you know’ and ‘i mean’ into single tokens. Automatic POS-tags generated from pocket_crf (Qian and Liu, 2013) are used as POS-tag in our experiments.

For Chinese experiments, we collect 25k spoken sentences from meeting minutes, which are transcribed using the iflyrec toolkit[3], and annotate them with only disfluency annotations according to the guideline proposed by Meteer et al. (1995).

4.2 Neural Network Training

Pretrained Word Embeddings. Following Dyer et al. (2015) and Wang et al. (2016), we use a variant of the skip n-gram model introduced by Ling et al. (2015), named “structured skip n-gram”, to create word embeddings. The AFP portion of English Gigaword corpus (version 5) is used as the training corpus. Word embeddings for Chinese are trained on Chinese baike corpus. We use an embedding dimension of 100 for English, 300 for chinese.

Hyper-Parameters. Both the Bi-LSTMs and the stack LSTMs have two hidden layers and their dimensions are set to 100. Pretrained word embeddings have 100 dimensions and the learned word embeddings have also 100 dimensions. Pos-tag embeddings have 12 dimensions. The dimension of action embeddings is set to 20.

4.3 Performance On English Swtichboard

We build two baseline systems using CRF and Bi-LSTM, respectively. The hand-crafted discrete features of CRF refer to those in Ferguson et al. (2015). For the Bi-LSTM model, the token embedding is the same with our transition-based method. Table 4 shows the result of our model on both the development and test sets. Beam search improves the F-score form 87.1% to 87.5%, which is consistent with the finding of Buckman et al. (2016) on the LSTM parser of (Dyer et al., 2015) (improvements by about 0.3 point). Scheduled sampling achieves the same improvements compared to beam-search. Because of high training speed, we conduct subsequent experiments based on scheduled sampling.

We compare our transition-based neural model to five top performing systems. Our model outperforms the state-of-the-art, achieving a 87.5% F-

[2] words are recognized as partial words if they are tagged as ‘XX’ or end with ‘-’

Attention-based (Wang et al., 2016)	91.6	82.3	86.7
Bi-LSTM (Zayats et al., 2016)	91.8	80.6	85.9
semi-CRF (Ferguson et al., 2015)	90.0	81.2	85.4
UBT (Wu et al., 2015)	90.3	80.5	85.1
M^3N (Qian and Liu, 2013)	-	-	84.1

Table 5: Comparison with previous state-of-the-art methods on the test set of English Switchboard.

score as shown in Table 5. It achieves 2.4 point improvements over UBT (Wu et al., 2015), which is the best syntax-based method for disfluency detection. The best performance by linear statistical sequence labeling methods is the semi-CRF method of Ferguson et al. (2015), achieving a 85.4% F-score leveraging prosodic features. Our model obtains a 2.1 point improvement compared to this. Our model also achieves 0.8 point improvement over the neural attention-based model (Wang et al., 2016), which regards the disfluency detection as a sequence-to-sequence problem. We attribute the success to the strong ability to learn global chunk-level features and the good state representation such as the stack-LSTM.

4.4 Result On DPS Corpus

As described in section 3.1, to directly compare with the transition-based parsing methods (Honnibal and Johnson, 2014; Wu et al., 2015), we only use MRG files, which are less than the DPS files. In fact, many methods, such as Qian and Liu (2013), have used all the DPS files as training data. We are curious about the performance of our system using all the DPS files. Following the experimental settings of Johnson and Charniak (2004), the corpus is split as follows: main training consisting of all sw[23]*.dps files, development training consisting of all sw4[5-9]*.dps files and test training consisting of all sw4[0-1]*.mrg files. Table 6 shows the result on the DPS files. The result of M^3N^* comes from our experiments with the toolkit[4] released by Qian and Liu (2013), which use the same data set and pre-processing. Our model achieves a 88.1% F-score by using more training data, obtaining 0.6 point improvement compared with the system training on MRG files. The performance is far better than the sequence labeling methods that use DPS files for training.

Method	**P**	**R**	**F1**
Our	93.1	83.5	**88.1**
Bi-LSTM	92.4	82.0	86.9

Bi-LSTM	60.1	41.3	48.9	65.3	38.2	48.2
CRF	73.7	33.5	46.1	77.7	32.0	45.3

Table 7: performance on Chinese annotated data

4.5 Performance on Chinese

Table 7 shows the results of Chinese disfluency detection. Our model obtains a 2.4 point improvement compared with the baseline Bi-LSTM model and a 5.3 point compared with the baseline CRF model. The performance on Chinese is much lower than that on English. Apart from the smaller training set, the main reason is that the proportion of repair type disflueny is much higher.

5 Analysis

5.1 Ablation Tests

As described in section 3.1, the sate representation has four components. We explicitly compare the impact of different parts. As shown in Table 8, the F-score decreases most heavily without *stack*, which indicates that it is very necessary to capture chunk-level information for disfluency detection and our model can model it effectively. The results also show that *output*, which can be seen as a pseudo language model, has important influence on model performance. Seen from the result, history of actions represented in *action* is also useful for predicting at each step. The F-score decreases

[4] The toolkit is available at https://code.google.com/p/disfluency-detection/downloads.

Method	P	R	F1
ALL	91.1	84.1	**87.5**
- *stack*	93.5	80.6	86.5
- *action*	91.6	83.0	87.1
- *output*	89.0	84.4	86.7
- Bi-LSTM	93.6	81.4	87.1

Table 8: Results of feature ablation experiments on English Switchboard test data. "- Bi-LSTM" means using unidirectional LSTM for *buffer*

about 0.4 point, which shows that Bi-LSTM can capture more information compared to simple unidirectional LSTM.

5.2 Repetitions vs Non-repetitions

Repetition disfluencies are easier to detect and even some simple hand-crafted features can handle them well. Other types of reparandums such as repair are more complex (Zayats et al., 2016; Ostendorf and Hahn, 2013). In order to better understand model performances, we evaluate our model's ability to detect repetition vs. non-repetition (other) reparandum. The results are shown in Table 9. All the three models achieve high score on repetition reparandum. Our transition-based model is much better in predicting non-repetitions compared to CRF and Bi-LSTM. We conjecture that our transition-based structure can capture more of the reparandum/repair "rough copy" similarities by learning represention of both chunks and global state.

6 Related Work

Common approaches take disfluency detection as a sequence labeling problem, where each sentential word is assigned with a label (Georgila, 2009; Qian and Liu, 2013). These methods achieve good performance, but are not powerful enough to capture complicated disfluencies with longer spans or distances. Another drawback is that they have no ability to exploit chunk-level features. There are also works that try to use recurrent neural network (RNN), which can capture dependencies at any length in theory, on disfluency detection problem (Zayats et al., 2016; Hough and Schlangen, 2015). The RNN method treats sequence tagging as classification on each input token. Hence, it also has no power to exploit chunk-level features. Some works (Wang et al., 2016) regard the disfluency detection as a sequence-to-sequence problem and propose a neural attention-based model for it. The attention-based model can capture a global representation of the input sentence by using a RNN when encoding. It can strongly capture long-range dependencies and achieves good performance, but are also not powerful enough to capture chunk-level information. To capture chunk-level information, Ferguson et al. (2015) try to use semi-CRF for disfluency detection, and reports improved results. Semi-CRF models still have their inefficiencies because they can only use the local chunk information limited by the markov assumption when decoding.

Method	Repetitions	Non-repetitions	Either
CRF	93.8	61.4	82.6
Bi-LSTM	93.1	65.3	85.8
OUR	93.3	68.7	**87.5**

Table 9: F-score of different types of reparandums on English Switchboard test data.

Many syntax-based approaches (Lease and Johnson, 2006; Rasooli and Tetreault, 2013; Honnibal and Johnson, 2014; Wu et al., 2015) have been proposed which jointly perform dependency parsing and disfluency detection. The main advantage of joint models is that they can capture long-range dependency of disfluencies. However, it requires that the training data contains both syntax trees and disfluency annotations, which reduces the practicality of the algorithm. The performance relies heavily on manual feature engineering.

Transition-based framework has been widely exploited in a number of other NLP tasks, including syntactic parsing (Zhang and Nivre, 2011; Zhu et al., 2013), information extraction (Li and Ji, 2014) and joint syntactic models (Zhang et al., 2013, 2014).

Recently, deep learning methods have been widely used in many nature language processing tasks, such as name entity recognition (Lample et al., 2016), zero pronoun resolution (Yin et al., 2017) and word segmentation (Zhang et al., 2016). The effectiveness of neural features has also been studied for this framework (Zhou et al., 2015; Watanabe and Sumita, 2015; Andor et al., 2016). We apply the transition-based neural framework to disfluency detection, which to our knowledge has not been investigated before.

7 Conclusion

We introduced a transition-based model for disfluency detection, which does not use any syntax information, learning represention of both chunks and global contexts. Experiments showed that our model achieves the state-of-the-art F-scores on both the commonly used English Switchboard test set and a in-house annotated Chinese data set.

Abstract

We propose an approach to N-best list re-ranking using neural sequence-labelling models. We train a compositional model for error *detection* that calculates the probability of each token in a sentence being correct or incorrect, utilising the full sentence as context. Using the error detection model, we then re-rank the N best hypotheses generated by statistical machine translation systems. Our approach achieves state-of-the-art results on error correction for three different datasets, and it has the additional advantage of only using a small set of easily computed features that require no linguistic input.

1 Introduction

Grammatical Error Correction (GEC) in non-native text attempts to automatically detect and correct errors that are typical of those found in learner writing. High precision and good coverage of learner errors is important in the development of GEC systems. Phrase-based Statistical Machine Translation (SMT) approaches to GEC have attracted considerable attention in recent years as they have been shown to achieve state-of-the-art results (Felice et al., 2014; Junczys-Dowmunt and Grundkiewicz, 2016). Given an ungrammatical input sentence, the task is formulated as "translating" it to its grammatical counterpart. Using a parallel dataset of input sentences and their corrected counterparts, SMT systems are typically trained to correct all error types in text without requiring any further linguistic input. To further adapt SMT approaches to the task of GEC and tackle the paucity of error-annotated learner data, previous work has investigated a number of extensions, ranging from the addition of further features into the decoding process (Felice et al., 2014) via re-ranking the SMT decoder's output (Yuan et al., 2016) to neural-network adaptation components to SMT (Chollampatt et al., 2016a).

In this paper, we propose an approach to N-best list re-ranking using neural sequence-labelling models. N-best list re-ranking allows for fast experimentation since the decoding process remains unchanged and only needs to be performed once. Crucially, it can be applied to any GEC system that can produce multiple alternative hypotheses. More specifically, we train a neural compositional model for error *detection* that calculates the probability of each token in a sentence being correct or incorrect, utilising the full sentence as context. Using the error detection model, we then re-rank the N best hypotheses generated by the SMT system. Detection models can be more fine-tuned to finer nuances of grammaticality and acceptability, and therefore better able to distinguish between correct and incorrect versions of a sentence.

Our approach achieves state-of-the-art results on GEC for three different datasets, and it has the additional advantage of using only a small set of easily computed features that require no linguistic information, in contrast to previous work that has utilised a large set of features in a supervised setting (Hoang et al., 2016; Yuan et al., 2016).

2 Previous work

The first approaches to GEC primarily treat the task as a classification problem over vectors of contextual lexical and syntactic features extracted from a fixed window around the target token. A large body of work has investigated error-type-specific models, and in particular models targeting preposition and article errors, which are among the most frequent ones in non-native English learner writing (Chodorow et al., 2007; De Felice and Pul-

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2795–2806
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

man, 2008; Han et al., 2010; Tetreault et al., 2010; Han et al., 2006; Tetreault and Chodorow, 2008; Gamon et al., 2008; Gamon, 2010; Rozovskaya and Roth, 2010; Rozovskaya et al., 2012; Dale and Kilgarriff, 2011; Leacock et al., 2014). Core components of one of the top systems in the CoNLL 2013 and 2014 shared tasks on GEC (Ng et al., 2013, 2014) include Averaged Perceptron classifiers, native-language error correction priors in Naive Bayes models, and joint inference frameworks capturing interactions between errors (e.g., noun number and verb agreement errors) (Rozovskaya et al., 2012, 2014, 2011; Rozovskaya and Roth, 2011). The power of the classification paradigm comes from its ability to generalise well to unseen examples, without necessarily requiring error-annotated learner data (Rozovskaya and Roth, 2016).

One of the first approaches to GEC as an SMT task is the one by Brockett et al. (2006), who generate artificial data based on hand-crafted rules to train a model that can correct countability errors. Dahlmeier and Ng (2011) focus on correcting collocation errors based on paraphrases extracted from parallel corpora, while Dahlmeier and Ng (2012a) are the first to investigate a discriminatively trained beam-search decoder for full-sentence correction, focusing on five different error types: spelling, articles, prepositions, punctuation insertion, and noun number. Yoshimoto et al. (2013) utilise SMT to tackle determiner and preposition errors, while Yuan and Felice (2013) use POS-factored, phrase-based SMT systems, trained on both learner and artificially generated data to tackle determiner, preposition, noun number, verb form, and subject–verb agreement errors. The SMT approach has better capacity to correct complex errors, and it only requires parallel corrected sentences as input.

Two state-of-the-art systems in the 2014 CoNLL shared task on correction of all errors regardless of type use SMT systems: Felice et al. (2014) use a hybrid approach that includes a rule-based and an SMT system augmented by a large web-based language model and combined with correction-type estimation to filter out error types with zero precision. Junczys-Dowmunt and Grundkiewicz (2016) investigate parameter tuning based on the MaxMatch (M^2) scorer, the shared-task evaluation metric (Dahlmeier and Ng, 2012b; Ng et al., 2014), and experiment with different optimisers and interactions of dense and sparse features.

Susanto et al. (2014) and Rozovskaya and Roth (2016) explore combinations of SMT systems and classifiers, the latter showing substantial improvements over the CoNLL state of the art. Chollampatt et al. (2016a) integrate a neural network joint model that has been adapted using native-language-specific learner text as a feature in SMT, while Chollampatt et al. (2016b) integrate a neural network global lexicon model and a neural network joint model to exploit continuous space representations of words rather than discrete ones, and learn non-linear mappings. Yuan and Briscoe (2016) present a Neural Machine Translation (NMT) model and propose an approach that tackles the rare-word problem in NMT.

Yuan et al. (2016) and Mizumoto and Matsumoto (2016) employ supervised discriminative methods to re-rank the SMT decoder's N-best list output based on language model and syntactic features respectively. Hoang et al. (2016) also exploit syntactic features in a supervised framework, but further extend their approach to generate new hypotheses. Our approach is similar in spirit, but differs in the following aspects: inspired by the work of Rei and Yannakoudakis (2016) who tackle error *detection* rather than *correction* within a neural network framework, we develop a neural sequence-labelling model for error *detection* to calculate the probability of each token in a sentence as being correct or incorrect; using the error detection model, we propose a small set of features that require no linguistic processing to re-rank the N best hypotheses. We evaluate our approach on three different GEC datasets and achieve state-of-the-art results, outperforming all previous approaches to GEC.

3 Datasets

We use the First Certificate in English (FCE) dataset (Yannakoudakis et al., 2011), and the NUS Corpus of Learner English (NUCLE) (Dahlmeier et al., 2013) that was used in the CoNLL GEC shared tasks. Both datasets are annotated with the language errors committed and suggested corrections from expert annotators. The former consists of upper-intermediate learner texts written by speakers from a number of different native language backgrounds, while the latter consists of essays written by advanced undergraduate university students from an Asian language background. We use the public FCE train/test split, and the NUCLE train/test set used in CoNLL 2014 (the test set has been annotated by two different annotators).

We also use the publicly available Lang-8 corpus (Mizumoto et al., 2012; Tajiri et al., 2012) and the JHU FLuency-Extended GUG corpus (J-FLEG) (Napoles et al., 2017). Lang-8 contains learner English from lang-8.com, a language-learning social networking service, which has been corrected by native speakers. JFLEG is a newly released corpus for GEC evaluation that contains fluency edits to make the text more native-like in addition to correcting grammatical errors, and contains learner data from a range of proficiency levels.

We use Lang-8 and the FCE and CoNLL training sets to train our neural sequence-labelling model, and test correction performance on JFLEG, and the FCE and CoNLL test sets. For JFLEG, we use the 754 sentences on which Napoles et al. (2017) have already benchmarked four leading GEC systems. As our development set, we use a subset of the FCE training data.

4 Neural sequence labelling

We treat error detection as a sequence labelling task and assign a label to each token in the input sentence, indicating whether it is correct or incorrect in context. These binary gold labels can be automatically extracted from the manual error annotation available in our data (see Section 3). Similarly to Rei and Yannakoudakis (2016), we construct a bidirectional recurrent neural network for detecting writing errors. The system receives a series of tokens $[w_1 ... w_T]$ as input, and predicts a probability distribution over the possible labels for each token.

Every token w_t is first mapped to a token representation $\widetilde{x}_t$, which is also optimised during training. These embeddings are composed together into context-specific representations using a bidirectional LSTM (Hochreiter and Schmidhuber, 1997):

$$\overrightarrow{h_t} = \text{LSTM}(\widetilde{x}_t, \overrightarrow{h_{t-1}}) \tag{1}$$

$$\overleftarrow{h_t} = \text{LSTM}(\widetilde{x}_t, \overleftarrow{h_{t+1}}) \tag{2}$$

$$h_t = [\overrightarrow{h_t}; \overleftarrow{h_t}] \tag{3}$$

where $\widetilde{x}_t$ is the token representation at position t, $\overrightarrow{h_t}$ is the hidden state of the forward-moving LSTM, $\overleftarrow{h_t}$ is the hidden state of the backward-moving LSTM, and h_t is the concatenation of both hidden states. A feedforward hidden layer with tanh activation is then used to map the representations from both directions into a more suitable combined space, and allow the model to learn higher-level features:

$$d_t = \tanh W_d h_t \tag{4}$$

where W_d is a weight matrix. Finally, a softmax output layer predicts the label distribution for each token, given the input sequence:

$$P(y_t | w_1 ... w_T) = \text{softmax}\, W_o d_t \tag{5}$$

where W_o is an output weight matrix.

We also make use of the character-level architecture proposed by Rei et al. (2016), allowing the model to learn morphological patterns and capture out-of-vocabulary words. Each individual character is mapped to a character embedding and a bidirectional LSTM is used to combine them together into a character-based token representation. This vector m, constructed only from individual characters, is then combined with the regular token embedding x_t using an adaptive gating mechanism:

$$z = \sigma\big(W_{z_1} \cdot \tanh(W_{z_2} x_t + W_{z_3} m)\big) \tag{6}$$

$$\widetilde{x}_t = z \cdot x_t + (1 - z) \cdot m \tag{7}$$

where W_{z_1}, W_{z_2} and W_{z_3} are weight matrices, z is a dynamically calculated gating vector, and $\widetilde{x}_t$ is the resulting token representation at position t.

We optimise the model by minimising cross-entropy between the predicted label distributions and the annotated labels. In addition to training the error detection objective, we make use of a multi-task loss function and train specific parts of the architecture as language models. This provides the model with a more informative loss function, while also encouraging it to learn more general compositional features and acting as a regulariser (Rei, 2017). First, two extra hidden layers are constructed:

$$\overrightarrow{m_t} = \tanh \overrightarrow{W}_m \overrightarrow{h_t} \tag{8}$$

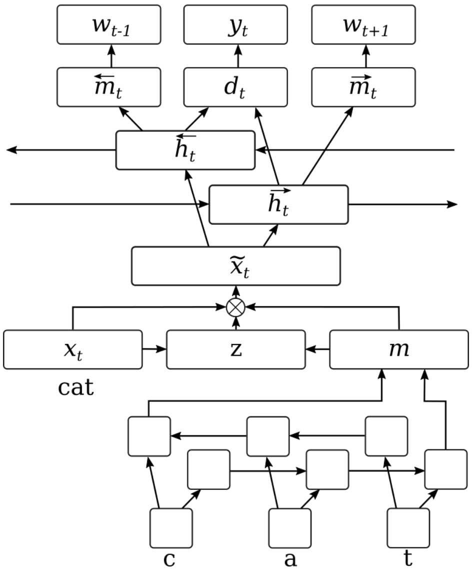

Figure 1: Error detection network architecture that is repeated for all the words in a sentence (illustration for the word "cat").

$$\overleftarrow{m_t} = \tanh \overleftarrow{W}_m \overleftarrow{h_t} \qquad (9)$$

where $\overrightarrow{W}_m$ and $\overleftarrow{W}_m$ are direction-specific weight matrices, used for connecting a forward or backward LSTM hidden state to a separate layer. The surrounding tokens are then predicted based on each hidden state using a softmax output layer:

$$P(w_{t+1}|w_1...w_t) = \text{softmax}\, \overrightarrow{W}_q \overrightarrow{m_t} \qquad (10)$$

$$P(w_{t-1}|w_t...w_T) = \text{softmax}\, \overleftarrow{W}_q \overleftarrow{m_t} \qquad (11)$$

During training, the following cost function is minimised, which combines the error detection loss function with the two language modeling objectives:

$$\begin{aligned} E = &- \sum_{t=1}^{T} \log P(y_t|w_t...w_T) \\ &- \gamma \sum_{t=1}^{T-1} \log P(w_{t+1}|w_1...w_t) \qquad (12) \\ &- \gamma \sum_{t=2}^{T} \log P(w_{t-1}|w_t...w_T) \end{aligned}$$

where γ is a weight that controls the importance of language modeling in relation to the error detection objective. Figure 1 shows the error detection network architecture.

4.1 Experimental settings

All digits in the text are replaced with the character '0'. Tokens that occur less than 2 times in the training data share an out-of-vocabulary (OOV) token embedding, whereas the character-level component still operates over the original tokens. The model hyperparameters are tuned based on $F_{0.5}$ on the FCE development set (Section 3) and γ is set to 0.1.[1] The model is optimised using Adam (Kingma and Ba, 2015), and training is stopped when $F_{0.5}$ does not improve on the development set over 5 epochs. Token representations have size 300 and are initialised with pre-trained word2vec embeddings trained on Google News (Mikolov et al., 2013). The character representations have size 50 and are initialised randomly. The LSTM hidden layers have size 200 for each direction.

4.2 Error detection performance

Rei and Yannakoudakis (2016)'s error detection framework uses token-level embeddings, bidirectional LSTMs for context representation, and a multi-layer architecture for learning more complex features. They train their model on the public FCE training set, and benchmark their results on the FCE and CoNLL test sets (Baseline LSTM_{FCE}). We also train and test our detection model on the same data and evaluate the effectiveness of our approach (LSTM_{FCE}). In Table 1, we can see that our architecture achieves a higher performance on both FCE and CoNLL, and particularly for FCE (7% higher $F_{0.5}$) and CoNLL test annotation 2 (around 2% higher $F_{0.5}$). When we use a larger training set that also includes the CoNLL training data and the public Lang-8 corpus (see Section 3), performance improves even further (LSTM), particularly for CoNLL test annotation 1 (at least 8% higher $F_{0.5}$ compared to LSTM_{FCE}). We use this model in the experiments reported in the following sections.

5 Statistical machine translation

SMT attempts to identify the 1-best correction hypothesis c^* of an input sentence s that maximises the following:

$$c^* = \arg\max_c p_{\text{LM}}(c)\, p(s|c) \qquad (13)$$

[1] Lower γ values tend to give better error detection results as this essentially prioritises the error detection objective.

	FCE test set			CoNLL test set annotation 1			CoNLL test annotation 2		
System	P	R	$F_{0.5}$	P	R	$F_{0.5}$	P	R	$F_{0.5}$
Baseline LSTM_{FCE}	46.10	28.50	41.10	15.40	22.80	16.40	23.60	25.10	23.90
LSTM_{FCE}	58.88	28.92	48.48	17.68	19.07	17.86	27.62	21.18	25.88
LSTM	79.10	21.19	**51.14**	54.51	8.69	**26.53**	69.60	7.91	**27.18**

Table 1: Token-level error detection performance of our detection models (LSTM_{FCE} and LSTM) on FCE and the two CoNLL 2014 test set annotations. Baseline LSTM_{FCE} and LSTM_{FCE} are trained only on the public FCE training set.

A Language Model (LM) is used to estimate the correction hypothesis probability $p_{\text{LM}}(c)$ from a corpus of correct English, and a translation model to estimate the conditional $p(s|c)$ from a parallel corpus of corrected learner sentences. State-of-the-art SMT systems are phrase-based (Koehn et al., 2003) in that they use phrases as "translation" units and therefore allow many-to-many "translation" mappings. The translation model is decomposed into a phrase-translation probability model and a phrase re-ordering probability model, and the 1-best correction hypothesis is of the following log-linear form (Och and Ney, 2002):

$$c^* = \arg\max_c \exp \sum_{i=1}^{K} \lambda_i \, h_i(c, s) \tag{14}$$

where h represents a feature function (e.g., phrase-translation probability) and λ the feature weight.

In this work, we employ two SMT systems: Yuan et al. (2016)[2] and Junczys-Dowmunt and Grundkiewicz (2016). We apply our re-ranking approach to each SMT system's N-best list using features derived from the neural sequence-labelling model for error detection described in the previous section, improve each of the SMT systems, and achieve state-of-the-art results on all three GEC datasets: FCE, CoNLL and JFLEG.

5.1 N-best list re-ranking

For each SMT system, we generate the list of all the 10 best candidate hypotheses. We then use the following set of features (tuned on the FCE development set, see Section 3) to assign a score to each candidate, and determine a new ranking for each SMT model:

Sentence probability: Our error detection model outputs a probabilty indicating whether a token is likely to be correct or incorrect in context. We therefore use as a feature the overall sentence probability, calculated based on the probability of each of its tokens being correct: $\sum_w \log P(w)$

Levenshtein distance: We first use Levenshtein distance (LD) to identify which tokens in the original/source sentence have been corrected by the candidate hypothesis. We then identify the tokens that our detection model predicts as incorrect (i.e., the probability of being incorrect is greater than 0.5). These give us two different sets of annotations for the source sentence: tokens in the source sentence that the candidate hypothesis identifies as incorrect; and tokens in the source sentence that the error detection model identifies as incorrect. We then convert these annotations to binary sequences – i.e., 1 if the token is identified as incorrect, and 0 otherwise – and use as a feature the LD between those binary representations. More specifically, we would like to select the candidate sentence that has the smallest LD from the binary sequence created by the detection model: $\frac{1}{\text{LD}}$

True and false positives: Given the binary sequences described above, we also use as a feature the ratio of true positives (TP) to false positives (FP) by treating the error detection model as the "gold standard". Specifically, we count how many times the candidate hypothesis agrees or not with the detection model on the tokens identified as incorrect: $\frac{\text{TP}}{\text{FP}}$

We use a linear combination of the above three scores together with the overall score (i.e., original rank) given by the SMT system (we do not include any other SMT features) to re-rank each SMT system's 10-best list in an unsupervised way. The new 1-best correction hypothesis c^* is then the one that maximises:

$$c^* = \arg\max_c \sum_{i=1}^{K} \lambda_i \, h_i(c) \tag{15}$$

[2] Yuan et al. (2016) propose a supervised N-best list re-ranking approach; however, we only use their baseline SMT system.

where h represents the score assigned to candidate hypothesis c according to feature i; λ is a parameter that controls the effect feature i has on the final ranking; and $K = 4$ as we have four different features (three features presented in this section, plus the original score output by the SMT system). λs are tuned on the FCE development set and are set to 1, except for the sentence probability feature which has $\lambda = 1.5$.[3]

6 Evaluation

We evaluate the effectiveness of our re-ranking approach on three different datasets: FCE, CoNLL 2014 and JFLEG. We report F$_{0.5}$ using the shared task's M^2 scorer (Dahlmeier and Ng, 2012b), and GLEU scores (Napoles et al., 2015). The latter is based on a variant of BLEU (Papineni et al., 2002) that is designed to reward correct edits and penalise ungrammatical ones. As mentioned in Section 5, we re-rank the 10-best lists of two SMT systems: Yuan et al. (2016) (CAMB16$_{\text{SMT}}$) and Junczys-Dowmunt and Grundkiewicz (2016) (AMU16$_{\text{SMT}}$). The results are presented in Table 2.

We replicate the AMU16$_{\text{SMT}}$ system to obtain the 10-best output, and report results using this version (AMU16$_{\text{SMT (replicated)}}$). Compared to the original results on CoNLL reported in their paper (AMU16$_{\text{SMT (reported)}}$), we obtain slightly lower performance.[4] We can see that AMU16$_{\text{SMT}}$ is the current state of the art on CoNLL, with an F$_{0.5}$ of 49.49. On the other hand, CAMB16$_{\text{SMT}}$ generalises better on FCE and JFLEG: 52.90 and 52.44 F$_{0.5}$ respectively. The lower performance of AMU16$_{\text{SMT}}$ can be attributed to the fact that it is tuned for the CoNLL shared task.

The current state of the art on FCE is a neural machine translation system, CAMB16$_{\text{NMT}}$ (Yuan and Briscoe, 2016), which is also the best model on JFLEG in terms of GLEU. The rest of the baselines we report are: Rozovskaya and Roth (2016), who explore combinations of SMT systems and classifiers (VT16$_{\text{SMT}}$ + classifiers); Chollampatt et al. (2016a), who integrate a neural network joint model that has been adapted using native-language-specific learner text as a feature in SMT (NUS16$_{\text{SMT+NNJM}}$); and Hoang et al. (2016), who perform supervised N-best list re-ranking using a large set of features, and further extend their approach to generate new hypotheses (NUS16$_{\text{SMT}}$ + re-ranker).[5]

[3] We experimented with a small set of values (from 0 to 2 with increments of .1), though not exhaustively.

[4] The differences are likely to be caused by different versions of the NLTK tokeniser and/or Moses.

[5] We note that Napoles et al. (2017) use an updated version of GLEU to evaluate AMU16$_{\text{SMT (reported)}}$, NUS16$_{\text{SMT+NNJM}}$ and CAMB16$_{\text{NMT}}$ on JFLEG. We therefore also use this updated version throughout all GLEU evaluations on JFLEG.

CAMB16$_{\text{SMT}}$ + LSTM$_{\text{camb}}$		
Ablated feature	F$_{0.5}$	GLEU
None	55.60	71.76
Sentence probability	54.13	70.65

True/false positives	55.14	71.75

Table 3: Ablation tests on the FCE test set when removing one feature of the re-ranking system at a time.

When using our LSTM detection model to re-rank the 10-best list (+ LSTM), we can see that performance improves across all three datasets for both SMT systems. F$_{0.5}$ performance of CAMB16$_{\text{SMT}}$ on FCE improves from 52.90 to 54.15, on CoNLL from 37.33 to 39.53, and on JFLEG from 52.44 to 53.50 (the latter demonstrating that the detection model also helps with fluency edits). This improved result is also better than the state of the art CAMB16$_{\text{NMT}}$ on FCE.[6] When looking at AMU16$_{\text{SMT}}$, we can see that re-ranking (+ LSTM) further improves the best result on CoNLL from 49.34 (replicated) to 49.66 F$_{0.5}$, and there is a similar level of improvement for both FCE and JFLEG.

As a further experiment, we re-train our error detection model on the same training data as CAMB16$_{\text{SMT}}$ (+ LSTM$_{\text{camb}}$). More specifically, we use the Cambridge Learner Corpus (CLC) (Nicholls, 2003), a collection of learner texts of various proficiency levels, written in response to exam prompts and manually annotated with the errors committed (around 2M sentence pairs). In Table 2, we can see that the detection model further improves performance across all datasets and SMT systems. Compared to just doing SMT with CAMB16$_{\text{SMT}}$, re-ranking improves F$_{0.5}$ from 52.90 to 55.60 on FCE (performance increases further even though CAMB16$_{\text{SMT}}$'s training set includes a large set of FCE data), from 37.33 to 42.44 on CoNLL, and from 52.44 to 54.66 on JFLEG. The largest improvement is on CoNLL (5%), which is likely because CoNLL is not included in the training set. AMU16$_{\text{SMT (replicated)}}$ is specifically tuned for CoNLL; nevertheless, the detection model also improves F$_{0.5}$ on CoNLL from 49.34 to 51.08. Re-ranking using a small set of detection-based features produces state-of-the-art results on all three datasets (we note that CAMB16$_{\text{SMT}}$ generalises better across all).

We next run ablation tests to investigate the extent to which each feature contributes to performance. Results obtained on the FCE test set after excluding each of the features of the 'CAMB16$_{\text{SMT}}$ + LSTM$_{\text{camb}}$' re-ranking system are presented in Table 3. Overall, all features have a positive effect on performance, though the sentence probability feature does have the biggest impact: its removal is responsible for a 1.47 and 1.11 decrease of F$_{0.5}$ and GLEU respectively. A similar pattern is observed on the other datasets too.

6.1 Oracle

To calculate an upper bound per SMT system per dataset, we calculate character-level LD between each candidate hypothesis in the 10-best list and the gold corrected sentence. We then calculate an oracle score by selecting the candidate hypothesis that has the smallest LD. Essentially the oracle is telling us the maximum performance that can be obtained with the given 10-best list on each dataset. For datasets for which we have more than one annotation available, we select the oracle that gives the highest F$_{0.5}$.

In Table 2, we can see that, overall, CAMB16$_{\text{SMT}}$ has a higher oracle performance compared to AMU16$_{\text{SMT}}$. More specifically, the maximum attainable F$_{0.5}$ on FCE is 71.60, on CoNLL 58.13, and on JFLEG 61.92. This shows empirically that the 10-best list has great potential and should be exploited further. AMU16$_{\text{SMT}}$ has a lower oracle performance overall, though again this can be attributed to the fact that it is specifically tuned for CoNLL.

6.2 N-best list size

Next, we examine performance as the N-best list varies in size, ranging from 1 to 10 (Table 4). We observe a positive effect: the larger the size, the better the model for all datasets. F$_{0.5}$ does not seem to have reached a plateau with $n < 10$, which suggests that increasing the size of the list further can potentially lead to better results. We do, however, observe that large improvements are obtained when increasing the size from 1 to 3, suggesting that, most of the time, better alternatives are identified within the top 3 candidate hypotheses. This, however, is not the case for the oracle ($\text{F}_{0.5}^{\text{oracle}}$), which consistently increases as n gets larger.

[6] We note that CAMB16$_{\text{NMT}}$ outperforms the re-ranking approach by Yuan et al. (2016).

	CAMB16$_{\text{SMT}}$					
	FCE test set		CoNLL test set		JFLEG	
N-best list	$F_{0.5}$	$F_{0.5}^{\text{oracle}}$	$F_{0.5}$	$F_{0.5}^{\text{oracle}}$	$F_{0.5}$	$F_{0.5}^{\text{oracle}}$
1	52.90	52.90	37.33	37.33	52.44	52.44

Table 5: Source sentences along with gold corrections (reference), 1-best candidates by CAMB16$_{\text{SMT}}$ and by CAMB16$_{\text{SMT}}$ + LSTM$_{\text{camb}}$.

6.3 Error type performance

In Table 5, we can see example source sentences, together with their corrected counterparts (reference), 1-best candidates by CAMB16$_{\text{SMT}}$ and 1-best candidates by CAMB16$_{\text{SMT}}$ + LSTM$_{\text{camb}}$. Re-ranking seems to fix errors such as subject–verb agreement ("the Computer help" to "the computer helps") and verb form ("I recommend you to visit" to "I recommend visiting"). In this section, we perform an analysis of performance per type to get a better understanding of where the strength of the re-ranking detection model comes from.

Until recently, GEC performance per error type was only analysed in terms of recall, as system output is not annotated. Recently, however, Bryant et al. (2017) proposed an approach to automatically annotating GEC output with error type information, which utilises a linguistically-enhanced alignment to automatically extract the edits between pairs of source sentences and their corrected counterparts, and a dataset-independent rule-based classifier to classify the edits into error types. Human evaluation showed that the predicted error types were rated as "Good" or "Acceptable" 95% of the time. We use their publicly available code to analyse per-error-type performance before and after re-ranking.

Table 6 presents the performance for a subset of error types that are affected the most before and after re-ranking CAMB16$_{\text{SMT}}$ on the FCE test set. The error types are interpreted as follows: **M**issing error; **R**eplace error; **U**nnecessary error. The largest improvement is observed in replacement errors referring to possessive nouns (R:NOUN:POSS) and verb agreement (R:VERB:SVA); and in unnecessary errors referring to adverbs (U:ADV), determiners (U:DET), pronouns (U:PRON), and verb tense (U:VERB:TENSE).

The LSTM architecture allows the network to learn advanced composition rules and remember dependencies over longer distances (e.g., R:VERB:SVA improves from 58.38 to 69.40). The network's language modelling objectives allow it to learn better and more general compositional features (e.g., U:ADV improves from 13.51 to 22.73), while the character-level architecture facilitates modelling of morphological patterns [e.g., replacement errors referring to verb form (R:VERB:FORM) improve from 53.62 to 58.06]. Between M, R, and U errors, the largest improvement is observed in U, for which there is at least 5% improvement in $F_{0.5}$.[7]

Overall, re-ranking improves $F_{0.5}$ across error types; however, there is a small subset that is

[7] U improves from 38.44 to 43.77; M from 43.43 to 45.40; R from 53.25 to 55.33.

	CAMB16$_{\text{SMT}}$	CAMB16$_{\text{SMT}}$ + LSTM$_{\text{camb}}$
Type	$F_{0.5}$	$F_{0.5}$

M:VERB:FORM	50.00	**38.46**
R:ADJ	45.45	37.67
R:CONTR	50.00	**27.78**
R:WO	53.63	48.74

Table 6: Error-type performance before and after re-ranking on the FCE test set (largest impact highlighted in bold; bottom part of the table displays negative effects on performance).

negatively affected (Table 6, bottom part); for example, performance on missing errors referring to verb form (M:VERB:FORM) drops from 50.00 to 38.46, and on replace contraction errors (R:CONTR) from 50.00 to 27.78. Importantly, such an analysis allows us to examine the strengths and weaknesses of the models, which is key for the deployment of GEC systems.

7 Conclusion

To the best of our knowledge, no prior work has investigated the impact of detection models on correction performance. We proposed an approach to N-best list re-ranking using a neural sequence-labelling model that calculates the probability of each token in a sentence being correct or incorrect in context. Detection models can be more fine-tuned to finer nuances of grammaticality, and therefore better able to distinguish between correct and incorrect versions of a sentence. Using a linear combination of a small set of features derived from the detection model output, we re-ranked the N-best list of SMT systems and achieved state-of-the-art results on GEC on three different datasets. Our approach can be applied to any GEC system that produces multiple alternative hypotheses. Our results demonstrate the benefits of integrating detection approaches with correction systems, and how one can complement the other.

Abstract

In a controlled experiment of sequence-to-sequence approaches for the task of sentence correction, we find that character-based models are generally more effective than word-based models and models that encode subword information via convolutions, and that modeling the output data as a series of diffs improves effectiveness over standard approaches. Our strongest sequence-to-sequence model improves over our strongest phrase-based statistical machine translation model, with access to the same data, by 6 M^2 (0.5 GLEU) points. Additionally, in the data environment of the standard CoNLL-2014 setup, we demonstrate that modeling (and tuning against) diffs yields similar or better M^2 scores with simpler models and/or significantly less data than previous sequence-to-sequence approaches.

1 Introduction

The task of *sentence correction* is to convert a natural language sentence that may or may not have errors into a corrected version. The task is envisioned as a component of a learning tool or writing-assistant, and has seen increased interest since 2011 driven by a series of shared tasks (Dale and Kilgarriff, 2011; Dale et al., 2012; Ng et al., 2013, 2014).

Most recent work on language correction has focused on the data provided by the CoNLL-2014 shared task (Ng et al., 2014), a set of corrected essays by second-language learners. The CoNLL-2014 data consists of only around 60,000 sentences, and as such, competitive systems have made use of large amounts of corrected text without annotations, and in some cases lower-quality crowd-annotated data, in addition to the shared data. In this data environment, it has been suggested that statistical phrase-based machine translation (MT) with task-specific features is the state-of-the-art for the task (Junczys-Dowmunt and Grundkiewicz, 2016), outperforming word- and character-based sequence-to-sequence models (Yuan and Briscoe, 2016; Xie et al., 2016; Ji et al., 2017), phrase-based systems with neural features (Chollampatt et al., 2016b,a), re-ranking output from phrase-based systems (Hoang et al., 2016), and combining phrase-based systems with classifiers trained for hand-picked subsets of errors (Rozovskaya and Roth, 2016).

We revisit the comparison across translation approaches for the correction task in light of the Automated Evaluation of Scientific Writing (AESW) 2016 dataset, a correction dataset containing over 1 million sentences, holding constant the training data across approaches. The dataset was previously proposed for the distinct binary classification task of grammatical error identification.

Experiments demonstrate that pure character-level sequence-to-sequence models are more effective on AESW than word-based models and models that encode subword information via convolutions over characters, and that representing the output data as a series of *diffs* significantly increases effectiveness on this task. Our strongest character-level model achieves statistically significant improvements over our strongest phrase-based statistical machine translation model by 6 M^2 (0.5 GLEU) points, with additional gains when including domain information. Furthermore, in the partially crowd-sourced data environment of the standard CoNLL-2014 setup in which there are comparatively few professionally annotated sentences, we find that tuning against the tags marking the diffs yields similar or superior effectiveness relative to existing sequence-

to-sequence approaches despite using significantly less data, with or without using secondary models. All code is available at https://github.com/allenschmaltz/grammar.

2 Background and Methods

Task We follow recent work and treat the task of sentence correction as translation from a source sentence (the unedited sentence) into a target sentence (a corrected version in the same language as the source). We do not make a distinction between grammatical and stylistic corrections.

We assume a vocabulary $\mathcal{V}$ of natural language word types (some of which have orthographic errors). Given a sentence $\mathbf{s} = [s_1 \cdots s_I]$, where $s_i \in \mathcal{V}$ is the i-th token of the sentence of length I, we seek to predict the corrected target sentence $\mathbf{t} = [t_1 \cdots t_J]$, where $t_j \in \mathcal{V}$ is the j-th token of the corrected sentence of length J. We are given both $\mathbf{s}$ and $\mathbf{t}$ for supervised training in the standard setup. At test time, we are only given access to sequence $\mathbf{s}$. We learn to predict sequence $\mathbf{t}$ (which is often identical to $\mathbf{s}$).

Sequence-to-sequence We explore word and character variants of the sequence-to-sequence framework. We use a standard word-based model (WORD), similar to that of Luong et al. (2015), as well as a model that uses a convolutional neural network (CNN) and a highway network over characters (CHARCNN), based on the work of Kim et al. (2016), instead of word embeddings as the input to the encoder and decoder. With both of these models, predictions are made at the word level. We also consider the use of bidirectional versions of these encoders (+BI).

Our character-based model (CHAR+BI) follows the architecture of the WORD+BI model, but the input and output consist of characters rather than words. In this case, the input and output sequences are converted to a series of characters and whitespace delimiters. The output sequence is converted back to $\mathbf{t}$ prior to evaluation.

The WORD models encode and decode over a closed vocabulary (of the 50k most frequent words); the CHARCNN models encode over an open vocabulary and decode over a closed vocabulary; and the CHAR models encode and decode over an open vocabulary.

Our contribution is to investigate the impact of sequence-to-sequence approaches (including those not considered in previous work) in a series of controlled experiments, holding the data constant. In doing so, we demonstrate that on a large, professionally annotated dataset, the most effective sequence-to-sequence approach can significantly outperform a state-of-the-art SMT system without augmenting the sequence-to-sequence model with a secondary model to handle low-frequency words (Yuan and Briscoe, 2016) or an additional model to improve precision or intersecting a large language model (Xie et al., 2016). We also demonstrate improvements over these previous sequence-to-sequence approaches on the CoNLL-2014 data and competitive results with Ji et al. (2017), despite using significantly less data.

The work of Schmaltz et al. (2016) applies WORD and CHARCNN models to the distinct binary classification task of error identification.

Additional Approaches The standard formulation of the correction task is to model the output sequence as $\mathbf{t}$ above. Here, we also propose modeling the diffs between $\mathbf{s}$ and $\mathbf{t}$. The diffs are provided in-line within $\mathbf{t}$ and are described via tags marking the starts and ends of insertions and deletions, with replacements represented as deletion-insertion pairs, as in the following example selected from the training set: "Some key points are worth <del> emphasiz </del> <ins> emphasizing </ins> .". Here, "emphasiz" is replaced with "emphasizing". The models, including the CHAR model, treat each tag as a single, atomic token.

The diffs enable a means of tuning the model's propensity to generate corrections by modifying the probabilities generated by the decoder for the 4 diff tags, which we examine with the CoNLL data. We include four bias parameters associated with each diff tag, and run a grid search between 0 and 1.0 to set their values based on the tuning set.

It is possible for models with diffs to output invalid target sequences (for example, inserting a word without using a diff tag). To fix this, a deterministic post-processing step is performed (greedily from left to right) that returns to source any non-source tokens outside of insertion tags. Diffs are removed prior to evaluation. We indicate models that *do not* incorporate target diff annotation tags with the designator –DIFFS.

The AESW dataset provides the paragraph context and a journal domain (a classification of the document into one of nine subject categories) for each sentence.[1] For the sequence-to-sequence

[1] The paragraphs are shuffled for purposes of obfuscation,

Model	GLEU Dev	GLEU Test	M^2 Dev	M^2 Test
No Change	89.68	89.45	00.00	00.00

Table 1: AESW development/test set correction results. GLEU and M^2 differences on test are statistically significant via paired bootstrap resampling (Koehn, 2004; Graham et al., 2014) at the 0.05 level, resampling the full set 50 times.

models we propose modeling the input and output sequences with a special initial token representing the journal domain (+dom).[2]

3 Experiments

Data AESW (Daudaravicius, 2016; Daudaravicius et al., 2016) consists of sentences taken from academic articles annotated with corrections by professional editors used for the AESW shared task. The training set contains 1,182,491 sentences, of which 460,901 sentences have edits. We set aside a 9,947 sentence sample from the original development set for tuning (of which 3,797 contain edits), and use the remaining 137,446 sentences as the dev set[3] (of which 53,502 contain edits). The test set contains 146,478 sentences.

The primary focus of the present study is conducting controlled experiments on the AESW dataset, but we also investigate results on the CoNLL-2014 shared task data in light of recent neural results (Ji et al., 2017) and to serve as a baseline of comparison against existing sequence-to-sequence approaches (Yuan and Briscoe, 2016; Xie et al., 2016). We use the common sets of public data appearing in past work for training: the National University of Singapore (NUS) Corpus of Learner English (NUCLE) (Dahlmeier et al., 2013) and the publicly available Lang-8 data (Tajiri et al., 2012; Mizumoto et al., 2012). The Lang-8 dataset of corrections is large[4] but is crowd-sourced[5] and is thus of a different nature than the professionally annotated AESW and NUCLE datasets. We use the revised CoNLL-2013 test set as a tuning/dev set and the CoNLL-2014 test set (without alternatives) for testing. We do not make use of the non-public Cambridge Learner Corpus (CLC) (Nicholls, 2003), which contains over 1.5 million sentence pairs.

Evaluation We follow past work and use the Generalized Language Understanding Evaluation (GLEU) (Napoles et al., 2016) and MaxMatch (M^2) metrics (Dahlmeier and Ng, 2012).

Parameters All our models, implemented with OpenNMT (Klein et al.), are 2-layer LSTMs with 750 hidden units. For the Word model, the word embedding size is also set to 750, while for the CharCNN and Char models we use a character embedding size of 25. The CharCNN model has a convolutional layer with 1000 filters of width 6 followed by max-pooling, which is fed into a 2-layer highway network. Additional training details are provided in Appendix A. For AESW, the Word+Bi model contains around 144 million parameters, the CharCNN+Bi model around 79 million parameters, and the Char+Bi model around 25 million parameters.

Statistical Machine Translation As a baseline of comparison, we experiment with a phrase-based machine translation approach (SMT) shown to be state-of-the-art for the CoNLL-2014 shared task data in previous work (Junczys-Dowmunt and Grundkiewicz, 2016), which adds task specific features and the M^2 metric as a scorer to the Moses statistical machine translation system. The SMT model follows the training, parameters, and dense and sparse task-specific features that generate state-of-the-art results for CoNLL-2014 shared task data, as implemented in publicly available code.[6] However, to compare models against the same training data, we remove language model features associated with external data.[7] We exper-

so document-level context is not available.

[2] Characteristics of the dataset preclude experiments with additional paragraph context features. (See Appendix A.)

[3] The dev set contains 13,562 unique deletion types, 29,952 insertion types, and 39,930 replacement types.

[4] about 1.4 million sentences after filtering

[5] derived from the Lang-8 language-learning website

[6] SRI International provided access to SRILM (Stolcke, 2002) for running Junczys-Dowmunt and Grundkiewicz (2016)

[7] We found that including the features and data associated with the large language models of Junczys-Dowmunt and Grundkiewicz (2016), created from Common Crawl text

iment with tuning against M^2 (+M^2) and BLEU (+BLEU). Models trained with diffs were only tuned with BLEU, since the tuning pipeline from previous work is not designed to handle removing such annotation tags prior to M^2 scoring.

4 Results and Analysis: AESW

Table 1 shows the full set of experimental results on the AESW development and test data.

The CHAR+BI+DOM model is stronger than the WORD+BI+DOM and CHARCNN+DOM models by 2.9 M^2 (0.2 GLEU) and 3.3 M^2 (0.3 GLEU), respectively. The sequence-to-sequence models were also more effective than the SMT models, as shown in Table 1. We find that training with target diffs is beneficial across all models, with an increase of about 5 M^2 points for the WORD+BI model, for example. Adding +DOM information slightly improves effectiveness across models.

We analyzed deletion, insertion, and replacement error types. Table 2 compares effectiveness across replacement errors. We found the CHARCNN+BI models were less effective than CHARCNN variants in terms of GLEU and M^2, and the strongest CHARCNN models were eclipsed by the WORD+BI models in terms of the GLEU and M^2 scores. However, Table 2 shows CHARCNN+DOM is stronger on lower frequency replacements than WORD models. The CHAR+BI+DOM model is relatively strong on article and punctuation replacements, as well as errors appearing with low frequency in the training set and overall across deletion and insertion error types, which are summarized in Table 3.

Errors never occurring in training The comparatively high Micro $F_{0.5}$ score (18.66) for the CHAR+BI+DOM model on replacement errors (Table 2) never occurring in training is a result of a high precision (92.65) coupled with a low recall (4.45). This suggests some limited capacity to generalize to items not seen in training. A selectively chosen example is the replacement from "discontinous" to "discontinuous", which never occurs in training. However, similar errors of low edit distance also occur once in the dev set and never in training, but the CHAR+BI+DOM model never correctly recovers many of these errors, and many of the correctly recovered errors are minor changes in capitalization or hyphenation.

Error frequency About 39% of the AESW training sentences have errors, and of those sentences, on average, 2.4 words are involved in changes in deletions, insertions, or replacements (i.e., the count of words occurring between diff tags) per sentence. In the NUCLE data, about 37% of the sentences have errors, of which on average, 5.3 words are involved in changes. On the AESW dev set, if we only consider the 9545 sentences in which 4 or more words are involved in a change (average of 5.8 words in changes per sentence), the CHAR+BI model is still more effective than SMT+BLEU, with a GLEU score of 67.21 vs. 65.34. The baseline GLEU score (No Change) is 60.86, reflecting the greater number of changes relative to the full dataset (cf. Table 1).

Re-annotation The AESW dataset only provides 1 annotation for each sentence, so we perform a small re-annotation of the data to gauge effectiveness in the presence of multiple annotations. We collected 3 outputs (source, gold, and generated sentences from the CHAR+BI+DOM model) for 200 randomly sampled sentences, reannotating to create 3 new references for each sentence. The GLEU scores for the 200 original source, CHAR+BI+DOM, and original gold sentences evaluated against the 3 new references were 79.79, 81.72, and 84.78, respectively, suggesting that there is still progress to be made on the task relative to human levels of annotation.

5 Results and Analysis: CoNLL

Table 4 shows the results on the CoNLL dev set, and Table 5 contains the final test results.

Since the CoNLL data does not contain enough data for training neural models, previous works add the crowd-sourced Lang-8 data; however, this data is not professionally annotated. Since the distribution of corrections differs between the dev/test and training sets, we need to tune the precision and recall.

As shown in Table 4, WORD+BI effectiveness increases significantly by tuning the weights[8] assigned to the diff tags on the CoNLL-2013 set[9].

filtered against the NUCLE corpus, *hurt* effectiveness for the phrase-based models. This is likely a reflection of the domain specific nature of the academic text and LaTeX holder symbols appearing in the text. Here, we conduct controlled experiments without introducing additional domain-specific monolingual data.

[8] In contrast, in early experiments on AESW, tuning yielded negligible improvements.

[9] The single model with highest M^2 score was then run on the test set. Here, a single set is used for tuning and dev.

Replacement Error Type (out of 39,930) – Frequency relative to training							
Model	Punctuation	Articles	Other				
			> 100	$[5, 100]$	$[2, 5)$	1	0
Raw frequency in dev	11507	1691	6788	8974	2271	1620	7079
Number of unique instances	371	367	215	2918	1510	1242	5819
SMT+BLEU	56.03	16.41	44.57	36.17	39.46	31.93	0.00
Word+Bi	56.13	18.58	55.38	44.33	18.79	6.38	0.77
Word+Bi+dom	56.87	19.16	59.02	44.57	19.70	4.42	2.01
CharCNN+dom	55.64	13.37	57.34	41.83	28.99	16.74	7.09
Char+Bi	58.71	28.40	55.34	44.59	28.98	24.48	14.14
Char+Bi+dom	58.93	27.64	59.32	46.08	32.82	26.48	18.66

Table 2: Micro $F_{0.5}$ scores on replacement errors on the dev set. Errors are grouped by 'Punctuation', 'Article', and 'Other'. 'Other' errors are further broken down based on frequency buckets on the training set, with errors grouped by the frequency in which they occur in the training set.

	Deletions	Insertions	Replacements
SMT+BLEU	46.56	31.48	42.21
Word+Bi	47.75	38.31	46.02
Word+Bi+dom	47.78	39.00	47.29
CharCNN+dom	48.30	39.57	46.24
Char+Bi	49.05	37.17	48.55
Char+Bi+dom	50.20	42.51	50.39

Table 3: Micro $F_{0.5}$ scores across error types

	Precision	Recall	$F_{0.5}$
Word+Bi–diffs	65.36	6.19	22.45
Word+Bi, before tuning	72.34	0.97	4.60
Word+Bi, after tuning	46.66	15.35	33.14

Table 4: M^2 scores on the CoNLL-2013 set.

Note that we are tuning the weights on this same CoNLL-2013 set. Without tuning, the model very rarely generates a change, albeit with a high precision. After tuning, it exceeds the effectiveness of Word+Bi–diffs. The comparatively low effectiveness of Word+Bi–diffs is consistent with past sequence-to-sequence approaches utilizing data augmentation, additional annotated data, and/or secondary models to achieve competitive levels of effectiveness.

Table 5 shows that Word+Bi is within 0.2 M^2 of Ji et al. (2017), despite using over 1 million fewer sentence pairs, and exceeds the M^2 scores of Xie et al. (2016) and Yuan and Briscoe (2016) without the secondary models of those systems. We hypothesize that further gains are possible utilizing the CLC data and moving to the character model. (The character model is omitted here due to the long training time of about 4 weeks.)

	Data	M^2
Yuan and Briscoe (2016)	CLC*	39.90
Xie et al. (2016)	NUCLE, Lang-8, Common Crawl LM	40.56
Ji et al. (2017)	NUCLE, Lang-8, CLC*	41.53
Word+Bi–diffs	NUCLE, Lang-8	35.73
Word+Bi	NUCLE, Lang-8	41.37

Table 5: M^2 scores on the CoNLL-2014 test set and data used for recent sequence-to-sequence based systems. Results for previous works are those reported by the original authors. *CLC is proprietary.

Notably, SMT systems (with LMs) are still more effective than reported sequence-to-sequence results, as in Ji et al. (2017), on CoNLL.[10]

6 Conclusion

Our experiments demonstrate that on a large, professionally annotated dataset, a sequence-to-sequence character-based model of diffs can lead to considerable effectiveness gains over a state-of-the-art SMT system with task-specific features, ceteris paribus. Furthermore, in the crowd-sourced environment of the CoNLL data, in which there are comparatively few professionally annotated sentences in training, modeling diffs enables a means of tuning that improves the effectiveness of sequence-to-sequence models for the task.

[10] For reference, the reported M^2 results of the carefully optimized SMT system of Junczys-Dowmunt and Grundkiewicz (2016) trained on NUCLE and Lang-8, with parameter vectors averaged over multiple runs, with a Wikipedia LM is 45.95 and adding a Common Crawl LM is 49.49. We leave to future work the intersection of a LM for the CoNLL environment and more generally, whether these patterns hold in the presence of additional monolingual data.

Abstract

Stylistic variations of language, such as formality, carry speakers' intention beyond literal meaning and should be conveyed adequately in translation. We propose to use lexical formality models to control the formality level of machine translation output. We demonstrate the effectiveness of our approach in empirical evaluations, as measured by automatic metrics and human assessments.

1 Introduction

Automatically analyzing and generating natural language requires capturing not only what is said, but also how to say it. Consider the sentences "anybody hurt?" and "is someone wounded?". The first one is less formal than the second one, and carries information beyond its literal meaning, such as the situation in which it might be used. Such differences in formality have been identified as an important dimension of style (Trudgill, 1992) or tone (Halliday, 1978) variation.

In this paper, we build on prior computational work that has focused on analyzing formality of texts (Lahiri and Lu, 2011; Brooke and Hirst, 2013; Pavlick and Nenkova, 2015; Pavlick and Tetreault, 2016) with a different aim: modeling formality for the purpose of controlling style in applications that generate language, with a focus on machine translation. Human translators translate a document for a specific audience (Nida and Taber Charles, 1969), and often ask what is the expected tone of the content when taking a new translation job. We design a machine translation system that operates under similar conditions and explicitly takes an expected level of formality as input. While ultimately we would like systems to preserve the formality of the source, this is a challenging task that requires not only automatically inferring the formality of the source, but also understanding how formality differs across languages and cultures. As a first step, we therefore limit our study to the scenario where the expected output formality is given to the MT system as an additional input.

We first select a formality model providing the most accurate scores on intrinsic formality datasets. We compare existing lexical formality models and novel variants based on inducing formality dimensions or subspaces in vector space models. We then turn to machine translation and show that a lexical formality model can have a positive impact when used to control the formality of machine translation output. When the expected formality matches the reference, we obtain improvement of translation quality evaluated by automatic metrics (BLEU). A human assessment also verified the effectiveness of our proposed system in generating translations at diverse levels of formality.

2 Formality-Sensitive MT

Our goal is to provide systems with the ability to generate language across a range of formality style. We propose a **Formality-Sensitive Machine Translation (FSMT)** scenario where the system takes two inputs: (1) text in the source language to be translated, and (2) a desired formality level capturing the intended audience of the translation. We propose to implement it as n-best re-ranking within a standard phrase-based MT architecture. Unlike domain adaptation approaches, which aim to produce domain-specific or potentially formality-specific systems, our goal is to obtain a single system trained on diverse data which can adaptively produce output for a range of styles.

We therefore introduce a formality-scoring fea-

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2814–2819
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

ture for re-ranking. For each translation hypothesis h, given the formality level ℓ as a parameter:

$$f(h;\ell) = |\,\mathrm{Formality}(h) - \ell|$$

where $\mathrm{Formality}(h)$ is the sentence-level formality score for h. $f(h;\ell)$, along with standard model features, is fed into a standard re-ranking model. When training the re-ranking model, the parameter ℓ is set to the actual formality score of the reference translation for each instance. At test time, ℓ is provided by the user. The re-scoring weights help promote candidate sentences whose formality scores approach the expected level.

3 Formality Modeling

The FSMT system requires quantifying the formality level of a sentence. Following prior work, we define sentence-level formality based on lexical formality scores (Brooke et al., 2010; Pavlick and Nenkova, 2015). We conduct an empirical comparison of existing techniques that can be adapted as lexical formality models, and introduce a sentence-level formality scheme based on weighted average.

3.1 Lexical Formality

State-of-the-art lexical formality models (Brooke et al., 2010; Brooke and Hirst, 2014) are based on vector space models of word meaning, and a set of pre-selected seed words that are representative of formal and informal language.

SimDiff Brooke et al. (2010) proposed to score the formality of a word w by comparing its meaning to that of seed words of known formality using cosine similarity. Intuitively, w is more likely formal if it is semantically closer to formal seed words than to informal seed words. Formally, given a formal word set S_f and an informal word set S_i, SimDiff scores a word w by

$$\mathrm{score}(w) = \frac{1}{|S_f|}\sum_{v\in S_f}\cos(e_w,e_v) - \frac{1}{|S_i|}\sum_{v\in S_i}\cos(e_w,e_v)$$

Turning this difference into a formality score requires further manipulation. A neutral word r has to be manually selected to anchor the midpoint of the formality score range. In other words, the final formality score for r is enforced to be zero:

$$\mathrm{Formality}(w) = \frac{\mathrm{score}(w) - \mathrm{score}(r)}{\mathrm{normalizer}(w,r)}$$

The neutral word is typically selected from function words. We select “at” because it appears in nearly every document and appears with nearly equivalent probabilities in formal/informal corpora. Finally, a normalizer which is maximized among the whole vocabulary ensures that scores cover the entire $[-1,1]$ range.

Instead of using cosine diff as the score function $\mathrm{score}(w)$, other standard techniques can be also applied under this framework.

SVM As an alternative to the model proposed by Brooke and Hirst (2014), we propose to train an Support Vector Machine (SVM) model to find a hyperplane that separates formal and informal words and define the score function as the distance to the hyperplane.

Formality Subspace Another category of methods consists in identifying a subspace that captures formality within the original vector space. Lexical scores can then simply be obtained by projecting word representations onto the formality subspace. One example is training a Principal Component Analysis (**PCA**) model on word representations of all seeds. This method is based on the assumption that representative formal/informal words principally vary along the direction of formality. Alternatively, inspired by **Densifier** (Rothe et al., 2016), we can learn a subspace that aims at separating words in S_f vs. words in S_i and grouping words in the same set.

3.2 From Word to Sentence Formality

While previous work scored sentence by averaging word scores (Brooke and Hirst, 2014; Pavlick and Nenkova, 2015), we propose a weighted average scheme for word sequences W to downgrade the formality contribution of neutral words:

$$\mathrm{Formality}(W) = \frac{\sum_{w_i\in W}|\,\mathrm{Formality}(w_i)| \cdot \mathrm{Formality}(w_i)}{\sum_{w_i\in W}|\,\mathrm{Formality}(w_i)|}$$

3.3 Evaluation

Before evaluating our FSMT framework, we evaluate the formality models at the sentence level. Lahiri (2015) and Pavlick and Tetreault (2016) collected 5-way human scores for 11,263 sentences in the genres of blog, email, answers and news. Following Pavlick and Tetreault (2016), we averaged human scores for each sentence as the gold standard. As in prior work, the score quality was evaluated by the Spearman correlation.

A large mixed-topic corpus is required to train vector space models. As suggested by Brooke et al. (2010), we used the ICWSM 2009 Spinn3r dataset (English tier-1) which consists of about 1.6 billion words (Burton et al., 2009). We also compared the term-document association model Latent Semantic Analysis (LSA) (Deerwester et al., 1990) and the term-term association model word2vec (W2V) (Mikolov et al., 2013). We used the same 105 formal seeds and 138 informal seeds as Brooke et al. (2010).

Followed Brooke et al. (2010), to achieve best performance, we used a small dimensionality (10) for training LSA and word2vec. In practice, we normalized the LSA word vectors to make them have unit length for SVM and PCA, but did not applied it to word2vec. This suggests that the magnitude of LSA word vectors is harmful for formality modeling.

We also compared formality models based on word representations to a baseline that relies on unigram models to compare word statistics in corpora representative of formal vs. informal language (Pavlick and Nenkova, 2015). This method requires language examples of diverse formality. Conversational transcripts are generally considered as casual text, so we concatenated corpora such as Fisher (Cieri et al., 2004), Switchboard (Godfrey et al., 1992), SBCSAE (Bois et al., 2000-2005), CallHome[1], CallFriend[2], BOLT SMS/Chat (Song et al., 2014) and NPS Chatroom (Forsythand and Martell, 2007). As the formal counterpart, we extracted comparable size of text from Europarl (Koehn, 2005). This results in 30 Million tokens of formal corpora (1.1M segments) and 29 Million tokens of informal corpora (2.7M segments).

Table 1 shows that all models based on the vector space achieve similar performance in terms of Spearman's ρ (except SVM-W2V which yields lower performance). The baseline method based on unigram models was outperformed by 0.1+ point. So we select DENSIFIER-LSA as a representative for our FSMT system.

	LSA	W2V
SimDiff	0.660	0.654
SVM	0.657	0.585
PCA	0.656	0.663
DENSIFIER	0.664	0.644
baseline	0.540	

Table 1: Sentence-level formality quantifying evaluation (Spearman's ρ) among different models with different vector spaces.

4 Evaluation of the FSMT System

Set-up We evaluate this approach on a French to English translation task. Two parallel French-English corpora are used: (1) MultiUN (Eisele and Chen, 2010), which is extracted from the United Nations website, and can be considered to be formal text; (2) OpenSubtitles2016 (Lison and Tiedemann, 2016), which is extracted from movie and TV subtitles, covers a wider spectrum of styles, but overall tends to be informal since it primarily contains conversations. Each parallel corpus was split into a training set (100M English tokens), a tuning set (2.5K segments) and a test set (5K segments). Two corpora are then concatenated, such that training, tuning and test sets all contained a diversity of styles.

Moses (Koehn et al., 2007) is used to build our phrase-based MT system. We followed the standard training pipeline with default parameters.[3] Word alignments were generated using fast_align (Dyer et al., 2013), and symmetrized using the *grow-diag-final-and* heuristic. We used 4-gram language models, trained using KenLM (Heafield, 2011). Model weights were tuned using batch MIRA (Cherry and Foster, 2012).

We used constant size n=1000 for n-best lists in all experiments. The re-ranking is a log-linear model trained using batch MIRA. [4] We report results averaged over 5 random tuning re-starts to compensate for tuning noise (Clark et al., 2011).

FSMT In order to evaluate the impact of different input formality (e.g. low/neutral/high) on translation quality, ideally, we would like to have three human reference translations with different

Desired formality	Informal test set	Neutral test set	Formal test set
None (baseline)	39.74	40.17	**47.97**
low	**40.27**	39.65	47.76
neutral	38.70	**40.46**	47.84
high	37.58	39.53	**47.97**

Table 2: Translation quality (BLEU scores) on informal/neutral/formal sentence sets given different desired formality levels (-0.4, 0.0, 0.4). Best results with statistical significance are highlighted.

formality for each source sentence. Since such references are not available, we construct three sets of test data where instances are divided according to the formality level of the available reference translation. The formality distribution in the tuning set shows that 97% reference translations fall into the range of $[-0.6, 0.6]$. We therefore set three formality bins – informal $[-1, -0.2)$, neutral formality $[-0.2, 0.2]$, and formal $(0.2, 1]$ – and split the test set into these bins. We use DENSIFIER-LSA and training setting described above to translate the entire test set three times, with three different formality levels: low (-0.4), neutral (0) and high (0.4).

4.1 Automatic Evaluation

We first report standard automatic evaluation results using the BLEU score to compare FSMT output given different desired formality level on each bins (See Table 2).

The best BLEU scores for each formality level are obtained when the level of formality given as input to the MT system matches the nature of the text being translated, as can be seen in the scores along the diagonal in Table 2. Comparing with the baseline system, which produces the top translation from each n-best list, translation quality improves by +0.5 BLEU on informal text, +0.3 BLEU on neutral text, and remains constant on formal text. The impact increases with the distance to formal language increases. This can be explained by the fact that more formal sentences tend to be longer, and the impact of alternate lexical choice for a small number of words per sentence is smaller in longer sentences. In addition, the formal sentences are mostly drawn from UN data which is sufficiently different from the other genres in the heterogeneous training corpus that the informal examples do not affect baseline performance on formal data.

4.2 Human Assessment

Automatic evaluation is limited to comparing output to a single reference: lower BLEU scores conflate translation errors and stylistic mismatch. Therefore, we conduct a human study of the formality vs. the quality.

We conducted a manual evaluation of the output of our FSMT system taking low/high formality levels (-0.4/0.4) as parameters. 42 translation pairs were randomly selected and were annotated by 15 volunteers. For each pair of segments, the volunteers were asked to select the segment that would be more appropriate in a formal setting (e.g., a job interview) than in a casual setting (e.g., chatting with friends). A default option of "neither of them is more formal or hard to say" was also available.

By majority voting, 20 pairs were annotated as "N", indicating the two translations has no distinctions w.r.t. formality. For example, "A: how can they do this" vs. "B: how can they do that". Given that the translations were restricted to the n-best list, not all sentences could be translated into stylistically different language.

Of the remaining 21 pairs where annotators judged one output more formal than the other, in all but one case the translation produced by our FSMT system with high formality level parameter was judged to be more formal. Overall this indicates that our formality scoring and ranking procedure are effective.

To determine whether re-ranking based on formality might have a detrimental effect on quality, we also had annotators rate the fluency and adequacy of the segments. Inspired by Graham et al. (2013), annotators were first asked to assess fluency without a reference and separately adequacy with a reference. Both assessments used a sliding scale. Each segment was evaluated by an average of 7 annotators. After rescaling the ratings into the $[0, 1]$ range, we observed a 0.75 level of fluency for informal translations and 0.70 for formal ones. This slight difference fits our expectation that more casual language may feel more fluent while more formal language may feel more stilted. The adequacy ratings were 0.65 and 0.64 for informal and translations respectively, indicating that adjusting the level of formality had minimal effect on the adequacy of the result.

Some examples are listed in Table 3. Occa-

ℓ	**Examples**	**Comments**
-0.4	... and then he **ran away** .	–
0.4	... and then he **escaped** .	*annotated as more formal*
-0.4	**anybody hurt** ?	–

-0.4	right next to the **body** .	*incorrect word choice*
0.4	right next to the **fund** .	*incorrect word choice*

Table 3: Examples of variant translations to the same French source segment using low/high output formality levels (-0.4/0.4) as parameters. In general the variations lie on the direction of formality as expected, but occasionally translation errors occur.

sionally, the n-best list had no translation hypotheses with diverse formality, so the FSMT system dropped necessary words, appended inessential words, or selected improper or even incorrect words to fit the target formality level. In the case of 'how do you do', the translation that was meant to be more casual was rated more formal. Because the system measures formality on the lexical level, it was not able to recognize this idiomatically formal phrase made up of words that are not inherently formal. Despite these issues, most of the output were formality-variant translations of the same French source segment, as expected.

5 Conclusion

We presented a framework for formality-sensitive machine translation, where a system produces translations at a desired formality level. Our evaluation shows the effectiveness of this system in controlling language formality without loss in translation quality.

Sharp Models on Dull Hardware: Fast and Accurate Neural Machine Translation Decoding on the CPU

Jacob Devlin
jdevlin@microsoft.com
Microsoft Research

Abstract

Attentional sequence-to-sequence models have become the new standard for machine translation, but one challenge of such models is a significant increase in training and decoding cost compared to phrase-based systems. Here, we focus on efficient decoding, with a goal of achieving accuracy close the state-of-the-art in neural machine translation (NMT), while achieving CPU decoding speed/throughput close to that of a phrasal decoder.

We approach this problem from two angles: First, we describe several techniques for speeding up an NMT beam search decoder, which obtain a 4.4x speedup over a very efficient baseline decoder without changing the decoder output. Second, we propose a simple but powerful network architecture which uses an RNN (GRU/LSTM) layer at bottom, followed by a series of stacked fully-connected layers applied at every timestep. This architecture achieves similar accuracy to a deep recurrent model, at a small fraction of the training and decoding cost. By combining these techniques, our best system achieves a very competitive accuracy of 38.3 BLEU on WMT English-French NewsTest2014, while decoding at 100 words/sec on single-threaded CPU. We believe this is the best published accuracy/speed trade-off of an NMT system.

1 Introduction

Attentional sequence-to-sequence models have become the new standard for machine translation over the last two years, and with the unprecedented improvements in translation accuracy comes a new set of technical challenges. One of the biggest challenges is the high training and decoding costs of these neural machine translation (NMT) system, which is often at least an order of magnitude higher than a phrase-based system trained on the same data. For instance, phrasal MT systems were able achieve single-threaded decoding speeds of 100-500 words/sec on decade-old CPUs (Quirk and Moore, 2007), while Jean et al. (2015) reported single-threaded decoding speeds of 8-10 words/sec on a shallow NMT system. Wu et al. (2016) was able to reach CPU decoding speeds of 100 words/sec for a deep model, but used 44 CPU cores to do so. There has been recent work in speeding up decoding by reducing the search space (Kim and Rush, 2016), but little in computational improvements.

In this work, we consider a production scenario which requires low-latency, high-throughput NMT decoding. We focus on CPU-based decoders, since GPU/FPGA/ASIC-based decoders require specialized hardware deployment and logistical constraints such as batch processing. Efficient CPU decoders can also be used for on-device mobile translation. We focus on single-threaded decoding and single-sentence processing, since multiple threads can be used to reduce latency but not total throughput.

We approach this problem from two angles: In Section 4, we describe a number of techniques for improving the speed of the decoder, and obtain a 4.4x speedup over a highly efficient baseline. These speedups do not affect decoding results, so they can be applied universally. In Section 5, we describe a simple but powerful network architecture which uses a single RNN (GRU/LSTM) layer at the bottom with a large number of fully-connected (FC) layers on top, and obtains improvements similar to a deep RNN model at a fraction of the training and decoding cost.

2 Data Set

The data set we evaluate on in this work is WMT English-French NewsTest2014, which has 380M words of parallel training data and a 3003 sentence test set. The NewsTest2013 set is used for validation. In order to compare our architecture to past work, we train a word-based system without any data augmentation techniques. The network architecture is very similar to Bahdanau et al. (2014), and specific details of layer size/depth are provided in subsequent sections. We use an 80k source/target vocab and perform standard unk-replacement (Jean et al., 2015) on out-of-vocabulary words. Training is performed using an in-house toolkit.

3 Baseline Decoder

Our baseline decoder is a standard beam search decoder (Sutskever et al., 2014) with several straightforward performance optimizations:

- It is written in pure C++, with no heap allocation done during the core search.
- A candidate list is used to reduce the output softmax from 80k to ~500. We run word alignment (Brown et al., 1993) on the training and keep the top 20 context-free translations for each source word in the test sentence.
- The Intel MKL library is used for matrix multiplication, as it is the fastest floating point matrix multiplication library for CPUs.
- Early stopping is performed when the top partial hypothesis has a log-score of $\delta = 3.0$ worse than the best completed hypothesis.
- Batching of matrix multiplication is applied when possible. Since each sentence is decoded separately, we can only batch over the hypotheses in the beam as well as the input vectors on the source side.

4 Decoder Speed Improvements

This section describes a number of speedups that can be made to a CPU-based attentional sequence-to-sequence beam decoder. Crucially, none of these speedups affect the actual mathematical computation of the decoder, so they can be applied to any network architecture with a guarantee that they will not affect the results.[1]

The model used here is similar to the original implementation of Bahdanau et al. (2014). The exact target GRU equation is:

$$\begin{aligned}
d_{ij} &= \tanh(W_a h_{i-1} + V_a x_i) {\cdot} \tanh(U_a s_j) \\
\alpha_{ij} &= \frac{e^{d_{ij}}}{\sum_{j'} e^{d_{ij'}}} \\
c_i &= \sum_j \alpha_{ij} s_j \\
u_i &= \sigma(W_u h_{i-1} + V_u x_i + U_u c_i + b_u) \\
r_i &= \sigma(W_r h_{i-1} + V_r x_i + U_r c_i + b_r) \\
\hat{h}_i &= \sigma(r_i \odot (W_h h_{i-1}) + V_h x_i + U_h c_i + b_h) \\
h_i &= u_i h_{i-1} + (1 - u_i) \hat{h}_i
\end{aligned}$$

Where W_*, V_*, U_*, b_* are learned parameters, s_j is the hidden vector of the j^{th} source word, h_{i-1} is the previous target recurrent vector, x_i is the target input (e.g., embedding of previous word).

We also denote the various hyperparameters: b for the beam size, r for the recurrent hidden size, e is the embedding size, $|S|$ for the source sentence length, and $|T|$ for the target sentence length, $|E|$ is the vocab size.

4.1 16-Bit Matrix Multiplication

Although CPU-based matrix multiplication libraries are highly optimized, they typically only operate on 32/64-bit floats, even though DNNs can almost always operate on much lower precision without degredation of accuracy (Han et al., 2016). However, low-precision math (1-bit to 7-bit) is difficult to implement efficiently on the CPU, and even 8-bit math has limited support in terms of vectorized (SIMD) instruction sets. Here, we use 16-bit fixed-point integer math, since it has first-class SIMD support and requires minimal changes to training. Training is still performed with 32-bit floats, but we clip the weights to the range [-1.0, 1.0] the `relu` activation to [0.0, 10.0] to ensure that all values fit into 16-bits with high precision. A reference implementation of 16-bit multiplication in C++/SSE2 is provided in the supplementary material, with a thorough description of low-level details.[2]

A comparison between our 16-bit integer implementation and Intel MKL's 32-bit floating point multiplication is given in Figure 1. We can see that 16-bit multiplication is 2x-3x faster than 32-bit multiplication for batch sizes between 2 and 8, which is the typical range of the beam size b. We

[1] Some speedups apply quantization which leads to small random perturbations, but these change the BLEU score by less than 0.02.

[2] Included as ancillary file in Arxiv submission, on right side of submission page.

are able to achieve greater than a 2x speedup in certain cases because we pre-process the weight matrix offline to have optimal memory layout, which is a capability BLAS libraries do not have.

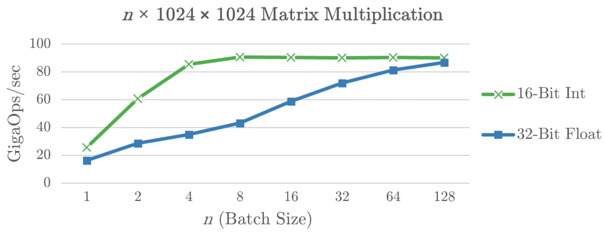

Figure 1: Single-threaded matrix multiplication using our 16-bit fixed-point vs. Intel MKL's 32-bit float, averaged over 10,000 multiplications. Both use the AVX2 instruction set.

4.2 Pre-Compute Embeddings

In the first hidden layer on the source and target sides, x_i corresponds to word embeddings. Since this is a closed set of values that are fixed after training, the vectors Vx_i can be pre-computed (Devlin et al., 2014) for each word in the vocabulary and stored in a lookup table. This can only be applied to the first hidden layer.

Pre-computation does increase the memory cost of the model, since we must store $r \times 3$ floats per word instead of e. However, if we only compute the k most frequently words (e.g., $k = 8,000$), this reduces the pre-computation memory by 90% but still results in 95%+ token coverage due to the Zipfian distribution of language.

4.3 Pre-Compute Attention

The attention context computation in the GRU can be re-factored as follows:

$$Uc_i = U(\sum_j \alpha_{ij} s_j) = \sum_j \alpha_{ij}(Us_j)$$

Crucially, the hidden vector representation s_j is only dependent on the source sentence, while a_{ij} is dependent on the target hypothesis. Therefore, the original computation Uc_i requires total $|T| \times b$ multiplications per sentence, but the re-factored version Us_j only requires total $|S|$ multiplications. The expectation over α must still be computed at each target timestep, but this is much less expensive than the multiplication by U.

4.4 SSE & Lookup Tables

For the element-wise vector functions use in the GRU, we can use vectorized instructions (SSE/AVX) for the `add` and `multiply` functions, and lookup tables for `sigmoid` and `tanh`. Reference implementations in C++ are provided in the supplementary material.

4.5 Merge Recurrent States

In the GRU equation, for the first target hidden layer, x_i represents the previously generated word, and h_{i-1} encodes the hypothesis up to *two* words before the current word. Therefore, if two partial hypotheses in the beam only differ by the last emitted word, their h_{i-1} vectors will be identical. Thus, we can perform matrix multiplication Wh_{i-1} only on the *unique* h_{i-1} vectors in the beam at each target timestep. For a beam size of $b = 6$, we measured that the ratio of unique h_{i-1} compared to total h_{i-1} is approximately 70%, averaged over several language pairs. This can only be applied to the first target hidden layer.

Table 1: Decoding speeds on an Intel E5-2660 CPU, processing each sentence independently.

4.6 Speedup Results

Cumulative results from each of the preceding speedups are presented in Table 1, measured on WMT English-French NewsTest2014. The NMT architecture evaluated here uses 3-layer 512-dimensional bidirectional GRU for the source, and a 1-layer 1024-dimensional attentional GRU for the target. Each sentence is decoded independently with a beam of 6. Since these speedups are all mathematical identities excluding quantization noise, all outputs achieve 36.2 BLEU and are 99.9%+ identical.

The largest improvement is from 16-bit matrix multiplication, but all speedups contribute a significant amount. Overall, we are able to achieve a 4.4x speedup over a fast baseline decoder. Although the absolute speed is impressive, the model only uses one target layer and is several BLEU behind the SOTA, so the next goal is to maximize model accuracy while still achieving speeds greater than some target, such as 100 words/sec.

5 Model Improvements

In NMT, like in many other deep learning tasks, accuracy can be greatly improved by adding more hidden layers, but training and decoding time increase significantly (Luong et al., 2014; Zhou et al., 2016; Wu et al., 2016). Several past works have noted that convolutional neural networks (CNNs) are significantly less expensive than RNNs, and replaced the source and/or target side with a CNN-based architecture (Gehring et al., 2016; Kalchbrenner et al., 2016). However, these works have found it is difficult to replace the target side of the model with CNN layers while maintaining high accuracy. The use of a recurrent target is especially important to track attentional coverage and ensure fluency.

Here, we propose a mixed model which uses an RNN layer at the bottom to both capture full-sentence context and perform attention, followed by a series of fully-connected (FC) layers applied on top at each timestep. The FC layers can be interpreted as a CNN without overlapping stride. Since each FC layer consists of a single matrix multiplication, it is $1/6^{\text{th}}$ the cost of a GRU (or $1/8^{\text{th}}$ an LSTM). Additionally, several of the speedups from Section 4 can only be applied to the first layer, so there is strong incentive to only use a single target RNN.

To avoid vanishing gradients, we use ResNet-style skip connections (He et al., 2016). These allow very deep models to be trained from scratch and do not require any additional matrix multiplications, unlike highway networks (Srivastava et al., 2015). With 5 intermediate FC layers, target timestep i is computed as:

$$\begin{aligned}
h_i^B &= \text{AttGRU}(h_{i-1}^B, x_i, S) \\
h_i^1 &= \text{relu}(W^1 h_i^B) \\
h_i^2 &= \text{relu}(W^2 h_i^1) \\
h_i^3 &= \text{relu}(W^3 h_i^2 + h_i^1) \\
h_i^4 &= \text{relu}(W^4 h_i^3) \\
h_i^5 &= \text{relu}(W^5 h_i^4 + h_i^3) \\
h_i^T &= \tanh(W^T h_i^5) \textbf{ or } \text{GRU}(h_{i-1}^T, h_i^5) \\
y_i &= \text{softmax}(V h_i^T)
\end{aligned}$$

Where x_i is the target input embedding, S is the set of source hidden vectors used for attention, and V is the target output vocabulary matrix. The superscripts h^B and h^T simply denote the "bottom" and "top" hidden layers, while the numbered layers h^n represent the intermediate fully-connected layers.

We follow He et al. (2016) and only use skip connections on every other FC layer, but do not use batch normalization. The same pattern can be used for more FC layers, and the FC layers can be a different size than the bottom or top hidden layers. The top hidden layer can be an RNN or an FC layer. It is important to use `relu` activations (opposed to tanh) for ResNet-style skip connections. The GRUs still use tanh.

5.1 Model Results

Results using the mixed RNN+FC architecture are shown in Table 2, using all speedups. We have found that the benefit of using RNN+FC layers on the source is minimal, so we only perform ablation on the target. For the source, we use a 3-layer 512-dim bidi GRU in all models (S1)-(S6).

Model (S1) and (S2) are one and two layer baselines. Model (S4), which uses 7 intermediate FC layers, has similar decoding cost to (S2) while doubling the improvement over (S1) to 1.2 BLEU. We see minimal benefit from using a GRU on the top layer (S5) or using more FC layers (S6). In (E1) and (E2) we present 2 and 3 model ensembles of (S4), trained from scratch with different random seeds. We can see that the 2-model ensemble improves results by 0.9 BLEU, but the 3-model ensemble has little additional improvment. Although not presented here, we have found these improvement from decoder speedups and RNN+FC to be consistent across many language pairs.

All together, we were able to achieve a BLEU score of 38.3 while decoding at 100 words/sec on a single CPU core. As a point of comparison, Wu et al. (2016) achieves similar BLEU scores on this test set (37.9 to 38.9) and reports a CPU decoding speed of ~100 words/sec (0.2226 sents/sec), but parallelizes this decoding across 44 CPU cores. System (S7), which is our re-implementation of Wu et al. (2016), decodes at 28 words/sec on one CPU core, using all of the speedups described in Section 4. Zhou et al. (2016) has a similar computational cost to (S7), but we were not able to replicate those results in terms of accuracy.

Although we are comparing an ensemble to a single model, we can see ensemble (E1) is over 3x faster to decode than the single model (S7). Additionally, we have found that model (S4) is roughly 3x faster to train than (S7) using the same GPU resources, so (E1) is also 1.5x faster to train than a single model (S7).

Abstract

In translation, considering the document as a whole can help to resolve ambiguities and inconsistencies. In this paper, we propose a cross-sentence context-aware approach and investigate the influence of historical contextual information on the performance of neural machine translation (NMT). First, this history is summarized in a hierarchical way. We then integrate the historical representation into NMT in two strategies: 1) a warm-start of encoder and decoder states, and 2) an auxiliary context source for updating decoder states. Experimental results on a large Chinese-English translation task show that our approach significantly improves upon a strong attention-based NMT system by up to +2.1 BLEU points.

1 Introduction

Neural machine translation (NMT) has been rapidly developed in recent years (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2015; Tu et al., 2016). The encoder-decoder architecture is widely employed, in which the encoder summarizes the source sentence into a vector representation, and the decoder generates the target sentence word by word from the vector representation. Using the encoder-decoder framework as well as gating and attention techniques, it has been shown that the performance of NMT has surpassed the performance of traditional statistical machine translation (SMT) on various language pairs (Luong et al., 2015).

The continuous vector representation of a symbol encodes multiple dimensions of similarity, equivalent to encoding more than one meaning of a word. Consequently, NMT needs to spend a substantial amount of its capacity in disambiguating source and target words based on the context defined by a source sentence (Choi et al., 2016). Consistency is another critical issue in document-level translation, where a repeated term should keep the same translation throughout the whole document (Xiao et al., 2011; Carpuat and Simard, 2012). Nevertheless, current NMT models still process a documents by translating each sentence alone, suffering from inconsistency and ambiguity arising from a single source sentence. These problems are difficult to alleviate using only limited intra-sentence context.

The cross-sentence context, or global context, has proven helpful to better capture the meaning or intention in sequential tasks such as query suggestion (Sordoni et al., 2015) and dialogue modeling (Vinyals and Le, 2015; Serban et al., 2016). The leverage of global context for NMT, however, has received relatively little attention from the research community.[1] In this paper, we propose a cross-sentence context-aware NMT model, which considers the influence of *previous source sentences* in the same document.[2]

Specifically, we employ a hierarchy of Recurrent Neural Networks (RNNs) to summarize the cross-sentence context from source-side previous sentences, which deploys an additional document-level RNN on top of the sentence-level RNN encoder (Sordoni et al., 2015). After obtaining the global context, we design several strategies to integrate it into NMT to translate the current sentence:

- *Initialization*, that uses the history represen-

[1] To the best of our knowledge, our work and Jean et al. (2017) are two independently early attempts to model cross-sentence context for NMT.

[2] In our preliminary experiments, considering target-side history inversely harms translation performance, since it suffers from serious error propagation problems.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2826–2831
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

tation as the initial state of the encoder, decoder, or both;

- *Auxiliary Context*, that uses the history representation as static cross-sentence context, which works together with the dynamic intra-sentence context produced by an attention model, to good effect.
- *Gating Auxiliary Context*, that adds a gate to Auxiliary Context, which decides the amount of global context used in generating the next target word at each step of decoding.

Experimental results show that the proposed *initialization* and *auxiliary context* (w/ or w/o gating) mechanisms significantly improve translation performance individually, and combining them achieves further improvement.

2 Approach

Given a source sentence $\mathbf{x}_m$ to be translated, we consider its K previous sentences in the same document as cross-sentence context $C = \{\mathbf{x}_{m-K}, ..., \mathbf{x}_{m-1}\}$. In this section, we first model C, which is then integrated into NMT.

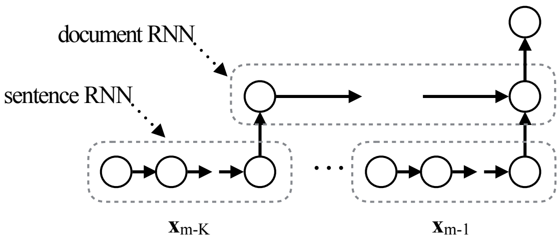

Figure 1: Summarizing global context with a hierarchical RNN ($\mathbf{x}_k$ is the k-th source sentence).

2.1 Summarizing Global Context

As shown in Figure 1, we summarize the representation of C in a hierarchical way:

Sentence RNN For a sentence $\mathbf{x}_k$ in C, the sentence RNN reads the corresponding words $\{x_{1,k}, ..., x_{n,k}, \dots, x_{N,k}\}$ sequentially and updates its hidden state:

$$h_{n,k} = f(h_{n-1,k}, x_{n,k}) \tag{1}$$

where $f(\cdot)$ is an activation function, and $h_{n,k}$ is the hidden state at time n. The last state $h_{N,k}$ stores order-sensitive information about all the words in $\mathbf{x}_k$, which is used to represent the summary of the whole sentence, i.e. $S_k \equiv h_{N,k}$. After processing each sentence in C, we can obtain all sentence-level representations, which will be fed into document RNN.

Document RNN It takes as input the sequence of the above sentence-level representations $\{S_1, ..., S_k, ..., S_K\}$ and computes the hidden state as:

$$h_k = f(h_{k-1}, S_k) \tag{2}$$

where h_k is the recurrent state at time k, which summarizes the previous sentences that have been processed to the position k. Similarly, we use the last hidden state to represent the summary of the global context, i.e. $D \equiv h_K$.

2.2 Integrating Global Context into NMT

We propose three strategies to integrate the history representation D into NMT:

Initialization We use D to initialize either NMT encoder, NMT decoder or both. For encoder, we use D as the initialization state rather than all-zero states as in the standard NMT (Bahdanau et al., 2015). For decoder, we rewrite the calculation of the initial hidden state $s_0 = \tanh(W_s h_N)$ as $s_0 = \tanh(W_s h_N + W_D D)$ where h_N is the last hidden state in encoder and $\{W_s, W_D\}$ are the corresponding weight metrices.

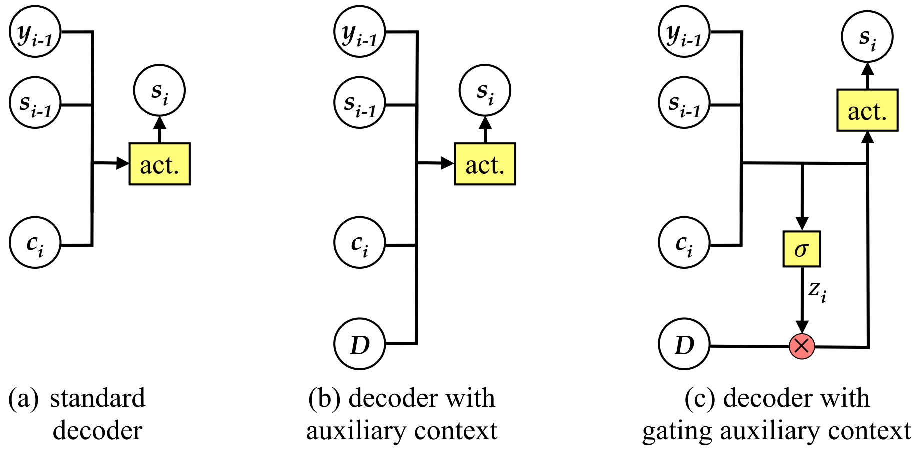
Auxiliary Context In standard NMT, as shown in Figure 2 (a), the decoder hidden state for time i is computed by

$$s_i = f(s_{i-1}, y_{i-1}, c_i) \tag{3}$$

where y_{i-1} is the most recently generated target word, and c_i is the intra-sentence context summarized by NMT encoder for time i. As shown in Figure 2 (b), *Auxiliary Context* method adds the representation of cross-sentence context D to jointly update the decoding state s_i:

$$s_i = f(s_{i-1}, y_{i-1}, c_i, D) \tag{4}$$

In this strategy, D serves as an auxiliary information source to better capture the meaning of the source sentence. Now the gated NMT decoder has four inputs rather than the original three ones. The concatenation $[c_i, D]$, which embeds both intra- and cross-sentence contexts, can be fed to the decoder as a single representation. We only need to modify the size of the corresponding parameter matrix for least modification effort.



(a) standard decoder

(b) decoder with auxiliary context

(c) decoder with gating auxiliary context

Figure 2: Architectures of NMT with auxiliary context integrations. *act.* is the decoder activation function, and σ is a sigmoid function.

Gating Auxiliary Context The starting point for this strategy is an observation: the need for information from the global context differs from step to step during generation of the target words. For example, global context is more in demand when generating target words for ambiguous source words, while less by others. To this end, we extend auxiliary context strategy by introducing a context gate (Tu et al., 2017a) to dynamically control the amount of information flowing from the auxiliary global context at each decoding step, as shown in Figure 2 (c).

Intuitively, at each decoding step i, the context gate looks at decoding environment (i.e., s_i, y_{i-1}, and c_i), and outputs a number between 0 and 1 for each element in D, where 1 denotes "completely transferring this" while 0 denotes "completely ignoring this". The global context vector D is then processed with an element-wise multiplication before being fed to the decoder activation layer.

Formally, the context gate consists of a sigmoid neural network layer and an element-wise multiplication operation. It assigns an element-wise weight to D, computed by

$$z_i = \sigma(U_z s_{i-1} + W_z y_{i-1} + C_z c_i) \qquad (5)$$

Here $\sigma(\cdot)$ is a logistic sigmoid function, and $\{W_z, U_z, C_z\}$ are the weight matrices, which are trained to learn when to exploit global context to maximize the overall translation performance. Note that z_i has the same dimensionality as D, and thus each element in the global context vector has its own weight. Accordingly, the decoder hidden state is updated by

$$s_i = f(s_{i-1}, y_{i-1}, c_i, z_i \otimes D) \qquad (6)$$

3 Experiments

3.1 Setup

We carried out experiments on Chinese–English translation task. As the document information is necessary when selecting the previous sentences, we collect all LDC corpora that contain document boundary. The training corpus consists of 1M sentence pairs extracted from LDC corpora[3] with 25.4M Chinese words and 32.4M English words. We chose the NIST05 (MT05) as our development set, and NIST06 (MT06) and NIST08 (MT08) as test sets. We used case-insensitive BLEU score (Papineni et al., 2002) as our evaluation metric, and sign-test (Collins et al., 2005) for calculating statistical significance.

We implemented our approach on top of an open source attention-based NMT model, Nematus[4] (Sennrich and Haddow, 2016; Sennrich et al., 2017). We limited the source and target vocabularies to the most frequent 35K words in Chinese and English, covering approximately 97.1% and 99.4% of the data in the two languages respectively. We trained each model on sentences of length up to 80 words in the training data with early stopping. The word embedding dimension was 600, the hidden layer size was 1000, and the batch size was 80. All our models considered the previous three sentences (i.e., $K = 3$) as cross-sentence context.

[3] The LDC corpora indexes are: 2003E07, 2003E14, 2004T07, 2005E83, 2005T06, 2006E24, 2006E34, 2006E85, 2006E92, 2007E87, 2007E101, 2007T09, 2008E40, 2008E56, 2009E16, 2009E95.

Table 1: Evaluation of translation quality. "Init" denotes Initialization of encoder ("enc"), decoder ("dec"), or both ("enc+dec"), and "Auxi" denotes Auxiliary Context. "†" indicates statistically significant difference ($P < 0.01$) from the baseline NEMATUS.

3.2 Results

Table 1 shows the translation performance in terms of BLEU score. Clearly, the proposed approaches significantly outperforms baseline in all cases.

Baseline (Rows 1-2) NEMATUS significantly outperforms Moses – a commonly used phrase-based SMT system (Koehn et al., 2007), by 2.3 BLEU points on average, indicating that it is a strong NMT baseline system. It is consistent with the results in (Tu et al., 2017b) (i.e., 26.93 vs. 29.41) on training corpora of similar scale.

Initialization Strategy (Rows 3-5) Init$_{\text{enc}}$ and Init$_{\text{dec}}$ improve translation performance by around +1.0 and +1.3 BLEU points individually, proving the effectiveness of warm-start with cross-sentence context. Combining them achieves a further improvement.

Auxiliary Context Strategies (Rows 6-7) The gating auxiliary context strategy achieves a significant improvement of around +1.0 BLEU point over its non-gating counterpart. This shows that, by acting as a critic, the introduced context gate learns to distinguish the different needs of the global context for generating target words.

Combining (Row 8) Finally, we combine the best variants from the initialization and auxiliary context strategies, and achieve the best performance, improving upon NEMATUS by +2.1 BLEU points. This indicates the two types of strategies are complementary to each other.

3.3 Analysis

We first investigate to what extent the mis-translated errors are fixed by the proposed system. We randomly select 15 documents (about 60 sentences) from the test sets. As shown in Table 2, we count how many related errors: i) are made by NMT (*Total*), and ii) fixed by our method (*Fixed*); as well as iii) newly generated (*New*). About *Ambiguity*, while we found that 38 words/phrases were translated into incorrect equivalents, 76% of them are corrected by our model. Similarly, we solved 75% of the *Inconsistency* errors including lexical, tense and definiteness (definite or indefinite articles) cases. However, we also observe that our system brings relative 21% new errors.

Errors	Ambiguity	Inconsistency	All
Total	38	32	70
Fixed	29	24	53
New	7	8	15

Table 2: Translation error statistics.

Hist.	这 不 等于 明着 提前 告诉 贪官 们 赶紧 转移 罪证 吗 ?
Input	能否 遏制 和 震慑 腐官 ?
Ref.	Can it inhibit and deter corrupt officials?
NMT	Can we contain and deter the *enemy*?
Our	Can it contain and deter the **corrupt officials**?

Table 3: Example translations. We italicize some *mis-translated* errors and highlight the **correct** ones in bold.

Case Study Table 3 shows an example. The word "腐官" (*corrupt officials*) is mis-translated as "*enemy*" by the baseline system. With the help of the similar word “贪官” in the previous sentence, our approach successfully correct this mistake. This demonstrates that cross-sentence context indeed helps resolve certain ambiguities.

4 Related Work

While our approach is built on top of hierarchical recurrent encoder-decoder (HRED) (Sordoni et al., 2015), there are several key differences which reflect how we have generalized from the original model. Sordoni et al. (2015) use HRED to summarize a single representation from both the current and previous sentences, which limits itself to (1) it is only applicable to encoder-decoder framework without attention model, (2) the representation can only be used to initialize decoder. In contrast, we use HRED to summarize the previous sentences alone, which provides additional cross-sentence context for NMT. Our approach is more flexible at (1) it is applicable to any encoder-decoder frameworks (e.g., with attention), (2) the cross-sentence context can be used to initialize either encoder, decoder or both.

While both our approach and Serban et al. (2016) use Auxiliary Context mechanism for incorporating cross-sentence context, there are two main differences: 1) we have separate parameters to better control the effects of the cross- and intra-sentence contexts, while they only have one parameter matrix to manage the single representation that encodes both contexts; 2) based on the intuition that not every target word generation requires equivalent cross-sentence context, we introduce a context gate (Tu et al., 2017a) to control the amount of information from it, while they don't.

At the same time, some researchers propose to use an additional set of an encoder and attention to model more information. For example, Jean et al. (2017) use it to encode and select part of the previous source sentence for generating each target word. Calixto et al. (2017) utilize global image features extracted using a pre-trained convolutional neural network and incorporate them in NMT. As additional attention leads to more computational cost, they can only incorporate limited information such as single preceding sentence in Jean et al. (2017). However, our architecture is free to this limitation, thus we use multiple preceding sentences (e.g. $K = 3$) in our experiments.

Our work is also related to multi-source (Zoph and Knight, 2016) and multi-target NMT (Dong et al., 2015), which incorporate additional source or target languages. They investigate one-to-many or many-to-one languages translation tasks by integrating additional encoders or decoders into encoder-decoder framework, and their experiments show promising results.

5 Conclusion and Future Work

We proposed two complementary approaches to integrating cross-sentence context: 1) a warm-start of encoder and decoder with global context representation, and 2) cross-sentence context serves as an auxiliary information source for updating decoder states, in which an introduced context gate plays an important role. We quantitatively and qualitatively demonstrated that the presented model significantly outperforms a strong attention-based NMT baseline system. We release the code for these experiments at `https://www.github.com/tuzhaopeng/LC-NMT`.

Our models benefit from larger contexts, and would be possibly further enhanced by other document level information, such as discourse relations. We propose to study such models for full length documents with more linguistic features in future work.

Abstract

Training a POS tagging model with cross-lingual transfer learning usually requires linguistic knowledge and resources about the relation between the source language and the target language. In this paper, we introduce a cross-lingual transfer learning model for POS tagging without ancillary resources such as parallel corpora. The proposed cross-lingual model utilizes a common BLSTM that enables knowledge transfer from other languages, and private BLSTMs for language-specific representations. The cross-lingual model is trained with language-adversarial training and bidirectional language modeling as auxiliary objectives to better represent language-general information while not losing the information about a specific target language. Evaluating on POS datasets from 14 languages in the Universal Dependencies corpus, we show that the proposed transfer learning model improves the POS tagging performance of the target languages without exploiting any linguistic knowledge between the source language and the target language.

1 Introduction

Bidirectional Long Short-Term Memory (BLSTM) based models (Graves and Schmidhuber, 2005), along with word embeddings and character embeddings, have shown competitive performance on Part-of-Speech (POS) tagging given sufficient amount of training examples (Ling et al., 2015; Lample et al., 2016; Plank et al., 2016; Yang et al., 2017).

Given insufficient training examples, we can improve the POS tagging performance by cross-lingual POS tagging, which exploits affluent POS tagging corpora from other source languages. This approach usually requires linguistic knowledge or resources about the relation between the source language and the target language such as parallel corpora (Täckström et al., 2013; Duong et al., 2013; Kim et al., 2015a; Zhang et al., 2016), morphological analyses (Hana et al., 2004), dictionaries (Wisniewski et al., 2014), and gaze features (Barrett et al., 2016).

Given no linguistic resources between the source language and the target language, transfer learning methods can be utilized instead. Transfer learning for cross-lingual cases is a type of transductive transfer learning, where the input domains of the source and the target are different (Pan and Yang, 2010) since each language has its own vocabulary space. When the input space is the same, lower layers of hierarchical models can be shared for knowledge transfer (Collobert et al., 2011; Kim et al., 2015b; Yang et al., 2017), but that approach is not directly applicable when the input spaces differ.

Yang et al. (2017) used shared character embeddings for different languages as a cross-lingual transfer method while using different word embeddings for different languages. Although the approach showed improved performance on Named Entity Recognition, it is limited to character-level representation transfer and it is not applicable for knowledge transfer between languages without overlapped alphabets.

In this work, we introduce a cross-lingual transfer learning model for POS tagging requiring no cross-lingual resources, where knowledge transfer is made in the BLSTM layers on top of word embeddings and character embeddings. Inspired by Kim et al. (2016)'s multi-task slot-filling model, our model utilizes a common BLSTM for representing language-generic information, which al-

Violet circles represent target labels that are predicted with different parameters for different languages, where the inputs are output summation of the common BLSTM and the private BLSTM. The model is trained with three objectives denoted with red boxes.

lows knowledge transfer from other languages, and private BLSTMs for representing language-specific information. The common BLSTM is additionally encouraged to be language-agnostic with language-adversarial training (Chen et al., 2016) so that the language-general representations to be more compatible among different languages.

Evaluating on POS datasets from 14 different target languages with English as the source language in the Universal Dependencies corpus 1.4 (Nivre et al., 2016), the proposed model showed significantly better performance when the source language and the target language are in the same language family, and competitive performance when the language families are different.

2 Model

Cross-Lingual Training Figure 1 shows the overall architecture of the proposed model. The baseline POS tagging model is similar to Plank et al. (2016)'s model, and it corresponds to having only word+char embeddings, common BLSTM, and Softmax Output in Figure 1. Given an input word sequence, a BLSTM is used for the character sequence of each word, where the outputs of the ends of the character sequences from the forward LSTM and the backward LSTM are concatenated to the word vector of the current word to supplement the word representation. These serve as an input to a BLSTM, and an output layer are used for POS tag prediction.

For the cross-lingual transfer learning, the character embedding, the BLSTM with the character embedding (Yang et al., 2017),[1] and the common BLSTM are shared for all the given languages while word embeddings and private BLSTMs have different parameters for different languages.

The outputs of the common BLSTM and the private BLSTM of the current language are summed to be used as the input to the softmax layer to predict the POS tags of given word sequences. The loss function of the POS tagging can be formulate as:

$$\mathcal{L}_p = -\sum_{i=1}^{S}\sum_{j=1}^{N} p_{i,j} \log\left(\hat{p}_{i,j}\right), \qquad (1)$$

where S is the number of sentences in the current minibatch, N is the number of words in the current sentence, $p_{i,j}$ is the label of the j-th tag of the i-th sentence in the minibatch, and $\hat{p}_{i,j}$ is the predicted tag. In addition to this main objective, two more objectives for improving the transfer learning are described in the following subsections.

Language-Adversarial Training We encourage the outputs of the common BLSTM to be language-agnostic by using language-adversarial training (Chen et al., 2016) inspired by domain-adversarial training (Ganin et al., 2016; Bousmalis et al., 2016). First, we encode a BLSTM output sequence as a single vector using a CNN/MaxPool encoder, which is implemented the same as a CNN for text classification (Kim, 2014). The encoder is with three convolution filters whose sizes are 3, 4, and 5. For each filter, we pass the BLSTM output sequence as the input sequence and obtain a single vector from the filter output by using max pooling, and then $tanh$ activation function is used for transforming the vector. Then, the vector outputs of the three filters are concatenated and forwarded to the language discriminator through the gradient reversal layer. The discriminator is implemented

[1] We also tried isolated character-level modules but the overall performance was worse.

as a fully-connected neural network with a single hidden layer, whose activation function is Leaky ReLU (Maas et al., 2013), where we multiply 0.2 to negative input values as the outputs.

Since the gradient reversal layer is below the language classifier, the gradients minimizing language classification errors are passed back with opposed sign to the sentence encoder, which adversarially encourages the sentence encoder to be language-agnostic. The loss function of the language classifier is formulated as:

$$\mathcal{L}_a = -\sum_{i=1}^{S} l_i \log \hat{l_i}, \tag{2}$$

where S is the number of sentences, l_i is the language of the i-th sentence, and $\hat{l_i}$ is the softmax output of the tagging. Note that though the language classifier is optimized to minimize the language classification error, the gradient from the language classifier is negated so that the bottom layers are trained to be language-agnostic.

Bidirectional Language Modeling Rei (2017) showed the effectiveness of the bidirectional language modeling objective, where each time step of the forward LSTM outputs predicts the word of the next time step, and each of the backward LSTM outputs predicts the previous word. For example, if the current sentence is "I am happy", the forward LSTM predicts "am happy <eos>" and the backward LSTM predicts "<bos> I am". This objective encourages the BLSTM layers and the embedding layers to learn linguistically general-purpose representations, which are also useful for specific downstream tasks (Rei, 2017). We adopted the bidirectional language modeling objective, where the sum of the common BLSTM and the private BLSTM is used as the input to the language modeling module. It can be formulated as:

$$\begin{aligned}\mathcal{L}_l = -\sum_{i=1}^{S}\sum_{j=1}^{N} &\log\left(P\left(w_{j+1}|f_j\right)\right) + \\ &\log\left(P\left(w_{j-1}|b_j\right)\right),\end{aligned} \tag{3}$$

where f_j and b_j represent the j-th outputs of the forward direction and the backward direction, respectively, given the output sum of the common BLSTM and the private BLSTM.

All the three loss functions are added to be optimized altogether as:

$$\mathcal{L} = w_s\left(\mathcal{L}_p + \lambda\mathcal{L}_a + \lambda\mathcal{L}_l\right), \tag{4}$$

where λ is gradually increased from 0 to 1 as epoch increases so that the model is stably trained with auxiliary objectives (Ganin et al., 2016). w_s is used to give different weights to the source language and the target language. Since the source language has a larger train set and we are focusing on improving the performance of the target language, w_s is set to 1 when training the target language. For the source language, instead, it is set as the size of the target train set divided by the size of the source train set.

3 Experiments

For the evaluation, we used the POS datasets from 14 different languages in Universal Dependencies corpus 1.4 (Nivre et al., 2016). We used English as the source language, which is with 12,543 training sentences.[2] We chose datasets with 1k to 14k training sentences. The number of tag labels differs for each language from 15 to 18 though most of them are overlapped within the languages.

Table 1 shows the POS tagging accuracies of different transfer learning models when we limited the number of training sentences of the target languages to be the same as 1,280 for fair comparison among different languages. The remainder training examples of the target languages are still used for both language-adversarial training and bidirectional language modeling since the objectives do not require tag labels. Training with only the train sets in the target languages (c) showed 91.61% on average. When bidirectional language modeling objective is used (c, l), the accuracies were significantly increased to 92.82% on average. Therefore, we used the bidirectional language modeling for all the transfer learning evaluations.

With transfer learning, the three cases of using only the common BLSTM (c), using only the private BLSTMs (p), and using both (c, p) were evaluated. They showed better average accuracies than target only cases, but they showed mixed results. However, our proposed model ($c, p, l + a$), which utilizes both the common BLSTM with language-adversarial training and the private BLSTMs, showed the highest average score, 93.26%. For all the Germanic languages, where the source language also belongs to, the accuracies are significantly higher than those of

[2] The accuracies of English POS tagging are 94.01 and 94.33 for models without the bidirectional language modeling and with it, respectively.

		Target only		Source (English) → Target

Uralic	Hungarian	93.20	93.27	94.40	94.66	**94.69**	94.29	94.45
	Total Avg	91.61	92.82	92.98	93.05	93.08	92.95	**93.26**

Table 1: POS tagging accuracies (%) when setting the numbers of the tag-labeled training examples of the target languages to be the same as 1,280 (The remaining training examples are still used for the language modeling and the adversarial training.) c: using common BLSTM, p: using private BLSTMs, l: bidirectional language modeling objectives, a: language-adversarial training. (Underlined scores denote that the differences between the highest score of the other models and those scores are statistically insignificant with McNemar's χ^2 test with p-value $<$ 0.05.)

other transfer learning models. For the languages belonging to Slavic, Romance, or Indo-Iranian, our model shows competitive performance with the highest average accuracies among the compared models. Since languages in the same family are more likely to be similar and compatible, it is expected that the gain from the knowledge transfer to the languages in the same family to be higher than transferring to the languages in different families, which was shown in the results. This shows that utilizing both language-general representations that are encouraged to be more language-agnostic and language-specific representations effectively helps improve the POS tagging performance with transfer learning.

Table 2 shows the results when using 320 tag-labeled training sentences. In this case, transfer learning methods still show better accuracies than target-only approaches on average. However, the performance gain is weakened compared to using 1,280 labeled training sentences and there are some mixed results. In several cases, just utilizing private BLSTMs without the common BLSTM showed better accuracies than utilizing the common BLSTM.

When training with only 32 tag-labeled sentences, which is an extremely low-resourced setting, transfer learning methods still showed better accuracies than target-only methods on average. However, not using the common BLSTM in transfer learning models showed better performance than using it on average.[3] The main reason would be that we are not given a sufficient number of labeled training sentences to train both the common BLSTM and the private BLSTMs. In this case, just having private BLSTMs without the common BLSTM can show better performance. We also evaluated the opposite cases, which use all the tag-labeled training sentences in the target languages, and they showed mixed results. For example, the accuracy of German with the target only model is 93.31% while that of the proposed model is 93.04%. This is expected since transfer learning is effective when the target train set is small.

An extension of this work is utilizing multiple languages as the source languages. Since we have four languages for each of Germanic, Slavic, and Romance language families, we evaluated the performance of those languages using the other languages in the same families as the source languages expecting that languages in the same language family are more likely to be helpful each other. For the efficiency, we performed multi-task learning for multiple languages rather than differentiating the targets from sources. When we tried to use 1,280, 320, and 32 tag-labeled training sentences for each language in the multi-source settings, the results showed noticeably better per-

[3] The results in detail are shown in the first authors dissertation Kim (2017).

Table 2: POS tagging accuracies (%) with 320 tag-labeled training examples for each target language. All the training examples are still used for the other objectives.

formance than the results of using English as a single source language. Considering that utilizing 1,280*3=3,840, 320*3=960, or 32*3=96 tag labels from three other languages showed better results than using 12,543 English tag labels as the source, we can see that the knowledge transfer from multiple languages can be more helpful than that from single resource-rich source language. We also tried to use Wasserstein distance (Arjovsky et al., 2017) for the adversarial training in the multi-source settings, but there were no significant differences on average.[4]

Implementation Details All the models were optimized using ADAM (Kingma and Ba, 2015)[5] with minibatch size 32 for total 100 epochs and we picked the parameters showing the best accuracy on the development set to report the score on the test set. The dimensionalites of all the BLSTM related layers follow Plank et al. (2016)'s model. Each word vector is 128 dimensional and each character vector is 100 dimensional. They are randomly initialized with Xavier initialization (Glorot and Bengio, 2010). For stable training, we use gradient clipping, where the threshold is set to 5. The dimensionality of each hidden output of LSTMs is 100, and the hidden outputs of both forward LSTM and backward LSTM are concatenated, thereby the output of each BLSTM for each time step is 200. Therefore, the input to the common BLSTM and the private BLSTM is 128+200=328 dimensional. The inputs and the outputs of the BLSTMs are regularized with dropout rate 0.5 (Pham et al., 2014). For the consistent dropout usages, we let the dropout masks to be identical for all the time steps of each sentence (Gal and Ghahramani, 2016). For all the BLSTMs, forget biases are initialized with 1 (Jozefowicz et al., 2015) and the other biases are initialized with 0. Each convolution filter output for the sentence encoding is 64 dimensional, and the three filter outputs are concatenated to represent each sentence with a 192 dimensional vector.

4 Conclusion

We introduced a cross-lingual transfer learning model for POS tagging which uses separate BLSTMs for language-general and language-specific representations. Evaluating on 14 different languages, including the source language improved tagging accuracies in almost all the cases. Specifically, our model showed noticeably better performance when the source language and the target languages belong to the same language family, and competitively performed with the highest average accuracies for target languages in different families.

Abstract

In this paper we propose a model to learn multimodal multilingual representations for matching images and sentences in different languages, with the aim of advancing multilingual versions of image search and image understanding. Our model learns a common representation for images and their descriptions in two different languages (which need not be parallel) by considering the image as a pivot between two languages. We introduce a new pairwise ranking loss function which can handle both symmetric and asymmetric similarity between the two modalities. We evaluate our models on image-description ranking for German and English, and on semantic textual similarity of image descriptions in English. In both cases we achieve state-of-the-art performance.

1 Introduction

In recent years there has been a significant amount of research in language and vision tasks which require the joint modeling of texts and images. Examples include text-based image retrieval, image description and visual question answering. An increasing number of large image description datasets has become available (Hodosh et al., 2013; Young et al., 2014; Lin et al., 2014) and various systems have been proposed to handle the image description task as a generation problem (Bernardi et al., 2016; Mao et al., 2015; Vinyals et al., 2015; Fang et al., 2015). There has also been a great deal of work on sentence-based image search or cross-modal retrieval where the objective is to learn a joint space for images and text (Hodosh et al., 2013; Frome et al., 2013; Karpathy et al., 2014; Kiros et al., 2015; Socher et al., 2014; Donahue et al., 2015).

Previous work on image description generation or learning a joint space for images and text has mostly focused on English due to the availability of English datasets. Recently there have been attempts to create image descriptions and models for other languages (Funaki and Nakayama, 2015; Elliott et al., 2016; Rajendran et al., 2016; Miyazaki and Shimizu, 2016; Specia et al., 2016; Li et al., 2016; Hitschler et al., 2016; Yoshikawa et al., 2017).

Most work on learning a joint space for images and their descriptions is based on Canonical Correlation Analysis (CCA) or neural variants of CCA over representations of image and its descriptions (Hodosh et al., 2013; Andrew et al., 2013; Yan and Mikolajczyk, 2015; Gong et al., 2014; Chandar et al., 2016). Besides CCA, a few others learn a visual-semantic or multimodal embedding space of image descriptions and representations by optimizing a ranking cost function (Kiros et al., 2015; Socher et al., 2014; Ma et al., 2015; Vendrov et al., 2016) or by aligning image regions (objects) and segments of the description (Karpathy et al., 2014; Plummer et al., 2015) in a common space. Recently Lin and Parikh (2016) have leveraged visual question answering models to encode images and descriptions into the same space.

However, all of this work is targeted at monolingual descriptions, i.e., mapping images and descriptions in a single language onto a joint embedding space. The idea of pivoting or bridging is not new and language pivoting is well explored for machine translation (Wu and Wang, 2007; Firat et al., 2016) and to learn multilingual multimodal representations (Rajendran et al., 2016; Calixto et al., 2017). Rajendran et al. (2016) propose a

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2839–2845
Copenhagen, Denmark, September 7–11, 2017.

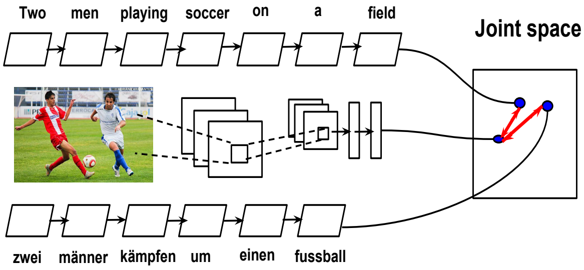

Figure 1: Our multilingual multimodal model with image as pivot

model to learn common representations between M views and assume there is parallel data available between a pivot view and the remaining $M-1$ views. Their multimodal experiments are based on English as the pivot and use large parallel corpora available between languages to learn their representations.

Related to our work Calixto et al. (2017) proposed a model for creating multilingual multimodal embeddings. Our work is different from theirs in that we choose the image as the pivot and use a different similarity function. We also propose a single model for learning representations of images and multiple languages, whereas their model is language-specific.

In this paper, we learn multimodal representations in multiple languages, i.e., our model yields a joint space for images and text in multiple languages using the image as a pivot between languages. We propose a new objective function in a multitask learning setting and jointly optimize the mappings between images and text in two different languages.

2 Dataset

We experiment with the Multi30k dataset, a multilingual extension of Flickr30k corpus (Young et al., 2014) consisting of English and German image descriptions (Elliott et al., 2016). The Multi30K dataset has 29k, 1k and 1k images in the train, validation and test splits respectively, and contains two types of multilingual annotations: (i) a corpus of one English description per image and its translation into German; and (ii) a corpus of five independently collected English and German descriptions per image. We use the independently collected English and German descriptions to train our models. Note that these descriptions are not translations of each other, i.e., they are not parallel, although they describe the same image.

3 Problem Formulation

Given an image i and its descriptions c_1 and c_2 in two different languages our aim is to learn a model which maps i, c_1 and c_2 onto same common space $\mathbb{R}^N$ (where N is the dimensionality of the embedding space) such that the image and its gold-standard descriptions in both languages are mapped close to each other (as shown in Figure 1). Our model consists of the embedding functions f_i and f_c to encode images and descriptions and a scoring function S to compute the similarity between a description–image pair.

In the following we describe two models: (i) the PIVOT model that uses the image as pivot between the description in both the languages; (ii) the PARALLEL model that further forces the image descriptions in both languages to be closer to each other in the joint space. We build two variants of PIVOT and PARALLEL with different similarity functions S to learn the joint space.

3.1 Multilingual Multimodal Representation Models

In both PIVOT and PARALLEL we use a deep convolutional neural network architecture (CNN) to represent the image i denoted by $f_i(i) = W_i \cdot CNN(i)$ where W_i is a learned weight matrix and $CNN(i)$ is the image vector representation. For each language we define a recurrent neural network encoder $f_c(c_k) = GRU(c_k)$ with gated recurrent units (GRU) activations to encode the description c_k.

In PIVOT, we use monolingual corpora from multiple languages of sentences aligned with images to learn the joint space. The intuition of this model is that an image is a universal representation across all languages, and if we constrain a sentence representation to be closer to image, sentences in different languages may also come closer. Accordingly we design a loss function as follows:

$$loss_{pivot} = \sum_k \left[\sum_{(c_k,i)} \left(\sum_{c'_k} \max\{0, \alpha - S(c_k,i) + S(c'_k,i)\} + \sum_{i'} \max\{0, \alpha - S(c_k,i) + S(c_k,i')\} \right) \right] \quad (1)$$

where k stands for each language. This loss function encourages the similarity $S(c_k, i)$ between gold-standard description c_k and image i to be greater than any other irrelevant description c'_k by a margin α. A similar loss function is useful for learning multimodal embeddings in a single language (Kiros et al., 2015). For each minibatch, we obtain invalid descriptions by selecting descriptions of other images except the current image of interest and vice-versa.

In PARALLEL, in addition to making an image similar to a description, we make multiple descriptions of the same image in different languages similar to each other, based on the assumption that these descriptions, although not parallel, share some commonalities. Accordingly we enhance the previous loss function with an additional term:

$$\begin{aligned} loss_{para} = loss_{pivot} + \sum_{(c_1,c_2)} \Bigg(\sum_{c'_1} \max\{0, \alpha - S(c_1,c_2) \\ + S(c'_1,c_2)\} + \sum_{c'_2} \max\{0, \alpha - S(c_1,c_2) + S(c_1,c'_2)\} \Bigg) \end{aligned} \quad (2)$$

Note that we are iterating over all pairs of descriptions (c_1, c_2), and maximizing the similarity between descriptions of the same image and at the same time minimizing the similarity between descriptions of different images.

We learn models using two similarity functions: symmetric and asymmetric. For the former we use cosine similarity and for the latter we use the metric of Vendrov et al. (2016) which is useful for learning embeddings that maintain an order, e.g., dog and cat are more closer to pet than animal while being distinct. Such ordering is shown to be useful in building effective multimodal space of images and texts. An analogy in our setting would be two descriptions of an image are closer to the image while at the same time preserving the identity of each (which is useful when sentences describe two different aspects of the image). The similarity metric is defined as:

$$S(a,b) = -||max(0, b-a)||^2 \quad (3)$$

where a and b are embeddings of image and description.

We call the symmetric similarity variants of our models as PIVOT-SYM and PARALLEL-SYM, and the asymmetric variants PIVOT-ASYM and PARALLEL-ASYM.

4 Experiments and Results

We test our model on the tasks of image-description ranking and semantic textual similarity. We work with each language separately. Since we learn embeddings for images and languages in the same semantic space, our hope is that the training data for each modality or language acts complementary data for the another modality or language, and thus helps us learn better embeddings.

Experiment Setup We sampled minibatches of size 64 images and their descriptions, and drew all negative samples from the minibatch. We trained using the Adam optimizer with learning rate 0.001, and early stopping on the validation set. Following Vendrov et al. (2016) we set the dimensionality of the embedding space and the GRU hidden layer N to 1024 for both English and German. We set the dimensionality of the learned word embeddings to 300 for both languages, and the margin α to 0.05 and 0.2, respectively, to learn asymmetric and symmetric similarity-based embeddings.[1] We keep all hyperparameters constant across all models. We used the L2 norm to mitigate over-fitting (Kiros et al., 2015). We tokenize and truecase both English and German descriptions using the Moses Decoder scripts.[2]

To extract image features, we used a convolutional neural network model trained on 1.2M images of 1000 class ILSVRC 2012 object classification dataset, a subset of ImageNet (Russakovsky et al., 2015). Specifically, we used VGG 19-layer CNN architecture and extracted the activations of the penultimate fully connected layer to obtain features for all images in the dataset (Simonyan and Zisserman, 2015). We use average features from 10 crops of the re-scaled images.[3]

Baselines As baselines we use monolingual models, i.e., models trained on each language separately. Specifically, we use Visual Semantic Embeddings (VSE) of Kiros et al. (2015) and Order Embeddings (OE) of Vendrov et al. (2016). We

[1] We constrain the embeddings of descriptions and images to have non-negative entries when using asymmetric similarity by taking their absolute value.

[2] https://github.com/moses-smt/mosesdecoder/tree/master/scripts

[3] We rescale images so that the smallest side is 256 pixels wide, we take 224 × 224 crops from the corners, center, and their horizontal reflections to get 10 crops for the image.

use a publicly available implementation to train both VSE and OE.[4]

4.1 Image-Description Ranking Results

To evaluate the multimodal multilingual embeddings, we report results on an image-description ranking task. Given a query in the form of a description or an image, the task its to retrieve all images or descriptions sorted based on the relevance. We use the standard ranking evaluation metrics of recall at position k (R@K, where higher is better) and median rank (Mr, where lower is better) to evaluate our models. We report results for both English and German descriptions. Note that we have one single model for both languages.

In Tables 1 and 2 we present the ranking results of the baseline models of Kiros et al. (2015) and Vendrov et al. (2016) and our proposed PIVOT and PARALLEL models. We do not compare our image-description ranking results with Calixto et al. (2017) since they report results on half of validation set of Multi30k whereas our results are on the publicly available test set of Multi30k. For English, PIVOT with asymmetric similarity is either competitive or better than monolingual models and symmetric similarity, especially in the R@10 category it obtains state-of-the-art. For German, both PIVOT and PARALLEL with the asymmetric scoring function outperform monolingual models and symmetric similarity. We also observe that the German ranking experiments benefit the most from the multilingual signal. A reason for this could be that the German description corpus has many singleton words (more than 50% of the vocabulary) and English description mapping might have helped in learning better semantic embeddings. These results suggest that the multilingual signal could be used to learn better multimodal embeddings, irrespective of the language. Our results also show that the asymmetric scoring function can help learn better embeddings. In Table 3 we present a few examples where PIVOT-ASYM and PARALLEL-ASYM models performed better on both the languages compared to baseline order embedding model even using descriptions of very different lengths as queries.

4.2 Semantic Textual Similarity Results

In the semantic textual similarity task (STS), we use the textual embeddings from our model to compute the similarity between a pair of sen-

Table 4: Results on Semantic Textual Similarity Image datasets (Pearson's $r \times 100$). Our systems that performed better than best reported shared task scores are in **bold**.

tences (image descriptions in this case). We evaluate on video task from STS-2012 and image tasks from STS-2014, STS-2015 (Agirre et al. 2012, Agirre et al. 2014, Agirre et al. 2015). The video descriptions in the STS-2012 task are from the MSR video description corpus (Chen and Dolan, 2011) and the image descriptions in STS-2014 and 2015 are from UIUC PASCAL dataset (Rashtchian et al., 2010).

In Table 4, we present the Pearson correlation coefficients of our model predicted scores with the gold-standard similarity scores provided as part of the STS image/video description tasks. We compare with the best reported scores for the STS shared tasks, achieved by MLMME (Calixto et al., 2017), paraphrastic sentence embeddings (Wieting et al., 2017), visual semantic embeddings (Kiros et al., 2015), and order embeddings (Vendrov et al., 2016). The shared task baseline is computed based on word overlap and is high for both the 2014 and the 2015 dataset, indicating that there is substantial lexical overlap between the STS image description datasets. Our models outperform both the baseline system and the best system submitted to the shared task. For the 2012 video paraphrase corpus, our multilingual methods performed better than the monolingual methods showing that similarity across paraphrases can be learned using multilingual signals. Similarly, Wieting et al. (2017) have reported to learn better paraphrastic sentence embeddings with multilingual signals. Overall, we observe that models learned using the asymmetric scoring function outperform the state-of-the-art on these datasets, suggesting that multilingual sharing is beneficial. Although the task has nothing to do German, because our models can make use of datasets from different languages, we were able to train on significantly larger training dataset of approximately 145k descriptions. Calixto et al. (2017) also train on a larger dataset like ours, but could not exploit this to their advantage. In Table 5 we present the example sentences with the highest and lowest difference between gold-standard and predicted semantic textual similarity scores using our best performing PARALLEL-ASYM model.

5 Conclusions

We proposed a new model that jointly learns multilingual multimodal representations using the image as a pivot between languages. We introduced new objective functions that can exploit similarities between images and descriptions across languages. We obtained state-of-the-art results on two tasks: image-description ranking and semantic textual similarity. Our results suggest that exploiting multilingual and multimodal resources can help in learning better semantic representations.

Abstract

Source dependency information has been successfully introduced into statistical machine translation. However, there are only a few preliminary attempts for Neural Machine Translation (NMT), such as concatenating representations of source word and its dependency label together. In this paper, we propose a novel attentional NMT with source dependency representation to improve translation performance of NMT, especially on long sentences. Empirical results on NIST Chinese-to-English translation task show that our method achieves 1.6 BLEU improvements on average over a strong NMT system.

1 Introduction

Neural Machine Translation (NMT) (Kalchbrenner and Blunsom, 2013; Bahdanau et al., 2014; Sutskever et al., 2014) relies heavily on source representations, which encode implicitly semantic information of source words by neural networks (Mikolov et al., 2013a,b). Recently, several research works have been proposed to learn richer source representation, such as multi-source information (Zoph and Knight, 2016; Firat et al., 2016), and particularly source syntactic information (Eriguchi et al., 2016; Li et al., 2017; Huadong et al., 2017; Eriguchi et al., 2017), thus improving the performance of NMT.

In this paper, we enhance source representations by dependency information, which can capture source long-distance dependency constraints for word prediction. Actually, source dependency information has been shown greatly effective in Statistical Machine Translation (SMT) (Garmash and Monz, 2014; Kazemi et al., 2015; Hadiwinoto et al., 2016; Chen et al., 2017; Hadiwinoto and Ng, 2017). In NMT, there has been a quite recent preliminary exploration (Sennrich and Haddow, 2016), in which vector representations of source word and its dependency label are simply concatenated as source input, achieving state-of-the-art performance in NMT (Bojar et al., 2016).

In this paper, we propose a novel NMT with source dependency representation to improve translation performance. Compared with the simple approach of vector concatenation, we learn the Source Dependency Representation (**SDR**) to compute dependency context vectors and alignment matrices in a more sophisticated manner, which has the potential to make full use of source dependency information. To this end, we create a dependency unit for each source word to capture long-distance dependency constraints. Then we design an *Encoder* with convolutional architecture to jointly learn SDRs (Section 3) and source dependency annotations, thus computing dependency context vectors and hidden states by a novel double-context based *Decoder* for word prediction (Section 4). Empirical results on NIST Chinese-to-English translation task show that the proposed approach achieves significant gains over the method by Sennrich and Haddow (2016), and thus delivers substantial improvements over the standard attentional NMT (Section 5).

2 Background

An NMT model consists of an *Encoder* process and a *Decoder* process, and hence it is often called *Encoder-Decoder* model (Sutskever et al., 2014; Bahdanau et al., 2014). Typically, each unit of source input $x_j \in (x_1, \ldots, x_J)$ is firstly embedded as a vector V_{x_j}, and then represented as

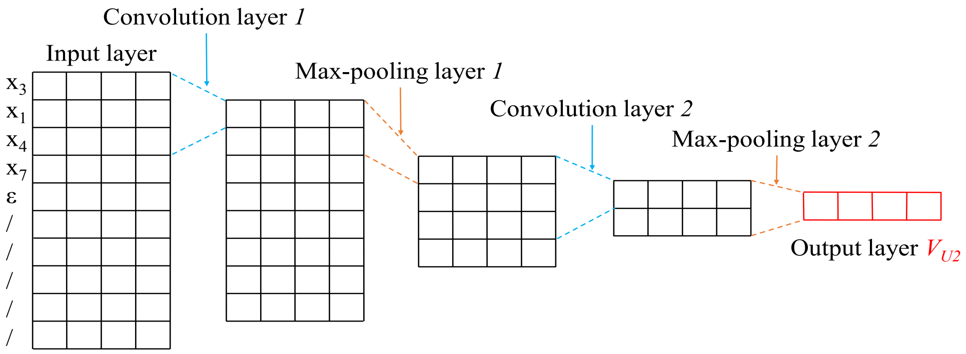

Figure 1: The CNN architecture for learning SRD.

an annotation vector h_j by

$$h_j = f_{enc}(V_{x_j}, h_{j-1}), \quad (1)$$

where f_{enc} is a bidirectional Recurrent Neural Network (**RNN**) (Bahdanau et al., 2014). These annotation vectors $H = (h_1, \dots, h_J)$ are used to generate the target word in the *Decoder*.

An RNN *Decoder* is used to compute the target word y_i probability by a softmax layer g:

$$p(y_i|y_{<i}, x) = g(\hat{y}_{i-1}, s_i, c_i), \quad (2)$$

where $\hat{y}_{i-1}$ is the previously emitted word, and s_i is an RNN hidden state for the current time step:

$$s_i = \varphi(\hat{y}_{i-1}, s_{i-1}, c_i), \quad (3)$$

and the context vector c_i is computed as a weighted sum of these source annotations h_j:

$$c_i = \sum_{j=1}^{J} \alpha_{ij} h_j, \quad (4)$$

where the normalized alignment weight α_{ij} is computed by

$$\alpha_{ij} = \frac{exp(e_{ij})}{\sum_{k=1}^{J} exp(e_{ik})}, \quad (5)$$

where e_{ij} is an alignment which indicates how well the inputs around position j and the output at the position i match:

$$e_{ij} = f(s_{i-1}, h_j). \quad (6)$$

where f is a feedforward neural network.

3 Source Dependency Representation

In order to capture source long-distance dependency constraints, we extract a dependency unit U_j for each source word x_j from dependency tree, inspired by a dependency-based bilingual composition sequence for SMT (Chen et al., 2017). The extracted U_j is defined as the following:

$$U_j = \langle PA_{x_j}, SI_{x_j}, CH_{x_j} \rangle, \quad (7)$$

where PA_{x_j}, SI_{x_j}, CH_{x_j} denote the parent, siblings and children words of source word x_j in a dependency tree. Take x_2 in Figure 2 as an example, the blue solid box U_2 denotes its dependency unit: $PA_{x_2} = \langle x_3 \rangle$, $SI_{x_2} = \langle x_1, x_4, x_7 \rangle$ and $CH_{x_2} = \langle \varepsilon \rangle$ (no child), that is, $U_2 = \langle x_3, x_1, x_4, x_7, \varepsilon \rangle$.

We design a simplified neural network following Chen et al. (2017)'s Convolutional Neural Network (**CNN**) method, to learn the SDR for each source dependency unit U_j, as shown in Figure 1. Our neural network consists of an input layer, two convolutional layers, two pooling layers and an output layer:

- **Input layer**: the input layer takes words of a dependency unit U_j in the form of embedding vectors $n \times d$, where n is the number of words in a dependency unit and d is vector dimension of each word. In our experiments, we set n to 10,[1] and d is 620. For dependency units shorter than 10, we perform "/" padding at the ending of U_j. For example, the padded U_2 is $\langle x_3, x_1, x_4, x_7, \varepsilon, /, /, /, /, / \rangle$.

[1] We find that 99% of all the source dependency units contain no more than 10 words. So if the length is more than 10, the extra words are abandoned; if the length is less than 10, the rest positions are padded with "/".

- **Convolutional layer**: the first convolution consists of one $3\times d$ convolution kernels (the stride is 1) to output an $(n\text{-}2)\times d$ matrix; the second convolution consists of one $3\times d$ convolution kernels to output a $\frac{n-2}{2}\times d$ matrix.

- **Max-Pooling layer**: the first pooling layer performs row-wise max over the two consecutive rows to output a $\frac{n-2}{4}\times d$ matrix; the second pooling layer performs row-wise max over the two consecutive rows to output a $\frac{n-2}{8}\times d$ matrix.

- **Output layer**: the output layer performs row-wise average based on the output of the second pooling layer to learn a compact d-dimension vector V_{U_j} for U_j. In our experiment, the output of the output layer is $1 \times d$-dimension vector.

It should be noted that the dependency unit is similar to the source dependency feature of Sennrich and Haddow (2016) and the SDR is the same to the source-side representation of Chen et al. (2017). In comparison with Sennrich and Haddow (2016), who concatenate the source dependency labels and word together to enhance the *Encoder* of NMT, we adapt a separate attention mechanism together with a CNN dependency *Encoder*. Compared with Chen et al. (2017), which expands the famous neural network joint model (Devlin et al., 2014) with source dependency information to improve the phrase pair translation probability estimation for SMT, we focus on source dependency information to enhance attention probability estimation and to learn corresponding dependency context and RNN hidden state for improving translation.

4 NMT with SDR

In this section, we propose two novel NMT models **SDRNMT**-*1* and **SDRNMT**-*2*, both of which can make use of source dependency information SDR to enhance *Encoder* and *Decoder* of NMT.

4.1 SDRNMT-*1*

Compared with standard attentional NMT, the *Encoder* of SDRNMT-*1* model consists of a convolutional architecture and an bidirectional RNN, as shown in Figure 2. Therefore, the proposed *Encoder* can not only learn compositional representations for dependency units but also greatly tackle the sparsity issues associated with large dependency units.

Motivated by (Sennrich and Haddow, 2016), we concatenate the V_{x_j} and V_{U_j} as input of the *Encoder*, as shown in the black dotted box in Figure 2. Source annotation vectors are learned based on the concatenated representation with dependency information:

$$h_j = f_{enc}(V_{x_j} : V_{U_j}, h_{j-1}), \tag{8}$$

where ":" denotes the operation of vectors concatenation. Finally, these learned annotation vectors are as the input of the standard NMT *Decoder* to jointly learn alignment and translation. The only difference between our method and (Sennrich and Haddow, 2016)'s method is that they only use dependency label representation instead of V_{U_j}.

4.2 SDRNMT-*2*

In SDRNMT-*1*, a single annotation, learned over concatenating word representation and SDR, is used to compute the context vector and the RNN hidden state for the current time step. To relieve more translation performance for NMT from the SDR, we propose a *double-context* mechanism, as shown in Figure 3.

First, the *Encoder* of SDRNMT-*2* consists of two independent annotations h_j and d_j:

$$\begin{aligned} h_j &= f_{enc}(V_{x_j}, h_{j-1}), \\ d_j &= f_{enc}(V_{U_j}, d_{j-1}), \end{aligned} \tag{9}$$

where $H = [h_1, \cdots, h_J]$ and $D = [d_1, \cdots, d_J]$ encode source sequential and long-distance dependency information, respectively.

The *Decoder* learns the corresponding alignment matrices and context vectors over the H and D, respectively. That is, according to eq.(6), given the previous hidden state s^s_{i-1} and s^d_{i-1}, the current alignments $e^s_{i,j}$ and $e^d_{i,j}$ are computed over source annotation vectors h_j and d_j, respectively:

$$\begin{aligned} e^s_{i,j} &= f(s^s_{i-1} + h_j), \\ e^d_{i,j} &= f(s^d_{i-1} + d_j). \end{aligned} \tag{10}$$

According to eq.(5), we further compute the current alignment $\tilde{\alpha}$:

$$\tilde{\alpha}_{i,j} = \frac{exp(\lambda e^s_{i,j} + (1-\lambda)e^d_{i,j})}{\sum_{j=1}^{J} exp(\lambda e^s_{i,j} + (1-\lambda)e^d_{i,j})}, \tag{11}$$

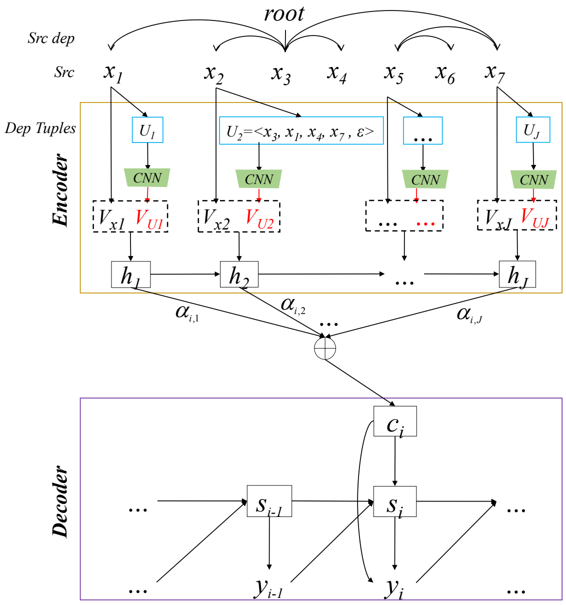

Figure 2: SDRNMT-*1* for the *i*-th time step.

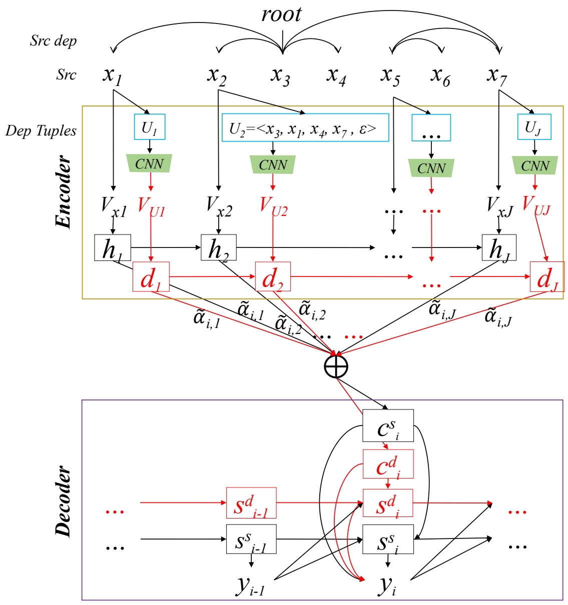

Figure 3: SDRNMT-*2* for the *i*-th time step.

where λ is a hyperparameter[2] to control the importance of H and D. Note that compared with the original alignment model only depending on the sequential annotation vectors H, the alignment weight $\tilde{\alpha}_{i,j}$ jointly compute statistic over source sequential annotation vectors H and dependency annotation vectors D.

The current context vector c_i^s and c_i^d are compute by eq.(4), respectively:

$$c_i^s = \sum_{j=1}^{J} \tilde{\alpha}_{i,j} h_j, \text{and } c_i^d = \sum_{j=1}^{J} \tilde{\alpha}_{i,j} d_j. \quad (12)$$

The current hidden state s_i^s and s_i^d are computed by eq.(3), respectively:

$$\begin{aligned} s_i^s &= \varphi(s_{i-1}^s, y_{i-1}, c_i^s), \\ s_i^d &= \varphi(s_{i-1}^d, y_{i-1}, c_i^d). \end{aligned} \quad (13)$$

Finally, according to eq.(2), the probabilities for the next target word are computed using two hidden states s_i^s and s_i^d, the previously emitted word $\hat{y}_{i-1}$, the current sequential context vector c_i^s and dependency context vector c_{d_i}:

$$p(y_i | y_{<i}, x, T) = g(\hat{y}_{i-1}, s_i^s, s_i^d, c_i^s, c_i^d). \quad (14)$$

5 Experiment

5.1 Setting up

We carry out experiments on Chinese-to-English translation. The training dataset consists of 1.42M sentence pairs extract from LDC corpora.[3] We use the Stanford dependency parser (Chang et al., 2009) to generate the dependency tree for Chinese. We choose the NIST 2002 (MT02) and the NIST 2003-2008 (MT03-08) datasets as the validation set and test sets, respectively. Case-insensitive *4*-gram NIST BLEU score (Papineni et al., 2002) is used as an evaluation metric, and *signtest* (Collins et al., 2005) is as statistical significance test.

The baseline systems include the standard Phrase-Based Statistical Machine Translation (**PBSMT**) implemented in Moses (Koehn et al., 2007) and the standard Attentional NMT (**AttNMT**) (Bahdanau et al., 2014), where only source word representation is utilized. We also compare with a state-of-the-art syntax enhanced NMT method (Sennrich and Haddow, 2016). For a fair comparison, we only utilize dependency information for (Sennrich and Haddow, 2016), called **Sennrich-deponly**. We try our best to re-implement the baseline methods on Nematus toolkit [4] (Sennrich et al., 2017).

For all NMT systems, we limit the source and target vocabularies to 30K, and the maximum sentence length is *80*. The word embedding dimension is *620*,[5] and the hidden layer dimension

[2] λ can be tuned according to a subset FBIS of training data and be set as *0.6* in the experiments.

[3] LDC2002E18, LDC2003E07, LDC2003E14, Hansards portion of LDC2004T07, LDC2004T08, and LDC2005T06.

[5] For SDRNMT-*1*, the *360* dimensions are from V_{x_j} and the *260* dimensions are from V_{U_j}.

System	Dev (MT02)	MT03	MT04	MT05	MT06	MT08	AVG
PBSMT	33.15	31.02	33.78	30.33	29.62	23.53	29.66
AttNMT	36.31	34.02	37.11	32.86	32.54	25.44	32.40
Sennrich-deponly	36.68	34.51	38.09	33.37	32.96	26.96	32.98
SDRNMT-*1*	36.88	34.98*	38.14	34.61	33.58	27.06	33.32
SDRNMT-2	**37.34**	**35.91****	**38.73***	**34.18****	**33.76****	**27.64***	**34.04**

Table 1: Results on NIST Chinese-to-English Translation Task. "*" indicates statistically significant better than "Sennrich-deponly" at p-value $<$ 0.05 and "**" at p-value $<$ 0.01. **AVG** = average BLEU scores for test sets.

is *1000*, and all the layers use the dropout training technique (Hinton et al., 2012). We shuffle training set before training and the mini-batch size is *80*. Training is conducted on a single Tesla P100 GPU. All NMT models train for *15* epochs using ADADELTA (Zeiler, 2012), and the train time is *6* days, which is *25%* slower than the standard NMT.

5.2 Results and Analyses

Table 1 shows the translation performances on test sets measured in BLEU score. The AttNMT significantly outperforms PBSMT by *2.74* BLEU points on average, indicating that it is a strong baseline NMT system. The baseline Sennrich-deponly improves the performance over the AttNMT by *0.58* BLEU points on average. This indicates that the proposed source dependency constraint is beneficial for improving the performance of NMT.

Moreover, SDRNMT-*1* gains improvements of *0.92* and *0.34* BLEU points on average than the AttNMT and Sennrich-deponly. These show that the proposed SDR can more effectively capture source dependency information than vector concatenation. Especially, the proposed SDRNMT-*2* outperforms the AttNMT and Sennrich-deponly on average by *1.64* and *1.03* BLEU points. These verify that the proposed double-context method is effective for word prediction.

5.3 Effect of Translating Long Sentences

We follow (Bahdanau et al., 2014) to group sentences of similar lengths all the test sets (MT03-08), for example, "*40*" indicates that the length of sentences is between 30 and 40, and compute a BLEU score per group. As demonstrated in Figure 4, the proposed models outperform other baseline systems, especially in translating long sentences. These results show that the proposed models can effective encode long-distance dependencies to improve translation.

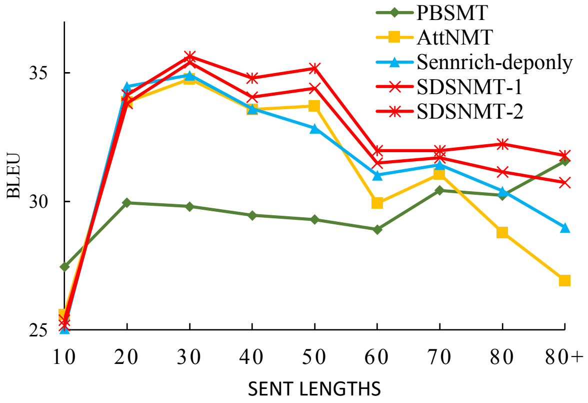

Figure 4: Translation qualities for different sentence lengths.

6 Conclusion and Future Work

In this paper, we explored the source dependency information to improve the performance of NMT. We proposed a novel attentional NMT with source dependency representation to capture source long-distance dependencies. In the future, we will try to exploit a general framework for utilizing richer syntax knowledge.

Abstract

In the logic approach to Recognizing Textual Entailment, identifying phrase-to-phrase semantic relations is still an unsolved problem. Resources such as the Paraphrase Database offer limited coverage despite their large size whereas unsupervised distributional models of meaning often fail to recognize phrasal entailments. We propose to map phrases to their visual denotations and compare their meaning in terms of their images. We show that our approach is effective in the task of Recognizing Textual Entailment when combined with specific linguistic and logic features.

1 Introduction and Related Work

Recognizing Textual Entailment (RTE) is a challenging task that was described as *the best way of testing an NLP system's semantic capacity* (Cooper et al., 1994). In this task, given a text T and a hypothesis H, the objective is to recognize whether T implies H (yes), whether T contradicts H (no) or otherwise (unk). For example, given:

(T) Some men walk in the tall and green grass.
(H) Some people walk in the field.

the system needs to recognize that T implies H (yes). Although humans can easily solve these problems, machines face great difficulties (Dagan et al., 2013). RTE has been approached from different perspectives, ranging from purely statistical systems (Lai and Hockenmaier, 2014; Zhao et al., 2014) to purely logical (Bos et al., 2004; Abzianidze, 2015; Mineshima et al., 2015) and hybrid systems (Beltagy et al., 2013).

We evaluate our idea on top of a logic system since they generally offer a high precision and interpretability, which is useful to our purposes. In this approach, there are two main challenges. The first challenge is to model the logical semantic composition of sentences guided by the syntax and logical words (e.g. *most*, *not*, *some*, *every*). The second challenge is to introduce lexical knowledge that describes the relationship between words or phrases (e.g. *men* → *people*, *tall and green grass* → *field*).

Whereas the relationship *men* → *people* can be found in high precision ontological resources such as WordNet (Miller, 1995), phrasal relations such as *tall and green grass* → *field* are not available in databases such as the Paraphrase Database (PPDB) (Ganitkevitch et al., 2013) despite their large size. Moreover, although unsupervised distributional similarity models have an infinite domain (given a compositional function on words), they often fail to identify entailments (e.g. *guitar* has a high similarity to *piano* but they do not entail each other). To address these issues, Roller et al. (2014) investigated supervised methods to identify word-to-word hypernym relations given word vectors whereas Beltagy et al. (2016) proposed a mechanism to extract phrase pairs from T and H and train a classifier to identify paraphrases in unseen T-H problems. Our approach is largely inspired by their work and our intention is to increase the performance of these phrase and sentence level entailment classifiers using multimodal features.

Our assumption is that *the same concept expressed using different phrase forms is mapped to similar visual representations* since humans tend to ground the meaning of phrases into the same visual denotation. In a similar line, Kiela and Bottou (2014) proposed a simple yet effective concatenation of pre-trained distributed word representations and visual features, whereas Izadinia et al. (2015) suggests a tighter parametric integration using a set of hand annotated phrasal entail-

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2853–2859
Copenhagen, Denmark, September 7–11, 2017.

ment relations; however, their work was limited to recognizing word or phrase relations, ignoring the additional challenges that come in RTE which we show is critical. Young et al. (2014) and Lai and Hockenmaier (2014) did tackle sentence-level RTE using visual denotations. However, their approach is only applicable to those RTE problems whose words or phrases appear in the FLICKR30K corpus, which is a considerable limitation. Lai and Hockenmaier (2017) extended the approach to also recognize unseen phrasal semantic relations using a neural network augmented with conditional probabilities estimated from visual denotations. Instead, our approach is much simpler and similarly effective.

Our contribution is a method to judge phrase-to-phrase semantic relations using an asymmetric similarity scoring function between their sets of visual denotations. We identify the conditions in which this function contributes to sentence-level RTE and show empirically its benefit. Our approach is simpler than previous methods and it does not require annotated phrase relations. Moreover, this approach is not limited to specific corpora or evaluation datasets and it is potentially language independent.

2 Methodology

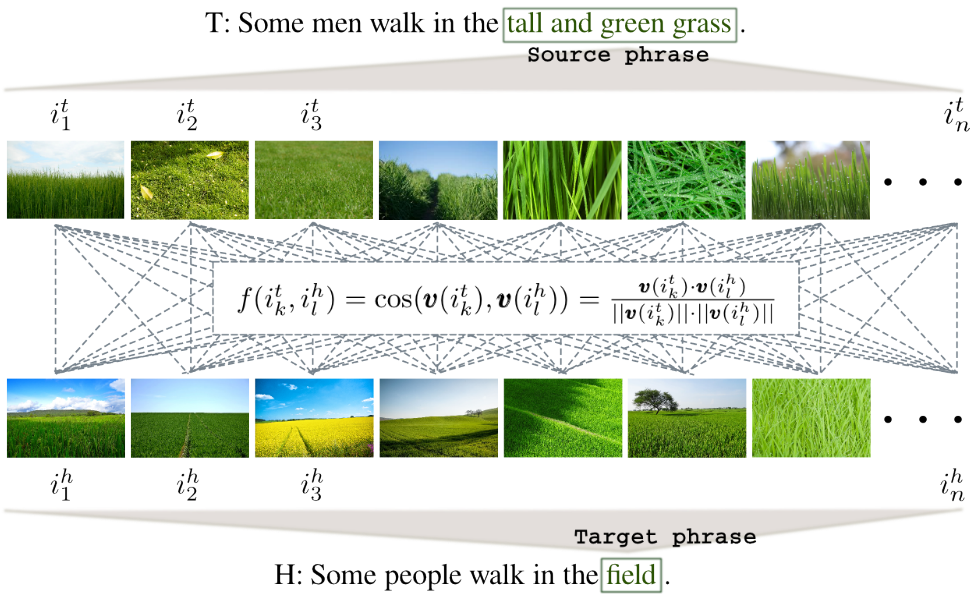
We formulate our framework in terms of a classifier $g_\theta : \mathcal{T} \times \mathcal{H} \rightarrow \{\text{yes}, \text{no}, \text{unk}\}$ that outputs an entailment judgment for any text $T \in \mathcal{T}$ and hypothesis $H \in \mathcal{H}$. There are three key issues in designing an effective classifier that uses visual denotations: i) to discern when it is appropriate to use visual denotations to recognize phrasal entailments, ii) to extract candidate phrase pairs and iii) to map those phrases into visual denotations[1] and measure their semantic similarity in terms of their associated images.

Textual and Logic Features The first issue is to understand the linguistic and logic limitations of visual denotations in recognizing phrasal entailments. From our observations, the linguistic phenomena that make visual denotations ineffective are word-to-word verb relations (e.g. *laughing* and *crying*) since their associated images may depict different actions with similar entities (e.g. pictures of *a baby crying* are similar to those of *a baby laughing*); antonym relations between any word in a phrase pair (e.g. similar images for *big car* and *small vehicle*); and words that denote people of different gender (e.g. *boy* versus *lady*, *man* versus *woman*) as they often display high visual similarity compared to other entities. The logic phenomena we identified signal sentences with small differences in critical words, phrases or structures, as in the presence of negations (e.g. images of *no cat* still display cats), passive-active constructions and subject-object case mismatches (e.g. images of *boy eats apple* and *apple eats boy* are similar) between T and H.

These logic phenomena can be easily detected from logic formulas with the aid of the variable unification during the theorem proving process. For instance, using event semantics (Davidson, 1967; Parsons, 1990), an active sentence *a boy eats an apple* and its corresponding passive sentence *an apple is eaten by a boy* can be compositionally mapped to the same logical formula, i.e., $\exists e \exists x \exists y (\textbf{boy}(x) \wedge \textbf{apple}(y) \wedge \textbf{eat}(e) \wedge (\textbf{subj}(e) = x) \wedge (\textbf{obj}(e) = y))$, while *a boy eats an apple* and *an apple eats a boy* are mapped to different formulas. When trying to prove the formula corresponding to H from the formula corresponding to T, one needs to unify the variables contained in these formulas, so that the non-logical predicates such as **boy**, **apple** and **eat** in T and H are aligned by taking into account logical signals.

Extract candidate phrase pairs between T and H The second issue is to find candidate phrase pairs between T and H for which we compare their visual denotations. In our running example (see Figure 1), a desirable candidate phrase pair would be *tall and green grass* and *field*. We use a tree mapping algorithm (Martínez-Gómez and Miyao, 2016) that finds node correspondences between the syntactic trees of T and H. The search is carried out bottom-up, guided by an ensemble of cost functions. This ensemble rewards word or phrase correspondences that are equal or if a linguistic relationship (i.e. synonymy, hypernymy, etc.) holds between them according to WordNet. This tree mapping implicitly defines hierarchical phrase pair correspondences between T and H. We only select those phrase pairs for which both phrases have less than 6 words. We believe that discerning the entailment relation between longer phrases should be left to the logic prover and the compositional mechanism of meaning.

[1] We approximate the visual denotations of a phrase by obtaining the images associated to that phrase.



T: Some men walk in the tall and green grass.
Source phrase
i_1^t
i_2^t
i_3^t
i_n^t
$f(i_k^t, i_l^h) = \cos(\boldsymbol{v}(i_k^t), \boldsymbol{v}(i_l^h)) = \frac{\boldsymbol{v}(i_k^t)\cdot\boldsymbol{v}(i_l^h)}{||\boldsymbol{v}(i_k^t)||\cdot||\boldsymbol{v}(i_l^h)||}$
i_1^h
i_2^h
i_3^h
i_n^h
Target phrase
H: Some people walk in the field.

Figure 1: Phrase-image mappings for the phrase pair *tall and green grass* and *field* in one RTE problem.

Visual Features At this stage it remains to measure the semantic relation between the candidate phrase pairs (extracted with the tree mapping algorithm described above) using their visual denotations (see Figure 1 for a schematic diagram[2]). For this purpose, we select the phrase pairs (t, h) with highest and lowest *similarity score*. We define the similarity score as the average cosine similarity between the *best* image correspondences. That is:

$$\text{score}(t, h) = \frac{1}{|I_h|} \sum_{i_l^h \in I_h} \max_{i_k^t \in I_t} f(i_k^t, i_l^h) \quad (1)$$

where $I_t = \{i_1^t, \ldots, i_n^t\}$ are the n images associated with phrase t from T and $I_h = \{i_1^h, \ldots, i_n^h\}$ are the n images for phrase h from H, for $1 \leq l, k \leq n$. Note the asymmetry in Eq. 1 which captures semantic subsumptions (a picture of *river* is among the pictures of *body of water*). The function f returns the cosine similarity between two images:

$$f(i_k^t, i_l^h) = \cos(\mathbf{v}(i_k^t), \mathbf{v}(i_l^h)) = \frac{\mathbf{v}(i_k^t) \cdot \mathbf{v}(i_l^h)}{||\mathbf{v}(i_k^t)|| \cdot ||\mathbf{v}(i_l^h)||} \quad (2)$$

where $\mathbf{v}(i)$ is the vector representation of an image i. We obtain these vector representations concatenating the activations of the first 7 layers of GoogLeNet (Szegedy et al., 2015) as it is common practice (Kiela and Bottou, 2014).

Given the phrases with the highest and lowest similarity score,[3] we extract four features from each pair. The first feature is the similarity score itself. The other three features capture statistics of the relationship $f(I_t \times I_h)$ between the two sets of visual denotations I_t and I_h. This relationship $f(I_t \times I_h)$ is defined as the the matrix of image cosine similarities:

$$f(I_t \times I_h) = \begin{bmatrix} f(i_1^t, i_1^h) & f(i_1^t, i_2^h) & \cdots & f(i_1^t, i_n^h) \\ f(i_2^t, i_1^h) & f(i_2^t, i_2^h) & \cdots & f(i_2^t, i_n^h) \\ \vdots & \vdots & \ddots & \vdots \\ f(i_n^t, i_1^h) & f(i_n^t, i_2^h) & \cdots & f(i_n^t, i_n^h) \end{bmatrix} \quad (3)$$

Specifically, these three features are:

- $\max f(I_t \times I_h)$ returns the cosine similarity between the two most similar images. This feature is robust against polysemic phrases (at least one image associated to *pupil* is similar to at least one image associated to *student*) and hypernymy.
- average$f(I_t \times I_h)$ returns the average similarity across all image pairs and aims to measure the visual denotation overlap between both phrases in the pair.
- $\min f(I_t \times I_h)$ returns the similarity between the two most different images and gives a notion of how different the meanings of the two phrases can be.

[2] Due to copyright, images in this paper are a subset of Google Image Search results for which we have a publishing license. Nevertheless, they are faithful representatives.

[3] If there are no candidate phrase pairs, the T-H problem is ignored. If there is only one phrase pair, such a pair is used as the pair with highest and lowest score.

All features above are concatenated into a feature vector which is paired with the T-H entailment gold label to train the classifier.

3 Experiments

Our system is independent from the logic backend but we use `ccg2lambda` (Martínez-Gómez et al., 2016)[4] for its high precision and capabilities to solve word-to-word divergences using WordNet and VerbOcean (Chklovski and Pantel, 2004).

We evaluate our system on the SemEval-2014 version of the SICK dataset (Marelli et al., 2014) with train/trial/test splits of $4,500/500/4,927$ T-H pairs and a yes/no/unk label distribution of $.29/.15/.56$. We chose SICK for its relatively limited vocabulary ($2,409$ words) and short sentences. The average T and H sentence length was 10.6 where 3.6 to 3.8 words appeared in T and not in H or vice versa. We used scipy's Random Forests (Breiman, 2001) as our entailment classifier with 500 trees and feature value standardization, trained and evaluated on those T-H pairs for which `ccg2lambda` outputs *unknown* (around 71% of the problems).

Using the tree mapping algorithm,[5] we obtained an average of 9.8 phrase pairs per T-H problem. We obtained $n = 30$ images for every phrase using Google Image Search API which we consider as our visual denotations. The images and their vector representations were obtained between Sept. 2016 and Feb. 2017 using the image miner and the feature extractor of Kiela (2016).[6]

Our main baseline is `ccg2lambda` when using only WordNet and VerbOcean to account for word-to-word lexical divergences. `ccg2lambda` is augmented with a classifier `c` that uses either text and logic features `t` or image features from 10, 20, or 30 images (`10i`, `20i` or `30i`). On the training data (Table 1), `ccg2lambda` obtains an accuracy of 82.89%. Using our classifier with all features, we carried out 10 runs of a 10-fold cross-validation on the training data and we obtained an accuracy (standard deviation) of 84.14 (0.06), 84.30 (0.14) and 84.28 (0.11) when using 10, 20 and 30 images, respectively. Thus, no significant differences in accuracy were observed for different numbers of images. When using only text and logic features (`c-t`), the accuracy dropped to 76.60 (0.03); when using only image features (`c-20i`), the accuracy dropped to 82.85%. These results show that using visual denotations to recognize phrasal entailments contributes to improvements in accuracy and that the interaction with text and logic features produces further gains.

System	Accuracy	Std.
`ccg2lambda`	82.89	–
`ccg2lambda, c-t-10i`	84.14	0.06
`ccg2lambda, c-t-20i`	**84.30**	0.14
`ccg2lambda, c-t-30i`	84.28	0.11
`ccg2lambda, c-t`	76.60	0.03
`ccg2lambda, c-20i`	82.85	0.08

Table 1: Results (accuracy and standard deviation) of the classifier `c` in a cross-validation on the training split of SICK dataset using text and logic features `t` for `10i`, `20i` and `30i` images.

System	Prec.	Rec.	Acc.
`ccg2lambda` + images	90.24	71.08	**84.29**
`ccg2lambda`, only text	96.95	62.65	83.13
L&H, text + images	–	–	82.70
L&H, only text	–	–	81.50
Illinois-LH, 2014	81.56	81.87	84.57
Yin & Schütze, 2017	–	–	87.10
Baseline (majority)	–	–	56.69

Table 2: Results on the test split of SICK dataset using precision, recall and accuracy. The system "`ccg2lambda` + images" uses text and logics features and 20 images per phrase: `c-t-20i`.

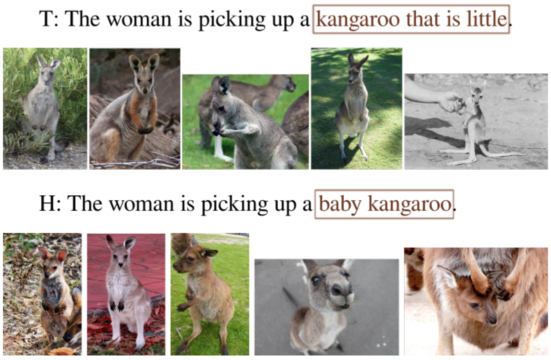
On the test data, we obtained 1.1% higher accuracy (84.29 versus 83.13) over the `ccg2lambda` baseline with a standard deviation of 0.07% over 10 runs (see Table 2) when using the setting `c-t-20i`. As a comparison, Lai and Hockenmaier (2017) obtain a similar accuracy increase when using visual denotations (1.2%) with a substantially more complex approach that requires training on the SNLI dataset (Bowman et al., 2015), a much larger corpus.

The best SemEval-2014 system obtained an accuracy of 84.57 (Lai and Hockenmaier, 2014) and other heavily engineered, finely-tuned systems (Beltagy et al., 2016; Yin and Schütze, 2017) reported up to 3% points of accuracy improvement since then. Thus, our results are still below the state of the art.

[4] https://github.com/mynlp/ccg2lambda

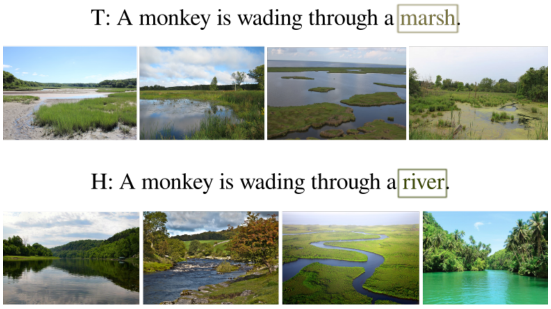
[5] https://github.com/pasmargo/t2t-qa

[6] https://github.com/douwekiela/mmfeat



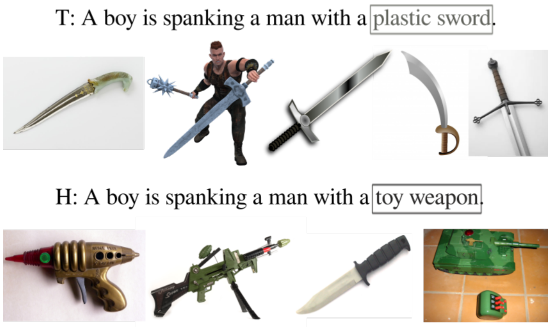
T: The woman is picking up a kangaroo that is little.
H: The woman is picking up a baby kangaroo.

Figure 2: True positive, ID: 4012; gold: yes.



T: A monkey is wading through a marsh.
H: A monkey is wading through a river.

Figure 3: False positive, ID: 1215; gold: unk.



T: A boy is spanking a man with a plastic sword.
H: A boy is spanking a man with a toy weapon.

Figure 4: False negative, ID: 1318; gold: yes.

4 Error analysis

We had an average of 126 true positives (gold label yes, system label yes) and 81 false positives (gold label unk, system label yes) in our cross-validation over the training data. Figure 2 shows an example of a true positive where the tree mapping algorithm extracted the phrase pair *kangaroo that is little* and *baby kangaroo*. The image similarity features showed a high score causing the classifier to correctly produce the judgment yes. Figure 3 shows a false positive where the extracted phrase pair was *marsh* and *river* and for which the image similarity is unfortunately high. These cases are common when comparing people (*boy* and *man*) or scenery (such as *beach* and *desert*).

Figure 4 shows a false negative (gold label yes, system label unk) where the candidate phrase pair was *plastic sword* and *toy weapon*. In this case, there was only one image with a plastic sword within the images associated to *toy weapon* which may have caused the cosine similarities to be low.

5 Discussion and Conclusion

In this paper we have evaluated our method on the SICK dataset which was originally created from image captions. For that reason, the proportion of concepts with good visual denotations might be higher than in typically occurring RTE problems. Our future work is to assess the applicability of our approach into other RTE problems such as the RTE challenges, SNLI (Bowman et al., 2015) and MultiNLI (Williams et al., 2017) datasets and further investigate what syntactic or semantic units can be best represented using visual denotations.

Another issue is the use of a commercial image search API as a black box to retrieve images. These search engines may include heuristics that map similar phrases or keywords into the same canonical form and that are difficult to control experimentally. However, we believe that our approach is still valid for a variety of image search mechanisms and it is generally useful to resolve lexical ambiguity at a high coverage.

We identified the conditions in which visual denotations are effective for sentence-level RTE and devised a simple scoring function to assess phrasal semantic subsumption, which may serve as the basis for more elaborated strategies. Our system is independent on the semantic parser but the entailment recognition mechanism requires a theorem prover that displays remaining sub-goals. The system and instructions are available at `https://github.com/mynlp/ccg2lambda`

Abstract

Manual data annotation is a vital component of NLP research. When designing annotation tasks, properties of the annotation interface can lead to unintentional artefacts in the resulting dataset, biasing the evaluation. In this paper, we explore sequence effects where annotations of an item are affected by the preceding items. Having assigned one label to an instance, the annotator may be less (or more) likely to assign the same label to the next. During rating tasks, seeing a low quality item may affect the score given to the next item either positively or negatively. We see clear evidence of both types of effects using auto-correlation studies over three different crowdsourced datasets. We then recommend a simple way to minimise sequence effects.

1 Introduction

NLP research relies heavily on annotated datasets for training and evaluation. The design of the annotation task can influence the decisions made by annotators in subtle ways: besides the actual features of the instance being annotated, annotators are also influenced by factors such as the user interface, wording of the question, and familiarity with the task or domain.

When collecting NLP annotations, care is usually taken to ensure that the annotations are of high quality, through careful design of label sets, annotation guidelines and training of annotators (Hovy et al., 2006), methods for aggregating annotations (Passonneau and Carpenter, 2014), and intuitive user interfaces (Stenetorp et al., 2012).

Crowdsourcing has emerged as a cheaper, faster alternative to expert NLP annotations (Snow et al., 2008; Callison-Burch and Dredze, 2010; Graham et al., 2017), although it entails additional effort to filter out unskilled or opportunistic workers, e.g. through the collection of redundant repeated judgements for each instance, or including some trap questions with known answers (Callison-Burch and Dredze, 2010; Hoßfeld et al., 2014). In most annotation exercises, the order of presentation of instances is randomised to remove bias due to similarities in topic, style and vocabulary (Koehn and Monz, 2006; Bojar et al., 2016).

When crowdsourcing judgements, the normal practise (as used in the datasets we analyse) is for the item ordering to be randomised in creating a “HIT” (i.e. a single collection of items presented to a crowdworker for judgement), and then to have each HIT annotated by multiple workers, for quality control purposes. The order of items is generally fixed across all annotators of an individual HIT (Snow et al., 2008; Graham et al., 2017).

In this paper, we show that worker scores are affected by sequence bias, whereby the order of presentation can affect individuals’ assessment of an item. Since all workers see the instances in the same order, this affects any other inferences made from the data, including aggregated assessment or inferences about individual annotators (such as their overall quality or individual thresholds).

Possible explanations for sequence effects include:

Gambler’s fallacy: Once annotators have developed an idea of the distribution of scores/labels, they can come to expect even small sequences to follow the distribution. In particular, in binary annotation tasks, if they expect that True (1) and False (0) items are equally likely, then they believe the sequence 00000 (100% False and 0% True) is less likely than the sequence 01010 (50% False and 50% True). So if they assign 0 to an item,

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2860–2865
Copenhagen, Denmark, September 7–11, 2017.

they may approach the next item with a prior belief that it is more likely to be a 1 than a 0. Chen et al. (2016) showed evidence for the gambler's fallacy in decisions of loan officers, asylum judges, and baseball umpires.

Sequential contrast effects: A high quality item may raise the bar for the next item. On the other hand, a bad item may make the next item seem better in comparison (Kenrick and Gutierres, 1980; Hartzmark and Shue, to appear)

Assimilation and anchoring: The annotator uses their score of the previous item as an anchor, and adjusts the score of the current item from this anchor, based on perceived similarities and differences with the previous item. If they focus on similarities between the previous and current instance, the annotations show an assimilation effect (Geiselman et al., 1984; Damisch et al., 2006). Anchoring effects may decrease as people gain experience and expertise in the task (Wilson et al., 1996).

2 Methodology

We test whether the annotation of an instance is correlated with the annotation on previous instances, conditioned on control variables such as the gold standard (i.e. expert annotations[1]), based on the following linear model:

$$\mathrm{Y}_{i,t} = \beta_0 + \beta_1 \mathrm{Y}_{i,t-1} + \beta_2 \mathrm{Gold} + \eta \qquad (1)$$

where $\mathrm{Y}_{i,t}$ is the annotation given by an annotator i to an instance t, and η is white Gaussian noise with zero mean. We use linear regression for continuous data and logistic regression for binary data.[2] If there is no dependence between consecutive instances, and annotators assign labels/scores based only on the aspects of the current instance, then the data can be explained from the gold score (learning a positive β_2 value) and bias term (β_0), with β_1 set to zero. When we use the ground truth as a control, if β_1 is non-zero, it is evidence of mistakes being made by annotators due to sequential bias. A positive value of β_1 can be explained by priming or anchoring, and a negative value with sequential contrast effects or the gambler's fallacy. Accordingly, we test the statistical significance of the $\beta_1 \neq 0$ to determine whether sequencing effects are present in crowdsourced text corpora.

Task	All	Good	Moderate
RTE	-0.102	-0.169^{*}	-0.192^{**}
TEMPORAL	0.198	-0.567^{***}	-0.511^{***}

Table 1: Autocorrelation coefficient β_1 for RTE and TEMPORAL data. Stars denote statistical significance: * = 0.05, ** = 0.01, and *** = 0.001.

3 Experiments

We analyse several influential datasets that have been constructed through crowdsourcing, including both binary and continuous annotation tasks: recognising textual entailment, event ordering, affective text analysis, and machine translation evaluation.

3.1 Recognising Textual Entailment (RTE) and Event Temporal Ordering

First, we examine the recognising textual entailment ("RTE") and event temporal ordering ("TEMPORAL") datasets from Snow et al. (2008). In the RTE task, annotators are presented with two sentences, and are asked to judge whether the second text can be inferred from the first. With the TEMPORAL dataset, they are shown two sentences describing events, and asked to indicate which of the two events occurred first. Both datasets include both expert annotations and crowdsourced annotations constructed using Amazon Mechanical Turk ("MTurk"). On MTurk, each RTE HIT contains 20 instances, and each TEMPORAL HIT contains 10 instances, which the workers see in sequential order. For both tasks, each HIT was annotated by 10 workers.

Results We use logistic regression on worker labels against labels on the previous instance in the current HIT, with the expert judgements as a control variable. We also add an additional control, namely the percentage of True labels assigned by the worker overall, which accounts for the overall annotator bias. To calculate this, we use scores by the worker excluding the current score, to avoid giving the model any information about the current instance.

As shown in Table 1, over all workers ("All"), we find a small negative autocorrelation for both the RTE and TEMPORAL tasks. One possibility

[1] For the Machine Translation dataset described in Section 3.3, we use the mean of at least fifteen crowd workers as a proxy for expert annotations.

[2] η is not included in the case of logistic regression

is that this is biased by opportunistic workers who assign the same label to all instances in the HIT, for which we would not expect any sequential bias effects. When we exclude these workers ("Moderate"), the autocorrelation increases, and is highly statistically significant. We also show results for workers with at least 60% accuracy when compared to expert annotations ("Good"), and observe a similar effect.

3.2 Affective text analysis

In the affective text analysis task ("AFFECTIVE"), annotators are asked to rate news headlines for anger, disgust, fear, joy, sadness, and surprise on a continuous scale of 0–100. Besides these emotions, they are asked to rate sentences for (emotive) valence, i.e., how strongly negative or positive they are (-100 to $+100$). In this dataset, there are 100 headlines divided into 10 HITs, with 10 workers annotating each HIT (Snow et al., 2008). We test for autocorrelation of scores of each aspect individually, controlling for the expert scores and worker correlation with the expert scores. We also look separately at datasets of good and bad workers, based on whether the correlation with the expert annotations is greater than 0.5.

Results For individual emotions, we do not observe any significant autocorrelation ($p \geq 0.05$). As there are only 1000 annotations per emotion, we also look at results when combining data for all aspects. Though we find a statistically significant negative autocorrelation for scores of the full dataset, this disappears when we filter out bad workers (Table 2). Given the difficulty of this very subjective task, it is likely that many of workers considered 'bad' might have simply found this task too difficult or arbitrary, and thus become more prone to sequence effects.

3.3 Machine Translation Adequacy

When evaluating machine translation ("MT"), we tend to focus on adequacy: the extent to which the meaning of the reference translation is captured in the MT output. In the method of Graham et al. (2015) — the current best-practise, as adopted by WMT (Bojar et al., 2016) — annotators are asked to judge the adequacy of translations using a 100-point sliding scale which is initialised at the mid point. There are 3 marks on the scale dividing it into 4 quarters to aid workers with internal calibration. They are given no other instructions or guidelines.

	All	Good	Bad
β_1	-0.03^{*}	-0.01	-0.04^{*}
β_2	0.45^{***}	0.66^{***}	0.23^{***}

Table 2: Autocorrelation coefficient β_1 for the AFFECTIVE dataset.

In this paper, we base our analysis on the adequacy dataset of Graham et al. (2015), on Spanish-English newswire data from WMT 2013 (Bojar et al., 2013). The dataset consists of 12 HITS of 100 sentence pairs each; each HIT is annotated by at least 15 workers.

HITs are designed to include quality control items to filter out poor quality scores. In addition to 70 MT system translations, each HIT contains degraded versions of 10 of these translations, 10 reference translations by a human expert corresponding to 10 of these translations, and repeats of another 10 translations. Good workers are assumed to give high scores to the references, similar scores to the pair of repeats, and high scores to the MT system translations when compared to corresponding degraded translations. Workers who submitted scores of clearly bad quality were rejected. For the remaining workers, the Wilcoxon rank-sum test is used to test whether the score difference between the repeat judgements is less than the score difference between translations and the corresponding degraded versions. We divide these workers into "good" and "moderate" based on the threshold of $p < 0.05$.

To eliminate differences due to different internal scales, every individual worker's scores are standardised by subtracting the mean and dividing by the standard deviation of their scores. Following Graham et al. (2015), we use the average of standardised scores of at least 15 good workers as the ground truth.

We refer to the final dataset as "MT_{adeq}".

Results As this is a (practically) continuous output, we use a linear regression model, whereby the current score is predicted based on the previous score, with the mean of all worker scores as control. We also controlled for worker correlation with mean score, and position of the sentence in the HIT, but these were not significant and did not affect the autocorrelation. As seen in Table 3, we see a small but significant positive autocorrelation for good workers. The bias is much stronger with

	Good	Moderate	Bad
β_1	0.030^{***}	0.037^{***}	0.192^{***}
β_2	0.741	0.661	0.256
N items	48216	24696	17738

Table 3: MT$_{adeq}$ dataset: Autocorrelation coefficient β_1, showing sequence bias of good, moderate and bad workers.

Position	Good	Moderate	Bad
1st Tertile	0.044^{***}	0.063^{***}	0.179^{***}
2nd Tertile	0.032^{***}	0.034^{***}	0.173^{***}
3rd Tertile	0.015^{**}	0.014^{*}	0.225^{***}

Table 4: MT$_{adeq}$ dataset: Regression coefficient β_1 of adequacy scores with the previous score. We also show results for translations in the first, second or third tertile based on the position of the sentence of the HIT

bad (rejected) workers.

An interesting question is whether the bias changes as workers annotate more data, which could be ascribed to learning through the task, calibrating their internal scales, or becoming fatigued on a monotonous task. Each HIT consists of 100 sentences, and we divide the dataset into 3 equal groups based on the position of sentence in the HIT. As shown in Table 4, for good and moderate workers, the bias is stronger in the first group of sentences annotated, decreases in the second, and is much smaller in the last. This could be because workers are familiarising themselves with the task earlier on, and calibrating their scale. There is no such trend with bad quality scores, possibly because the workers are not putting in sufficient effort to produce accurate scores.

Next we assess the impact of the bias in the worst case situation. We discretize scores into low, middle and high based on equal-frequency binning, and divide the dataset into 3 groups based on the score assigned to the previous sentence. As shown in Table 5 we can see that the sentences in the "low" partition and the "high" partition have a difference of 0.18, which is highly significant;[3] moreover, this difference is likely to be sufficiently large to alter the rankings of systems in an evaluation. The bias remains even when we increase the number of workers and use the average score, as all workers scored the translations in the same order. This shows that the mean is also affected by sequence bias.

N	All	Low	Middle	High	H − L
1	0.01	−0.09	0.05	0.08	0.18^{***}
5	0.00	−0.05	−0.02	0.08	0.14^{***}
10	−0.00	−0.05	−0.04	0.09	0.13^{***}
15	−0.00	−0.05	−0.02	0.07	0.12^{***}

Table 5: MT$_{adeq}$ dataset: Translations following a low quality translation receive a lower score than those following a good translation: "All" is the mean score of all sentences in the dataset, where each sentence score is calculated as the average of N (standardised) worker scores. "Low", "Middle", and "High" are mean scores of sentences where the previous sentence annotated is of low, medium and high quality, resp. "H − L" is the difference between the average high and low scores.

Thus, it is theoretically possible to exploit sequence bias to artificially deflate (or inflate) a specific system's computed score by ordering a HIT such that the system's output is seen consistently immediately after a bad (or good) output.

4 Discussion and Conclusions

We have shown significant sequence effects across several independent crowdsourced datasets: a negative autocorrelation in the RTE and TEMPORAL datasets, and a positive autocorrelation in the MT$_{adeq}$ dataset. The negative autocorrelation can be attributed either to sequential contrast effects or the gambler's fallacy. These effects were not significant for the AFFECTIVE dataset, perhaps due to the nature of the annotation task, whereby annotations of one emotion are separated by six other annotations, thus limiting the potential for sequencing effects. It is also possible that the dataset is too small to obtain statistical significance.

MT judgements are subjective, and when people are asked to rate them on a continuous scale, they need time to calibrate their scale. We show that the sequential bias decreases for better workers as they annotate more sentences in the HIT, indicating a learning effect. Since the ordering of the systems is random, system scores obtained by averaging scores of all sentences translated by the system would be unbiased, assuming a sufficiently large sample of sentences. Thus we do not expect sequential bias to have a marked effect on system rankings or other macro-level conclusions on the basis of this data. However, the scores of in-

[3] $p < 0.001$ using Welch's two-sample t-test

dividual translations remain biased, which augurs poorly for the use of these annotations at the sentence level, such as when used in error analysis or for training automatic metrics.

Sequence problems can be easily addressed by adequate randomisation — providing each individual worker with a separate dataset that has been randomised, such that no two workers see the same ordered data. In this way sequence bias effects can be considered as independent noise sources, rather than a systematic bias, and consequently the aggregate results over several workers will remain unbiased.

This study has shown that sequence bias is real, and can distort evaluation and annotation exercises with crowd-workers. We limited our scope to binary and continuous responses, however it is likely that sequence effects are prevalent for multinomial and structured outputs, e.g., in discourse and parsing, where priming is known to have a significant effect (Reitter et al., 2006). Another important question for future work is whether sequence bias is detectable in expert annotators, not just crowd workers.

No Need to *Pay Attention*: Simple Recurrent Neural Networks Work! (for Answering "Simple" Questions)

Ferhan Ture and **Oliver Jojic**
Comcast Labs, Washington, DC 20005
{ferhan_ture, oliver_jojic}@cable.comcast.com

Abstract

First-order factoid question answering assumes that the question can be answered by a single fact in a knowledge base (KB). While this does not seem like a challenging task, many recent attempts that apply either complex linguistic reasoning or deep neural networks achieve 65%–76% accuracy on benchmark sets. Our approach formulates the task as two machine learning problems: detecting the entities in the question, and classifying the question as one of the relation types in the KB. We train a recurrent neural network to solve each problem. On the SimpleQuestions dataset, our approach yields substantial improvements over previously published results — even neural networks based on much more complex architectures. The simplicity of our approach also has practical advantages, such as efficiency and modularity, that are valuable especially in an industry setting. In fact, we present a preliminary analysis of the performance of our model on real queries from Comcast's X1 entertainment platform with millions of users every day.

1 Introduction

First-order factoid question answering (QA) assumes that the question can be answered by a single fact in a knowledge base (KB). For example, "How old is Tom Hanks" is about the [age] of [Tom Hanks]. Also referred to as *simple* questions by Bordes et al. (2015), recent attempts that apply either complex linguistic reasoning or attention-based complex neural network architectures achieve up to 76% accuracy on benchmark sets (Golub and He, 2016; Yin et al., 2016). While it is tempting to study QA systems that can handle more complicated questions, it is hard to reach reasonably high precision for unrestricted questions. For more than a decade, successful industry applications of QA have focused on first-order questions. This bears the question: are users even interested in asking questions beyond first-order (or are these use cases more suitable for interactive dialogue)? Based on voice logs from a major entertainment platform with millions of users every day, Comcast X1, we find that most existing use cases of QA fall into the first-order category.

Our strategy is to tailor our approach to first-order QA by making strong assumptions about the problem structure. In particular, we assume that the answer to a first-order question is a *single* property of a *single* entity in the KB, and decompose the task into two subproblems: (a) detecting entities in the question and (b) classifying the question as one of the relation types in the KB. We simply train a vanilla recurrent neural network (RNN) to solve each subproblem (Elman, 1990). Despite its simplicity, our approach (RNN-QA) achieves the highest reported accuracy on the SimpleQuestions dataset. While recent literature has focused on building more complex neural network architectures with attention mechanisms, attempting to generalize to broader QA, we enforce stricter assumptions on the problem structure, thereby reducing complexity. This also means that our solution is efficient, another critical requirement for real-time QA applications. In fact, we present a performance analysis of RNN-QA on Comcast's X1 entertainment system, used by millions of customers every day.

Copenhagen, Denmark, September 7–11, 2017.

proach to QA is to transform the question and knowledge into a compatible form, and perform reasoning to determine which fact in the KB answers a given question. Examples of this approach include pattern-based question analyzers (Buscaldi et al., 2010), combination of syntactic parsing and semantic role labeling (Bilotti et al., 2007, 2010), as well as lambda calculus (Berant et al., 2013) and combinatory categorical grammars (CCG) (Reddy et al., 2014). A downside of these approaches is the reliance on linguistic resources/heuristics, making them language- and/or domain-specific. Even though Reddy et al. (2014) claim that their approach requires less supervision than prior work, it still relies on many English-specific heuristics and hand-crafted features. Also, their most accurate model uses a corpus of paraphrases to generalize to linguistic diversity. Linguistic parsers can also be too slow for real-time applications.

In contrast, an RNN can detect entities in the question with high accuracy and low latency. The only required resources are word embeddings and a set of questions with entity words tagged. The former can be easily trained for any language/domain in an unsupervised fashion, given a large text corpus without annotations (Mikolov et al., 2013; Pennington et al., 2014). The latter is a relatively simple annotation task that exists for many languages and domains, and it can also be synthetically generated. Many researchers have explored similar techniques for general NLP tasks (Collobert et al., 2011), such as named entity recognition (Lu et al., 2015; Hammerton, 2003), sequence labeling (Graves, 2008; Chung et al., 2014), part-of-speech tagging (Huang et al., 2015; Wang et al., 2015), chunking (Huang et al., 2015).

Deep learning techniques have been studied extensively for constructing parallel neural networks for modeling a joint probability distribution for question-answer pairs (Hsu et al., 2016; Yang et al., 2014; He et al., 2015; Mueller and Thyagarajan, 2016) and re-ranking answers output by a retrieval engine (Rao et al., 2016; Yang et al., 2016). These more complex approaches might be needed for general-purpose QA and sentence similarity, where one cannot make assumptions about the structure of the input or knowledge. However, as noted in Section 1, first-order factoid questions can be represented by an entity and a relation type, and the answer is usually stored in a structured knowledge base. Dong et al. (2015) similarly assume that the answer to a question is at most two hops away from the target entity. However, they do not propose how to obtain the target entity, since it is provided as part of their dataset. Bordes et al. (2014) take advantage of the KB structure by projecting entities, relations, and subgraphs into the same latent space. In addition to finding the target entity, the other key information to first-order QA is the relation type corresponding to the question. Many researchers have shown that classifying the question into one of the predefined types (e.g., based on patterns (Zhang and Lee, 2003) or support vector machines (Buscaldi et al., 2010)) improves QA accuracy.

3 Approach

(a) From Question to Structured Query. Our approach relies on a *knowledge base*, containing a large set of *facts*, each one representing a binary [subject, relation, object] relationship. Since we assume *first-order questions*, the answer can be retrieved from a single fact. For instance, "How old is Sarah Michelle Gellar?" can be answered by the fact:

```
[Sarah Michelle Gellar,bornOn,4/14/1977]
```

The main idea is to dissect a first-order factoid natural-language question by converting it into a structured query: {entity "Sarah Michelle Gellar", relation: `bornOn`}. The process can be modularized into two machine learning problems, namely ***entity detection*** and ***relation prediction***. In the former, the objective is to *tag* each question word as either entity or not. In the latter, the objective is to *classify* the question into one of the K relation types. We modeled both using an RNN.

We use a standard RNN architecture: Each word in the question passes through an embedding lookup layer E, projecting the one-hot vector into a d-dimensional vector x_t. A recurrent layer combines this *input representation* with the hidden layer representation from the *previous word* and applies a non-linear transformation to compute the hidden layer representation for the *current word*. The hidden representation of the final recurrent layer is projected to the output space of k dimensions and normalized into a probability distribution via soft-max.

In *relation prediction*, the question is classified into one of the 1837 classes (i.e., relation types in Freebase). In the *entity detection* task, each word is classified as either *entity* or *context* (i.e., $k = 2$).

Given a new question, we run the two RNN models to construct the structured query. Once every question word is classified as entity (denoted by `E`) or context (denoted by `C`), we can extract entity phrase(s) by grouping consecutive entity words. For example, for question "How old is Michelle Gellar", the output of entity detection is [`C C C E E`], from which we can extract a single entity "Michelle Gellar". The output of relation prediction is `bornOn`. The inferred structured query q becomes the following:
{*entityText*: "michelle gellar", *relation*: `bornOn`}

(b) Entity Linking. The textual reference to the entity (entityText in q) needs to be linked to an actual entity node in our KB. In order to achieve that, we build an *inverted index* I_{entity} that maps all n-grams of an entity ($n \in \{1, 2, 3\}$) to the entity's alias text (e.g., name or title), each with an associated $TF\text{-}IDF$ score. We also map the exact text ($n = \infty$) to be able to prioritize exact matches.

Following our running example, let us demonstrate how we construct I_{entity}. Let us assume there is a node e_i in our KB that refers to the actress "Sarah Michelle Gellar". The alias of this entity node is the name, which has three unigrams ("sarah", "michelle", "gellar"), two bigrams ("sarah michelle", "michelle gellar") and a single trigram (i.e., the entire name). Each one of these n-grams gets indexed in I_{entity} with $TF\text{-}IDF$ weights. Here is how the weights would be computed for unigram "sarah" and bigram "michelle gellar" ($\Rightarrow$ denotes mapping):

$$I_{\text{entity}}(\text{“sarah”}) \Rightarrow \{\text{node} : e_i,$$
$$\text{score} : TF\text{-}IDF(\text{“sarah”}, \text{“sarah michelle gellar”})\}$$
$$I_{\text{entity}}(\text{“michelle gellar”}) \Rightarrow \{\text{node} : e_i,$$
$$\text{score} : TF\text{-}IDF(\text{“michelle gellar”}, \text{“sarah michelle gellar”})\}$$

This is performed for every n-gram ($n \in \{1, 2, 3, \infty\}$) of every entity node in the KB. Assuming there is an entity node, say e_j, for the actress "Sarah Jessica Parker", we would end up creating a second mapping from unigram "sarah":

$$I_{\text{entity}}(\text{“sarah”}) \Rightarrow \{\text{node} : e_j,$$
$$\text{score} : TF\text{-}IDF(\text{“sarah”}, \text{“sarah jessica parker”})\}$$

In other words, "sarah" would be linked to both e_i and e_j, with corresponding $TF\text{-}IDF$ weights.

Once the index I_{entity} is built, we can link *entityText* from the structured query (e.g., "michelle gellar") to the intended entity in the KB (e.g., e_i). Starting with $n = \infty$, we iterate over n-grams of *entityText* and query I_{entity}, which returns all matching entities in the KB with associated $TF\text{-}IDF$ relevance scores. For each n-gram, retrieved entities are appended to the candidate set C. We continue this process with decreasing value of n (i.e., $n \in \{\infty, 3, 2, 1\}$)

Early termination happens if C is non-empty and n is less than or equal to the number of tokens in *entityText*. The latter criterion is to avoid cases where we find an exact match but there are also partial matches that might be more relevant: For "jurassic park", for $n = \infty$, we get an exact match to the original movie "Jurassic Park". But we would also like to retrieve "Jurassic Park II" as a candidate entity, which is only possible if we keep processing until $n = 2$.

(c) Answer Selection. Once we have a list of candidate entities C, we use each candidate node e_{cand} as a starting point to reach candidate answers.

A *graph reachability index* I_{reach} is built for mapping each entity node e to all nodes e' that are reachable, with the associated path $p(e, e')$. For the purpose of the current approach, we limit our search to a single hop away, but this index can be easily expanded to support a wider search.

$$I_{reach}(e_i) \Rightarrow$$
$$\{\text{node:}e_{i_1}, \text{text:The Grudge}, \text{path:}[\texttt{actedIn}]\}$$
$$\{\text{node:}e_{i_2}, \text{text:4/14/1977}, \text{path:}[\texttt{bornOn}]\}$$
$$\{\text{node:}e_{i_3}, \text{text:F. Prinze}, \text{path:}[\texttt{marriedTo}]\}$$

We use I_{reach} to retrieve all nodes e' that are reachable from e_{cand}, where the path from is consistent with the predicted relation r (i.e., $r \in p(e_{\text{cand}}, e')$). These are added to the candidate answer set A. For example, in the example above, node e_{i_2} would have been added to the answer set A, since the path [`bornOn`] matches the predicted relation in the structured query. After repeating this process for each entity in C, the highest-scored node in A is our best answer to the question.

4 Experimental Setup

Data. Evaluation of RNN-QA was carried out on SimpleQuestions, which uses a subset of Freebase containing 17.8M million facts, 4M unique entities, and 7523 relation types. Indexes I_{entity} and I_{reach} are built based on this knowledge base.

SimpleQuestions was built by (Bordes et al., 2014) to serve as a larger and more diverse factoid QA dataset.[1] Freebase facts are sampled in a way to ensure a diverse set of questions, then given to human annotators to create questions from, and get labeled with corresponding entity and relation type. There are a total of 1837 unique relation types that appear in SimpleQuestions.

Training. We fixed the embedding layer based on the pre-trained 300-dimensional Google News embedding,[2] since the data size is too small for training embeddings. Out-of-vocabulary words were assigned to a random vector (sampled from uniform distribution). Parameters were learned via stochastic gradient descent, using categorical cross-entropy as objective. In order to handle variable-length input, we limit the input to N tokens and prepend a special pad word if input has fewer.[3] We tried a variety of configurations for the RNN: four choices for the type of RNN layer (GRU or LSTM, bidirectional or not); depth from 1 to 3; and drop-out ratio from 0 to 0.5, yielding a total of 48 possible configurations. For each possible setting, we trained the model on the training portion and used the validation portion to avoid over-fitting. After running all 48 experiments, the most optimal setting was selected by micro-averaged F-score of predicted entities (entity detection) or accuracy (relation prediction) on the validation set. We concluded that the optimal model is a 2-layer bidirectional LSTM (BiLSTM2) for entity detection and BiGRU2 for relation prediction. Drop-out was 10% in both cases.

5 Results

End-to-End QA. For evaluation, we apply the relation prediction and entity detection models on each test question, yielding a structured query $q = \{entityText\colon t_e, relation\colon r\}$ (Section 3a). Entity linking gives us a list of candidate entity nodes (Section 3b). For each candidate entity e_{cand}, we can limit our relation choices to the set of unique relation types that some candidate entity e_{cand} is associated with. This helps eliminate the artificial ambiguity due to overlapping relation types as well as the spurious ambiguity due to redundancies in a typical knowledge base. Even though there are 1837 relation types in Freebase, the number of relation types that we need to consider per question (on average) drops to 36. The highest-scored answer node is selected by finding the highest scored entity node e that has an outward edge of type r (Section 3c). We follow Bordes et al. (2015) in comparing the predicted entity-relation pair to the ground truth. A question is counted as correct if and only if the entity we select (i.e., e) and the relation we predict (i.e, r) match the ground truth.

Table 1 summarizes end-to-end experimental results. We use the best models based on validation set accuracy and compare it to three prior approaches: a specialized network architecture that explicitly memorizes facts (Bordes et al., 2015), a network that learns how to convolve sequence of characters in the question (Golub and He, 2016), and a complex network with attention mechanisms to learn most important parts of the question (Yin et al., 2016). Our approach outperforms the state of the art in accuracy (i.e., precision at top 1) by 11.9 points (15.6% relative).

Model	P@1
Memory Network (2015)	63.9
Char-level CNN (2016)	70.9
Attentive max-pooling (2016)	76.4
RNN-QA (best models)	**88.3**
naive ED	58.9
naive RP	4.1
naive ED and RP	3.7

Table 1: Top-1 accuracy on test portion of SimpleQuestions. Ablation study on last three rows.

Last three rows quantify the impact of each component via an ***ablation study***, in which we replace either entity detection (ED) or relation prediction (RP) models with a naive baseline: (i) we assign the relation that appears most frequently in training data (i.e., `bornOn`), and/or (ii) we tag the entire question as an entity (and then perform the n-gram entity linking). Results confirm that RP is absolutely critical, since both datasets include a diverse and well-balanced set of relation types. When we applied the naive ED baseline, our results drop significantly, but they are still comparable to prior results. Given that most prior work do not use the network to detect entities, we can

[1] 75910/10845/21687 question-answer pairs for training/validation/test is an order of magnitude larger than comparable datasets. Vocabulary size is 55K as opposed to around 3K for WebQuestions (Berant et al., 2013).

[2] `word2vec.googlecode.com`

[3] Input length (N) was set to 36, the maximum number of tokens across training and validation splits.

deduce that our RNN-based entity detection is the reason our approach performs so well.

Error Analysis. In order to better understand the weaknesses of our approach, we performed a *blame analysis*: Among 2537 errors in the test set, 15% can be blamed on entity detection — the relation type was correctly predicted, but the detected entity did not match the ground truth. The reverse is true for 48% cases.[4] We manually labeled a sample of 50 instances from each blame scenario. When entity detection is to blame, 20% was due to spelling inconsistencies between question and KB, which can be resolved with better text normalization during indexing (e.g., "la kings" refers to "Los Angeles Kings"). We found 16% of the detected entities to be correct, even though it was not the same as the ground truth (e.g., either "New York" or "New York City" is correct in "what can do in new york?"); 18% are inherently ambiguous and need clarification (e.g., "where bin laden got killed?" might mean "Osama" or "Salem"). When blame is on relation prediction, we found that the predicted relation is reasonable (albeit different than ground truth) 29% of the time (e.g., "what was nikola tesla known for" can be classified as `profession` or `notable_for`).

RNN-QA in Practice. In addition to matching the state of the art in effectiveness, we also claimed that our simple architecture provides an efficient and modular solution. We demonstrate this by applying our model (without any modifications) to the entertainment domain and deploying it to the Comcast X1 platform serving millions of customers every day. Training data was generated synthetically based on an internal entertainment KB. For evaluation, 295 unique question-answer pairs were randomly sampled from real usage logs of the platform.

We can draw two important conclusions from Table 2: First of all, we find that almost all of the user-generated natural-language questions (278/295∼95%) are first-order questions, supporting the significance of first-order QA as a task. Second, we show that even if we simply use an open-sourced deep learning toolkit (`keras.io`) for implementation and limit the computational resources to 2 CPU cores per thread, RNN-QA answers 75% of questions correctly with very reasonable latency.

Error	Count
Correct	220
Incorrect entity	16
Incorrect relation	42
Not first-order question	17
Total Latency	76±16 ms

Table 2: Evaluation of RNN-QA on real questions from X platform.

6 Conclusions and Future work

We described a simple yet effective approach for QA, focusing primarily on first-order factual questions. Although we understand the benefit of exploring task-agnostic approaches that aim to capture semantics in a more general way (e.g., (Kumar et al., 2015)), it is also important to acknowledge that there is no "one-size-fits-all" solution as of yet.

One of the main novelties of our work is to decompose the task into two subproblems, entity detection and relation prediction, and provide solutions for each in the form of a RNN. In both cases, we have found that bidirectional networks are beneficial, and that two layers are sufficiently deep to balance the model's ability to fit versus its ability to generalize.

While an ablation study revealed the importance of both entity detection and relation prediction, we are hoping to further study the degree of which improvements in either component affect QA accuracy. Drop-out was tuned to 10% based on validation accuracy. While we have not implemented attention directly on our model, we can compare our results side by side on the same benchmark task against prior work with complex attention mechanisms (e.g., (Yin et al., 2016)). Given the proven strength of attention mechanisms, we were surprised to find our simple approach to be clearly superior on SimpleQuestions.

Even though deep learning has opened the potential for more generic solutions, we believe that taking advantage of problem structure yields a more accurate and efficient solution. While first-order QA might seem like a solved problem, there is clearly still room for improvement. By revealing that 95% of real use cases fit into this paradigm, we hope to convince the reader that this is a valuable problem that requires more *attention*.

[4] In remaining 37% incorrect answers, both models fail, so the blame is shared.

The strange geometry of skip-gram with negative sampling

David Mimno and **Laure Thompson**
Cornell University
mimno@cornell.edu, laurejt@cs.cornell.edu

Abstract

Despite their ubiquity, word embeddings trained with skip-gram negative sampling (SGNS) remain poorly understood. We find that vector positions are not simply determined by semantic similarity, but rather occupy a narrow cone, diametrically opposed to the context vectors. We show that this geometric concentration depends on the ratio of positive to negative examples, and that it is neither theoretically nor empirically inherent in related embedding algorithms.

1 Introduction

It is generally assumed that the geometry of word embeddings is determined by semantic relatedness. Vectors are assumed to be distributed throughout a K-dimensional space, with specific regions devoted to specific concepts. We find that vectors trained with the skip-gram with negative sampling (SGNS) algorithm (Mikolov et al., 2013) are not only influenced by semantics but are also strongly influenced by the negative sampling objective. In fact, far from spanning the possible space, they exist only in a narrow cone in $\mathbb{R}^K$. Nevertheless, SGNS vectors have become a foundational tool in NLP and perform as well or better than numerous methods with similar objectives (Turian et al., 2010; Dhillon et al., 2012; Pennington et al., 2014; Luo et al., 2015) with respect to evaluations of intrinsic and extrinsic quality (Schnabel et al., 2015).

SGNS works by training two sets of embeddings: the “official” word embeddings and a second set of *context* embeddings, with one K-dimensional vector in each set for each word in the vocabulary. The objective tries to make the word vector and context vector closer for a pair of words that actually occur together than for randomly sampled “negative” words. Following training, the word vectors are typically saved; the context vectors are deleted. Any difference between these two sets of vectors is puzzling, since the sliding window used in training is symmetrical: a word and its context word reverse roles almost immediately. Indeed, the superficially similar GloVe algorithm (Pennington et al., 2014) also defines word and context vectors and by default returns the mean of these two vectors.

Previous work has analyzed what the algorithm might be doing in theory, as an approximation to a matrix factorization (Levy and Goldberg, 2014). Other work has considered the empirical effects of some of the more arbitrary-seeming algorithmic choices (Levy et al., 2015). But we still have relatively little understanding of how the algorithm actually determines parameter values.

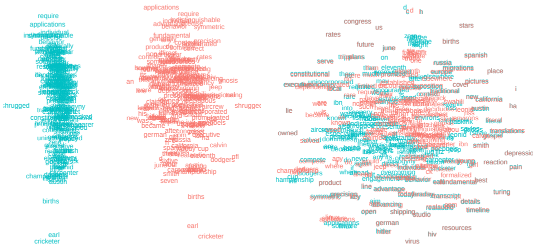

Figure 1: SGNS word vectors and their context vectors projected using PCA (left) and t-SNE (right). t-SNE provides a more readable layout, but masks the divergence between word and context vectors.

In this work we measure geometric properties of SGNS-trained word vectors and their context vectors. Although the word vectors appear to span K-dimensional space, we find that the SGNS objective results in vectors that are narrowly clustered in a single orthant, and can be made non-negative without significant loss. Figure 1 shows two visualizations of SGNS vectors and context vectors. The context vectors mirror the “official” word vectors, with the angle between vectors effectively controlled by the number of negative samples. We

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2873–2878
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

show that this effect is due to negative sampling and not the general embedding objective. We note that this relationship between vectors is effectively hidden by the commonly-used t-SNE projection (van der Maaten and Hinton, 2008).

2 Word embeddings with SGNS

The SGNS algorithm defines two sets of parameters, K-dimensional word vectors $\boldsymbol{w}_i$ and context vectors $\boldsymbol{c}_i$ for each word i. We define a weight between a word i and a context word j as $\sigma_{ij} = \frac{\exp(w_i^T c_j)}{1+\exp(w_i^T c_j)}$. For each observed pair i, j we sample S "negative" context words from a modified unigram distribution $p(w)^{0.75}$. The stochastic gradient update for one parameter w_{ik} is then

$$\frac{d\ell}{dw_{ik}} = (1 - \sigma_{ij})c_{jk} + \sum_{s=1}^{S} -\sigma_{is}c_{sk}, \qquad (1)$$

suppressing for clarity a learning rate parameter λ. A symmetrical update is performed for the context word parameters $\boldsymbol{c}_j$ and $\boldsymbol{c}_s$, substituting $\boldsymbol{w}_i$ for $\boldsymbol{c}$. This update has been shown to be equivalent to the gradient of a factorization of a pointwise mutual information matrix (Levy and Goldberg, 2014).

The impact of the update is to push the vector $\boldsymbol{w}_i$ closer to the context vector of the observed context word $\boldsymbol{c}_j$ and away from the context vectors of the negatively sampled words. The amount of change at any given update is dependent on the degree to which the current model predicts the "correct" source of the context word, whether from the real data distribution or the negative sampling distribution. If the model is infinitely certain that the real word is real ($\sigma_{ij} = 1.0$) and the fake words are fake ($\sigma_{is} = 0.0 \; \forall s$), it will make no change to the current parameters.

3 Results

We first present a series of empirical observations based on vectors trained from a corpus of Wikipedia articles that is commonly distributed with word embedding implementations.[1] We then evaluate the sensitivity of these properties to different algorithmic parameters. We make no assertion that these are optimal (or even particularly good) vectors, only that they are representative of the properties of the algorithm.

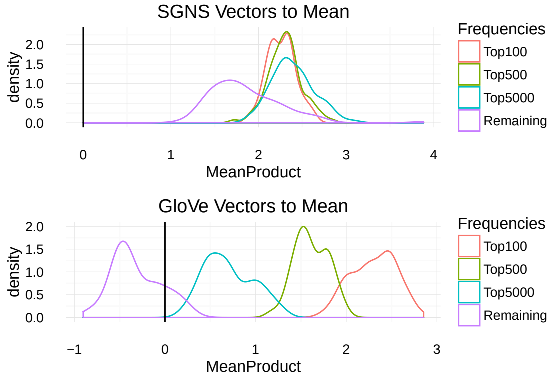

Figure 2: SGNS-trained vectors mostly point in the same direction, towards a mean vector $\hat{\boldsymbol{w}}$.

To determine whether observed properties are due to SGNS specifically or to embeddings in general, we compare SGNS-trained vectors to vectors trained by the GloVe algorithm (Pennington et al., 2014). The choice of GloVe as a comparison is due to its popularity and superficial similarity to SGNS.[2] We begin by examining one set of embeddings from each algorithm, both with $K = 50$ dimensions, a vocabulary of $\approx$ 70k words, and context window 5. We then evaluate sensitivity to negative samples, window size, and dimension.

Embeddings are sensitive to word frequency (Hellrich and Hahn, 2016). Following Zipf's law, words in natural language tend to sort into ranges of frequent words (the majority of tokens) and rare words (the majority of types), with a large class of intermediate-frequency terms in the middle. As a result, the large majority of interactions are between frequent terms or between frequent and infrequent terms. Interactions between infrequent terms are rare, no matter how large the corpus. We define four categories of words by ranked frequency: the top 100 words (ultra-high frequency), the 100–500th ranked words (high frequency), the 500–5000th ranked words (moderate frequency) and the remaining (low frequency) words.

SGNS vectors are arranged along a primary axis. Our first observation is that SGNS-trained vectors all point in roughly the same direction. We can define a mean vector $\bar{w}$ by averaging the vectors of the complete vocabulary $\boldsymbol{w}$. We sample a balanced set of 400 total words with 100 each from the four frequency categories. Figure 2 shows the

[1] http://mattmahoney.net/dc/text8.zip

[2] We make no attempt in this work to compare the *quality* of SGNS and GloVe vectors, nor should the omission of other algorithms be attributed to anything but space constraints.

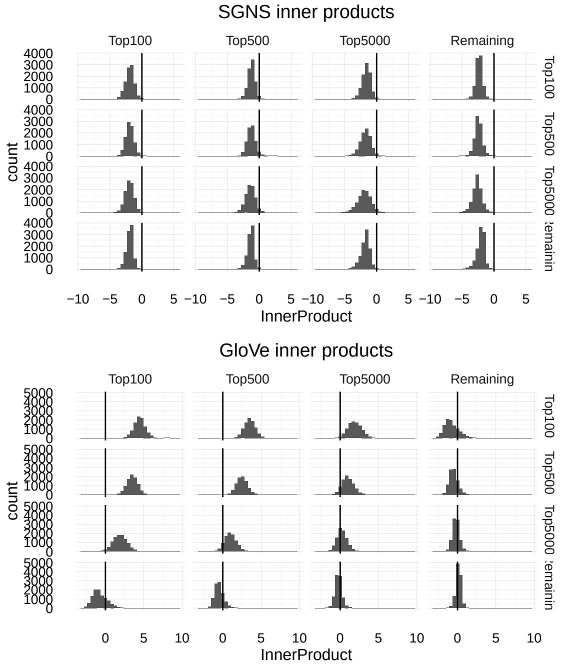

Figure 3: Almost all combinations of words have negative inner products for SGNS, unlike GloVe.

distribution of inner products between these 400 sampled words and their mean vector $\hat{\boldsymbol{w}}$. All vectors have a large, positive inner product with the mean, indicating that they are not evenly dispersed through the space. Furthermore, the frequency category of words has relatively little effect on the inner product, with the exception of the rare words, which have slightly less positive inner products. As a comparison, the vectors trained by GloVe show a clear relationship with word frequency, with low-frequency words opposing the frequency-balanced mean vector.

This result does not depend on a specific mean vector. Using the *global* mean vector rather than the frequency-balanced mean vector reverses the order of frequency categories within each plot, but does not change their overall shape. SGNS vector inner products are all positive, with low-frequency words the most positive. GloVe inner products become positive for low-frequency words and negative for high-frequency words.

The inner product between vectors is used by the algorithm during training, but in practice vectors are often normalized to have unit length before use. It is possible that the apparent pattern shown in Figure 2 may be an artifact of differing average lengths between words of different frequencies. After normalizing SGNS vectors to length 1.0, the lowest and highest frequency words are most similar to the mean vector, with the moderate-frequency words showing the greatest deviation. Normalization does not change the relative order for GloVe vectors.

SGNS vectors point away from context vectors. It is possible that vectors could have a positive inner product with the mean vector but be mutually orthogonal. Figure 3 shows the distribution of inner products $\boldsymbol{w}_i^T \boldsymbol{c}_j$ for pairs of words divided by frequency for SGNS and GloVe. Almost all interactions have similar, negative inner products for SGNS, while GloVe interactions are sensitive to frequency and vary more widely. We note that the high-frequency words in GloVe appear to form a cohesive cluster between themselves (positive inner products) that points away from the lower frequency words (negative inner products), while infrequent words are more dispersed and have no clear pattern relative to each other.

SGNS vectors are mostly non-negative. Not only do SGNS vectors occupy a narrow region of embedding space, it appears that the vectors can be rotated to fall mostly within the positive orthant. For each column of the matrix of vectors $\boldsymbol{w}$ we can compute the dimension-wise mean $\bar{w}_k$. Multiplying $\boldsymbol{w}$ by a diagonal matrix of the signs of the means $diag(sign(\bar{w}_k))$ flips each dimension so that its mean is positive. Figure 4 shows the resulting positive-mean histogram for 12 of the 50 dimensions trained by SGNS (the remaining dimensions are similar). Some dimensions have medians close to 0.0, but most skew positive.

Indeed, it is possible to simply drop all remaining negative values without radically changing the properties of the vectors. Embeddings are often evaluated based on word similarity prediction (Schnabel et al., 2015). Using only positive entries, Spearman rank correlation drops from 0.283 to .276 on the SIMLEX word similarity task and from 0.556 to 0.542 on the MEN task. Subtracting the global mean vector has similarly little impact, reducing SIMLEX correlation to 0.271 and increasing MEN correlation to 0.575. This property may help explain why sparse (Faruqui et al., 2015) and non-negative (Luo et al., 2015) embeddings do not lose significant performance.

SGNS context vectors point away from the word vectors. What then is the geometry of the *context* vectors $\boldsymbol{c}$? The two sets of vectors appear to present a noisy mirror image of each other. Figure 5 shows the distribution of inner products between

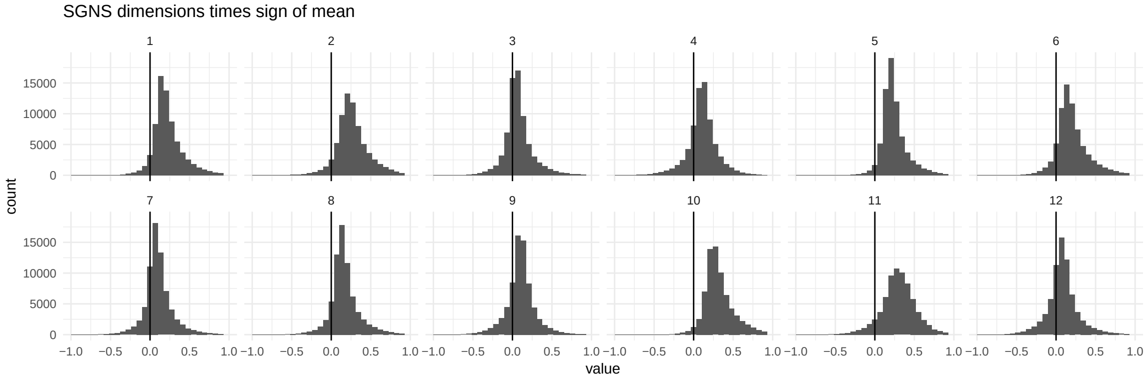

Figure 4: Most latent dimensions show significant skew. Each panel shows a histogram of values for one of the first 12 latent dimensions, after multiplication by the sign of the mean for that dimension.

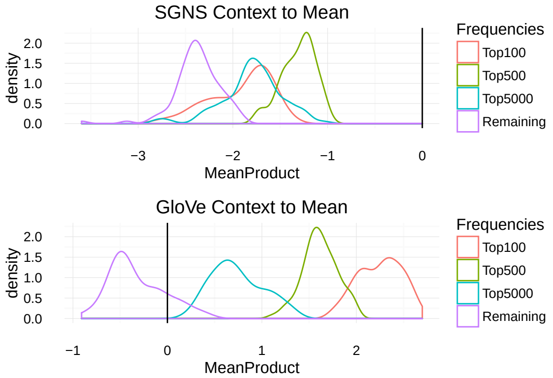

Figure 5: SGNS context vectors point *away* from the mean vector $\hat{\boldsymbol{w}}$, GloVe context vectors do not.

the context vectors and the same mean vector $\hat{\boldsymbol{w}}$ used in Figure 2. These inner products are negative, indicating that the context vectors point in the opposite direction from the word vectors. In contrast, the GloVe context vectors have essentially the same relationship to the mean of the word vectors as the word vectors themselves. This property explains why it is common to output the mean of $\boldsymbol{w}_i$ and $\boldsymbol{c}_i$ for each word for GloVe but not for SGNS: in Glove these two vectors are essentially noisy copies of one another, while in SGNS the two vectors are pointing almost in the opposite direction.

Positive and negative weights come to equilibrium. Eq. 1 balances two terms, a positive interaction term $1.0 - \sigma_{ij}$ between a word and a context word and negative interaction terms $0.0 - \sigma_{is}$ between a word and one of S randomly sampled words. These terms can be viewed as a "label" minus an expectation, as in the gradient for logistic regression. Since there is no $1/S$ term to balance the number of random samples, one might expect that the "power" of the sampled context terms might overwhelm the true interaction term. In practice, these samples appear to find an equilibrium that effectively balances out the number of random samples after a short burn-in phase. We recorded a moving average of positive and negative weights for an ultra-frequent word (*the*) and a moderately frequent word (*tuesday*). In both cases, the mean of the values for positive samples starts at 0.5 and for the negative samples at -0.5. The positive values converge toward $S = 5$ times the mean of the values for negative samples: 0.581 vs. -0.182 for *the* and 0.693 vs. -0.138 for *tuesday*.

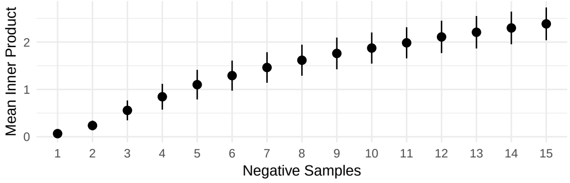

Figure 6: The number of negative samples affects the inner product between vectors and the mean vector. Results are indistinguishable across 10 initializations for each value.

The negative objective is optimized when each model vector points away from the context vectors. The positive objective, in contrast, is maximized when word and context vectors for related words are pointing in the same direction. The negative force acts to repel the vectors, the positive force acts to pull them together.

During the crucial early phases of the algorithm, negative samples have more weight than positive samples: when inner products are near zero, both types of samples will have values of σ_{ij} and σ_{is} close to 0.5, so negative samples will "count" S times more than positive. The early phases of the algorithm will focus on pushing the two sets of vectors apart into separate regions of the latent space. Once vectors and context vectors separate, inner products will become negative, so σ_{ij} and σ_{is} will move closer to 0.0.

The balance between positive and negative samples consistently affects the geometry of the vectors, and is not sensitive to random initialization. We varied the number of negative samples from $S = 1$ to $S = 15$, and ran 10 trials for each value with different random initializations. As shown in Figure 6, as we increase S, the average inner product between vectors and the mean vector within each model increases.

SGNS vectors are concentrated and point away from their context vectors, and changing the number of negative samples appears to affect this property. We now consider whether other factors could also cause this behavior.

Effect of window size Both SGNS and GloVe operate over word co-occurrences within a sliding window centered around each token in the corpus. This window size parameter has an effect on the semantics of vectors, so it is important to consider whether it has an effect on the geometry of vectors. Simply setting an equal window size for SGNS and GloVe does not, however, guarantee that the two algorithms are seeing equivalent data, because each pair is weighted linearly by token distance in SGNS and by $1/distance$ in GloVe. Figure 7 shows average inner products for each frequency with the global mean vector for 10 trials each at window size 5, 10, 15, 20 with $K = 50$. Increasing window size leads to greater divergence between high- and low-frequency words for word and context vectors, but does not change their pattern. GloVe results are similarly unchanged.

Effect of vector size As with window size, the dimensionality K of the word vectors can affect their ability to represent semantic relationships. Figure 8 shows an increase in inner product with the global mean as we increase K (10 trials each, window size 15), but the effect is small relative to that of the number of negative samples S. GloVe inner products change by less than 0.05.

4 Conclusion

SGNS vectors encode semantic relatedness, but their arrangement is much more strongly influenced by the negative sampling objective than is usually assumed. We find that vectors lie on a narrow primary axis that is effectively non-negative. Users should not interpret relationships between vectors without recognizing this geometric context.

In this work we have deliberately restricted ourselves to describing the geometric properties of vectors. We see several areas for further work. First, there are likely to be theoretical reasons why the observed concentration of SGNS vectors in a narrow cone does not appear to affect performance relative to algorithms that do not have this property. Second, measuring the interplay between positive and negative objectives may provide insight into algorithmic choices that are now poorly understood, such as the effect of reducing the occurrence of frequent words in the corpus and the sampling distribution of negative examples. Finally, we suggest that in addition to theoretical analysis, more work should be done to understand the actual working of algorithms on real data.

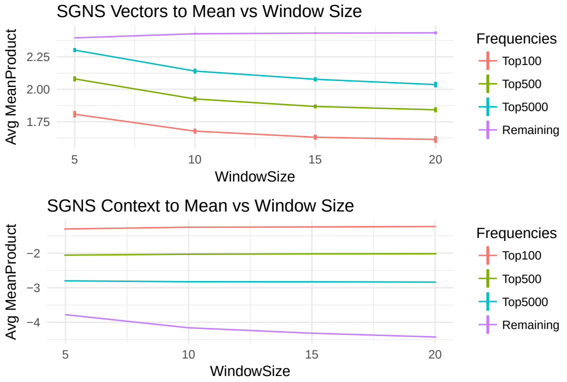

Figure 7: SGNS word and context vectors face in opposite directions regardless of window size.

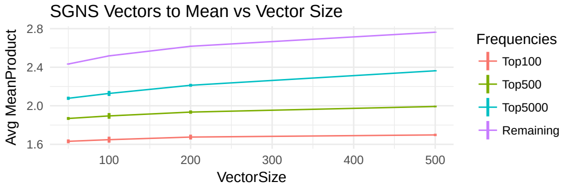

Figure 8: As vector size increases SGNS vectors shift toward the mean vector $\bar{\boldsymbol{w}}$. (GloVe vectors change by < 0.05.)

Abstract

We show that small and shallow feed-forward neural networks can achieve near state-of-the-art results on a range of unstructured and structured language processing tasks while being considerably cheaper in memory and computational requirements than deep recurrent models. Motivated by resource-constrained environments like mobile phones, we showcase simple techniques for obtaining such small neural network models, and investigate different tradeoffs when deciding how to allocate a small memory budget.

1 Introduction

Deep and recurrent neural networks with large network capacity have become increasingly accurate for challenging language processing tasks. For example, machine translation models have been able to attain impressive accuracies, with models that use hundreds of millions (Bahdanau et al., 2014; Wu et al., 2016) or billions (Shazeer et al., 2017) of parameters. These models, however, may not be feasible in all computational settings. In particular, models running on mobile devices are often constrained in terms of memory and computation.

Long Short-Term Memory (LSTM) models (Hochreiter and Schmidhuber, 1997) have achieved good results with small memory footprints by using character-based input representations: e.g., the part-of-speech tagging models of Gillick et al. (2016) have only roughly 900,000 parameters. Latency, however, can still be an issue with LSTMs, due to the large number of matrix multiplications they require (eight per LSTM cell): Kim and Rush (2016) report speeds of only 8.8 words/second when running a two-layer LSTM translation system on an Android phone.

Feed-forward neural networks have the potential to be much faster. In this paper, we show that small feed-forward networks can achieve results at or near the state-of-the-art on a variety of natural language processing tasks, with an order of magnitude speedup over an LSTM-based approach.

We begin by introducing the network model structure and the character-based representations we use throughout all tasks (§2). The four tasks that we address are: language identification (Lang-ID), part-of-speech (POS) tagging, word segmentation, and preordering for translation. In order to use feed-forward networks for structured prediction tasks, we use transition systems (Titov and Henderson, 2007, 2010) with feature embeddings as proposed by Chen and Manning (2014), and introduce two novel transition systems for the last two tasks. We focus on *budgeted* models and ablate four techniques (one on each task) for improving accuracy for a given memory budget:

1. Quantization: Using more dimensions and less precision (Lang-ID: §3.1).
2. Word clusters: Reducing the network size to allow for word clusters and derived features (POS tagging: §3.2).
3. Selected features: Adding explicit feature conjunctions (segmentation: §3.3).
4. Pipelines: Introducing another task in a pipeline and allocating parameters to the auxiliary task instead (preordering: §3.4).

We achieve results at or near state-of-the-art with small ($<$ 3 MB) models on all four tasks.

2 Small Feed-Forward Network Models

The network architectures are designed to limit the memory and runtime of the model. Figure 1 illustrates the model architecture:

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2879–2885
Copenhagen, Denmark, September 7–11, 2017.

1. Discrete features are organized into groups (e.g., $\mathbf{E}_{bigrams}$), with one embedding matrix $\mathbf{E}_g \in \mathbb{R}^{V_g \times D_g}$ per group.
2. Embeddings of features extracted for each group are reshaped into a single vector and concatenated to define the output of the embedding layer as $\mathbf{h}_0 = [\mathbf{X}_g \mathbf{E}_g \mid \forall g]$.
3. A single hidden layer, $\mathbf{h}_1$, with M rectified linear units (Nair and Hinton, 2010) is fully connected to $\mathbf{h}_0$.
4. A softmax function models the probability of an output class y: $P(y) \propto \exp(\beta_y^T \mathbf{h}_1 + b_y)$, where $\beta_y \in \mathbb{R}^M$ and b_y are the weight vector and bias, respectively.

Memory needs are dominated by the embedding matrix sizes ($\sum_g V_g D_g$, where V_g and D_g are the vocabulary sizes and dimensions respectively for each feature group g), while runtime is strongly influenced by the hidden layer dimensions.

Hashed Character *n*-grams Previous applications of this network structure used (pretrained) word embeddings to represent words (Chen and Manning, 2014; Weiss et al., 2015). However, for word embeddings to be effective, they usually need to cover large vocabularies (100,000+) and dimensions (50+). Inspired by the success of character-based representations (Ling et al., 2015), we use features defined over character *n*-grams instead of relying on word embeddings, and learn their embeddings from scratch.

We use a distinct feature group g for each n-gram length N, and control the size V_g directly by applying *random feature mixing* (Ganchev and Dredze, 2008). That is, we define the feature value v for an n-gram string x as $v = \mathcal{H}(x) \mod V_g$, where $\mathcal{H}$ is a well-behaved hash function. Typical values for V_g are in the 100-5000 range, which is far smaller than the exponential number of unique raw n-grams. A consequence of these small feature vocabularies is that we can also use small feature embeddings, typically D_g=16.

Quantization A commonly used strategy for compressing neural networks is quantization, using less precision to store parameters (Han et al., 2015). We compress the embedding weights (the vast majority of the parameters for these shallow models) by storing scale factors for each embedding (details in the supplementary material). In §3.1, we contrast devoting model size to higher precision and lower dimensionality versus lower precision and more network dimensions.

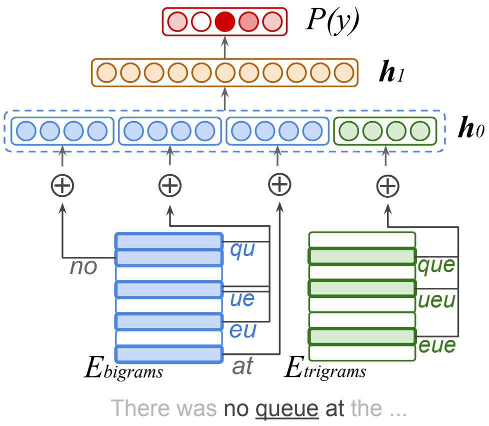

Figure 1: An example network structure for a model using bigrams of the previous, current and next word, and trigrams of the current word. Does not illustrate hashing.

Training Our objective function combines the cross-entropy loss for model predictions relative to the ground truth with L2 regularization of the biases and hidden layer weights. For optimization, we use mini-batched averaged stochastic gradient descent with momentum (Bottou, 2010; Hinton, 2012) and exponentially decaying learning rates. The mini-batch size is fixed to 32 and we perform a grid search for the other hyperparameters, tuning against the task-specific evaluation metric on held-out data, with early stopping. Full feature templates and optimal hyperparameter settings are given in the supplementary material.

3 Experiments

We experiment with small feed-forward networks for four diverse NLP tasks: language identification, part-of-speech tagging, word segmentation, and preordering for statistical machine translation.

Evaluation Metrics In addition to standard task-specific quality metrics, our evaluations also consider model size and computational cost. We skirt implementation details by calculating size as the number of kilobytes (1KB=1024 bytes) needed to represent all model parameters and resources. We approximate the computational cost as the number of floating-point operations (FLOPs) performed for one forward pass through the network given an embedding vector $\mathbf{h}_0$. This cost is dominated by the matrix multiplications to compute (unscaled) activation unit values, hence our metric excludes the non-linearities and softmax normalization, but still accounts for the final layer logits. To ground this metric, we also provide indicative absolute speeds for each task, as measured on a modern workstation CPU (3.50GHz Intel Xeon E5-1650 v3).

3.1 Language Identification

Recent shared tasks on code-switching (Molina et al., 2016) and dialects (Malmasi et al., 2016) have generated renewed interest in language identification. We restrict our focus to single language identification across diverse languages, and compare to the work of Baldwin and Lui (2010) on predicting the language of Wikipedia text in 66 languages. For this task, we obtain the input $\mathbf{h}_0$ by separately *averaging* the embeddings for each n-gram length ($N = [1, 4]$), as summation did not produce good results.

Table 1 shows that we outperform the low-memory nearest-prototype model of Baldwin and Lui (2010). Their nearest neighbor model is the most accurate but its memory scales linearly with the size of the training data.

Moreover, we can apply quantization to the embedding matrix without hurting prediction accuracy: it is better to use less precision for each dimension, but to use more dimensions. Our subsequent models all use quantization. There is no noticeable variation in processing speed when performing dequantization on-the-fly at inference time. Our 16-dim Lang-ID model runs at 4450 documents/second (5.6 MB of text per second) on the preprocessed Wikipedia dataset.

Relationship to Compact Language Detector These techniques back the open-source Compact Language Detector v3 (CLD3)[1] that runs in Google Chrome browsers.[2] Our experimental Lang-ID model uses the same overall architecture as CLD3, but uses a simpler feature set, less involved preprocessing, and covers fewer languages.

3.2 POS Tagging

We apply our model as an unstructured classifier to predict a POS tag for each token independently, and compare its performance to that of the byte-to-span (BTS) model (Gillick et al., 2016). BTS is a 4-layer LSTM network that maps a sequence of bytes to a sequence of labeled spans, such as tokens and their POS tags. Both approaches limit model size by using small input vocabularies: byte values in the case of BTS, and hashed character n-grams and (optionally) cluster ids in our case.

Model	Micro F1	Size
Baldwin and Lui (2010): NN	90.2	-
Baldwin and Lui (2010): NP	87.0	-
Small FF, 6 dim	87.3	334 KB
Small FF, 16 dim	88.0	800 KB
Small FF, 16 dim, *quantized*	88.0	302 KB

Table 1: Language Identification. Quantization allows trading numerical precision for larger embeddings. The two models from Baldwin and Lui (2010) are the nearest neighbor (NN) and nearest prototype (NP) approaches.

Model	Acc.	Wts.	MB	Ops.
Gillick et al. (2016)	95.06	900k	-	6.63m
Small FF	94.76	241k	0.6	0.27m
+Clusters	95.56	261k	1.0	0.31m
$\frac{1}{2}$ Dim.	95.39	143k	0.7	0.18m

Table 2: POS tagging. Embedded word clusters improves accuracy and allows the use of smaller embedding dimensions.

Bloom Mapped Word Clusters It is well known that word clusters can be powerful features in linear models for a variety of tasks (Koo et al., 2008; Turian et al., 2010). Here, we show that they can also be useful in neural network models. However, naively introducing word cluster features drastically increases the amount of memory required, as a word-to-cluster mapping file with hundreds of thousands of entries can be several megabytes on its own.[3] By representing word clusters with a Bloom map (Talbot and Talbot, 2008), a key-value based generalization of Bloom filters, we can reduce the space required by a factor of ∼15 and use 300KB to (approximately) represent the clusters for 250,000 word types.

In order to compare against the monolingual setting of Gillick et al. (2016), we train models for the same set of 13 languages from the Universal Dependency treebanks v1.1 (Nivre et al., 2016) corpus, using the standard predefined splits.

As shown in Table 2, our best models are 0.3% more accuate on average across all languages than the BTS monolingual models, while using 6x fewer parameters and 36x fewer FLOPs. The cluster features play an important role, providing a 15% relative reduction in error over our vanilla model, but also increase the overall size. Halv-

[3] For example, the commonly used English clusters from the BLLIP corpus is over 7 MB – people.csail.mit.edu/maestro/papers/bllip-clusters.gz

Transition	
SPLIT	$([\sigma],[i\|\beta]) \rightarrow ([\sigma\|i],[\beta])$
MERGE	$([\sigma],[i\|\beta]) \rightarrow ([\sigma],[\beta])$

Table 3: Segmentation Transition system. Initially all characters are on the buffer β and the stack σ is empty: $([],[c_1c_2...c_n])$. In the final state the buffer is empty and the stack contains the first character for each word.

ing all feature embedding dimensions (except for the cluster features) still gives a 12% reduction in error and trims the overall size back to 1.1x the vanilla model, staying well under 1MB in total. This halved model configuration has a throughput of 46k tokens/second, on average.

Two potential advantages of BTS are that it does not require tokenized input and has a more accurate multilingual version, achieving 95.85% accuracy. From a *memory* perspective, one multilingual BTS model will take less space than separate FF models. However, from a *runtime* perspective, a pipeline of our models doing language identification, word segmentation, and then POS tagging would still be faster than a single instance of the deep LSTM BTS model, by about 12x in our FLOPs estimate.[4]

3.3 Segmentation

Word segmentation is critical for processing Asian languages where words are not explicitly separated by spaces. Recently, neural networks have significantly improved segmentation accuracy (Zhang et al., 2016; Cai and Zhao, 2016; Liu et al., 2016; Yang et al., 2017; Kong et al., 2015). We use a structured model based on the transition system in Table 3, and similar to the one proposed by Zhang and Clark (2007). We conduct the segmentation experiments on the Chinese Treebank 6.0 with the recommended data splits. No external resources or pretrained embeddings are used. Hashing was detrimental to quality in our preliminary experiments, hence we do not use it for this task. To learn an embedding for unknown characters, we cast characters occurring only once in the training set to a special symbol.

Selected Features Because we are not using hashing here, we need to be careful about the size of the input vocabulary. The neural network with its non-linearity is in theory able to learn bigrams by conjoining unigrams, but it has been shown that explicitly using character bigram features leads to better accuracy (Zhang et al., 2016; Pei et al., 2014). Zhang et al. (2016) suggests that embedding manually specified feature conjunctions further improves accuracy ('Zhang et al. (2016)-combo' in Table 4). However, such embeddings could easily lead to a model size explosion and thus are not considered in this work.

Model	Accuracy	Size
Zhang et al. (2016)	95.01	–
Zhang et al. (2016)-combo	95.95	–
Small FF, 64 dim	94.24	846KB
Small FF, 256 dim	94.16	3.2MB
Small FF, 64 dim, *bigrams*	95.18	2.0MB

Table 4: Segmentation results. Explicit bigrams are useful.

The results in Table 4 show that spending our memory budget on small bigram embeddings is more effective than on larger character embeddings, in terms of both accuracy and model size. Our model featuring bigrams runs at 110KB of text per second, or 39k tokens/second.

3.4 Preordering

Preordering source-side words into the target-side word order is a useful preprocessing task for statistical machine translation (Xia and McCord, 2004; Collins et al., 2005; Nakagawa, 2015; de Gispert et al., 2015). We propose a novel transition system for this task (Table 5), so that we can repeatedly apply a small network to produce these permutations. Inspired by a non-projective parsing transition system (Nivre, 2009), the system uses a SWAP action to permute spans. The system is sound for permutations: any derivation will end with all of the input words in a permuted order, and complete: all permutations are reachable (use SHIFT and SWAP operations to perform a bubble sort, then APPEND $n-1$ times to form a single span). For training and evaluation, we use the English-Japanese manual word alignments from Nakagawa (2015).

Transition	Precondition
APPEND	$([\sigma\|i\|j],[\beta]) \rightarrow ([\sigma\|[ij]],[\beta])$
SHIFT	$([\sigma],[i\|\beta]) \rightarrow ([\sigma\|i],[\beta])$
SWAP	$([\sigma\|i\|j],[\beta]) \rightarrow [\sigma\|j],[i\|\beta]); i < j$

Table 5: Preordering Transition system. Initially all words are part of singleton spans on the buffer: $([],[[w_1][w_2]...[w_n]])$. In the final state the buffer is empty and the stack contains a single span.

[4] Our calculation of BTS FLOPs is very conservative and favorable to BTS, as detailed in the supplementary material.

Model	FRS	Size
Nakagawa (2015)	81.6	-
Small FF	75.2	0.5MB
Small FF + POS tags	81.3	1.3MB
Small FF + Tagger input fts.	76.6	3.7MB

Table 6: Preordering results for English → Japanese. *FRS* (in $[0, 100]$) is the fuzzy reordering score (Talbot et al., 2011).

Pipelines For preordering, we experiment with either spending all of our memory budget on reordering, or spending some of the memory budget on features over predicted POS tags, which also requires an additional neural network to predict these tags. Full feature templates are in the supplementary material. As the POS tagger network uses features based on a three word window around the token, another possibility is to add all of the features that would have affected the POS tag of a token to the reorderer directly.

Table 6 shows results with or without using the predicted POS tags in the preorderer, as well as including the features used by the tagger in the reorderer directly and only training the downstream task. The preorderer that includes a separate network for POS tagging and then extracts features over the predicted tags is more accurate and smaller than the model that includes all the features that contribute to a POS tag in the reorderer directly. This pipeline processes 7k tokens/second when taking pretokenized text as input, with the POS tagger accounting for 23% of the computation time.

4 Conclusions

This paper shows that small feed-forward networks are sufficient to achieve useful accuracies on a variety of tasks. In resource-constrained environments, speed and memory are important metrics to optimize as well as accuracies. While large and deep recurrent models are likely to be the most accurate whenever they can be afforded, feed-foward networks can provide better value in terms of runtime and memory, and should be considered a strong baseline.

Abstract

We propose a novel LSTM-based deep multi-task learning framework for aspect term extraction from user review sentences. Two LSTMs equipped with extended memories and neural memory operations are designed for jointly handling the extraction tasks of aspects and opinions via memory interactions. Sentimental sentence constraint is also added for more accurate prediction via another LSTM. Experiment results over two benchmark datasets demonstrate the effectiveness of our framework.

1 Introduction

The aspect-based sentiment analysis (ABSA) task is to identify opinions expressed towards specific entities such as *laptop* or attributes of entities such as *price* (Liu, 2012a). This task involves three subtasks: Aspect Term Extraction (ATE), Aspect Polarity Detection and Aspect Category Detection. As a fundamental subtask in ABSA, the goal of the ATE task is to identify opinionated aspect expressions. One of most important characteristics is that opinion words can provide indicative clues for aspect detection since opinion words should co-occur with aspect words. Most publicly available datasets contain the gold standard annotations for opinionated aspects, but the ground truth of the corresponding opinion words is not commonly provided. Some works tackling the ATE task ignore the consideration of opinion words and just focus on aspect term modeling and learning (Jin et al., 2009; Jakob and Gurevych, 2010; Toh and Wang, 2014; Chernyshevich, 2014; Manek et al., 2017; San Vicente et al., 2015; Liu et al., 2015; Poria et al., 2016; Toh and Su, 2016; Yin et al., 2016). They fail to leverage opinion information which is supposed to be useful clues.

Some works tackling the ATE task consider opinion information (Hu and Liu, 2004a,b; Popescu and Etzioni, 2005; Zhuang et al., 2006; Qiu et al., 2011; Liu et al., 2012b, 2013a,b, 2014) in an unsupervised or partially supervised manner. Qiu et al. (2011) proposed Double Propagation (DP) to collectively extract aspect terms and opinion words based on information propagation over a dependency graph. One drawback is that it heavily relies on the dependency parser, which is prone to generate mistakes when applying on informal online reviews. Liu et al. (2014) modeled relation between aspects and opinions by constructing a bipartite heterogenous graph. It cannot perform well without a high-quality phrase chunker and POS tagger reducing its flexibility. As unsupervised or partially supervised frameworks cannot take the full advantages of aspect annotations commonly found in the training data, the above methods lead to deficiency in leveraging the data. Recently, Wang et al. (2016) considered relation between opinion words and aspect words in a supervised model named RNCRF. However, RNCRF tends to suffer from parsing errors since the structure of the recursive network hinges on the dependency parse tree. CMLA (Wang et al., 2017a) used a multilayer neural model where each layer consists of aspect attention and opinion attention. However CMLA merely employs standard GRU without extended memories.

We propose MIN (Memory Interaction Network), a novel LSTM-based deep multi-task learning framework for the ATE task. Two LSTMs with extended memory are designed for handling

the extraction tasks of aspects and opinions. The aspect-opinion relationship is established based on neural memory interactions between aspect extraction and opinion extraction where the global indicator score of opinion terms and local positional relevance between aspects and opinions are considered. To ensure that aspects are from sentimental sentences, MIN employs a third LSTM for sentimental sentence classification facilitating more accurate aspect term extraction. Experiment results over two benchmark datasets show that our framework achieves superior performance.

2 Model

2.1 Overview

Let an input review sentence with T word tokens and the corresponding distributed representations be w $= \{w_1, ..., w_T\}$ and x $= \{x_1, ..., x_T\}$ respectively. The ATE task is treated as a sequence labeling task with BIO tagging scheme and the set of aspect tags for the word w_t is $y_t^A \in \{B, I, O\}$, where B, I, O represent beginning of, inside and outside of the aspect span respectively. Commonly found training data contains gold annotations for aspect terms and opinionated sentences, but the gold standard of opinion words are usually not available.

In our multi-task learning framework, three tasks are involved: (1) aspect term extraction (ATE), (2) opinion word extraction and (3) sentimental sentence classification. We design a task-specific LSTM, namely, A-LSTM, O-LSTM and S-LSTM, for tackling each of the above tasks respectively. The first component of our proposed framework consists of A-LSTM and O-LSTM where we equip LSTMs with extended operational memories and some operations are defined over the memories for task-level memory interactions. The second component is to determine if a review sentence is sentimental. This is achieved by employing a vanilla LSTM, namely, S-LSTM.

2.2 Model Description

The first component of our framework MIN is composed of A-LSTM and O-LSTM. Both LSTMs have extended memories for task-level memory interactions. A-LSTM involves a large aspect memory $H_t^A \in \mathbb{R}^{n_m \times dim_h^A}$ and an opinion summary vector $m_t^O \in \mathbb{R}^{dim_h^O}$ where H_t^A contains n_m pieces of aspect hidden states of dimension dim_h^A and m_t^O is distilled from H_t^O. As for O-LSTM, similarly, an opinion memory $H_t^O \in \mathbb{R}^{n_m \times dim_h^O}$ and an aspect-specific summary vector $m_t^A \in \mathbb{R}^{dim_h^A}$ are included.

We use the aspect term annotations in the training data for training A-LSTM. As there is no ground truth available for opinion words in the training data, sentiment lexicon and high-precision dependency rules are introduced to find potential opinion words. Commonly used opinion words can be found in some general sentiment lexicons. To find opinion words, not in sentiment lexicons, in a sentence, we build a small rule set $\mathcal{R}$ composed of dependency relations with high confidence, e.g., $amod$, $nsubj$, and determine if w_t directly depends on the gold aspect word through the dependencies in $\mathcal{R}$. If so, w_t will be treated as a potential opinion word. Then such opinion words are used as training data for O-LSTM.

In the memory-enhanced A-LSTM and O-LSTM, we manually design three kinds of operations: (1) **READ** to select n_m pieces of aspect (opinion) hidden states from the past memories and build H_t^A (H_t^O); (2) **DIGEST** to distill an aspect (opinion)-specific summary m_t^A (m_t^O) from H_t^A (H_t^O) where influences of opinion terms and relative positions of inputs are considered; (3) **INTERACT** to perform interaction between A-LSTM and O-LSTM using the task specific summaries (i.e., m_t^A and m_t^O).

Consider the work flow of A-LSTM for aspect term extraction. Since opinion words and aspect terms should co-occur, the goal of A-LSTM participating in memory interactions is to acquire opinion summaries from O-LSTM (i.e., m_t^O) for better aspect prediction. First of all, MIN will **READ** n_m pieces of opinion memories which are most related to w_t from O-LSTM. Syntax structure could be used but syntactic parsers are not effective for processing short informal review sentences. Therefore, MIN selects memory segments temporally related to w_t. Precisely, the opinion memory at the time step t is $H_t^O = [h_{t-1}^O; ...; h_{t-n_m}^O]$ where h_{t-i}^O is the $(t-i)$-th hidden state from O-LSTM. Since the linear context contains most of the parent nodes and the child nodes of w_t on the dependency parse tree, treating the corresponding memory segments as relevant segments to w_t is reasonable.

Then MIN will **DIGEST** the collected opinion memories H_t^O in the A-LSTM. As different memory segments are not of equal importance for the current decision and the same segment in different memories (i.e., different H_t^O) also makes a difference, MIN leverages two kind of weights to summarize the collected content. The first weight is the indicator score of being opinion terms denoted as $v^I \in \mathbb{R}^{n_m}$, which is used to measure how much opinion information the word w_{t-i} ($i = 1, .., n_m$) holds. We adopt Euclidean distance between distributed representations of w_{t-i} and opinion words. It is obvious that computing the distance between x_{t-i} and each opinion word is expensive. Thus, we run an off-the-shelf clustering algorithm over opinion words in the training set and then use the produced n_c centroids to estimate the indicator score v_i^I of w_{t-i} being an opinion word:

$$v_i^I = \sum_{j=1}^{n_c} \frac{1}{||x_{t-i} - c_j||_2} \tag{1}$$

where x_{t-i} is the distributed representation of w_{t-i} and c_j is the centroid vector representation of j-th cluster. This weighting scheme ensures that w_{t-i} is assigned a high score as long as x_{t-i} is close to a particular centroid. The aspect decision of w_t is also affected by relative position between w_{t-i} and w_t. Thus, MIN employs the second weight v^P to explicitly model their positional relevance and the initial weight for the i-th segment v_i^P is calculated as below:

$$v_i^P = \frac{n_m - i + 1}{\sum_{k=1}^{n_m} k} \tag{2}$$

where n_m is the number of hidden state in H_t^O. This position-aware weight enables that the closer the word w_{t-i} is to the current input, the more the corresponding memory segment will contribute to the current decision. To better capture the local positional relevance, we make the initialized v^P as learnable parameters. Combining the above two weights helps to utilize each active memory segment according to the importance for prediction and m_t^O, the summary of H_t^O is generated:

$$m_t^O = (H_t^O)^\top \left(\frac{v^I \odot v^P}{||v^I||_2}\right) \tag{3}$$

where $\odot$ denotes element-wise multiplication and $|| * ||_2$ is Euclidean norm of vectors. From Equation 3, m_t^O is dominated by the associated memory segment of w_{t-i} that obtains the high combined weights.

In the last operation **INTERACT**, A-LSTM communicates with O-LSTM by acquiring m_t^O from O-LSTM and incorporating the summary into the memory update. The update process is as follows:

$$\begin{aligned}
i_t^A &= \sigma(W_i^A x_t + U_i^A [H_t^A[1] : m_t^O]) + b_i^A) \\
f_t^A &= \sigma(W_f^A x_t + U_f^A [H_t^A[1] : m_t^O]) + b_f^A) \\
\hat{c}_t^A &= \tanh(W_c^A x_t + U_c^A [H_t^A[1] : m_t^O]) + b_c^A) \\
o_t^A &= \sigma(W_o^A x_t + U_o^A [H_t^A[1] : m_t^O]) + b_o^A) \\
c_t^A &= i_t^A \odot \hat{c}_t^A + c_{t-1}^A \odot f_t^A \\
h_t^A &= \tanh(c_t^A) \odot o_t^A
\end{aligned} \tag{4}$$

where W_*^A, U_*^A and b_*^A are weight parameters of the A-LSTM and σ is the *sigmoid* activation function. [:] denotes vector concatenation operation. m_t^O can be seen as the summary of the opinion indicator in the left context of w_t and $H_t^A[1]$ is the most immediate hidden memory of A-LSTM. MIN blends the opinion summary from O-LSTM with the memory from A-LSTM. The co-occurrence relation between aspects and opinion words is modeled by such "memory fusion" strategy. Since opinion words can appear on both sides of w_t, memory segments corresponding to the right context (i.e., "future" memory) should be included. Hence, we conduct bi-directional training for A-LSTM.

The work flow of memory interaction and the update process of the internal memories in O-LSTM are kept same with those in A-LSTM except the **DIGEST** operation. Specifically, we set m_t^A, the task-specific summary of A-LSTM, as h_t^A.

The second component of MIN is a generic LSTM called S-LSTM for discriminating sentimental sentences and non-sentimental sentences. The design and the process of the memory update in this component are similar to that in Jozefowicz et al. (2015). In sentences not conveying any sentimental meanings, some words like *food*, *service* tend to be misclassified as aspect terms since they are commonly used in user reviews. To avoid this kind of error, we add a constraint that an aspect term should come from sentimental sentence. Specifically, S-LSTM learns the sentimental representation h_T^S of the sentence and then feeds it in aspect prediction as a soft constraint:

$$P(y_t^A | x_t) = \text{softmax}(W_{fc}^A([h_t^A : h_T^S])) \tag{5}$$

where W_{fc}^A denotes the weight matrix of the fully-connected softmax layer.

On the whole, our proposed MIN framework has three LSTMs and each of them is differentiable. Thus, our MIN framework can be efficiently trained with gradient descent. For A-LSTM and O-LSTM, we use the token-level cross-entropy error between the predicted distribution $P(y_t^{\mathcal{T}}|x_t)$ and the gold standard distribution $P(y_t^{\mathcal{T},g}|x_t)$ as the loss function ($\mathcal{T} \in \{A, O\}$):

$$Loss(\mathcal{T}) = -\frac{1}{N*T}\sum_{i=1}^{N}\sum_{t=1}^{T} P(Y_{i,t}^{\mathcal{T},g}|X_{i,t}) \odot \log[P(Y_{i,t}^{\mathcal{T}}|X_{i,t})] \tag{6}$$

For S-LSTM, sentence-level cross entropy error are employed to calculate the corresponding loss:

$$Loss(S) = -\frac{1}{N}\sum_{i=1}^{N} P(Y_i^{S,g}|X_i) \odot \log[P(Y_i^{S}|X_i)] \tag{7}$$

Then, losses from different LSTMs are combined to form the training objective of the MIN framework:

$$J(\theta) = Loss(A) + Loss(O) + Loss(S) \tag{8}$$

.

D_2	2000/676	1743/622

Table 1: Statistics of datasets.

3 Experiment

3.1 Dataset

We conduct experiments on two benchmark datasets from SemEval ABSA challenge (Pontiki et al., 2014, 2016) as shown in Table 1. D_1 (SemEval 2014) contains reviews from the laptop domain and D_2 (SemEval 2016) contains reviews from the restaurant domain. In these datasets, aspect terms have been labeled and sentences containing at least one golden truth aspect are regarded as sentimental sentences. As gold standard annotations for opinion words are not provided, we select words with strong subjectivity from MPQA[1] as potential opinion words. Apart from the common opinion words in the sentiment lexicon, we also treat words, which directly depend on gold standard aspect terms through high-precision dependency rules, as opinion words.

3.2 Experiment Design

To evaluate the proposed MIN framework, we perform comparison with the following two groups of methods:

(1) *CRF* based methods:

- **CRF**: Conditional Random Fields with basic feature templates[2] and word embeddings.
- **Semi-CRF**: First-order semi-Markov conditional random fields (Sarawagi et al., 2004) and the feature template in Cuong et al. (2014) is adopted.
- **IHS_RD** (Chernyshevich, 2014), **NLANGP** (Toh and Su, 2016): Best systems in ATE subtask in SemEval ABSA challenges (Pontiki et al., 2014, 2016).
- **DLIREC** (Toh and Wang, 2014), **AUEB** (Xenos et al., 2016): Top-ranked CRF-based systems in ATE subtask in SemEval ABSA challenges (Pontiki et al., 2014, 2016).
- **WDEmb** (Yin et al., 2016): Enhanced CRF with word embeddings, linear context embeddings and dependency path embeddings.

(2) *Neural Network* based methods

- **LSTM**: Vanilla bi-directional LSTM with pre-trained word embeddings[3].
- **RNCRF** (Wang et al., 2016): Dependency Tree based Recursive Neural Network with CRF extractor[4].

For datasets in the restaurant domain, we train word embeddings of dimension 200 with word2vec (Mikolov et al., 2013) on Yelp reviews[5]. For those in laptop domain, we use pre-trained $glove.840B.300d$[6].

[1] http://mpqa.cs.pitt.edu/

[2] http://sklearn-crfsuite.readthedocs.io/en/latest/

[3] As we use our own implementation of LSTM, the reported results are different from those in (Liu et al., 2015)

[4] Specifically, we list the result of RNCRF over D_1 without opinion annotations for fair comparison. As no result is provided for RNCRF-no-opinion over D_2, we report the corresponding performance of the full model. See their following works (Wang et al., 2017a,b). Also, CMLA (Wang et al., 2017a) reports better results than RNCRF but we do not compare with it. The reason is that CMLA introduces the gold standard opinion labels in the training data while such labels are not available for our experiments

[6] https://nlp.stanford.edu/projects/glove/

	D_1	D_2
CRF	74.01%	69.56%
Semi-CRF	68.75%	66.35%
IHS_RD	74.55%	-
DLIREC	73.78%	-
NLANGP	-	72.34%
AUEB	-	70.44%
WDEmb	75.16%	-
LSTM	75.25%	71.26%
RNCRF	77.26%	69.74%
Our Work	**77.58%**	**73.44%**

Table 2: Experiment results

The hyper-parameters are selected via ten-fold cross validation. The dimension of hidden representations are 100, 20, 40 for A-LSTM, O-LSTM and S-LSTM respectively. The dropout rate for O-LSTM and S-LSTM is 0.4. The size of the aspect (opinion) memory n_m is 4. The batch size is set to 32. As for initialization of network parameters, we adopt the strategy that the initial weights are sampled from the uniform distribution (Glorot and Bengio, 2010). We employ ADAM (Kingma and Ba, 2014) as optimizer and the default settings of ADAM are used.

To better reveal the capability of the proposed MIN, we train 5 models with the same group of hyper-parameters and report the average F_1 score over the testing set.

3.3 Results and Analysis

Table 2 depicts experiment results. Compared to the best systems in SemEval challenge, MIN achieves 3.0% and 1.1% absolute gains on D_1 and D_2 respectively. Besides, our MIN outperforms WDEmb, a strong CRF-based system benefiting from several kinds of useful word embeddings, by 2.1% on D_1. With memory interactions and consideration of sentimental sentence, our MIN boosts the performance of vanilla bi-directional LSTM (+2.0% and +1.7% respectively). It validates the effectiveness of the manually designed memory operations and the proposed memory interaction mechanism. MIN also outperforms the state-of-the-art RNCRF on each dataset suggesting that memory interactions can be an alternative strategy instead of syntactic parsing. To further study the impact of each element in MIN, we conduct ablation experiments. As shown in Table 3, removing bi-directionality decreases the extraction performances (-2.0% and -1.0%). The soft sentimental constraint proves to be useful since MIN is 1.5% and 1.0% superior than the framework without S-LSTM on D_1 and D_2 respectively. O-LSTM brings in the largest performance gains on D_2 compared with ablated framework (i.e., MIN without O-LSTM), verifying our postulation that aspect-opinion "interaction" is more effective than only considering aspect terms. We also observe that the contribution of O-LSTM is less significant than that of bi-directionality on D_1 (+1.6% vs +2.0%). This is reasonable since using opinion words as adjective modifiers placed after the aspects is common in English.

	D_1	D_2
MIN without bi-directionality	75.59%	71.87%
MIN without S-LSTM	76.04%	72.55%
MIN without O-LSTM	75.97%	71.80%
MIN	**77.58%**	**73.44%**

Table 3: Ablation experiment results.

4 Conclusions

We propose Memory Interaction Network (MIN), a multi-task learning framework, to detect aspect terms from the online user reviews. Compared with previous studies, our MIN has following features:

- Co-occurrence pattern between aspects and opinions is captured via memory interactions, where the neural memory operations are designed to summarize task-level information and perform interactions.
- A novel LSTM unit with extended memories is developed for memory interactions.

Analogs of Linguistic Structure in Deep Representations

Jacob Andreas and **Dan Klein**

Abstract

We investigate the compositional structure of message vectors computed by a deep network trained on a communication game. By comparing truth-conditional representations of encoder-produced message vectors to human-produced referring expressions, we are able to identify aligned (vector, utterance) pairs with the same meaning. We then search for structured relationships among these aligned pairs to discover simple vector space transformations corresponding to negation, conjunction, and disjunction. Our results suggest that neural representations are capable of spontaneously developing a "syntax" with functional analogues to qualitative properties of natural language.[1]

1 Introduction

The past year has seen a renewal of interest in end-to-end learning of communication strategies between pairs of agents represented with deep networks (Wagner et al., 2003). Approaches of this kind make it possible to learn decentralized policies from scratch (Foerster et al., 2016; Sukhbaatar et al., 2016), with multiple agents coordinating via learned communication protocol. More generally, any encoder–decoder model (Sutskever et al., 2014) can be viewed as implementing an analogous communication protocol, with the input encoding playing the role of a message in an artificial "language" shared by the encoder and decoder (Yu et al., 2016). Earlier work has found that under suitable conditions, these protocols acquire simple interpretable lexical (Dircks and Stoness, 1999; Lazaridou et al., 2016) and sequential structure (Mordatch and Abbeel, 2017), even without natural language training data.

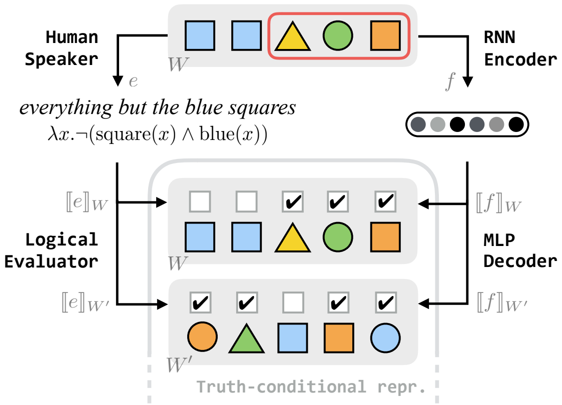

Figure 1: Overview of our task. Given a dataset of referring expression games, example human expressions, and their associated logical forms, we compute explicit denotations both for the original task and in other possible tasks—giving rise to a truth-conditional representation of the natural language. We train a recurrent encoder–decoder model to solve the same tasks directly, and use the decoder to generate comparable truth-conditional representations of neural encodings.

One of the distinguishing features of natural language is compositionality: the existence of operations like negation and coordination that can be applied to utterances with predictable effects on meaning. RNN models trained for natural language processing tasks have been found to learn representations that encode some of this compositional structure—for example, sentence representations for machine translation encode explicit features for certain syntactic phenomena (Shi et al., 2016) and represent some semantic relationships translationally (Levy et al., 2014). It is thus natural to ask whether these "language-like" structures also arise spontaneously in models trained directly from an environment signal. Rather than using language as a form of supervision, we propose to use it as a *probe*—exploiting post-hoc statistical correspondences between natural language descriptions and neural encodings to discover regular structure in representation space.

To do this, we need to find (vector, string) pairs with matching semantics, which requires first aligning unpaired examples of human–human

communication with network hidden states. This is similar to the problem of "translating" RNN representations recently investigated in Andreas et al. (2017). Here we build on that approach in order to perform a detailed analysis of *compositional* structure in learned "languages". We investigate a communication game previously studied by FitzGerald et al. (2013), and make two discoveries: in a model trained without any access to language data,

1. The strategies employed by human speakers in a given communicative context are surprisingly good predictors of RNN behavior in the same context: humans and RNNs send messages whose interpretations agree on nearly 90% of object-level decisions, even outside the contexts in which they were produced.

2. Interpretable language-like structure naturally arises in the space of representations. We identify geometric regularities corresponding to negation, conjunction, and disjunction, and show that it is possible to linearly transform representations in ways that approximately correspond to these logical operations.

2 Task

We focus our evaluation on a communication game due to FitzGerald et al. (2013) (Figure 1, top). In this game, the *speaker* observes (1) a *world* W of 1–20 objects labeled with with attributes and (2) a designated *target* subset X of objects in the world. The *listener* observes only W, and the speaker's goal is to communicate a representation of X that enables the listener to accurately reconstruct it. The GENX dataset collected for this purpose contains 4170 human-generated natural-language referring expressions and corresponding logical forms for 273 instances of this game. Because these human-generated expressions have all been pre-annotated, we treat language and logic interchangeably and refer to both with the symbol e. We write $e(W)$ for the expression generated by a human for a particular world W, and $[\![e]\!]_W$ for the result of evaluating the logical form e against W.

We are interested in using language data of this kind to analyze the behavior of a deep model trained to play the same game. We focus our analysis on a standard RNN encoder–decoder, with the encoder playing the role of the speaker and the decoder playing the role of the listener. The encoder is a single-layer RNN with GRU cells (Cho et al., 2014) that consumes both the input world and target labeling and outputs a 64-dimensional hidden representation. We write $f(W)$ for the output of this encoder model on a world W. To make predictions, this representation is passed to a decoder implemented as a multilayer perceptron. The decoder makes an independent labeling decision about every object in W (taking as input both f and a feature representation of a particular object W_i). We write $[\![f]\!]_W$ for the full vector of decoder outputs on W. We train the model maximize classification accuracy on randomly-generated scenes and target sets of the same form as in the GENX dataset.

3 Approach

We are not concerned with the RNN model's raw performance on this task (it achieves nearly perfect accuracy). Instead, our goal is to explore what kinds of messages the model computes in order to achieve this accuracy—and specifically whether these messages contain high-level semantics and low-level structure similar to the referring expressions produced by humans. But how do we judge semantic equivalence between natural language and vector representations? Here, as in Andreas et al. (2017), we adopt an approach inspired by formal semantics, and represent the meaning of messages via their *truth conditions* (Figure 1).

For every problem instance W in the dataset, we have access to one or more human messages $e(W)$ as well as the RNN encoding $f(W)$. The truth-conditional account of meaning suggests that we should judge e and f to be equivalent if they designate the same set of of objects in the world (Davidson, 1967). But it is not enough to compare their predictions solely in the context where they were generated—testing if $[\![e]\!]_W = [\![f]\!]_W$—because any pair of models that achieve perfect accuracy on the referring expression task will make the same predictions in this initial context, regardless of the meaning conveyed.

Instead, we sample a collection of alternative worlds $\{W_i\}$ observed elsewhere in the dataset, and compute a tabular meaning representation *rep*$(e) = \{[\![e]\!]_{W_i}\}$ by evaluating e in each world W_i. We similarly compute *rep*$(f) = \{[\![f]\!]_{W_i}\}$, allowing the learned decoder model to play the role of logical evaluation for message vectors. For

	Human	0.92	0.63	0.35

Table 1: Agreement with predicted model behavior for the high-level semantic correspondence task, computed for objects (single entries in tabular representation), worlds (rows), and full tables. Referring expressions e generated by humans in a single communicative context are highly predictive of how learned representations f will be interpreted by the decoder across multiple contexts.

logically equivalent messages, these tabular representations are guaranteed to be identical, so the sampling procedure can be viewed as an approximate test of equivalence. It additionally allows us to compute softer notions of equivalence by measuring agreement on individual worlds or objects.

4 Interpreting the meaning of messages

We begin with the simplest question we can answer with this tool: how often do the messages generated by the encoder model have the same meaning as messages generated by humans for the same context? Again, our goal is not to evaluate the performance of the RNN model, but instead our ability to understand its behavior. Does it send messages with human-like semantics? Is it more explicit? Or does it behave in a way indistinguishable from a random classifier?

For each scene in the GENX test set, we compute the model-generated message f and its tabular representation $rep(f)$, and measure the extent to which this agrees with representations produced by three "theories" of model behavior (Figure 2): (1) a **random** theory that accepts or rejects objects with uniform probability, (2) a **literal** theory that predicts membership only for objects that exactly match some object in the original target set, and (3) a **human** theory that predicts according to the most frequent logical form associated with natural language descriptions of the target set (as described in the preceding section). We evaluate agreement at the level of individual objects, worlds, and full tabular meaning representations.

Results are shown in Table 1. Model behavior is well explained by human decisions in the same context: object-level decisions can be predicted with close to 90% accuracy based on human judgments alone, and a third of message pairs agree exactly in every sampled scene, providing strong evidence that they carry the same semantics.

These results suggest that the model has learned a communication strategy that is at least superficially language-like: it admits representations of the same kinds of communicative abstractions that humans use, and makes use of these abstractions with some frequency. But this is purely a statement about the high-level behavior of the model, and not about the structure of the space of representations. Our primary goal is to determine whether this behavior is achieved using low-level structural regularities in vector space that can themselves be associated with aspects of natural language communication.

5 Interpreting the structure of messages

For this we turn to a focused investigation of three specific logical constructions used in natural language: a unary operation (negation) and two binary operations (conjunction and disjunction). All are used in the training data, with a variety of scopes (e.g. *all green objects that are not a triangle*, *all the pieces that are not tan arches*).

Because humans often find it useful to specify the target set by exclusion rather than inclusion, we first hypothesize that the RNN language might find it useful to incorporate some mechanism cor-

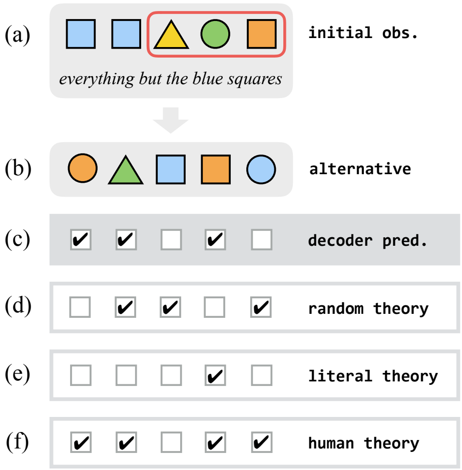

Figure 2: Evaluating theories of model behavior. First, the encoder is run on an initial world (a), producing a representation whose meaning we would like to understand (see Figure 1). We then observe the behavior of the decoder holding this representation fixed but replacing the underlying world representation with alternatives like (b). We compare the true decoder output to a number of *theories* of its behavior. The random theory (d) outputs a random decision for every object. The literal theory (e) predicts that the decoder will output a positive label only on those objects that exactly match some object in the initial observation. The human theory (f) assigns labels according to the logical semantics of the utterance produced by a human presented with the initial observation.

	Conjunction	0.90	0.56	0.37

Table 2: Agreement with predicted model behavior for negation, conjunction, and disjunction tasks (top to bottom). Evaluation is performed on transformed message vectors as described in Section 5. We discover a robust linear transformation of message vectors corresponding to negation, as well as evidence of structured representations of binary operations.

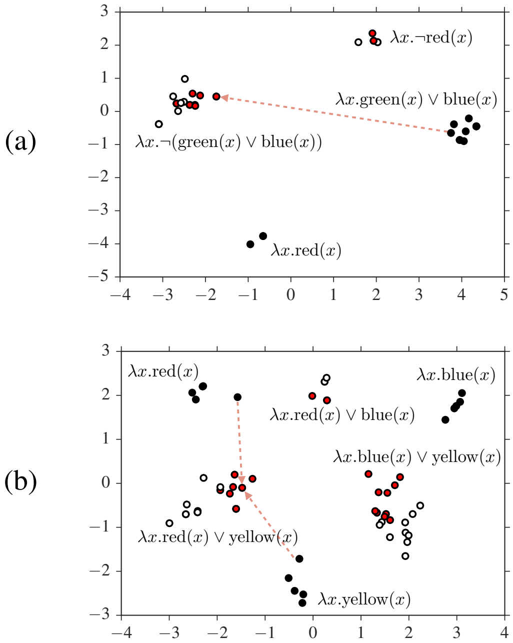

Figure 3: Principal components of structured message transformations discovered by our experiments. (a) Negation: black and white dots show raw message vectors denotationally equivalent to the provided logical cluster label (Section 3). Red dots show the result of transforming black dots with the estimated negation operation N. (b) The corresponding experiment for disjunction using the transformation M.

responding to negation, and that messages can be predictably "negated" in vector space. To test this hypothesis, we first collect examples of the form (e, f, e', f'), where $e' = \neg e$, $\textit{rep}(e) = \textit{rep}(f)$, and $\textit{rep}(e') = \textit{rep}(f')$. In other words, we find pairs of pairs of RNN representations f and f' for which the natural language messages (e, e') serve as a denotational *certificate* that f' behaves as a negation of f. If the learned model does not have any kind of primitive notion of negation, we expect that it will not be possible to find any kind of predictable relationship between pairs (f, f'). (As an extreme example, we could imagine every possible prediction rule being associated with a different point in the representation space, with the correspondence between position and behavior essentially random.) Conversely, if there is a first-class notion of negation, we should be able to select an arbitrary representation vector f with an associated referring expression e, apply some transformation N to f, and be able to predict *a priori* how the decoder model will interpret the representation Nf—i.e. in correspondence with $\neg e$.

Here we make the strong assumption that the negation operation is not only predictable but *linear*. Previous work has found that linear operators are powerful enough to capture many hierarchical and relational structures (Paccanaro and Hinton, 2002; Bordes et al., 2014). Using examples (f, f') collected from the training set as described above, we compute the least-squares estimate $\hat{N} = \arg\min_N \sum ||Nf - f'||_2^2$. To evaluate, we collect example representations from the test set that are equivalent to known logical forms, and measure how frequently model behaviors $\textit{rep}(Nf)$ agree with the logical predictions $\textit{rep}(\neg e)$—in other words, how often the linear operator N actually corresponds to logical negation. Results are shown in the top portion of Table 2. Correspondence with the logical form is quite high, resulting in 97% agreement at the level of individual objects and 45% agreement on full representations. We conclude that the estimated linear operator $\hat{N}$ is analogous to negation in natural language. Indeed, the behavior of this operator is readily visible in Figure 3: predicted negated forms (in red) lie close in vector space to their true values, and negation corresponds roughly to mirroring across a central point.

In our final experiment, we explore whether the same kinds of linear maps can be learned for the binary operations of conjunction and disjunction. As in the previous section, we collect examples from the training data of representations whose denotations are known to correspond to groups of logical forms in the desired relationship—in this case tuples (e, f, e', f', e'', f''), where $\textit{rep}(e) = \textit{rep}(f)$, $\textit{rep}(e') = \textit{rep}(f')$, $\textit{rep}(e'') = \textit{rep}(f'')$ and either $e'' = e \wedge e'$ (conjunction) or $e'' = e \vee e'$ (disjunction). Since we expect that our operator will be symmetric in its arguments, we solve for $\hat{M} = \arg\min_M \sum ||Mf + Mf' - f''||_2^2$.

Results are shown in the bottom portions of Table 2. Correspondence between the behavior predicted by the contextual logical form and the model's actual behavior is less tight than for negation. At the same time, the estimated operators are clearly capturing some structure: in the case of disjunction, for example, model interpretations are correctly modeled by the logical form 92% of the time at the object level and 19% of the time at the denotation level. This suggests that the operations of conjunction and disjunction do have some functional counterparts in the RNN language, but that these functions are not everywhere well approximated as linear.

6 Conclusions

Building on earlier tools for identifying neural codes with natural language strings, we have presented a technique for exploring compositional structure in a space of vector-valued representations. Our analysis of an encoder–decoder model trained on a reference game identified a number of language-like properties in the model's representation space, including transformations corresponding to negation, disjunction, and conjunction. One major question left open by this analysis is what happens when multiple transformations are applied hierarchically, and future work might focus on extending the techniques in this paper to explore recursive structure. We believe our experiments so far highlight the usefulness of a denotational perspective from formal semantics when interpreting the behavior of deep models.

Abstract

Learning word embeddings has received a significant amount of attention recently. Often, word embeddings are learned in an unsupervised manner from a large collection of text. The genre of the text typically plays an important role in the effectiveness of the resulting embeddings. How to effectively train word embedding models using data from different domains remains a problem that is underexplored. In this paper, we present a simple yet effective method for learning word embeddings based on text from different domains. We demonstrate the effectiveness of our approach through extensive experiments on various down-stream NLP tasks.

1 Introduction

Recently, the learning of distributed representations for natural language words (or word embeddings) has received a significant amount of attention (Mnih and Hinton, 2007; Turian et al., 2010; Mikolov et al., 2013a,b,c; Pennington et al., 2014). Such representations were shown to be able to capture syntactic and semantic level information associated with words (Mikolov et al., 2013a). Word embeddings were shown effective in tasks such as named entity recognition (Sienčnik, 2015), sentiment analysis (Li and Lu, 2017) and syntactic parsing (Durrett and Klein, 2015). One common assumption made by most of the embedding methods is that, the text corpus is from one single domain; e.g., articles from bioinformatics. However, in practice, there are often text corpora from multiple domains; e.g., we may have text collections from broadcast news or Web blogs, whose words are not necessarily limited to bioinformatics. Can these corpora from different domains help learn better word embeddings, so as to improve the downstream NLP applications in a target domain like bioinformatics? Our answer is yes, because despite the domain differences, these additional domains do introduce more text data converying useful information (i.e., more words, more word co-occurrences), which can be helpful for consolidating the word embeddings in the target bioinformatics domain.

In this paper, we propose a simple and easy-to-implement approach for learning cross-domain word embeddings. Our model can be seen as a regularized *skip-gram* model (Mikolov et al., 2013a,b), where the source domain information is selectively incorporated for learning the target domain word embeddings in a principled manner.

2 Related Work

Learning a continuous representation for words has been studied for quite a while (Hinton et al., 1986). Many earlier word embedding methods employed the computationally expensive neural network architectures (Collobert and Weston, 2008; Mikolov et al., 2013c). Recently, an efficient method for learning word representations, namely the skip-gram model (Mikolov et al., 2013a,b) was proposed and implemented in the widely used word2vec toolkit. It tries to use the current word to predict the surrounding context words, where the prediction is defined over the embeddings of these words. As a result, it learns the word embeddings by maximizing the likelihood of predictions.

Domain adaptation is an important research topic (Pan et al., 2013), and it has been considered in many NLP tasks. For example, domain adaptation is studied for sentiment classification (Glorot et al., 2011) and parsing (McClosky et al., 2010), just to name a few. However, there is very

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2898–2904
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

little work on domain adaptation for word embedding learning. One major reason preventing people from using text corpora from different domains for word embedding learning is the lack of guidance on which kind of information is worth learning from the source domain(s) for the target domain. In order to address this problem, some pioneering work has looked into this problem. For example, Bollegala et al. (2015) considered those frequent words in the source domain and the target domain as the "pivots". Then it tried to use the pivots to predict the surrounding "non-pivots", meanwhile ensuring the pivots to have the same embedding across two domains. Embeddings learned from such an approach were shown to be able to improve the performance on a cross-domain sentiment classification task. However, this model fails to learn embeddings for many words which are neither pivots nor non-pivots, which could be crucial for some downstream tasks such as named entity recognition.

3 Our Approach

Let us first state the objective of the skip-gram model (Mikolov et al., 2013a) as follows:

$$\begin{aligned}\mathcal{L}_{\mathcal{D}} &= \sum_{(w,c)\in\mathcal{D}} \#(w,c)\Big(\log\sigma(\mathbf{w}\cdot\mathbf{c}) \\ &+ \sum_{i=1}^{k}\mathbb{E}_{c'_i\sim P(w)}[\log\sigma(-\mathbf{w}\cdot\mathbf{c'}_i)]\Big)\end{aligned} \quad (1)$$

where $\mathcal{D}$ refers to the complete text corpus from which we learn the word embeddings. The word w is the current word, c is the context word, and $\#(w,c)$ is the number of times they co-occur in $\mathcal{D}$. We use $\mathbf{w}$ and $\mathbf{c}$ to denote the vector representations for w and c, respectively. The function $\sigma(\cdot)$ is the sigmoid function. The word c'_i is a "negative sample" sampled from the distribution $P(w)$ – typically chosen as the unigram distribution $U(w)$ raised to the $3/4$rd power (Mikolov et al., 2013b).

In our approach, we first learn for each word w an embedding $\mathbf{w}_s$ from the source domain $\mathcal{D}_s$. Next we learn the target domain embeddings as follows:

$$\mathcal{L}'_{\mathcal{D}_t} = \mathcal{L}_{\mathcal{D}_t} + \sum_{w\in\mathcal{D}_t\cap\mathcal{D}_s} \alpha_w \cdot ||\mathbf{w}_t - \mathbf{w}_s||^2 \quad (2)$$

where $\mathcal{D}_t$ refers to the target domain, and $\mathbf{w}_t$ is the target domain representation for w. Such an regularized objective can still be optimized using standard stochastic gradient descent. Note that in the above formula, the regularization term only considers words that appear in both source and target domain, ignoring words that only appear in either the source or the target domain only.

Our approach is inspired by the recent regularization-based domain adaptation framework (Lu et al., 2016). Here, α_w measures the amount of transfer across the two domains when learning the representation for word w. If it is large, it means we require the embeddings of word w in the two domains to be similar. We define α_w as follows:

$$\alpha_w = \sigma(\lambda\cdot\phi(w)) \quad (3)$$

where λ is a hyper-parameter to decide the scaling factor of the significance function $\phi(\cdot)$, which allows the user to control the degree of "knowledge transfer" from source domain to target domain.

How do we define the significance function $\phi(w)$ that controls the amount of transfer for the word w? We first define the frequency of the word w in the dataset $\mathcal{D}$ as $f_{\mathcal{D}}(w)$, the number of times the word w appears in the domain $\mathcal{D}$. Based on this we can define the *normalized* frequency for the word w as follows:

$$\mathcal{F}_{\mathcal{D}}(w) = \frac{f_{\mathcal{D}}(w)}{\max_{w'\in\mathcal{D}_k} f_{\mathcal{D}}(w')} \quad (4)$$

where $\mathcal{D}_k \subset \mathcal{D}$ consists of all except for the top k most frequent words from $\mathcal{D}$[1].

We define the function $\phi(\cdot)$ based on the following metric that is motivated by the well-known Sørensen-Dice coefficient (Sørensen, 1948; Dice, 1945) commonly used for measuring similarities:

$$\phi(w) = \frac{2\cdot\mathcal{F}_{\mathcal{D}_s}(w)\cdot\mathcal{F}_{\mathcal{D}_t}(w)}{\mathcal{F}_{\mathcal{D}_s}(w)+\mathcal{F}_{\mathcal{D}_t}(w)} \quad (5)$$

Why does such a definition make sense? We note that the value of $\phi(w)$ would be high only if both both $\mathcal{F}_{\mathcal{D}_s}(w)$ and $\mathcal{F}_{\mathcal{D}_t}(w)$ are high – in this case the word w is a frequent word across different domains. Intuitively, these are likely those words whose semantics do not change across the two domains, and we should be confident about making their embeddings similar in the two domains. On the other hand, domain-specific words

[1] In all our experiments, we empirically set k to 20.

Table 1: Statistics for datasets used for embedding learning in all experiments.

tend to be more frequent in one domain than the other. In this case, the resulting $\phi(w)$ will also have a lower score, indicating a smaller amount of transfer across the two domains. While other user-defined significance functions are also possible, in this work we simply adopt such a function based on the above simple observations. We will validate our assumptions with experiments in the next section.

4 Experiments

We present extensive evaluations to assess the effectiveness of our approach. Following recent advice by Nayak et al. (2016) and Faruqui et al. (2016), to assess the quality of the learned word embeddings, we considered employing the learned word embeddings as continuous features in several down-stream NLP tasks, including entity recognition, sentiment classification, and targeted sentiment analysis.

We have used various datasets from different domains for learning cross-domain word embeddings under different tasks. We list the data statistics in Table 1.

4.1 Baseline Methods

We consider the following baseline methods when assessing the effectiveness of our approach.

- Discrete: only discrete features (such as bag of words, POS tags, word n-grams and POS tag n-grams, depending on the actual down-stream task) were considered. All following systems include both these base features and the respective additional features.

- Source: we train word embeddings from the source domain as additional features.

- Target: we train word embeddings from the target domain as additional features.

- All: we combined the data from two domains to form a single dataset for learning word embeddings as additional features.

- Concat: we simply concatenate the learned embeddings from both source and target domains as additional features.

Table 2: Results on entity recognition.

- DARep: we use the previous approach of Bollegala et al. (2015) for learning cross-lingual word representations as additional features.

4.2 Entity Recognition

Our first experiment was conducted on entity recognition (Tjong Kim Sang and De Meulder, 2003; Florian et al., 2004), where the task is to extract semantically meaning entities and their mentions from the text.

For this task, we built a standard entity recognition model using conditional random fields (Lafferty et al., 2001). We used the standard features which are commonly used for different methods, including word unigrams and bigrams, bag-of-words features, POS tag window features, POS tag unigrams and bigram features. We conducted two sets of experiments on two different datasets. The first dataset is the GENIA dataset (Ohta et al., 2002), a popular dataset used in bioinformatics, and the second is the ACE-2005 dataset (Walker et al., 2006), which is a standard dataset used for various information extraction tasks.

For the GENIA dataset which consists of 10,946 sentences, we used Enwik9 as the source domain and PubMed as the target domain for learning word embeddings. We set the dimension of word representations as 50.

For the experiments on ACE, we selected the BN subset of ACE2005, which consists of 4,460 CNN headline news and share a similar domain with Gigaword. We used Enwik9 as the source domain and Gigaword as the target domain. We followed a procedure similar to GENIA for experiments.

To tune our hyperparameter λ, we first split the last 10% of the training set as the development

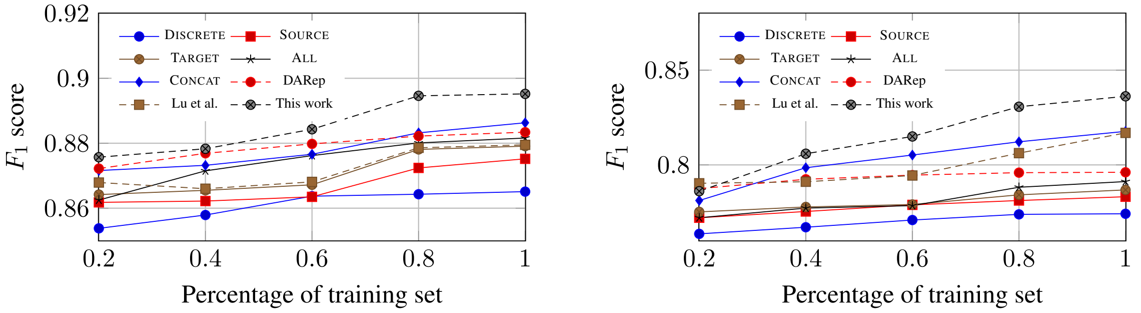

Figure 1: Results on sentiment classification. Left: Yelp (source) to IMDB (target). Right: IMDB (source) to Yelp (target).

portion. We then trained a model using the remaining 90% as the training portion and used the development portion for development of the hyperparameter λ. After development, we re-trained the models using the original training set[2].

We report the results in Table 2. From the results we can observe that the embeddings learned using our algorithm can lead to improved performance when used in this particular down-stream NLP task. We note that in such a task, many entities consist of domain-specific terms, therefore learning good representations for such words can be crucial. As we have discussed earlier, our regularization method enables our model to differentiate domain-specific words from words which are more general in the learning process. We believe this mechanism can lead to improved learning of representations for both types of words.

4.3 Sentiment Classification

The second task we consider is sentiment classification, which is essentially a text classification task, where the goal is to assign each text document a class label indicating its sentiment polarity (Pang et al., 2002; Liu, 2012).

This is also the only task presented in the previous DARep work by Bollegala et al. (2015). As such, we largely followed Bollegala et al. (2015) for experiments. Instead of using the dataset they used which only consists of 2,000 reviews, we considered two much larger datasets – IMDB and Yelp 2014 – for such a task, which was previously used in a sentiment classification task (Tang et al., 2015). IMDB dataset (Diao et al., 2014) is crawled from the movie review site IMDB[3] which consists of 84,919 reviews. Yelp 2014 dataset consists of 231,163 online reviews provided by the Yelp Dataset Challenge[4].

Following Bollegala et al. (2015), for this task we simply learned the word embeddings from the training portion of the review datasets themselves only. No external data was used for learning word embeddings. As Bollegala et al. (2015) only evaluated on a small dataset in their paper for such a task, to understand the effect of varying the amount of training data, we also tried to train our model on datasets with different sizes. We conducted two sets of experiments: we first used the Yelp dataset as the source domain and IMDB as the target domain, and then we switched these two datasets in our second set of experiments. Figure 1 shows the F_1 measures for different word embeddings when different amounts of training data were used. We also compared with the previous approach for domain adaptation (Lu et al., 2016) which only employs discrete features. We can observe that when the dataset becomes large, our learned word embeddings are shown to be more effective than all other approaches. When the complete training set is used, our model significantly outperforms DARep ($p < 0.05$ for both directions with bootstrap resampling test (Koehn, 2004)). DARep appears to be effective when the training dataset is small. However, as the training set size increases, there is no significant improvement for such an approach. As we can also observe from the figure, our approach consistently gives better results than baseline approaches (except for the second experiment when 20% of the data was used). Furthermore, when the amount of training data increases, the differences between our approach and other approaches generally become larger.

Such experiments show that our model works

[2] We selected the optimal value for the hyper-parameter λ from the set $\lambda \in \{0.1, 1, 5, 10, 20, 30, 50\}$ for all experiments in this paper.

well when different amounts of data are available, and our approach appears to be more competitive when a large amount of data is available.

4.4 Targeted Sentiment Analysis

We also conducted experiments on targeted sentiment analysis (Mitchell et al., 2013) – the task of jointly recognizing entities and their sentiment information. We used the state-of-the-art system for targeted sentiment analysis by Li and Lu (2017) whose code is publicly available [5], and used the data from (Mitchell et al., 2013) which consists of 7,105 Spanish tweets and 2,350 English tweets, with named entities and their sentiment information annotated. Note that the model of Li and Lu (2017) is a structured prediction model that involves latent variables. The experiments here therefore allow us to assess the effectiveness of our approach on such a setup involving latent variables. We follow Li and Lu (2017) and report precision ($P.$), recall ($R.$) and F1-measure (F_1) for such a targeted sentiment analysis task, where the prediction is regarded as correct if and only if both the entity's boundary and its sentiment information are correct. Also, unlike previous experiments, which are conducted on English only, these experiments additionally allow us to assess our approach's effectiveness when a different language other than English is considered.

For the English task, we used Enwik9 as the source domain for learning word embeddings, and our crawled English tweets as the target domain. For the Spanish task, we used Eswiki as the source domain, and we also crawled Spanish tweets as the target domain. See Table 1 for the statistics. Similar to the experiments conducted for entity recognition, we split the first 80% of the data for training, the next 10% for development and the last 10% for evaluation. We tuned the hyper-parameter λ using the development set and re-trained the embeddings on the dataset combining the training and the development set, which are then used in final evaluations. Results are reported in Table 3, which show our approach is able to achieve the best results across two datasets in such a task, and outperforms DARep ($p < 0.05$). Interestingly, the concatenation approach appears to be competitive in this task, especially for the Spanish dataset, which appears to be better than the DARep approach. However, we note such an approach does not capture any information transfer across different domains in the learning process. In contrast, our approach learns embeddings for the target domain by capturing useful cross-domain information and therefore can lead to improved modeling of embeddings that are shown more helpful for this specific down-stream task.

5 Conclusion and Future Work

In this paper, we presented a simple yet effective algorithm for learning cross-domain word embeddings. Motivated by the recent regularization-based domain adaptation framework (Lu et al., 2016), the algorithm performs learning by augmenting the skip-gram objective with a simple regularization term. Our work can be easily extended to multi-domain scenarios. The method is also flexible, allowing different user-defined metrics to be incorporated for defining the function controlling the amount of domain transfer.

Future work includes performing further investigations to better understand and to visualize what types of information has been transferred across domains and how such information influence different types of down-stream NLP tasks. It is also important to understand how such an approach will work on other types of models such as neural networks based NLP models. Our code is available at `http://statnlp.org/research/lr/`.

Learning what to read: Focused machine reading

Abstract

Recent efforts in bioinformatics have achieved tremendous progress in the machine reading of biomedical literature, and the assembly of the extracted biochemical interactions into large-scale models such as protein signaling pathways. However, batch machine reading of literature at today's scale (PubMed alone indexes over 1 million papers per year) is unfeasible due to both cost and processing overhead. In this work, we introduce a focused reading approach to guide the machine reading of biomedical literature towards *what* literature should be read to answer a biomedical query as efficiently as possible. We introduce a family of algorithms for focused reading, including an intuitive, strong baseline, and a second approach which uses a reinforcement learning (RL) framework that learns when to explore (widen the search) or exploit (narrow it). We demonstrate that the RL approach is capable of answering more queries than the baseline, while being more efficient, i.e., reading fewer documents.

1 Introduction

The millions of academic papers in the biomedical domain contain a vast amount of information that may lead to new hypotheses for disease treatment. However, scientists are faced with a problem of "undiscovered public knowledge," as they struggle to read and assimilate all of this information (Swanson, 1986). Furthermore, the literature is growing at an exponential rate (Pautasso, 2012); PubMed[1] has been adding more than a million papers per year since 2011. We have surpassed our ability to keep up with and integrate these findings through manual reading alone.

Large ongoing efforts, such as the BioNLP task community (Nédellec et al., 2013; Kim et al., 2012, 2009) and the DARPA Big Mechanism Program (Cohen, 2015), are making progress in advancing methods for machine reading and assembly of extracted biochemical interactions into large-scale models. However, to date, these methods rely either on the manual selection of relevant documents, or on the processing of large batches of documents that may or may not be relevant to the model being constructed.

Batch machine reading of literature at this scale poses a new, growing set of problems. First, access to some documents is costly. The PubMedCentral (PMC) Open Access Subset[2] (OA) is estimated[3] to comprise 20%[4] of the total literature; the remaining full-text documents are only available through paid access. Second, while there have been great advances in quality, machine reading is still not solved. Updates to our readers requires reprocessing the documents. For large document corpora, this quickly becomes the chief bottleneck in information extraction for model construction and analysis. Finally, even if we could cache all reading results, the search for connections between concepts within the extracted results should not be done blindly. At least in the biology domain, the many connections between biological entities and processes leads to a very high branching factor, making blind search for paths intractable.

To effectively read at this scale, we need to incorporate methods for *focused reading*: develop the ability to pose queries about concepts of interest and perform targeted, incremental search

through the literature for connections between concepts while minimizing reading documents that are likely irrelevant.

In this paper we present what we believe is the first algorithm for focused reading. We make the following contributions:
(1) Present a general framework for a family of possible focused reading algorithms along with a baseline instance.
(2) Cast the design of focused reading algorithms in a reinforcement learning (RL) setting, where the machine decides if it should explore (i.e., cast a wider net) or exploit (i.e., focus reading on a specific topic).
(3) Evaluate our focused reading policies in terms of search efficiency and quality of information extracted. The evaluation demonstrates the effectiveness of the RL method: this approach found more information than the strong baseline we propose, while reading fewer documents.

2 Related Work

The past few years have seen a large body of work on information extraction (IE), particularly in the biomedical domain. This work is too vast to be comprehensively discussed here. We refer the interested reader to the BioNLP community (Nédellec et al., 2013; Kim et al., 2012, 2009, inter alia) for a starting point. However, most of this work focuses on *how* to read, not on *what* to read given a goal. To our knowledge, we are the first to focus on the latter task.

Reinforcement learning has been used to achieve state of the art performance in several natural language processing (NLP) and information retrieval (IR) tasks. For example, RL has been used to guide IR and filter irrelevant web content (Seo and Zhang, 2000; Zhang and Seo, 2001). More recently, RL has been combined with deep learning with great success, e.g., for improving coreference resolution (Clark and Manning, 2016). Finally, RL has been used to improve the efficiency of IE by learning how to incrementally reconcile new information and help choose what to look for next (Narasimhan et al., 2016), a task close to ours. This serves as an inspiration for the work we present here, but with a critical difference: Narasimhan et al. (2016) focus on slot filling using a pre-existing template. This makes both the information integration and stopping criteria well-defined. On the other hand, in our focused reading domain, we do not know ahead of time which new pieces of information are necessarily relevant and must be taken in context.

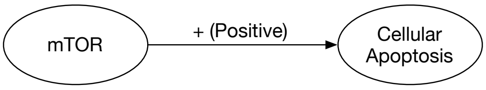

Figure 1: Example of a graph edge encoding the relation extracted from the text: *mTOR triggers cellular apoptosis*.

3 Focused Reading

Here we consider focused reading for the biomedical domain, and we focus on binary promotion/inhibition interactions between biochemical entities. In this setting, the machine reading (or IE) component constructs a directed graph, where vertices represent *participants* in an interaction (e.g., protein, gene, or a biological process), and edges represent directed activation interactions. Edge labels indicate whether the controller entity has a *positive* (promoting) or *negative* (inhibitory) influence on the controlled participant. Figure 1 shows an example edge in this graph.

We use REACH[5], an open source IE system (Valenzuela-Escárcega et al., 2015), to extract interactions from unstructured biomedical text and construct the graph above. We couple this IE system with a Lucene[6] index of biomedical publications to retrieve papers based on queries about participant mentions in the text (as discussed below).

Importantly, we essentially use IE as a black box (thus, our method could potentially work with any IE system), and focus on strategies that guide *what* the IE system reads for a complex information need. In particular, we consider the common scenario where a biologist (or other model-building process) queries the literature on:

> How does one participant (source) affect another (destination), where the connection is typically indirect?

This type of queries is common in biology, where such direct/indirect interactions are observed in experiments, but the explanation of why these dependencies exist is unclear.

Algorithm 1 outlines the general focused reading algorithm for this task. In the algorithm,

[5] https://github.com/clulab/reach
[6] https://lucene.apache.org

S, D, A, and B represent individual participants, where S and D are the **s**ource and **d**estination entities in the initial user query. G is the interaction graph that is iteratively constructed during the focused reading procedure, with V being the set of vertices (biochemical entities), and E the set of edges (promotion/inhibition interactions). Σ is the strategy that chooses which two entities/vertices to be used in the next information retrieval iteration. Q is a Lucene query automatically constructed in each iteration to retrieve new papers to read.

Algorithm 1 Focused reading framework

```
 1: procedure FOCUSEDREADING($S, D$)
 2:     $G \leftarrow \{\{S, D\}, \emptyset\}$
 3:     repeat
 4:         $\Sigma \leftarrow$ ENDPOINTSTRATEGY($G$)
 5:         $(A, B) \leftarrow$ CHOOSEENDPOINTS($\Sigma, G$)
 6:         $Q \leftarrow$ CHOOSEQUERY($A, B, G$)
 7:         $(V, E) \leftarrow$ LUCENE+REACH($Q$)
 8:         EXPAND($V, E, G$)
 9:     until ISCONNECTED($S, D$) OR STOPCONDITIONMET($G$)
10: end procedure
```

The algorithm initializes the search graph as containing the two unconnected participants as vertices: $\{S, D\}$ (line 2). The algorithm then enters into its central loop (lines 3 through 9). The loop terminates when one or more directed paths connecting S to D are found, or when a stopping condition is met: either G has not changed since the previous run through the loop, or after exceeding some number of iterations through the loop (in this work, ten).

At each pass through the loop the algorithm grows the search graph as follows:

1. The graph G is initialized with two nodes, the source and destination in the user's information need, and no edges (because we have not read any papers yet).
2. Given the current graph, choose a strategy, Σ, for selecting which entities to query next: *exploration* or *exploitation* (line 4). In general, exploration aims to widen the search space by adding many more nodes to the graph, whereas exploitation aims to narrow the search by focusing on entities in a specific region of the graph.
3. Using strategy Σ, choose the next entities to attempt to link: (A, B) (line 5).
4. Choose a query, Q: again, using *exploration* or *exploitation*, following the same intuition as with the entity choice strategy (line 6). Here exploration queries retrieve a wider range of documents, while exploitation queries are more restrictive.
5. Run the Lucene query to retrieve papers and process the papers using the IE system. The result of this call is a set of interactions, similar to that in Figure 1 (line 7).
6. Add the new interaction participant entities (vertices V) and directed influences (edges E) to the search graph (line 8).
7. If the source and destination entities are connected in G, stop: the user's information need has been addressed. Otherwise, continue from step 2.

The central loop performs a bidirectional search in which each iteration expands the search horizon outward from S and D. Algorithm 1 represents a family of possible focused reading algorithms, differentiated by how each of the functions in the main loop are implemented. In this work, ISCONNECTED stops after a single path is found, but a variant could consider finding multiple paths, paths of some length, or incorporate other criteria about the properties of the path. We next consider particular choices for the inner loop functions.

4 Baseline Algorithm and Evaluation

The main functions that affect the search behavior of Algorithm 1 are ENDPOINTSTRATEGY and CHOOSEQUERY. Here we describe a *baseline* focused reading implementation in which ENDPOINTSTRATEGY and CHOOSEQUERY aim to find any path between S and D as quickly as possible.

For ENDPOINTSTRATEGY, we follow the intuition that some participants in a biological graph tend to be connected to more participants than others, and therefore more likely to yield interactions providing paths between participants in general. Our heuristic is therefore to choose new participants to query that currently have the most inward and outgoing edges (i.e., highest vertex degree) in the current state of G (disallowing choosing an entity pair used in a previous query).

Now that we have our candidate participants (A, B), our next step is to formulate how we will use these participants to retrieve new papers. Here we consider two classes of query: (1) we restrict our query to only retrieve papers that simultaneously mention both A and B, therefore more likely retrieving a paper with a direct link between A and B (*exploit*), or (2) we retrieve papers that mention

	Baseline	**RL Query Policy**	
# IR queries	573	433	25% decrease
Unique papers read	26,197	19,883	24% decrease
# Paths recovered (out of 289)	189 (65%)	198 (68%)	3% increase

Table 1: Results of the baseline and RL Query Policy for the focused reading of biomedical literature.

either A or B, therefore generally retrieving more papers that will introduce more new participants (*explore*). For our baseline, where we are trying to find a path between S and D as quickly as possible, we implement a greedy ChooseQuery: first try the conjunctive exploitation query; if no documents are retrieved, then "relax" the search to the disjunctive exploration query.

To evaluate the baseline, we constructed a data set based on a collection of papers seeded by a set of 132 entities that come from the University of Pittsburgh DyCE[7] model, a biomolecular model of pancreatic cancer (Telmer et al., 2017). Using these entities, we retrieved 70,719 papers that mention them. We processed all papers using REACH, extracting all of the interactions mentioned, and converted them into a single graph. The resulting graph consisted of approximately 80,000 vertices, 115,000 edges, and had an average (undirected) vertex degree of 24. We will refer to this graph as the *REACH graph*, as it represents what *can* be retrieved by REACH from the set of 70K papers. Next, we identified which pairs of the original 132 entities are connected by directed paths in DyCE. A total of 789 pairs were found. We used 289 of these entity pairs as testing queries (i.e., generating queries that aim to explain how a given pair is connected according to the literature). The other 500 pairs were held out to train the RL method described below.

We ran this baseline focused reading algorithm on each of the 289 pairs of participants, in each case attempting to recover a directed path from one to the other. The results are summarized in the middle column of Table 1. By issuing 573 queries, the baseline read 26,197 papers out of the total 70,719 papers (37% of the corpus), in order to recover 189 of the 289 paths (65%).

5 Reinforcement Learning for Focussed Reading

We analyzed the baseline's behavior in the evaluation to identify the conditions under which it failed to find paths. From this, we found that some of the failures could be avoided had we used a different strategy for ChooseQuery, i.e., the baseline chose to exploit when it should have explored more. The conditions for making different choices depend on the current state of G, and earlier query behavior can affect later query opportunities, making this an iterative decision making problem and a natural fit for a RL formulation.

Inspired by this observation, we consider RL for finding a better policy for ChooseQuery. We'll refer to an instance of the focused reading algorithm with a learned ChooseQuery policy as the *RL Query Policy*. All other focus reading functionality is the same as in the baseline. For actions, we consider a simple binary action choice: exploit (conjunctive query) or explore (disjunctive query). We represent the state of the search using a set of features that include: (f1) the current iteration of the search; (f2) the number of times a participant has been used in previous queries; (f3) whether the participants are chosen from the same connected component in G; (f4) the vertex degree of participants; and (f5) the search iteration in which a participant was introduced. With the goal of recovering paths as quickly as possible, we provide a reward of $+1$ if the algorithm successfully finds a path, a reward of -1 if the search fails to find a path, and assess a "living reward" of -0.05 for each step during the search, to encourage trying to finish the search as quickly as possible.

We trained the RL Query Policy using the SARSA (Sutton and Barto, 1998) RL algorithm. As the number of unique states is large, we used a linear approximation of the q-function. Once the policy converged during training, we then fixed the linear estimate of the q-function and used this as a fixed policy for selecting queries. We trained the RL Query Policy on the separate set of 500 entity pairs, and evaluated it on the same data set of 289 participant pairs used to evaluate the baseline. Table 1 summaries the results of both the baseline and the RL Query Policy. The Query Policy resulted in a 25% decrease in the number of queries that were run, leading to a 24% drop in the number of papers that were read, while at the same time *increasing* the number of paths recovered by 3%. We tested the statistical significance of the

[7] **Dy**namic **C**ell **E**nvironment model of pancreatic cancer.

	All features	− Iteration number (f1)	− Query counts (f2)	− Same component (f3)	− Ranks (f4)	− Particip. intro. (f5)
Paths found	198	199	200	201	**202**	196
Papers read	19,883	20,918	20,531	20,463	27,708	**17,936**
Queries made	433	484	484	467	469	**403**

Table 2: Ablation test on the features used to represent the RL state.

	Empty query results	Ungrounded participant(s)	Low yield from IE
Error cause	12	4	2

Table 3: Error analysis on 18 queries that failed under the RL algorithm.

difference in results between the baseline and RL policy by performing a bootstrap resampling test. Our hypotheses were that the policy reads fewer papers, makes fewer queries and finds more paths. The resulting estimated p-values for fewer papers and fewer queries was found to be near 0, and < 0.003 for finding more paths. An ablation study of the state features found that features (f2) and (f5) had the largest impact on number of papers read; both model the history of the reading task (see the next section for details). This highlights that the RL model is indeed learning to model the entire iterative process.

6 Analysis

Feature Ablation Test: We performed an ablation test on the features that encode the RL state. The results are summarized in Table 2. Similar to Section 5, we grouped the features into five different groups, and we measured the impact of removing one feature group at a time. Overall, the amount of paths found doesn't have a significant amount of variance, but the efficiency of the search (amount of papers read and number of queries made) depends on several feature groups. For example, features (f1), (f2), and (f4) have a large effect on both the number of papers read and the number of queries made. Removing the feature (f5) actually reduces the number of papers read by approximately 2K with a minimal reduction in the number of paths found, which suggests that this task could benefit from feature selection.

RL Policy Error Analysis: Lastly, we analyzed the execution trace of eighteen (20% of the errors) of the searches that failed to find a path under RL. The results are summarized in Table 3. The table shows that the main source of failures is receiving *no results* from the information retrieval query, i.e., when the IR system returns zero documents for the chosen query. This is typically caused by over-constrained queries. The second most common source of failures was *ungrounded participants*, i.e., when at least one of the selected participants that form the query could not be linked to our protein knowledge base. This is generally caused by mistakes in our NER sequence model, and also tends to yield no results from the IR component. Finally, the *low yield from IE* situation appears when the the information produced through machine reading in one iteration is scarce and adds no new components to the interaction graph, again resulting in a stop condition.

7 Discussion and future work

We introduced a framework for the focused reading of biomedical literature, which is necessary to handle the data overload that plagues even machine reading approaches. We have presented a generic focused reading algorithm, an intuitive, strong baseline algorithm that instantiates it, and formulated an RL approach that learns how to efficiently query the paper repository that feeds the machine reading component. We showed that the RL-based focused reading is more efficient than the baseline (i.e., it reads 24% fewer papers), while answering 7% more queries.

There are many exciting directions in which to take this work. First, more of the focused reading algorithm can be subject to RL, with the CHOOSEENDPOINTS policy being the clear next candidate. Second, we can expand focused reading to efficiently search for multiple paths between S and D. Finally, we will incorporate additional biological constraints (e.g., focus on pathways that exist in specific species) into the search itself.

DOC: Deep Open Classification of Text Documents

Lei Shu, Hu Xu, Bing Liu
Department of Computer Science
University of Illinois at Chicago
{lshu3, hxu48, liub}@uic.edu

Abstract

Traditional supervised learning makes the *closed-world* assumption that the classes appeared in the test data must have appeared in training. This also applies to text learning or text classification. As learning is used increasingly in dynamic open environments where some new/test documents may not belong to any of the training classes, identifying these novel documents during classification presents an important problem. This problem is called *open-world classification* or *open classification*. This paper proposes a novel deep learning based approach. It outperforms existing state-of-the-art techniques dramatically.

1 Introduction

A key assumption made by classic supervised text classification (or learning) is that classes appeared in the test data must have appeared in training, called the *closed-world* assumption (Fei and Liu, 2016; Chen and Liu, 2016). Although this assumption holds in many applications, it is violated in many others, especially in dynamic or open environments. For example, in social media, a classifier built with past topics or classes may not be effective in classifying future data because new topics appear constantly in social media (Fei et al., 2016). This is clearly true in other domains too, e.g., self-driving cars, where new objects may appear in the scene all the time.

Ideally, in the text domain, the classifier should classify incoming documents to the right existing classes used in training and also detect those documents that don't belong to any of the existing classes. This problem is called *open world classification* or *open classification* (Fei and Liu, 2016). Such a classifier is aware *what it does and does not know*. This paper proposes a novel technique to solve this problem.

Problem Definition: Given the training data $D = \{(\mathbf{x}_1, y_1), (\mathbf{x}_2, y_2), \ldots, (\mathbf{x}_n, y_n)\}$, where $\mathbf{x}_i$ is the i-th document, and $y_i \in \{l_1, l_2, \ldots, l_m\} = \mathcal{Y}$ is $\mathbf{x}_i$'s class label, we want to build a model $f(\mathbf{x})$ that can classify each test instance $\mathbf{x}$ to one of the m training or *seen* classes in $\mathcal{Y}$ or reject it to indicate that it does not belong to any of the m training or seen classes, i.e., *unseen*. In other words, we want to build a $(m+1)$-class classifier $f(\mathbf{x})$ with the classes $\mathcal{C} = \{l_1, l_2, \ldots, l_m, \textit{rejection}\}$.

There are some prior approaches for open classification. One-class SVM (Schölkopf et al., 2001; Tax and Duin, 2004) is the earliest approach. However, as no negative training data is used, one-class classifiers work poorly. Fei and Liu (2016) proposed a Center-Based Similarity (CBS) space learning method (Fei and Liu, 2015). This method first computes a center for each class and transforms each document to a vector of similarities to the center. A binary classifier is then built using the transformed data for each class. The decision surface is like a "ball" encircling each class. Everything outside the ball is considered not belonging to the class. Our proposed method outperforms this method greatly. Fei et al. (2016) further added the capability of incrementally or cumulatively learning new classes, which connects this work to *lifelong learning* (Chen and Liu, 2016) because without the ability to identify novel or new things and learn them, a system will never be able to learn by itself continually.

In computer vision, Scheirer et al. (2013) studied the problem of recognizing unseen images that the system was not trained for by reducing *open space risk*. The basic idea is that a classifier should not cover too much open space where there are few or no training data. They proposed to reduce the half-space of a binary SVM classifier

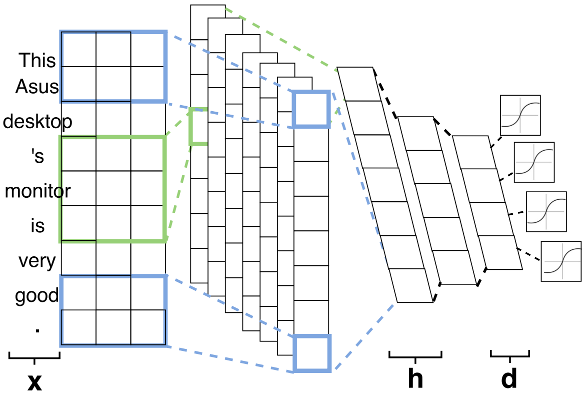

Figure 1: Overall Network of DOC

with a positive region bounded by two parallel hyperplanes. Similar works were also done in a probability setting by Scheirer et al. (2014) and Jain et al. (2014). Both approaches use probability threshold, but choosing thresholds need prior knowledge, which is a weakness of the methods. Dalvi et al. (2013) proposed a multi-class semi-supervised method based on the EM algorithm. It has been shown that these methods are poorer than the method in (Fei and Liu, 2016).

The work closest to ours is that in (Bendale and Boult, 2016), which leverages an algorithm called *OpenMax* to add the rejection capability by utilizing the logits that are trained via closed-world softmax function. One weak assumption of OpenMax is that examples with equally likely logits are more likely from the unseen or rejection class, which can be examples that are hard to classify. Another weakness is that it requires validation examples from the unseen/rejection class to tune the hyperparameters. Our method doesn't make these weak assumptions and performs markedly better.

Our proposed method, called DOC (*Deep Open Classification*), uses deep learning (Goodfellow et al., 2016; Kim, 2014). Unlike traditional classifiers, DOC builds a multi-class classifier with a 1-vs-rest final layer of sigmoids rather than softmax to reduce the open space risk. It reduces the open space risk further for rejection by tightening the decision boundaries of sigmoid functions with Gaussian fitting. Experimental results show that DOC dramatically outperforms state-of-the-art existing approaches from both text classification and image classification domains.

2 The Proposed DOC Architecture

DOC uses CNN (Collobert et al., 2011; Kim, 2014) as its base and augments it with a 1-vs-rest final sigmoid layer and Gaussian fitting for classification. Note: other existing deep models like RNN (Williams and Zipser, 1989; Schuster and Paliwal, 1997) and LSTM (Hochreiter and Schmidhuber, 1997; Gers et al., 2002) can also be adopted as the base. Similar to RNN, CNN also works on embedded sequential data (using 1D convolution on text instead of 2D convolution on images). We choose CNN because OpenMax uses CNN and CNN performs well on text (Kim, 2014), which enables a fairer comparison with OpenMax.

2.1 CNN and Feed Forward Layers of DOC

The proposed DOC system (given in Fig. 1) is a variant of the CNN architecture (Collobert et al., 2011) for text classification (Kim, 2014)[1]. The first layer embeds words in document $\mathbf{x}$ into dense vectors. The second layer performs convolution over dense vectors using different filters of varied sizes (see Sec. 3.4). Next, the max-over-time pooling layer selects the maximum values from the results of the convolution layer to form a k-dimension feature vector $\boldsymbol{h}$. Then we reduce $\boldsymbol{h}$ to a m-dimension vector $\boldsymbol{d} = d_{1:m}$ (m is the number of training/seen classes) via 2 fully connected layers and one intermediate ReLU activation layer:

$$\boldsymbol{d} = \boldsymbol{W}'(\text{ReLU}(\boldsymbol{W}\boldsymbol{h} + \boldsymbol{b})) + \boldsymbol{b}', \qquad (1)$$

where $\boldsymbol{W} \in \mathbb{R}^{r\times k}$, $\boldsymbol{b} \in \mathbb{R}^r$, $\boldsymbol{W}' \in \mathbb{R}^{m\times r}$, and $\boldsymbol{b}' \in \mathbb{R}^m$ are trainable weights; r is the output dimension of the first fully connected layer. The output layer of DOC is a 1-vs-rest layer applied to $d_{1:m}$, which allows rejection. We describe it next.

2.2 1-vs-Rest Layer of DOC

Traditional multi-class classifiers (Goodfellow et al., 2016; Bendale and Boult, 2016) typically use softmax as the final output layer, which does not have the rejection capability since the probability of prediction for each class is normalized across all training/seen classes. Instead, we build a 1-vs-rest layer containing m sigmoid functions for m seen classes. For the i-th sigmoid function corresponding to class l_i, DOC takes all examples with $y = l_i$ as positive examples and all the rest examples $y \neq l_i$ as negative examples.

The model is trained with the objective of summation of all log loss of the m sigmoid functions

[1] `https://github.com/alexander-rakhlin/CNN-for-Sentence-Classification-in-Keras`

on the training data D.

$$\text{Loss} = \sum_{i=1}^{m}\sum_{j=1}^{n} -\mathbb{I}(y_j = l_i)\log p(y_j = l_i) \\ -\mathbb{I}(y_j \neq l_i)\log(1 - p(y_j = l_i)), \qquad (2)$$

where $\mathbb{I}$ is the indicator function and $p(y_j = l_i) = \text{Sigmoid}(d_{j,i})$ is the probability output from ith sigmoid function on the jth document's ith-dimension of $\boldsymbol{d}$.

During testing, we reinterpret the prediction of m sigmoid functions to allow rejection, as shown in Eq. 3. For the i-th sigmoid function, we check if the predicted probability $\text{Sigmoid}(d_i)$ is less than a threshold t_i belonging to class l_i. If all predicted probabilities are less than their corresponding thresholds for an example, the example is rejected; otherwise, its predicted class is the one with the highest probability. Formally, we have

$$\hat{y} = \begin{cases} \textit{reject}, \text{ if } \text{Sigmoid}(d_i) < t_i, \forall l_i \in \mathcal{Y}; \\ \arg\max_{l_i \in \mathcal{Y}} \text{Sigmoid}(d_i), \text{ otherwise.} \end{cases} \qquad (3)$$

Note that although multi-label classification (Huang et al., 2013; Zhang and Zhou, 2006; Tsoumakas and Katakis, 2006) may also leverage multiple sigmoid functions, Eq. 3 forbids multiple predicted labels for the same example, which is allowed in multi-label classification. DOC is also related to multi-task learning (Huang et al., 2013; Caruana, 1998), where each label l_i is related to a 1-vs-rest binary classification task with shared representations from CNN and fully connected layers. However, Eq. 3 performs classification and rejection based on the outputs of these binary classification tasks.

Comparison with OpenMax: OpenMax builds on the traditional closed-world multi-class classifier (softmax layer). It reduces the open space for each seen class, which is weak for rejecting unseen classes. DOC's 1-vs-rest sigmoid layer provides a reasonable representation of all other classes (the rest of seen classes and unseen classes), and enables the 1 class forms a good boundary. Sec. 3.5 shows that this basic DOC is already much better than OpenMax. Below, we improve DOC further by tightening the decision boundaries more.

2.3 Reducing Open Space Risk Further

Sigmoid function usually uses the default probability threshold of $t_i = 0.5$ for classification of each class i. But this threshold does not consider potential open space risks from unseen (rejection) class data. We can improve the boundary by increasing t_i. We use Fig. 2 to illustrate. The x-axis represents d_i and y-axis is the predicted probability $p(y = l_i|d_i)$. The sigmoid function tries to push positive examples (belonging to the i-th class) and negative examples (belonging to the other seen classes) away from the y-axis via a high gain around $d_i = 0$, which serves as the default decision boundary for d_i with $t_i = 0.5$. As demonstrated by those 3 circles on the right-hand side of the y-axis, during testing, unseen class examples (circles) can easily fill in the gap between the y-axis and those dense positive (+) examples, which may reduce the recall of rejection and the precision of the i-th seen class prediction. Obviously, a better decision boundary is at $d_i = T$, where the decision boundary more closely "wrap" those dense positive examples with the probability threshold $t_i \gg 0.5$.

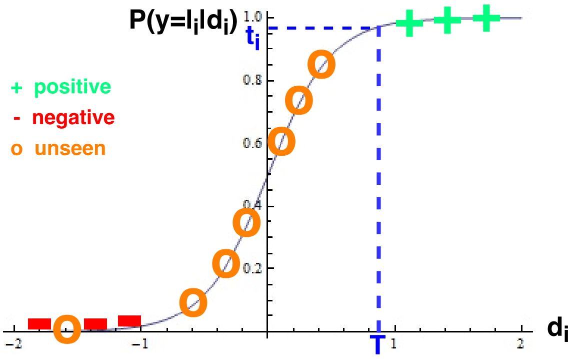

Figure 2: Open space risk of sigmoid function and desired decision boundary $d_i = T$ and probability threshold t_i.

To obtain a better t_i for each seen class i-th, we use the idea of outlier detection in statistics:

1. Assume the predicted probabilities $p(y = l_i|\mathbf{x}_j, y_j = l_i)$ of all training data of each class i follow one half of the Gaussian distribution (with mean $\mu_i = 1$), e.g., the three positive points in Fig. 2 projected to the y-axis (we don't need d_i). We then artificially create the other half of the Gaussian distributed points (≥ 1): for each existing point $p(y = l_i|\mathbf{x}_j, y_j = l_i)$, we create a mirror point $1 + (1 - p(y = l_i|\mathbf{x}_j, y_j = l_i)$ (not a probability) mirrored on the mean of 1.

2. Estimate the standard deviation σ_i using both the existing points and the created points.

3. In statistics, if a value/point is a certain number (α) of standard deviations away from the mean, it is considered an outlier. We thus set the probability threshold $t_i = \max(0.5, 1 - \alpha\sigma_i)$. The commonly used number for α is 3, which also works well in our experiments.

Note that due to Gaussian fitting, different class l_i can have a different classification threshold t_i.

3 Experimental Evaluation

3.1 Datasets

We perform evaluation using two publicly available datasets, which are exactly the same datasets used in (Fei and Liu, 2016).

(1) **20 Newsgroups**[2] (Rennie, 2008): The 20 newsgroups data set contains 20 non-overlapping classes. Each class has about 1000 documents.

(2) **50-class reviews** (Chen and Liu, 2014): The dataset has Amazon reviews of 50 classes of products. Each class has 1000 reviews. Although product reviews are used, we do not do sentiment classification. We still perform topic-based classification. That is, given a review, the system decides what class of product the review is about.

For every dataset, we keep a 20000 frequent word vocabulary. Each document is fixed to 2000-word length (cutting or padding when necessary).

3.2 Test Settings and Evaluation Metrics

For a fair comparison, we use exactly the same settings as in (Fei and Liu, 2016). For each class in each dataset, we randomly sampled 60% of documents for training, 10% for validation and 30% for testing. Fei and Liu (2016) did not use a validation set, but the test data is the same 30%. We use the validation set to avoid overfitting. For open-world evaluation, we hold out some classes (as unseen) in training and mix them back during testing. We vary the number of training classes and use 25%, 50%, 75%, or 100% classes for training and all classes for testing. Here using 100% classes for training is the same as the traditional closed-world classification. Taking 20 newsgroups as an example, for 25% classes, we use 5 classes (we randomly choose 5 classes from 20 classes for 10 times and average the results, as in (Fei and Liu, 2016)) for training and all 20 classes for testing (15 classes are unseen in training). We use macro F_1-score over $5 + 1$ classes (1 for rejection) for evaluation. Please note that examples from unseen classes are dropped in the validation set.

Table 1: Macro-F_1 scores for 20 newsgroups

% of seen classes	**25%**	**50%**	**75%**	**100%**
cbsSVM	59.3	70.1	72.0	85.2
OpenMax	35.7	59.9	76.2	91.9
DOC ($t = 0.5$)	75.9	84.0	87.4	92.6
DOC	82.3	85.2	86.2	92.6

Table 2: Macro-F_1 scores for 50-class reviews

% of seen classes	**25%**	**50%**	**75%**	**100%**
cbsSVM	55.7	61.5	58.6	63.4
OpenMax	41.6	57.0	64.2	69.2
DOC ($t = 0.5$)	51.1	63.6	66.2	69.8
DOC	61.2	64.8	66.6	69.8

3.3 Baselines

We compare DOC with two state-of-the-art methods published in 2016 and one DOC variant.

cbsSVM: This is the latest method published in NLP (Fei and Liu, 2016). It uses SVM to build 1-vs-rest CBS classifiers for multiclass text classification with rejection option. The results of this system are taken from (Fei and Liu, 2016).

OpenMax: This is the latest method from computer vision (Bendale and Boult, 2016). Since it is a CNN-based method for image classification, we adapt it for text classification by using CNN with a softmax output layer, and adopt the OpenMax layer[3] for open text classification. When all classes are seen (100%), the result from softmax is reported since OpenMax layer always performs rejection. We use default hyperparameter values of OpenMax (Weibull tail size is set to 20).

DOC($t = 0.5$): This is the basic DOC ($t = 0.5$). Gaussian fitting isn't used to choose each t_i.

Note that (Fei and Liu, 2016) compared with several other baselines. We don't compare with them as it was shown that cbsSVM was superior.

3.4 Hyperparameter Setting

We use word vectors pre-trained from Google News[4] (3 million words and 300 dimensions). For the CNN layers, 3 filter sizes are used $[3, 4, 5]$. For each filter size, 150 filters are applied. The dimension r of the first fully connected layer is 250.

[2] http://qwone.com/~jason/20Newsgroups/

[3] https://github.com/abhijitbendale/OSDN

[4] https://code.google.com/archive/p/word2vec/

3.5 Result Analysis

The results of 20 newsgroups and 50-class reviews are given in Tables 1 and 2, respectively. From the tables, we can make the following observations:

1. DOC is markedly better than OpenMax and cbsSVM in macro-F_1 scores for both datasets in the 25%, 50%, and 75% settings. For the 25% and 50% settings (most test examples are from unseen classes), DOC is dramatically better. Even for 100% of traditional closed-world classification, it is consistently better too. DOC($t = 0.5$) is better too.

2. For the 25% and 50% settings, DOC is also markedly better than DOC($t = 0.5$), which shows that Gaussian fitting finds a better probability threshold than $t = 0.5$ when many unseen classes are present. In the 75% setting (most test examples are from seen classes), DOC($t = 0.5$) is slightly better for 20 newsgroups but worse for 50-class reviews. DOC sacrifices some recall of seen class examples for better precision, while $t = 0.5$ sacrifices the precision of seen classes for better recall. DOC($t = 0.5$) is also worse than cbsSVM for 25% setting for 50-class reviews. It is thus not as robust as DOC.

3. For the 25% and 50% settings, cbsSVM is also markedly better than OpenMax.

4 Conclusion

This paper proposed a novel deep learning based method, called DOC, for open text classification. Using the same text datasets and experiment settings, we showed that DOC performs dramatically better than the state-of-the-art methods from both the text and image classification domains. We also believe that DOC is applicable to images.

In our future work, we plan to improve the cumulative or incremental learning method in (Fei et al., 2016) to learn new classes without training on all past and new classes of data from scratch. This will enable the system to learn by self to achieve continual or lifelong learning (Chen and Liu, 2016). We also plan to improve model performance during testing (Shu et al., 2017).

CharManteau: Character Embedding Models For Portmanteau Creation

Varun Gangal [*], **Harsh Jhamtani** [*], **Graham Neubig, Eduard Hovy, Eric Nyberg**

Abstract

Portmanteaus are a word formation phenomenon where two words are combined to form a new word. We propose character-level neural sequence-to-sequence (S2S) methods for the task of portmanteau generation that are end-to-end-trainable, language independent, and do not explicitly use additional phonetic information. We propose a noisy-channel-style model, which allows for the incorporation of unsupervised word lists, improving performance over a standard source-to-target model. This model is made possible by an exhaustive candidate generation strategy specifically enabled by the features of the portmanteau task. Experiments find our approach superior to a state-of-the-art FST-based baseline with respect to ground truth accuracy and human evaluation.

1 Introduction

Portmanteaus (or lexical blends Algeo (1977)) are novel words formed from parts of multiple root words in order to refer to a new concept which can't otherwise be expressed concisely. Portmanteaus have become frequent in modern-day social media, news reports and advertising, one popular example being *Brexit* (Britain + Exit). Petri (2012). These are found not only in English but many other languages such as Bahasa Indonesia Dardjowidjojo (1979), Modern Hebrew Bat-El (1996); Berman (1989) and Spanish Piñeros (2004). Their short length makes them ideal for headlines and brandnames (Gabler, 2015). Unlike better-defined morphological phenomenon such as inflection and derivation, portmanteau generation is difficult to capture using a set of rules. For instance, Shaw et al. (2014) state that the composition of the portmanteau from its root words depends on several factors, two important ones being maintaining prosody and retaining character segments from the root words, especially the head. An existing work by Deri and Knight (2015) aims to solve the problem of predicting portmanteau using a multi-tape FST model, which is data-driven, unlike prior approaches. Their methods rely on a grapheme to phoneme converter, which takes into account the phonetic features of the language, but may not be available or accurate for non-dictionary words, or low resource languages.

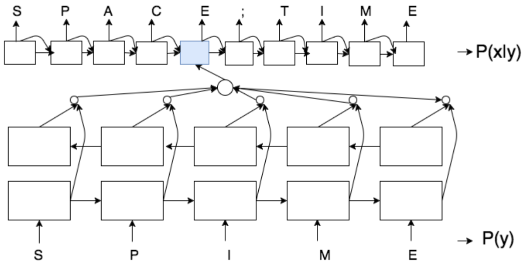

Figure 1: A sketch of our Backward, noisy-channel model. The attentional S2S model with bidirectional encoder gives $P(x|y)$ and next-character model gives $P(y)$, where y (*spime*) is the portmanteau and $\boldsymbol{x} = \text{concat}(\boldsymbol{x}^{(1)}, \text{“;”}, \boldsymbol{x}^{(2)})$ are the concatenated root words (*space* and *time*).

Prior works, such as Faruqui et al. (2016), have demonstrated the efficacy of neural approaches for morphological tasks such as inflection. We hypothesize that such neural methods can (1) provide a simpler and more integrated end-to-end framework than multiple FSTs used in the previous work, and (2) automatically capture features such as phonetic similarity through the use of character embeddings, removing the need for explicit

Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

grapheme-to-phoneme prediction. To test these hypotheses, in this paper, we propose a neural S2S model to predict portmanteaus given the two root words, specifically making 3 major contributions:

- We propose an S2S model that attends to the two input words to generate portmanteaus, and an additional improvement that leverages noisy-channel-style modelling to incorporate a language model over the vocabulary of words (§2).
- Instead of using the model to directly predict output character-by-character, we use the features of portmanteaus to exhaustively generate candidates, making scoring using the noisy channel model possible (§3).
- We curate and share a new and larger dataset of 1624 portmanteaus (§4).

In experiments (§5), our model performs better than the baseline Deri and Knight (2015) on both objective and subjective measures, demonstrating that such methods can be used effectively in a morphological task.

2 Proposed Models

This section describes our neural models.

2.1 Forward Architecture

Under our first proposed architecture, the input sequence $\boldsymbol{x} = \text{concat}(\boldsymbol{x}^{(1)}, \text{“;”}, \boldsymbol{x}^{(2)})$, while the output sequence is the portmanteau $\boldsymbol{y}$. The model learns the distribution $P(\boldsymbol{y}|\boldsymbol{x})$.

The network architecture we use is an attentional S2S model (Bahdanau et al., 2014). We use a bidirectional encoder, which is known to work well for S2S problems with similar token order, which is true in our case. Let $\overrightarrow{LSTM}$ and $\overleftarrow{LSTM}$ represent the forward and reverse encoder; $e_{enc}()$ and $e_{dec}()$ represent the character embedding functions used by encoder and decoder The following equations describe the model:

$$
\begin{aligned}
h_0^{\overrightarrow{enc}} &= \overrightarrow{0}, h_{|x|}^{\overleftarrow{enc}} = \overrightarrow{0} \\
h_t^{\overrightarrow{enc}} &= \overrightarrow{LSTM}(h_{t-1}^{enc}, e_{enc}(x_t)) \\
h_t^{\overleftarrow{enc}} &= \overleftarrow{LSTM}(h_{t+1}^{enc}, e_{enc}(x_t)) \\
h_t^{enc} &= h_t^{\overrightarrow{enc}} + h_t^{\overleftarrow{enc}} \\
h_0^{dec} &= h_{|x|}^{enc} \\
h_t^{dec} &= LSTM(h_{t-1}^{dec}, [\text{concat}(e_{dec}(y_{t-1}), c_{t-1})]) \\
p_t &= \text{softmax}(W_{hs}[\text{concat}(h_t^{dec}, c_t)] + b_s)
\end{aligned}
$$

The context vector c_t is computed using dot-product attention over encoder states. We choose dot-product attention because it doesn't add extra parameters, which is important in a low-data scenario such as portmanteau generation.

$$
\begin{aligned}
a_i^t &= dot(h_t^{dec}, h_i^{enc}), \alpha^t = \text{softmax}(a^t) \\
c_t &= \sum_{i=1}^{i=|x|} \alpha_i^t h_i^{enc}
\end{aligned}
$$

In addition to capturing the fact that portmanteaus of two English words typically sound *English-like*, and to compensate for the fact that available portmanteau data will be small, we pretrain the character embeddings on English language words. We use character embeddings learnt using an LSTM language model over words in an English dictionary,[1] where each word is a sequence of characters, and the model will predict next character in sequence conditioned on previous characters in the sequence.

2.2 Backward Architecture

The second proposed model uses Bayes's rule to reverse the probabilities $P(\boldsymbol{y}|\boldsymbol{x}) = \frac{P(\boldsymbol{x}|\boldsymbol{y})P(\boldsymbol{y})}{P(\boldsymbol{x})}$ to get $\text{argmax}_{\boldsymbol{y}} P(\boldsymbol{y}|\boldsymbol{x}) = \text{argmax}_{\boldsymbol{y}} P(\boldsymbol{x}|\boldsymbol{y})P(\boldsymbol{y})$. Thus, we have a reverse model of the probability $P(\boldsymbol{x}|\boldsymbol{y})$ that the given root words were generated from the portmanteau and a character language model model $P(\boldsymbol{y})$. This is a probability distribution over all character sequences $y \in A^*$, where A is the alphabet of the language. This way of factorizing the probability is also known as a *noisy channel model*, which has recently also been shown to be effective for neural MT (Hoang et al. (2017), Yu et al. (2016)). Such a model offers two advantages

1. The reverse direction model (or alignment model) gives higher probability to those portmanteaus from which one can discern the root words easily, which is one feature of good portmanteaus.
2. The character language model $P(\boldsymbol{y})$ can be trained on a large vocabulary of words in the language. The likelihood of a word y is factorized as $P(y) = \Pi_{i=1}^{i=|y|} P(y_i|y_1^{i-1})$, where $y_j^i = y_i, y_{i+1} \dots y_j$, and we train a LSTM to maximize this likelihood.

[1] Specifically in our experiments, 134K words from the CMU dictionary (Weide, 1998).

3 Making Predictions

Given these models, we must make predictions, which we do by two methods

Greedy Decoding: In most neural sequence-to-sequence models, we perform auto-regressive greedy decoding, selecting the next character greedily based on the probability distribution for the next character at current time step. We refer to this decoding strategy as GREEDY.

Exhaustive Generation: Many portmanteaus were observed to be concatenation of a prefix of the first word and a suffix of the second. We therefore generate all candidate outputs which follow this rule. Thereafter we score these candidates with the decoder and output the one with the maximum score. We refer to this decoding strategy as SCORE.

Given that our training data is small in size, we expect ensembling (Breiman, 1996) to help reduce model variance and improve performance. In this paper, we ensemble our models wherever mentioned by training multiple models on 80% subsamples of the training data, and averaging log probability scores across the ensemble at test-time.

4 Dataset

The existing dataset by Deri and Knight (2015) contains 401 portmanteau examples from Wikipedia. We refer to this dataset as D_{Wiki}. Besides being small for detailed evaluation, D_{Wiki} is biased by being from just one source. We manually collect D_{Large}, a dataset of 1624 distinct English portmanteaus from following sources:

- Urban Dictionary[2]
- Wikipedia
- Wiktionary
- BCU's Neologism Lists from '94 to '12.

Naturally, $D_{Wiki} \subset D_{Large}$. We define $D_{Blind} = D_{Large} - D_{Wiki}$ as the dataset of 1223 examples not from Wikipedia. We observed that 84.7% of the words in D_{Large} can be generated by concatenating prefix of first word with a suffix of the second.

Model	Attn	Ens	Init	Search	Matches	Distance
BASELINE	-	-	-	-	**45.39%**	1.59
FORWARD	✓	×	×	GREEDY	22.00%	1.98
	✓	×	✓	GREEDY	28.00%	1.90
	✓	×	×	BEAM	13.25%	2.47
	✓	×	✓	BEAM	15.25%	2.37
	✓	×	×	SCORE	30.25%	1.64
	✓	×	✓	SCORE	32.88%	1.53
	✓	✓	✓	SCORE	42.25%	1.33
	✓	✓	×	SCORE	41.25%	1.34

Table 1: 10-Fold Cross-Validation results, D_{Wiki}. *Attn, Ens, Init* denote attention, ensembling, and initializing character embeddings respectively.

5 Experiments

In this section, we show results comparing various configurations of our model to the baseline FST model of Deri and Knight (2015) (BASELINE). Models are evaluated using exact-matches (*Matches*) and average Levenshtein edit-distance (*Distance*) w.r.t ground truth.

5.1 Objective Evaluation Results

In *Experiment 1*, we follow the same setup as Deri and Knight (2015). D_{Wiki} is split into 10 folds. Each fold model uses 8 folds for training, 1 for validation, and 1 for test. The average (10 fold cross-validation style approach) performance metrics on the test fold are then evaluated. *Table 1* shows the results of *Experiment 1* for various model configurations. We get the BASELINE numbers from Deri and Knight (2015). Our best model obtains 48.75% *Matches* and 1.12 *Distance*, compared to 45.39% *Matches* and 1.59 *Distance* using BASELINE.

For *Experiment 2*, we seek to compare our best approaches from *Experiment 1* to the BASELINE on a large, held-out dataset. Each model is trained on D_{Wiki} and tested on D_{Blind}. BASELINE was similarly trained only on D_{Wiki} , making it a fair comparison. Table 2 shows the results[3]. Our best model gets *Distance* of 1.96 as compared to 2.32 from BASELINE.

We observe that the *Backward* architecture performs better than *Forward* architecture, confirming our hypothesis in §2.2. In addition, ablation results confirm the importance of attention, and

[2] Not all neologisms are portmanteaus, so we manually choose those which are for our dataset.

[3] For BASELINE (Deri and Knight, 2015), we use their trained model from `http://leps.isi.edu/fst/step-all.php`

Model	Attn	Ens	Init	Search	Matches	Distance
BASELINE	-	-	-	-	**31.56%**	2.32
FORWARD	✓	×	✓	SCORE	25.26%	2.13
	✓	×	×	SCORE	24.93%	2.32
	✓	✓	×	SCORE	31.23%	1.98
	✓	✓	✓	SCORE	28.94%	2.04
BACKWARD	✓	×	✓	SCORE	25.75%	2.14
	✓	×	×	SCORE	25.26%	2.17
	✓	✓	×	SCORE	**31.72%**	**1.96**
	✓	✓	✓	SCORE	**32.78%**	**1.96**

Table 2: Results on D_{Blind} (1223 Examples). In general, BACKWARD architecture performs better than FORWARD architecture.

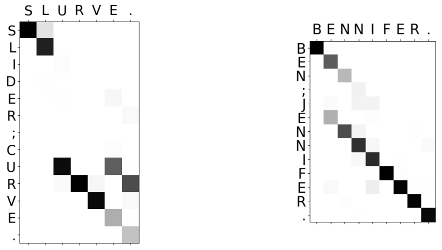

Figure 2: Attention matrices while generating *slurve* from *slider;curve*, and *bennifer* from *ben;jennifer* respectively, using *Forward* model. **;** and **.** are separator and stop characters. Darker cells are higher-valued

initializing the word embeddings. We believe this is because portmanteaus have high fidelity towards their root word characters and its critical that the model can observe all root sequence characters, which attention manages to do as shown in Fig. 2.

5.1.1 Performance on Uncovered Examples

The set of candidates generated before scoring in the approximate SCORE decoding approach sometimes do not cover the ground truth. This holds true for 229 out of 1223 examples in D_{Blind}. We compare the FORWARD approach along with a GREEDY decoding strategy to the BASELINE approach for these examples.

Both FORWARD+GREEDY and the BASELINE get 0 *Matches* on these examples. The *Distance* for these examples is 4.52 for BASELINE and 4.09 for FORWARD+GREEDY. Hence, we see that one of our approaches (FORWARD+GREEDY) outperforms BASELINE even for these examples.

5.2 Significance Tests

Since our dataset is still small relatively small (1223 examples), it is essential to verify whether BACKWARD is indeed statistically significantly better than BASELINE in terms of *Matches*.

Input	FORWARD	BACKWARD	GROUND TRUTH
shopping;marathon	shopparathon	shoathon	shopathon
fashion;fascism	fashism	fashism	fashism
wiki;etiquette	wikiquette	wiquette	wikiquette
clown;president	clowident	clownsident	clownsident

Table 3: Example outputs from different models (Refer to appendix for more examples)

Judgement	Percentage of total
Much Better (1)	29.06
Better (2)	29.06
Worse (3)	25.11
Much Worse (4)	16.74

Table 4: AMT annotator judgements on whether our system's proposed portmanteau is better or worse compared to the baseline

In order to do this, we use a paired bootstrap[4] comparison (Koehn, 2004) between BACKWARD and BASELINE in terms of *Matches*. BACKWARD is found to be better (gets more *Matches*) than BASELINE in 99.9% ($p = 0.999$) of the subsets.

Similarly, BACKWARD has a lower *Distance* than BASELINE by a margin of 0.2 in 99.5% ($p = 0.995$) of the subsets.

5.3 Subjective Evaluation and Analysis

On inspecting outputs, we observed that often output from our system seemed good in spite of high edit distance from ground truth. Such aspect of an output *seeming good* is not captured satisfactorily by measures like edit distance. To compare the errors made by our model to the baseline, we designed and conducted a human evaluation task on AMT.[5] In the survey, we show human annotators outputs from our system and that of the baseline. We ask them to judge which alternative is *better* overall based on following criteria: 1. It is a good shorthand for two original words 2. It sounds better. We requested annotation on a scale of 1-4. To avoid ordering bias, we shuffled the order of two portmanteau between our system and that of baseline. We restrict annotators to be from Anglophone countries, have HIT Approval Rate > 80% and pay 0.40$ per HIT (5 Questions per HIT).

As seen in Table 4, output from our system was labelled better by humans as compared to the baseline 58.12% of the time. Table 3 shows outputs from different models for a few examples.

[4] We average across $M = 1000$ randomly chosen subsets of D_{Blind}, each of size $N = 611$ ($\approx 1223/2$)

[5] We avoid ground truth comparison because annotators can be biased to ground truth due to its existing popularity.

6 Related Work

Özbal and Strapparava (2012) generate new words to describe a product given its category and properties. However, their method is limited to handcrafted rules as compared to our data driven approach. Also, their focus is on brand names. Hiranandani et al. (2017) have proposed an approach to recommend brand names based on brand/product description. However, they consider only a limited number of features like memorability and readability. Smith et al. (2014) devise an approach to generate portmanteaus, which requires user-defined weights for attributes like *sounding good*. Generating a portmanteau from two root words can be viewed as a S2S problem. Recently, neural approaches have been used for S2S problems (Sutskever et al., 2014) such as MT. Ling et al. (2015) and Chung et al. (2016) have shown that character-level neural sequence models work as well as word-level ones for language modelling and MT. Zoph and Knight (2016) propose S2S models for multi-source MT, which have multi-sequence inputs, similar to our case.

7 Conclusion

We have proposed an end-to-end neural system to model portmanteau generation. Our experiments show the efficacy of proposed system in predicting portmanteaus given the root words. We conclude that pre-training character embeddings on the English vocabulary helps the model. Through human evaluation we show that our model's predictions are superior to the baseline. We have also released our dataset and code[6] to encourage further research on the phenomenon of portmanteaus. We also release an online demo [7] where our trained model can be queried for portmanteau suggestions. An obvious extension to our work is to try similar models on multiple languages.

Abstract

The diagnosis of serious mental health conditions such as schizophrenia is based on the judgment of clinicians whose training takes many years and cannot be easily formalized into objective measures. However, clinical research suggests there are disturbances in aspects of the language use of patients with schizophrenia, which opens a door for the use of NLP tools in schizophrenia diagnosis and prognosis. Using metaphor-identification and sentiment-analysis algorithms to automatically generate features, we create a classifier that, with high accuracy, can predict which patients will develop (or currently suffer from) schizophrenia. To our knowledge, this study is the first to demonstrate the utility of automated metaphor identification algorithms for detection or prediction of disease.

1 Introduction

Schizophrenia is a severe mental disorder that has a devastating impact on those who suffer from it, as well as on their families and communities. Schizophrenia is characterized by psychotic behaviors (hallucinations, delusions, thought disorders, movement disorders), flat affect and anhedonia, and trouble with focusing and executive functioning, among other symptoms (American Psychiatric Association, 2013). It afflicts over 21 million people worldwide, and is associated with a 100-150 percent increase in early mortality (Goff et al., 2005; World Health Organization, 2016; Simeone et al., 2015). As a result, diagnosis and treatment of schizophrenia has important public health consequences. Unfortunately, practitioners who are qualified to diagnose and treat serious mental health issues such as schizophrenia are in chronically short supply, and their accumulated knowledge cannot be easily formalized into reproducible metrics (Patel et al., 2007).

However, clinical research into the symptoms and mechanisms of schizophrenia suggests that disturbances in language use, and especially in metaphor use and affect, characterize schizophrenia. This suggests that automated NLP methods may have the potential to help in diagnosis and prognosis of schizophrenia. In this paper, we work from open-ended transcripts of patients interviewed by non-specialists. We then apply NLP algorithms for metaphor identification and sentiment analysis to automatically generate features for a classifier that, with high accuracy, can predict which patients will develop schizophrenia and which patients would currently be diagnosed with schizophrenia by psychiatrists.

2 Background & Related work

2.1 NLP and Computational Psychiatry

Several recent studies have proven that NLP text-analysis techniques can be successfully applied to predict mental illness. Vincze et al. (2016) use linguistic and demographic features to predict whether a speech transcript was produced by an individual with mild cognitive impairment or by a healthy control. To our knowledge, Elvevåg et al. (2007) were the first to use automated NLP methods to predict whether or not patients suffered from schizophrenia. The technical specifics of their method are unclear, as the paper was intended for a clinical audience, but they use a k-nearest neighbors algorithm in a feature space made up of n-gram features and distributional semantic features to classify 26 schizophrenia patients and 25 healthy controls. They achieve classification accuracy of 78.4% on this task. Mota et al. (2012) employ a graph-based method to classify transcripts taken from interviews with eight patients with

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2923–2930
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

schizophrenia, eight healthy controls, and eight manic patients, achieving both precision and recall of 0.875. Bedi et al. (2015) apply semantic coherence measures and measures based on part-of-speech tags to predict whether 34 youths at risk of psychosis would have a psychotic episode within 2.5 years of being interviewed (five of whom did transition within the study period). They correctly classify 100% of participants.

2.2 Metaphor, Affect and Schizophrenia

Mental-health clinicians have long had intuitions that schizophrenia patients differ from healthy individuals in their use of metaphor. A survey by Kuperberg (2010) of over 50 years of observations in the schizophrenia literature concludes that schizophrenia patients "may use common words in an idiosyncratic or bizarre manner." Particularly colorful (and metaphorical) examples of bizarre speech recorded by Andreasen (1986) include patients who referred to watches as "time vessels" and to gloves as "hand shoes."

Billow et al. (1997) carried out the first experimental exploration of this phenomenon. They measure the metaphor production of patients with schizophrenia and healthy controls during free responses to a structured interview. They find that patients with schizophrenia produce comparable rates of felicitous, coherent metaphors as healthy controls, but produce deviant metaphorical speech with significantly greater frequency.

It is not clear what could account for these differences in metaphor production, but neuroscientific studies of patients with schizophrenia offer some clues. Research shows that schizophrenia is associated with dysfunction of the amygdala, a brain structure responsible for regulating emotion (Rasetti et al., 2009). Other work demonstrates impairments in emotion perception and production in patients with schizophrenia (Vaskinn et al., 2008) and even demonstrates that face emotion recognition deficits are a predictor of psychosis onset (Corcoran et al., 2015). Based on these findings, and recognizing the important role that metaphor plays in emotional language (see (Kövecses, 2003)), Elvevåg et al. (2011) hypothesize that metaphor production disturbances in patients with schizophrenia are deeply tied to "emotional" language (i.e., language with high affective polarity). However, it should be noted in this regard that most work on metaphor processing has focused on cortical regions involved (Chen et al., 2008; Schmidt et al., 2010; Benedek et al., 2014).

2.3 Sentiment Analysis & Metaphor Detection Algorithms

Sentiment analysis is a natural-language processing task that involves determining, for given text, whether the text conveys a positive or negative sentiment, and how positive or negative the sentiment is. The book by Liu (2015) gives a comprehensive overview of sentiment analysis.

Metaphor detection is the task of determining whether a given word, phrase, or passage is being used metaphorically or literally. It is an emerging field in NLP, with research still in relatively early stages. A variety of different machine-learning and statistical methods have been applied to the task, including clustering (Birke and Sarkar, 2006; Shutova et al., 2010; Li and Sporleder, 2010; Shutova and Sun, 2013); topic models (Bethard et al., 2009; Li et al., 2010; Heintz et al., 2013); topical structure and imageability analysis (Strzalkowski et al., 2013); semantic similarity graphs (Sporleder and Li, 2009), and feature-based classifiers (Gedigian et al., 2006; Li and Sporleder, 2009; Turney et al., 2011; Dunn, 2013a,b; Hovy et al., 2013; Mohler et al., 2013; Neuman et al., 2013; Tsvetkov et al., 2013, 2014; Klebanov et al.). Metaphor detection methods differ in how they define the task of metaphor detection–for instance, some algorithms seek to determine whether a phrase (such as *sweet victory*) is metaphorical (Krishnakumaran and Zhu, 2007; Turney et al., 2011; Tsvetkov et al., 2014; Bracewell et al., 2014; Gutiérrez et al., 2016), while others attempt to tag metaphoricity at the level of the utterance (Dunn, 2013a), or at the level of individual tokens in running text (Klebanov et al.; Schulder and Hovy, 2014; Do Dinh and Gurevych, 2016). For a recent review, see Shutova (2015). For our purposes, we decided that token-level metaphor detection offered the most appropriate level of granularity, and we chose the algorithm of (Do Dinh and Gurevych, 2016) because of its state-of-the-art performance at this task at the time we began this project.

3 Data

3.1 First-Episode Schizophrenia Transcripts

Our main data set[1] consists of interviews with 17 patients who have suffered a first episode of schizophrenia (denoted by 1EP+) and 15 healthy

[1] Patient data are confidential and can only be used via a Data-Sharing Agreement with authors Corcoran and Corlett; please contact these authors for more information.

controls (denoted by 1EP-). Healthy controls were obtained from the same source population as patients with schizophrenia in the metropolitan New York City region, using web-based advertising on Craigslist, as well as by posting of flyers in and around the region. Participants engaged in open-ended interviews lasting approximately one hour, during which they were encouraged to express themselves narratively. Participants were queried on four topics, for which interviewers provided clarifying questions if they were not spontaneously discussed. The four discussion topics, as well as details of interviewer training and participant selection criteria, are discussed in more detail in the supplementary materials as well as in (Ben-David et al., 2014). Independent transcribers transcribed the interviews. Participants were matched for socioeconomic characteristics and education level. The average age of the 1EP- cohort was 35, and the average age of the 1EP+ cohort was 39. However, the 1EP- cohort was 47% male, while the 1EP+ cohort was 76% male. We refer to this data set as 1EP.

3.2 Prodromal Psychosis Transcripts

We use the data set introduced by Bedi et al. (2015) of transcripts from 34 youths at clinical high risk (CHR) for psychosis, based on the Structured Interview for Prodromal Syndromes (Miller et al., 2003). Demographic details are provided in Bedi et al. (2015). There were no significant differences for age, gender, ethnicity or medication usage between CHR converters vs. CHR non-converters. Notably, all CHR participants were ascertained using gold-standard clinical measures for which the researchers obtained excellent inter-rater reliability with other CHR programs in North America. Open-ended baseline interviews were collected from the participants using the same protocol as above. Participants were then assessed quarterly for 2.5 years to determine whether they had transitioned to psychosis. Five of the participants suffered a first episode of psychosis within the assessment period (denoted by CHR+); the remainder did not (denoted by CHR-).

4 Experiments

The review of the literature in §2.2 suggests that a constellation of disturbances in metaphor use and extremeness/lability of sentiment may characterize schizophrenia. In order to assess whether these phenomena can truly distinguish patients with schizophrenia from healthy controls or to predict future schizophrenic episodes, we produce five features. Four of these features are derived from sentiment scores produced by a sentiment analysis algorithm, and one is derived from metaphor tags produced by a metaphor identification algorithm.

4.1 Feature Set

Metaphoricity We hope to detect the alteration in metaphor production observed in patients with schizophrenia by Billow et al. (1997) using an automated metaphor detection algorithm that tag word tokens as metaphorical or not. We adapt the token-level metaphor identification algorithm of Do Dinh and Gurevych (2016) to our task. In particular, we use a multilayer perceptron (MLP) architecture with three layers. The input layer is comprised of the concatenation of the word embeddings for each token and the two tokens before and after (not including non-content tokens, and padded with a randomly created embedding at sentence beginnings and endings). The vector for each token is composed of the word's 300-dimensional Word2Vec skip-gram negative sampling word embedding [2], concatenated with a one-hot binary vector that indicates the token's part of speech. The hidden layer has ten fully connected hidden units with the hyperbolic tangent activation function. The output node classifies a token as literal or metaphorical using the softmax activation function.

Training is accomplished by minimizing a cross-entropy objective using stochastic gradient descent; the learning rate is decremented linearly during each epoch, for a maximum of 100 epochs. As in Do Dinh and Gurevych (2016), the MLP is trained on the VU Amsterdam Metaphor Corpus (VUAMC), a subset of the BNC where each token has been annotated as metaphorical or not (Steen et al., 2010), using cross-validation with an 80%-20% train-test split to optimize the regularization and learning rate parameters.

We then measure the percentage of all tokens labeled metaphorical by the metaphor identification algorithm in each transcript, denoting it by Met. We present an example text tagged by this algorithm in figure 1. Notably, the algorithm mistakenly tags the adverbially used preposition *up* in *ended up* as metaphorical; Do Dinh and Gurevych

[2] http://drive.google.com/file/d/0B7XkCwpI5KDYNlNUTTlSS21pQmM/

> We ended **up** going to different high schools ...and then at home we also ran in different social **circles** and things like that.

Figure 1: Sample sentence from one of the transcripts in the 1ep data set. Tokens in **bold** was tagged metaphorical by the token-level metaphor detection algorithm.

(2016) cite this as one of the common failure modes of their algorithm, along with failure to detect metaphors that are only clearly metaphorical from a large amount of surrounding context.

Sentiment We posit that the sentiment scores produced by automated sentiment analysis algorithms should be able to detect disturbances in the production of emotional language, particularly in regard to metaphor. To this end, we create two features that summarize the distribution of sentiment scores in each transcript. In order to obtain token- and phrase-level sentiment scores, we use the implementation of the Recursive Neural Tensor Network sentiment analysis algorithm (Socher et al., 2012) that is included in the Stanford CoreNLP toolkit, with default settings. This implementation comes pre-trained on the Stanford Sentiment Treebank. Tokens are tagged on an integer scale from 1 (Very Negative) to 5 (Very Positive). For each transcript, we take the percentage of all token-level sentiment scores that were either extremely positive (score of 1) or extremely negative (score of 5), which we denote by SentTok and similarly compute the percentage of all phrase-level sentiment scores, which we denote by SentPhr. We also compute sentiment coherence as

$$\frac{1}{N}\sum_{i=1}^{N}|s_i - s_{i-1}|$$

where the s_i denotes either the sentiment score for token i (to compute CohTok), or the sentiment score for phrase i (to compute CohPhr).

4.2 Classification Algorithms

For all algorithms and data sets, we present results produced by leave-one-out cross-validation because of the small number of transcripts available. We use a radial-basis-function support-vector classifier and a convex-hull classifier to classify transcripts based on the variables above. The convex-hull classifier was previously used by Bedi et al. (2015). A test point is classified as originating from a CHR- participant if it lies within the convex-hull of all the CHR- data points in the training set; otherwise, it is classified as CHR+. The intuition behind the convex-hull approach is that individuals that eventually develop psychosis do not necessarily do so following a unique path to conversion, and moreover psychosis itself cannot be considered a well-defined single condition (Binbay et al., 2012); thus it is reasonable to hypothesize that the "breakdown" of mental abilities may occur along different trajectories for individual CHR+ patients.

5 Results & Discussion

5.1 Statistical Analysis

As predicted, we find that the metaphor identification algorithm does indeed tag a significantly higher proportion of the tokens in the transcripts of patients with schizophrenia as metaphorical (6.3%) than in the healthy controls' transcripts (5.2%); ($t = 3.76$, $p < .001$). No significant difference was found between the other variables of interest between patients with schizophrenia and healthy controls. No significant difference was found between males and females in metaphor use frequency ($t = 1.105$, $p = 0.28$).

5.2 Classification Performance

First-Episode Schizophrenia Transcripts Table 1 shows the performance of classifiers that individually use each of the five features §4.1 as predictors, as well as the classifier that uses all five in tandem (All)[3]. Baseline represents the results of a simple majority classifier (because 18 of the 33 transcripts belonged to patients with schizophrenia, this entails classifying all transcripts as belonging to patients with schizophrenia). Because the 1EP set was not balanced for gender or age, we also present the results of classifying men as having schizophrenia and women as not having schizophrenia (Gender) as well as the results of training a classifier on age (Age). Bedi and Mota represent the classification results attained by applying the features/method of Bedi et al. (2015) and Mota et al. (2012), respectively. Using all of the features to train the support-vector classifier performed better than using any of the features individually. The accuracy of the classifier based on all the features was significantly better than baseline (Fisher's exact test, $p < .005$). Notably, our features outperformed the features

[3] The All classifier does not use gender or age features.

suggested by Bedi et al. (2015) and by Mota et al. (2012).

Prodromal Psychosis Transcripts On the prodromal transcripts, a classifier trained on all the features once again outperformed classifiers on any of the features individually, which performed at or near baseline. Interestingly, the convex-hull classifier outperformed the support vector classifier on this data. The convex-hull classifier trained on all five features correctly identified the outcome of 33 of the 34 CHR patients (97.1% accuracy). The sole patient who was misclassified belonged to the CHR+ group. This is comparable to the 100% accuracy of the Bedi et al. (2015) method and superior to the 79.4% accuracy of the Mota et al. (2012) method.

In order to explore the relationship between the two data sets, we also applied the best classifier trained on the 1EP data to the prodromal data. Interestingly, the 1EP classifier tagged 29 of the 34 CHR patients as patients with schizophrenia, including all five patients in the CHR+ group. The hypersensitivity of the 1EP classifier when applied to the prodromal data suggests that the cues that discriminate between patients with first-episode schizophrenia and healthy controls tend to place CHR patients into the same category as patients with first-episode schizophrenia. It is worth noting that the classifier tagged all of the CHR+ patients as 1EP+. We believe this indicates that our method would be useful as a tool meant to channel limited attention and resources toward patients with particularly high risk (above and beyond the criteria that currently flag a patient as being CHR).

6 Conclusion

To our knowledge, this study is the first to demonstrate the utility of automated metaphor identification algorithms in a public-health setting, and particularly for the prediction or detection of schizophrenia. Our algorithm's performance on the task of schizophrenia diagnosis from transcripts outperforms the two existing methods detailed in existing literature.

Table 1: Classification performance on 1ep set.

Variables	F-score	Accuracy
Baseline	0.703	0.563
Gender	0.703	0.656
Age	0.629	0.594
CohTok	0.694	0.531
CohPhr	0.703	0.656
Met	0.789	0.750
SentTok	0.732	0.688
SentPhr	0.718	0.656
All	**0.848**	**0.844**
Bedi	0.744	0.688
Mota	0.732	0.688

Our results also contribute to clinical knowledge of the nature of language-use abnormalities in schizophrenia, as they support previous research which finds that those suffering from schizophrenia produce more metaphors in free speech than healthy controls. Previously it was only possible to measure such disturbances by labor-intensive and subjective hand-coding of transcripts for metaphoricity, or by the assessment of expert clinicians, whose time is limited. This work breaks new ground by showing that such disturbances can be measured in an automated and reproducible fashion, using features generated via machine learning.

Our work is somewhat constrained by the small sample size available to us. As our data comes from a vulnerable population, obtaining a larger data set is challenging, but essential for future work. In fact, two of the authors are in the process of collecting data from a total of 120 CHR individuals. This would enable a more thorough investigation of a larger and more sophisticated suite of linguistic features, and especially a more fine-grained analysis of the interaction of metaphor and emotional language in schizophrenia.

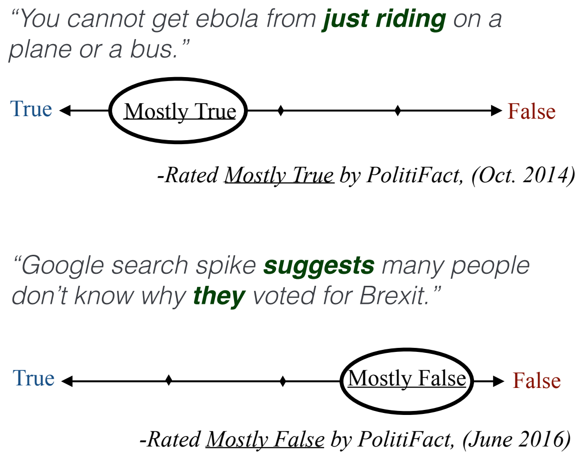
Abstract

We present an analytic study on the language of news media in the context of political fact-checking and fake news detection. We compare the language of real news with that of satire, hoaxes, and propaganda to find linguistic characteristics of untrustworthy text. To probe the feasibility of automatic political fact-checking, we also present a case study based on PolitiFact.com using their factuality judgments on a 6-point scale. Experiments show that while media fact-checking remains to be an open research question, stylistic cues can help determine the truthfulness of text.



"You cannot get ebola from **just riding** on a plane or a bus."
True
Mostly True
False
-Rated Mostly True by PolitiFact, (Oct. 2014)
"Google search spike **suggests** many people don't know why **they** voted for Brexit."

-Rated Mostly False by PolitiFact, (June 2016)

Figure 1: Example statements rated by PolitiFact as *mostly true* and *mostly false*. Misleading phrasing - bolded in green - was one reason for the in-between ratings.

1 Introduction

Words in news media and political discourse have a considerable power in shaping people's beliefs and opinions. As a result, their truthfulness is often compromised to maximize impact. Recently, fake news has captured worldwide interest, and the number of organized efforts dedicated solely to fact-checking has almost tripled since 2014.[1] Organizations, such as PolitiFact.com, actively investigate and rate the veracity of comments made by public figures, journalists, and organizations.

Figure 1 shows example quotes rated for truthfulness by PolitiFact. Per their analysis, one component of the two statements' ratings is the misleading phrasing (bolded in green in the figure). For instance, in the first example, the statement is true as stated, though only because the speaker hedged their meaning with the quantifier *just*. In the second example, two correlated events – Brexit and Google search trends – are presented ambiguously as if they were directly linked.

Importantly, like above examples, most fact-checked statements on PolitiFact are rated as neither entirely true nor entirely false. Analysis indicates that falsehoods often arise from subtle differences in phrasing rather than outright fabrication (Rubin et al., 2015). Compared to most prior work on deception literature that focused on binary categorization of truth and deception, political fact-checking poses a new challenge as it involves a graded notion of truthfulness.

While political fact-checking generally focuses on examining the accuracy of a single quoted statement by a public figure, the reliability of general news stories is also a concern (Connolly et al., 2016; Perrott, 2016). Figure 2 illustrates news types categorized along two dimensions: the *intent* of the authors (desire to deceive) and the *content* of the articles (true, mixed, false).

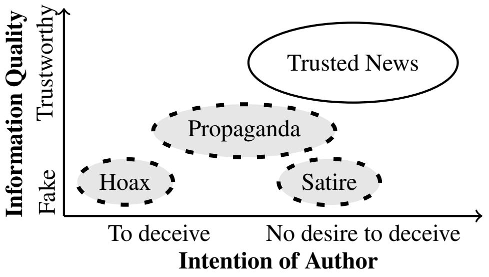

Figure 2: Types of news articles categorized based on their intent and information quality.

In this paper, we present an analytic study characterizing the language of political quotes and news media written with varying intents and degrees of truth. We also investigate graded deception detection, determining the truthfulness on a 6-point scale using the political fact-checking database available at PolitiFact.[2]

2 Fake News Analysis

News Corpus with Varying Reliability To analyze linguistic patterns across different types of articles, we sampled standard trusted news articles from the English Gigaword corpus and crawled articles from seven different unreliable news sites of differing types. Table 1 displays sources identified under each type according to US News & World Report.[3] These news types include:

- *Satire*: mimics real news but still cues the reader that it is not meant to be taken seriously
- *Hoax*: convinces readers of the validity of a paranoia-fueled story
- *Propaganda*: misleads readers so that they believe a particular political/social agenda

Unlike hoaxes and propaganda, satire is intended to be notably different from real news so that audiences will recognize the humorous intent. Hoaxes and satire are more likely to invent stories, while propaganda frequently combines truths, falsehoods, and ambiguities to confound readers.

To characterize differences between news types, we applied various lexical resources to trusted and fake news articles. We draw lexical resources from prior works in communication theory and stylistic analysis in computational linguistics. We tokenize the text with NLTK (Bird et al., 2009) and compute per-document count for each lexicon, and report averages per article of each type.

News Type	Source	# of Doc	# Tokens per Doc.
Trusted	Gigaword News	13,995	541
Satire	The Onion	14,170	350
	The Borowitz Report	627	250
	Clickhole	188	303
Hoax	American News	6,914	204
	DC Gazette	5,133	582
Propaganda	The Natural News	15,580	857
	Activist Report	17,869	1,169

Table 1: News articles used for analysis in Section 2.

First among these lexicons is the Linguistic Inquiry and Word Count (LIWC), a lexicon widely used in social science studies (Pennebaker et al., 2015). In addition, we estimate the use of strongly and weakly subjective words with a sentiment lexicon (Wilson et al., 2005). Subjective words can be used to dramatize or sensationalize a news story. We also use lexicons for hedging from (Hyland, 2015) because hedging can indicate vague, obscuring language. Lastly, we introduce intensifying lexicons that we crawled from Wiktionary based on a hypothesis that fake news articles try to enliven stories to attract readers. We compiled five lists from Wiktionary of words that imply a degree a dramatization (comparatives, superlatives, action adverbs, manner adverbs, and modal adverbs) and measured their presence.

Discussion Table 2 summarizes the ratio of averages between unreliable news and truthful news for a handful of the measured features. Ratios greater than one denote features more prominent in fake news, and ratios less than one denote features more prominent in truthful news. The ratios between unreliable/reliable news reported are statistically significant ($p < 0.01$) with Welsch t-test after Bonferroni correction.

Our results show that first-person and second-person pronouns are used more in less reliable or deceptive news types. This contrasts studies in other domains (Newman et al., 2003), which found fewer self-references in people telling lies about their personal opinions. Unlike that domain, news writers are trying to appear indifferent. Editors at trustworthy sources are possibly more

[2] All resources created for this paper including corpus of news articles from unreliable sources, collection of Politifact ratings, and compiled Wiktionary lexicons have been made publicly available at `homes.cs.washington.edu/~hrashkin/factcheck.html`

Table 2: Linguistic features and their relationship with fake news. The ratio refers to how frequently it appears in fake news articles compared to the trusted ones. We list linguistic phenomena more pronounced in the fake news first, and then those that appear less in the fake news. Examples illustrate sample texts from news articles containing the lexicon words. All reported ratios are statistically significant. The last column (MAX) lists compares which type of fake news most prominently used words from that lexicon (P = propaganda, S = satire, H = hoax)

rigorous about removing language that seems too personal, which is one reason why this result differs from other lie detection domains. This finding instead corroborates previous work in written domains found by Ott et al. (2011) and Rayson et al. (2001), who found that such pronouns were indicative of imaginative writing. Perhaps imaginative storytelling domains is a closer match to detecting unreliable news than lie detection on opinions.

Our results also show that words that can be used to exaggerate – subjectives, superlatives, and modal adverbs – are all used more by fake news. Words used to offer concrete figures – comparatives, money, and numbers – appear more in truthful news. This also builds on previous findings by Ott et al. (2011) on the difference between superlative/comparative usage.

Trusted sources are more likely to use assertive words and less likely to use hedging words, indicating that they are less vague about describing events, as well. This relates to psychology theories (Buller and Burgoon, 1996) that deceivers show more "uncertainty and vagueness" and "indirect forms of expression". Similarly, the trusted sources use the *hear* category words more often, possibly indicating that they are citing primary sources more often.

The last column in Table 2 shows the fake news type that uses the corresponding lexicon most prominently. We found that one distinctive feature of satire compared to other types of untrusted news is its prominent use of adverbs. Hoax stories tend to use fewer superlatives and comparatives. In contrast, compared to other types of fake news, propaganda uses relatively more assertive verbs and superlatives.

News Reliability Prediction We study the feasibility of predicting the reliability of the news article into four categories: trusted, satire, hoax, or propaganda. We split our collected articles into balanced training (20k total articles from the Onion, American News, The Activist, and the Gigaword news excluding 'APW', 'WPB' sources) and test sets (3k articles from the remaining sources). Because articles in the training and test set come from different sources, the models must classify articles without relying on author-specific cues. We also use 20% of the training articles as an in-domain development set. We trained a Max-Entropy classifier with L2 regularization on n-gram tf-idf feature vectors (up to trigrams).[4]

The model achieves F1 scores of 65% on the out-of-domain test set (Table 3). This is a promising result as it is much higher than random, but still leaves room for improvement compared to the

[4] N-gram tfidf vectors have acted as competitive means of cross-domain text-classification. Zhang et al. (2015) found that for data sets smaller than a million examples, this was the best model, outperforming neural models.

Data	Sources	Random	MaxEnt
Dev	in-domain	0.26	0.91
Test	out-of-domain	0.26	0.65

Table 3: F1 scores of 4-way classification of news reliability.

performance on the development set consisting of articles from in-domain sources.

We examined the 50 highest weighted n-gram features in the MaxEnt classifier for each class. The highest weighted n-grams for trusted news were often specific places (e.g., “washington”) or times (“on monday”). Many of the highest weighted from satire were vaguely facetious hearsay (“reportedly”, “confirmed”). For hoax articles, heavily weighted features included divisive topics (“liberals”, “trump”) and dramatic cues (“breaking”). Heavily weighted features for propaganda tend towards abstract generalities (“truth”, “freedom”) as well as specific issues (“vaccines”, “syria”). Interestingly, “youtube” and “video” are highly weighted for the propaganda and hoax classes respectively; indicating that they often rely on video clips as sources.

3 Predicting Truthfulness

Politifact Data Related to the issue of identifying the truthfulness of a news article is the fact-checking of individual statements made by public figures. Misleading statements can also have a variety of intents and levels of reliability depending on whom is making the statement.

PolitiFact[5] is a site led by Tampa Bay Times journalists who actively fact-check suspicious statements. One unique quality of PolitiFact is that each quote is evaluated on a 6-point scale of truthfulness ranging from “True” (factual) to “Pants-on-Fire False” (absurdly false). This scale allows for distinction between categories like mostly true (the facts are correct but presented in an incomplete manner) or mostly false (the facts are not correct but are connected to a small kernel of truth).

We collected labelled statements from PolitiFact and its spin-off sites (PunditFact, etc.) (10,483 statements in total). We analyze a subset of 4,366 statements that are direct quotes by the original speaker. The distributions of ratings on the PolitiFact scale for this subset are shown in Table 4. Most statements are labeled as neither completely true nor false.

	More True			More False		
	True	Mostly True	Half True	Mostly False	False	Pants-on-fire
6-class	20%	21%	21%	14%	17%	7%
2-class	62%			38%		

Table 4: PolitiFact label distribution. PolitiFact uses a 6-point scale ranging from: True, Mostly True, Half-true, Mostly False, False, and Pants-on-fire False.

We formulate a fine-grained truthfulness prediction task with Politifact data. We split quotes into training/development/test set of {2575, 712, 1074} statements, respectively, so that all of each speaker’s quotes are in a single set. Given a statement, the model returns a rating for how reliable the statement is (Politifact ratings are used as gold labels). We ran the experiment in two settings, one considering all 6 classes and the other considering only 2 (treating the top three truthful ratings as true and the lower three as false).

Model We trained an LSTM model (Hochreiter and Schmidhuber, 1997) that takes the sequence of words as the input and predicts the Politifact rating. We also compared this model with Maximum Entropy (MaxEnt) and Naive Bayes models, frequently used for text categorization.

For input to the MaxEnt and Naive Bayes models, we tried two variants: one with the word tf-idf vectors as input, and one with the LIWC measurements concatenated to the tf-idf vectors. For the LSTM model, we used word sequences as input and also a version where LSTM output is concatenated with LIWC feature vectors before undergoing the activation layer. The LSTM word embeddings are initialized with 100-dim embeddings from GLOVE (Pennington et al., 2014) and fine-tuned during training. The LSTM was implemented with Theano and Keras with 300-dim hidden state and a batch size of 64. Training was done with ADAM to minimize categorical cross-entropy loss over 10 epochs.

Classifier Results Table 5 summarizes the performance on the development set. We report macro averaged F1 score in all tables. The LSTM outperforms the other models when only using text as input; however the other two models improve substantially with adding LIWC features, particu-

[5] www.politifact.com/

	2-CLASS		6-CLASS	
	text	+ LIWC	text	+ LIWC
Majority Baseline	.39	-	.06	-
Naive Bayes	.44	.58	.16	.21
MaxEnt	.55	.58	.20	.21
LSTM	.58	.57	.21	.22

Table 5: Model performance on the Politifact validation set.

MODEL	FEATURE	2-CLASS	6-CLASS
Majority Baseline		.39	.06
Naive Bayes	text + LIWC	.56	.17
MaxEnt	text + LIWC	.55	.22
LSTM	text + LIWC	.52	.19
LSTM	text	.56	.20

Table 6: Model performance on the Politifact test set.

larly in the case of the multinomial naive Bayes model. In contrast, the LIWC features do not improve the neural model much, indicating that some of this lexical information is perhaps redundant to what the model was already learning from text.

We report results on the test set in Table 6. We again find that LIWC features improves MaxEnt and NB models to perform similarly to the LSTM model. As in the dev. set results, the LIWC features do not improve the LSTM's performance, and even seem to hurt the performance slightly.

4 Related Work

Deception Detection Psycholinguistic work in interpersonal deception theory (Buller and Burgoon, 1996) has postulated that certain speech patterns can be signs of a speaker trying to purposefully obscure the truth. Hedge words and other vague qualifiers (Choi et al., 2012; Recasens et al., 2013), for example, may add indirectness to a statement that obscures its meaning.

Linguistic aspects deception detection has been well-studied in a variety of NLP applications (Ott et al., 2011; Mihalcea and Strapparava, 2009; Jindal and Liu, 2008; Girlea et al., 2016; Zhou et al., 2004). In these applications, people purposefully tell lies to receive an extrinsic payoff. In our study, we compare varying types of unreliable news source, created with differing intents and levels of veracity.

Fact-Checking and Fake News There is research in political science exploring how effective fact-checking is at improving people's awareness (Lord et al., 1979; Thorson, 2016; Nyhan and Reifler, 2015). Prior computational works (Vlachos and Riedel, 2014; Ciampaglia et al., 2015) have proposed fact-checking through entailment from knowledge bases. Our work takes a more linguistic approach, performing lexical analysis over varying types of falsehood.

Biyani et al. (2016) examine the unique linguistic styles found in clickbait articles, and Kumar et al. (2016) also characterize hoax documents on Wikipedia. The differentiation between these fake news types is also proposed in previous work (Rubin et al., 2015). Our paper extends this work by offering a quantitative study of linguistic differences found in articles of different types of fake news, and build predictive models for graded deception across multiple domains – PolitiFact and news articles. More recent work (Wang, 2017) has also investigated PolitiFact data though they investigated meta-data features for prediction whereas our investigation is focused on linguistic analysis through stylistic lexicons.

5 Conclusion

We examine truthfulness and its contributing linguistic attributes across multiple domains e.g., online news sources and public statements. We perform multiple prediction tasks on fact-checked statements of varying levels of truth (graded deception) as well as a deeper linguistic comparison of differing types of fake news e.g., propaganda, satire and hoaxes. We have shown that fact-checking is indeed a challenging task but that various lexical features can contribute to our understanding of the differences between more reliable and less reliable digital news sources.

Topic-Based Agreement and Disagreement in US Electoral Manifestos

Abstract

We present a topic-based analysis of agreement and disagreement in political manifestos, which relies on a new method for topic detection based on key concept clustering. Our approach outperforms both standard techniques like LDA and a state-of-the-art graph-based method, and provides promising initial results for this new task in computational social science.

1 Introduction

During the last decade, the adoption of natural language processing (NLP) techniques for the study of political phenomena has gained considerable momentum (Grimmer and Stewart, 2013), arguably because of both the availability of parliamentary proceedings (van Aggelen et al., 2017), electoral manifestos (Volkens et al., 2011) and campaign debates (Woolley and Peters, 2008), and the interest of the computational social science (CSS) community in the potential of text mining methods for advancing political science research (Lazer et al., 2009).

Previous work focused on the automatic detection of sentiment expressions in political news (Young and Soroka, 2012), the identification of ideological proportions (Sim et al., 2013) and the scaling on a left-right spectrum of politicians' speeches (Slapin and Proksch, 2008). More recently, researchers looked at topic-centered approaches to provide finer-grained analyses, including segmentation methods for topic-labeled manifestos (Glavaš et al., 2016), supporting manual coders in identifying coarse-grained political topics (Zirn et al., 2016), as well as topic-based and cross-lingual political scaling (Nanni et al., 2016; Glavaš et al., 2017).

Measuring Agreement. Automatically measuring the level of agreement in political documents (Gottipati et al., 2013; Menini and Tonelli, 2016) has the potential of supporting political analyses such as the comparisons between campaign strategies (Burton et al., 2015), the study of promises kept and broken after elections (Naurin, 2011), the formation of coalitions (Debus, 2009) and the interactions between government and opposition (Hix and Noury, 2016). However, previous work relies on the availability of pre-defined topics, including supervised methods (Galley et al., 2004; Hillard et al., 2003), approaches leveraging collaboratively generated resources (Gottipati et al., 2013; Awadallah et al., 2012) or pairwise agreement detection from political debates (Menini and Tonelli, 2016).

Our Contributions. *a) New task:* Given a collection of political documents such as, e.g., electoral manifestos, we look at ways to perform an automatic, topic-based agreement-disagreement classification. *b) New approach:* We first segment the texts into coarse-grained domains. Next, coarse domains are used to extract a fine-grained list of topic-based points of view which, in turn, are used to perform classification. We achieve this by developing a novel approach for topic detection on the basis of key concept clustering techniques: this is shown to outperform not only LDA-based Topic Modeling – the *de facto* standard approach for this task in CSS (Grimmer and Stewart, 2013) – but also established unsupervised (k-means) and state-of-the-art graph-based clustering techniques. *c) Experimental study and resources:* We use manifestos from the Comparative Manifesto Project (Volkens et al., 2011). As in previous works (Zirn et al., 2016), we focus on a subset consisting of six U.S. manifestos (Republican and Democrat) from the 2004, 2008 and 2012 elections. We show

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 2938–2944
Copenhagen, Denmark, September 7–11, 2017.

that our method leads to promising results when measuring the topic-based agreement between the party manifestos, thus indicating the overall feasibility of the task. Additionally, we release all code and annotations related to this paper to foster further work from the research community.

2 System Overview

We present a new system for measuring the topic-based agreement of political manifestos. Our approach consists of four main steps: i) macro-domain detection, e.g. *foreign policy, economy, welfare*, ii) key concept extraction, iii) topic detection as key concept clustering, e.g., *energy consumption, new energy solution, petroleum dependence* for the topic *green economy*, and iv) pairwise, topic-based agreement detection.

The central component of our pipeline is a new approach for fine-grained topic detection in political contents based on key concept clustering. This is because, among existing methods, supervised approaches cannot be applied here due to the scarce availability of in-domain labeled data, as well as the already remarked high complexity of the annotation process (Benoit et al., 2016). Moreover, the application of unsupervised topic detection techniques like LDA has been shown during prototyping to produce low-quality topics that are rather coarse (cf. the results in Section 3).

Similar to LDA-based approaches, we view each topic as a cluster of words or phrases. However, given that we are in a domain with topics built around rather specific lexical cues, we do not rely on the entire vocabulary of the documents. Instead, we build clusters that are made up of semantically similar key concepts extracted from the documents themselves, including both single and multiwords (i.e. keywords and keyphrases). In the next paragraph we present an overview of each component of our system.

1) Domain Detection. We are given as input sentences from a political manifesto. The first step of our work is to classify them into the seven macro-domains defined by the Manifesto Project, namely *external relations*, *freedom and democracy*, *political system*, *economy*, *welfare and quality of life*, *fabric of society*, *social groups*. To achieve this goal, we use ClassyMan, a system developed in a previous work (Zirn et al., 2016), which predicts the domains and domain shifts between pairs of adjacent sentences.

2) Key concept Extraction. Next, for each domain we process each sentence using Keyphrase Digger (KD) (Moretti et al., 2015). KD is a rule-based (hence domain-agnostic) system for key concept extraction that combines statistical measures with linguistic information, and which has shown competitive performance on the SemEval 2010 benchmark (Kim et al., 2010). We set the tool to extract lemmatized key concepts up to three tokens. For each key concept, we compute its tf-idf, considering each domain as a different document. The result is a list of key concepts for each domain, with a score representing their relevance to the domain.

3) Key concept Clustering. Starting from the flat lists of key concepts extracted by KD, we adopt a recursive procedure to merge them into meaningful clusters. First, we build a distributional semantic vector for each key concept by averaging the embeddings of each word in the key concept (we use the GloVe embeddings from Pennington et al. (2014) with 50 dimensions, pre-trained on Wikipedia). Next, we build a semantic graph representation where *a)* each node consists of a key concept, *b)* the weight of each edge is the cosine distance between their respective embedding vectors and *c)* edges are directed, pointing to the node of the key concept with the higher tf-idf. For ties, we create multiple edges. To direct the nodes we adopt tf-idf, since we want to weigh the key concepts according to the relevance for the macro-domain we are processing. This allows us to obtain well-defined groups within the domains.

To reduce the number of weak edges, we set a cosine similarity threshold of 0.8,[1] and we set an edge between two multi-word keyphrases if they have at least one word in common (e.g. *ethnic minority*, *black minority*).

Finally, we obtain clusters of semantically related key concepts from the graph as follows: *a)* we extract all groups of key concepts with an edge directed to the same node and create a first set of clusters. Then, *b)* clusters sharing at least 50% of the key concepts are merged. Next, *c)* the clusters purity is improved by removing the less relevant key concepts. These are identified as those key concepts whose cosine distance is more than 1.5 times the standard deviation from the centroid of

[1] We evaluated the clustering output with different thresholds ranging from 0.6 to 0.9. The value of 0.8 is the one leading to the best accuracy. In Table 1 and 2 we report the results using this threshold.

the cluster. At the end of this process, we obtain for each domain a set of clusters or *topics*, made of semantically related key concepts. The number of clusters is determined dynamically during the process and does not need to be defined a priori.

4) Statement Extraction. We use the clusters of key concepts to identify pairs of statements, related to the same topic, from the Republican (R) and Democratic (D) manifestos. For each topic, we first collect the statements from D and R manifestos having among their key concepts one of the key concepts defining the topic and then we pair groups of three statements from D with groups of three statements from R. We use groups of three statements because it allows us *i)* to obtain a sufficient number of pairs to perform automatic classification, and *ii)* to improve the quality of the manual annotations. We noticed during an initial evaluation that annotators focus easier on groups of 3 sentences rather than larger groups and that, on the other hand, using less than 3 sentences decreases the chances to obtain at least two statements in agreement/disagreement within a pair.

5) Agreement Classification. The last step is the automatic classification of agreement and disagreement between Republicans and Democrats. To classify pairs of statements, we rely on a supervised machine learning approach with the set of features used in Menini and Tonelli (2016), in which a similar task is addressed. The classification relies on features related to surface information such as lexical overlap and negation, to the semantic content of the statements (e.g. sentiment) and to their relation (e.g. entailment).

3 Evaluation

3.1 Topic Extraction

Having a set of manifestos annotated with coarse-grained domains – using *ClassyMan*, which achieved a micro F1-Score of 0.78 across the seven macro-topics in a 10-fold cross validation setting – the central step of our pipeline is to detect clusters of key concepts representing fine-grained topics in each macro domain. To do that, we adopt the method described above, that we call here *Key Concept Clusters*. We examine its performance in comparison with two types of baselines.

LDA Baselines. We first employ vanilla LDA, a common approach for topic detection in CSS (Grimmer and Stewart, 2013), relying on the assumption that tokens often co-occurring together in a corpus belong to the same topic. For this task, we use the Mallet topic model package.[2] Given the fact that our method for key concept clustering identifies on average 30 topics per domain, we create a corpus for each domain with all its sentences and we run LDA with 10,000 iterations to obtain 30 topics. We test LDA by considering all the tokens in the corpus (*Vanilla LDA*) and only the extracted key concepts (*Key concept LDA*).

Clustering Baselines. The second type of baseline adopts the same representation of key concepts used in our approach, i.e., we represent candidate phrases by averaging the embeddings of their constituent words. We test two different clustering approaches to group them into topics: the first uses *K-means* (with 30 clusters). The second (*Graph-based*) builds a fully-connected semantic relatedness graph by measuring the cosine similarity between all pairs of key concepts: topic clustering is then obtained by finding all maximal cliques in the graph using the Bron-Kerbosch algorithm.

Evaluation. In order to assess the overall quality of the topics produced by each approach, we adopt the word-intrusion post-hoc evaluation method (Chang et al., 2009) using the platform presented in Lauscher et al. (2016). For each approach, we randomly pick 100 topics and for each topic we keep two sets of key concepts, respectively the four and eight top-relevant elements of the cluster.[3] Then, we add to these four/eight words a new word from another topic (i.e. the intruder), and we shuffle the obtained five/nine words. Finally, we ask three political science experts to identify the intruder. The more the topics are coherent, the easier the intruder is detected. While this type of post-hoc evaluation is extremely time-consuming – no less than 45 minutes of work for annotator for each produced ranking, thus hindering the experimental assessment of, for instance, the role of different numbers of topics for each baseline – it is necessary given the already remarked limits of existing gold standards manually-created for the task (Mikhaylov et al., 2012; King et al., 2017).

Results. As shown in Table 1, our system outperforms the other methods with an accuracy of 0.86 in the word-intrusion task with four key con-

[2] http://mallet.cs.umass.edu/

[3] For LDA, Mallet provides already ranked results. For the other approaches, the most relevant key concepts are the key concepts closest to the centroid of the cluster.

Method	Acc.@4	Acc.@8
Vanilla-LDA	0.22	0.35
Key concept-LDA	0.29	0.36
Graph-based Clusters	0.46	0.44
k-means Clusters	0.72	0.67
Key concept Clusters	0.86	0.67

Table 1: Topics evaluation: accuracy in word intrusion task. The table reports the accuracy values on the first 4 and 8 key concepts in the clusters.

Method	Kappa@4	Kappa@8
Vanilla LDA	0.32	0.46
Key concept LDA	0.50	0.40
Graph-based Clusters	0.39	0.32
k-means Clusters	0.65	0.61
Key concept Clusters	0.79	0.62

Table 2: Inter-annotator agreement (IAA) evaluation (Fleiss' kappa) in the word intrusion task. The table reports the IIA on the first 4 and 8 key concepts in the clusters.

cepts in each cluster, while it decreases to 0.67 if we extend the evaluation to include eight key concepts. Besides, inter-annotator agreement (Fleiss' kappa), reported in Table 2, varies a lot across the different methods. In particular, the agreement in the intrusion task with four key concepts is higher for clusters generated with our method (0.79), while it is very low using LDA (0.32). This confirms the findings by Chang et al. (2009) that LDA topics are often difficult to interpret.

If we extend the evaluation to the first eight elements of each cluster, we notice that the difference between the agreement with our pipeline (0.62) and LDA (0.46) decreases. This shows that, with *key concept clusters*, increasing the number of key concepts in a topic affects their interpretation, although there is still an improvement with respect to the other approaches.

Final Tuning. We next tune clustering to classify fine-grained topics as in agreement or disagreement. Tuning is performed as to maximize clustering accuracy while obtaining a sufficient number of topics shared by both Democrats and Republicans. Since a cosine similarity threshold of 0.8 in the clustering process leads to clusters that are too specific, often addressed only by one of the two parties, we reduce the threshold to 0.7, so that the topics are likely to be covered by both manifestos. In addition, we want to compare the agreement focusing on small clusters, composed by a maximum of 10 key concepts. To obtain them, we iterate the clustering process over the key concepts of larger clusters, progressively increasing the cosine similarity threshold until there are no groups larger than 10 key concepts. We reach this goal with a threshold of 0.85. Using these settings, the accuracy (Acc. @4) of the clusters decreases to 0.74, but we obtain clusters that allow us to extract a total of 351 pairs covering 87 fine-grained topics. Table 3 shows some of the clusters extracted.

3.2 Agreement Classification

Data Annotation. The statements in the pairs have been annotated by three scholars of political science in terms of agreement, disagreement or none of the two. The annotation results in 158 pairs in disagreement, 135 in agreement and 58 neither in agreement nor in disagreement, with an inter-annotator agreement (IAA) of 0.64 (Fleiss' Kappa). Note that only in three cases the annotators claimed that the meaning of a sentence pair did not match with the topic detected with our approach. This additional finding highlights again the quality of our method for topic detection based on key concept clustering.

Agreement Classification. Agreement classification is carried out using Support Vector Machine (SVM) tested in two configurations. In the first setting, we train and test the classifier with 10-fold cross validation over the manually annotated pairs from the political manifestos. In the second configuration, we explore instead a cross-domain approach: we train the SVM on the 1960 Elections dataset from Menini and Tonelli (2016) and use all the pairs in our gold standard of political manifestos as test set. This experiment is aimed at assessing the impact of training on comparable data are from the same domain (i.e., transcript of political speeches vs. manifestos).

The results of both configurations are shown in Table 4, where they are compared to a random baseline. The results show that the set of features used suits our task, classifying the data with an accuracy comparable to the performance of human annotators, if we consider IAA as an upper bound for the task. We achieve nevertheless results that are in a lower range than Menini and Tonelli (2016), thus suggesting that agreement and disagreement is harder to detect in political mani-

festos than in speeches. Finally the accuracy of the classifier in the cross-domain setting is lower than the one obtained with in-domain cross-validation, but still comparable with that of human annotators.

4 Conclusion

In this paper, we presented a system for supporting automatic topic-bases analyses of agreement and disagreement in political manifestos. This approach goes beyond established approaches for the task, which are either too coarse-grained or rely intensively on manual annotations.

Our method can provide insights into agreement and disagreement between parties, covering several topics of internal and foreign policy. By examining the results, we find an overall cross-party agreement of 46% regarding the discussed issues. However, this agreement varies substantially if we consider the different macro-domains. For example, while we notice a strong disagreement over the domain *political system*, especially for what concerns the responsibilities of previous administrations, other domains, such as *external relations*, present a more balanced ratio of agreement and disagreement between Republicans and Democrats. The possibility of measuring agreement at a finer level (topics) that is offered by our approach, shows, for example, that between 2004 and 2012 two opposite positions have been defined regarding the Middle East. On the contrary, there has been a general agreement on the role of the U.S. concerning the relations with Europe.

In the future, we hope that the pipeline presented in this paper will support political science researchers in studying topics such as party polarization through the analysis and comparison of electoral manifestos, parliamentary proceedings and campaign speeches. On the computational side, we will to extend our approach to cross-lingual data, in order to enable computer-assisted political analysis across different languages.

Zipporah: a Fast and Scalable Data Cleaning System for Noisy Web-Crawled Parallel Corpora

Hainan Xu **Philipp Koehn**

hxu31@jhu.edu phi@jhu.edu

Abstract

We introduce Zipporah, a fast and scalable data cleaning system. We propose a novel type of bag-of-words translation feature, and train logistic regression models to classify good data and synthetic noisy data in the proposed feature space. The trained model is used to score parallel sentences in the data pool for selection. As shown in experiments, Zipporah selects a high-quality parallel corpus from a large, mixed quality data pool. In particular, for one noisy dataset, Zipporah achieves a 2.1 BLEU score improvement with using 1/5 of the data over using the entire corpus.

1 Introduction

Statistical machine translation (SMT) systems require the use of parallel corpora for training the internal model parameters. Data quality is vital for the performance of the SMT system (Simard, 2014). To acquire a massive parallel corpus, many researchers have been using the Internet as a resource, but the quality of data acquired from the Internet usually has no guarantee, and data cleaning/data selection is needed before the data is used in actual systems. Usually data cleaning refers to getting rid of a small amount of very noisy data from a large data pool, and data selection refers to selecting a small subset of clean (or in-domain) data from the data pool; both have the objective of improving translation performances. For practical purposes, it is highly desirable to perform data selection in a very fast and scalable manner. In this paper we introduce Zipporah[1], a fast and scalable system which can select an arbitrary size of good data from a large noisy data pool to be used in SMT model training.

2 Prior Work

Many researchers have studied the data cleaning/selection problem. For data selection, there have been a lot of work on selecting a subset of data based on domain-matching. Duh et al. (2013) used a neural network based language model trained on a small in-domain corpus to select from a larger data pool. Moore and Lewis (2010) computed cross-entropy between in-domain and out-of-domain language models to select data for training language models. XenC (Rousseau, 2013), an open-source tool, also selects data based on cross-entropy scores on language models. Axelrod et al. (2015) utilized part-of-speech tags and used a class-based n-gram language model for selecting in-domain data. There are a few works that utilize other metrics. Lü et al. (2007) redistributed different weights for sentence pairs/predefined sub-models. Shah and Specia (2014) described experiments on quality estimation which, given a source sentence, select the best translation among several options. The qe-clean system (Denkowski et al., 2012; Dyer et al., 2010; Heafield, 2011) uses word alignments and language models to select sentence pairs that are likely to be good translations of one another.

For data cleaning, a lot of researchers worked on getting rid of noising data. Taghipour et al. (2011) proposed an outlier detection algorithm which leads to an improved translation quality when trimming a small portion of data. Cui et al. (2013) used a graph-based random walk algorithm to do bilingual data cleaning. BiTextor (Esplá-Gomis and Forcada, 2009) utilizes sentence alignment scores and source URL information to filter out bad URL pairs and selects good sentence pairs.

In this paper we propose a novel way to evaluate the quality of a sentence pair which runs efficiently. We do not make a clear distinction

[1] https://github.com/hainan-xv/zipporah

Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

between data selection and data cleaning in this work, because under different settings, our method can perform either based on the computed quality scores of sentence pairs.

3 Method

The method in this paper works as follows: we first map all sentence pairs into the proposed feature space, and then train a simple logistic regression model to separate known good data and (synthetic) bad data. Once the model is trained, it is used to score sentence pairs in the noisy data pool. Sentence pairs with better scores are added to the selected subset until the desired size constraint is met.

3.1 Features

Since good adequacy and fluency are the major two elements that constitute a good parallel sentence pair, we propose separate features to address both of them. For adequacy, we propose bag-of-words translation scores, and for fluency we use n-gram language model scores. For notational simplicity, in this section we assume the sentence pair is French-English in describing the features, and we will use subscripts f and e to indicate the languages. In designing the features, we prioritize efficiency as well as performance since we could be dealing with corpora of huge sizes.

3.1.1 Adequacy scores

We view each sentence as a bag of words, and design a "distance" between the sentence pairs based on a bag-of-words translation model. To do this, we first generate dictionaries from an aligned corpus, and represent them as sets of triplets. Formally,

$$D_{\text{f2e}} = \{(w_{f_i}, w_{e_i}, p(w_{e_i}|w_{f_i})), i = 1, ..., m\}.$$

Given a sentence pair (s_f, s_e) in the noisy data pool, we represent the two sentence as two sparse word-frequency vectors v_f and v_e. For example for any French word w_f, we have $v_f[w_f] = \frac{c(w_f, s_f)}{l(s_f)}$, where $c(w_f, s_f)$ is the number of occurrences of w_f in s_f and $l(s_f)$ is the length of s_f. We do the same for v_e. Notice that by construction, both vectors add up to 1 and represent a proper probability distribution on their respective vocabularies. Then we "translate" v_f into v'_e, based on the probabilistic f2e dictionary, where

$$v'_e[w_e] = \sum_{w_f} v_f[w_f] p(w_e|w_f)$$

For a French word w that does not appear in the dictionary, we keep it as it is in the translated vector, i.e. assume there is an entry of $(w, w, 1.0)$ in the dictionary. Since the dictionary is probabilistic, the elements in v'_e also add up to 1, and v'_e represents another probability distribution on the English vocabulary. We compute the (smoothed) cross-entropy between v_e and v'_e,

$$\text{xent}(v_e, v'_e) = \sum_{w_e} v_e[w_e] \log \frac{1}{v'_e[w_e] + c} \quad (1)$$

where c is a smoothing constant to prevent the denominator from being zero, and set $c = 0.0001$ for all experiments in this paper (more about this in Section 4).

We perform similar procedures for English-to-French, and compute $\text{xent}(v_f, v'_f)$. We define the adequacy score as the sum of the two:

$$\text{adequacy}(s_f, s_e) = \text{xent}(v_e, v'_e) + \text{xent}(v_f, v'_f)$$

3.1.2 Fluency scores

We train two n-gram language models with a clean French and English corpus, and then for each sentence pair (s_f, s_e), we score each sentence with the corresponding model, $\mathcal{F}_{\text{ngram}}(s_f)$ and $\mathcal{F}_{\text{ngram}}(s_e)$, each computed as the ratio between the sentence negative log-likelihood and the sentence length. We define the fluency score as the sum of the two:

$$\text{fluency}(s_f, s_e) = \mathcal{F}_{\text{ngram}}(s_f) + \mathcal{F}_{\text{ngram}}(s_e)$$

3.2 Synthetic noisy data generation

We generate synthetic noisy data from good data, and make sure the generated noisy data include sentence pairs with a) good fluency and bad adequacy, b) good adequacy and bad fluency and c) bad both.

Respectively, we generate 3 types of "noisy" sentence pairs from a good corpus: a) shuffle the sentences in the target language file (each sentence in the source language would be aligned to a random sentence in the target language); b) shuffle the words within each sentence (each sentence will be bad but the pairs are good translations in the "bag-of-words" sense); c) shuffle both the sentences and words. We emphasize that, while the synthetic data might not represent "real" noisy data, it has the following advantages: 1) each type of noisy data is equally represented so the classifier has to do well on all of them; 2) the data generated this way would be among the hardest to classify, especially type a and type b, so if a classifier separates such hard data with good performance, we expect it to also be able to do well in real world situations.

3.3 Logistic regression feature mapping

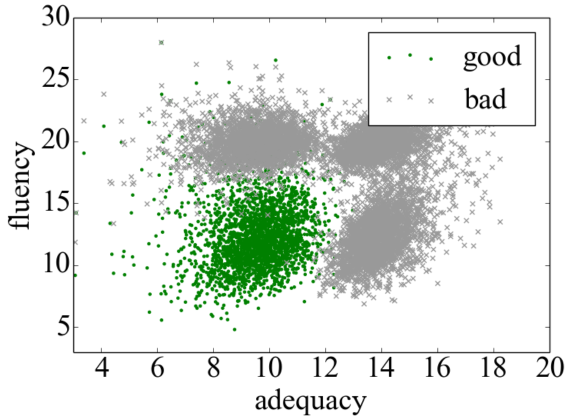

Figure 1: newstest09 fr-en data in the feature space

We plot the newstest09 data (original and auto-generated noisy ones as described in Section 3.2) into the proposed feature space in Figure 1. We observe that the clusters are quite separable, though the decision function would not be linear. We map the features into higher order forms of (x^n, y^n) in order for logistic regression to train a non-linear decision boundary.[2] We use $n = 8$ in this work since it gives the best classification performance on the newstest09 fr-en corpus.

4 Hyper-parameter Tuning

We conduct experiments to determine the value of the constant c in the smoothed cross-entropy computation in equation 1. We choose the newstest09 German-English corpus, and shuffle the sentences in the English file and combine the original (clean) corpus with the shuffled (noisy) corpus into a larger corpus, where half of them are good sentence pairs. We set different values of c and use the adequacy scores to pick the better half, and compute the retrieval accuracy. Table 1 shows that the best value for c is 0.0001, and we use that in all experiments.

c	accuracy
0.001	0.975
0.0001	**0.984**
0.00001	0.983
0.000001	0.981

Table 1: Tuning cross-entropy constant c

5 Evaluation

We evaluate Zipporah on 3 language pairs, French-English, German-English and Spanish-English. The noisy web-crawled data comes from an early version of `http://statmt.org/paracrawl`. The number of words are (in millions) 340, 487 and 70 respectively.

To generate the dictionaries for computing the adequacy scores, we use fast_align (Dyer et al., 2013) to align the Europarl (Koehn, 2005) corpus and generate probabilistic dictionaries from the alignments. We set the n-gram order to be 5 and use SRILM (Stolcke et al., 2011) to train language models on the Europarl corpus and generate the n-gram scores.

For each language pair, we use scikit-learn (Pedregosa et al., 2011) to train a logistic regression model to classify between the original and the synthetic noisy corpus of newstest09, and the trained model is used to score all sentence pairs in the data pool. We keep selecting the best ones until the desired number of words is reached.

To evaluate the quality, we train a Moses (Koehn et al., 2007) SMT system on selected data, and evaluate each trained SMT system on 3 test corpora: newstest2011 which contains 3003 sentence pairs, and a random subset of the TED-talks corpus and the movie-subtitle corpus from OPUS (Tiedemann, 2012), each of which contains 3000 sentence pairs.

Tables 2, 3 and 4 show the BLEU performance of the selected subsets of the Zipporah system compared to the baseline, which selects sentence pairs at random; for comparison, we also give the BLEU performance of systems trained on Europarl. The Zipporah system gives consistently better performance across multiple datasets and multiple languages than the baseline.[3]

[2] We avoid using multiple mappings of one feature because we want the scoring function to be monotonic both w.r.t x and y, which could break if we allow multiple higher-order mappings of the same feature and they end up with weights with different signs.

[3] We also point out that the performance of the selected

Europarl	25.4		28.4		19.8	

Table 4: BLEU Performance, Spanish-English

In particular, for the Germen-English corpus, when selecting less than 2% of the data (10 million words), on the TED-talk dataset, Zipporah achieves a 5.5 BLEU score improvement over the baseline; by selecting less than 4% of the data (20 million words) the system gives better performance than using all data. Peak performance is achieved when selecting 100 million words, where an improvement of 2.1 BLEU score over all data is achieved on the movie-subtitle dataset, despite only using less than 1/5 of the data.

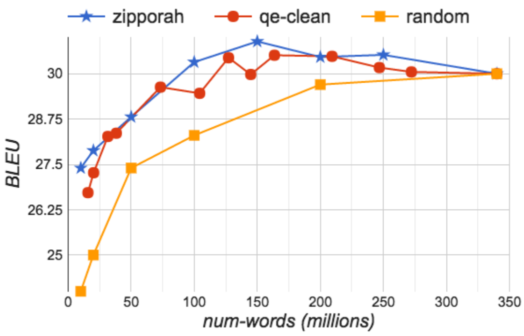

Figure 2: BLEU performance of Zipporah, qe-clean and random on TED-talks, French-English

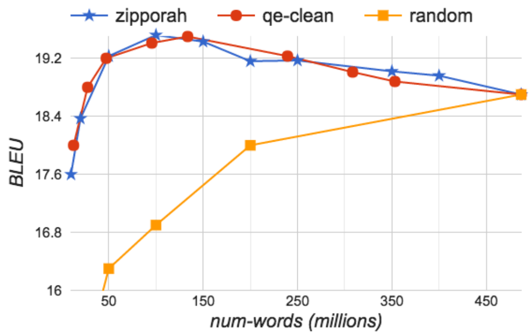

Figure 3: BLEU performance of Zipporah, qe-clean and random on newstest11, German-English

Figures 2, 3 and 4 compare the result of Zipporah with that of qe-clean (Denkowski et al., 2012; Dyer et al., 2010; Heafield, 2011) and the random baseline. We use the same data when running qe-clean, with Europarl for training and newstest09 for dev. While they both perform comparably and better than the baseline, Zipporah achieves a better peak in all the datasets, and the peak is usually achieved when selecting a smaller number of words compared to qe-clean, Another advantage of Zipporah is it allows the user to select an arbi-

subsets of the Zipporah system can surpass that of Europarl, although the Europarl corpus acts like an "oracle" in the system, upon which the dictionaries and language models for feature computations are trained.

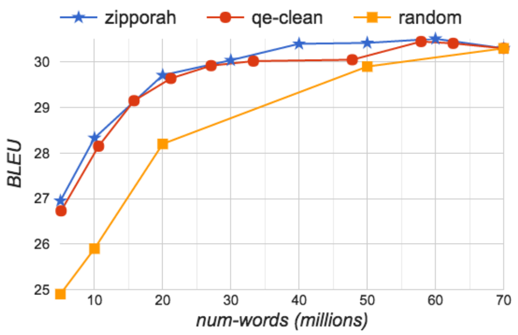

Figure 4: BLEU performance of Zipporah, qe-clean and random on TED-talks, Spanish-English

trary size from the pool.[4] We also want to emphasize that unlike qe-clean, which requires running word-alignments for all sentence pairs in the noisy corpus, Zipporah's feature computation is simple, fast and can easily be scaled for huge datasets.

6 Conclusion and Future Work

In this paper we introduced Zipporah, a fast data selection system for noisy parallel corpora. SMT results demonstrate that Zipporah can select a high-quality subset of the data and significantly improve SMT performance.

Zipporah currently selects sentences based on the "individual quality" only, and we plan in future work to also consider other factors, e.g. encourage selection of a subset that has a better n-gram coverage.

Bringing Structure into Summaries:
Crowdsourcing a Benchmark Corpus of Concept Maps

Tobias Falke and **Iryna Gurevych**
Research Training Group AIPHES and UKP Lab
Department of Computer Science, Technische Universität Darmstadt
https://www.aiphes.tu-darmstadt.de

Abstract

Concept maps can be used to concisely represent important information and bring structure into large document collections. Therefore, we study a variant of multi-document summarization that produces summaries in the form of concept maps. However, suitable evaluation datasets for this task are currently missing. To close this gap, we present a newly created corpus of concept maps that summarize heterogeneous collections of web documents on educational topics. It was created using a novel crowdsourcing approach that allows us to efficiently determine important elements in large document collections. We release the corpus along with a baseline system and proposed evaluation protocol to enable further research on this variant of summarization.[1]

1 Introduction

Multi-document summarization (MDS), the transformation of a set of documents into a short text containing their most important aspects, is a long-studied problem in NLP. Generated summaries have been shown to support humans dealing with large document collections in information seeking tasks (McKeown et al., 2005; Maña-López et al., 2004; Roussinov and Chen, 2001). However, when exploring a set of documents manually, humans rarely write a fully-formulated summary for themselves. Instead, user studies (Chin et al., 2009; Kang et al., 2011) show that they note down important keywords and phrases, try to identify relationships between them and organize them accordingly. Therefore, we believe that the study of summarization with similarly structured outputs is an important extension of the traditional task.

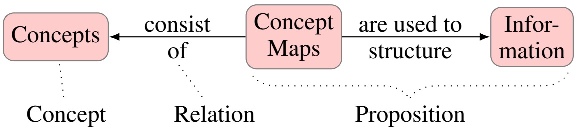

Figure 1: Elements of a concept map.

A representation that is more in line with observed user behavior is a *concept map* (Novak and Gowin, 1984), a labeled graph showing concepts as nodes and relationships between them as edges (Figure 1). Introduced in 1972 as a teaching tool (Novak and Cañas, 2007), concept maps have found many applications in education (Edwards and Fraser, 1983; Roy, 2008), for writing assistance (Villalon, 2012) or to structure information repositories (Briggs et al., 2004; Richardson and Fox, 2005). For summarization, concept maps make it possible to represent a summary concisely and clearly reveal relationships. Moreover, we see a second interesting use case that goes beyond the capabilities of textual summaries: When concepts and relations are linked to corresponding locations in the documents they have been extracted from, the graph can be used to navigate in a document collection, similar to a table of contents. An implementation of this idea has been recently described by Falke and Gurevych (2017).

The corresponding task that we propose is *concept-map-based MDS*, the summarization of a document cluster in the form of a concept map. In order to develop and evaluate methods for the task, gold-standard corpora are necessary, but no suitable corpus is available. The manual creation of such a dataset is very time-consuming, as the annotation includes many subtasks. In particular, an annotator would need to manually identify all concepts in the documents, while only a few of them will eventually end up in the summary.

Copenhagen, Denmark, September 7–11, 2017.

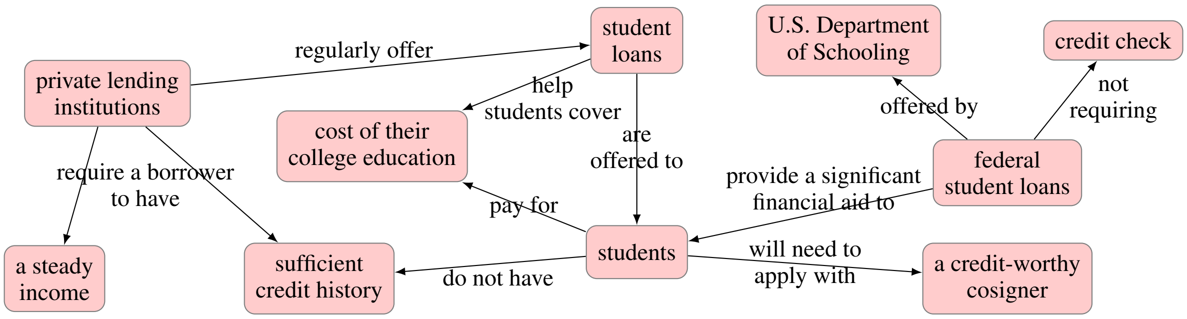

Figure 2: Excerpt from a summary concept map on the topic "*students loans without credit history*".

To overcome these issues, we present a corpus creation method that effectively combines automatic preprocessing, scalable crowdsourcing and high-quality expert annotations. Using it, we can avoid the high effort for single annotators, allowing us to scale to document clusters that are 15 times larger than in traditional summarization corpora. We created a new corpus of 30 topics, each with around 40 source documents on educational topics and a summarizing concept map that is the consensus of many crowdworkers (see Figure 2).

As a crucial step of the corpus creation, we developed a new crowdsourcing scheme called *low-context importance annotation*. In contrast to traditional approaches, it allows us to determine important elements in a document cluster without requiring annotators to read all documents, making it feasible to crowdsource the task and overcome quality issues observed in previous work (Lloret et al., 2013). We show that the approach creates reliable data for our focused summarization scenario and, when tested on traditional summarization corpora, creates annotations that are similar to those obtained by earlier efforts.

To summarize, we make the following contributions: (1) We propose a novel task, concept-map-based MDS (§2), (2) present a new crowdsourcing scheme to create reference summaries (§4), (3) publish a new dataset for the proposed task (§5) and (4) provide an evaluation protocol and baseline (§7). We make these resources publicly available under a permissive license.

2 Task

Concept-map-based MDS is defined as follows: *Given a set of related documents, create a concept map that represents its most important content, satisfies a specified size limit and is connected.*

We define a concept map as a labeled graph showing concepts as nodes and relationships between them as edges. Labels are arbitrary sequences of tokens taken from the documents, making the summarization task extractive. A concept can be an entity, abstract idea, event or activity, designated by its unique label. Good maps should be propositionally coherent, meaning that every relation together with the two connected concepts form a meaningful proposition.

The task is complex, consisting of several interdependent subtasks. One has to extract appropriate labels for concepts and relations and recognize different expressions that refer to the same concept across multiple documents. Further, one has to select the most important concepts and relations for the summary and finally organize them in a graph satisfying the connectedness and size constraints.

3 Related Work

Some attempts have been made to automatically construct concept maps from text, working with either single documents (Zubrinic et al., 2015; Villalon, 2012; Valerio and Leake, 2006; Kowata et al., 2010) or document clusters (Qasim et al., 2013; Zouaq and Nkambou, 2009; Rajaraman and Tan, 2002). These approaches extract concept and relation labels from syntactic structures and connect them to build a concept map. However, common task definitions and comparable evaluations are missing. In addition, only a few of them, namely Villalon (2012) and Valerio and Leake (2006), define summarization as their goal and try to compress the input to a substantially smaller size. Our newly proposed task and the created large-cluster dataset fill these gaps as they emphasize the summarization aspect of the task.

For the subtask of selecting summary-worthy concepts and relations, techniques developed for traditional summarization (Nenkova and McKeown, 2011) and keyphrase extraction (Hasan and Ng, 2014) are related and applicable. Approaches

Imagine you want to learn something about **students loans without credit history**.
How useful would the following statements be for you?

(P1) students with bad credit history - apply for - federal loans with the FAFSA
□ Extremely Important □ Very Important □ Moderately Important □ Slightly Important □ Not at all Important

(P2) students - encounter - unforeseen financial emergencies
□ Extremely Important □ Very Important □ Moderately Important □ Slightly Important □ Not at all Important

Figure 3: Likert-scale crowdsourcing task with topic description and two example propositions.

that build graphs of propositions to create a summary (Fang et al., 2016; Li et al., 2016; Liu et al., 2015; Li, 2015) seem to be particularly related, however, there is one important difference: While they use graphs as an intermediate representation from which a textual summary is then generated, the goal of the proposed task is to create a graph that is directly interpretable and useful for a user. In contrast, these intermediate graphs, e.g. AMR, are hardly useful for a typical, non-linguist user.

For traditional summarization, the most well-known datasets emerged out of the DUC and TAC competitions.[2] They provide clusters of news articles with gold-standard summaries. Extending these efforts, several more specialized corpora have been created: With regard to size, Nakano et al. (2010) present a corpus of summaries for large-scale collections of web pages. Recently, corpora with more heterogeneous documents have been suggested, e.g. (Zopf et al., 2016) and (Benikova et al., 2016). The corpus we present combines these aspects, as it has large clusters of heterogeneous documents, and provides a necessary benchmark to evaluate the proposed task.

For concept map generation, one corpus with human-created summary concept maps for student essays has been created (Villalon et al., 2010). In contrast to our corpus, it only deals with single documents, requires a two orders of magnitude smaller amount of compression of the input and is not publicly available .

Other types of information representation that also model concepts and their relationships are knowledge bases, such as Freebase (Bollacker et al., 2009), and ontologies. However, they both differ in important aspects: Whereas concept maps follow an open label paradigm and are meant to be interpretable by humans, knowledge bases and ontologies are usually more strictly typed and made to be machine-readable. Moreover, approaches to automatically construct them from text typically try to extract as much information as possible, while we want to summarize a document.

4 Low-Context Importance Annotation

Lloret et al. (2013) describe several experiments to crowdsource reference summaries. Workers are asked to read 10 documents and then select 10 summary sentences from them for a reward of $0.05. They discovered several challenges, including poor work quality and the subjectiveness of the annotation task, indicating that crowdsourcing is not useful for this purpose.

To overcome these issues, we introduce a new task design, *low-context importance annotation*, to determine summary-worthy parts of documents. Compared to Lloret et al.'s approach, it is more in line with crowdsourcing best practices, as the tasks are simple, intuitive and small (Sabou et al., 2014) and workers receive reasonable payment (Fort et al., 2011). Most importantly, it is also much more efficient and scalable, as it does not require workers to read all documents in a cluster.

4.1 Task Design

We break down the task of importance annotation to the level of single propositions. The goal of our crowdsourcing scheme is to obtain a score for each proposition indicating its importance in a document cluster, such that a ranking according to the score would reveal what is most important and should be included in a summary. In contrast to other work, we do not show the documents to the workers at all, but provide only a description of the document cluster's topic along with the propositions. This ensures that tasks are small, simple and can be done quickly (see Figure 3).

In preliminary tests, we found that this design, despite the minimal context, works reasonably on our focused clusters on common educational topics. For instance, consider Figure 3: One can easily say that P1 is more important than P2 without reading the documents.

[2] duc.nist.gov, tac.nist.gov

We distinguish two task variants:

Likert-scale Tasks Instead of enforcing binary importance decisions, we use a 5-point Likert-scale to allow more fine-grained annotations. The obtained labels are translated into scores (5..1) and the average of all scores for a proposition is used as an estimate for its importance. This follows the idea that while single workers might find the task subjective, the consensus of multiple workers, represented in the average score, tends to be less subjective due to the "wisdom of the crowd". We randomly group five propositions into a task.

Comparison Tasks As an alternative, we use a second task design based on pairwise comparisons. Comparisons are known to be easier to make and more consistent (Belz and Kow, 2010), but also more expensive, as the number of pairs grows quadratically with the number of objects.[3] To reduce the cost, we group five propositions into a task and ask workers to order them by importance per drag-and-drop. From the results, we derive pairwise comparisons and use TrueSkill (Herbrich et al., 2007), a powerful Bayesian rank induction model (Zhang et al., 2016), to obtain importance estimates for each proposition.

4.2 Pilot Study

To verify the proposed approach, we conducted a pilot study on Amazon Mechanical Turk using data from TAC2008 (Dang and Owczarzak, 2008). We collected importance estimates for 474 propositions extracted from the first three clusters[4] using both task designs. Each Likert-scale task was assigned to 5 different workers and awarded $0.06. For comparison tasks, we also collected 5 labels each, paid $0.05 and sampled around 7% of all possible pairs. We submitted them in batches of 100 pairs and selected pairs for subsequent batches based on the confidence of the TrueSkill model.

Quality Control Following the observations of Lloret et al. (2013), we established several measures for quality control. First, we restricted our tasks to workers from the US with an approval rate of at least 95%. Second, we identified low quality workers by measuring the correlation of each worker's Likert-scores with the average of the other four scores. The worst workers (at most 5% of all labels) were removed.

Peer Scoring	Pearson	Spearman
Modified Pyramid	0.4587	0.4676
ROUGE-2	0.3062	0.3486
Crowd-Likert	0.4589	0.4196
Crowd-Comparison	0.4564	0.3761

Table 1: Correlation of peer scores with manual responsiveness scores on TAC2008 topics 01-03.

In addition, we included trap sentences, similar as in (Lloret et al., 2013), in around 80 of the tasks. In contrast to Lloret et al.'s findings, both an obvious trap sentence (*This sentence is not important*) and a less obvious but unimportant one (*Barack Obama graduated from Harvard Law*) were consistently labeled as unimportant (1.08 and 1.14), indicating that the workers did the task properly.

Agreement and Reliability For Likert-scale tasks, we follow Snow et al. (2008) and calculate agreement as the average Pearson correlation of a worker's Likert-score with the average score of the remaining workers.[5] This measure is less strict than exact label agreement and can account for close labels and high- or low-scoring workers. We observe a correlation of 0.81, indicating substantial agreement. For comparisons, the majority agreement is 0.73. To further examine the reliability of the collected data, we followed the approach of Kiritchenko and Mohammed (2016) and simply repeated the crowdsourcing for one of the three topics. Between the importance estimates calculated from the first and second run, we found a Pearson correlation of 0.82 (Spearman 0.78) for Likert-scale tasks and 0.69 (Spearman 0.66) for comparison tasks. This shows that the approach, despite the subjectiveness of the task, allows us to collect reliable annotations.

Peer Evaluation In addition to the reliability studies, we extrinsically evaluated the annotations in the task of summary evaluation. For each of the 58 peer summaries in TAC2008, we calculated a score as the sum of the importance estimates of the propositions it contains. Table 1 shows how these peer scores, averaged over the three topics, correlate with the manual responsiveness scores assigned during TAC in comparison

[3] Even with intelligent sampling strategies, such as the active learning in CrowdBT (Chen et al., 2013), the number of pairs is only reduced by a constant factor (Zhang et al., 2016).

[4] D0801A-A, D0802A-A, D0803A-A

[5] As workers are not consistent across all items, we create five meta-workers by sorting the labels per proposition.

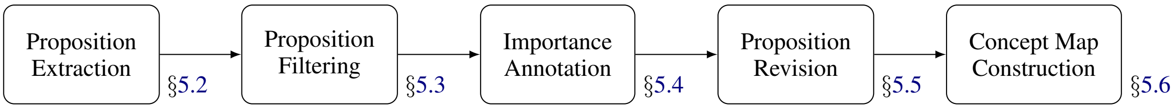

Figure 4: Steps of the corpus creation (with references to the corresponding sections).

to ROUGE-2 and Pyramid scores.[6] The results demonstrate that with both task designs, we obtain importance annotations that are similarly useful for summary evaluation as pyramid annotations or gold-standard summaries (used for ROUGE).

Conclusion Based on the pilot study, we conclude that the proposed crowdsourcing scheme allows us to obtain proper importance annotations for propositions. As workers are not required to read all documents, the annotation is much more efficient and scalable as with traditional methods.

5 Corpus Creation

This section presents the corpus construction process, as outlined in Figure 4, combining automatic preprocessing, scalable crowdsourcing and high-quality expert annotations to be able to scale to the size of our document clusters. For every topic, we spent about $150 on crowdsourcing and 1.5h of expert annotations, while just a single annotator would already need over 8 hours (at 200 words per minute) to read all documents of a topic.

5.1 Source Data

As a starting point, we used the DIP corpus (Habernal et al., 2016), a collection of 49 clusters of 100 web pages on educational topics (e.g. bullying, homeschooling, drugs) with a short description of each topic. It was created from a large web crawl using state-of-the-art information retrieval. We selected 30 of the topics for which we created the necessary concept map annotations.

5.2 Proposition Extraction

As concept maps consist of propositions expressing the relation between concepts (see Figure 1), we need to impose such a structure upon the plain text in the document clusters. This could be done by manually annotating spans representing concepts and relations, however, the size of our clusters makes this a huge effort: 2288 sentences per topic (69k in total) need to be processed. Therefore, we resort to an automatic approach.

The Open Information Extraction paradigm (Banko et al., 2007) offers a representation very similar to the desired one. For instance, from

Students with bad credit history should not lose hope and apply for federal loans with the FAFSA.

Open IE systems extract tuples of two arguments and a relation phrase representing propositions:

(s. with bad credit history, should not lose, hope)
(s. with bad credit history, apply for, federal loans with the FAFSA)

While the relation phrase is similar to a relation in a concept map, many arguments in these tuples represent useful concepts. We used Open IE 4[7], a state-of-the-art system (Stanovsky and Dagan, 2016) to process all sentences. After removing duplicates, we obtained 4137 tuples per topic.

Since we want to create a gold-standard corpus, we have to ensure that we produce high-quality data. We therefore made use of the confidence assigned to every extracted tuple to filter out low quality ones. To ensure that we do not filter too aggressively (and miss important aspects in the final summary), we manually annotated 500 tuples sampled from all topics for correctness. On the first 250 of them, we tuned the filter threshold to 0.5, which keeps 98.7% of the correct extractions in the unseen second half. After filtering, a topic had on average 2850 propositions (85k in total).

5.3 Proposition Filtering

Despite the similarity of the Open IE paradigm, not every extracted tuple is a suitable proposition for a concept map. To reduce the effort in the subsequent steps, we therefore want to filter out unsuitable ones. A tuple is suitable if it (1) is a correct extraction, (2) is meaningful without any context and (3) has arguments that represent proper concepts. We created a guideline explaining when to label a tuple as suitable for a concept map and performed a small annotation study. Three annotators independently labeled 500 randomly sam-

[6] Correlations for ROUGE and Pyramid are lower than reported in TAC since we only use 3 topics instead of all 48.

[7] `https://github.com/knowitall/openie`

pled tuples. The agreement was 82% ($\kappa = 0.60$). We found tuples to be unsuitable mostly because they had unresolvable pronouns, conflicting with (2), or arguments that were full clauses or propositions, conflicting with (3), while (1) was mostly taken care of by the confidence filtering in §5.2.

Due to the high number of tuples we decided to automate the filtering step. We trained a linear SVM on the majority voted annotations. As features, we used the extraction confidence, length of arguments and relations as well as part-of-speech tags, among others. To ensure that the automatic classification does not remove suitable propositions, we tuned the classifier to avoid false negatives. In particular, we introduced class weights, improving precision on the negative class at the cost of a higher fraction of positive classifications. Additionally, we manually verified a certain number of the most uncertain negative classifications to further improve performance. When 20% of the classifications are manually verified and corrected, we found that our model trained on 350 labeled instances achieves 93% precision on negative classifications on the unseen 150 instances. We found this to be a reasonable trade-off of automation and data quality and applied the model to the full dataset.

The classifier filtered out 43% of the propositions, leaving 1622 per topic. We manually examined the 17k least confident negative classifications and corrected 955 of them. We also corrected positive classifications for certain types of tuples for which we knew the classifier to be imprecise. Finally, each topic was left with an average of 1554 propositions (47k in total).

5.4 Importance Annotation

Given the propositions identified in the previous step, we now applied our crowdsourcing scheme as described in §4 to determine their importance. To cope with the large number of propositions, we combine the two task designs: First, we collect Likert-scores from 5 workers for each proposition, clean the data and calculate average scores. Then, using only the top 100 propositions[8] according to these scores, we crowdsource 10% of all possible pairwise comparisons among them. Using TrueSkill, we obtain a fine-grained ranking of the 100 most important propositions.

For Likert-scores, the average agreement over all topics is 0.80, while the majority agreement for comparisons is 0.78. We repeated the data collection for three randomly selected topics and found the Pearson correlation between both runs to be 0.73 (Spearman 0.73) for Likert-scores and 0.72 (Spearman 0.71) for comparisons. These figures show that the crowdsourcing approach works on this dataset as reliably as on the TAC documents.

In total, we uploaded 53k scoring and 12k comparison tasks to Mechanical Turk, spending \$4425.45 including fees. From the fine-grained ranking of the 100 most important propositions, we select the top 50 per topic to construct a summary concept map in the subsequent steps.

5.5 Proposition Revision

Having a manageable number of propositions, an annotator then applied a few straightforward transformations that correct common errors of the Open IE system. First, we break down propositions with conjunctions in either of the arguments into separate propositions per conjunct, which the Open IE system sometimes fails to do. And second, we correct span errors that might occur in the argument or relation phrases, especially when sentences were not properly segmented. As a result, we have a set of high quality propositions for our concept map, consisting of, due to the first transformation, 56.1 propositions per topic on average.

5.6 Concept Map Construction

In this final step, we connect the set of important propositions to form a graph. For instance, given the following two propositions

(student, may borrow, Stafford Loan)
(the student, does not have, a credit history)

one can easily see, although the first arguments differ slightly, that both labels describe the concept *student*, allowing us to build a concept map with the concepts *student*, *Stafford Loan* and *credit history*. The annotation task thus involves deciding which of the available propositions to include in the map, which of their concepts to merge and, when merging, which of the available labels to use. As these decisions highly depend upon each other and require context, we decided to use expert annotators rather than crowdsource the subtasks.

Annotators were given the topic description and the most important, ranked propositions. Using

[8] We also add all propositions with the same score as the 100th, yielding 112 propositions on average.

Corpus	Cluster	Cluster Size	Docs	Doc. Size	Rel. Std.
This work	30	97,880 ± 50,086.2	40.5 ± 6.8	2,412.8 ± 3,764.1	1.56
DUC 2006	50	17,461 ± 6,627.8	25.0 ± 0.0	729.2 ± 542.3	0.74
DUC 2004	50	6,721 ± 3,017.9	10.0 ± 0.0	672.1 ± 506.3	0.75
TAC 2008A	48	5,892 ± 2,832.4	10.0 ± 0.0	589.2 ± 480.3	0.82

Table 2: Topic clusters in comparison to classic corpora (size in token, mean with standard deviation).

a simple annotation tool providing a visualization of the graph, they could connect the propositions step by step. They were instructed to reach a size of 25 concepts, the recommended maximum size for a concept map (Novak and Cañas, 2007). Further, they should prefer more important propositions and ensure connectedness. When connecting two propositions, they were asked to keep the concept label that was appropriate for both propositions. To support the annotators, the tool used ADW (Pilehvar et al., 2013), a state-of-the-art approach for semantic similarity, to suggest possible connections. The annotation was carried out by graduate students with a background in NLP after receiving an introduction into the guidelines and tool and annotating a first example.

If an annotator was not able to connect 25 concepts, she was allowed to create up to three synthetic relations with freely defined labels, making the maps slightly abstractive. On average, the constructed maps have 0.77 synthetic relations, mostly connecting concepts whose relation is too obvious to be explicitly stated in text (e.g. between *Montessori teacher* and *Montessori education*).

To assess the reliability of this annotation step, we had the first three maps created by two annotators. We casted the task of selecting propositions to be included in the map as a binary decision task and observed an agreement of 84% ($\kappa = 0.66$). Second, we modeled the decision which concepts to join as a binary decision on all pairs of common concepts, observing an agreement of 95% ($\kappa = 0.70$). And finally, we compared which concept labels the annotators decided to include in the final map, observing 85% ($\kappa = 0.69$) agreement. Hence, the annotation shows substantial agreement (Landis and Koch, 1977).

6 Corpus Analysis

In this section, we describe our newly created corpus, which, in addition to having summaries in the form of concept maps, differs from traditional summarization corpora in several aspects.

6.1 Document Clusters

Size The corpus consists of document clusters for 30 different topics. Each of them contains around 40 documents with on average 2413 tokens, which leads to an average cluster size of 97,880 token. With these characteristics, the document clusters are 15 times larger than typical DUC clusters of ten documents and five times larger than the 25-document-clusters (Table 2). In addition, the documents are also more variable in terms of length, as the (length-adjusted) standard deviation is twice as high as in the other corpora. With these properties, the corpus represents an interesting challenge towards real-world application scenarios, in which users typically have to deal with much more than ten documents.

Genres Because we used a large web crawl as the source for our corpus, it contains documents from a variety of genres. To further analyze this property, we categorized a sample of 50 documents from the corpus. Among them, we found professionally written articles and blog posts (28%), educational material for parents and kids (26%), personal blog posts (16%), forum discussions and comments (12%), commented link collections (12%) and scientific articles (6%).

Textual Heterogeneity In addition to the variety of genres, the documents also differ in terms of language use. To capture this property, we follow Zopf et al. (2016) and compute, for every topic, the average Jensen-Shannon divergence between the word distribution of one document and the word distribution in the remaining documents. The higher this value is, the more the language differs between documents. We found the average divergence over all topics to be 0.3490, whereas it is 0.3019 in DUC 2004 and 0.3188 in TAC 2008A.

6.2 Concept Maps

As Table 3 shows, each of the 30 reference concept maps has exactly 25 concepts and between 24 and 28 relations. Labels for both concepts and

	per Map	Token	Character
Concepts	25.0 ± 0.0	3.2 ± 0.5	22.0 ± 4.1
Relations	25.2 ± 1.3	3.2 ± 0.5	17.1 ± 2.6

Table 3: Size of concept maps (mean with std).

relations consist on average of 3.2 tokens, whereas the latter are a bit shorter in characters.

To obtain a better picture of what kind of text spans have been used as labels, we automatically tagged them with their part-of-speech and determined their head with a dependency parser. Concept labels tend to be headed by nouns (82%) or verbs (15%), while they also contain adjectives, prepositions and determiners. Relation labels, on the other hand, are almost always headed by a verb (94%) and contain prepositions, nouns and particles in addition. These distributions are very similar to those reported by Villalon et al. (2010) for their (single-document) concept map corpus.

Analyzing the graph structure of the maps, we found that all of them are connected. They have on average 7.2 central concepts with more than one relation, while the remaining ones occur in only one proposition. We found that achieving a higher number of connections would mean compromising importance, i.e. including less important propositions, and decided against it.

7 Baseline Experiments

In this section, we briefly describe a baseline and evaluation scripts that we release, with a detailed documentation, along with the corpus.

Baseline Method We implemented a simple approach inspired by previous work on concept map generation and keyphrase extraction. For a document cluster, it performs the following steps:

1. Extract all NPs as potential concepts.
2. Merge potential concepts whose labels match after stemming into a single concept.
3. For each pair of concepts co-occurring in a sentence, select the tokens in between as a potential relation if they contain a verb.
4. If a pair of concepts has more than one relation, select the one with the shortest label.
5. Assign an importance score to every concept and rank them accordingly.
6. Find a connected graph of 25 concepts with high scores among all extracted concepts and relations.

Metric	Pr	Re	F1
Strict Match	.0006	.0026	.0010
METEOR	.1512	.1949	.1700
ROUGE-2	.0603	.1798	.0891

Table 4: Baseline performance on test set.

For (5), we trained a binary classifier to identify the important concepts in the set of all potential concepts. We used common features for keyphrase extraction, including position, frequency and length, and Weka's Random Forest (Hall et al., 2009) implementation as the model. At inference time, we use the classifiers confidence for a positive classification as the score.

In step (6), we start with the full graph of all extracted concepts and relations and use a heuristic to find a subgraph that is connected, satisfies the size limit of 25 concepts and has many high-scoring concepts: We iteratively remove the weakest concept until only one connected component of 25 concepts or less remains, which is used the summary concept map. This approach guarantees that the concept map is connected, but might not find the subset of concepts that has the highest total importance score.

Evaluation Metrics In order to automatically compare generated concept maps with reference maps, we propose three metrics.[9] As a concept map is fully defined by the set of its propositions, we can compute precision, recall and F1-scores between the two proposition set of generated and reference map. A proposition is represented as the concatenation of concept and relation labels. *Strict Match* compares them after stemming and only counts exact and complete matches. Using *METEOR* (Denkowski and Lavie, 2014), we offer a second metric that takes synonyms and paraphrases into account and also scores partial matches. And finally, we compute *ROUGE-2* (Lin, 2004) between the concatenation of all propositions from the maps. These automatic measures might be complemented with a human evaluation.

Results Table 4 shows the performance of the baseline. An analysis of the single pipeline steps

[9] For precise definitions of the metrics, please refer to the published scripts and accompanying documentation.

revealed major bottlenecks of the method and challenges of the task. First, we observed that around 76% of gold concepts are covered by the extraction (step 1+2), while the top 25 concepts (step 5) only contain 17% of the gold concepts. Hence, content selection is a major challenge, stemming from the large cluster sizes in the corpus. Second, while also 17% of gold concepts are contained in the final maps (step 6), scores for strict proposition matching are low, indicating a poor performance of the relation extraction (step 3). The propagation of these errors along the pipeline contributes to overall low scores.

8 Conclusion

In this work, we presented low-context importance annotation, a novel crowdsourcing scheme that we used to create a new benchmark corpus for concept-map-based MDS. The corpus has large-scale document clusters of heterogeneous web documents, posing a challenging summarization task. Together with the corpus, we provide implementations of a baseline method and evaluation scripts and hope that our efforts facilitate future research on this variant of summarization.

Acknowledgments

We would like to thank Teresa Botschen, Andreas Hanselowski and Markus Zopf for their help with the annotation work and Christian Meyer for his valuable feedback. This work has been supported by the German Research Foundation as part of the Research Training Group "Adaptive Preparation of Information from Heterogeneous Sources" (AIPHES) under grant No. GRK 1994/1.

Natural Language Does Not Emerge ‘Naturally’ in Multi-Agent Dialog

Abstract

A number of recent works have proposed techniques for end-to-end learning of communication protocols among cooperative multi-agent populations, and have simultaneously found the *emergence of grounded human-interpretable language* in the protocols developed by the agents, learned without any human supervision!

In this paper, using a *Task & Talk* reference game between two agents as a testbed, we present a sequence of ‘negative’ results culminating in a ‘positive’ one – showing that while most agent-invented languages are effective (*i.e.* achieve near-perfect task rewards), they are decidedly *not* interpretable or compositional. In essence, we find that natural language does not emerge ‘naturally’, despite the semblance of ease of natural-language-emergence that one may gather from recent literature. We discuss how it is possible to coax the invented languages to become more and more human-like and compositional by increasing restrictions on how two agents may communicate.

1 Introduction

One fundamental goal of artificial intelligence (AI) is the development of goal-driven dialog agents – specifically, agents that can perceive their environment (through vision, audition, or other sensors), and communicate with humans or other agents in natural language towards a goal.

While historically such agents have been based on *slot filling* (Lemon et al., 2006), the dominant paradigm today is neural dialog models (Bordes and Weston, 2016; Weston, 2016; Serban et al., 2016a,b) trained on large quantities of data. Perhaps somewhat counterintuitively, this current paradigm treats dialog as a static supervised learning problem, rather than as the interactive agent learning problem that it naturally is. Specifically, a typical pipeline is to collect a large dataset of human-human dialog (Lowe et al., 2015; Das et al., 2017a; de Vries et al., 2017; Mostafazadeh et al., 2017), inject a machine in the middle of a dialog from the dataset, and supervise it to mimic the human response. While this teaches the agent correlations between symbols, it does not convey the functional meaning of language, grounding (mapping physical concepts to words), compositionality (combining knowledge of simpler concepts to describe richer concepts), or aspects of planning (why are we having this conversation?).

An alternative paradigm that has a long history (Winograd, 1971; Kirby et al., 2014) and is witnessing a recent resurgence (Wang et al., 2016; Foerster et al., 2016; Sukhbaatar et al., 2016; Jorge et al., 2016; Lazaridou et al., 2017; Havrylov and Titov, 2017; Mordatch and Abbeel, 2017; Das et al., 2017b) – is situated language learning. A number of recent works have proposed reinforcement learning techniques for learning the communication protocols of agents situated in virtual environments in a completely end-to-end manner – from perceptual input (*e.g.* pixels) to communication (discrete symbols without any prespecified meanings) to action (*e.g.* signaling in reference games or navigating in an environment) – and have simultaneously found the *emergence of grounded human-interpretable (often compositional) language* among agents, without any human supervision or pretraining, simply to succeed at the task.

In this short paper, we study the following question – what are the conditions that lead to the emergence of human-interpretable or compositional grounded language? Our key finding is that

(a) World. (b) Q-BOT (left) and A-BOT (right) policy networks. (c) Task Encoding. (d) Prediction.

Figure 1: *Task & Talk*: The testbed for our study is cooperative 2-player game, *Task & Talk*, grounded in a synthetic world of objects with 4 *shapes* × 4 *colors* × 4 *styles*. The two agents, Q-BOT and A-BOT, are modeled as neural networks, and their policies are learned via REINFORCE. We find that the languages invented by the two agents are typically *not* 'natural'.

natural language *does not emerge 'naturally'* in multi-agent dialog, despite independently reported successful demonstrations in recent literature.

Specifically, in a sequence of 'negative' results culminating in a 'positive' one, we find that while agents always successfully invent communication protocols and languages to achieve their goals with near-perfect accuracies, the invented languages are decidedly *not* compositional, interpretable, or 'natural'; and that it is possible to coax the invented languages to become more and more human-like and compositional by increasing restrictions on how two agents may communicate.

Related work and novelty. The starting point for our investigation is the recent work of Das et al. (2017b), who proposed a cooperative reference game between two agents, where communication is necessary to accomplish the goal due to an information asymmetry. Our key contribution over Das et al. (2017b) is an exhaustive study of the conditions that must be present before compositional grounded language emerges, and subtle but important differences in execution – tabular Q-Learning (which does not scale) *vs.* REINFORCE (which does), and generalization to novel environments (not studied in prior work). In the spirit of Abbeel et al. (2017), we hope our findings shed more light into the interpretability of languages invented in cooperative multi-agent settings, place recent work in appropriate context, and inform fruitful directions for future work.

2 The *Task & Talk* Game

Our testbed is a reference game (*Task & Talk*) between two agents, Q-BOT and A-BOT. The game is grounded in a synthetic world of objects comprised of three attributes – *color*, *style*, and *shape* – each with four possible values for a total of $4 \times 4 \times 4 = 64$ objects. Fig. 1a shows some example instances from this set.

Task & Talk plays out over multiple rounds of dialog. At the start, A-BOT is given an instance (*e.g. (green, dotted, square)*) unseen by Q-BOT, and Q-BOT is assigned a task G (unknown to A-BOT) consisting of two attributes for Q-BOT to discover from A-BOT (*e.g. (color, style)*). For two rounds, Q-BOT and A-BOT exchange utterances from finite vocabularies V_Q and V_A, with Q-BOT speaking first. The game culminates in Q-BOT guessing a pair of attribute values (*e.g. (green, dotted)*) and both agents are rewarded identically based on the accuracy of this prediction.

Note that the Task & Talk game setting involves an informational asymmetry between the agents – A-BOT sees the object while Q-BOT does not; similarly Q-BOT knows the task while A-BOT does not. Thus, a two-way communication is necessary for success. Without this asymmetry, A-BOT could simply convey the target attributes from the task without Q-BOT having to speak. Such a setting has been widely studies in economics and game theory as the classic Lewis Signaling (LS) game (Lewis, 2008). By necessitating *dialog* between agents, we are able ground both V_A and V_Q in our final setting (Sec. 4.3).

3 Modeling Q-BOT and A-BOT

We formalize Q-BOT and A-BOT as agents operating in a partially observable world and optimize their policies using deep reinforcement learning.

States and Actions. Each agent observes its own input (task G for Q-BOT and object instance I for A-BOT) and the output of the other agent as a stochastic environment. At the beginning of round t, Q-BOT observes state $s^t_Q{=}[G, q_1, a_1, \ldots, q_{t-1}, a_{t-1}]$ and acts by uttering some token q_t from its vocabulary V_Q. Similarly, A-BOT observes the history and this new utterance as state $s^t_A{=}[I, q_1, a_1, \ldots, q_{t-1}, a_{t-1}, q_t]$ and emits a response a_t from V_A. At the last round, Q-BOT takes a final action by predicting a pair of attribute values $\hat{w}^G = (\hat{w}^G_1, \hat{w}^G_2)$ to solve the task.

Cooperative Reward. Both Q-BOT and A-BOT are rewarded identically based on the accuracy of

Q-BOT's prediction $\hat{w}^G$, receiving a positive reward of $R{=}1$ if the prediction matches ground truth and a negative reward of $R{=}{-}10$ otherwise. We arrive at these values empirically.

Policy Networks. We model Q-BOT and A-BOT as operating under stochastic policies $\pi_Q(q_t|s_t^Q;\theta_Q)$ and $\pi_A(a_t|s_t^A;\theta_A)$ respectively, which we instantiate as LSTM-based models. We use lower case characters (*e.g.* s_t^Q) to denote the strings (*e.g.* Q-BOT's token at round t), and upper case S_t^Q to denote the corresponding vector as encoded by the model.

As shown in Fig. 1, Q-BOT is modeled with three modules – speaking, listening, and prediction. The task G is received as a 6-dimensional one-hot encoding over the space of possible tasks and embedded via the listener LSTM. At each round t, the *speaker network* models the probability of output utterances $q_t \in V_Q$ based on the state S_{t-1}^Q. This is modeled as a fully-connected layer followed by a softmax that transforms S_{t-1}^Q to a distribution over V_Q. After receiving the reply a_t from A-BOT, the *listener LSTM* updates the state by processing both tokens of the dialog exchange. In the final round, the *prediction LSTM* is unrolled twice to produce Q-BOT's prediction based on the final state S_T^Q and the task G. As before, task G is fed in one-hot to the prediction LSTM for two time steps, resulting in a pair of outputs used as the prediction $\hat{w}_G$.

Analogously, A-BOT is modeled as a combination of a *speaker network*, a *listener LSTM*, and an *instance encoder*. Like in Q-BOT, the speaker network models the probability of utterances $a_t \in V_A$ given the state S_t^A and the listener LSTM updates the state S_t^A based on dialog exchanges. The instance encoder embeds each one-hot attribute vector via a linear layer and concatenates all three encodings to obtain a unified instance representation.

Learning Policies with REINFORCE. We train these models using the popular REINFORCE (Williams, 1992) policy gradient algorithm. Note that while the game is fully-cooperative, we do not assume full observability of one agent by another, opting instead to treat one agent as part of the unknown stochastic environment when updating the other. During training, we sample 1000 two round dialog episodes per batch and update policy parameters with Adam (Kingma and Ba, 2015) based on these approximate gradients. Our code is publicly available[1].

4 The Road to Compositionality

This section details our key observation – that while the agents always successfully invent a language to solve the game with near-perfect accuracies, the invented languages are decidedly *not* compositional, interpretable, or 'natural' (*e.g.* A-BOT ignoring Q-BOT's utterances and simply encoding every object with a unique symbol if the vocabulary is sufficiently large). In our setting, the language being compositional simply amounts to the ability of the agents to communicate the compositional atoms of a task (*e.g. shape* or *color*) and an instance (*e.g. square* or *blue*) independently.

Through this section, we present a series of settings that get progressively more restrictive to coax the agents towards adopting a compositional language, providing analysis of the learned languages developed along the way. Table 1 summarizes results for all settings. In all experiments, optimal policies (achieving near-perfect rewards) were found. For each setting, we provide qualitative analysis of the learned languages and report their ability to generalize to unseen instances. We use 80% of the object-instances for training and the remaining 20% to evaluate these learned policies. Further, greedy argmax policies are used at evaluation time.

4.1 Overcomplete Vocabularies

We begin with the simplest setting where both A-BOT and Q-BOT are given arbitrarily large vocabularies. We find that when $|V_A|$ is greater than the number of instances (64), the learned policy simply has A-BOT ignore what Q-BOT asks and instead convey the instance using a single symbol, *e.g.* token 1≡*(red, square, filled)*. Notice that this means no 'dialog' is necessary and amounts to each agent having a codebook that maps symbols to object instances.

Perhaps as expected, the generalization of this language to unseen instances is quite poor (success rate: 25.6%). The adopted strategy of mapping instances to token pairs fails for test instances containing novel combinations of attributes for which the agents lack an agreed-upon code from training.

It seems clear that like in human communication (Nowak et al., 2000), a limited vocabulary that cannot possibly encode the richness of the world seems to be necessary for non-trivial dialog to emerge. We explore such a setting next.

[1] github.com/batra-mlp-lab/lang-emerge

Setting	Vocab.		Memory		Gen.(%)	
	V_Q	V_A	A	Q	Both	One
Overcomplete (§4.1)	64	64	✓	✓	25.6	79.5
Attr-Value (§4.2)	3	12	✓	✓	38.5	88.4
NoMem-Min (§4.3)	3	4	✗	✓	**74.4**	**94.9**

Table 1: Overview of settings we explore to analyze the language learnt by two agents in a cooperative game, Task & Talk. Last two columns measure generalization in terms of prediction accuracy of **both** or at least **one** of the attribute pair, on a held-out test set containing unseen instances.

4.2 Attribute & Value Vocabulary

Since our world has 3 attributes (*shape/color/style*) and $4+4+4=12$ possible settings of their states, one may believe that the intuitive choice of $|V_Q|=3$ and $|V_A|=12$ will be enough to circumvent the 'cheating' enumeration strategy from the previous experiment. Surprisingly, we find that the new language learned in this setting is not only decidedly non-compositional but also very difficult to interpret! We present two salient observations.

We observe that Q-BOT uses only the first round to convey the task to A-BOT by encoding tasks in an order-independent fashion *e.g.* the *(style,color)* and *(color,style)* tasks are both expressed as the utterance *Z* in the first round. Consequentially, multiple rounds of dialog are rended unnecssary and the second round is inconsistent across instances even for the same task.

Given the task from Q-BOT in the first round, A-BOT only needs to identify one of the 4×4=16 attribute pairs for a given task. Rather than ground its symbols into individual states, A-BOT follows a 'set partitioning' strategy, *i.e.* A-BOT identifies a pair of attributes with a unique combinations of round 1 and 2 utterances (*i.e.* the round 2 utterance has no meaning independent from round 1). Thus, symbols are reused across tasks to describe different attributes (*i.e.* symbols do not have individual consistent groundings). This 'set partitioning' strategy is consistent with known results from game theory on Nash equilibria in 'cheap talk' games (Crawford and Sobel, 1982).

This strategy has improved generalization to unseen instances because it is able to communicate the task; however, it fails on unseen attribute value combinations because it is not compositional.

4.3 Memoryless A-BOT, Minimal Vocabulary

The key problem with the previous setting is that A-BOT's utterances *mean different things* based on the round of dialog ($a_1=1$ is different from $a_2=1$). Essentially, the communication protocol is overparameterized and we must limit it further. First, we limit A-BOT's vocabulary to $|V_A|$=4 to reduce the number of 'synonyms' the agents learn. Second, we *remove* A-BOT*'s memory* by reseting the state vector S^A at each time step, which eliminates its ability to enumerate all attribute pairs.

These restrictions result in a learned language that grounds *individual symbols* into attributes and their states. For example, Q-BOT learns that $Y\rightarrow$ shape, $X\rightarrow$ color, and $Z\rightarrow$ style. Q-BOT does not however learn to always utter these symbols in the same order as the task, *e.g.* asking for *shape* first for both $(color, shape)$ and $(shape, color)$. Notice that this is perfectly valid as Q-BOT can later re-arrange the attributes in the task desired order. Similarly, A-BOT learns mappings to attribute values for each attribute query that remain consistent regardless of round (*i.e.* when asked for $color$, 1 always means $blue$).

This is similar to learned languages reported in recent works and is most closely related to Das et al. (2017b), who solve this problem by taking away Q-BOT's state rather than A-BOT's memory. Their approach can be interpreted as Q-BOT 'forgetting' the task after interacting with A-BOT. However, this behavior of Q-BOT to remember the task only during dialog but not while predicting is somewhat unnatural compared to our setting.

Tab. 2 enumerates the learnt groundings for both the agents. Given this mapping, we can predict a plausible dialog between the agents for any unseen instance and task combination. Notice that this is possible only due to the compositionality in the emergent language between the two agents. For example, consider solving *(shape, color)* for an instance *(red, square, filled)* from Fig. 2(b). Q-BOT queries *Y (shape)* and *X (color)* across two rounds, and receives *2 (square)* and *4 (red)* as answers.

Intuitively, this consistently grounded and compositional language has the greatest ability to generalize among the settings we have explored, correctly answering 74.4% of the held out instances. We note that errors in this setting seem to largely be due to A-BOT giving an incorrect answers despite Q-BOT asking the correct questions to accomplish the task. A plausible reason could be the model approximation error stemming from the instance encoder as test instances are unseen and have novel attribute combinations.

Fig. 2(b) shows the dialog for the instance *(red, square, filled)* and task *(shape, color)*. Q-BOT queries *Y (shape)* and *(color)* across two rounds,

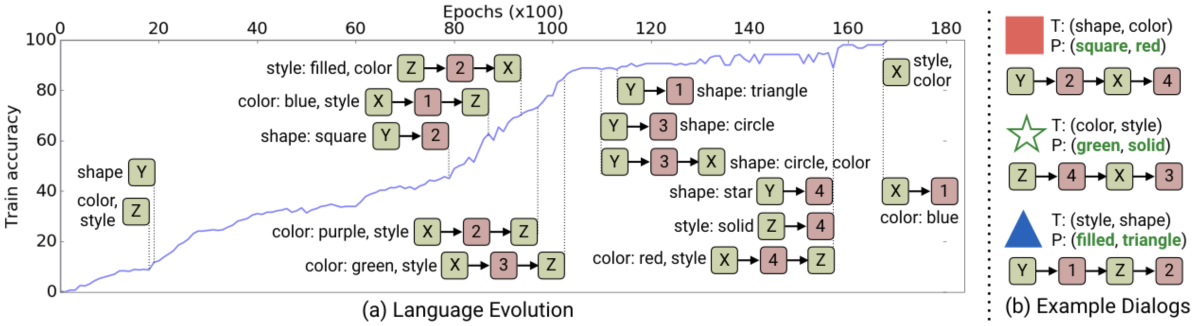

Figure 2: (a) Evolution of Language: timeline shows groundings learned by the agents during training, overlaid on the accuracy. Note that Q-BOT learns encodings for all tasks early (around epoch 20) except *(style, color)*. Improvement in accuracy is strongly correlated with groundings learnt. (b) Example dialogs for memoryless A-BOT, minimal vocabulary setting (§4.3.

	Attributes		
	color	*shape*	*style*
V_A	*X*	*Y*	*Z*
1	*blue*	*triangle*	*dotted*
2	*purple*	*square*	*filled*
3	*green*	*circle*	*dashed*
4	*red*	*start*	*solid*

(a) A-BOT

Task	q_1, q_2
(color, shape)	*Y, X*
(shape, color)	
(shape, style)	*Y, Z*
(style, shape)	
(color, style)	*Z, X*
(style, color)	*X, Z*

(b) Q-BOT

Table 2: Emergence of compositional grounding for language learnt by the agents. **A-BOT** (Tab. 2a) learns consistent mapping across rounds, depending on the query attribute. Token grounding for **Q-BOT** (Tab. 2b) depends on the task at hand. Though compositional, Q-BOT does not necessarily query attribute in the order of task, but instead re-arranges accordingly at prediction time as it contains memory.

and receives *2 (square)* and *4 (red)* as answers.

4.4 Evolution of Language Timeline

To gain further insight into the languages learned, we create a *language evolution* plot in Fig. 2. Specifically, at regular intervals during policy learning, we construct 'dialog trees'. A dialog tree enumerates all plausible dialogs between the two agents (q_1, a_1, q_2, a_2), as a tree. The root node is q_1, and at any node, we go deeper by choosing a branch based on the next utterance in the dialog. Since Task & Talk runs for two rounds, our dialog trees are 4 layers deep with $|V_A|^2|V_Q|^2$ leaves. Notice that a single input instance could potentially result in different dialogs depending on the task. Hence, we consider *(instance, task)* pairs and assign each to a leaf by traversing the tree according to the resulting dialog. At some point in the learning, the nodes become and stay 'pure' (the common trend among all *(instance, task)* at the node stays constant till the end of training), at which point we can say that the agents have learned this dialog subsequence.

Construction. After constructing dialog trees at regular intervals, we identify 'concepts' at each node/leaf using the dialog tree of the completely trained model, which achieves a perfect accuracy on train set. A concept is simply the common trend among all the *(instance, task)* tuples either assigned to a leaf or contained within the subtree with a node as root. Next, given a resultant concept for each of the node/leaf, we backtrack in time and check for the first occurrence when only tuples which satisfy the corresponding concept are assigned to that particular node/leaf. In other words, we compute the earliest time when a node/leaf is 'pure' with respect to its final learned concept. Finally, we plot these leaves/nodes and the associated concept with their backtracked time to get Fig. 2.

Observations. We highlight key observations below: (a) The agents ground most of the tasks initially at around epoch 20. Specifically, Q-BOT assigns *Y* to both *(shape, style)*, *(style, shape)*, *(shape,color)* and *(color, shape)*, while *(color, style)* is mapped to *Z*. Hence, Q-BOT learns its first token very early into the training procedure. (b) The only other task *(style, color)* is grounded towards the end (around epoch 170) using *X*, leading to an immediate convergence. (c) We see a strong correlation between improvement in performance and when agents learn a language grounding. In particular, there is an improvement from 40% to 80% within a span of 25 epochs where most of the grounding is achieved, as seen from Fig. 2.

5 Conclusion

In conclusion, we presented a sequence of 'negative' results culminating in a 'positive' one – showing that while most invented languages are effective (*i.e.* achieve near-perfect rewards), they are decidedly *not* interpretable or compositional. Our goal is simply to improve understanding and interpretability of invented languages in multi-agent dialog, place recent work in context, and inform fruitful directions for future work.

Abstract

Users suffering from mental health conditions often turn to online resources for support, including specialized online support communities or general communities such as Twitter and Reddit. In this work, we present a framework for supporting and studying users in both types of communities. We propose methods for identifying posts in support communities that may indicate a risk of self-harm, and demonstrate that our approach outperforms strong previously proposed methods for identifying such posts. Self-harm is closely related to depression, which makes identifying depressed users on general forums a crucial related task. We introduce a large-scale general forum dataset consisting of users with self-reported depression diagnoses matched with control users. We show how our method can be applied to effectively identify depressed users from their use of language alone. We demonstrate that our method outperforms strong baselines on this general forum dataset.

1 Introduction

Mental health remains a major challenge in public health care. Depression is one of the most common mental disorders and 350 million people are estimated to suffer from depression worldwide (WHO, 2010). In 2014 an estimated 7% of all U.S. adults had experienced at least one major depressive disorder (2015). Suicide and self-harm are major related concerns in public mental health. Suicide is one of the leading causes of death (CDC, 2015), and each suicide case has major consequences on the physical and emotional well-being of families and on societies in general. Therefore identifying individuals at risk of self-harm and providing support to prevent it remains an important problem (Ferrari et al., 2014).

Social media is often used by people with mental health problems to express their mental issues and seek support. This makes social media a significant resource for studying language related to depression, suicide, and self-harm, as well as understanding the authors' reasons for making such posts, and identifying individuals at risk of harm (Coppersmith et al., 2014a). Depression and suicide are closely related given that depression is the psychiatric diagnosis most commonly associated with suicide. Research has demonstrated that forums are powerful platforms for self-disclosure and social support seeking around mental health concerns (De Choudhury and De, 2014; Manikonda and De Choudhury, 2017). Such support forums are often staffed by moderators who are mental health experts, trained volunteers, or more experienced users whose role is to identify forum posts suggesting that a user is at risk of self-harm and to provide support.

Studies have shown that self expression and social support are beneficial in improving the individual's state of the mind (Turner et al., 1983; Choudhury and Kiciman, 2017) and thus such communities and interventions are important in suicide prevention. However, there are often thousands of user posts published in such support forums daily, making it difficult to manually identify individuals at risk of self-harm. Additionally, users in acute distress need prompt attention, and any delay in responding to these users could have adverse consequences. Therefore, identifying individuals at risk of self-harm in such support forums is an important challenge. Identifying signs of depression in general social media, on the other hand, is also a difficult task that has appli-

cations for both better understanding the relationship between mental health and language use and for monitoring a specific user's state (e.g., in the context of monitoring a user's response to clinical care). In this work we propose and evaluate a framework for performing self-harm risk assessment and for identifying depression in online forums.

We present a general neural network architecture for combining posts into a representation of a user's activity that is used to classify the user. To address the challenge of depression risk assessment over the general forums, we introduce a large-scale novel Reddit dataset that is substantially larger than the existing data and has a much more realistic number of control users. The dataset contains over 9,000 users with self-reported depression diagnoses matched with over 107,000 control users. We apply our approach to *(1)* identify the users with depression on a general forum like Reddit, and to *(2)* estimate the risk of self-harm indicated by posts in a more specific mental-health support forum. Our methods perform significantly better on both datasets than strong existing methods, demonstrating that our approach can be used both to identify depressed users and to estimate the risk of self-harm posed by individual posts.

2 Related Work

There is a growing body of related work analyzing mental health-related discourse and language usage in social media to better discover and understand mental health related concerns (Resnik et al., 2013; De Choudhury et al., 2013; Coppersmith et al., 2014b,a; Mitchell et al., 2015; Tsugawa et al., 2015; Coppersmith et al., 2015a; Althoff et al., 2016; Mowery et al., 2016; Benton et al., 2017b). To investigate NLP methods for identifying depression and PTSD users on Twitter, a shared task (Coppersmith et al., 2015b) at the 2nd Computational Linguistics and Clinical Psychology Workshop (CLPsych 2015) was introduced where the participants evaluated their methods on a dataset of about 1800 Twitter users. Other work has used data from approximately 900 Reddit.com users to support self-reported diagnosis detection (Losada and Crestani, 2016). Previous work identifying depression and other mental health problems, including the methods participating in CLPsych 2015 (e.g. (Resnik et al., 2015; Preoţiuc-Pietro et al., 2015)) heavily rely on utilizing features such as LIWC (Pennebaker et al., 2015), topic modeling, manual lexicons, or other domain-dependent application-specific features. Aside from the effort required to design effective features, these approaches usually model the problem with respect to the selected features and ignore other indicators and signals that can improve prediction. In contrast, our model only relies on text and is not dependent on any external or domain-specific features. Previous self-reported diagnosis detection datasets contained a limited number of both control users and diagnosed users. In contrast to this, we construct a new dataset with over 9,000 depressed users matched with a realistic number of control users.

In addition to general studies addressing mental health, related work has also specifically studied suicide and self-harm through social media (Jashinsky et al., 2014; Thompson et al., 2014; Gunn and Lester, 2015; De Choudhury et al., 2016; Coppersmith et al., 2016). Recently, CLPsych 2016 (Hollingshead and Ungar, 2016) investigated approaches for detecting the self-harm risk of mental health forum posts (Milne et al., 2016). Most related work in this area uses variations of linear classifiers with some sort of feature engineering; successful methods have employed: a combination of sparse (bag-of-words) and dense (doc2vec) representation of the target forum posts (Kim et al., 2016), a stack of feature-rich Random Forest and linear Support Vector Machine (SVM) (Malmasi et al., 2016), an RBF SVM classifier utilizing similar sets of features (Brew, 2016), and various contextual and psycholinguistic features (Cohan et al., 2016, 2017). In contrast to the above works, our model does not use any general or domain specific feature engineering; it learns appropriate representations of documents by considering only their textual content.

Our proposed models consist of a shared architecture based on a CNN, a merge layer, model-specific loss functions, and an output layer (as we will describe in §4). While our model shares similarities with CNN-based models in prior work (Kalchbrenner et al., 2014; Kim, 2014; Xiao and Cho, 2016), it focuses on learning representations of user's posts and combining the post representations into an overall representation of the user's activity. In the case of self-harm risk assessment, we experiment with several loss functions to determine whether considering the ordinal nature of self-harm risk labels (i.e., green, amber, red, and crisis) can improve performance. Evaluation results suggest that the model variant using this loss function is more robust than our other variants.

3 Data

3.1 Depression dataset construction.

We created a new dataset to support the task of identifying forum users with self-reported depression diagnoses. The Reddit Self-reported Depression Diagnosis (RSDD) dataset was created by annotating users from a publicly-available Reddit dataset[1]. Users to annotate were selected by identifying all users who made a post between January 2006 and October 2016 matching a high-precision diagnosis pattern.[2] Users with fewer than 100 posts made before their diagnosis post were discarded. Each of the remaining diagnosis posts was then viewed by three layperson annotators to decide whether the user was claiming to have been diagnosed with depression; the most common false positives included hypotheticals (e.g., "if I was diagnosed with depression"), negations (e.g., "it's not like I've been diagnosed with depression"), and quotes (e.g., "my brother announced 'I was just diagnosed with depression' "). Only users with at least two positive annotations were included in the final group of diagnosed users.

A pool of potential control users was identified by selecting only those users who had *(1)* never posted in a subreddit related to mental health, and *(2)* never used a term related to depression or mental health. These restrictions minimize the likelihood that users with depression are included in the control group. In order to prevent the diagnosed users from being easily identified by the usage of specific keywords that are never used by the control users, we removed all posts by diagnosed users that met either one of the aforementioned conditions (i.e., that was posted in a mental health subreddit or included a depression term).

For each diagnosed user and potential control user, we calculated the probability that the user would post in each subreddit (while ignoring diagnosed users' posts made to mental health subreddits). Each diagnosed user was then greedily matched with the 12 control users who had the smallest Hellinger distance between the diagnosed user's and the control user's subreddit post probability distributions, excluding control users with 10% more or fewer posts than the diagnosed user. This matching approach ensures that diagnosed users are matched with control users who are interested in similar subreddits and have similar activity levels, preventing biases based on the subreddits users are involved in or based on how active the users are on Reddit. This yielded a dataset containing 9,210 diagnosed users and 107,274 control users. On average each user in the dataset has 969 posts (median 646). The mean post length is 148 tokens (median 74).

The Reddit Self-reported Depression Diagnosis (RSDD) dataset differs from prior work creating self-reported diagnoses datasets in several ways: it is an order of magnitude larger, posts were annotated to confirm that they contained claims of a diagnosis, and a realistic number of control users were matched with each diagnosed user. The lists of terms related to mental health, subreddits related to mental health, high-precision depression diagnosis patterns, and further information are available[3]. We note that this dataset has some (inevitable) caveats: *(i)* the method only captures a subpopulation of depressed people (i.e. those with self-reported diagnosis), *(ii)* Reddit users may not be a representative sample of the population as a whole, and *(iii)* there is no way to verify whether the users with self-reported diagnoses are truthful.

3.2 Self-harm assessment.

For self-harm risk assessment we use data from mental health forum posts from ReachOut.com, which is a successful Australian support forum for young people. In addition to providing peer-support, ReachOut moderators and trained volunteers monitor and participate in the forum discussions. The NAACL 2016 Computational Linguistics and Clinical Psychology Workshop (Hollingshead and Ungar, 2016) released a Triage dataset containing 65,024 forum posts from ReachOut, with annotations for 1,227 posts indicating the author's risk of self-harm (Milne et al., 2016). The annotations consist of one of four labels: green (indicating no action is required from ReachOut's moderators), amber (non-urgent attention is required), red (urgent attention is required), and crisis (a risk that requires immediate attention).

[1] https://files.pushshift.io/reddit/

[2] e.g., "I was just diagnosed with depression."

[3] http://ir.cs.georgetown.edu/data/reddit_depression/

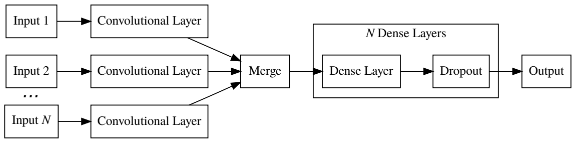

Figure 1: The general neural network architecture shared among our user and post classification models. Each input (e.g., each of a user's posts) is processed by a convolutional network and merged to create a vector representation of the user's activity. This vector representation is passed through one or more dense layers followed by an output layer that performs classification. The type of input received, merge operation, and output layer vary with the specific model.

3.3 Ethical concerns.

Social media data are often sensitive, and even more so when the data are related to mental health. Privacy concerns and the risk to the individuals in the data should always be considered (Hovy and Spruit, 2016; Šuster et al., 2017; Benton et al., 2017a). We note that the risks associated with the data used in this work are minimal. This assessment is supported by previous work on the ReachOut dataset (Milne et al., 2016), on Twitter data (Coppersmith et al., 2015b), and on other Reddit data (Losada and Crestani, 2016). The RSDD dataset contains only publicly available Reddit posts. Annotators were shown only anonymized posts and agreed to make no attempts to deanonymize or contact them. The RSDD dataset will only be made available to researchers who agree to follow ethical guidelines, which include requirements not to contact or attempt to deanonymize any of the users. Additionally, for the ReachOut forum data that was explicitly related to mental health, the forum's rules require the users to stay anonymous; moderators actively redact any user identifying information.

4 Methodology

We describe a general neural network architecture for performing text classification over multiple input texts. We propose models based on this architecture for performing two tasks in the social media and mental health domains that we call *self-harm risk classification* and *detecting depression*. The task of self-harm risk classification is estimating a user's current self-harm risk given the user's post on a mental health support forum and the previous posts in the thread. The task of detecting depressions in users is identifying Reddit users with self-reported depression diagnoses given the users' post histories (excluding posts containing mental health keywords or posted in subreddits related to mental health).

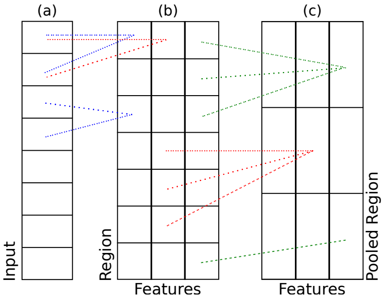

Figure 2: The convolutional network component of our architecture. A convolutional layer takes a series of terms as input *(a)* and applies l filters to a k-term sliding window to derive feature values for each window or region *(b)*; $k = 2$ and $l = 3$ shown here. A max pooling layer considers non-overlapping region sequences of length n *(b)* and keeps the highest feature value for the sequence *(c)*; $n = 3$ shown here.

While both tasks are focused on predicting a user's mental health status, they differ in both the type of classification performed (i.e., estimating severity on a four point scale vs. boolean classification) and in the amount of data available. Our general architecture is based on a two step process: *(1)* identifying relevant features in each input text, and *(2)* combining the features observed in the model's inputs to classify the user.

4.1 Shared Architecture

Our proposed models share a common architecture that takes one or more posts as input, processes the posts using a convolutional layer to identify features present in sliding windows of text, merges the features identified into a vector representation of the user's activity, and uses a series of dense layers to perform classification on the merged vector representation. The type of merging performed and the output layers are properties of the model variant, which we describe in detail in the following section. Convolutional networks have commonly been applied to the task of text classification, such as by Kim (2014). We use categorical cross-entropy as a loss function with both methods, but also experiment with other loss functions when performing severity classification.

First, the model takes one or more posts as input and processes each post with a convolutional network containing a convolutional layer and a pooling layer. This process is illustrated with a max pooling layer in Figure 2. The convolutional layer applies filters to a sliding window of k terms *(a)* and outputs a feature value for each sliding window region and each filter *(b)*. The same filters are applied to each window; each filter can be viewed as a feature detector and the overall process can be conceptualized as looking for windows of terms that contain specific features. The features are not specified a priori through feature engineering, but instead are learned automatically when the model is trained. After identifying the features present in each region (i.e., sliding window), a max pooling layer considers non-overlapping regions of length n and keeps the highest feature value for each region *(c)*. This step eliminates the regions (i.e., sliding windows) that do not contain useful features, which reduces the size of the convolutional network's output. The same convolutional network is applied to each input post, meaning that the model learns to look for the same set of features in each.

After each input post has been processed by a convolutional network, the output of each convolutional network is merged to create a representation of the user's activity across all input posts. This representation is processed by one or more dense layers (i.e., fully connected layers) with dropout (Srivastava et al., 2014) before being processed by a final output layer to perform classification. The type of output layer is dependent on the model variant. Our shared model architecture is illustrated in Figure 1. The architecture's hyperparameters (e.g., the sliding window size k, the number of convolutional filters used, and type of pooling) also vary among models and are described in the supplemental material. Both the convolutional and dense layers use ReLU activations (Nair and Hinton, 2010) in all model variants.

4.2 Models

4.2.1 Depression detection

Our model for depression detection takes a user's posts as input and processes each post with a convolutional network. Each convolutional network performs average pooling to produce its output. That is, the model considers non-overlapping sequences of n posts and keeps the average feature value across all sequences. These post representations are then merged with a second convolutional layer to create a user representation; we found this approach led to more stable performance than using a second average pooling or max pooling layer. The user representation created by the merge step is then passed to one or more dense layers before being passed to a dense output layer with a softmax activation function to perform classification. The number of dense layers used is a hyperparameter described in §5. Categorical cross-entropy is used as the model's loss function.

4.2.2 Self-harm risk assessment

Our model for self-harm risk classification takes two inputs: the target post being classified and the prior posts (if any) in the target post's thread. The prior posts provide context and are thus useful for estimating the risk of self-harm present in the target post. The two inputs are both processed by a convolutional network as in user-level classification, but in this case the convolutional network's outputs correspond to a representation of the target post and to a representation of the target post's context (i.e., the prior posts in the thread). Given that these two outputs represent different aspects, they are merged by concatenating them together. This merged representation is then passed to one or more dense layers and to an output layer; the type of output layer depends on the loss function used. There are four self-harm risk assessment model variants in total:

Categorical Cross Ent. uses an output layer with a softmax activation function, and categorical cross-entropy as its loss function. This mirrors the output layer and loss function used in the user level classification model.

MSE uses an output layer with a linear activation function, and mean squared error as its loss function. The model's output is thus a single value; to perform classification, this output value is rounded to the nearest integer in the interval $[0, t-1]$, where t is the number of target classes.

The final two loss functions perform metric learning rather than performing classification directly. They learn representations of a user's activity and of the four self-harm risk severity labels; classification is performed by comparing the euclidean distance between a representation of a user's activity (produced by the final layer) and each of the four severity label representations.

Method		Convolution			Dense Layers	Dropout	Class Balance
		Size	Filters	Pool Len.			
Reddit	Cat. Cross Ent.	3	25	all (avg)	1 w/ 50 dims	0.0	Sampled
ReachOut	Cat. Cross Ent.	3	150	3 (max)	2 w/ 250 dims	0.3	Weighted
	MSE	3	100	3 (max)	2 w/ 250 dims	0.5	Sampled
	Class Metric	3	100	3 (max)	2 w/ 150 dims	0.3	Sampled

Table 1: The hyperparameters used by each model.

Class Metric: Let d be the size of the output layer and X be the layer's d-dimensional output. *Class Metric* learns a d-dimensional representation of each class C_i such that $||X - C_i||_2$ is minimized for the correct class i; this is accomplished with the loss function: $L_{i,p,n} = max(0, ||X_i - C_p||_2 - ||X_i - C_n||_2 + \alpha)$ where C_p is the correct (i.e., positive) class for X_i, C_n is a randomly chosen incorrect (i.e., negative) class, and α is a constant to enforce a minimum margin between classes. Classification is performed by computing the similarity between X_i and each class C_j.

Class Metric (Ordinal) extends *Class Metric* to enforce a margin between ordinal classes as a function of the distance between classes. Given a ranked list of classes such that more similar classes have closer rankings, that is $\forall i\ sim(C_i, C_{i\pm1}) > sim(C_i, C_{i\pm2})$, we incorporate the class distance into the margin such that more distant incorrect class labels must be further away from the correct class label in the metric space. The loss function becomes $L_{i,p,n} = max(0, ||X_i - C_p||_2 - ||X_i - C_n||_2 + \alpha|p - n|)$ where $|p - n|$ causes the margin to scale with the distance between classes p and n.

5 Experiments

In this section we describe the model hyperparameters used and present our results on the depression detection and self-harm risk assessment tasks. To facilitate reproducibility we provide our code and will provide the Reddit depression dataset to researchers who sign a data usage agreement[4].

5.1 Experimental setup.

The hyperparameters used with our models are shown in Table 1. The severity risk assessment models' hyperparameters were chosen using 10-fold cross validation on the 947 ReachOut training posts, with 15% of each fold used as validation data. The depression identification model's hyperparameters were chosen using the Reddit validation set. The depression identification model's second convolutional layer (i.e., the layer used to merge post representations) used filters of length 15, a stride of length 15, and the same number of filters as the first convolutional layer. All models were trained using stochastic gradient descent with the Adam optimizer (Kingma and Ba, 2014). The hyperparameters that varied across models are shown in Table 1. The convolution size, number of convolutional filters, pooling type, pooling length, and number of dense layers was similar across all post models. Class balancing was performed with *Categorical Cross Ent.* by weighting classes inversely proportional to their frequencies, whereas sampling an equal number of instances for each class worked best with the other methods.

Addressing limited data. The post classification models' input consists of skip-thought vectors (Kiros et al., 2015); each vector used is a 7200-dimensional representation of a sentence. Thus, the convolutional windows used for post classification are over sentences rather than over terms. This input representation was chosen to mitigate the effects of the ReachOut dataset's relatively small size. The skip-thought vectors were generated from the the ReachOut forum dataset by sequentially splitting the posts in the training set into sentences, tokenizing them, and training skip-thoughts using Kiros et al.'s implementation with the default parameters. Sentence boundary detection was performed using the Punkt sentence tokenizer (Kiss and Strunk, 2006) available in NLTK (Bird et al., 2009). These 2400-dimensional forum post skip-thought vectors were concatenated with the 4800-dimensional book corpus skip-thought vectors available from Kiros et al.. Experiments on the training set indicated that using only the ReachOut skip-thought vectors slightly decreased

[4] http://ir.cs.georgetown.edu/data/reddit_depression/

performance, while using only the book corpus skip-thought vectors substantially decreased performance. As input the post models received the last 20 sentences in each target post and the last 20 sentences in the thread prior to the target post; any prior sentences are ignored.

5.2 Depression detection.

The data used for depression detection was described in §3. We compare our model against several baselines using MNB and SVM classifiers (Wang and Manning, 2012). Specifically, we consider two sets of features for the classifiers. The first set of features is the post content itself represented as sparse bag of words features (*BoW baselines*). The second set of features (*feature-rich baselines*) comprises a large set of features including bag of words features encoded as sparse weighted vectors, external psycholinguistic features captured by LIWC[5] (2015), and emotion lexicon features (Staiano and Guerini, 2014). Since our problem is identifying depression among users, psycholinguistic signals and emotional attributes in the text are potentially important features for the task. These features (as described in §2) have been also previously used by successful methods in the Twitter self-reported diagnosis detection task (Coppersmith et al., 2015b). Thus, we argue that these are strong baselines for our self-reported diagnosis detection task. We apply count based and tf-idf based feature weighting for bag of words features. We perform standard preprocessing by removing stopwords and lowercasing the input text.[6]

The data is split into training, validation, and testing datasets each containing approximately 3,000 diagnosed users and their matched control users. The validation set is used for tuning development and hyperparameter tuning of our models and the baselines. The reported results are on the test set. The depression detection models' input consisted of raw terms encoded as one-hot vectors. We used an input layer to learn 50-dimensional representation of the terms. For each target user, the CNN received up to 400 posts containing up to 100 terms; experiments on the validation data indicated that increasing the maximum number of posts did not significantly improve performance.

Method	Precision	Recall	F1
BoW - MNB	0.44	0.31	0.36
BoW - SVM	**0.72**	0.29	0.42
Feature-rich - MNB	0.69	0.32	0.44
Feature-rich - SVM	0.71	0.31	0.44
User model - CNN	0.59	**0.45**	**0.51**

Table 2: Performance identifying depressed users on the Reddit test set. The differences between the CNN and baselines are statistically significant (McNemar's test, $p < 0.05$).

Results. The results of identifying depressed users for our model and baselines are shown in Table 2. Our proposed model outperforms the baselines by a large margin in terms of recall and F1 on the diagnosed users (increases of 41% and 16%, respectively), but performs worse in terms of precision. As described later in the analysis section, the CNN identifies language associated with negative sentiment across a user's posts.

5.3 Self-harm risk classification.

We train our methods to label the ReachOut posts and compare them against the top methods from CLPsych '16. We use the same experimental protocol as was used in CLPsych '16; our methods were trained on the 947 training posts and evaluated on the remaining 280 testing posts. We used 15% of the 947 training posts as validation data.

We report results using the same metrics used in CLPsych, which were: the macro-averaged F1 for the $amber$, red, and $crisis$ labels (*non-green* posts); the macro-averaged F1 of $green$ posts vs. $amber \cup red \cup crisis$ (*flagged* posts); and the macro-averaged F1 of $green \cup amber$ vs. $red \cup crisis$ (*urgent* posts). The *non-green* F1 was used as the official CLPsych metric with the intention of placing emphasis on classification performance for the non-green categories (i.e., those that required some response). The binary *flagged* meta-class was chosen to measure models' abilities to differentiate between posts that require attention and posts that do not, and the binary *urgent* meta-class was chosen to measure their abilities to differentiate between posts that require quick responses and posts that do not. In addition to macro-averaged F1, CLPsych also reported the accuracy for each category. We additionally report F1 macro-averaged over all classes.

[5] http://liwc.wpengine.com/

[6] During experimentation, we found tf-idf sparse feature weighting to be superior than other weighting schemes. Additional features such as LDA topics and χ^2 feature selection did not result in any further improvements.

Method	Non-green	Flagged		Urgent		All	
	F1	F1	Acc.	F1	Acc.	F1	Acc.
Baseline (Milne et al., 2016)	0.31	0.78	0.86	0.38	0.89	-	-
Kim et al. (2016)	0.42	0.85	0.91	0.62	0.91	0.55	0.85
Malmasi et al. (2016)	0.42	0.87	0.91	0.64	0.93	0.55	0.83
Brew (2016)	0.42	0.78	0.85	0.69	0.93	0.54	0.79
Cohan et al. (2016)	0.41	0.81	0.87	0.67	0.92	0.53	0.80
Categorical Cross Ent.	**0.50**	**0.89**	**0.93**	0.70	**0.94**	**0.61**	**0.89**
MSE	0.42	0.80	0.85	0.64	0.93	0.53	0.78
Class Metric	0.46	0.79	0.84	0.70	**0.94**	0.56	0.80
Class Metric (Ordinal)	0.47	0.88	**0.93**	**0.72**	0.93	0.59	0.87

Table 3: Self-harm risk assessment performance on the ReachOut test posts. F1 and accuracy are aggregated as specified by CLPsych '16. The reported results for the other methods are the official numbers from (Milne et al., 2016). The differences in performance between the following method pairs are statistically significant (McNemar's test, $p < 0.05$): *Categorical Cross Ent.* and *Class Metric*, *MSE* and *Categorical Cross Ent.*, *MSE* and *Class Metric (Ordinal)*, and *Class Metric (Ordinal)* and *Class Metric*.

Method	Non-green	Flagged		Urgent		All	
	F1	F1	Acc.	F1	Acc.	F1	Acc.
Categorical Cross Ent.	0.54	0.87	0.89	0.69	0.91	0.63	0.80
MSE	**0.87**	**0.95**	**0.96**	**0.91**	**0.98**	**0.89**	**0.93**
Class Metric	0.73	0.90	0.91	0.81	0.94	0.78	0.86
Class Metric (Ordinal)	0.85	**0.95**	**0.96**	0.89	0.97	0.88	0.92

Table 4: Self-harm risk assessment performance on the ReachOut training set using 10-fold cross validation. *Categorical Cross Ent.* performs substantially worse than on the test set, while *MSE* performs substantially better. *Class Metric (Ordinal)* continues to perform well. The difference in performance between the following method pairs are statistically significant (McNemar's test, $p < 0.05$): *Categorical Cross Ent.* and *MSE*, *Categorical Cross Ent.* and *Class Metric*, *Categorical Cross Ent.* and *Class Metric (Ordinal)*, *MSE* and *Class Metric*, and *Class Metric* and *Class Metric (Ordinal)*.

Results. The results on the self-harm risk assessment task for our models and for the current best-performing methods (briefly explained in §2) are shown in Table 3. We also report a baseline result which is based on a SVM classifier with bigram features. When measured by *non-green* F1, the official metric of the CLPsych '16 Triage Task, our proposed models perform up to 19% better than the best existing methods. Similarly, our models perform up to 11% better when measured with an F1 macro-averaged across all categories (i.e., *all* column) and up to 5% better with measured accuracy across all categories. *Categorical Cross Ent.* performs best in all of these cases, though the difference between the performance of *Categorical Cross Ent.* and *Class Metric* with an ordinal margin is not statistically significant.

We also evaluate the performance of our methods on the training set using 10-fold cross validation to better observe the performance differences between our model variants (Table 4). All models' perform substantially better on the training set than on the test set. This is partially explained by the fact that the models were tuned on the training set, but the large difference in some cases (e.g., the increase in the highest non-green F1 from 0.50 to 0.87) suggest there may be qualitative differences between the training and testing sets. The best-performing method on the test set, *Categorical Cross Ent.*, performs the worst on the training set. Similarly, the worst-performing method on the test set, *MSE*, performs the best on the training set. *Class Metric (Ordinal)* performs well on both the testing and training sets, however, suggesting that it is more robust than the other methods. Furthermore, there is no statistically significant difference between *Class Metric (Ordinal)* and the best-performing method on either dataset.

Top Phrases	
i went to	to scare you
my whole	to have it
sometimes i	my son was
i'm so sorry	it wasn't

Table 5: Example phrases that strongly contributed to a user's depression classification on the RSDD dataset.

5.4 Analysis

In this section we analyze the language that strongly contributed to the identification of depressed users on the Reddit dataset. Note that it is impossible to show entire Reddit posts without compromising users' anonymity; we found that even when a post is paraphrased, enough information remains that it can easily be identified using a Web search engine. For example, one Reddit post that strongly contributed to the author's classification as a depressed user contained the mention of a specific type of abuse and several comments vaguely related to this type of abuse. We attempted to paraphrase this post, but found that any paraphrase containing general language related to both the type of abuse and to the user's comments was enough to identify the user. Thus, to protect the anonymity of the users in our dataset, we do not publish posts in any form.

Rather than publishing posts, we identify key phrases in posts from users who were correctly identified as being depressed. Phrases from eight self-reported depressed users are shown in Table 5; to prevent these phrases from being used to identify users, we retain only the top phrase from each user. These phrases were identified by using the model's convolutional filter weights to identify posts in the validation dataset that are strongly contributing to the model's classification decision, and then using the convolutional filter weights to identify the phrase within each post that most strongly contributed to the post's classification (i.e., had the highest feature values).

In keeping with the design of our dataset, terms related to depression or diagnoses are not present. Instead, the model identifies phrases that often could be associated with a negative sentiment or outlook. For example, "my whole" could be part of a negative comment referring to the poster's whole life. It should be noted that the model makes classification decisions based on the occurrence of phrases across many posts by the same user. Though one can imagine how the phrases shown here could be used to convey negative sentiment, the presence of a single such phrase is not sufficient to cause the model to classify a user as depressed.

6 Conclusion

In this work we argued for the close connection between social media and mental health, and described a neural network architecture for performing self-harm risk classification and depression detection on social media posts. We described the construction of the Reddit Self-reported Depression Diagnosis (RSDD) dataset, containing over 9,000 users with self-reported depression diagnoses matched with over 107,000 similar control users; the dataset is available under a data usage agreement. We applied our classification approach to the task of identifying depressed users on this dataset and found that it substantially outperformed strong existing methods in terms of Recall and F1. While these depression detection results are encouraging, the absolute values of the metrics illustrate that this is a challenging task and worthy of further exploration. We also applied our classification approach to the task of estimating the self-harm risk posed by posts on the ReachOut.com mental health support forum, and found that it substantially outperformed strong previously-proposed methods.

Our approach and results are significant from several perspectives: they provide a strong approach to identifying posts indicating a risk of self-harm in social media; they demonstrate a means for large scale public mental health studies surrounding the state of depression; and they demonstrate the possibility of sensitive applications in the context of clinical care, where clinicians could be notified if the activities of their patients suggest they are at risk of self-harm. Furthermore, large-scale datasets such as the one presented in this paper can provide complementary information to existing data on mental health which are generally relatively smaller collections.

Abstract

Language is increasingly being used to define rich visual recognition problems with supporting image collections sourced from the web. Structured prediction models are used in these tasks to take advantage of correlations between co-occurring labels and visual input but risk inadvertently encoding social biases found in web corpora. In this work, we study data and models associated with multilabel object classification and visual semantic role labeling. We find that (a) datasets for these tasks contain significant gender bias and (b) models trained on these datasets further amplify existing bias. For example, the activity `cooking` is over 33% more likely to involve females than males in a training set, and a trained model further amplifies the disparity to 68% at test time. We propose to inject corpus-level constraints for calibrating existing structured prediction models and design an algorithm based on Lagrangian relaxation for collective inference. Our method results in almost no performance loss for the underlying recognition task but decreases the magnitude of bias amplification by 47.5% and 40.5% for multilabel classification and visual semantic role labeling, respectively.

1 Introduction

Visual recognition tasks involving language, such as captioning (Vinyals et al., 2015), visual question answering (Antol et al., 2015), and visual semantic role labeling (Yatskar et al., 2016), have emerged as avenues for expanding the diversity of information that can be recovered from images. These tasks aim at extracting rich semantics from images and require large quantities of labeled data, predominantly retrieved from the web. Methods often combine structured prediction and deep learning to model correlations between labels and images to make judgments that otherwise would have weak visual support. For example, in the first image of Figure 1, it is possible to predict a `spatula` by considering that it is a common tool used for the activity `cooking`. Yet such methods run the risk of discovering and exploiting societal biases present in the underlying web corpora. Without properly quantifying and reducing the reliance on such correlations, broad adoption of these models can have the inadvertent effect of magnifying stereotypes.

In this paper, we develop a general framework for quantifying bias and study two concrete tasks, visual semantic role labeling (vSRL) and multilabel object classification (MLC). In vSRL, we use the imSitu formalism (Yatskar et al., 2016, 2017), where the goal is to predict activities, objects and the roles those objects play within an activity. For MLC, we use MS-COCO (Lin et al., 2014; Chen et al., 2015), a recognition task covering 80 object classes. We use gender bias as a running example and show that both supporting datasets for these tasks are biased with respect to a gender binary[1].

Our analysis reveals that over 45% and 37% of verbs and objects, respectively, exhibit bias toward a gender greater than 2:1. For example, as seen in Figure 1, the `cooking` activity in imSitu is a heavily biased verb. Furthermore, we show that after training state-of-the-art structured predictors, models amplify the existing bias, by 5.0% for vSRL, and 3.6% in MLC.

[1] To simplify our analysis, we only consider a gender binary as perceived by annotators in the datasets. We recognize that a more fine-grained analysis would be needed for deployment in a production system. Also, note that the proposed approach can be applied to other NLP tasks and other variables such as identification with a racial or ethnic group.

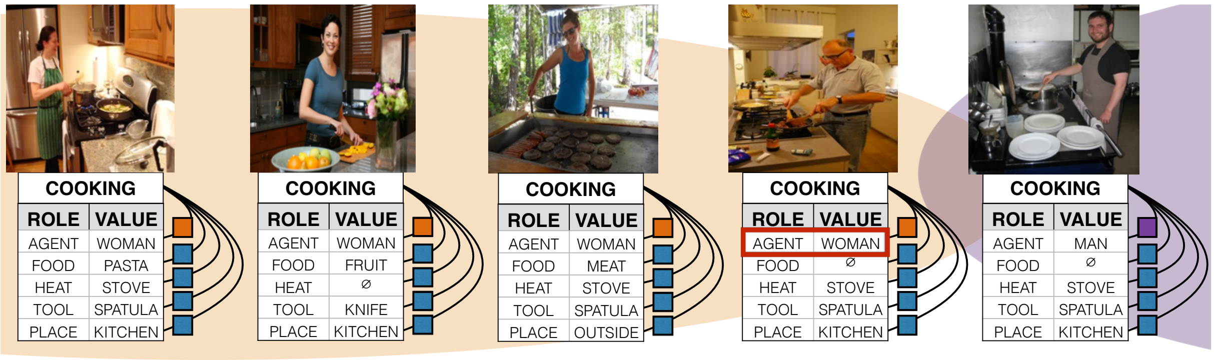

Figure 1: Five example images from the imSitu visual semantic role labeling (vSRL) dataset. Each image is paired with a table describing a situation: the verb, `cooking`, its semantic roles, i.e `agent`, and noun values filling that role, i.e. `woman`. In the imSitu training set, 33% of `cooking` images have `man` in the `agent` role while the rest have `woman`. After training a Conditional Random Field (CRF), bias is amplified: `man` fills 16% of `agent` roles in `cooking` images. To reduce this bias amplification our calibration method adjusts weights of CRF potentials associated with biased predictions. After applying our methods, `man` appears in the `agent` role of 20% of `cooking` images, reducing the bias amplification by 25%, while keeping the CRF vSRL performance unchanged.

To mitigate the role of bias amplification when training models on biased corpora, we propose a novel constrained inference framework, called RBA, for **R**educing **B**ias **A**mplification in predictions. Our method introduces corpus-level constraints so that gender indicators co-occur no more often together with elements of the prediction task than in the original training distribution. For example, as seen in Figure 1, we would like noun `man` to occur in the `agent` role of the `cooking` as often as it occurs in the imSitu training set when evaluating on a development set. We combine our calibration constraint with the original structured predictor and use Lagrangian relaxation (Korte and Vygen, 2008; Rush and Collins, 2012) to reweigh bias creating factors in the original model.

We evaluate our calibration method on imSitu vSRL and COCO MLC and find that in both instances, our models substantially reduce bias amplification. For vSRL, we reduce the average magnitude of bias amplification by 40.5%. For MLC, we are able to reduce the average magnitude of bias amplification by 47.5%. Overall, our calibration methods do not affect the performance of the underlying visual system, while substantially reducing the reliance of the system on socially biased correlations[2].

2 Related Work

As intelligence systems start playing important roles in our daily life, ethics in artificial intelligence research has attracted significant interest. It is known that big-data technologies sometimes inadvertently worsen discrimination due to implicit biases in data (Podesta et al., 2014). Such issues have been demonstrated in various learning systems, including online advertisement systems (Sweeney, 2013), word embedding models (Bolukbasi et al., 2016; Caliskan et al., 2017), online news (Ross and Carter, 2011), web search (Kay et al., 2015), and credit score (Hardt et al., 2016). Data collection biases have been discussed in the context of creating image corpus (Misra et al., 2016; van Miltenburg, 2016) and text corpus (Gordon and Van Durme, 2013; Van Durme, 2010). In contrast, we show that given a gender biased corpus, structured models such as conditional random fields, amplify the bias.

The effect of the data imbalance can be easily detected and fixed when the prediction task is simple. For example, when classifying binary data with unbalanced labels (i.e., samples in the majority class dominate the dataset), a classifier trained exclusively to optimize accuracy learns to always predict the majority label, as the cost of making mistakes on samples in the minority class can be neglected. Various approaches have been proposed to make a “fair” binary classification (Barocas and Selbst, 2014; Dwork et al., 2012; Feldman

[2] Code and data are available at `https://github.com/uclanlp/reducingbias`

et al., 2015; Zliobaite, 2015). For structured prediction tasks the effect is harder to quantify and we are the first to propose methods to reduce bias amplification in this context.

Lagrangian relaxation and dual decomposition techniques have been widely used in NLP tasks (e.g., (Sontag et al., 2011; Rush and Collins, 2012; Chang and Collins, 2011; Peng et al., 2015)) for dealing with instance-level constraints. Similar techniques (Chang et al., 2013; Dalvi, 2015) have been applied in handling corpus-level constraints for semi-supervised multilabel classification. In contrast to previous works aiming for improving accuracy performance, we incorporate corpus-level constraints for reducing gender bias.

3 Visualizing and Quantifying Biases

Modern statistical learning approaches capture correlations among output variables in order to make coherent predictions. However, for real-world applications, some implicit correlations are not appropriate, especially if they are amplified. In this section, we present a general framework to analyze inherent biases learned and amplified by a prediction model.

Identifying bias We consider that prediction problems involve several inter-dependent output variables $y_1, y_2, ...y_K$, which can be represented as a structure $y = \{y_1, y_2, ...y_K\} \in Y$. This is a common setting in NLP applications, including tagging, and parsing. For example, in the vSRL task, the output can be represented as a structured table as shown in Fig 1. Modern techniques often model the correlation between the sub-components in y and make a joint prediction over them using a structured prediction model. More details will be provided in Section 4.

We assume there is a subset of output variables $g \subseteq y, g \in G$ that reflects demographic attributes such as gender or race (e.g. $g \in G = \{\texttt{man}, \texttt{woman}\}$ is the agent), and there is another subset of the output $o \subseteq y, o \in O$ that are co-related with g (e.g., o is the activity present in an image, such as `cooking`). The goal is to identify the correlations that are potentially amplified by a learned model.

To achieve this, we define the bias score of a given output, o, with respect to a demographic variable, g, as:

$$b(o,g) = \frac{c(o,g)}{\sum_{g' \in G} c(o,g')},$$

where $c(o,g)$ is the number of occurrences of o and g in a corpus. For example, to analyze how genders of agents and activities are co-related in vSRL, we define the gender bias toward `man` for each verb $b(verb, \texttt{man})$ as:

$$\frac{c(verb, \texttt{man})}{c(verb, \texttt{man}) + c(verb, \texttt{woman})}. \qquad (1)$$

If $b(o,g) > 1/\|G\|$, then o is positively correlated with g and may exhibit bias.

Evaluating bias amplification To evaluate the degree of bias amplification, we propose to compare bias scores on the training set, $b^*(o,g)$, with bias scores on an unlabeled evaluation set of images $\tilde{b}(o,g)$ that has been annotated by a predictor. We assume that the evaluation set is identically distributed to the training set. Therefore, if o is positively correlated with g (i.e, $b^*(o,g) > 1/\|G\|$) and $\tilde{b}(o,g)$ is larger than $b^*(o,g)$, we say bias has been amplified. For example, if $b^*(\texttt{cooking}, \texttt{woman}) = .66$, and $\tilde{b}(\texttt{cooking}, \texttt{woman}) = .84$, then the bias of `woman` toward `cooking` has been amplified. Finally, we define the mean bias amplification as:

$$\frac{1}{|O|} \sum_{g} \sum_{o \in \{o \in O | b^*(o,g) > 1/\|G\|\}} \tilde{b}(o,g) - b^*(o,g).$$

This score estimates the average magnitude of bias amplification for pairs of o and g which exhibited bias.

4 Calibration Algorithm

In this section, we introduce **R**educing **B**ias **A**mplification, RBA, a debiasing technique for calibrating the predictions from a structured prediction model. The intuition behind the algorithm is to inject constraints to ensure the model predictions follow the distribution observed from the training data. For example, the constraints added to the vSRL system ensure the gender ratio of each verb in Eq. (1) are within a given margin based on the statistics of the training data. These constraints are applied at the corpus level, because computing gender ratio requires the predictions of all test instances. As a result, a joint inference over test instances is required[3]. Solving such a giant inference problem with constraints is hard. Therefore, we present an approximate inference algorithm based on Lagrangian relaxation. The advantages of this approach are:

- Our algorithm is iterative, and at each iteration, the joint inference problem is decomposed to a per-instance basis. This can be solved by the original inference algorithm. That is, our approach works as a meta-algorithm and developers do not need to implement a new inference algorithm.
- The approach is general and can be applied in any structured model.
- Lagrangian relaxation guarantees the solution is optimal if the algorithm converges and all constraints are satisfied.

In practice, it is hard to obtain a solution where all corpus-level constrains are satisfied. However, we show that the performance of the proposed approach is empirically strong. We use imSitu for vSRL as a running example to explain our algorithm.

Structured Output Prediction As we mentioned in Sec. 3, we assume the structured output $y \in Y$ consists of several sub-components. Given a test instance i as an input, the inference problem is to find

$$\arg\max_{y \in Y} \quad f_\theta(y, i),$$

where $f_\theta(y, i)$ is a scoring function based on a model θ learned from the training data. The structured output y and the scoring function $f_\theta(y, i)$ can be decomposed into small components based on an independence assumption. For example, in the vSRL task, the output y consists of two types of binary output variables $\{y_v\}$ and $\{y_{v,r}\}$. The variable $y_v = 1$ if and only if the activity v is chosen. Similarly, $y_{v,r} = 1$ if and only if both the activity v and the semantic role r are assigned [4]. The scoring function $f_\theta(y, i)$ is decomposed accordingly such that:

$$f_\theta(y, i) = \sum_v y_v s_\theta(v, i) + \sum_{v,r} y_{v,r} s_\theta(v, r, i),$$

represents the overall score of an assignment, and $s_\theta(v, i)$ and $s_\theta(v, r, i)$ are the potentials of the sub-assignments. The output space Y contains all feasible assignments of y_v and $y_{v,r}$, which can be represented as instance-wise constraints. For example, the constraint, $\sum_v y_v = 1$ ensures only one activity is assigned to one image.

Corpus-level Constraints Our goal is to inject constraints to ensure the output labels follow a desired distribution. For example, we can set a constraint to ensure the gender ratio for each activity in Eq. (1) is within a given margin. Let $y^i = \{y^i_v\} \cup \{y^i_{v,r}\}$ be the output assignment for test instance i[5]. For each activity v^*, the constraints can be written as

$$b^* - \gamma \leq \frac{\sum_i y^i_{v=v^*, r \in M}}{\sum_i y^i_{v=v^*, r \in W} + \sum_i y^i_{v=v^*, r \in M}} \leq b^* + \gamma \tag{2}$$

where $b^* \equiv b^*(v^*, man)$ is the desired gender ratio of an activity v^*, γ is a user-specified margin. M and W are a set of semantic role-values representing the agent as a `man` or a `woman`, respectively.

Note that the constraints in (2) involve all the test instances. Therefore, it requires a joint inference over the entire test corpus. In general, these corpus-level constraints can be represented in a form of $A \sum_i y^i - b \leq 0$, where each row in the matrix $A \in R^{l \times K}$ is the coefficients of one constraint, and $b \in R^l$. The constrained inference problem can then be formulated as:

$$\begin{aligned} \max_{\{y^i\} \in \{Y^i\}} \quad & \sum_i f_\theta(y^i, i), \\ \text{s.t.} \quad & A \sum_i y^i - b \leq 0, \end{aligned} \tag{3}$$

where $\{Y^i\}$ represents a space spanned by possible combinations of labels for all instances. Without the corpus-level constraints, Eq. (3) can be optimized by maximizing each instance i

$$\max_{y_i \in Y^i} f_\theta(y^i, i),$$

separately.

Lagrangian Relaxation Eq. (3) can be solved by several combinatorial optimization methods. For example, one can represent the problem as an

[3] A sufficiently large sample of test instances must be used so that bias statistics can be estimated. In this work we use the entire test set for each respective problem.

[4] We use r to refer to a combination of role and noun. For example, one possible value indicates an `agent` is a `woman`.

[5] For the sake of simplicity, we abuse the notations and use i to represent both input and data index.

Dataset	Task	Images	O-Type	$\|O\|$
imSitu	vSRL	60,000	verb	212
MS-COCO	MLC	25,000	object	66

Table 1: Statistics for the two recognition problems. In vSRL, we consider gender bias relating to verbs, while in MLC we consider the gender bias related to objects.

integer linear program and solve it using an off-the-shelf solver (e.g., Gurobi (Gurobi Optimization, 2016)). However, Eq. (3) involves all test instances. Solving a constrained optimization problem on such a scale is difficult. Therefore, we consider relaxing the constraints and solve Eq. (3) using a Lagrangian relaxation technique (Rush and Collins, 2012). We introduce a Lagrangian multiplier $\lambda_j \geq 0$ for each corpus-level constraint. The Lagrangian is

$$L(\lambda, \{y^i\}) = \sum_i f_\theta(y^i) - \sum_{j=1}^{l} \lambda_j \left(A_j \sum_i y^i - b_j \right), \tag{4}$$

where all the $\lambda_j \geq 0, \forall j \in \{1, \ldots, l\}$. The solution of Eq. (3) can be obtained by the following iterative procedure:

1) At iteration t, get the output solution of each instance i

$$y^{i,(t)} = \operatorname*{argmax}_{y \in \mathcal{Y}'} L(\lambda^{(t-1)}, y) \tag{5}$$

2) update the Lagrangian multipliers.

$$\lambda^{(t)} = \max\left(0, \lambda^{(t-1)} + \sum_i \eta(Ay^{i,(t)} - b)\right),$$

where $\lambda^{(0)} = \mathbf{0}$. η is the learning rate for updating λ. Note that with a fixed $\lambda^{(t-1)}$, Eq. (5) can be solved using the original inference algorithms. The algorithm loops until all constraints are satisfied (i.e. optimal solution achieved) or reach maximal number of iterations.

5 Experimental Setup

In this section, we provide details about the two visual recognition tasks we evaluated for bias: visual semantic role labeling (vSRL), and multi-label classification (MLC). We focus on gender, defining $G = \{\texttt{man}, \texttt{woman}\}$ and focus on the `agent` role in vSRL, and any occurrence in text associated with the images in MLC. Problem statistics are summarized in Table 1. We also provide setup details for our calibration method.

5.1 Visual Semantic Role Labeling

Dataset We evaluate on imSitu (Yatskar et al., 2016) where activity classes are drawn from verbs and roles in FrameNet (Baker et al., 1998) and noun categories are drawn from WordNet (Miller et al., 1990). The original dataset includes about 125,000 images with 75,702 for training, 25,200 for developing, and 25,200 for test. However, the dataset covers many non-human oriented activities (e.g., `rearing`, `retrieving`, and `wagging`), so we filter out these verbs, resulting in 212 verbs, leaving roughly 60,000 of the original 125,000 images in the dataset.

Model We build on the baseline CRF released with the data, which has been shown effective compared to a non-structured prediction baseline (Yatskar et al., 2016). The model decomposes the probability of a realized situation, y, the combination of activity, v, and realized frame, a set of semantic (role,noun) pairs (e, n_e), given an image i as :

$$p(y|i;\theta) \propto \psi(v, i; \theta) \prod_{(e,n_e) \in R_f} \psi(v, e, n_e, i; \theta)$$

where each potential value in the CRF for subpart x, is computed using features f_i from the VGG convolutional neural network (Simonyan and Zisserman, 2014) on an input image, as follows:

$$\psi(x, i; \theta) = e^{w_x^T f_i + b_x},$$

where w and b are the parameters of an affine transformation layer. The model explicitly captures the correlation between activities and nouns in semantic roles, allowing it to learn common priors. We use a model pretrained on the original task with 504 verbs.

5.2 Multilabel Classification

Dataset We use MS-COCO (Lin et al., 2014), a common object detection benchmark, for multi-label object classification. The dataset contains 80 object types but does not make gender distinctions between man and woman. We use the five associated image captions available for each image in this dataset to annotate the gender of people in the images. If any of the captions mention the word man or woman we mark it, removing any images that mention both genders. Finally, we filter any object category not strongly associated with humans by removing objects that do not occur with man or woman at least 100 times in the training set, leaving a total of 66 objects.

Model For this multi-label setting, we adapt a similar model as the structured CRF we use for vSRL. We decompose the joint probability of the output y, consisting of all object categories, c, and gender of the person, g, given an image i as:

$$p(y|i;\theta) \propto \psi(g,i;\theta) \prod_{c \in y} \psi(g,c,i;\theta)$$

where each potential value for x, is computed using features, f_i, from a pretrained ResNet-50 convolutional neural network evaluated on the image,

$$\psi(x,i;\theta) = e^{w_x^T f_i + b_x}.$$

We trained a model using SGD with learning rate 10^{-5}, momentum 0.9 and weight-decay 10^{-4}, fine tuning the initial visual network, for 50 epochs.

5.3 Calibration

The inference problems for both models are:

$$\arg\max_{y \in Y} f_\theta(y,i) = \log p(y|i;\theta).$$

We use the algorithm in Sec. (4) to calibrate the predictions using model θ. Our calibration tries to enforce gender statistics derived from the training set of corpus applicable for each recognition problem. For all experiments, we try to match gender ratios on the test set within a margin of .05 of their value on the training set. While we do adjust the output on the test set, we never use the ground truth on the test set and instead working from the assumption that it should be similarly distributed as the training set. When running the debiasing algorithm, we set $\eta = 10^{-1}$ and optimize for 100 iterations.

6 Bias Analysis

In this section, we use the approaches outlined in Section 3 to quantify the bias and bias amplification in the vSRL and the MLC tasks.

6.1 Visual Semantic Role Labeling

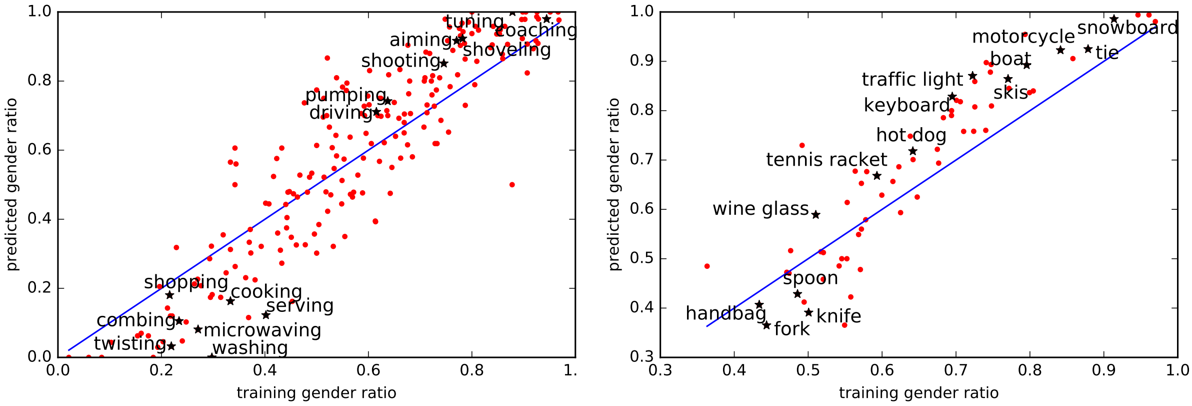
imSitu is gender biased In Figure 2(a), along the x-axis, we show the male favoring bias of imSitu verbs. Overall, the dataset is heavily biased toward male agents, with 64.6% of verbs favoring a male agent by an average bias of 0.707 (roughly 3:1 male). Nearly half of verbs are extremely biased in the male or female direction: 46.95% of verbs favor a gender with a bias of at least 0.7.[6] Figure 2(a) contains several activity labels revealing problematic biases. For example, `shopping`, `microwaving` and `washing` are biased toward a female `agent`. Furthermore, several verbs such as `driving`, `shooting`, and `coaching` are heavily biased toward a male `agent`.

Training on imSitu amplifies bias In Figure 2(a), along the y-axis, we show the ratio of male agents (% of total people) in predictions on an unseen development set. The mean bias amplification in the development set is high, 0.050 on average, with 45.75% of verbs exhibiting amplification. Biased verbs tend to have stronger amplification: verbs with training bias over 0.7 in either the male or female direction have a mean amplification of 0.072. Several already problematic biases have gotten much worse. For example, `serving`, only had a small bias toward females in the training set, 0.402, is now heavily biased toward females, 0.122. The verb `tuning`, originally heavily biased toward males, 0.878, now has exclusively male agents.

6.2 Multilabel Classification

MS-COCO is gender biased In Figure 2(b) along the x-axis, similarly to imSitu, we analyze bias of objects in MS-COCO with respect to males. MS-COCO is even more heavily biased toward men than imSitu, with 86.6% of objects biased toward men, but with smaller average magnitude, 0.65. One third of the nouns are extremely biased toward males, 37.9% of nouns favor men with a bias of at least 0.7. Some problematic examples include kitchen objects such as `knife`, `fork`, or `spoon` being more biased toward woman. Outdoor recreation related objects such `tennis racket`, `snowboard` and `boat` tend to be more biased toward men.

[6] In this gender binary, bias toward `woman` is $1-$ the bias toward `man`



(a) Bias analysis on imSitu vSRL

(b) Bias analysis on MS-COCO MLC

Figure 2: Gender bias analysis of imSitu vSRL and MS-COCO MLC. (a) gender bias of verbs toward `man` in the training set versus bias on a predicted development set. (b) gender bias of nouns toward `man` in the training set versus bias on the predicted development set. Values near zero indicate bias toward `woman` while values near 0.5 indicate unbiased variables. Across both dataset, there is significant bias toward males, and significant bias amplification after training on biased training data.

Training on MS-COCO amplifies bias In Figure 2(b), along the y-axis, we show the ratio of man (% of both gender) in predictions on an unseen development set. The mean bias amplification across all objects is 0.036, with 65.67% of nouns exhibiting amplification. Larger training bias again tended to indicate higher bias amplification: biased objects with training bias over 0.7 had mean amplification of 0.081. Again, several problematic biases have now been amplified. For example, kitchen categories already biased toward females such as `knife`, `fork` and `spoon` have all been amplified. Technology oriented categories initially biased toward men such as `keyboard` and `mouse` have each increased their bias toward males by over 0.100.

6.3 Discussion

We confirmed our hypothesis that (a) both the imSitu and MS-COCO datasets, gathered from the web, are heavily gender biased and that (b) models trained to perform prediction on these datasets amplify the existing gender bias when evaluated on development data. Furthermore, across both datasets, we showed that the degree of bias amplification was related to the size of the initial bias, with highly biased object and verb categories exhibiting more bias amplification. Our results demonstrate that care needs be taken in deploying such uncalibrated systems otherwise they could not only reinforce existing social bias but actually make them worse.

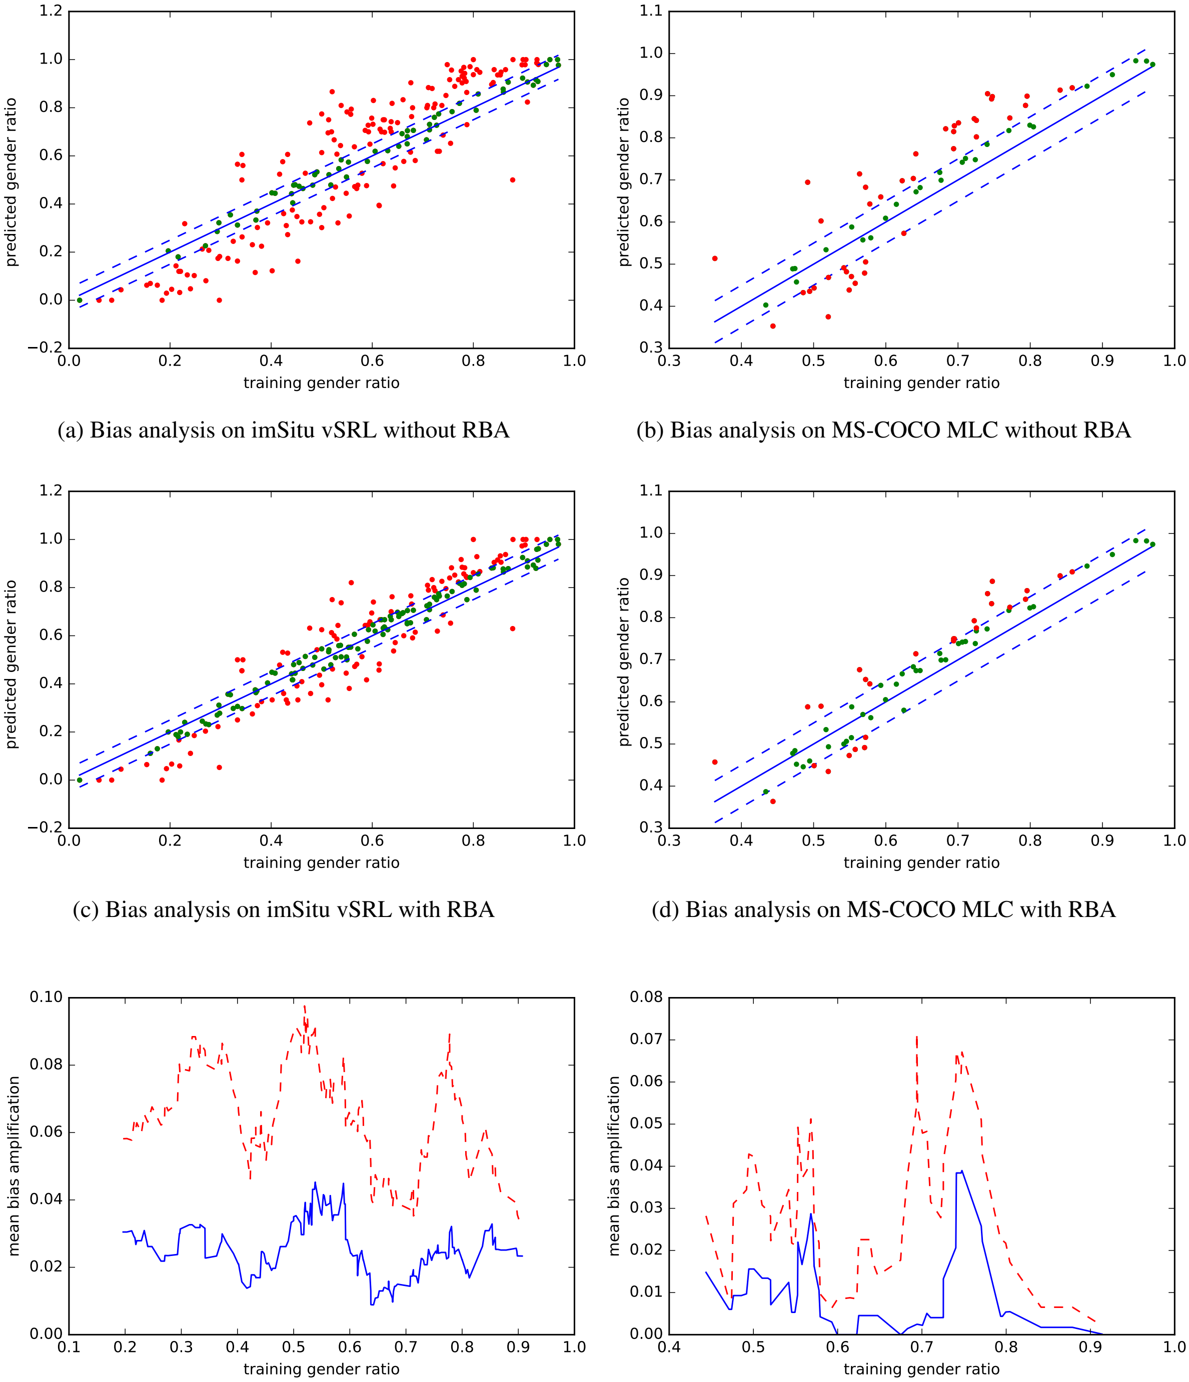
7 Calibration Results

We test our methods for reducing bias amplification in two problem settings: visual semantic role labeling in the imSitu dataset (vSRL) and multilabel image classification in MS-COCO (MLC). In all settings we derive corpus constraints using the training set and then run our calibration method in batch on either the development or testing set. Our results are summarized in Table 2 and Figure 3.

7.1 Visual Semantic Role Labeling

Our quantitative results are summarized in the first two sections of Table 2. On the development set, the number of verbs whose bias exceed the original bias by over 5% decreases 30.5% (Viol.). Overall, we are able to significantly reduce bias amplification in vSRL by 52% on the development set (Amp. bias). We evaluate the underlying recognition performance using the standard measure in vSRL: top-1 semantic role accuracy, which tests how often the correct verb was predicted and the noun value was correctly assigned to a semantic role. Our calibration method results in a negligible decrease in performance (Perf.). In Figure 3(c) we can see that the overall distance to the training set distribution after applying RBA decreased significantly, over 39%.

Figure 3(e) demonstrates that across all initial training bias, RBA is able to reduce bias amplification. In general, RBA struggles to remove bias amplification in areas of low initial training bias,



(a) Bias analysis on imSitu vSRL without RBA

(b) Bias analysis on MS-COCO MLC without RBA

(c) Bias analysis on imSitu vSRL with RBA

(d) Bias analysis on MS-COCO MLC with RBA

(e) Bias in vSRL with (blue) / without (red) RBA

(f) Bias in MLC with (blue) / without (red) RBA

Figure 3: Results of reducing bias amplification using RBA on imSitu vSRL and MS-COCO MLC. Figures 3(a)-(d) show initial training set bias along the x-axis and development set bias along the y-axis. Dotted blue lines indicate the 0.05 margin used in RBA, with points violating the margin shown in red while points meeting the margin are shown in green. Across both settings adding RBA significantly reduces the number of violations, and reduces the bias amplification significantly. Figures 3(e)-(f) demonstrate bias amplification as a function of training bias, with and without RBA. Across all initial training biases, RBA is able to reduce the bias amplification.

Method	Viol.	Amp. bias	Perf. (%)
vSRL: Development Set			
CRF	154	0.050	24.07
CRF + RBA	107	0.024	23.97
vSRL: Test Set			
CRF	149	0.042	24.14
CRF + RBA	102	0.025	24.01
MLC: Development Set			
CRF	40	0.032	45.27
CRF + RBA	24	0.022	45.19
MLC: Test Set			
CRF	38	0.040	45.40
CRF + RBA	16	0.021	45.38

Table 2: Number of violated constraints, mean amplified bias, and test performance before and after calibration using RBA. The test performances of vSRL and MLC are measured by top-1 semantic role accuracy and top-1 mean average precision, respectively.

likely because bias is encoded in image statistics and cannot be removed as effectively with an image agnostic adjustment. Results on the test set support our development set results: we decrease bias amplification by 40.5% (Amp. bias).

7.2 Multilabel Classification

Our quantitative results on MS-COCO RBA are summarized in the last two sections of Table 2. Similarly to vSRL, we are able to reduce the number of objects whose bias exceeds the original training bias by 5%, by 40% (Viol.). Bias amplification was reduced by 31.3% on the development set (Amp. bias). The underlying recognition system was evaluated by the standard measure: top-1 mean average precision, the precision averaged across object categories. Our calibration method results in a negligible loss in performance. In Figure 3(d), we demonstrate that we substantially reduce the distance between training bias and bias in the development set. Finally, in Figure 3(f) we demonstrate that we decrease bias amplification for all initial training bias settings. Results on the test set support our development results: we decrease bias amplification by 47.5% (Amp. bias).

7.3 Discussion

We have demonstrated that RBA can significantly reduce bias amplification. While were not able to remove all amplification, we have made significant progress with little or no loss in underlying recognition performance. Across both problems, RBA was able to reduce bias amplification at all initial values of training bias.

8 Conclusion

Structured prediction models can leverage correlations that allow them to make correct predictions even with very little underlying evidence. Yet such models risk potentially leveraging social bias in their training data. In this paper, we presented a general framework for visualizing and quantifying biases in such models and proposed RBA to calibrate their predictions under two different settings. Taking gender bias as an example, our analysis demonstrates that conditional random fields can amplify social bias from data while our approach RBA can help to reduce the bias.

Our work is the first to demonstrate structured prediction models amplify bias and the first to propose methods for reducing this effect but significant avenues for future work remain. While RBA can be applied to any structured predictor, it is unclear whether different predictors amplify bias more or less. Furthermore, we presented only one method for measuring bias. More extensive analysis could explore the interaction among predictor, bias measurement, and bias deamplification method. Future work also includes applying bias reducing methods in other structured domains, such as pronoun reference resolution (Mitkov, 2014).
