It remains an open question whether it is better to use a model with a smaller accuracy disparity (e.g. UDPipe), or a model with higher average accuracy, but a worse disparity (e.g. Deep Biaffine). The emerging literature on fairness in algorithms suggests interesting further challenges; for example, Kleinberg et al. (2017) and Corbett-Davies et al. (2017) argue that as various commonly applied notions of fairness are mutually incompatible, algorithm designers must grapple with such trade-offs. Regardless, the modeling decision should be made in light of the application of interest; for example, applications like opinion analysis and information retrieval may benefit from equal (and possibly weaker) performance between groups, so that concepts or opinions inferred from groups of authors (e.g. AAE speakers) are not under-counted or under-represented in results returned to a user or analyst.

Abstract

Language exhibits hierarchical structure, but recent work using a subject-verb agreement diagnostic argued that state-of-the-art language models, LSTMs, fail to learn long-range syntax-sensitive dependencies. Using the same diagnostic, we show that, in fact, LSTMs do succeed in learning such dependencies—provided they have enough capacity. We then explore whether models that have access to explicit syntactic information learn agreement more effectively, and how the way in which this structural information is incorporated into the model impacts performance. We find that the mere presence of syntactic information does not improve accuracy, but when model architecture is determined by syntax, number agreement is improved. Further, we find that the choice of *how* syntactic structure is built affects how well number agreement is learned: top-down construction outperforms left-corner and bottom-up variants in capturing long-distance structural dependencies.

1 Introduction

Recurrent neural networks (RNNs) are remarkably effective models of sequential data. Recent years have witnessed the widespread adoption of recurrent architectures such as LSTMs (Hochreiter and Schmidhuber, 1997) in various NLP tasks, with state of the art results in language modeling (Melis et al., 2018) and conditional generation tasks like machine translation (Bahdanau et al., 2015) and text summarization (See et al., 2017).

Here we revisit the question asked by Linzen et al. (2016): as RNNs model word sequences without explicit notions of hierarchical structure,

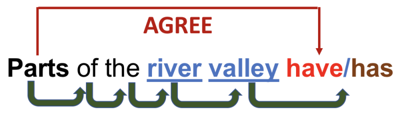

Figure 1: An example of the number agreement task with two attractors and a subject-verb distance of five.

to what extent are these models able to learn non-local syntactic dependencies in natural language? Identifying number agreement between subjects and verbs—especially in the presence of *attractors*—can be understood as a cognitively-motivated probe that seeks to distinguish hierarchical theories from sequential ones, as models that rely on sequential cues like the most recent noun would favor the incorrect verb form. We provide an example of this task in Fig. 1, where the plural form of the verb ***have*** agrees with the distant subject ***parts***, rather than the adjacent attractors (underlined) of the singular form.

Contrary to the findings of Linzen et al. (2016), our experiments suggest that sequential LSTMs are able to capture structural dependencies to a large extent, even for cases with multiple attractors (§2). Our finding suggests that network capacity plays a crucial role in capturing structural dependencies with multiple attractors. Nevertheless, we find that a strong character LSTM language model—which lacks explicit word representation and has to capture much longer sequential dependencies in order to learn non-local structural dependencies effectively—performs much worse in the number agreement task.

Given the strong performance of word-based LSTM language models, are there are any substantial benefits, in terms of number agreement accuracy, to explicitly modeling hierarchical structures as an inductive bias? We discover that a certain class of LSTM language models that explicitly models syntactic structures, the recurrent neural network grammars (Dyer et al., 2016, RNNGs), considerably outperforms sequential LSTM language models for cases with multiple attractors (§3). We present experiments affirming that this gain is due to an explicit *composition* operator rather than the presence of predicted syntactic annotations. Rather surprisingly, syntactic LSTM language models without explicit composition have no advantage over sequential LSTMs that operate on word sequences, although these models can nevertheless be excellent predictors of phrase structures (Choe and Charniak, 2016).

Having established the importance of modeling structures, we explore the hypothesis that *how* we build the structure affects the model's ability to identify structural dependencies in English. As RNNGs build phrase-structure trees through top-down operations, we propose extensions to the structure-building sequences and model architecture that enable left-corner (Henderson, 2003, 2004) and bottom-up (Chelba and Jelinek, 2000; Emami and Jelinek, 2005) generation orders (§4).

Extensive prior work has characterized top-down, left-corner, and bottom-up *parsing* strategies in terms of cognitive plausibility (Pulman, 1986; Abney and Johnson, 1991; Resnik, 1992) and neurophysiological evidence in human sentence processing (Nelson et al., 2017). Here we move away from the realm of parsing and evaluate the three strategies as models of *generation* instead, and address the following empirical question: which generation order is most appropriately biased to model structural dependencies in English, as indicated by number agreement accuracy? Our key finding is that the top-down generation outperforms left-corner and bottom-up variants for difficult cases with multiple attractors.

In theory, the three traversal strategies approximate the same chain rule that decompose the joint probability of words and phrase-structure trees, denoted as $p(\boldsymbol{x}, \boldsymbol{y})$, differently and as such will impose different biases on the learner. In §4.3, we show that the three variants achieve similar perplexities on a held-out validation set. As we observe different patterns in number agreement, this demonstrates that while perplexity can be a useful diagnostic tool, it may not be sensitive enough for comparing models in terms of how well they capture grammatical intuitions.

2 Number Agreement with LSTM Language Models

We revisit the number agreement task with LSTMs trained on language modeling objectives, as proposed by Linzen et al. (2016).

Experimental Settings. We use the same parsed Wikipedia corpus, verb inflectors, preprocessing steps, and dataset split as Linzen et al. (2016).[1] Word types beyond the most frequent 10,000 are converted to their respective POS tags. We summarize the corpus statistics of the dataset, along with the test set distribution of the number of attractors, in Table 1. Similar to Linzen et al. (2016), we only include test cases where *all* intervening nouns are of the opposite number forms than the subject noun. All models are implemented using the DyNet library (Neubig et al., 2017).

	Train	**Test**
Sentences	141,948	1,211,080
Types	10,025	10,025
Tokens	3,159,622	26,512,851

# Attractors	**# Instances**	**% Instances**
$n = 0$	1,146,330	94.7%
$n = 1$	52,599	4.3%
$n = 2$	9,380	0.77%
$n = 3$	2,051	0.17%
$n = 4$	561	0.05%
$n = 5$	159	0.01%

Table 1: Corpus statistics of the Linzen et al. (2016) number agreement dataset.

Training was done using a language modeling objective that predicts the next word given the prefix; at test time we compute agreement error rates by comparing the probability of the correct verb form with the incorrect one. We report performance of a few different LSTM hidden layer configurations, while other hyper-parameters are selected based on a grid search.[2] Following Linzen

[1]The dataset and scripts are obtained from `https://github.com/TalLinzen/rnn_agreement`.

[2]Based on the grid search results, we used the following hyper-parameters that work well across different hidden layer sizes: 1-layer LSTM, SGD optimizers with an initial learning rate of 0.2, a learning rate decay of 0.10 after 10 epochs, LSTM dropout rates of 0.2, an input embedding dimension of 50, and a batch size of 10 sentences. Our use of single-layer LSTMs and 50-dimensional word embedding (learned from scratch) as one of the baselines is consistent with the experimental settings of Linzen et al. (2016).

	n=0	n=1	n=2	n=3	n=4
Random	50.0	50.0	50.0	50.0	50.0
Majority	32.0	32.0	32.0	32.0	32.0
LSTM, H=50†	6.8	32.6	$\approx$50	$\approx$65	$\approx$70
Our LSTM, H=50	2.4	8.0	15.7	26.1	34.65
Our LSTM, H=150	1.5	4.5	9.0	14.3	17.6
Our LSTM, H=250	1.4	3.3	5.9	**9.7**	13.9
Our LSTM, H=350	**1.3**	**3.0**	**5.7**	**9.7**	**13.8**
1B Word LSTM (repl)	2.8	8.0	14.0	21.8	20.0
Char LSTM	**1.2**	5.5	11.8	20.4	27.8

Table 2: Number agreement error rates for various LSTM language models, broken down by the number of attractors. The top two rows represent the random and majority class baselines, while the next row (†) is the reported result from Linzen et al. (2016) for an LSTM language model with 50 hidden units (some entries, denoted by $\approx$, are approximately derived from a chart, since Linzen et al. (2016) did not provide a full table of results). We report results of our LSTM implementations of various hidden layer sizes, along with our re-run of the Jozefowicz et al. (2016) language model, in the next five rows. We lastly report the performance of a state of the art character LSTM baseline with a large model capacity (Melis et al., 2018).

et al. (2016), we include the results of our replication[3] of the large-scale language model of Jozefowicz et al. (2016) that was trained on the One Billion Word Benchmark.[4] Hyper-parameter tuning is based on validation set perplexity.

Discussion. Table 2 indicates that, given enough capacity, LSTM language models without explicit syntactic supervision are able to perform well in number agreement. For cases with multiple attractors, we observe that the LSTM language model with 50 hidden units trails behind its larger counterparts by a substantial margin despite comparable performance for zero attractor cases, suggesting that network capacity plays an especially important role in propagating relevant structural information across a large number of steps.[5] Our experiment independently derives the same finding as the recent work of Gulordava et al. (2018), who also find that LSTMs trained with language modeling objectives are able to learn number agreement well; here we additionally identify model capacity as one of the reasons for the discrepancy with the Linzen et al. (2016) results.

While the pretrained large-scale language model of Jozefowicz et al. (2016) has certain advantages in terms of model capacity, more training data, and richer vocabulary, we suspect that the poorer performance is due to differences between their training domain and the number agreement testing domain, although the model still performs reasonably well in the number agreement test set.

Prior work has confirmed the notion that, in many cases, statistical models are able to achieve good performance under some aggregate metric by overfitting to patterns that are predictive in *most* cases, often at the expense of more difficult, infrequent instances that require deeper language understanding abilities (Rimell et al., 2009; Jia and Liang, 2017). In the vast majority of cases, structural dependencies between subjects and verbs highly overlap with sequential dependencies (Table 1). Nevertheless, the fact that number agreement accuracy gets worse as the number of attractors increases is consistent with a *sequential recency* bias in LSTMs: under this conjecture, identifying the correct structural dependency becomes harder when there are more adjacent nouns of different number forms than the true subject.

If the sequential recency conjecture is correct, then LSTMs would perform worse when the structural dependency is more distant in the sequences, compared to cases where the structural dependency is more adjacent. We empirically test this conjecture by running a strong character-based LSTM language model of Melis et al. (2018) that achieved state of the art results on EnWiki8 from the Hutter Prize dataset (Hutter, 2012), with 1,800 hidden units and 10 million parameters. The character LSTM is trained, validated, and tested[6] on the same split of the Linzen et al. (2016) number agreement dataset.

A priori, we expect that number agreement is harder for character LSTMs for two reasons. First, character LSTMs lack explicit word representa-

[3]When evaluating the large-scale language model, the primary difference is that we do not map infrequent word types to their POS tags and that we subsample to obtain 500 test instances of each number of attractor due to computation cost; both preprocessing were also done by Linzen et al. (2016).

[4]The pretrained large-scale language model is obtained from `https://github.com/tensorflow/models/tree/master/research/lm_1b`.

[5]This trend is also observed by comparing results with H=150 and H=250. While both models achieve near-identical performance for zero attractor, the model with H=250 performs much better for cases with multiple attractors.

[6]For testing, we similarly evaluate number agreement accuracy by comparing the probability of the correct and incorrect verb form given the prefix, as represented by the respective character sequences.

tions, thus succeeding in this task requires identifying structural dependencies between two *sequences* of character tokens, while word-based LSTMs only need to resolve dependencies between *word tokens*. Second, by nature of modeling characters, non-local structural dependencies are sequentially further apart than in the word-based language model. On the other hand, character LSTMs have the ability to exploit and share informative morphological cues, such as the fact that plural nouns in English tend to end with '*s*'.

As demonstrated on the last row of Table 2, we find that the character LSTM language model performs much worse at number agreement with multiple attractors compared to its word-based counterparts. This finding is consistent with that of Sennrich (2017), who find that character-level decoders in neural machine translation perform worse than subword models in capturing morphosyntactic agreement. To some extent, our finding demonstrates the limitations that character LSTMs face in learning structure from language modeling objectives, despite earlier evidence that character LSTM language models are able to implicitly acquire a lexicon (Le Godais et al., 2017).

3 Number Agreement with RNNGs

Given the strong performance of sequential LSTMs in number agreement, is there any further benefit to explicitly modeling hierarchical structures? We focus on recurrent neural network grammars (Dyer et al., 2016, RNNGs), which jointly model the probability of phrase-structure trees and strings, $p(\boldsymbol{x}, \boldsymbol{y})$, through structure-building actions and explicit compositions for representing completed constituents.

Our choice of RNNGs is motivated by the findings of Kuncoro et al. (2017), who find evidence for syntactic headedness in RNNG phrasal representations. Intuitively, the ability to learn heads is beneficial for this task, as the representation for the noun phrase "*The* ***flowers*** *in the* *vase*" would be similar to the syntactic head ***flowers*** rather than *vase*. In some sense, the composition operator can be understood as injecting a *structural recency* bias into the model design, as subjects and verbs that are sequentially apart are encouraged to be close together in the RNNGs' representation.

3.1 Recurrent Neural Network Grammars

RNNGs (Dyer et al., 2016) are language models that estimate the *joint* probability of string terminals and phrase-structure tree nonterminals. Here we use stack-only RNNGs that achieve better perplexity and parsing performance (Kuncoro et al., 2017). Given the current stack configuration, the objective function of RNNGs is to predict the correct structure-building operation according to a top-down, left-to-right traversal of the phrase-structure tree; a partial traversal for the input sentence "*The flowers in the vase are blooming*" is illustrated in Fig. 3(a).[7]

The structural inductive bias of RNNGs derives from an explicit *composition* operator that represents completed constituents; for instance, the constituent (NP *The flowers*) is represented by a single composite element on the stack, rather than as four separate symbols. During each REDUCE action, the topmost stack elements that belong to the new constituent are popped from the stack and then composed by the composition function; the composed symbol is then pushed back into the stack. The model is trained in an end-to-end manner by minimizing the cross-entropy loss relative to a sample of gold trees.

3.2 Experiments

Here we summarize the experimental settings of running RNNGs on the number agreement dataset and discuss the empirical findings.

Experimental settings. We obtain phrase-structure trees for the Linzen et al. (2016) dataset using a publicly available discriminative model[8] trained on the Penn Treebank (Marcus et al., 1993). At training time, we use these predicted trees to derive action sequences on the training set, and train the RNNG model on these sequences.[9] At test time, we compare the probabilities of the correct and incorrect verb forms given the prefix, which now includes both nonterminal and terminal symbols. An example of the stack contents (i.e. the prefix) when predicting the verb is provided in Fig. 3(a). We similarly run a grid search over the same hyper-parameter range as the sequential

[7]For a complete example of action sequences, we refer the reader to the example provided by Dyer et al. (2016).

[8]`https://github.com/clab/rnng`

[9]Earlier work on RNNGs (Dyer et al., 2016; Kuncoro et al., 2017) train the model on gold phrase-structure trees on the Penn Treebank, while here we train the RNNG on the number agreement dataset based on predicted trees from another parser.

LSTM and compare the results with the strongest sequential LSTM baseline from §2.

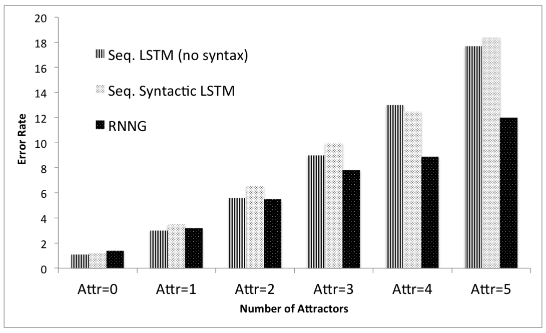

Figure 2: Number agreement error rates for sequential LSTM language models (left), sequential syntactic LSTM language models (Choe and Charniak, 2016, center), and RNNGs (right).

Discussion. Fig. 2 shows that RNNGs (rightmost) achieve much better number agreement accuracy compared to LSTM language models (leftmost) for difficult cases with four and five attractors, with around 30% error rate reductions, along with a 13% error rate reduction (from 9% to 7.8%) for three attractors. We attribute the slightly worse performance of RNNGs on cases with zero and one attractor to the presence of intervening structure-building actions that separate the subject and the verb, such as a REDUCE (step 6 in Fig. 3(a)) action to complete the noun phrase and at least one action to predict a verb phrase (step 15 in Fig. 3(a)) before the verb itself is introduced, while LSTM language models benefit from shorter dependencies for zero and one attractor cases.

The performance gain of RNNGs might arise from two potential causes. First, RNNGs have access to predicted syntactic annotations, while LSTM language models operate solely on word sequences. Second, RNNGs incorporate explicit compositions, which encourage hierarhical representations and potentially the discovery of syntactic (rather than sequential) dependencies.

Would LSTMs that have access to syntactic annotations, but without the explicit composition function, benefit from the same performance gain as RNNGs? To answer this question, we run sequential LSTMs over the same phrase-structure trees (Choe and Charniak, 2016), similarly estimating the joint probability of phrase-structure nonterminals and string terminals but without an explicit composition operator. Taking the example in Fig. 3(a), the sequential syntactic LSTM would have fifteen[10] symbols on the LSTM when predicting the verb, as opposed to three symbols in the case of RNNGs' stack LSTM. In theory, the sequential LSTM over the phrase-structure trees (Choe and Charniak, 2016) may be able to incorporate a similar, albeit implicit, composition process as RNNGs and consequently derive similarly syntactic heads, although there is no inductive bias that explicitly encourages such process.

Fig. 2 suggests that the sequential syntactic LSTMs (center) perform comparably with sequential LSTMs without syntax for multiple attractor cases, and worse than RNNGs for nearly all attractors; the gap is highest for multiple attractors. This result showcases the importance of an explicit composition operator and hierarchical representations in identifying structural dependencies, as indicated by number agreement accuracy. Our finding is consistent with the recent work of Yogatama et al. (2018), who find that introducing elements of hierarchical modeling through a stack-structured memory is beneficial for number agreement, outperforming LSTM language models and attention-augmented variants by increasing margins as the number of attractor grows.

3.3 Further Analysis

In order to better interpret the results, we conduct further analysis into the perplexities of each model, followed by a discussion on the effect of incrementality constraints on the RNNG when predicting number agreement.

Perplexity. To what extent does the success of RNNGs in the number agreement task with multiple attractors correlate with better performance under the perplexity metric? We answer this question by using an importance sampling marginalization procedure (Dyer et al., 2016) to obtain an estimate of $p(\boldsymbol{x})$ under both RNNGs and the sequential syntactic LSTM model. Following Dyer et al. (2016), for each sentence on the validation set we sample 100 candidate trees from a discriminative model[11] as our proposal distribution. As demonstrated in Table 3, the LSTM language model has the lowest validation set perplexity despite substantially worse performance than RNNGs in number agreement with multiple attractors, suggesting that lower perplexity is not neces-

[10]In the model of Choe and Charniak (2016), each nonterminal, terminal, and closed parenthesis symbol is represented as an element on the LSTM sequence.

[11]`https://github.com/clab/rnng`

sarily correlated with number agreement success.

	Validation ppl.
LSTM LM	**72.6**
Seq. Syntactic LSTM	79.2
RNNGs	77.9

Table 3: Validation set perplexity of LSTM language model, sequential syntactic LSTM, and RNNGs.

Incrementality constraints. As the syntactic prefix was derived from a discriminative model that has access to unprocessed words, one potential concern is that this prefix might violate the incrementality constraints and benefit the RNNG over the LSTM language model. To address this concern, we remark that the empirical evidence from Fig. 2 and Table 3 indicates that the LSTM language model *without* syntactic annotation outperforms the sequential LSTM *with* syntactic annotation in terms of both perplexity and number agreement throughout nearly all attractor settings, suggesting that the predicted syntactic prefix does not give any unfair advantage to the syntactic models.

Furthermore, we run an experiment where the syntactic prefix is instead derived from an incremental beam search procedure of Fried et al. (2017).[12] To this end, we take the highest scoring beam entry at the time that the verb is generated to be the syntactic prefix; this procedure is applied to both the correct and incorrect verb forms.[13] We then similarly compare the probabilities of the correct and incorrect verb form given each respective syntactic prefix to obtain number agreement accuracy. Our finding suggests that using the fully incremental tree prefix leads to even *better* RNNG number agreement performance for four and five attractors, achieving 7.1% and 8.2% error rates, respectively, compared to 9.4% and 12% for the RNNG error rates in Fig. 2.

4 Top-Down, Left-Corner, and Bottom-Up Traversals

In this section, we propose two new variants of RNNGs that construct trees using a different construction order than the top-down, left-to-right order used above. These are a bottom-up construction order (§4.1) and a left-corner construction order (§4.2), analogous to the well-known parsing strategies (e.g. Hale, 2014, chapter 3). They differ from these classic strategies insofar as they do not announce the phrase-structural content of an entire branch at the same time, adopting instead a node-by-node enumeration reminescent of Markov Grammars (Charniak, 1997). This step-by-step arrangement extends to the derived string as well; since all variants generate words from left to right, the models can be compared using number agreement as a diagnostic.[14]

Here we state our hypothesis on why the build order matters. The three generation strategies represent different chain rule decompositions of the joint probability of strings and phrase-structure trees, thereby imposing different biases on the learner. Earlier work in *parsing* has characterized the plausibility of top-down, left-corner, and bottom-up strategies as viable candidates of human sentence processing, especially in terms of memory constraints and human difficulties with center embedding constructions (Johnson-Laird, 1983; Pulman, 1986; Abney and Johnson, 1991; Resnik, 1992, *inter alia*), along with neurophysiological evidence in human sentence processing (Nelson et al., 2017). Here we cast the three strategies as models of language generation (Manning and Carpenter, 1997), and focus on the empirical question: which generation order has the most appropriate bias in modeling non-local structural dependencies in English?

These alternative orders organize the learning problem so as to yield intermediate states in generation that condition on different aspects of the grammatical structure. In number agreement, this amounts to making an agreement controller, such as the word *flowers* in Fig. 3, more or less salient. If it is more salient, the model should be better-able to inflect the main verb in agreement with this controller, without getting distracted by the attractors. The three proposed build orders are compared in Fig. 3, showing the respective configurations (i.e. the prefix) when generating the main verb in a sentence with a single attractor.[15] In ad-

[12]As the beam search procedure is time-consuming, we randomly sample 500 cases for each attractor and compute the number agreement accuracy on these samples.

[13]Consequently, the correct and incorrect forms of the sentence might have different partial trees, as the highest scoring beam entries may be different for each alternative.

[14]Only the order in which these models build the nonterminal symbols is different, while the terminal symbols are still generated in a left-to-right manner in all variants.

[15]Although the stack configuration at the time of verb generation varies only slightly, the configurations encountered

dition, we show concrete action sequences for a simpler sentence in each section.

4.1 Bottom-Up Traversal

In bottom-up traversals, phrases are recursively constructed and labeled with the nonterminal type once all their daughters have been built, as illustrated in Fig. 4. Bottom-up traversals benefit from shorter stack depths compared to top-down due to the lack of incomplete nonterminals. As the commitment to label the nonterminal type of a phrase is delayed until its constituents are complete, this means that the generation of a child node cannot condition on the label of its parent node.

In n-ary branching trees, bottom-up completion of constituents requires a procedure for determining how many of the most recent elements on the stack should be daughters of the node that is being constructed.[16] Conceptually, rather than having a single REDUCE operation as we have before, we have a complex REDUCE(X, n) operation that must determine the type of the constituent (i.e., X) as well as the number of daughters (i.e., n).

In step 5 of Fig. 4, the newly formed NP constituent only covers the terminal *worms*, and neither the unattached terminal *eats* nor the constituent (NP *The fox*) is part of the new noun phrase. We implement this extent decision using a stick-breaking construction—using the stack LSTM encoding, a single-layer feedforward network, and a logistic output layer—which decides whether the top element on the stack should be the leftmost child of the new constituent (i.e. whether or not the new constituent is complete after popping the current topmost stack element), as illustrated in Fig. 5. If not, the process is then repeated after the topmost stack element is popped. Once the extent of the new nonterminal has been decided, we parameterize the decision of the nonterminal label type; in Fig. 5 this is an NP. A second difference to top-down generation is that when a single constituent remains on the stack, the sentence is not necessarily complete (see step 3 of Fig. 4 for examples where this happens). We thus introduce an explicit STOP action (step 8, Fig. 4), indicating the tree is complete, which is only assigned non-zero probability when the stack has a single complete constituent.

during the history of the full generation process vary considerably in the invariances and the kinds of actions they predict.

[16]This mechanism is not necessary with strictly binary branching trees, since each new nonterminal always consists of the two children at the top of the stack.

	Avg. stack depth	**Ppl.**
TD	12.29	94.90
LC	11.45	95.86
BU	7.41	96.53

Table 4: Average stack depth and validation set perplexity for top-down (TD), left-corner (LC), and bottom-up (BU) RNNGs.

4.2 Left-Corner Traversal

Left-corner traversals combine some aspects of top-down and bottom-up processing. As illustrated in Fig. 6, this works by first generating the leftmost terminal of the tree, *The* (step 0), before proceeding bottom-up to predict its parent NP (step 1) and then top-down to predict the rest of its children (step 2). A REDUCE action similarly calls the composition operator once the phrase is complete (e.g. step 3). The complete constituent (NP *The fox*) is the leftmost child of its parent node, thus an NT_SW(S) action is done next (step 4).

The NT_SW(X) action is similar to the NT(X) from the top-down generator, in that it introduces an open nonterminal node and must be matched later by a corresponding REDUCE operation, but, in addition, swaps the two topmost elements at the top of the stack. This is necessary because the parent nonterminal node is not built until after its left-most child has been constructed. In step 1 of Fig. 6, with a single element *The* on the stack, the action NT_SW(NP) adds the open nonterminal symbol NP to become the topmost stack element, but after applying the swap operator the stack now contains (NP | *The* (step 2).

4.3 Experiments

We optimize the hyper-parameters of each RNNG variant using grid searches based on validation set perplexity. Table 4 summarizes average stack depths and perplexities[17] on the Linzen et al. (2016) validation set. We evaluate each of the variants in terms of number agreement accuracy as an evidence of its suitability to model structural dependencies in English, presented in Table 5. To account for randomness in training, we report the error rate summary statistics of ten different runs.

[17]Here we measure perplexity over $p(\boldsymbol{x}, \boldsymbol{y})$, where y is the presumptive gold tree on the Linzen et al. (2016) dataset. Dyer et al. (2016) instead used an importance sampling procedure to marginalize and obtain an estimate of $p(\boldsymbol{x})$.

Figure 6: Example Derivation for left-corner traversal. Each NT_SW(X) action adds the open nonterminal symbol (X to the stack, followed by a deterministic **swap** operator that swaps the top two elements on the stack.

Discussion. In Table 5, we focus on empirical results for cases where the structural dependencies matter the most, corresponding to cases with two, three, and four attractors. All three RNNG variants outperform the sequential LSTM language model baseline for these cases. Nevertheless, the top-down variant outperforms both left-corner and bottom-up strategies for difficult cases with three or more attractors, suggesting that the top-down strategy is most appropriately biased to model difficult number agreement dependencies in English. We run an approximate randomization test by stratifying the output and permuting within each stratum (Yeh, 2000) and find that, for four attractors, the performance difference between the top-down RNNG and the other variants is statistically significant at $p < 0.05$.

The success of the top-down traversal in the domain of number-agreement prediction is consistent with a classical view in parsing that argues top-down parsing is the most human-like parsing strategy since it is the most *anticipatory*. Only anticipatory representations, it is said, could explain the rapid, incremental processing that humans seem to exhibit (Marslen-Wilson, 1973; Tanenhaus et al., 1995); this line of thinking similarly motivates Charniak (2010), among others. While most work in this domain has been concerned with the parsing problem, our findings suggest that anticipatory mechanisms are also beneficial in capturing structural dependencies in language modeling. We note that our results are achieved using models that, in theory, are able to condition on the entire derivation history, while earlier work in sentence processing has focused on cognitive memory considerations, such as the memory-bounded model of Schuler et al. (2010).

5 Conclusion

Given enough capacity, LSTMs trained on language modeling objectives are able to learn syntax-sensitive dependencies, as evidenced by accurate number agreement accuracy with multiple attractors. Despite this strong performance, we discover explicit modeling of structure does improve the model's ability to discover non-local structural dependencies when determining the distribution over subsequent word generation. Recurrent neural network grammars (RNNGs), which jointly model phrase-structure trees and strings and employ an explicit composition operator, substantially outperform LSTM language models and syntactic language models without explicit compositions; this highlights the importance of a hierarchical inductive bias in capturing structural dependencies. We explore the possibility that how the structure is built affects number agreement performance. Through novel extensions to RNNGs that enable the use of left-corner and bottom-up generation strategies, we discover that this is indeed the case: the three RNNG variants have different generalization properties for number agreement, with the top-down traversal strategy performing best for cases with multiple attractors.

Abstract

Existing solutions to task-oriented dialogue systems follow pipeline designs which introduce architectural complexity and fragility. We propose a novel, holistic, extendable framework based on a single sequence-to-sequence (seq2seq) model which can be optimized with supervised or reinforcement learning. A key contribution is that we design text spans named *belief spans* to track dialogue believes, allowing task-oriented dialogue systems to be modeled in a seq2seq way. Based on this, we propose a simplistic *Two Stage CopyNet* instantiation which demonstrates good scalability: significantly reducing model complexity in terms of number of parameters and training time by an order of magnitude. It significantly outperforms state-of-the-art pipeline-based methods on two datasets and retains a satisfactory entity match rate on out-of-vocabulary (OOV) cases where pipeline-designed competitors totally fail.

1 Introduction

The challenge of achieving both task completion and human-like response generation for task-oriented dialogue systems is gaining research interest. Wen et al. (2017b, 2016a, 2017a) pioneered a set of models to address this challenge. Their proposed architectures follow traditional pipeline designs, where the belief tracking component is the key component (Chen et al., 2017).

In the current paradigm, such a belief tracker builds a complex multi-class classifier for each slot (See §3.2) which can suffer from high complexity, especially when the number of slots and their values grow. Since all the possible slot values have to be pre-defined as classification labels, such trackers also cannot handle the requests that have out-of-vocabulary (OOV) slot values. Moreover, the belief tracker requires delexicalization, i.e., replacing slot values with their slot names in utterances (Mrkšić et al., 2017). It does not scale well, due to the lexical diversity. The belief tracker also needs to be pre-trained, making the models unrealistic for end-to-end training (Eric and Manning, 2017a). While Eric and Manning (2017a,b) investigated building task-oriented dialogue systems by using a seq2seq model, unfortunately, their methods are rather preliminary and do not perform well in either task completion or response generation, due to their omission of a belief tracker.

Questioning the basic pipeline architecture, in this paper, we re-examine the tenets of belief tracking in light of advances in deep learning. We introduce the concept of a *belief span* (bspan), a text span that tracks the belief states at each turn. This leads to a new framework, named *Sequicity*, with a single seq2seq model. Sequicity decomposes the task-oriented dialogue problem into the generation of bspans and machine responses, converting this problem into a sequence optimization problem. In practice, Sequicity decodes in two stages: in the first stage, it decodes a bspan to facilitate knowledge base (KB) search; in the second, it decodes a machine response on the condition of knowledge base search result and the bspan.

Our method represents a shift in perspective compared to existing work. Sequicity employs a single seq2seq model, resulting in a vastly simplified architecture. Unlike previous approaches with an overly parameterized delexicalization-based belief tracker, Sequicity achieves much less train-

[*] Work performed during an internship at Data Science Lab, JD.com.

ing time, better performance on larger a dataset and an exceptional ability to handle OOV cases. Furthermore, Sequicity is a theoretically and aesthetically appealing framework, as it achieves true end-to-end trainability using only one seq2seq model. As such, Sequicity leverages the rapid development of seq2seq models (Gehring et al., 2017; Vaswani et al., 2017; Yu et al., 2017) in developing solutions to task-oriented dialogue scenarios. In our implementation, we improve on CopyNet (Gu et al., 2016) to instantiate Sequicity framework in this paper, as key words present in bspans and machine responses recur from previous utterances. Extensive experiments conducted on two benchmark datasets verify the effectiveness of our proposed method.

Our contributions are fourfold: (1) We propose the *Sequicity* framework, which handles both task completion and response generation in a single seq2seq model; (2) We present an implementation of the Sequicity framework, called *Two Stage CopyNet* (*TSCP*), which has fewer number of parameters and trains faster than state-of-the-art baselines (Wen et al., 2017b, 2016a, 2017a); (3) We demonstrate that TSCP significantly outperforms state-of-the-art baselines on two large-scale datasets, inclusive of scenarios involving OOV; (4) We release source code of TSCP to assist the community to explore Sequicity[1].

2 Related Work

Historically, task-oriented dialog systems have been built as pipelines of separately trained modules. A typical pipeline design contains four components: 1) a user intent classifier, 2) a belief tracker, 3) a dialogue policy maker and a 4) response generator. User intent detectors classify user utterances to into one of the pre-defined intents. SVM, CNN and RNN models (Silva et al., 2011; Hashemi et al., 2016; Shi et al., 2016) perform well for intent classification. Belief trackers, which keep track of user goals and constraints every turn (Henderson et al., 2014a,b; Kim et al., 2017) are the most important component for task accomplishment. They model the probability distribution of values over each slot (Lee, 2013). Dialogue policy makers then generate the next available system action. Recent experiments suggest that reinforcement learning is a promising paradigm to accomplish this task (Young et al., 2013a; Cuayáhuitl et al., 2015; Liu and Lane, 2017), when state and action spaces are carefully designed (Young et al., 2010). Finally, in the response generation stage, pipeline designs usually pre-define fixed templates where placeholders are filled with slot values at runtime (Dhingra et al., 2017; Williams et al., 2017; Henderson et al., 2014b,a). However, this causes rather static responses that could lower user satisfaction. Generating a fluent, human-like response is considered a separate topic, typified by the topic of conversation systems (Li et al., 2015).

3 Preliminaries

3.1 Encoder-Decoder Seq2seq Models

Current seq2seq models adopt encoder–decoder structures. Given a source sequence of tokens $X = x_1 x_2 ... x_n$, an encoder network represent X as hidden states: $\mathbf{H}^{(x)} = \mathbf{h}_1^{(x)}\mathbf{h}_2^{(x)}...\mathbf{h}_n^{(x)}$. Based on $\mathbf{H}^{(x)}$, a decoder network generates a target sequence of tokens $Y = y_1 y_2 ... y_m$ whose likelihood should be maximized given the training corpus.

As of late, the recurrent neural network with attention (Att-RNN) is now considered a baseline encoder–decoder architecture. Such networks employ two (sometimes identical) RNNs, one for encoding (i.e., generating $\mathbf{H}^{(x)}$) and another for decoding. Particularly, for decoding y_j, the decoder RNN takes the embedding $\mathbf{y}_{j-1}$ to generate a hidden vector $\mathbf{h}_j^{(y)}$. Afterwards, the decoder attends to X: calculating attention scores between all $\mathbf{h}_i^{(x)} \in \mathbf{H}^{(x)}$ and $\mathbf{h}_j^{(y)}$ (Eq. (1)), and then sums all $\mathbf{h}_i^{(x)}$, weighted by their corresponding attention scores (Eqs. (2)). The summed result $\tilde{\mathbf{h}}_j^{(x)}$ concatenates $\mathbf{h}_j^{(y)}$ as a single vector which is mapped into an output space for a $softmax$ operation (Eq. (3)) to decode the current token:

$$u_{ij} = \mathbf{v}^T tanh(\mathbf{W}_1 \mathbf{h}_i^{(x)} + \mathbf{W}_2 \mathbf{h}_j^{(y)}) \quad (1)$$

$$\tilde{\mathbf{h}}_j^{(x)} = \sum_{i=1}^{n} \frac{e^{u_{ij}}}{\sum_i e^{u_{ij}}} \mathbf{h}_i^{(x)} \quad (2)$$

$$y_j = softmax(\mathbf{O} \begin{bmatrix} \tilde{\mathbf{h}}_j^{(x)} \\ \mathbf{h}_j^{(y)} \end{bmatrix}) \quad (3)$$

where $\mathbf{v} \in \mathbb{R}^{1\times l}$; $\mathbf{W}_1$, $\mathbf{W}_2 \in \mathbb{R}^{l\times d}$ and $\mathbf{O} \in \mathbb{R}^{|V|\times d}$. d is embedding size and V is vocabulary set and $|V|$ is its size.

3.2 Belief Trackers

In the multi-turn scenarios, a belief tracker is the key component for task completion as it records key information from past turns (Wen et al., 2017b; Henderson et al., 2013, 2014a,b). Early belief trackers are designed as Bayesian networks where each node is a dialogue belief state (Paek and Horvitz, 2000; Young et al., 2013b). Recent work successfully represents belief trackers as discriminative classifiers (Henderson et al., 2013; Williams, 2012; Wen et al., 2017b).

Wen et al. (2017b) apply discrimination approaches (Henderson et al., 2013) to build one classifier for each slot in their belief tracker. Following the terminology of (Wen et al., 2017b), a slot can be either **informable** or **requestable**, which have been annotated in CamRes676 and KVRET. Individually, an informable slot, specified by user utterances in previous turns, is set to a constraint for knowledge base search; whereas a requestable slot records the user's need in the current dialogue. As an example of belief trackers in CamRes676, `food_type` is an informable slot, and a set of food types is also predefined (e.g., `Italian`) as corresponding slot values. In (Wen et al., 2017b), the informable slot `food_type` is recognized by a classifier, which takes user utterances as input to predict if and which type of food should be activated, while the requestable slot of `address` is a binary variable. `address` will be set to true if the slot is requested by the user.

4 Method

We now describe the Sequicity framework, by first explaining the core concept of bspans. We then instantiate the Sequicity framework with our introduction of an improved CopyNet (Gu et al., 2016).

4.1 Belief Spans for Belief Tracking

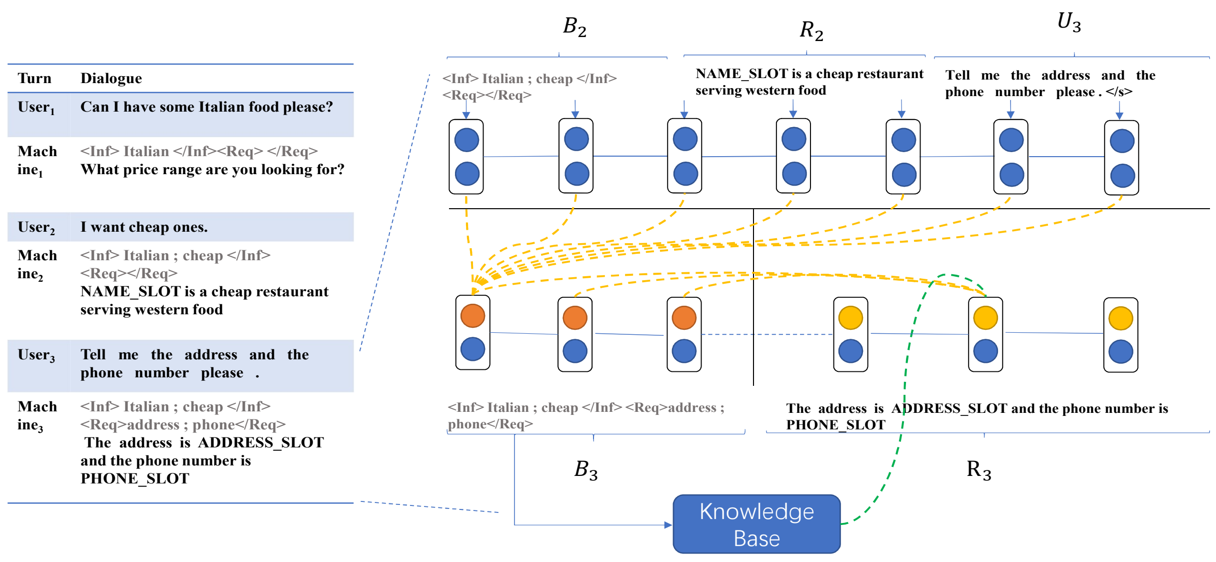
The core of belief tracking is keeping track of informable and requestable slot values when a dialogue progresses. In the era of pipeline-based methods, supervised classification is a straightforward solution. However, we observe that this traditional architecture can be updated by applying seq2seq models directly to the problem. In contrast to (Wen et al., 2017b) which treats slot values as classification labels, we record them in a text span, to be decoded by the model. This leverages the state-of-the-art neural seq2seq models to learn and dynamically generate them. Specifically, our bspan has an information field (marked with `<Inf></Inf>`) to store values of informable slots since only values are important for knowledge base search. Bspans can also feature a requested field (marked with `<Req></Req>`), storing requestable slot names if the corresponding value is `True`.

At turn t, given the user utterance U_t, we show an example of both bspan B_t and machine response R_t generation in Figure 1, where annotated slot values at each turn are decoded into bspans. B_1 contains an information slot `Italian` because the user stated "Italian food" in U_1. During the second turn, the user adds an additional constraint `cheap` resulting in two slot values in B_2's information field. In the third turn, the user further asks for the restaurant's phone and address, which are stored in requested slots of B_3.

Our bspan solution is concise: it simplifies multiple sophisticated classifiers with a single sequence model. Furthermore, it can be viewed as an explicit data structure that expedite knowledge base search as its format is fixed: following (Wen et al., 2017b), we use the informable slots values directly for matching fields of entries in databases.

4.2 The Sequicity Framework

We make a key observation that at turn t, a system only needs to refer to B_{t-1}, R_{t-1} and U_t to generate a new belief span B_t and machine response R_t, without appealing to knowing all past utterances. Such Markov assumption allows Sequicity to concatenate B_{t-1}, R_{t-1} and U_t (denoted as $B_{t-1}R_{t-1}U_t$) as a source sequence for seq2seq modeling, to generate B_t and R_t as target output sequences at each turn. More formally, we represent the dialogue utterances as $\{(B_0R_0U_1; B_1R_1); (B_1R_1U_2; B_2R_2); ...; (B_{t-1}R_{t-1}U_t; B_tR_t)\}$ where B_0 and R_0 are initialized as empty sequences. In this way, Sequicity fulfills both task accomplishment and response generation in an unified seq2seq model. Note that we process B_t and R_t separately, as the belief state B_t depends only on $B_{t-1}R_{t-1}U_t$, while the response R_t is additionally conditioned on B_t and the knowledge base search results (denoted as $\mathbf{k}_t$); that is, B_t informs the R_t's contents. For example, R_t must include all the request slots from B_t when communicating the entities fulfilling the requests found in the knowledge base. Here, $\mathbf{k}_t$ helps generate R_t pragmatically.



Turn	Dialogue
$User_1$	Can I have some Italian food please?
$Machine_1$	<Inf> Italian </Inf><Req> </Req> What price range are you looking for?
$User_2$	I want cheap ones.

Knowledge Base

Figure 1: Sequicity overview. The left shows a sample dialogue; the right illustrates the Sequicity. B_t is employed only by the model, and not visible to users. During training, we substitute slot values with placeholders bearing the slot names for machine response. During testing, this is inverted: the placeholders are replaced by actual slot values, according to the item selected from the knowledge base.

Generally, $\mathbf{k}_t$ has three possibilities: 1) multiple matches, 2) exact match and 3) no match, while the machine responses differ accordingly. As an example, let's say a user requests an Italian restaurant. In the scenario of multiple matches, the system should prompt for additional constraints for disambiguation (such as restaurant price range). In the second exact match scenario where a single target (i.e., restaurant) has been found, the system should inform the user their requested information (e.g., restaurant address). If no entity is obtained, the system should inform the user and perhaps generate a cooperative response to retry a different constraint.

We thus formalize Sequicity as a seq2seq model which encodes $B_{t-1}R_{t-1}U_t$ jointly, but decodes B_t and R_t separately, in two serial stages. In the first stage, the seq2seq model decodes B_t unconditionally (Eq. 4a). Once B_t obtained, the decoding pauses to perform the requisite knowledge base search based on B_t, resulting in $\mathbf{k}_t$. Afterwards, the seq2seq model continues to the second decoding stage, where R_t is generated on the additional conditions of B_t and $\mathbf{k}_t$ (Eq. 4b).

$$B_t = \mathbf{seq2seq}(B_{t-1}R_{t-1}U_t|0,0) \tag{4a}$$
$$R_t = \mathbf{seq2seq}(B_{t-1}R_{t-1}U_t|B_t,\mathbf{k}_t) \tag{4b}$$

Sequicity is a general framework suitably implemented by any of the various seq2seq models. The additional modeling effort beyond a general seq2seq model is to add the conditioning on B_t and $\mathbf{k}_t$ to decode the machine response R_t. Fortunately, natural language generation with specific conditions has been extensively studied (Wen et al., 2016b; Karpathy and Fei-Fei, 2015; Mei et al., 2016) which can be employed within this framework.

4.3 Sequicity Instantiation: A Two Stage CopyNet

Although there are many possible instantiations, in this work we purposefully choose a simplistic architecture, leaving more sophisticated modeling for future work. We term our instantiated model a *Two Stage CopyNet* (*TSCP*). We denote the first m' tokens of target sequence Y are B_t and the rests are R_t, i.e. $B_t = y_1...y_{m'}$ and $R_t = y_{m'+1}...y_m$.

Two-Stage CopyNet. We choose to improve upon CopyNet (Gu et al., 2016) as our seq2seq model. This is a natural choice as we observe that target sequence generation often requires the copying of tokens from the input sequence. Let's discuss this in more detail. From a probabilistic point of view, the traditional encoder–decoder structure learns a language model. To decode y_j, we can employ a $softmax$ (e.g., Eq. 3) to calculate the probability distribution over V i.e., $P^g_j(v)$ where $v \in V$, and then choose the token with the highest generation probability. However, in our case, tokens in the target sequence Y might be exactly copied from the input X (e.g., "Italian"). These copied words need to be explicitly modeled. CopyNet (Gu et al., 2016) is a natural fit here, as it enlarges the decoding output space from V to $V \cup X$. For y_j, it considers an additional copy probability $P_j^c(v)$, indicating the likelihood of y_j copied from $v \in X$. Following (Gu et al., 2016), the simple summation of both probabilities $P_j(v) = P_j^g(v) + P_j^c(v), v \in V \cup X$ is treated as the final probability in the original paper.

In Sequicity, simply applying original CopyNet architecture is insufficient, since B_t and R_t have different distributions. We here employ two separate RNN (GRU in our implementation) in decoder: one for B_t and the other for R_t. In the first decoding stage, we have a copy-attention mechanism on X to decode B_t; then calculate the generation probability through attending to X as introduced in Sec 3.1, as well as the copy probability for each word $v \in X$ following (Gu et al., 2016) by Eq. 5:

$$P_j^c(v) = \frac{1}{Z} \sum_{i:x_i=v}^{|X|} e^{\psi(x_i)}, j \leqslant m' \tag{5}$$

where Z is a normalization term and $\psi(x_i)$ is the score of "copying" word x_i and is calculated by:

$$\psi(x_i) = \sigma({\mathbf{h}_i^{(x)}}^T \mathbf{W}_c)\mathbf{h}_j^{(y)}, j \leqslant m' \tag{6}$$

where $\mathbf{W}_c \in \mathbb{R}^{d \times d}$.

In the second decoding stage (i.e., decoding R_t), we apply the last hidden state of B_t as the initial hidden state of the R_t GRU. However, as we need to explicitly model the dependency on B_t, we have copy-attention mechanism on B_t instead of on X: treating all tokens of B_t as the candidate for copying and attention. Specifically, we use hidden state generated by B_t GRU, i.e., $\mathbf{h}_1^{(y)}, ..., \mathbf{h}_{m'}^{(y)}$, to calculate copying using Eqs. 7 and 8 and attention score as introduced in Sec 3.1. It helps to reduce search space because all key information of X for task completion has been included in B_t.

$$P_j^c(v) = \frac{1}{Z} \sum_{i:y_i=v} e^{\psi(y_i)}, i \leqslant m' < j \leqslant m \tag{7}$$

$$\psi(y_i) = \sigma({\mathbf{h}_i^{(y)}}^T \mathbf{W}_c)\mathbf{h}_j^{(y)}, i \leqslant m' < j \leqslant m \tag{8}$$

In contrast to recent work (Eric and Manning, 2017a) that also employs a copy-attention mechanism to generate a knowledge-base search API and machine responses, our proposed method advances in two aspects: on one hand, bspans reduce the search space from $U_1R_1...U_tR_t$ to $B_{t-1}R_{t-1}U_t$ by compressing key points for the task completion given past dialogues; on the other hand, because bspans revisit context by only handling the B_t with a fixed length, the time complexity of TSCP is only $O(T)$, comparing $O(T^2)$ in (Eric and Manning, 2017a).

Involving $\mathbf{k}_t$ when decoding R_t. As $\mathbf{k}_t$ has three possible values: obtaining only one, multiple or no entities. We let $\mathbf{k}_t$ be a vector of three dimensions, one of which signals a value. We append $\mathbf{k}_t$ to the embeddings $\mathbf{y}_j$, as shown in Eq. (9) that is fed into an GRU for generating $\mathbf{h}_{j+1}^{(y)}$. This approach is also referred to as Language Model Type condition (Wen et al., 2016b)

$$\mathbf{y}'_j = \begin{bmatrix} \mathbf{y}_j \\ \mathbf{k}_t \end{bmatrix}, j \in [m'+1, m] \tag{9}$$

4.4 Training

The standard cross entropy is adopted as our objective function to train a language model:

$$\sum_{j=1}^{m} y_j log P_j(y_j) \tag{10}$$

In response generation, every token is treated equally. However, in our case, tokens for task completion are more important. For example, when a user asks for the address of a restaurant, it matters more to decode the placeholder `<address>` than decode words for language fluency. We can employ reinforcement learning to fine tune the trained response decoder with an emphasis to decode those important tokens.

Inspired by (Wen et al., 2017a), in the context of reinforcement learning, the decoding network can be viewed as a policy network, denoted as $\pi_\Theta(y_j)$ for decoding y_j ($m'+1 \leqslant j \leqslant$ m). Accordingly, the choice of word y_j is an action and its hidden vector generated by decoding GRU is the corresponding state. In reinforcement tuning stage, the trained response decoder is the initial policy network. By defining a proper reward function $r^{(j)}$ for decoding y_j, we can update the trained

response model with policy gradient:

$$\frac{1}{m-m'} \sum_{j=m'+1}^{m} r^{(j)} \frac{\partial log\pi_{\Theta}(y_j)}{\partial\Theta} \quad (11)$$

where $r^{(j)} = r^{(j)} + \lambda r^{(j+1)} + \lambda^2 r^{(j+2)} + ... + \lambda^{m-j+1} r^{(m)}$. To encourage our generated response to answer the user requested information but avoid long-winded response, we set the reward at each step $r^{(j)}$ as follows: once the placeholder of requested slot has been decoded, the reward for current step is 1; otherwise, current step's reward is -0.1. λ is a decay parameter. Sec 5.2 for λ settings.

5 Experiments

We assess the effectiveness of Sequicity in three aspects: the task completion, the language quality, and the efficiency. The evaluation metrics are listed as follows:

· **BLEU** to evaluate the language quality (Papineni et al., 2002) of generated responses (hence top-1 candidate in (Wen et al., 2017b)).
· **Entity match rate** evaluates task completion. According to (Wen et al., 2017b), it determines if a system can generate all correct constraints to search the indicated entities of the user. This metric is either 0 or 1 for each dialogue.
· **Success F_1** evaluates task completion and is modified from the success rate in (Wen et al., 2017b, 2016a, 2017a). The original success rate measures if the system answered all the requested information (e.g. address, phone number). However, this metric only evaluates recall. A system can easily achieve a perfect task success by always responding all possible request slots. Instead, we here use success F_1 to balance both recall and precision. It is defined as the F_1 score of requested slots answered in the current dialogue.
· **Training time.** The training time is important for iteration cycle of a model in industry settings.

5.1 Datasets

We adopt the CamRest676 (Wen et al., 2017a) and KVRET (Eric and Manning, 2017b) datasets. Both datasets are created by a Wizard-of-Oz (Kelley, 1984) method on Amazon Mechanical Turk platform, where a pair of workers are recruited to carry out a fluent conversation to complete an assigned task (e.g. restaurant reservation). During conversation, both informable and requestable slots are recorded by workers.

CamRest676's dialogs are in the single domain of restaurant searching, while KVRET is broader, containing three domains: calendar scheduling, weather information retrieval and point of interest (POI) Navigation. Detailed slot information in each domain are shown in Table 1. We follow the data splits of the original papers as shown in 1.

5.2 Parameter Settings

For all models, the hidden size and the embedding size d is set to 50. $|V|$ is 800 for CamRes676 and 1400 for KVRET. We train our model with an Adam optimizer (Kingma and Ba, 2015), with a learning rate of 0.003 for supervised training and 0.0001 for reinforcement learning. Early stopping is performed on developing set. In reinforcement learning, the decay parameter λ is set to 0.8. We also use beam search strategy for decoding, with a beam size of 10.

5.3 Baselines and Comparisons

We first compare our model with the state-of-the-art baselines as follow:

- NDM (Wen et al., 2017b). As described in Sec 1, it adopts pipeline designs with a belief tracker component depending on delexicalization.

- NDM+Att+SS. Based on the NDM model, an additional attention mechanism is performed on the belief trackers and a snapshot learning mechanism (Wen et al., 2016a) is adopted.

- LIDM (Wen et al., 2017a). Also based on NDM, this model adopts neural variational inference with reinforcement learning.

	CamRes676					KVRET				
	Mat.	BLEU	Succ. F_1	$Time_{full}$	$Time_{N.B.}$	Mat.	BLEU	Succ. F_1	$Time_{full}$	$Time_{N.B.}$

(7) TSCP\\k_t	**0.927**	0.232	0.835	7.2 min	–	**0.845**	0.168	0.759	25.3 min	–
(8) TSCP\\RL	**0.927**	0.234	0.834	**4.1** min	–	**0.845**	0.191	0.774	**17.5** min	–
(9) TSCP\\B_t	0.888	0.197	0.809	22.9 min	–	0.628	0.182	0.755	42.7 min	–

Table 2: Model performance on CamRes676 and KVRET. This table is split into two parts: competitors on the upper side and our ablation study on the bottom side. **Mat.** and **Succ. F1** are for match rate and success F1 respectively. $\mathbf{Time_{full}}$ column reports training time till converge. For NDM, NDM+Att+SS and LIDM, we also calculate the training time for the rest parts except for the belief tracker ($\mathbf{Time_{N.B.}}$).

- KVRN (Eric and Manning, 2017b) uses one seq2seq model to generate response as well as interacting with knowledge base. However, it does not incorporate a belief tracking mechanism.

For NDM, NDM+Att+SS, LIDM, we run the source code released by the original authors[2]. For KVRN, we replicate it since there is no source code available. We also performed an ablation study to examine the effectiveness of each component.

- TSCP\\k_t. We removed the conditioning on k_t when decoding R_t.
- TSCP\\RL. We removed reinforcement learning which fine tunes the models for response generation.
- Att-RNN. The standard seq2seq baseline as described in the preliminary section (See §3.1).
- TSCP\\B_t. We removed bspans for dialogue state tracking. Instead, we adopt the method in (Eric and Manning, 2017a): concatenating all past utterance in a dialogue into a CopyNet to generate user information slots for knowledge base search as well as machine response.

5.4 Experimental Results

As shown in Table 2, TSCP outperforms all baselines (Row 5 vs. Rows 1–4) in task completion (entity match rate, success F1) and language quality (BLEU). The more significant performance of TSCP in KVRET dataset indicates the scalability of TSCP. It is because KVRET dataset has significant lexical variety, making it hard to perform delexicalization for Wen et al.'s model (Rows 1–3)[3]. However, CamRes676 is relatively small with simple patterns where all systems work well. As predicted, KVRN (Row 4) performs worse than TSCP (Row 5) due to lack of belief tracking.

Compared with Wen et al.'s models (Rows 1–3), TSCP takes a magnitude less time to train. Although TSCP is implemented in PyTorch while Wen et al.'s models in Theano, such speed comparison is still valid, as the rest of the NDM model — apart from its belief tracker — has a comparable training speed to TSCP (7.3 mins vs. 8.6 mins on CamRes676 and 25.5 mins vs. 29.3 mins on KVRET), where model complexities are similar. The bottleneck in the time expense is due to belief tracker training. In addition, Wen et al.'s models perform better at the cost of more training time (Rows 1, 2 and 3), suggesting the intrinsic complexity of pipeline designs.

Importantly, ablation studies validate the necessity of bspans. With bspans, even a standard seq2seq model (Att-RNN, Row 6) beats sophisticated models such as attention copyNets (TSCP\\$B_t$, Row 9) in KVRET. Furthermore, TSCP (Row 5) outperforms TSCP\\$B_t$ (Row 9) in all aspects: task completion, language quality and training speed. This validate our theoretical analysis in Sec 4.3. Other components of TSCP are also important. If we only use vanilla Attention-based RNN instead of copyNet, all metrics for model effectiveness decrease, validating our hypothesize that the copied words need to be specifically modeled. Secondly, BLEU score is sensitive to knowl-

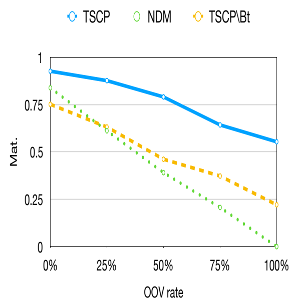
[2]https://github.com/shawnwun/NNDIAL

[3]We use the delexicalization lexicon provided by the original author of KVRET(Eric and Manning, 2017b)

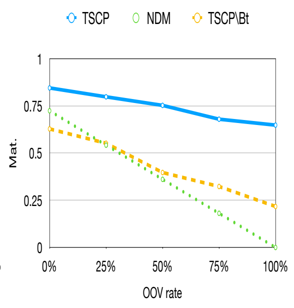
edge base search result $\mathbf{k}_t$ (Row 7 vs. Row 5). By examining error cases, we find that the system is likely to generate common sentences like "you are welcome" regardless of context, due to corpus frequency. Finally, reinforcement learning effectively helps both BLEU and success F_1 although it takes acceptable additional time for training.

5.5 OOV Tests

Previous work predefines all slot values in a belief tracker. However, a user may request new attributes that has not been predefined as a classification label, which results in an *entity mismatch*. TSCP employs copy mechanisms, gaining an intrinsic potential to handle OOV cases. To conduct the OOV test, we synthesize OOV test instances by adding a suffix `unk` to existing slot fillers. For example, we change "I would like Chinese food" into "I would like Chinese_unk food." We then randomly make a proportion of testing data OOV and measure its entity match rate. For simplicity, we only show the three most representative models pre-trained in the in-vocabulary data: TSCP, TSCP$\backslash B_t$ and NDM.



(a) CamRes676



(b) KVRET

Figure 2: OOV tests. 0% OOV rate means no OOV instance while 100% OOV rate means all instances are changed to be OOV.

Compared with NDM, TSCP still performs well when all slot fillers are unknown. This is because TSCP actually learns sentence patterns. For example, CamRes676 dataset contains a frequent pattern "I would like `[food_type]` food" where the `[food_type]` should be copied in B_t regardless what exact word it is. In addition, the performance of TSCP$\backslash B_t$ decreases more sharply than TSCP as more instances set to be OOV. This might be because handling OOV cases is much harder when search space is large.

5.6 Empirical Model Complexity

Traditional belief trackers like (Wen et al., 2017b) are built as a multi-class classifier, which models each individual slot and its corresponding values, introducing considerable model complexities. This is especially severe in large datasets with a number of slots and values. In contrast, Sequicity reduces such a complex classifier to a language model. To compare the model complexities of two approaches, we empirically measure model size. We split KVRET dataset by their domains, resulting in three sub-datasets. We then accumulatively add the sub-datasets into training set to examine how the model size grows. We here selectively present TSCP, NDM and its separately trained belief tracker, since Wen et al.'s set of models share similar model sizes.

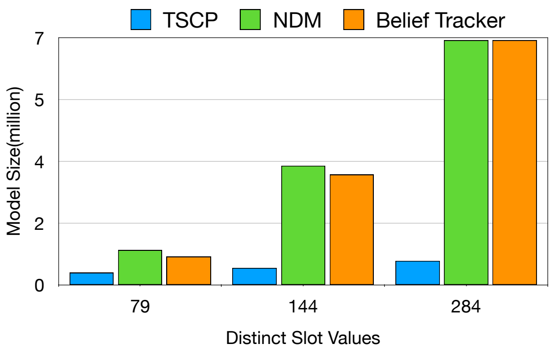


Figure 3: Model size sensitivity with respect to KVRET. Distinct slot values of 79, 144, 284 correspond to the number of slots in KVRET's *calendar*, *calendar + weather info.*, and all 3 domains.

As shown in Figure 3, TSCP has a magnitude less number of parameters than NDM and its model size is much less sensitive to distinct slot values increasing. It is because TSCP is a seq2seq language model which has a approximate linear complexity to vocabulary size. However, NDM employs a belief tracker which dominates its model size. The belief tracker is sensitive to the increase of distinct slot values because it employs complex structures to model each slot and corresponding values. Here, we only perform empirical evaluation, leaving theoretically complexity analysis for future works.

5.7 Discussions

In this section we discuss if Sequicity can tackle *inconsistent user requests* , which happens when users change their minds during a dialogue. Inconsistent user requests happen frequently and are difficult to tackle in belief tracking (Williams, 2012; Williams et al., 2013). Unlike most of previous pipeline-based work that explicitly defines model actions for each situation, Sequicity is proposed to directly handle various situations from the training data with less manual intervention. Here, given examples about restaurant reservation, we provide three different scenarios to discuss:

- **A user totally changes his mind**. For example, the user request a Japanese restaurant first and says "I dont want Japanese food anymore, I'd like French now." Then, all the slot activated before should be invalid now. The slot annotated for this turn is only *French*. Sequicity can learn this pattern, as long as it is annotated in the training set.

- **User requests cannot be found in the KB** (e.g., *Japanese food*). Then the system should respond like "Sorry, there is no Japanese food...". Consequently, the user can choose a different option: "OK, then French food." The activated slot *Japanese* will be replaced as *French*, which our system can learn. Therefore, an important pattern is the machine-response (e.g., "there is no [XXX constraint]") in the immediate previous utterance.

- **Other cases.** Sequicity is expected to generate both slot values in a belief span if it doesn't know which slot to replace. To maintain the belief span, we run a simple post-processing script at each turn, which detects whether two slot values have the same slot name (e.g., `food_type`) in a pre-defined slot name-value table. Then, such script only keeps the slot value in the current turn of user utterance. Given this script, Sequicity can accurately discover the slot requested by a user in each utterance. However, this script only works when slot values are pre-defined. For inconsistent OOV requests, we need to build another classifier to recognize slot names for slot values.

To sum up, Sequicity, as a framework, is able to handle various inconsistent user input despite its simple design. However, detailed implementations should be customized depends on different applications.

6 Conclusion

We propose Sequicity, an extendable framework, which tracks dialogue believes through the decoding of novel text spans: belief spans. Such belief spans enable a task-oriented dialogue system to be holistically optimized in a single seq2seq model. One simplistic instantiation of Sequicity, called Two Stage CopyNet (TSCP), demonstrates better effectiveness and scalability of Sequicity. Experiments show that TSCP outperforms the state-of-the-art baselines in both task accomplishment and language quality. Moreover, our TSCP implementation also betters traditional pipeline architectures by a magnitude in training time and adds the capability of handling OOV. Such properties are important for real-world customer service dialog systems where users' inputs vary frequently and models need to be updated frequently. For our future work, we will consider advanced instantiations for Sequicity, and extend Sequicity to handle unsupervised cases where information and requested slots values are not annotated.

An End-to-end Approach for Handling Unknown Slot Values in Dialogue State Tracking

Puyang Xu **Qi Hu**[†]

Abstract

We highlight a practical yet rarely discussed problem in dialogue state tracking (DST), namely handling unknown slot values. Previous approaches generally assume predefined candidate lists and thus are not designed to output unknown values, especially when the spoken language understanding (SLU) module is absent as in many end-to-end (E2E) systems. We describe in this paper an E2E architecture based on the pointer network (PtrNet) that can effectively extract unknown slot values while still obtains state-of-the-art accuracy on the standard DSTC2 benchmark. We also provide extensive empirical evidence to show that tracking unknown values can be challenging and our approach can bring significant improvement with the help of an effective feature dropout technique.

1 Introduction

A dialogue state tracker is a core component in most of today's spoken dialogue systems (SDS). The goal of dialogue state tracking (DST) is to monitor the user's intentional states during the course of the conversation, and provide a compact representation, often called the dialogue states, for the dialogue manager (DM) to decide the next action to take.

In task-oriented dialogues, or *slot-filling* dialogues in the simplistic form, the dialogue agent is tasked with helping the user achieve simple goals such as finding a restaurant or booking a train ticket. As the name itself suggests, a slot-filling dialogue is composed of a predefined set of slots that need to be filled through the conversation. The dialogue states in this case are therefore the values of these slot variables, which are essentially the search constraints the DM has to maintain in order to perform the database lookup.

Traditionally in the research community, as exemplified in the dialogue state tracking challenge (DSTC) (Williams et al., 2013), which has become a standard evaluation framework for DST research, the dialogues are usually constrained by a fixed *domain ontology*, which essentially describes in detail all the possible values that each predefined slot can take. Having access to such an ontology can simplify the tracking problem in many ways, however, in many of the SDS applications we have built in the industry, such an ontology was not obtainable. Oftentimes, the backend databases are only exposed through an external API, which is owned and maintained by our partners. It is usually not possible to gain access to their data or enumerate all possible slot values in their knowledge base. Even if such lists or dictionaries exist, they can be very large in size and highly dynamic (e.g. new songs added, new restaurants opened etc.). It is therefore not amiable to many of the previously introduced DST approaches, which generally rely on classification over a fixed ontology or scoring each slot value pairs separately by enumerating the candidate list.

In this paper, we will therefore focus on this particular aspect of the DST problem which has rarely been discussed in the community – namely how to perform state tracking in the absence of a comprehensive domain ontology and how to handle unknown slot values effectively.

It is worth noting that end-to-end (E2E) modeling for task-oriented dialogue systems has become a popular trend (Williams and Zweig, 2016; Zhao and Eskenazi, 2016; Li et al., 2017; Liu et al.,

[0]The first author is now with Facebook. Qi contributed to the work during an internship at Mobvoi.

2017; Wen et al., 2017), although most of them focus on E2E policy learning and language generation, and still rely on explicit dialogue states in their models. While fully E2E approaches which completely obviate explicit DST have been attempted (Bordes and Weston, 2016; Eric and Manning, 2017a,b; Dhingra et al., 2017), their generality and scalability in real world applications remains to be seen. In reality, a dedicated DST component remains a central piece to most dialogue systems, even in most of the proclaimed E2E models.

E2E approaches for DST, i.e. joint modeling of SLU and DST has also been presented in the literature (Henderson et al., 2014b,c; Mrksic et al., 2015; Zilka and Jurcicek, 2015; Perez and Liu, 2017; Mrksic et al., 2017). In these methods, the conventional practice of having a separate spoken language understanding (SLU) module is replaced by various E2E architectures that couple SLU and DST altogether. They are sometimes called word based state tracking as the dialogue states are derived directly from word sequences as opposed to SLU outputs. In the absence of SLU to generate value candidates, most E2E trackers today can only operate with fixed value sets. To address this limitation, we introduce an E2E tracker that allows us to effectively handle unknown value sets. The proposed solution is based on the recently introduced pointer network (PtrNet) (Vinyals et al., 2015), which essentially performs state tracking in an extractive fashion similar to the sequence labeling techniques commonly utilized for slot tagging in SLU (Tur and Mori, 2011).

Our proposed technique is similar in spirit as the recent work in (Rastogi et al., 2018), which also targets the problem of unbounded and dynamic value sets. They introduce a sophisticated candidate generation strategy followed by a neural network based scoring mechanism for each candidate. Despite the similarity in the motivation, their system relies on SLU to generate value candidates, resulting in an extra module to maintain and potential error propagation as commonly faced by pipelined systems.

The contributions of this paper are three-folds: Firstly, we target a very practical yet rarely investigated problem in DST, namely handling unknown slot values in the absence of a predefined ontology. Secondly, we describe a novel E2E architecture without SLU based on the PtrNet to perform state tracking. Thirdly, we also introduce an effective *dropout* technique for training the proposed model which drastically improves the recall rate of unknown slot values.

The rest of the paper is structured as follows: We give a brief review of related work in the field in Section 2 and point out its limitations. The PtrNet and its proposed application in DST are described in Section 3. In Section 4, we demonstrate some caveats regarding the use of PtrNet and propose an additional classification module as a complementary component. The targeted dropout technique, which can be essential for generalization on some datasets, is described in Section 5. Experimental setup and results are presented in Section 6, followed by conclusions in Section 7.

2 Dialogue State Tracking

In DSTC tasks, the dialogue states are defined as a set of search constraints (i.e. informable slots or goals) the user specified through the dialogue and a set of attribute questions regarding the search results (i.e. requestable slots or requests). The DST component is expected to track the values of the aforementioned slots taking into account the current user utterance as well as the entire dialogue context. As mentioned in the previous section, the values each slot variable can take are specified beforehand through an ontology. This is a hidden assumption that previous techniques usually rely upon implicitly and also what motivates our work in this paper.

Discriminative DST While generative models aiming at modeling the joint distribution of dialogue states and miscellaneous evidences have been a popular modeling choice for DST for many years, the scalability issue resulting from large state spaces has limited the broader application of this family of models, despite the success of various approximation techniques.

The discriminative methods, on the other hand, directly model the posterior distribution of dialogue states given the evidences accumulated through the conversation history. Models such as maximum entropy (Metallinou et al., 2013) and particularly the more recent deep learning based models (Henderson et al., 2014b,c; Zilka and Jurcicek, 2015; Mrksic et al., 2015, 2017; Perez and Liu, 2017) have demonstrated state-of-the-art results on public benchmarks. Such techniques often involve a multi-class classification step at the end (e.g. in the form of a softmax layer) which for each slot predicts the corresponding value based on the dialogue history. Sometimes the multi-class classification is replaced by a binary prediction that decides whether a particular slot value pair was expressed by the user, and the list of candidates comes from either a fixed ontology or the SLU output.

E2E DST Previous work has also investigated joint modeling strategies merging SLU and DST altogether. In this line of work, the SLU module is removed from the standard SDS architecture, resulting in reduced development cost and alleviating the error propagation problem commonly affecting cascaded systems.

In the absence of SLU providing fine-grained semantic features, the E2E approaches these days typically rely on variants of neural networks such as recurrent neural networks (RNN) or memory networks (Weston et al., 2014) to automatically learn features from the raw dialogue history. The deep learning based techniques cited in the previous subsection generally fall into this category.

Current Limitations In short, most of the previous DST approaches, particularly E2E ones, are not designed to handle slot values that are not known to the tracker.

As we have described in the introduction, the assumption that a predefined ontology exists for the dialogue and one can enumerate all possible values for each slot is often not valid in real world scenarios. Such an assumption has implicitly influenced many design choices of previous systems. The methods based on classification or scoring each slot value pair separately can be very difficult to apply when the set of slot values is not enumerable, either due to its size or its constantly changing nature, especially in E2E models where there is no SLU module to generate an enumerable candidate list for the tracker.

It is important to point out the difference between *unseen* states and *unknown* states, as previous work has tried to address the problem of unseen slot values, i.e. values that were not observed during training. E2E approaches in particular, frequently employ a featurization strategy called *delexicalization*, which replaces slots and values mentioned in the dialogue text with generic labels. Such a conversion allows the models to generalize much better to new values that are infrequent or unseen in the training data. However, such slot values are still expected to be known to the tracker, either through a predefined value set or provided by SLU, otherwise the delexicalization cannot be performed, nor can the classifier properly output such values.

3 Pointer Network

In this section, we briefly introduce the PtrNet (Vinyals et al., 2015), which is the main basis of the proposed technique, and how the DST problem can be reformulated to take advantage of the flexibility enabled by such a model.

In the PtrNet architecture, similar as other sequence-to-sequence (seq2seq) models, there is an encoder which takes the input and iteratively produces a sequence of hidden states corresponding to the feature vector at each input position. There is also a decoder which generates outputs with the help of the weighted encoded states where the weights are computed through attention. Here, instead of using softmax to predict the distribution over a set of predefined candidates, the decoder directly normalizes the attention score at each position and obtains an output distribution over the input sequence. The index of the maximum probability is the pointed position, and the corresponding element is selected as decoder output, which is then fed into next decoding step. Both the encoder and decoder are based on various RNN models, capable of dealing with sequences of variable length.

The PtrNet specifically targets the problems where the output corresponds to positions in the input sequence, and it is widely used for seq2seq tasks where some kind of *copying* from the input is needed. Among its various applications, machine comprehension (a form of question answering), such as in (Wang and Jiang, 2016), is the closest to how we apply the model to DST.

The output of DST, same as in machine comprehension, is a word segment in the input sequence most of the time, thus can be naturally formulated as a *pointing* problem. Instead of generating longer output sequences, the decoder only has to predict the starting index and the ending index in order to identify the word segment.

More specifically, words are mapped to embeddings and the dialogue history $w_0, w_1, ..., w_t$ up to the current turn t is bidirectionally encoded using LSTM models. To differentiate words spoken by the user versus by the system, the word embeddings are further augmented with speaker role information. Other features, such as the entity type of each word, can also be fed into the encoder simultaneously in order to extract richer information from the dialogue context.

The encoded state at each position can then be denoted as h_i, which is the concatenation of forward state and backward state ($[h_i^f, h_i^b]$). The final forward state h_t^f is used as the initial hidden state of the decoder. We use a special symbol denoting the type of slot (e.g. <food>) as the first decoder input, which is also mapped to a trainable embedding E_{type}. Therefore, the starting index s^0 of the slot value is computed as the following, where u_i^0 is the attention score of the i_{th} word in the input against the decoder state d^0.

$$d^0 = LSTM(h_t^f, E_{type})$$

$$u_i^0 = v^T \tanh(W_h h_i + W_d d_0)$$

$$a_i^0 = \exp(u_i^0) / \sum_{j=0}^{t} \exp(u_j^0)$$

$$s^0 = \arg\max_i a_i^0$$

The attention scores at the second decoding step are computed similarly as below, where $E_{w_{s^0}}$ is the embedding of the word at the selected starting position, and the ending position s^1 can be obtained in the same way as s^0.

$$d^1 = LSTM(d^0, E_{w_{s^0}})$$

$$u_i^1 = v^T \tanh(W_h h_i + W_d d^1)$$

Note that there is no guarantee that $s^1 > s^0$, although most of the time the model is able to identify consistent patterns in the data and therefore output reasonable word segments. When $s^1 < s^0$, it is often a good indication that the answer does not exist in the input (such as the *none* slot in DSTC2).[1] Depending on the nature of the task, it is certainly possible to set a constraint at the second decoding step, forcing s^1 to be larger than s^0.

One can clearly see how the described model can handle unknown slot values – as long as they are mentioned explicitly during the dialogue, we

[1]It is the backoff strategy we take in our experiments on DSTC2.

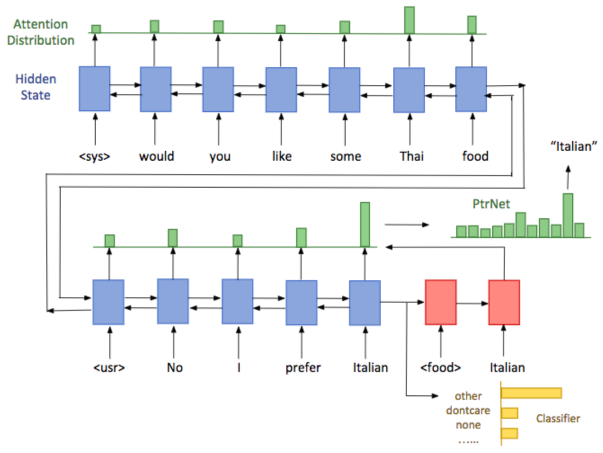

Figure 1: An illustration of the proposed PtrNet based architecture for DST. The classifier outputs "other" indicating the decision should be made by PtrNet; The decoder (red) in PtrNet is predicting the ending word of the slot value given the predicted starting word via attention against the encoded states (blue).

have a chance of finding them. Compared with previous approaches, which all require some kind of candidate lists, the proposed technique takes a different perspective on DST: For most slots in dialogue systems, tracking up-to-date values in a dialogue is not very different from tagging slots in a user query. While sequence labeling models such as conditional random field (CRF) has proven to be a great fit for slot tagging, the same formulation may as well be used for DST.

4 Rephrasing and Non-pointable Values

Our PtrNet based architecture works by directly pinpointing in the conversation history the slot value that the user expressed in its surface form. The model is totally unaware of the different ways of referring to the same entity. Therefore, the derived dialogue states may not have canonical forms that are consistent with the values in the backend database, making it more difficult to retrieve the correct results. A good example from the DSTC2 dataset is the price slot which can take the reference value "moderate", in the actual dialogues however, they are frequently expressed as "moderately priced", causing problems for searching the database and also computing accuracy.

While such a problem can be easily remedied by an extra *canonicalization* step (setting dialogue states to standard forms) before performing the

	Classifer	**PtrNet**
Rephrasing	Yes	*Yes
none, dontcare, etc	Yes	No
ASR errors	Hard	Hard
Unknown values	No	Yes

Table 1: Classifier vs. Pointer network in handling various difficult conditions. *PtrNet requires post-normalization to handle rephrasing.

database lookup, it is a much bigger problem if the slot value is not indicated explicitly by any particular word or phrase in the dialogue history, we describe these slot values as *non-pointable*. To give an example, in DSTC tasks, the special *none* value is given when the user has not specified any constraint for the slot. While this information can be easily inferred from the dialogue, it is not possible to point to any specific word segment in the sentence as the corresponding slot value. The same problem also exists for the *dontcare* value in DSTC, which implies that the user can accept any values for a slot constraint.

To address this issue, we add a classification component into our neural network architecture to handle non-pointable values. For each turn of the dialogue, the classifier makes a multi-class decision on whether the target slot should take any of the non-pointable values (e.g. dontcare or none) or it should be processed by the PtrNet.

As illustrated in Figure 1, the final forward state out of the dialogue encoder is used as the feature vector for the classification layer, which is trained with cross entropy loss and jointly with the PtrNet.

The best choice of the set of values to be handled by the classifier may not be obvious. In most cases both the classifier and the PtrNet are capable of extracting the correct slot value, although they both offer unique advantages over the other. Table 1 briefly summarizes the pros and cons of each model.

The proposed combined architecture, taking the best of both worlds, is similar to the pointer-generator model introduced in (See et al., 2017) for abstractive text summarization. In their approach the PtrNet is also augmented with a classification based word generator, and the model can choose to generate words from a predefined vocabulary or copy words from the input. Other *classify-and-copy* mechanisms have also been explored in (Gu et al., 2016; Gulcehre et al., 2016; Eric and Manning, 2017a), and demonstrated improved performance on various seq2seq tasks such as summarization and E2E dialogue generation. [2] As we have shown in this paper, DST can also be formulated to incorporate such copying mechanisms, allowing itself to handle unknown slot values as well.

5 Targeted Feature Dropout

Feature dropout is an effective technique to prevent feature co-adaption and improve model generalization (Hinton et al., 2012). It is most widely used for neural network based models but may as well be utilized for other feature based models. Targeted feature dropout however, was introduced in (Xu and Sarikaya, 2014) to address a very specific co-adaptation problem in slot filling, namely insufficient training of word context features.

For slot filling, this problem often occurs when 1) the dictionary (a precompiled list of possible slot values) covers the majority of the slot values in the training data, or 2) most slot values repeat frequently resulting in insufficient tail representations. In both cases, the contextual features tend to get severely under-trained and as a result the model is not able to generalize to unknown slot values that are neither in the dictionary nor observed in training.

The way our architecture works essentially extracts slot values in the same way as in slot filling, although the goal is to identify slots considering the entire dialogue context rather than a (usually) single user query. The same problem can also happen for DST if training data are not examined carefully. As an example, the DSTC2 task comes with a fixed ontology, it is not originally designed to track unknown slots (see the OOV rate in Table 2). Taking a closer look at the data, as shown in the histogram in Figure 2, the majority of the food type slot appears more than 10 times in the training data. As a result, the model oftentimes only learns to memorize these frequent slot values, and not the contextual patterns which can be more crucial for extracting slot values not known in advance.

To alleviate the generalization issue, we adapt the targeted dropout trick to work with our neural

[2] The copy-augmented model in (Eric and Manning, 2017a) also outputs API call parameters (which are essentially dialogue states) in a seq2seq fashion, including unknown parameters by copying from dialogue history, although the work focuses entirely on dialogue generation.

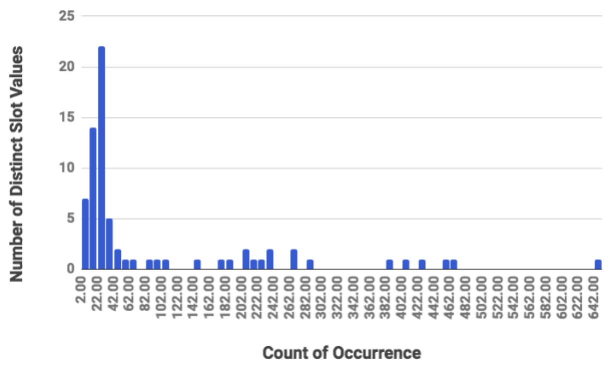

Figure 2: Histogram of *food type* slot on DSTC2 training data.

network based architecture. Instead of randomly disabling unigram and dictionary features for CRF models as done in the original work, we randomly set to zero the input word embeddings that correspond to the slot values in the dialogue utterances. For example, the *italian* food type in DSTC2 appears almost 500 times in the training data. During training, every time “italian” gets mentioned in the dialogue as the labeled user goal, we turn off the word embedding of “italian” in the model input with some probability, forcing the model to learn from the context to identify the slot value. Dictionary features are not used in our experiments, otherwise they can be turned off similarly.

As we will show later in the results, this proves to be a particularly effective yet simple trick for improving generalization to unknown slot values, without sacrificing accuracy for the known and observed ones.

6 Experiments and Results

6.1 Datasets

We conduct our experiments on the DSTC2 dataset (Henderson et al., 2014a), and on the bAbI dialogue dataset as used in (Bordes and Weston, 2016).

The DSTC2 dataset is the standard DST benchmark comprised of real dialogues between human and dialogue systems. We are mainly interested in tracking user goals, whereas the other two components of the dialogue state, namely search methods and requested slots, are not concerned with unknown slot values, and thus are not the focus in this paper. Meanwhile, the non-pointable values, none and dontcare, constitute a significant portion in DSTC2. Overall almost 60% of the user goals

	Original	New
#food types in train	74	48
#train instances	11677	8546
#test instances	9890	9890
OOV food types in test (%)	0	30.4

Table 2: Statistics of the new modified DSTC2 dataset with unknown food types. About 27% of the training instances are discarded. The test set remains the same.

are labeled as either none or dontcare, the two predominant non-pointable values, it is therefore particularly suitable for evaluating our proposed hybrid architecture.

An important part of our experimental evaluation is to demonstrate our ability to identify unknown slots. Although it happens frequently in real world situations, the original DSTC2 dataset does not suffer from this particular problem – on the test data, there are no unknown values that we have not observed in training for all of the three slot types. To conduct our investigation, we pick the food type slot to simulate unknown values. Specifically, we randomly select about 35% of the food types in the training set (26 out of 74) as unknown and discard all the training instances where the correct food type is one of the 26 unknown types that we selected. The statistics of the resulting dataset is shown in Table 2.

On the other hand, the bAbI dialogue dataset is initially designed for evaluating E2E goal oriented dialogue systems and has not been used specifically for DST. The model is expected to predict both the system utterances and the API calls to access the database. We notice that the parameters of the API calls are essentially the dialogue states at the point of the dialogue, it may as well be used as a dataset for measuring the accuracy of the state tracker. We therefore convert Task 5 of the bAbI dataset, which is the full dialogue combination of Tasks 1-4, into a DST dataset for our experiments.

Although simulated and with highly regular behaviors, the nice thing about the bAbI dialogue dataset is that it comes with an out-of-vocabulary (OOV) test set in which the entities (locations and food types) are not seen in any training dialogues. This poses exactly the same problem we are trying to address in this paper, namely predicting the API call parameters when they are not only unseen but also unknown to the system. Many of the previous E2E approaches simplifies the prediction problem as a selection among all API calls appeared in the entire dataset, thus bypassing the problem of tracking unknown dialogue states explicitly, although we believe it is not a realistic simplification.

6.2 Model and Training Details

The proposed model is implemented in TensorFlow. We use the provided development set to tune the hyper-parameters, track the training progress and select the best performing model for reporting the accuracy on test sets. The joint architecture is trained separately for each slot type by minimizing the sum of the cross entropy loss from the PtrNet and the classifier. Mini-batch SGD with a batch size of 50 and Adam optimizer (Kingma and Ba, 2014) is used for training.

Each word is mapped to a *randomly initialized* 100 dimensional embedding and each dialogue instance is represented as a 540 * 100 dimensional vector with zero paddings on the left when necessary. Instead of the using the raw word sequences, the system utterances are replaced by the more succinct and consistent dialogue act representations such as "request slot food". One layer of LSTM is used with a state size of 200 (additional layers did not help noticeably). Standard dropout with a keep probability of 0.5 is performed for training at the input and output of the LSTM cells. To keep it simple, targeted dropout is done only once for the entire training set before training begins, the dataset is therefore static across epochs.

To train the PtrNet, the location of the reference slot value in the dialogue needs to be provided. It does not require manual labeling though, and we simply use the *last* occurrence of the reference slot value in the dialogue history as the reference location. The occurrence is found via exact string match and the two most frequent spelling variations, "moderate" and "moderately", "center" and "centre" are considered equivalent. If no occurrence exists in a training instance (due to ASR errors or rephrasing), it will not be used for training the PtrNet.

On the other hand, the classifier serves as a gatekeeper that decides which slot values should be handed over to the PtrNet. On the bAbI dataset, there are zero non-pointable slots, and therefore everything is handled by the PtrNet. On DSTC2, we train the classifier to perform a *three-way* classification that determines if the slot values is none, dontcare or other. As we have described, other slot values can also become non-pointable in the actual dialogue: Those resulting from different surface forms are usually easier to handle, all we need is an extra post-processing step to normalize the value; The ones caused by ASR errors though, are much more challenging. One can argue that a classifier may be better equipped for these cases since it does not require locating the actual values in the word sequence, but unless there are consistent misrecognition patterns, they are difficult to handle for either the classifier or the PtrNet.

The non-pointable values in DSTC2, besides none and dontcare, are predominantly due to recognition errors, and we decide not to do anything specific about them – the PtrNet is tasked with processing these misrecognized utterances, and no normalization (except for "moderately" and "center") is performed on the network output for computing the accuracy. [3]

6.3 Evaluation Setup

The DSTC2 dataset is a standard benchmark for the task, we therefore compare the joint goal accuracy (a turn is considered correct if values are predicted correctly for all slots) of the proposed model with previous reported numbers to show the efficacy of our approach under regular circumstances, i.e. all slot values are known and observed in training. However, it is not our goal to outperform all previous DST systems – the main theme is that our technique allows identifying unknown slot values effectively and even if used in the standard setting, our model yields state-of-the-art results.

Measuring the accuracy on unknown slot values, however, does not have well-established baselines in the literature. Most previous systems are not concerned with this problem, and many of them are inherently not capable of outputting unknown values. So instead of comparisons with previous techniques, we will focus on demonstrating how this could be a serious problem tracking unknown slot values and how the targeted dropout can improve things drastically.

6.4 Results

The joint goal accuracy on the standard DSTC2 test set is shown in Table 3 comparing our Ptr-

[3]Non-pointable values besides none and dontcare constitute 9.7% of *food*, 7.6% of *location* and 4.7% of *price* on the test data, effectively setting an upper bound on the accuracy.

Table 3: Joint goal accuracy on DSTC2 test set vs. various approaches as reported in the literature.

Net based model against various previous reported baselines.

It is important to emphasize that the PtrNet model is an E2E model without using any SLU output and makes use of only the 1-best ASR hypothesis without any confidence measure for testing. Although more sophisticated DST models sometimes demonstrate better accuracy, our PtrNet model holds various advantages against all baseline models: In comparison with our approach, the delexicalized RNN models (Henderson et al., 2014b,c) utilize the n-best list and/or the SLU output; The NBT (Mrksic et al., 2017) and MemN2N (Perez and Liu, 2017) models are E2E but both depend on candidate lists as given and hence are not designed to handle unknown (different from unseen) slot values; The scalable DST model (Rastogi et al., 2018), although addressing the same problem of unbounded value set, relies on SLU to generate value candidates, and also does not perform equally well on the standard test set.

On the modified DSTC2 dataset with the reduced training set, the accuracy of the known/seen and unknown food types is shown in Figure 3. The standard training process with no targeted dropout performs poorly when the food types are not known beforehand, epitomizing the often overlooked challenge of handling unknown slot values. With a small dropout probability of 5%, the accuracy on unknown values essentially increases by three times (from 11.6% to 34.4%), while the accuracy on other values remains roughly the same.

Similar observations can also be made on the bAbI dataset predicting OOV API parameters (Table 4). While the dataset is quite artificial and in most cases we can achieve perfect accuracy on the regular test set, the OOV parameter values are not nearly as easy to predict. The targeted dropout

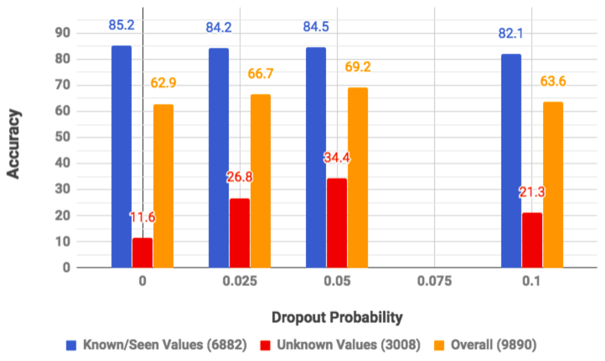

Figure 3: Accuracy of known/seen and unknown food types on the modified DSTC2 dataset with different dropout probabilities.

	Regular Test		OOV Test	
	p=0	p=0.1	p=0	p=0.1
food	100	100	86.2	100
location	100	100	74.7	99.6

Table 4: Accuracy of predicting regular and OOV *food* and *location* parameters in bAbI (Task 5) API calls w/ (p=0.1) and w/o (p=0) targeted dropout.

however, allows us to bridge the accuracy gap entirely.

7 Conclusion

An E2E dialogue state tracker is introduced based on the pointer network. The model outputs slot values in an extractive fashion similar to the slot filling task in SLU. We also add a jointly trained classification component to combine with the pointer network, forming a hybrid architecture that not only achieves state-of-the-art accuracy on the DSTC2 dataset, but also more importantly is able to handle unknown slot values, which is a problem often neglected although particularly valuable in real world situations. A feature dropout trick is also described and proves to be particularly effective.

Global-Locally Self-Attentive Dialogue State Tracker

Abstract

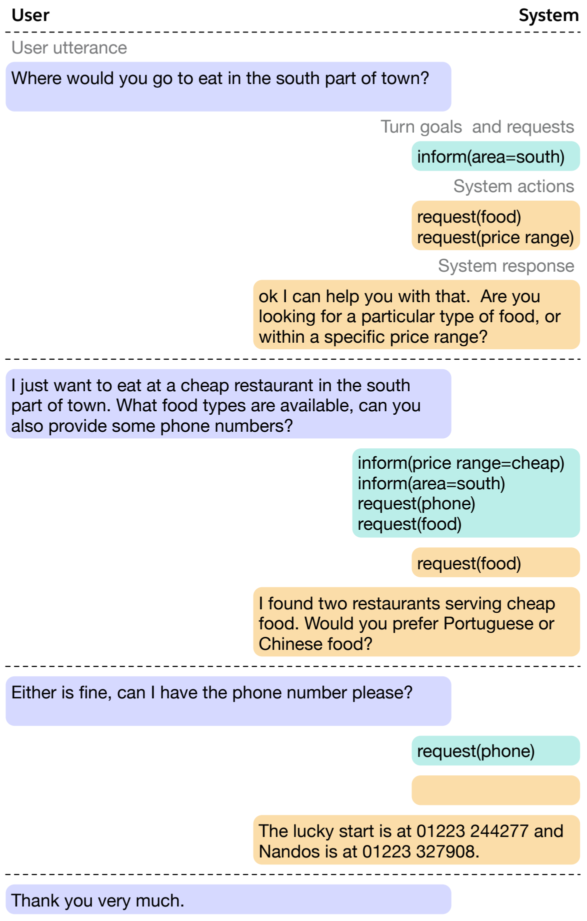
Dialogue state tracking, which estimates user goals and requests given the dialogue context, is an essential part of task-oriented dialogue systems. In this paper, we propose the Global-Locally Self-Attentive Dialogue State Tracker (GLAD), which learns representations of the user utterance and previous system actions with global-local modules. Our model uses global modules to share parameters between estimators for different types (called slots) of dialogue states, and uses local modules to learn slot-specific features. We show that this significantly improves tracking of rare states and achieves state-of-the-art performance on the WoZ and DSTC2 state tracking tasks. GLAD obtains 88.1% joint goal accuracy and 97.1% request accuracy on WoZ, outperforming prior work by 3.7% and 5.5%. On DSTC2, our model obtains 74.5% joint goal accuracy and 97.5% request accuracy, outperforming prior work by 1.1% and 1.0%.

1 Introduction

Task oriented dialogue systems can significantly reduce operating costs by automating processes such as call center dispatch and online customer support. Moreover, when combined with automatic speech recognition systems, task-oriented dialogue systems provide the foundation of intelligent assistants such as Amazon Alexa, Apple Siri, and Google Assistant. In turn, these assistants allow for natural, personalized interactions with users by tailoring natural language system responses to the dialogue context. Dialogue state tracking (DST) is a crucial part of dialogue systems. In DST, a dialogue state tracker estimates the state of the conversation using the current user utterance and the conversation history. This estimated state is then used by the system to plan the next action and respond to the user. A state in DST typically consists of a set of *requests* and *joint goals*. Consider the task of restaurant reservation as an example. During each turn, the user may inform the system of particular *goals* the user would like to achieve (e.g. `inform(food=french)`), or *request* for more information from the system (e.g. `request(address)`). The set of goal and request slot-value pairs (e.g. `(food, french)`, `(request, address)`) given during a turn are referred to as the *turn goal* and *turn request*. The *joint goal* is the set of accumulated turn goals up to the current turn. Figure 1 shows an example dialogue with annotated turn states, in which the user reserves a restaurant.

Traditional dialogue state trackers rely on Spoken Language Understanding (SLU) systems (Henderson et al., 2012) in order to understand user utterances. These trackers accumulate errors from the SLU, which sometimes do not have the necessary dialogue context to interpret the user utterances. Subsequent DST research forgo the SLU and directly infer the state using the conversation history and the user utterance (Henderson et al., 2014b; Zilka and Jurcicek, 2015; Mrkšić et al., 2015). These trackers rely on hand-crafted semantic dictionaries and delexicalization — the anonymization of slots and values using generic tags — to achieve generalization. Recent work by Mrkšić et al. (2017) apply representation learning using convolutional neural networks to learn features relevant for each state as opposed to hand-crafting features.

A key problem in DST that is not addressed by existing methods is the extraction of rare slot-value pairs that compose the state during each turn. Because task oriented dialogues cover large



User
System
User utterance
Where would you go to eat in the south part of town?
Turn goals and requests
inform(area=south)
System actions
request(food)
request(price range)
System response
ok I can help you with that. Are you looking for a particular type of food, or within a specific price range?
I just want to eat at a cheap restaurant in the south part of town. What food types are available, can you also provide some phone numbers?
inform(price range=cheap)
inform(area=south)
request(phone)
request(food)
request(food)
I found two restaurants serving cheap food. Would you prefer Portuguese or Chinese food?
Either is fine, can I have the phone number please?
request(phone)
The lucky start is at 01223 244277 and Nandos is at 01223 327908.
Thank you very much.

Figure 1: An example dialogue from the WoZ restaurant reservation corpus. Dashed lines divide turns in the dialogue. A turn contains an user utterance (purple), followed by corresponding turn-level goals and requests (blue). The system then executes actions (yellow), and formulates the result into a natural language response (yellow).

state spaces, many slot-value pairs that compose the state rarely occur in the training data. Although the chance of a particular rare slot-value pair being specified by the user in a turn is small, the chance that at least one rare slot-value pair is specified is large. Failure to predict these rare slot-value pairs results in incorrect turn-level goal and request tracking. Accumulated errors in turn-level goal tracking significantly degrade joint goal-tracking. For example, in the WoZ state tracking dataset, slot-value pairs have 214.9 training examples on average, while 38.6% of turns have a joint goal that contains a rare slot-value pair with less than 20 training examples.

In this work, we propose the **G**lobal-**L**ocally Self-**A**ttentive **D**ialogue State Tracker (GLAD), a new state-of-the-art model for dialogue state tracking. In contrast to previous work that estimate each slot-value pair independently, GLAD uses global modules to share parameters between estimators for each slot and local modules to learn slot-specific feature representations. We show that by doing so, GLAD generalizes on rare slot-value pairs with few training examples. GLAD achieves state-of-the-art results of 88.1% goal accuracy and 97.1% request accuracy on the WoZ dialogue state tracking task (Wen et al., 2017), outperforming prior best by 3.7% and 5.5%. On DSTC2 (Henderson et al., 2014a), we achieve 74.5% goal accuracy and 97.5% request accuracy, outperforming prior best by 1.1% and 1.0%.

2 Global-Locally Self-Attentive Dialogue State Tracker

One formulation of state tracking is to predict the turn state given an user utterance and previous system actions (Williams and Young, 2007). Like previous methods (Henderson et al., 2014b; Wen et al., 2017; Mrkšić et al., 2017), GLAD decomposes the multi-label state prediction problem into a collection of binary prediction problems by using a distinct estimator for each slot-value pair that make up the state. Hence, we describe GLAD with respect to a slot-value pair that is being predicted by the model.

Shown in Figure 2, GLAD is comprised of an encoder module and a scoring module. The encoder module consists of separate global-locally self-attentive encoders for the user utterance, the previous system actions, and the slot-value pair under consideration. The scoring module consists of two scorers. One scorer considers the contribution from the utterance while the other considers the contribution from previous system actions.

2.1 Global-Locally Self-Attentive Encoder

We begin by describing the global-locally self-attentive encoder, which makes up the encoder module. DST datasets tend to be small relative to their state space in that many slot-value pairs rarely occur in the dataset. Because each state is comprised of a set of slot-value pairs, many of them rare, poor inference of rare slot-value pairs subsequently results in poor turn-level tracking. This problem is amplified in joint tracking, due to the accumulation of turn-level errors. In developing this encoder, we seek to better model

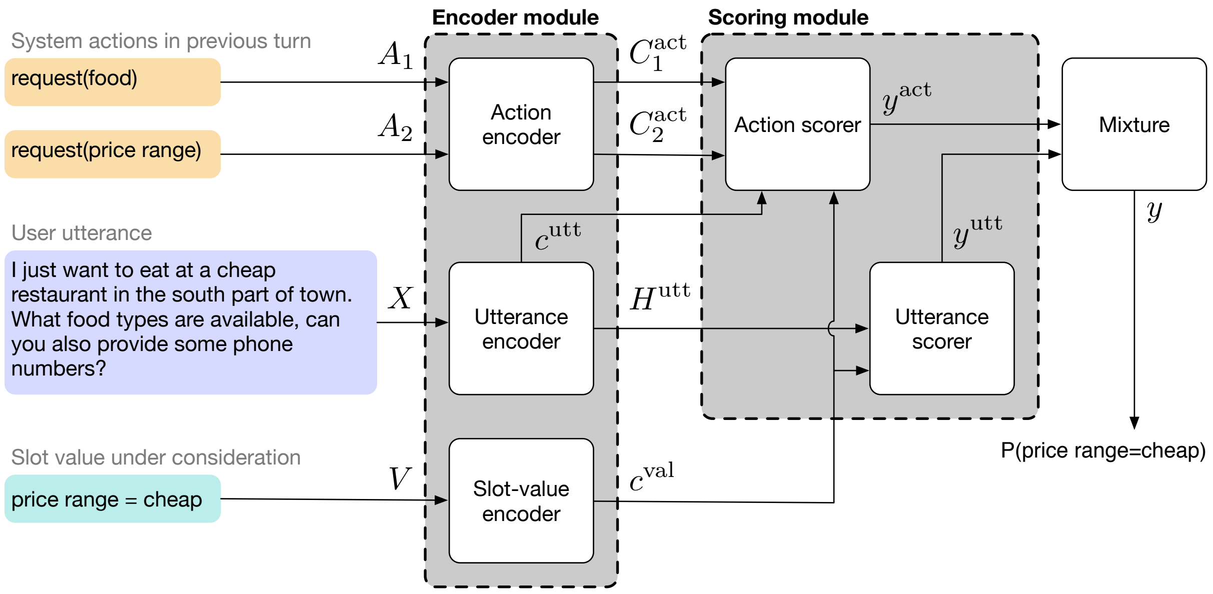


Figure 2: The Global-Locally Self-Attentive Dialogue State Tracker.

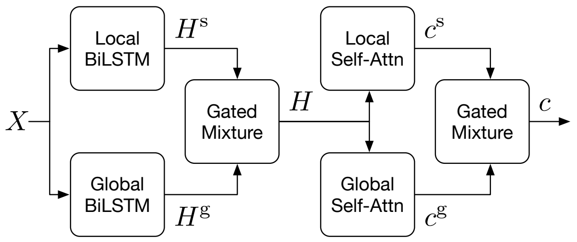

Figure 3: Global-locally self-attentive encoder.

rare slot-value pairs by sharing parameters between each slot through global modules and learning slot-specific features through local modules.

The global-locally self-attentive encoder consists of a bidirectional LSTM (Hochreiter and Schmidhuber, 1997), which captures temporal relationships within the sequence, followed by a self-attention layer to compute the summary of the sequence. Figure 3 illustrates the global-locally self-attentive encoder.

Consider the process of encoding a sequence with respect to a particular slot s. Let n denote the number of words in the sequence, d_{emb} the dimension of the embeddings, and $X \in \mathbb{R}^{n \times d_{\mathrm{emb}}}$ the word embeddings corresponding to words in the sequence. We produce a global encoding H^{g} of X using a global bidirectional LSTM.

$$H^{\mathrm{g}} = \mathrm{biLSTM}^{\mathrm{g}}(X) \in \mathbb{R}^{n \times d_{\mathrm{rnn}}} \qquad (1)$$

where d_{rnn} is the dimension of the LSTM state. We similarly produce a local encoding H^{s} of X, taking into account the slot s, using a local bidirectional LSTM.

$$H^{\mathrm{s}} = \mathrm{biLSTM}^{\mathrm{s}}(X) \in \mathbb{R}^{n \times d_{\mathrm{rnn}}} \qquad (2)$$

The outputs of the two LSTMs are combined through a mixture layer to yield a global-local encoding H of X.

$$H = \beta^{\mathrm{s}} H^{\mathrm{s}} + (1 - \beta^{\mathrm{s}}) H^{\mathrm{g}} \in \mathbb{R}^{n \times d_{\mathrm{rnn}}} \qquad (3)$$

Here, the scalar β^{s} is a learned parameter between 0 and 1 that is specific to the slot s. Next, we compute a global-local self-attention context c over H. Self-attention, or intra-attention, is a very effective method of computing summary context over variable-length sequences for natural language processing tasks (Cheng et al., 2016; Vaswani et al., 2017; He et al., 2017; Lee et al., 2017). In our case, we use a global self-attention module to compute attention context useful for general-purpose state tracking, as well as a local self-attention module to compute slot-specific attention context.

For each ith element H_i, we compute a scalar global self-attention score a_i^{g} which is subsequently normalized across all elements using a softmax function.

$$a_i^{\mathrm{g}} = W^{\mathrm{g}} H_i + b^{\mathrm{g}} \in \mathbb{R} \qquad (4)$$

$$p^{\mathrm{g}} = \mathrm{softmax}(a^{\mathrm{g}}) \in \mathbb{R}^n \qquad (5)$$

The global self-attention context c^{g} is then the sum of each element H_i, weighted by the corresponding normalized global self-attention score p_i^{g}.

$$c^{\mathrm{g}} = \sum_i p_i^{\mathrm{g}} H_i \in \mathbb{R}^{d_{\mathrm{rnn}}} \tag{6}$$

We similarly compute the local self-attention context c^{s}.

$$\begin{aligned} a_i^{\mathrm{s}} &= W^{\mathrm{s}} H_i + b^{\mathrm{s}} \in \mathbb{R} && (7) \\ p^{\mathrm{s}} &= \mathrm{softmax}\left(a^{\mathrm{s}}\right) \in \mathbb{R}^n && (8) \\ c^{\mathrm{s}} &= \sum_i p_i^{\mathrm{s}} H_i \in \mathbb{R}^{d_{\mathrm{rnn}}} && (9) \end{aligned}$$

The global-local self-attention context c is the mixture

$$c = \beta^{\mathrm{s}} c^{\mathrm{s}} + \left(1 - \beta^{\mathrm{s}}\right) c^{\mathrm{g}} \in \mathbb{R}^{n \times d_{\mathrm{rnn}}} \tag{10}$$

For ease of exposition, we define the multi-value encode function $\mathrm{encode}\left(X\right)$.

$$\mathrm{encode} : X \to H, c \tag{11}$$

This function maps the sequence X to the encoding H and the self-attention context c.

2.2 Encoding module

Having defined the global-locally self-attentive encoder, we now build representations for the user utterance, the previous system actions, and the slot-value pair under consideration. Let U denote word embeddings of the user utterance, A_j denote those of the jth previous system action (e.g. `request ( price range )`, and V denote those of the slot-value pair under consideration (e.g. `food = french`). We have

$$\begin{aligned} H^{\mathrm{utt}}, c^{\mathrm{utt}} &= \mathrm{encode}\left(U\right) && (12) \\ H_j^{\mathrm{act}}, C_j^{\mathrm{act}} &= \mathrm{encode}\left(A_j\right) && (13) \\ H^{\mathrm{val}}, c^{\mathrm{val}} &= \mathrm{encode}\left(V\right) && (14) \end{aligned}$$

2.3 Scoring module

Intuitively, there are two sources of contribution to whether the user has expressed the slot-value pair under consideration. The first source of contribution is the user utterance, in which the user directly states the goals and requests. An example of this is the user saying "how about a French restaurant in the centre of town?", after the system asked "how may I help you?" To handle these cases, we determine whether the utterance specifies the slot-value pair. Namely, we attend over the user utterance H^{utt}, taking into account the slot-value pair being considered c^{val}, and use the resulting attention context q^{utt} to score the slot-value pair.

$$\begin{aligned} a_i^{\mathrm{utt}} &= \left(H_i^{\mathrm{utt}}\right)^{\intercal} c^{\mathrm{val}} \in \mathbb{R} && (15) \\ p^{\mathrm{utt}} &= \mathrm{softmax}\left(a^{\mathrm{utt}}\right) \in \mathbb{R}^m && (16) \\ q^{\mathrm{utt}} &= \sum_i p_i^{\mathrm{utt}} H_i^{\mathrm{utt}} \in \mathbb{R}^{d_{\mathrm{rnn}}} && (17) \\ y^{\mathrm{utt}} &= W q^{\mathrm{utt}} + b \in \mathbb{R} && (18) \end{aligned}$$

where m is the number of words in the user utterance. The score y^{utt} indicates the degree to which the value was expressed by the user utterance.

The second source of contribution is the previous system actions. This source is informative when the user utterance does not present enough information and instead refers to previous system actions. An example of this is the user saying "yes", after the system asked "would you like a restaurant in the centre of town?" To handle these cases, we examine previous actions after considering the user utterance. First, we attend over the previous action representations $C^{\mathrm{act}} = [C_1^{\mathrm{act}} \cdots C_l^{\mathrm{act}}]$, taking into account the current user utterance c^{utt}. Here, l is the number of previous system actions. Then, we use the similarity between the attention context q^{act} and the slot-value pair c^{val} to score the slot-value pair.

$$\begin{aligned} a_j^{\mathrm{act}} &= \left(C_j^{\mathrm{act}}\right)^{\intercal} c^{\mathrm{utt}} \in \mathbb{R} && (19) \\ p^{\mathrm{act}} &= \mathrm{softmax}\left(a^{\mathrm{act}}\right) \in \mathbb{R}^{l+1} && (20) \\ q^{\mathrm{act}} &= \sum_j p_j^{\mathrm{act}} C_j^{\mathrm{act}} \in \mathbb{R}^{d_{\mathrm{rnn}}} && (21) \\ y^{\mathrm{act}} &= \left(q^{\mathrm{act}}\right)^{\intercal} c^{\mathrm{val}} \in \mathbb{R} && (22) \end{aligned}$$

In addition to real previous system actions, we introduce a sentinel action to each turn which allows the attention mechanism to ignore previous system actions. The score y^{act} indicates the degree to which the value was expressed by the previous actions.

The final score y is then a weighted sum between the two scores y^{utt} and y^{act}, normalized by the sigmoid function σ.

$$y = \sigma\left(y^{\text{utt}} + w y^{\text{act}}\right) \in \mathbb{R} \qquad (23)$$

Here, the weight w is a learned parameter.

3 Experiments

3.1 Dataset

The Dialogue Systems Technology Challenges (DSTC) provides a common framework for developing and evaluating dialogue systems and dialogue state trackers (Williams et al., 2013; Henderson et al., 2014a). Under this framework, dialogue semantics such as states and actions are based on a task ontology such as restaurant reservation. During each turn, the user may inform the system of particular *goals* (e.g. `inform(food=french)`), or *request* for more information from the system (e.g. `request(address)`). For instance, `food` and `area` are examples of slots in the DSTC2 task, and `french` and `chinese` are example values within the `food` slot. We train and evaluate our model using DSTC2 as well as the Wizard of Oz (WoZ) restaurant reservation task (Wen et al., 2017), which also adheres to the DSTC framework and has the same ontology as DSTC2.

For DSTC2, it is standard to evaluate using the N-best list of the automatic speech recognition system (ASR) that is included with the dataset. Because of this, each turn in the DSTC2 dataset contains several noisy ASR outputs instead of a noise-free user utterance. The WoZ task does not provide ASR outputs, and we instead train and evaluate using the user utterance.

3.2 Metrics

We evaluate our model using turn-level request tracking accuracy as well as joint goal tracking accuracy. Our definition of GLAD in the previous sections describes how to obtain turn goals and requests. To compute the joint goal, we simply accumulate turn goals. In the event that the current turn goal specifies a slot that has been specified before, the new specification takes precedence. For example, suppose the user specifies a `food=french` restaurant during the current turn. If the joint goal has no existing `food` specifications, then we simply add `food=french` to the joint goal. Alternatively, if `food=thai` had been specified in a previous turn, we simply replace it with `food=french`.

3.3 Implementation Details

We use fixed, pretrained GloVe embeddings (Pennington et al., 2014) as well as character n-gram embeddings (Hashimoto et al., 2017). Each model is trained using ADAM (Kingma and Ba, 2015). For regularization, we apply dropout with 0.2 drop rate (Srivastava et al., 2014) to the output of each local module and each global module. We use the development split for hyperparameter tuning and apply early stopping using the joint goal accuracy.

For the DSTC2 task, we train using transcripts of user utterances and evaluate using the noisy ASR transcriptions. During evaluation, we take the sum of the scores resulting from each ASR output as the output score of a particular slot-value. We then normalize this sum using a sigmoid function as shown in Equation (23). We also apply word dropout, in which the embeddings of a word is randomly set to zero with a probability of 0.3. This accounts for the poor quality of ASR outputs in DSTC2, which frequently miss several words in the user utterance. We did not find word dropout to be helpful for the WoZ task, which does not contain noisy ASR outputs.

3.4 Comparison to Existing Methods

Table 1 shows the performance of GLAD compared to previous state-of-the-art models. The delexicalisation models, which replace slots and values in the utterance with generic tags, are from Henderson et al. (2014b) for DSTC2 and Wen et al. (2017) for WoZ. Semantic dictionaries map slot-value pairs to hand-engineered synonyms and phrases. The NBT (Mrkšić et al., 2017) applies CNN over word embeddings learned over a paraphrase database (Wieting et al., 2015) instead of delexicalised n-gram features.

On the WoZ dataset, we find that GLAD significantly improves upon previous state-of-the-art performance by 3.7% on joint goal tracking accuracy and 5.5% on turn-level request tracking accuracy. On the DSTC dataset, which evaluates using noisy ASR outputs instead of user utterances, GLAD improves upon previous state of the art performance by 1.1% on joint goal tracking accuracy and 1.0% on turn-level request tracking accuracy.

Model	DSTC2		WoZ	
	Joint goal	Turn request	Joint goal	Turn request
Delexicalisation-Based Model	69.1%	95.7%	70.8%	87.1%
Delex. Model + Semantic Dictionary	72.9%	95.7%	83.7%	87.6%
Neural Belief Tracker (NBT) - DNN	72.6%	96.4%	84.4%	91.2%
Neural Belief Tracker (NBT) - CNN	73.4%	96.5%	84.2%	91.6%
GLAD	**74.5± 0.2%**	**97.5± 0.1%**	**88.1± 0.4%**	**97.1± 0.2%**

Table 1: Test accuracies on the DSTC2 and WoZ restaurant reservation datasets. The other models are: delexicalisation DSTC2 (Henderson et al., 2014b), delexicalisation WoZ (Wen et al., 2017), and NBT (Mrkšić et al., 2017). We run 10 models using random seeds with early stopping on the development set, and report the mean and standard deviation test accuracies for each dataset.

Model	Tn goal	Jnt goal	Tn request
GLAD	93.7%	88.8%	97.3%
- global	88.8%	73.4%	97.3%
- local	93.1%	86.6%	95.1%
- self-attn	91.6%	84.4%	97.1%
- LSTM	88.7%	71.5%	93.2%

Table 2: Ablation study showing turn goal, joint goal, and turn request accuracies on the dev. split of the WoZ dataset. For "- self-attn", we use mean-pooling instead of self-attention. For "- LSTM", we compute self-attention over word embeddings.

3.5 Ablation study

We perform ablation experiments on the development set to analyze the effectiveness of different components of GLAD. The results of these experiments are shown in Table 2. In addition to the joint goal accuracy and the turn request accuracy, we also show the turn goal accuracy for reference.

Temporal order is important for state tracking. We experiment with an embedding-matching variant of GLAD with self-attention but without LSTMs. The weaker performance by this model suggests that representations that capture temporal dependencies is helpful for understanding phrases for state tracking.

Self-attention allows slot-specific, robust feature learning. We observe a consistent drop in performance for models that use mean-pooling as opposed to self-attention (Equations (4) to (6)). This stems from the flexibility in the attention context computation afforded by the self-attention mechanism, which allows the model to focus on select words relevant to the slot-value pair under consideration. Figure 4 illustrates an example in which local self-attention modules focus on relevant parts of the utterance. We note that the model attends to relevant phrases that n-gram and embedding matching techniques do not capture (e.g. "within 5 miles" for the "area" slot).

Global-local sharing improves goal tracking. We study the two extremes of sharing between the global module and the local module. The first uses only the local module and results in degradation in goal tracking but does not affect request tracking (e.g. $\beta^s = 1$). This is because the former is a joint prediction over several slot-values with few training examples, whereas the latter predicts a single slot that has the most training examples.

The second uses only the global module and underperforms in both goal tracking and request tracking (e.g. $\beta^s = 0$). This model is less expressive, as it lacks slot-specific specializations except for the final scoring modules.

Figure 5 shows the performance of the original model and the two sharing variants across different numbers of occurrences in the training data. GLAD consistently outperforms both variants for rare slot-value pairs. For slot-value pairs with an abundance of training data, there is no significant performance difference between models as there is sufficient data to generalize.

3.6 Qualitative analysis

Table 3 shows example predictions by GLAD. In the first example, the user explicitly outlines requests and goals in a single utterance. In the second example, the model previously prompted the user for confirmation of two requests (e.g. for the restaurant's address and phone number), and the user simply answers in the affirmative. In this case, the model still obtains the correct result by leveraging the system actions in the previous turn. The last example demonstrates an error made by

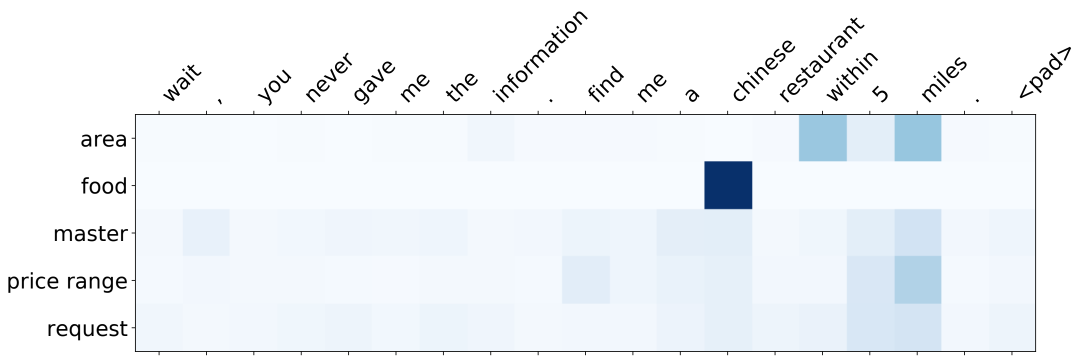

Figure 4: Global and local self-attention scores on user utterances. Each row corresponds to the self-attention score for a particular slot. Slot-specific local self-attention modules emphasize relevant key words and phrases to that slot, whereas the global module attends to all relevant words.

the model. Here, the user does not answer the system's previous request for the choice of food and instead asks for what food is available. The model misinterprets the lack of response as the user not caring about the choice of food.

4 Related Work

Dialogue State Tracking. Traditional dialogue state trackers rely on a separate SLU component that serves as the initial stage in the dialogue agent pipeline. The downstream tracker then combines the semantics extracted by the SLU with previous dialogue context in order to estimate the current dialogue state (Thomson and Young, 2010; Wang and Lemon, 2013; Williams, 2014; Perez and Liu, 2017). Recent results in dialogue state tracking show that it is beneficial to jointly learn speech understanding and dialogue tracking (Henderson et al., 2014b; Zilka and Jurcicek, 2015; Wen et al., 2017). These approaches directly take as input the N-best list produced by the ASR system. By avoiding the accumulation of errors from the initial SLU component, these joint approaches typically achieved stronger performance on tasks such as DSTC2. One drawback to these approaches is that they rely on hand-crafted features and complex domain-specific lexicon (in addition to the ontology), and consequently are difficult to extend and scale to new domains. The recent Neural Belief Tracker (NBT) by Mrkšić et al. (2017) avoids reliance on hand-crafted features and lexicon by using representation learning. The NBT employs convolutional filters over word embeddings in lieu of previously-used hand-engineered features. Moreover, to outperform previous methods, the NBT uses pretrained embeddings tailored to retain semantic relationships by injecting semantic similarity constraints from the Paraphrase Database (Wieting et al., 2015; Ganitkevitch et al., 2013). On the one hand, these specialized embeddings are more difficult to obtain than word embeddings from language modeling. On the other hand, these embeddings are not specific to any dialogue domain and are directly usable for new domains.

Neural attention models in NLP. Attention mechanisms have led to improvements on a variety of natural language processing tasks. Bahdanau et al. (2015) propose attentional sequence to sequence models for neural machine translation. Luong et al. (2015) analyze various attention techniques and highlight the effectiveness of the simple, parameterless dot product attention. Similar models have also proven successful in tasks such as summarization (See et al., 2017; Paulus et al., 2018). Self-attention, or intra-attention, has led improvements in language modeling, sentiment

analysis, natural language inference (Cheng et al., 2016), semantic role labeling (He et al., 2017), and coreference resolution (Lee et al., 2017). Deep self-attention has also achieved state-of-the-art results in machine translation (Vaswani et al., 2017). Coattention, or bidirectional attention that codependently encode two sequences, have led to significant gains in question answering (Xiong et al., 2017; Seo et al., 2017) as well as visual question answering (Lu et al., 2016).

Parameter sharing between related tasks. Sharing parameters between related tasks to improve joint performance is prominent in multi-task learning (Caruana, 1998; Thrun, 1996). Early works in multi-tasking use Gaussian processes whose covariance matrix is induced from shared kernels (Lawrence and Platt, 2004; Yu et al., 2005; Seeger et al., 2005; Bonilla et al., 2008). Hashimoto et al. (2017) propose a progressively trained joint model for NLP tasks. When a new task is introduced, a new section is added to the network whose inputs are intermediate representations from sections for previous tasks. In this sense, tasks share parameters in a hierarchical manner. Johnson et al. (2016) propose a single model that jointly learns to translate between multiple language pairs, including one-to-many, many-to-one, and many-to-many translation. Kaiser et al. (2017) propose a model that jointly learns multiple tasks across modalities. Each modality has a corresponding modality net, which extracts a representation that is fed into a shared encoder.

5 Conclusion

We introduced the Global-Locally Self-Attentive Dialogue State Tracker (GLAD), a new state-of-the-art model for dialogue state tracking. At the core of GLAD is the global-locally self-attention encoder, whose global modules allow parameter sharing between slots and local modules allow slot-specific feature learning. This allows GLAD to generalize on rare slot-value pairs with few training data. GLAD achieves state-of-the-art results of 88.1% goal accuracy and 97.1% request accuracy on the WoZ dialogue state tracking task, as well as 74.5% goal accuracy and 97.5% request accuracy on DSTC2.

Abstract

End-to-end task-oriented dialog systems usually suffer from the challenge of incorporating knowledge bases. In this paper, we propose a novel yet simple end-to-end differentiable model called memory-to-sequence (Mem2Seq) to address this issue. Mem2Seq is the first neural generative model that combines the multi-hop attention over memories with the idea of pointer network. We empirically show how Mem2Seq controls each generation step, and how its multi-hop attention mechanism helps in learning correlations between memories. In addition, our model is quite general without complicated task-specific designs. As a result, we show that Mem2Seq can be trained faster and attain the state-of-the-art performance on three different task-oriented dialog datasets.

1 Introduction

Task-oriented dialog systems help users to achieve specific goals with natural language such as restaurant reservation and schedule arrangement. Traditionally, they have been built with several pipelined modules: language understanding, dialog management, knowledge query, and language generation (Williams and Young, 2007; Hori et al., 2009; Lee et al., 2009; Levin et al., 2000; Young et al., 2013). Moreover, the ability to query external Knowledge Bases (KBs) is essential in task-oriented dialog systems, since the responses are guided not only by the dialog history but also by the query results (e.g. Table 1). However, despite the stability of such pipelined systems via combining domain-specific knowledge and slot-filling techniques, modeling the dependencies between modules is complex and the KB interpretation requires human effort.

Point of interest (poi)	Distance	Traffic info	Poi type	Address

	GOLD	Palo Alto is located at 436 Alger Dr.

Table 1: Example of generated responses for the In-Car Assistant on the navigation domain.

Recently, end-to-end approaches for dialog modeling, which use recurrent neural networks (RNN) encoder-decoder models, have shown promising results (Serban et al., 2016; Wen et al., 2017; Zhao et al., 2017). Since they can directly map plain text dialog history to the output responses, and the dialog states are latent, there is no need for hand-crafted state labels. Moreover, attention-based copy mechanism (Gulcehre et al., 2016; Eric and Manning, 2017) have been recently introduced to copy words directly from the input sources to the output responses. Using such mechanism, even when unknown tokens appear in the dialog history, the models are still able to produce correct and relevant entities.

However, although the above mentioned approaches were successful, they still suffer from two main problems: 1) They struggle to effectively incorporate external KB information into the RNN hidden states (Sukhbaatar et al., 2015),

[*] These two authors contributed equally.

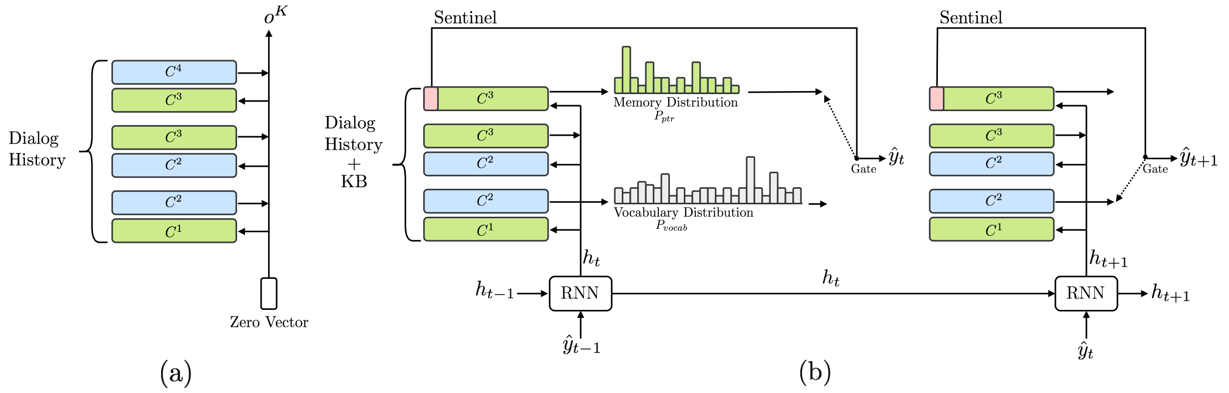

Figure 1: The proposed Mem2Seq architecture for task-oriented dialog systems. (a) Memory encoder with 3 hops; (b) Memory decoder over 2 step generation.

since RNNs are known to be unstable over long sequences. 2) Processing long sequences is very time-consuming, especially when using attention mechanisms.

On the other hand, end-to-end memory networks (MemNNs) are recurrent attention models over a possibly large external memory (Sukhbaatar et al., 2015). They write external memories into several embedding matrices, and use query vectors to read memories repeatedly. This approach can memorize external KB information and rapidly encode long dialog history. Moreover, the multi-hop mechanism of MemNN has empirically shown to be essential in achieving high performance on reasoning tasks (Bordes and Weston, 2017). Nevertheless, MemNN simply chooses its responses from a predefined candidate pool rather than generating word-by-word. In addition, the memory queries need explicit design rather than being learned, and the copy mechanism is absent.

To address these problems, we present a novel architecture that we call Memory-to-Sequence (Mem2Seq) to learn task-oriented dialogs in an end-to-end manner. In short, our model augments the existing MemNN framework with a sequential generative architecture, using global multi-hop attention mechanisms to copy words directly from dialog history or KBs. We summarize our main contributions as such: 1) Mem2Seq is the first model to combine multi-hop attention mechanisms with the idea of pointer networks, which allows us to effectively incorporate KB information. 2) Mem2Seq learns how to generate dynamic queries to control the memory access. In addition, we visualize and interpret the model dynamics among hops for both the memory controller and the attention. 3) Mem2Seq can be trained faster and achieve state-of-the-art results in several task-oriented dialog datasets.

2 Model Description

Mem2Seq [1] is composed of two components: the MemNN encoder, and the memory decoder as shown in Figure 1. The MemNN encoder creates a vector representation of the dialog history. Then the memory decoder reads and copies the memory to generate a response. We define all the words in the dialog history as a sequence of tokens $X = \{x_1, \ldots, x_n, \$\}$, where \$ is a special charter used as a sentinel, and the KB tuples as $B = \{b_1, \ldots, b_l\}$. We further define $U = [B; X]$ as the concatenation of the two sets X and B, $Y = \{y_1, \ldots, y_m\}$ as the set of words in the expected system response, and $PTR = \{ptr_1, \ldots, ptr_m\}$ as the pointer index set:

$$ptr_i = \begin{cases} max(z) & \text{if } \exists z \text{ s.t. } y_i = u_z \\ n+l+1 & \text{otherwise} \end{cases} \quad (1)$$

where $u_z \in U$ is the input sequence and $n + l + 1$ is the sentinel position index.

2.1 Memory Encoder

Mem2Seq uses a standard MemNN with adjacent weighted tying (Sukhbaatar et al., 2015) as an encoder. The input of the encoder is word-level information in U. The memories of MemNN are represented by a set of trainable embedding matrices $C = \{C^1, \ldots, C^{K+1}\}$, where each C^k maps tokens to vectors, and a query vector q^k is used as a reading head. The model loops over K hops and

[1]The code is available at https://github.com/HLTCHKUST/Mem2Seq

it computes the attention weights at hop k for each memory i using:

$$p_i^k = \text{Softmax}((q^k)^T C_i^k), \tag{2}$$

where $C_i^k = C^k(x_i)$ is the memory content in position i, and $\text{Softmax}(z_i) = e^{z_i}/\Sigma_j e^{z_j}$. Here, p^k is a soft memory selector that decides the memory relevance with respect to the query vector q^k. Then, the model reads out the memory o^k by the weighted sum over C^{k+1} [2],

$$o^k = \sum_i p_i^k C_i^{k+1}. \tag{3}$$

Then, the query vector is updated for the next hop by using $q^{k+1} = q^k + o^k$. The result from the encoding step is the memory vector o^K, which will become the input for the decoding step.

2.2 Memory Decoder

The decoder uses RNN and MemNN. The MemNN is loaded with both X and B, since we use both dialog history and KB information to generate a proper system response. A Gated Recurrent Unit (GRU) (Chung et al., 2014), is used as a dynamic query generator for the MemNN. At each decoding step t, the GRU gets the previously generated word and the previous query as input, and it generates the new query vector. Formally:

$$h_t = \text{GRU}(C^1(\hat{y}_{t-1}), h_{t-1}); \tag{4}$$

Then the query h_t is passed to the MemNN which will produce the token, where h_0 is the encoder vector o^K. At each time step, two distribution are generated: one over all the words in the vocabulary (P_{vocab}), and one over the memory contents (P_{ptr}), which are the dialog history and KB inofrmation. The first, P_{vocab}, is generated by concatenating the first hop attention read out and the current query vector.

$$P_{vocab}(\hat{y}_t) = \text{Softmax}(W_1[h_t; o^1]) \tag{5}$$

where W_1 is a trainable parameter. On the other hand, P_{ptr} is generated using the attention weights at the last MemNN hop of the decoder: $P_{ptr} = p_t^K$. Our decoder generates tokens by pointing to the input words in the memory, which is a similar mechanism to the attention used in pointer networks (Vinyals et al., 2015).

[2]Here is C^{k+1} since we use adjacent weighted tying.

We designed our architecture in this way because we expect the attention weights in the first and the last hop to show a "looser" and "sharper" distribution, respectively. To elaborate, the first hop focuses more on retrieving memory information and the last one tends to choose the exact token leveraging the pointer supervision. Hence, during training all the parameters are jointly learned by minimizing the sum of two standard cross-entropy losses: one between $P_{vocab}(\hat{y}_t)$ and $y_t \in Y$ for the vocabulary distribution, and one between $P_{ptr}(\hat{y}_t)$ and $ptr_t \in PTR$ for the memory distribution.

2.2.1 Sentinel

If the expected word is not appearing in the memories, then the P_{ptr} is trained to produce the sentinel token \$, as shown in Equation 1. Once the sentinel is chosen, our model generates the token from P_{vocab}, otherwise, it takes the memory content using the P_{ptr} distribution. Basically, the sentinel token is used as a hard gate to control which distribution to use at each time step. A similar approach has been used in (Merity et al., 2017) to control a soft gate in a language modeling task. With this method, the model does not need to learn a gating function separately as in Gulcehre et al. (2016), and is not constrained by a soft gate function as in See et al. (2017).

2.3 Memory Content

We store word-level content X in the memory module. Similar to Bordes and Weston (2017), we add temporal information and speaker information in each token of X to capture the sequential dependencies. For example, "hello $t1$ $\$u$" means "hello" at time step 1 spoken by a user.

On the other hand, to store B, the KB information, we follow the works of Miller et al. (2016); Eric et al. (2017) that use a (subject, relation, object) representation. For example, we represent the information of The Westin in Table 1: (The Westin, Distance, 5 miles). Thus, we sum word embeddings of the subject, relation, and object to obtain each KB memory representation. During decoding stage, the object part is used as the generated word for P_{ptr}. For instance, when the KB tuple (The Westin, Distance, 5 miles) is pointed, our model copies "5 miles" as an output word. Notice that only a specific section of the KB, relevant to a specific dialog, is loaded into the memory.

Task	1	2	3	4	5	DSTC2	In-Car

Table 2: Dataset statistics for 3 different datasets.

3 Experimental Setup

3.1 Dataset

We use three public multi-turn task-oriented dialog datasets to evaluate our model: the bAbI dialog (Bordes and Weston, 2017), DSTC2 (Henderson et al., 2014) and In-Car Assistant (Eric et al., 2017). The train/validation/test sets of these three datasets are split in advance by the providers. The dataset statistics are reported in Table 2.

The bAbI dialog includes five end-to-end dialog learning tasks in the restaurant domain, which are simulated dialog data. Task 1 to 4 are about API calls, refining API calls, recommending options, and providing additional information, respectively. Task 5 is the union of tasks 1-4. There are two test sets for each task: one follows the same distribution as the training set and the other has out-of-vocabulary (OOV) entity values that does not exist in the training set.

We also used dialogs extracted from the Dialog State Tracking Challenge 2 (DSTC2) with the refined version from Bordes and Weston (2017), which ignores the dialog state annotations. The main difference with bAbI dialog is that this dataset is extracted from real human-bot dialogs, which is noisier and harder since the bots made mistakes due to speech recognition errors or misinterpretations.

Recently, In-Car Assistant dataset has been released. which is a human-human, multi-domain dialog dataset collected from Amazon Mechanical Turk. It has three distinct domains: calendar scheduling, weather information retrieval, and point-of-interest navigation. This dataset has shorter conversation turns, but the user and system behaviors are more diverse. In addition, the system responses are variant and the KB information is much more complicated. Hence, this dataset requires stronger ability to interact with KBs, rather than dialog state tracking.

3.2 Training

We trained our model end-to-end using Adam optimizer (Kingma and Ba, 2015), and chose learning rate between $[1e^{-3}, 1e^{-4}]$. The MemNNs, both encoder and decoder, have hops $K = 1, 3, 6$ to show the performance difference. We use simple greedy search and without any re-scoring techniques. The embedding size, which is also equivalent to the memory size and the RNN hidden size (i.e., including the baselines), has been selected between $[64, 512]$. The dropout rate is set between $[0.1, 0.4]$, and we also randomly mask some input words into unknown tokens to simulate OOV situation with the same dropout ratio. In all the datasets, we tuned the hyper-parameters with grid-search over the validation set, using as measure to the Per-response Accuracy for bAbI dialog and DSTC2, and BLEU score for the In-Car Assistant.

3.3 Evaluation Metrics

Per-response/dialog Accuracy: A generative response is correct only if it is exactly the same as the gold response. A dialog is correct only if every generated responses of the dialog are correct, which can be considered as the task-completion rate. Note that Bordes and Weston (2017) tests their model by selecting the system response from predefined response candidates, that is, their system solves a multi-class classification task. Since Mem2Seq generates each token individually, evaluating with this metric is much more challenging for our model.

BLEU: It is a measure commonly used for machine translation systems (Papineni et al., 2002), but it has also been used in evaluating dialog systems (Eric and Manning, 2017; Zhao et al., 2017) and chat-bots (Ritter et al., 2011; Li et al., 2016). Moreover, BLEU score is a relevant measure in task-oriented dialog as there is not a large variance between the generated answers, unlike open domain generation (Liu et al., 2016). Hence, we include BLEU score in our evaluation (i.e. using Moses `multi-bleu.perl` script).

Entity F1: We micro-average over the entire set of system responses and compare the entities in plain text. The entities in each gold system response are selected by a predefined entity list. This metric evaluates the ability to generate relevant entities from the provided KBs and to capture the semantics of the dialog (Eric and Manning, 2017; Eric et al., 2017). Note that the original In-Car Assis-

Table 5: Evaluation on In-Car Assistant. Human, rule-based and KV Retrieval Net evaluation (with *) are reported from (Eric et al., 2017), which are not directly comparable. Mem2Seq achieves highest BLEU and entity F1 score over baselines.

tant F1 scores reported in Eric et al. (2017) uses the entities in their canonicalized forms, which are not calculated based on real entity value. Since the datasets are not designed for slot-tracking, we report entity F1 rather than the slot-tracking accuracy as in (Wen et al., 2017; Zhao et al., 2017).

4 Experimental Results

We mainly compare Mem2Seq with hop 1,3,6 with several existing models: query-reduction networks (QRN, Seo et al. (2017)), end-to-end memory networks (MemNN, Sukhbaatar et al. (2015)), and gated end-to-end memory networks (GMemNN, Liu and Perez (2017)). We also implemented the following baseline models: standard sequence-to-sequence (Seq2Seq) models with and without attention (Luong et al., 2015), and pointer to unknown (Ptr-Unk, Gulcehre et al. (2016)). Note that the results we listed in Table 3 and Table 4 for QRN are different from the original paper, because based on their released code, [3] we discovered that the per-response accuracy was not correctly computed.

bAbI Dialog: In Table 3, we follow Bordes and Weston (2017) to compare the performance based on per-response and per-dialog accuracy. Mem2Seq with 6 hops can achieve per-response 97.9% and per-dialog 69.6% accuracy in T5, and 84.5% and 2.3% for T5-OOV, which surpass existing methods by far. One can find that in T3 especially, which is the task to recommend restaurant based on their ranks, our model can achieve promising results due to the memory pointer. In terms of per-response accuracy, this indicates that our model can generalize well with few performance loss for test OOV data, while others have around 15-20% drop. The performance gain in OOV data is also mainly attributed to the use of copy mechanism. In addition, the effectiveness of hops is demonstrated in tasks 3-5, since they require reasoning ability over the KB information. Note that QRN, MemNN and GMemNN viewed bAbI dialog tasks as classification problems. Although their tasks are easier compared to our generative methods, Mem2Seq models can still overpass the performance. Finally, one can find that Seq2Seq and Ptr-Unk models are also strong baselines, which further confirms that generative methods can also achieve good performance in task-oriented dialog systems (Eric and Manning, 2017).

[3] We simply modified the evaluation part and reported the results. (https://github.com/uwnlp/qrn)

DSTC2: In Table 4, the Seq2Seq models from Eric and Manning (2017) and the rule-based from Bordes and Weston (2017) are reported. Mem2Seq has the highest 75.3% entity F1 score and an high of 55.3 BLEU score. This further confirms that Mem2Seq can perform well in retrieving the correct entity, using the multiple hop mechanism without losing language modeling. Here, we do not report the results using match type (Bordes and Weston, 2017) or entity type (Eric and Manning, 2017) feature, since this meta-information are not commonly available and we want to have an evaluation on plain input output couples. One can also find out that, Mem2Seq comparable per-response accuracy (i.e. 2% margin) among other existing solution. Note that the per-response accuracy for every model is less than 50% since the dataset is quite noisy and it is hard to generate a response that is exactly the same as the gold one.

In-Car Assistant: In Table 5, our model can achieve highest 12.6 BLEU score. In addition, Mem2Seq has shown promising results in terms of Entity F1 scores (33.4%), which are, in general, much higher than those of other baselines. Note that the numbers reported from Eric et al. (2017) are not directly comparable to ours as we mention below. The other baselines such as Seq2Seq or Ptr-Unk especially have worse performances in this dataset since it is very inefficient for RNN methods to encode longer KB information, which is the advantage of Mem2Seq.

Furthermore, we observe an interesting phenomenon that humans can easily achieve a high entity F1 score with a low BLEU score. This implies that stronger reasoning ability over entities (hops) is crucial, but the results may not be similar to the golden answer. We believe humans can produce good answers even with a low BLEU score, since there could be different ways to express the same concepts. Therefore, Mem2Seq shows the potential to successfully choose the correct entities.

Note that the results of KV Retrieval Net baseline reported in Table 5 come from the original paper (Eric et al., 2017) of In-Car Assistant, where they simplified the task by mapping the expression of entities to a canonical form using named entity recognition (NER) and linking. Hence the evaluation is not directly comparable to our system. For example, their model learned to generate responses such as "You have a football game at football_time with football_party," instead of generating a sentence such as "You have a football game at 7 pm with John." Since there could be more than one football_party or football_time, their model does not learn how to access the KBs, but it rather learns the canonicalized language model.

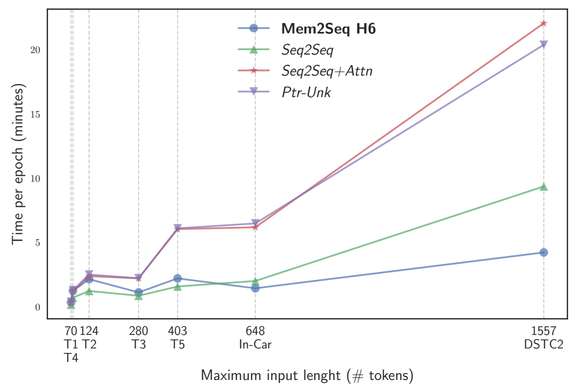

Figure 2: Training time per-epoch for different tasks (lower is better). The speed difference becomes larger as the maximal input length increases.

Time Per-Epoch: We also compare the training time [4] in Figure 2. The experiments are set with batch size 16, and we report each model with the hyper-parameter that can achieved the highest performance. One can observe that the training time is not that different for short input length (bAbI dialog tasks 1-4) and the gap becomes larger as the maximal input length increases. Mem2Seq is around 5 times faster in In-Car Assistant and DSTC2 compared to Seq2Seq with attention. This difference in training efficiency is mainly attributed to the fact that Seq2Seq models have input sequential dependencies which limit any parallelization. Moreover, it is unavoidable for Seq2Seq models to encode KBs, instead Mem2Seq only encodes with dialog history.

5 Analysis and Discussion

Memory Attention: Analyzing the attention weights has been frequently used to show the memory read-out, since it is an intuitive way to understand the model dynamics. Figure 3 shows the attention vector at the last hop for each generated token. Each column represents the P_{ptr} vector at the corresponding generation step. Our model has a sharp distribution over the memory, which im-

[4]Intel(R) Core(TM) i7-3930K CPU@3.20GHz, using a GeForce GTX 1080 Ti

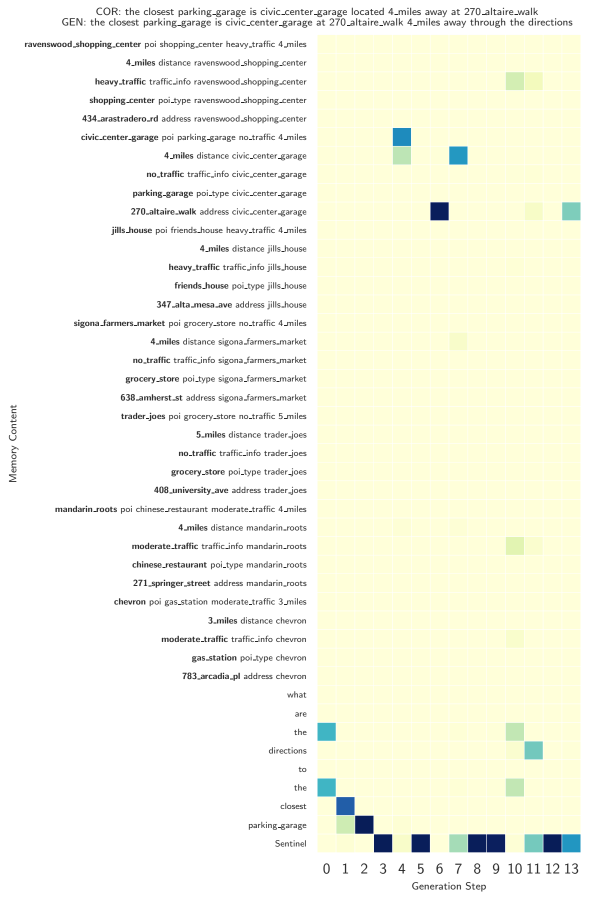

Figure 3: Last hop memory attention visualization from the In-Car dataset. COR and GEN on the top are the correct response and our generated one.

plies that it is able to select the right token from the memory. For example, the KB information "270_altarie_walk" was retrieved at the sixth step, which is an address for "civic_center_garage". On the other hand, if the sentinel is triggered, then the generated word comes from vocabulary distribution P_{vocab}. For instance, the third generation step triggered the sentinel, and "is" is generated from the vocabulary as the word is not present in the dialog history.

Multiple Hops: Mem2Seq shows how multiple hops improve the model performance in several datasets. Task 3 in the bAbI dialog dataset serves as an example, in which the systems need to recommend restaurants to users based on restaurant ranking from highest to lowest. Users can reject the recommendation and the system has to reason over the next highest restaurant. We found out there are two common patterns between hops among different samples: 1) the first hop is usually used to score all the relevant memories and

retrieve information; 2) the last hop tends to focus on a specific token and makes mistakes when the attention is not sharp. Such mistakes can be attributed to lack of hops, for some samples. For more information, we report two figures in the supplementary material.

Query Vectors: In Figure 4, the principal component analysis of Mem2Seq queries vectors is shown for different hops. Each dot is a query vector h_t during each decoding time step, and it has its corresponding generated word y_t. The blue dots are the words generated from P_{vocab}, which triggered the sentinel, and orange ones are from P_{ptr}. One can find that in (a) hop 1, there is no clear separation of two different colors but each of which tends to group together. On the other hand, the separation becomes clearer in (b) hop 6 as each color clusters into several groups such as location, cuisine, and number. Our model tends to retrieve more information in the first hop, and points into the memories in the last hop.

Examples: Table 1 and 6 show the generated responses of different models in the two test set samples from the In-Car Assistant dataset. We report examples from this dataset since their answers are more human-like and not as structured and repetitive as others. Seq2Seq generally cannot produce related information, and sometimes fail in language modeling. Instead, using attention helps with this issue, but it still rarely produces the correct entities. For example, Seq2Seq with attention generated 5 miles in Table 1 but the correct one is 4 miles. In addition, Ptr-Unk often cannot copy the correct token from the input, as shown by "PAD" in Table 1. On the other hand, Mem2Seq is able to produce the correct responses in this two examples. In particular in the navigation domain, shown in Table 1, Mem2Seq produces a different but still correct utterance. We report further examples from all the domains in the supplementary material.

Discussions: Conventional task-oriented dialog systems (Williams and Young, 2007), which are still widely used in commercial systems, require a multitude of human efforts in system designing and data collection. On the other hand, although end-to-end dialog systems are not perfect yet, they require much less human interference, especially in the dataset construction, as raw conversational text and KB information can be used directly without the need of heavy preprocessing (e.g. NER, dependency parsing). To this extent, Mem2Seq is a simple generative model that is able to incorporate KB information with promising generalization ability. We also discovered that the entity F1 score may be a more comprehensive evaluation metric than per-response accuracy or BLEU score, as humans can normally choose the right entities but have very diversified responses. Indeed, we want to highlight that humans may have a low BLEU score despite their correctness because there may not be a large n-gram overlap between the given response and the expected one. However, this does not imply that there is no correlation between BLEU score and human evaluation. In fact, unlike chat-bots and open domain dialogs where BLEU score does not correlate with human evaluation (Liu et al., 2016), in task-oriented dialogs the answers are constrained to particular entities and recurrent patterns. Thus, we believe BLEU score still can be considered as a relevant measure. In future works, several methods could be applied (e.g. Reinforcement Learning (Ranzato et al., 2016), Beam Search (Wiseman and Rush, 2016)) to improve both responses relevance and entity F1 score. However, we preferred to keep our model as simple as possible in order to show that it works well even without advanced training methods.

6 Related Works

End-to-end task-oriented dialog systems train a single model directly on text transcripts of dialogs (Wen et al., 2017; Serban et al., 2016; Williams et al., 2017; Zhao et al., 2017; Seo et al., 2017; Serban et al., 2017). Here, RNNs play an important role due to their ability to create a latent representation, avoiding the need for artificial state labels. End-to-End Memory Networks (Bordes and Weston, 2017; Sukhbaatar et al., 2015), and its variants (Liu and Perez, 2017; Wu et al., 2017, 2018) have also shown good results in such tasks. In each of these architectures, the output is produced by generating a sequence of tokens, or by selecting a set of predefined utterances.

Sequence-to-sequence (Seq2Seq) models have also been used in task-oriented dialog systems (Zhao et al., 2017). These architectures have better language modeling ability, but they do not work well in KB retrieval. Even with sophisticated attention models (Luong et al., 2015; Bahdanau et al., 2015), Seq2Seq fails to map the correct entities to the generated input. To alleviate this problem, copy augmented Seq2Seq models Eric and Manning (2017), were used. These models outperform utterance selection methods by copying relevant information directly from the KBs. Copy mechanisms has also been used in question answering tasks (Dehghani et al., 2017; He et al., 2017), neural machine translation (Gulcehre et al., 2016; Gu et al., 2016), language modeling (Merity et al., 2017), and summarization (See et al., 2017).

Less related to dialog systems, but related to our work, are the memory based decoders and the non-recurrent generative models: 1) Mem2Seq query generation phase used to access our memories can be seen as the memory controller used in Memory Augmented Neural Networks (MANN) (Graves et al., 2014, 2016). Similarly, memory encoders have been used in neural machine translation (Wang et al., 2016), and meta-learning application (Kaiser et al., 2017). However, Mem2Seq differs from these models as such: it uses multi-hop attention in combination with copy mechanism, whereas other models use a single matrix representation. 2) non-recurrent generative models (Vaswani et al., 2017), which only rely on self-attention mechanism, are related to the multi-hop attention mechanism used in MemNN.

7 Conclusion

In this work, we present an end-to-end trainable Memory-to-Sequence model for task-oriented dialog systems. Mem2Seq combines the multi-hop attention mechanism in end-to-end memory networks with the idea of pointer networks to incorporate external information. We empirically show our model's ability to produce relevant answers using both the external KB information and the predefined vocabulary, and visualize how the multi-hop attention mechanisms help in learning correlations between memories. Mem2Seq is fast, general, and able to achieve state-of-the-art results in three different datasets.

Abstract

Sequence to sequence (Seq2Seq) models have been widely used for response generation in the area of conversation. However, the requirements for different conversation scenarios are distinct. For example, customer service requires the generated responses to be specific and accurate, while chatbot prefers diverse responses so as to attract different users. The current Seq2Seq model fails to meet these diverse requirements, by using a general average likelihood as the optimization criteria. As a result, it usually generates safe and commonplace responses, such as *'I don't know'*. In this paper, we propose two tailored optimization criteria for Seq2Seq to different conversation scenarios, i.e., the maximum generated likelihood for specific-requirement scenario, and the conditional value-at-risk for diverse-requirement scenario. Experimental results on the Ubuntu dialogue corpus (Ubuntu service scenario) and Chinese Weibo dataset (social chatbot scenario) show that our proposed models not only satisfies diverse requirements for different scenarios, but also yields better performances against traditional Seq2Seq models in terms of both metric-based and human evaluations.

1 Introduction

This paper focuses on the problem of the single-turn dialogue generation, which is critical in many natural language processing applications such as customer services, intelligent assistant and chatbot. Recently, sequence to sequence (Seq2Seq) models (Sutskever et al., 2014) have been widely used in this area. In these Seq2Seq models, a recurrent neural network (RNN) based encoder is first utilized to encode the input post to a vector, and another RNN decoder is then used to automatically generate the response word by word. The parameters of the encoder and decoder are learned by maximizing the averaged likelihood of the training data.

It is clear that the requirements for generated responses are distinct in different dialogue scenarios. For instance, in the scenario of customer service or mobile assistant, users mainly expect the system to help them solve a problem. Therefore, the responses should be specific and accurate to provide useful assistance. For example, if the user asks a question *'How can I get the AMD driver running on Ubuntu 12.10?'*, the system is expected to reply *'The fglrx driver is in the repo. But it may depend on your exact chipset.'*, rather than *'I do not know about the package.'*, even though the latter can also be viewed as relevant for the proposed question. We called this kind of scenario as specific-requirement scenario. While in other scenarios such as chatbot, users are interacting with the dialogue system for fun. Therefore, the generated responses should be diverse to attract different users. Take the post *'Can you recommend me a tourist city?'* as an example. If the user prefers the magnificent mountains and rivers, it is better to reply *'You may like the Bernina Express to the Alps'*. While if the user loves literature, it is better to reply *'Paris is a beautiful city with full of the literary atmosphere'*. This kind of scenario is called diverse-requirement scenario.

However, the current generation model Seq2Seq (Sutskever et al., 2014) usually tend to generate common responses, such as *'I don't know'* and *'What does this mean?'* (Li et al., 2016a,b; Zhou et al., 2017), which fails to meet diverse requirements for different conversation scenarios. Intrinsically, conversation is a typical one-to-many application, i.e., multiple responses with different semantic meanings are correspondent to a same post. That means there are various post-response matching patterns in the training data. Seq2Seq optimizes an averaged likelihood, so it can only capture the common matching patterns, leading to common responses.

The purpose of this paper is to propose two tailored optimization criteria for Seq2Seq models to accommodate different conversation scenarios, i.e. specific-requirement scenario and diverse-requirement scenario. The key idea is to how capture the required post-response matching patterns. For the specific-requirement scenario, we define the maximum generated likelihood as the objective function. With this kind of criterion, we just require one ground-truth response to be close to the given post, instead of requiring the average of multiple ground-truth responses to be close to the post. Therefore, the most significant post-response matching pattern will be learned from the data, to facilitate generating a specific response. While for the diverse-requirement scenario, the conditional value-at-risk (CVaR) is used as the objective function. CVaR is a risk-sensitive function widely used in finances (Rockafellar and Uryasev, 2002; Alexander et al., 2006; Chen et al., 2015), defined to assessing the likelihood (at a specific confidence level) that a specific loss will exceed the value at risk. With CVaR as the objective function, the worst 1-α responses are required to be close to the post, therefore various post-response patterns can be captured, and the learned model has the ability to generate diverse responses.

We use public data to evaluate our proposed models. For the specific-requirement scenario, the experiments on public Ubuntu dialogue corpus(Ubuntu service) show that optimizing the maximum generated likelihood produces more specific and accurate responses than traditional Seq2Seq models. While for the diverse-requirement scenario, the experiments on the public Chinese Weibo dataset (social chatbot) show that optimizing CVaR produces diverse responses, as compared with Seq2Seq and the variants.

2 Related Work

The basic neural-based Seq2Seq framework for dialogue generation is inspired by the studies of statistical machine translation. Sutskever et al. (Sutskever et al., 2014) proposed the original Seq2Seq framework(Seq2Seq), which used a multilayered Long Short-Term Memory(LSTM) to map the input sequence to a fixed dimension vector and then used another LSTM to decode the target sequence from the vector. Then Cho et al. (Cho et al., 2014) followed the above architecture, and proposed to feed the last hidden state of encoder to every cell of decoder(RNN-encdec), which enhanced the influence of contexts in generating each word of the targets. To further alleviate the long dependency problem, Bahdanau et al. (Bahdanau et al., 2015) introduced the attention mechanism into the neural network and achieved encouraging performances(Seq2Seq-att). Many studies (Shang et al., 2015; Vinyals and Le, 2015) directly applied the above neural SMT models to the task of dialogue generation, and gained some promising performances.

Although the current Seq2Seq model is capable to generate fluent responses, these responses are usually general. Therefore, many researchers focused on how to improve the generation quality and specification. Li et al. (Li et al., 2016a) proposed a mutual information model(MMI) to tackle this problem. However, it is not a unified training model, instead it still trained original Seq2Seq model, and used the Maximum Mutual Information criterion only for testing to rerank the primary top-n list. Mou et al. (Mou et al., 2017) proposed a forward-backward keyword method which used a pointwise mutual information to predict a noun as a keyword and then used two Seq2Seq models to generate the forward sentence and the backward sentence. Xing et al. (Xing et al., 2017) proposed a joint attention mechanism model, which modified the generation probability by adding the topic keywords likelihood to the generated maximum likelihood with extra corpus. The recent works such as seqGAN (Yu et al., 2017) and Adver-REGS (Li et al., 2017) try to use Generative Adversarial Networks(GAN) for generation, where the discriminator scores are used as rewards for reinforcement learning.

For the study of generating diverse responses, Vijayakumar et al. (Vijayakumar et al., 2016) introduced a diverse beam search which decoded a list of diverse outputs by optimizing for a diversity-augmented objective, which can control for the exploration and exploitation of the search space. Zhou (Zhou et al., 2017) proposed to apply a hidden state as a generating style(Mechanism). They make an assumption that some latent responding mechanisms can generate different responses, and model these mechanisms as latent embedding. With these latent embedding in the mid of Seq2Seq, the mechanism-aware Seq2Seq can generate different mechanism responses.

However, most of these models are using an averaged approach for optimization, similar to that in Seq2Seq. This paper proposes two new criteria for different conversation scenarios. For the specific-requirement scenario, the maximum generated likelihood is used as the objective function. While for the diverse-requirement scenario, CVaR is used for optimization.

3 Sequence to Sequence Models

We first introduce the typical LSTM-based Seq2Seq framework (Bahdanau et al., 2015) used in dialogue generation.

Given a post $X = \{x_1, \dots, x_M\}$ as the input, a standard LSTM first maps the input sequence to a fixed-dimension vector h_M as follows.

$$\begin{aligned} i_k &= \sigma(W_i[h_{k-1}, w_k]),\ f_k = \sigma(W_f[h_{k-1}, w_k]), \\ o_k &= \sigma(W_o[h_{k-1}, w_k]),\ l_k = \tanh(W_l[h_{k-1}, w_k]), \\ c_k &= f_k c_{k-1} + i_k l_k, \qquad h_i = o_k \tanh(c_k), \end{aligned} \tag{1}$$

where i_k, f_k and o_k are the input gate, the memory gate, and the output gate, respectively. w_k is the word embedding for x_k, and h_k stands for the vector computed by LSTM at time k by combining w_k and h_{k-1}. c_k is the cell at time k, and σ denotes the sigmoid function. W_i, W_f, W_o and W_l are parameters.

Then another LSTM is used as the decoder to map the vector h_M to the ground-truth response $Y = \{y_1, \cdots, y_N\}$. Typically, the decoder is trained to predict the next word g_i, given the context vector h_M and the previous generated words $\{g_1, \dots, g_{i-1}\}$. In other words, the decoder defines a probability over the output Y by decomposing the joint probability into the ordered conditionals by chain rule in the probability theory:

$$\begin{aligned} P(Y|X) &= \prod_{i=1}^{N} p(y_i | h_M, y_1, \dots, y_{i-1}) \\ &= \prod_{i=1}^{N} g(h_M, y_{i-1}, h'_i), \end{aligned}$$

where g_θ is a softmax function, h'_i is the hidden state in the decoder LSTM.

Usually the attention mechanism is further introduced to the above Seq2Seq framework in real applications. Instead of using h_M as the context vector in the decoder, we let the context vector, denoted as s_i, to be dependent on the sequence $(h_1, \cdots, h_M)$. Each h_k contains information about the input sequence with a strong focus on the parts surrounding the k-th word of the input sentence. The context vector s_i is then computed as a weighted sum of these h_k:

$$s_i = \sum_{k=1}^{M} \alpha_{ik} h_k.$$

The weight α_{ik} of each representation h_k is computed by:

$$\begin{aligned} \alpha_{ik} &= \frac{\exp(e_{ik})}{\sum_{j=1}^{M} \exp(e_{ij})}, \\ e_{ik} &= v^T \tanh(W_1 h'_{i-1} + W_2 h_k), \end{aligned}$$

where v^T,W_1 and W_2 are learned parameters. e_{ik} is an alignment model which scores how well the inputs around position k and the output at position i match. The score is based on the LSTM hidden state h'_{i-1} (just before emitting y_i), and h_k of the input sentence.

Given a set of training data $\mathcal{D}$, Seq2Seq assumes that data are i.i.d. sampled from a probability P, and uses the following log likelihood as the objective for maximization:

$$\mathcal{L} = \sum_{(X,Y)\in\mathcal{D}} \log P(Y|X). \tag{2}$$

4 Tailored Sequence to Sequence Models

We can see that a general averaged likelihood of the training data is used as the objective function in Seq2Seq. However, this objective function is usually criticized for generating common responses, such as *'I don't know'* and *'What does this mean?'*. Clearly, this kind of responses cannot satisfy either the specific or the diverse requirements. The underlying reason is not difficult to understand. Intrinsically, conversation is a typical one-to-many application, i.e., multiple responses with different semantic meanings are correspondent to a same post. That means there are various post-response matching patterns in the training data. If we optimize an averaged likelihood, we can only capture the common matching patterns, which leads to generating common responses. Therefore, if we want to generate specific responses, we need to capture the most significant matching pattern; while if we want to generate diverse responses, we need to define a criteria which has the ability to capture the various matching patterns. Motivated by this idea, we propose two optimization criteria, i.e. maximum generated likelihood, and CVaR, to adapt two different scenarios.

4.1 Maximum Generated Likelihood Criteria

To meet the specific requirement, we need to capture a specific matching pattern between post and response, rather than the common matching pattern. Therefore, instead of optimizing the averaged likelihood, we turn to use the maximum generated likelihood (MGL) as the objective function. Mathematically, for a given post X and its associated ground-truth responses $(Y_X^{(1)}, Y_X^{(2)}, \cdots, Y_X^{(m_X)})$, the objective function is defined as:

$$\mathcal{L} = \sum_X \max_{k=1}^{m_X} \log P(Y_X^{(k)}|X).$$

From the definition, we can see that we aim to capture the most significant post-response matching pattern in the training data. Therefore, the learned model can output specific responses for a given post. Since there is a max operator in the objective function, which is difficult for accurate optimization, we approximate it by the softmax function. Then the objective function becomes the following form:

$$\mathcal{L} = \sum_X \sum_{k=1}^{m_X} \log \frac{P(Y_X^{(k)}|X)}{\sum_{j=1}^{m_X} P(Y_X^{(j)}|X)}.$$

If the probability for one ground-truth $Y_X^{(k)}$ is small, it contributes little to the objective function. That is to say, we just require the top ground-truth responses with relative large probabilities to be close to the post.

4.2 CVaR Criteria

To meet the diverse requirements, we need to capture various matching patterns between post and its multiple ground-truth responses. Therefore, instead of optimizing the averaged likelihood, we turn to optimize the conditional value-at-risk, named CVaR for short. CVaR is a prominent risk measure used extensively in finance, and it is proved to be coherent (Artzner et al., 1999) and numerically effective (Krokhmal et al., 2002; Uryasev, 2013).

The definitions of VaR and CVaR are as follows. For a confidence level $\alpha \in [0, 1]$, and a continuous random cost Z whose distribution is parameterized by a controllable parameter θ, the α-VaR of the cost Z, denoted by $\nu_\alpha(\theta)$, is defined as:

$$\nu_\alpha(\theta) = \inf\{\nu \in \mathbb{R} | P(Z \leq \nu) \geq \alpha\}.$$

α-VaR denotes the maximum cost that might be incurred with probability at least α, or can be simply regarded as the α-quantile of Z. And the α-CVaR, denoted by $\Phi_\alpha(\theta)$, is defined as:

$$\Phi_\alpha(\theta) = \frac{1}{1-\alpha} \int_\alpha^1 \nu_r(\theta) dr = \mathbb{E}^\theta[Z | Z \geq \nu_\alpha(\theta)].$$

It can be viewed as the expected cost over the $(1-\alpha)$ worst outcomes of Z.

Applying CVaR to generating diverse responses, we can define the random cost Z as $-\log P(Y|X)$, the corresponding CVaR is:

$$\Phi_\alpha(\theta) = \frac{1}{1-\alpha} \int_\alpha^1 \nu_r(\theta) dr,$$

where $\nu_r(\theta) = \inf\{\nu \in \mathbb{R} | P(-\log P(Y|X) \leq \nu) \geq r\}$, and θ are parameters of the Seq2Seq model. Therefore, we have:

$$\nu_r(\theta) = \inf\{\nu \in \mathbb{R} | P(P(Y|X) \geq e^\nu) \geq r\}.$$

Therefore, for a given post X and its ground-truth responses $(Y_X^{(1)}, Y_X^{(2)}, \cdots, Y_X^{(m_X)})$, optimizing CVaR is equivalent to maximizing the following objective function:

$$\mathcal{L} = \sum_X \frac{1}{1-\alpha} \sum_{Y_X^{(k)} \in \mathcal{Y}_{1-\alpha}} P(Y_X^{(k)}|X),$$

where $\mathcal{Y}_{1-\alpha}$ is a collection of ground-truth responses such that:

$$\sup\{P(Y_X^{(i)}|X) : Y_X^i \in \mathcal{Y}_{1-\alpha}\} \leq \alpha.$$

We can see that maximizing the above objective function requires the worst $1-\alpha$ responses to be close to the post. Therefore, we aim to capture each distinct post-response matching pattern by optimizing the CVaR criteria, which can meet the requirement for generating diverse responses.

5 Experiments

In this section, we conduct experiments on both specific-requirement and diverse-requirement scenarios, to evaluate the performances of our proposed methods.

5.1 Experimental Settings

5.1.1 Datasets

We use two public datasets in our experiments. For the specific-requirement scenario, we use the Ubuntu dialogue corpus[1] extracted from Ubuntu question-answering forum, named Ubuntu (Lowe et al., 2015). The original training data consists of 7 million conversational post-responses pairs from 2014 to April 27,2012. The validation data are conversational pairs from April 27,2014 to August 7,2012, and the test data are from August 7,2012 to December 1,2012. We set the number of positive examples as 4,000,000 in the Github to directly sample data from the whole corpus. Then we construct post and response pairs based on the period from both context and utterance. We also conduct some data pro-processing. For example, we use the official script to tokenize, stem and lemmatize, and the duplicates and sentences with length less than 5 or longer than 50 are removed. Finally, we obtain 3,200,000, 100,000 and 100,000 for training, validation and testing, respectively.

For the diverse-requirement scenario, we use the Chinese Weibo dataset, named STC (Shang et al., 2015). It consists of 3,788,571 post-response pairs extracted from the Chinese Weibo website and cleaned by the data publishers. We randomly split the data to training, validation, and testing sets, which contains 3,000,000, 388,571 and 400,000 pairs, respectively. [2]

5.1.2 Baseline Methods

Six baseline methods are used for comparison, including traditional Seq2Seq (Sutskever et al., 2014), RNN-encdec (Cho et al., 2014), Seq2Seq with attention(Seq2Seq-att) (Bahdanau et al., 2015), mutual information(MMI) (Li et al., 2016b), Adver-REGS (Li et al., 2017) and Mechanism model (Zhou et al., 2017). Here are some empirical settings. We first introduce the input embeddings. For STC, we utilize character-level embeddings rather than word-level embeddings, due to the word sparsity, segmentation mistakes and unknown Chinese words which may lead to inferior performance (Hu et al., 2015). For Ubuntu, we use word embeddings trained by word2vec on the training dataset. In the training process, the dimension is set to be 300, the size of negative sample is set to be 3, and the learning rate is 0.05. For fair comparison among all the baseline methods and our methods, the number of hidden nodes is all set to 300, and batch size is set to 200. Stochastic gradient decent (SGD) is utilized in our experiment for optimization, instead of Adam, because SGD yields better performances in our experiments. The learning rate is set to be 0.5, and adaptively decays with rate 0.99 in the optimization process. We run our model on a Tesla K80 GPU card with Tensorflow framework. All the methods are pretrained with the same Seq2Seq model. For maximum generated likelihood(MGL) model, some people may argue that the specific results may be due to the usage of single post-response pair. Thus we also implement the baseline of using a single post-response pair, by random selecting the response from the ground-truth for each post, denoted as Single Model.

5.1.3 Evaluation Measures

We use both quantitative metrics and human judgements to evaluate the proposed MGL model and the CVaR model. Specifically, we use two kinds of metrics for quantitative comparisons. The first one kind is the traditional metric, including PPL and Bleu score (Xing et al., 2017). They are both widely used in natural language processing, and here we use them to evaluate the quality of the generated responses. The other kind is to evaluate the specific degree[3] in (Li et al., 2016a,b). It measures the specific degree of the generated responses, by calculating the number of distinct unigrams and bigrams in the generated responses, denoted as *distinct*. If a model usually generates common responses, the *distinct* will be low.

For the diverse-requirement scenario, we define two measures to evaluate the performance. Specifically, we set the beam as 10. Group-diversity is

[1]https://github.com/rkadlec/ubuntu-ranking-dataset-creator

[2]https://github.com/zhanghainan/TailoredSeq2Seq2DifferentConversationScenarios

[3]Though it is named as diversity in Li's paper, this diversity is not the same as that used in our paper. This diversity measures the specific degree of the generated responses over all generations. While the diversity used in our paper means that the responses are required to be relevant to a post from different aspects.

model	distinct-1	distinct-2	BLEU	PPL
Seq2Seq	0.140	1.11	1.231	51.26
RNN-encdec	0.125	1.24	1.231	46.97
Seq2Seq-att	0.351	4.36	1.294	47.84
MMI	0.283	4.84	1.297	42.52
Adver-REGS	0.268	5.07	1.279	37.71
Single	0.324	5.27	1.342	30.36
MGL	**0.358**	**6.30**	**1.354**	**26.34**
CVaR	0.294	5.52	1.290	30.03

Table 1: The metric-based evaluation results(%) of different models on Ubuntu.

model	human score distribution(%)			Ave.	Kappa
	1	2	3		
Seq2Seq-att	46.5	38.6	14.9	1.684	0.387
MMI	42	38	20	1.78	0.395
Adver-REGS	42	26	32	1.9	0.379
Single	49	14	37	1.88	0.383
MGL	33	16	51	2.18	0.372
CVaR	40	12	48	2.08	0.381

Table 2: The comparisons of different models by human evaluation on Ubuntu.

defined to calculate the difference between each two generations for one post, denoted as divrs. Group-overlap is defined to calculate the overlap between each two generations for one post, denoted as overlap. The detailed definitions are shown as follows.

$$divrs = \frac{1}{N}\sum_{i=1}^{N}\sum_{X_i} cosine(G_{i1}, G_{i2}),$$

$$overlap = \frac{1}{N}\sum_{i=1}^{N}\sum_{X_i} overlap(G_{i1}, G_{i2}),$$

where G_{i1} and G_{i2} are the generated responses from the model for post X, $cosine(G_{i1}, G_{i2})$ is the cosine similarity, and the $overlap(G_{i1}, G_{i2})$ is defined as the intersection divided by union.

For human evaluation, given 200 randomly sampled post and it's generated responses, three annotators, randomly selected from a class of computer science majored students(48 students), are required to give 3-graded judgements. The annotation criteria are defined as follows:

1. the response is nonfluent or has wrong logic; or the response is fluent but not related with the post;
2. the response is fluent and weak related, but it's common which can reply many other posts;
3. the response is fluent and strong related with its post, which is like following a real person's tone.

5.2 Specific-Requirement Scenario

We demonstrate the experimental results on the specific-requirement scenario, based on the Ubuntu dataset.

5.2.1 Metric-based Evaluation

The quantitative evaluation results are shown in Table 1. From the results, we can see that both MMI and Adver-REGS outperform Seq2Seq baselines in terms of BLUE, PPL and *distinct* measures. That's because both MMI and Adver-REGS further consider some reward functions in the optimization process to encourage specific results. Specifically, MMI uses a predefined reward function to penalize generating common responses, and Adver-REGS uses a learned discriminator to define the reward function. Our MGL model obtains higher BLEU and lower PPL than baseline models. Take the BLEU score on Ubuntu dataset for example, the BLEU score of MGL model is 1.354, which is significantly better than that of MMI and Adver-REGS, i.e., 1.297 and 1.279. These results indicate that our MGL generates responses with higher quality. When compared with the Single model, MGL is also better because MGL considers more data in the model computation process. The *distinct* scores of MGL are also higher than baseline models, which indicate that our model can generate more specific responses. That's because it has the ability to learn the significant matching pattern between post and responses, by optimizing the maximum generated likelihood rather than the averaged one. In summary, our maximum generated likelihood model produces more fluent and specific results, as compared with baseline methods.

5.2.2 Human Evaluation

The human evaluation results are shown in Table 2, in which the percentage of sentences belonging to each grade and the averaged grade are demonstrated to evaluate the quality of generated responses. Kappa (Fleiss, 1971) value is presented to demonstrate the consistency of different annotators. From the results, we can see that MGL significantly outperforms baseline methods. The averaged score of MGL Model is 2.18, which is much higher than that of MMI and Adver-REGS, i.e., 1.78 and 1.9, respectively. The percentage of

post	Install grub to the hdd where the bios is set to boot.
response1	So I would not just install it to /boot?
Seq2Seq-att	A log file a bug with the install cd.
MMI	What do you mean?
Adver-REGS	How do I install grub?
Single	Do you delete grub?
MGL	I have boot with the window from the grub and it go from the boot menu.
CVaR	If you have grub on the same pc, it is 0 0 boot partition.
post	I want to have a backup , sad I use up all my space with dual boot and game.
response1	Oh you can get a sata to usb adapt :)
Seq2Seq-att	What about your computer ?
MMI	It is not in the install , you can do that.
Adver-REGS	Game game game game.
Single	And other user will do too ?
MGL	And do you buy direct driver from the kernel and it cause run ?
CVaR	Yes , you can also use a text file to your file .
post	Take a look at install .
response1	I am to cd to the directories contain the folder.
Seq2Seq-att	How do you install it?
MMI	I think it be a good idea to do that.
Adver-REGS	I have no idea what I am looking for.
Single	I think it is a bite , but I do not know a good thing to do that. I am use.
MGL	I think so, I have a lot of nautilus. I am already install.
CVaR	I just install it from synaptics, but I want to install it on the same repository.

Table 3: The generated responses from different models on Ubuntu.

strongly related sentences (i.e., the grade '3') of MGL Model is 51%, which is also higher than that of MMI, Adver-REGS and Single Model, i.e., 20% , 32% and 37%. In summary, our maximum generated likelihood model produces better responses compared with baselines. As compared with MMI and Adver-REGS, both the metric-based improvements and human evaluation improvements of MGL are significant on Ubuntu datasets (p-value < 0.01).

5.2.3 Case Study

Here we show some generated responses for demonstration. Specifically, Table 3 gives one example post and its ground-truth responses from Ubuntu. We also list the generated responses from different models. We can see that Seq2Seq-att, MMI and Adver-REGS all produce common responses, such as *'What do you mean?'*,*'I have no idea what I am looking for.'* and*'What about your computer?'*. Our models give interesting responses with specific meanings. Take the post *'Install grub to the hdd where the bios is set to boot.'* as an example, our model conveys more specific information by replying *'I have boot with the window from the grub and it go from the boot menu.'* . And in another case, for the given post *'I want to have a backup , sad I use up all my space with dual boot and game.'*, our MGL model generates a question for the post *'And do you buy direct driver from the kernel and it cause run?'*, which is more intelligent. Similar observations have been obtained for many other posts, and we omit them for space limitations.

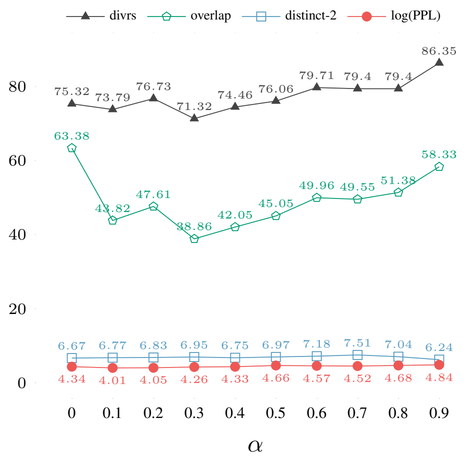

Figure 1: Influences of different α in CVaR.

model	BLEU	PPL	overlap	divrs
Seq2Seq	1.616	132.93	67.26	87.83
RNN-encdec	1.636	130.56	65.72	87.85
Seq2Seq-att	1.620	76.95	63.38	85.32
Adver-REGS	1.635	84.77	57.96	84.94
Mechanism	1.642	90.48	57.67	84.64
MGL	**1.703**	**36.25**	66.92	86.22
CVaR	1.652	70.94	**38.96**	**71.38**

Table 4: The metric-based evaluation results(%) of different models on STC.

5.3 Diverse-Requirement Scenario

Now we introduce the experimental results for the diverse-requirement scenario, based on STC.

5.3.1 Parameters Setting

First, we study the influences of different parameter α in CVaR. Specifically, we show the validation result with α ranging from 0 to 0.9 with step 0.1, to see the change of CVaR performances. Figure 1 show the results of different α in terms of divrs , overlap, distinct-2 and PPL. From the results, we can see that the performances of divrs , overlap and PPL are all changing in a similar trend, i.e. first drop and then increase. The best α for CVaR is 0.3, which is used in the following experiments.

5.3.2 Metric-based Evaluation

The quantitative evaluation results are shown in Table 4. From the results, we can see that both Adver-REGS and Mechanism outperform Seq2Seq models in terms of BLUE and PPL measures. That's because they both use some techniques to enhance the generation ability. Adver-REGS uses a learned discriminator to define the reward function, while Mechanism uses a style

model	human score distribution(%)			Ave.	Kappa
	1	2	3		
Seq2Seq-att	54.5	21	24.5	1.7	0.452
MMI	56	15.5	28.5	1.725	0.447
Adver-REGS	48.5	20	31.5	1.83	0.436
Mechanism	52.5	17.5	30	1.775	0.427
MGL	37	11	52	2.15	0.451
CVaR	44.5	11.5	44	1.995	0.437

Table 5: The comparisons of different models by human evaluation on STC.

hidden state to describe the generation mechanism. Both MGL and CVaR obtain better results in terms of BLUE and PPL, compared with other baselines. These results indicate that our proposed models generate more fluent responses in the diverse-requirement scenario. As for the evaluation for the diversity, we can see that CVaR model obtains the lowest overlap and divrs among all the baseline models. Take the overlap score on STC for example, the overlap score of CVaR model is 38.86, which is significantly lower than that of Adver-REGS, Mechanism and GLM, i.e., 57.96, 57.67 and 66.92. These results indicate that our CVaR model can generate responses with higher diversity. That's because it has the capability to capture various matching patterns in the training data, by optimizing the worst $1 - \alpha$ costs. Therefore, our CVaR model produces both fluent and diverse results, as compared with baseline methods.

5.3.3 Human Evaluation

The human evaluation results are shown in Table 5. From the results, we can see MGL and CVaR models achieve comparable results, which are significantly better than baseline methods. Specifically, the averaged score of MGL and CVaR is 2.15 and 1.995, which is significantly higher than that of Adver-REGS and Mechanism, i.e., 1.83 and 1.775, respectively. The percentage of strongly related sentences (i.e., the grade '3') of MGL Model and CVaR are 52% and 44%, which are also significantly higher than that of Adver-REGS and Mechanism, i.e., 31.5% and 30%. We conducted significant test for the improvement. As compared with Adver-REGS and Mechanism, both the metric-based improvements and human evaluation improvements of CVaR are significant on STC datasets (p-value < 0.01).

5.3.4 Case Study

Here we show some generated responses for demonstration. Specifically, Table 6 gives one post and its three ground-truth responses from STC. We also give three generated responses from Mechanism and CVaR model. We can see that Mechanism produces responses with the same meaning, such as *'Wade is so amazing'* and *'It is really good'*. However, our CVaR models give specific responses with diverse meanings. Take the post *'Waiting for Wade in the final games.'* for example, CVaR's responses are related to different topics. The response *'I must go and see the final games '* focuses on the game, while another response of *'James is so fast '* focuses on the person, James. For the other case, the post is about the docking of two spacecrafts and the CVaR responses are related to different users, such as the supporter of the event, the newspaper reader and the children who have a father concerned with the current news . We have obtained similar observations for many other posts, but we have to omit them for space limitations.

post	总决赛继续等待韦德.(Waiting for Wade in the final games.)
response	每个人都有每个人的喜爱(Everyone has his favorite stars.)
response	分析比新浪分析的好多了(Analysis is much better than Sina)
response	等待闪电侠彻底爆发！(Waiting for the explosion of Mr.Flash)
Mechanism	韦德真伟大啊!支持!(Wade is really great! Support him!)
Mechanism	韦德越来越好。(Wade will be better)
Mechanism	韦德威武!(Wade is mighty)
CVaR	决赛一定要去看看的!(I must go and see the final games)
CVaR	詹皇怎么还能这么快啊(James is so fast)
CVaR	决赛是一种对对手的打击,热火加油 (The final games is a blow for the opposite. Heat come on)
post	神舟八号飞船与天宫一号第二次对接成功. (Shenzhou 8 spacecraft and Tiangong-1 has the second successful docking)
response	希望其它方面也赶快领先世界(Hope other aspects will soon lead the world)
response	过硬的技术，紧密地配合促成了这次成功。 Strong technology and close cooperation contributed to this success
response	下一次就是载人对接啦.(Next will have a human in it)
Mechanism	周末报还会直播?(Will broadcast in the Weekend Newspaper?)
Mechanism	不错，就是不错(It is really good)
Mechanism	不错，就是在一起。(It is really good, they should be together)
CVaR	是啊，还是要坚持在一起。(Yes, they should insisted on being together)
CVaR	您这是在看头版吗？(Are you see it in the front page of the newspaper?)
CVaR	不错，有空推荐给爸爸！ (It is really good, you could recommend it to your father if you have time)

Table 6: The generated responses from different models on STC.

6 Conclusion

In this paper, we propose two new optimization criteria for Seq2Seq model to adapt different conversation scenario. For the specific-requirement scenario, such as customer service, which requires specific and high quality responses, maximum generated likelihood is used as the objective function instead of the averaged one. While for the diverse-requirement, such as chatbot, which requires diverse and high quality responses even if for the same post, CVaR is used as the objective function for worst case optimization. Experimental results on both specific-requirement

(Ubuntu data) and diverse-requirement scenarios (STC data) demonstrate that the proposed optimization criteria can meet the corresponding requirement, yielding better performances against traditional Seq2Seq models in terms of both metric-based and human evaluations.

The contribution of this paper is to use tailored Seq2Seq model for different conversation scenarios. The study shows that if we want to generate specific responses, it is important to design the model to learn the most significant matching pattern between post and response. While if we want to generate diverse responses, a risk-sensitive objective functions is helpful. In future work, we plan to further investigate the impact of risk-sensitive objective functions, including the relations between model robustness and diverse generations.

Abstract

End-to-end neural dialogue generation has shown promising results recently, but it does not employ knowledge to guide the generation and hence tends to generate short, general, and meaningless responses. In this paper, we propose a neural knowledge diffusion (NKD) model to introduce knowledge into dialogue generation. This method can not only match the relevant facts for the input utterance but diffuse them to similar entities. With the help of facts matching and entity diffusion, the neural dialogue generation is augmented with the ability of convergent and divergent thinking over the knowledge base. Our empirical study on a real-world dataset proves that our model is capable of generating meaningful, diverse and natural responses for both factoid-questions and knowledge grounded chi-chats. The experiment results also show that our model outperforms competitive baseline models significantly.

1 Introduction

Dialogue systems are receiving more and more attention in recent years. Given previous utterances, a dialogue system aims to generate a proper response in a natural way. Compared with the traditional pipeline based dialogue system, the new method based on sequence-to-sequence model (Shang et al., 2015; Vinyals and Le, 2015; Cho et al., 2014) impressed the research communities with its elegant simplicity. Such methods are usually in an end-to-end manner: utterances are encoded by a recurrent neural network while responses are generated sequentially by another (sometimes identical) recurrent neural network. However, due to lack of universal background knowledge and common senses, the end-to-end data-driven structure inherently tends to generate meaningless and short responses, such as "haha" or "I don't know."

To bridge the gap of the common knowledge between human and computers, different kinds of knowledge bases (e.g., the freebase (Google, 2013) and DBpedia (Lehmann et al., 2017)) are leveraged. A related application of knowledge bases is question answering, where the given questions are first analyzed, followed by retrieving related facts from knowledge bases (KBs), and finally the answers are generated.The facts are usually presented in the form of "subject-relation-object" triplets, where the subject and object are entities. With the aid of knowledge triplets, neural generative question answering systems are capable of answering facts related inquiries (Yin et al., 2016; Zhu et al., 2017; He et al., 2017a), *WH* questions in particular, like "*who is Yao Ming's wife ?*".

Although answering enquiries is essential for dialogue systems, especially for task-oriented dialogue systems (Eric et al., 2017), it is still far behind a natural knowledge grounded dialogue system, which should be able to understand the facts involved in current dialogue session (so-called facts matching), as well as diffuse them to other similar entities for knowledge-based chit-chats (i.e. entity diffusion):

1) *facts matching*: in dialogue systems, matching utterances to exact facts is much harder than explicit factoid inquiries answering. Though some utterances are facts related inquiries, whose subjects and relations can be easily recognized, for some utterances, the subjects and relations are elusive, which leads the trouble in exact facts matching.

ID	Dialogue
1	A: Who is the director of the Titanic? 泰坦尼克号的导演是谁? B: James Cameron. 詹姆斯卡梅隆。
2	A: Titanic is my favorite film! 泰坦尼克号是我最爱的电影! B: The love inside it is so touching. 里面的爱情太感人了。
3	A: Is there anything like the Titanic? 有什么像泰坦尼克号一样的电影吗? B: I think the love story in film Waterloo Bridge is beautiful, too. 我觉得魂断蓝桥中的爱情故事也很美。
4	A: Is there anything like the Titanic? 有什么像泰坦尼克号一样的电影吗? B: Poseidon is also a classic marine film. 海神号也是一部经典的海难电影。

Table 1: Examples of knowledge grounded conversations. Knowledge entities are underlined.

Table 1 shows an example: Item 1 and 2 are talking about the film "Titanic", Unlike item 1, which is a typical question answering conversation,item 2 is a knowledge related chit-chat without any explicit relation. It is difficult to define the exact fact match for item 2.

2) *entity diffusion*: another noticeable phenomenon is that the conversation usually drifts from one entity to another. In Table 1, utterances in item 3 and 4 are about entity "Titanic", however, the entity of responses are other similar films. Such entity diffusion relations are rarely captured by the current knowledge triplets. The response in item 3 shows that the two entities "Titanic" and "Waterloo Bridge" are relevant through "love stories". Item 4 suggests another similar shipwreck film of "Titanic".

To deal with the aforementioned challenges, in this paper, we propose a **n**eural **k**nowledge **d**iffusion (NKD) dialogue system to benefit the neural dialogue generation with the ability of both convergent and divergent thinking over the knowledge base, and handle factoid QA and knowledge grounded chit-chats simultaneously. NKD learns to match utterances to relevant facts; the matched facts are then diffused to similar entities; and finally, the model generates the responses with respect to all the retrieved knowledge items.

In general, our contributions are as follows:

- We identify the problem of incorporating knowledge bases and dialogue systems as facts matching and entity diffusion.
- We manage both facts matching and entity diffusion by introducing a novel knowledge diffusion mechanism and generate the responses with the retrieved knowledge items, which enable the convergent and divergent thinking over the knowledge base.
- The experimental results show that the proposed model effectively generate more diverse and meaningful responses involving more accurate relevant entities compared with the state-of-the-art baselines.

The corpus will be released upon publication.

2 Model

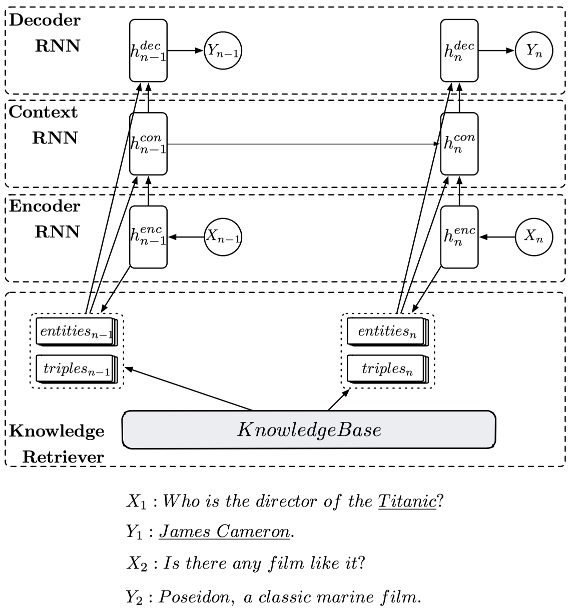

Figure 1: Neural Knowledge Diffusion Dialogue System.

Given the input utterance $X = (x_1, x_2, ..., x_{N_X})$, NKD produces a response $Y = (y_1, y_2, ..., y_{N_Y})$ containing the entities from the knowledge base K. N_X and N_Y are the number of tokens in the utterance and response respectively. The knowledge base K is a collection of knowledge facts in the form of triplets *(subject, relation, object)*. In particular, both subjects and objects are entities in this work. As illustrated in Figure 1, the model mainly consists of four components:

1. An encoder encodes the input utterance X into a vector representation.

2. A context RNN keeps the dialogue state along a conversation session. It takes the utterance representation as input, and outputs a vector guiding the response generation each turn.

3. A decoder generates the final response Y.

4. A knowledge retriever performs the facts matching and diffuses to similar entities at each turn.

Our work is built on hierarchical recurrent encoder-decoder architecture (Sordoni et al., 2015a), and a knowledge retriever network integrates the structured knowledge base into the dialogue system.

2.1 Encoder

The encoder transforms discrete tokens into vector representations. To capture information at different aspects, we learn utterance representations with two independent RNNs resulting with two hidden state sequences $H^C = (h_1^C, h_2^C, ..., h_{N_X}^C)$ and $H^K = (h_1^K, h_2^K, ..., h_{N_X}^K)$ respectively. One final hidden state $h_{N_X}^C$ is used as the input of context RNN to track the dialogue state. The other final hidden state $h_{N_X}^K$ is utilized in knowledge retriever and is designed to encode the knowledge entities and relations within the input utterances. For instance, in Figure 1, *"director"* and *"Titanic"* in X_1 are knowledge elements.

2.2 Knowledge Retriever

Knowledge retriever extracts a certain number of facts from knowledge base and specifies their importance. It enables the knowledge grounded neural dialogue system with convergent and divergent thinking ability through facts matching and entity diffusion. Figure 2 illustrates the process.

2.2.1 Facts Matching

Given the input utterance X and $h_{N_X}^K$, relevant facts are extracted from both the knowledge base and the dialogue history. A predefined number of relevant facts $F = \{f_1, f_2, ..., f_{N_f}\}$ are obtained through string matching, entity linking or named entity recognition. As shown in Figure 2, in the first sentence, *"Titanic"* is recognized as an entity, all the relevant knowledge triplets are extracted. Then, these entities and knowledge triplets are transformed into fact representations $h_f = \{h_{f1}, h_{f2}, ...h_{fN_f}\}$ by averaging the entity embedding and relation embedding. The relevance coefficient r^f between a fact and the input utterances, ranging from 0 to 1, is calculated by a nonlinear function or a sub neural network. Here, we apply a multi-layer perceptron (MLP):

$$r_k^f = MLP([h_{N_X}^K, h_{fk}]).$$

For the multi-turn conversation, entities in previous utterances are also inherited and reserved as depicted in Figure 2 the dotted lines. For instance, in the second sentence of Figure 2 (right one), no new fact is extracted from the input utterance. Thus it is necessary to record the history entities *"Titanic"* and *"James Cameron"*. We summarize the facts as *relevant fact representation* C^f through a weighted average of fact representations h_f:

$$C^f = \frac{\sum_{k=1}^{N_f} r_k^f h_{fk}}{\sum_{k=1}^{N_f} r_k^f}.$$

2.2.2 Entity Diffusion

To retrieve other relevant entities, which are typically not mentioned in the dialogue utterance, we diffuse the matched facts. We calculate the similarity between the entities (except the entities that have occurred in previous utterances) in the knowledge base and the relevant fact representation through a multi-layer perceptron, resulting with a similarity coefficient r^e, ranging from 0 to 1:

$$r_k^e = MLP([h_{N_X}^K, C^f, e_k]),$$

where e_k is the entity embedding. The top N_e number of entities $E = \{e_1, e_2, ..., e_{N_e}\}$ are selected as similar entities. Then, the *similar entity representation* C^s is formalized as:

$$C^s = \frac{\sum_{k=1}^{N_e} r_k^e e_k}{\sum_{k=1}^{N_e} r_k^e}.$$

Back to the example in Figure 2, in the first turn, the matched fact of the input utterance $(Titanic, direct\_by, JamesCameron)$ is of a high relevance coefficient in "facts matching" as expected. When a fact getting matched, intuitively it is not necessary for entity diffusion. In such case, from the Figure 2, we observe that the entities in "entity diffusing" are of low similarities. In the second turn, there is no triplets matched to the utterance, while the entity *"Titanic"* achieves a much higher relevance score. Then in "entity

diffusion", the similar entities *"Waterloo Bridge"* and *"Poseidon"* get relatively higher similarity weights than in the first turn.

2.3 Context RNN

Context RNN records the utterance level dialogue state. It takes in the utterance representation and the knowledge representations. The hidden state of the context RNN is updated as:

$$h_t^T = RNN(h_t^C, [C^f, C^s], h_{t-1}^T).$$

h_t^T is then conveyed to the decoder to guide the response generation.

2.4 Decoder

The decoder generates the response sequentially through a word generator conditioned on h_t^T, C^f and C^s. Let C denotes the concatenation of h_t^T, C^f and C^s. Knowledge items coefficient R is the concatenation of relevance coefficient r^f and similarity coefficient r^e. We introduce two variants of word generator:

Vanilla decoder simply generates the response $Y = (y_1, y_2, ..., y_{N_y})$ according to C, R. The probability of Y is defined as

Figure 3: The decoder generates words from both vocabulary and knowledge base. A score updater keeps tracking of the knowledge item coefficients to ensure its coverage during response generation.

$$p(y_1, .., y_{N_y} | C, R; \theta)$$
$$= p(y_1 | C, R; \theta) \prod_{t=2}^{N_y} p(y_t | y_1, .., y_{t-1}, C, R; \theta),$$

where θ denotes the model parameters. The conditional probability of y_t is specified by

$$\begin{aligned} &p(y_t|y_1, ..., y_{t-1}, C, R; \theta) \\ &\quad = p(y_t|y_{t-1}, s_t, C, R; \theta), \end{aligned}$$

where y_t is the embedding of the vocabulary or object entities of retrieved knowledge items, s_t is the decoder RNN hidden state .

Probabilistic gated decoder utilizes a gating variable z_t (Yin et al., 2016) to indicate whether the t^{th} word is generated from common vocabulary or knowledge entities. The probability of generating the t^{th} word is given by:

$$\begin{aligned} &p(y_t|y_{t-1}, s_t, C, R; \theta) \\ &\quad = p(z_t = 0|s_t; \theta)p(y_t|y_{t-1}, s_t, C, R, z_t = 0; \theta) \\ &\quad + p(z_t = 1|s_t; \theta)p(y_t|R, z_t = 1; \theta), \end{aligned}$$

where $p(z_t|s_t; \theta)$ is computed by a logistic regression, $p(y_t|R, z_t = 1; \theta)$ is approximated with the knowledge items coefficient R, and θ is the model parameter.

During response generation, if an entity is overused, the response diversity will be reduced. Therefore, once a knowledge item occurred in the response, the corresponding coefficient should be reduced in case that an item occurs multiple times. To keep tracking the coverage of knowledge items, we update the knowledge items coefficient R at each time step. We also explore two coverage tracking mechanisms: 1) *Mask coefficient tracker* directly reduces the coefficient of the chosen knowledge item to 0 to ensure it can never be selected as the response word again. 2) *Coefficient attenuation tracker* calculates an attenuation score i_t based on s_t, R_0, R_{t-1} and y_{t-1}:

$$i_t = DNN(s_t, y_{t-1}, R_0, R_{t-1}),$$

and then update the coefficient as:

$$R_t = i_t \cdot R_{t-1},$$

where i_t ranges from 0 to 1 to gradually decrease the coefficient.

2.5 Training

The model parameters include the embedding of vocabulary, entities, relations, and all the model components. The model is differential and can be optimized in an end-to-end manner using back-propagation. Given the training data

$$D = \{(X_1^{N_d}, Y_1^{N_d}, F_1^{N_d}, E_1^{N_d})\}$$

where N_d is the max turns of a dialogue, F denotes the set of relevant knowledge and E denotes the set of similar knowledge in response, the objective function is to minimize the negative log-likelihood:

$$\ell(D, \theta) = -\sum \sum_{i=1}^{N_D} \log p(Y_i|X_i, F_i, E_i)$$

3 Experiment

3.1 Dataset

Most existing knowledge related datasets are mainly focused on single-turn factoid question answering (Yin et al., 2016; He et al., 2017b). We here collect a multi-turn conversation corpus grounded on the knowledge base, which includes not only facts related inquiries but also knowledge-based chit-chats. The data is publicly available online[1].

We first obtain the element information of each movie, including the movie's title, publication time, directors, actors and other attributes from `https://movie.douban.com/`, a popular Chinese social network for movies. Then, entities and relations are extracted as triplets to build the knowledge base K.

To collect the question-answering dialogues, we crawled the corpus from a question-answering forum `https://zhidao.baidu.com/`. To gather the knowledge related chit-chat corpus, we mined the dataset from the social forum `https://www.douban.com/group/`. Users post their comments, feedbacks, and impressions of films and televisions on it.

The conversations are grounded on the knowledge using NER, string match, and artificial scoring and filtering rules. The statistical information of the dataset is shown in Table 2. We observed that the conversations follow the long tail distribution, where famous films and televisions are discussed repeatedly and the low rating ones are rarely mentioned.

3.2 Experiment Detail

The total 32977 conversations consisting of 104567 utterances are divided into training (32177) and testing set (800). Bi-directional LSTM (Schuster and Paliwal, 1997) is used for encoder, and the dimension of the LSTM hidden

layer is set to 512. For the context RNN, the dimension of the LSTM unit is set to 1024. The dimension of word embedding shared by the vocabulary, entities and relations is also set to 512 empirically. We use Adam learning (Kingma and Ba, 2014) to update the gradient and clip the gradient in 5.0. It takes 140 to 150 epochs to train the model with a batch size of 80.

3.3 Baselines

We compare our neural knowledge diffusion model with three state-of-the-art baselines:

- **Seq2Seq**: a sequence to sequence model with vanilla RNN encoder-decoder (Shang et al., 2015; Vinyals and Le, 2015).
- **HRED**: a hierarchical recurrent encoder-decoder model.
- **GenDS**: a neural generative dialogue system that is capable of generating responses based on input message and related knowledge base (KB) (Zhu et al., 2017) .

Three variants of the neural diffusion dialogue generation model are implemented to verify different configurations of decoders.

- **NKD-ori** is the original model with a vanilla decoder and a mask coefficient tracker.
- **NKD-gated** is augmented with a probabilistic gated decoder and a mask coefficient tracker.
- **NKD-atte** utilizes a vanilla decoder and the coefficient attenuation tracker.

3.4 Evaluation Metric

Both automatic and human evaluation metrics are used to analyze the model's performance. To validate the effectiveness of facts matching and diffusion, we calculate **entity accuracy and recall** on factoid QA data set as well as the whole data set. Human evaluation rates the model in three aspects: **fluency**, **knowledge relevance** and **correctness** of the response. All these metrics range from 0 to 3, where 0 represents complete error, 1 for partially correct, 2 for almost correct, 3 for absolutely correct.

model	**accuracy(%)**	**recall(%)**
LSTM	7.8	7.5
HRED	3.7	3.9
GenDS	70.3	63.1
NKD-ori	67.0	56.2
NKD-gated	**77.6**	**77.3**
NKD-atte	55.1	46.6

Table 3: Evaluation results on factoid question answering dialogues.

model	**accuracy(%)**	**recall(%)**	**entity number**
LSTM	2.6	2.5	1.65
HRED	1.4	1.5	1.79
GenDS	20.9	17.4	1.34
NKD-ori	22.9	19.7	2.55
NKD-gated	**24.8**	**25.6**	1.59
NKD-atte	18.4	16.0	**3.41**

Table 4: Evaluation results on entire dataset.

3.5 Experiment Result

Table 3 displays the accuracy and recall of entities on factoid question answering dialogues. The performance of NKD is slightly better than the specific QA solution GenDS, while LSTM and HRED which are designed for chi-chat almost fail in this task. All the variants of NKD models are capable of generating entities with an accuracy of 60% to 70%, and NKD-gated achieves the best performance with an accuracy of 77.6% and a recall of 77.3%.

Table 4 lists the accuracy and recall of entities on the entire dataset including both the factoid QA and knowledge grounded chit-chats. Not surprisingly, both NKD-ori and NKD-gated outperform GenDS on the entire dataset, and the relative improvement over GenDS is even higher than the improvement in QA dialogues. It confirms that although NKD and GenDS are comparable in answering factoid questions, NKD is better at introducing the knowledge entities for knowledge grounded chit-chats.

All the NKD variants in Table 4 generate more entities than GenDS. LSTM and HRED also produce a certain amount of entities, but are of low

model	Fluency	Appropriateness of knowledge	Entire Correctness
LSTM	2.52	0.88	0.8
HRED	2.48	0.36	0.32
GenDS	**2.76**	1.36	1.34
NKD-ori	2.42	**1.92**	**1.58**
NKD-gated	2.08	1.72	1.44
NKD-atte	2.7	1.54	1.38

Table 5: Human evaluation result.

accuracies and recalls. We also noticed that NKD-gated achieves the highest accuracy and recall, but generates fewer entities compared with NKD-ori and NKD-gated, whereas NKD-atte generates more entities but also with relatively low accuracies and recalls.This demonstrates that NKD-gated not only learns to generate more entities but also maintains the quality (with a relatively high accuracy and recall).

The results of human evaluation in Table 5 also validate the superiority of the proposed model, especially on appropriateness. Responses generated by LSTM and HRED are of high fluency, but are simply repetitions, or even dull responses as "I don't know.", "Good.". NKD-gated is more adept at incorporating the knowledge base with respect to appropriateness and correctness, while NKD-atte generates more fluent responses. NKD-ori is a compromise, and obtains the best correctness in completing an entire dialogue. Four evaluators rated the scores independently. The pairwise Cohen's Kappa agreement scores are 0.67 on fluency, 0.54 on appropriateness, and 0.60 on entire correctness, which indicate a strong annotator agreement.

To our surprise, one of the variant model of NKD, which utilized both probabilistic gated decoder and coefficient attenuation tracker does not perform well on entire dataset. The accuracy of the model is quite high, but the recall is very low compared to others. We speculate that this is due to the method of minimizing negative log-likelihood during the training process, which makes the model tend to generate completely correct answers, and therefore reduces the number of generated entities.

3.6 Case Study

Table 6 shows typical examples of the generated responses. Both Item 1 and 2 are based on facts relevant utterances. NKD handles these questions by facts matching. Item 3 asks for a recommendation. NKD obtains similar entities by diffusing the entities. For item 4, 5 and 6, no explicit entity appears in the utterances. NKD is able to output appropriate recommendations through entity diffusion. The entities are recorded during the whole dialogue session, so NKD keeps recommending for several turns. Item 7 fails to generate an appropriate response because the entity in the golden response does not appear in the training set, which suggests the future work for out-of-vocabulary cases.

4 Related Work

The successes of sequence-to-sequence architecture (Cho et al., 2014; Sutskever et al., 2014) motivated investigation in dialogue systems that can effectively learn to generate a response sequence given the previous utterance sequence (Shang et al., 2015; Sordoni et al., 2015b; Vinyals and Le, 2015). The model is trained to minimize the negative log-likelihood of the training data. Despite the current progress, the lack of response diversity is a notorious problem, where the model inherently tends to generate short, general responses in spite of different inputs. Li et al. (2016a); Serban et al. (2017); Cao and Clark (2017) suggested that theses boring responses are common in training data and shorter responses are more likely to be given a higher likelihood. To tackle the problem, Li et al. (2016a) introduced a maximum mutual information training objective. Serban et al. (2017), Cao and Clark (2017) and Chen et al. (2018) used latent variables to introduce stochasticity to enhance the response diversity. Vijayakumar et al. (2016),Shao et al. (2017) and Li et al. (2016b) recognized that the greedy search decoding process, especially beam-search with a wide beam size, leads the short responses possess higher likelihoods. They reserved more diverse candidates during beam-search decoding. In this paper, we present that the absence of background knowledge and common sense is another source of lacking diversity. We augment the knowledge base to end-to-end dialogue generation.

Another research line comes from the utilizing of knowledge bases. A typical application is question-answering (QA) systems. The end-to-end QA also resort to the encoder-decoder framework (Yin et al., 2016; He et al., 2017a). Yin et al. (2016) enquired the knowledge-base to achieve one fact and answer the simple factoid questions

Table 6: Examples of the generated response. Entities are underlined and Y_i denotes the gold response.

by referring to the fact. He et al. (2017a) extended this approach by augmenting the copying mechanism and enabled the output words to copy from the original input sequence. Eric et al. (2017) noticed that neural task-oriented dialogue systems often struggle to smoothly interface with a knowledge base and they addressed the problem by augmenting the end-to-end structure with a key-value retrieval mechanism where a separate attention is performed over the key of each entry in the KB. Ghazvininejad et al. (2017) represented the unstructured text as bag of words representation and also performed soft attention over the facts to retrieve a facts vector. Zhu et al. (2017) generated responses with any number of answer entities in the structured KB, even when these entities never appear in the training set. Dhingra et al. (2017) proposed a multi-turn dialogue agent which helps users search knowledge base by soft KB lookup. In our model, we perform not only facts matching to answer factoid inquiries, but also entity diffusion to infer similar entities. Given previous utterances, we retrieve the relevant facts, diffuse them, and generate responses based on diversified relevant knowledge items.

5 Conclusion

In this paper, we identify the knowledge diffusion in conversations and propose an end-to-end neural knowledge diffusion model to deal with the problem. The model integrates the dialogue system with the knowledge base through both facts matching and entity diffusion, which enable the convergent and divergent thinking over the knowledge base. Under such mechanism, the factoid question answering and knowledge grounded chitchats can be tackled together. Empirical results show the proposed model is able to generate more meaningful and diverse responses, compared with the state-of-the-art baselines. In future work, we plan to introduce reinforcement learning and knowledge base reasoning mechanisms to improve the performance.

Abstract

Sentence function is a significant factor to achieve the purpose of the speaker, which, however, has not been touched in large-scale conversation generation so far. In this paper, we present a model to generate informative responses with controlled sentence function. Our model utilizes a continuous latent variable to capture various word patterns that realize the expected sentence function, and introduces a type controller to deal with the compatibility of controlling sentence function and generating informative content. Conditioned on the latent variable, the type controller determines the type (i.e., *function-related*, *topic*, and *ordinary* word) of a word to be generated at each decoding position. Experiments show that our model outperforms state-of-the-art baselines, and it has the ability to generate responses with both controlled sentence function and informative content.

1 Introduction

Sentence function is an important linguistic feature and a typical taxonomy in terms of the purpose of the speaker (Rozakis, 2003). There are four major function types in the language including *interrogative, declarative, imperative*, and *exclamatory*, as described in (Rozakis, 2003). Each sentence function possesses its own structure, and transformation between sentence functions needs a series of changes in word order, syntactic patterns and other aspects (Akmajian, 1984; Yule, 2010).

Since sentence function is regarding the purpose of the speaker, it can be a significant factor indicating the conversational purpose during interactions, but surprisingly, this problem is rather untouched in dialogue systems. As shown in Figure 1, responses with different functions can be used to achieve different conversational purposes: **Interrogative** responses can be used to acquire further information from the user; **imperative** responses are used to make requests, directions, instructions or invitations to elicit further interactions; and **declarative** responses commonly make statements to state or explain something.[1] Interrogative and imperative responses can be used to avoid stalemates (Li et al., 2016b), which can be viewed as important proactive behaviors in conversation (Yu et al., 2016). Thus, conversational systems equipped with the ability to control the sentence function can adjust its strategy for different purposes within different contexts, behave more proactively, and may lead the dialogue to go further.

Post		I'm really hungry now.
Response	**Interrogative**	**What did** you have at breakfast**?**
	Imperative	**Let's** have dinner together**!**
	Declarative	Me, **too. But** you ate too much at lunch**.**

Figure 1: Responses with three sentence functions. Function-related words are in **red**, topic words in blue, and others are ordinary words.

Generating responses with controlled sentence functions differs significantly from other tasks on controllable text generation (Hu et al., 2017; Ficler and Goldberg, 2017; Asghar et al., 2017; Ghosh et al., 2017; Zhou and Wang, 2017; Dong et al., 2017; Murakami et al., 2017). These studies, involving the control of sentiment polarity, emotion, or tense, fall into **local** control, more or less, because the controllable variable can be *locally* re-

*Corresponding author: Minlie Huang.

[1] Note that we did not include the *exclamatory* category in this paper because an exclamatory sentence in conversation is only a strong emotional expression of the original sentence with few changes.

flected by decoding local variable-related words, e.g., *terrible* for negative sentiment (Hu et al., 2017; Ghosh et al., 2017), *glad* for happy emotion (Zhou et al., 2018; Zhou and Wang, 2017), and *was* for past tense (Hu et al., 2017). By contrast, sentence function is a **global** attribute of text, and controlling sentence function is more challenging in that it requires to adjust the **global structure** of the entire text, including changing word order and word patterns.

Controlling sentence function in conversational systems faces another challenge: in order to generate informative and meaningful responses, it has to deal with the compatibility of the sentence function and the content. Similar to most existing neural conversation models (Li et al., 2016a; Mou et al., 2016; Xing et al., 2017), we are also struggling with universal and meaningless responses for different sentence functions, e.g., "*Is that right?*" for interrogative responses, "*Please!*" for imperative responses and "*Me, too.*" for declarative responses. The lack of meaningful topics in responses will definitely degrade the utility of the sentence function so that the desired conversational purpose can not be achieved. Thus, the task needs to generate responses with both informative content and controllable sentence functions.

In this paper, we propose a conversation generation model to deal with the global control of sentence function and the compatibility of controlling sentence function and generating informative content. We devise an encoder-decoder structure equipped with a latent variable in conditional variational autoencoder (CVAE) (Sohn et al., 2015), which can not only project different sentence functions into different regions in a latent space, but also capture various word patterns within each sentence function. The latent variable, supervised by a discriminator with the expected function label, is also used to realize the global control of sentence function. To address the compatibility issue, we use a type controller which lexicalizes the sentence function and the content explicitly. The type controller estimates a distribution over three word types, i.e., **function-related**, **topic**, and **ordinary** words. During decoding, the word type distribution will be used to modulate the generation distribution in the decoder. The type sequence of a response can be viewed as an abstract representation of sentence function. By this means, the model has an explicit and strong control on the function and the content. Our contributions are as follows:

- We investigate how to control sentence functions to achieve different conversational purposes in open-domain dialogue systems. We analyze the difference between this task and other controllable generation tasks.

- We devise a structure equipped with a latent variable and a type controller to achieve the global control of sentence function and deal with the compatibility of controllable sentence function and informative content in generation. Experiments show the effectiveness of the model.

2 Related Work

Recently, language generation in conversational systems has been widely studied with sequence-to-sequence (seq2seq) learning (Sutskever et al., 2014; Bahdanau et al., 2015; Vinyals and Le, 2015; Shang et al., 2015; Serban et al., 2016, 2017). A variety of methods has been proposed to address the important issue of content quality, including enhancing diversity (Li et al., 2016a; Zhou et al., 2017) and informativeness (Mou et al., 2016; Xing et al., 2017) of the generated responses.

In addition to the content quality, controllability is a critical problem in text generation. Various methods have been used to generate texts with controllable variables such as sentiment polarity, emotion, or tense (Hu et al., 2017; Ghosh et al., 2017; Zhou and Wang, 2017; Zhou et al., 2018) . There are mainly two solutions to deal with controllable text generation. First, the variables to be controlled are embedded into vectors which are then fed into the models to reflect the characteristics of the variables (Ghosh et al., 2017; Zhou et al., 2018). Second, latent variables are used to capture the information of controllable attributes as in the variational autoencoders (VAE) (Zhou and Wang, 2017). (Hu et al., 2017) combined the two techniques by disentangling a latent variable into a categorical code and a random part to better control the attributes of the generated text.

The task in this paper differs from the above tasks in two aspects: (1) Unlike other tasks that realize controllable text generation by decoding attribute-related words locally, our task requires to not only decode function-related words, but also

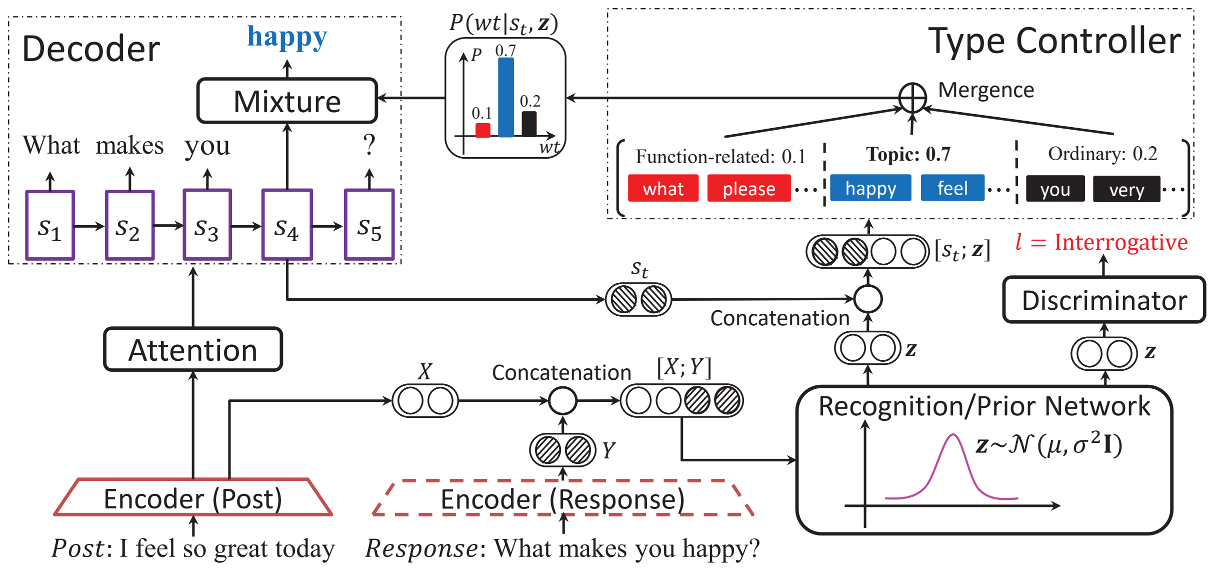

Figure 2: Model overview. During training, the latent variable z is sampled from the recognition network which is supervised by the function label in the discriminator. In the type controller, the latent variable and the decoder's state are used to estimate a type distribution which modulates the final generation distribution. During test, z is sampled from the prior network whose input is only the post. The response encoder in the dotted box appears only in training.

plan the words globally to realize the function type to be controlled. (2) The compatibility of controllable variables and content quality is less studied in the literature. The most similar work in (Zhao et al., 2017) proposed to control the dialogue act of a response, which is also a global attribute. However, the model controls dialog act by directly feeding a latent variable into the decoder, instead, our model has a stronger control on the generation process via a type controller in which words of different types are concretely modeled.

3 Model

3.1 Task Definition and Model Overview

Our problem is formulated as follows: given a post $X = x_1x_2\cdots x_n$ and a sentence function category l, our task is to generate a response $Y = y_1y_2\cdots y_m$ that is not only coherent with the specified function category l but also informative in content. We denote $\boldsymbol{c}$ as the concatenation of all the input information, i.e. $\boldsymbol{c} = [X; l]$. Essentially, the goal is to estimate the conditional probability:

$$P(Y, \boldsymbol{z}|\boldsymbol{c}) = P(\boldsymbol{z}|\boldsymbol{c}) \cdot P(Y|\boldsymbol{z}, \boldsymbol{c}) \quad (1)$$

The latent variable $\boldsymbol{z}$ is used to capture the sentence function of a response. $P(\boldsymbol{z}|\boldsymbol{c})$, parameterized as the prior network in our model, indicates the sampling process of $\boldsymbol{z}$, i.e., drawing $\boldsymbol{z}$ from $P(\boldsymbol{z}|\boldsymbol{c})$. And $P(Y|\boldsymbol{z}, \boldsymbol{c}) = \prod_{t=1}^{m} P(y_t|y_{<t}, \boldsymbol{z}, \boldsymbol{c})$ is applied to model the generation of the response Y conditioned on the latent variable $\boldsymbol{z}$ and the input $\boldsymbol{c}$, which is implemented by a decoder in our model.

Figure 2 shows the overview of our model. As aforementioned, the model is constructed in the encoder-decoder framework. The encoder takes a post and a response as input, and obtains the hidden representations of the input. The recognition network and the prior network, adopted from the CVAE framework (Sohn et al., 2015), sample a latent variable $\boldsymbol{z}$ from two normal distributions, respectively. Supervised by a discriminator with the function label, the latent variable encodes meaningful information to realize a sentence function. The latent variable, along with the decoder's state, is also used to control the type of a word in generation via the type controller. In the decoder, the final generation distribution is mixed by the type distribution which is obtained from the type controller. By this means, the latent variable encodes information not only from sentence function but also from word types, and in return, the decoder and the type controller can deal with the compatibility of realizing sentence function and information content in generation.

3.2 Encoder-Decoder Framework

The encoder-decoder framework has been widely used in language generation (Sutskever et al., 2014; Vinyals and Le, 2015). The encoder transforms the post sequence $X = x_1 x_2 \cdots x_n$ into hidden representations $\boldsymbol{H} = \boldsymbol{h}_1 \boldsymbol{h}_2 \cdots \boldsymbol{h}_n$, as follows:

$$\boldsymbol{h}_t = \mathbf{GRU}(\boldsymbol{e}(x_t), \boldsymbol{h}_{t-1}) \tag{2}$$

where $\mathbf{GRU}$ is gated recurrent unit (Cho et al., 2014), and $\boldsymbol{e}(x_t)$ denotes the embedding of the word x_t.

The decoder first updates the hidden states $\boldsymbol{S} = \boldsymbol{s}_1 \boldsymbol{s}_2 \cdots \boldsymbol{s}_m$, and then generates the target sequence $Y = y_1 y_2 \cdots y_m$ as follows:

$$\boldsymbol{s}_t = \mathbf{GRU}(\boldsymbol{s}_{t-1}, \boldsymbol{e}(y_{t-1}), \boldsymbol{cv}_{t-1}) \tag{3}$$

$$y_t \sim P(y_t | y_{<t}, \boldsymbol{s}_t) = softmax(\boldsymbol{W}\boldsymbol{s}_t) \tag{4}$$

where this $\mathbf{GRU}$ does not share parameters with the encoder's network. The context vector $\boldsymbol{cv}_{t-1}$ is a dynamic weighted sum of the encoder's hidden states, i.e., $\boldsymbol{cv}_{t-1} = \sum_{i=1}^{n} \alpha_i^{t-1} \boldsymbol{h}_i$, and α_i^{t-1} scores the relevance between the decoder's state $\boldsymbol{s}_{t-1}$ and the encoder's state $\boldsymbol{h}_i$ (Bahdanau et al., 2015).

3.3 Recognition/Prior Network

On top of the encoder-decoder structure, our model introduces the recognition network and the prior network of CVAE framework, and utilizes the two networks to draw latent variable samples during training and test respectively. The latent variable can project different sentence functions into different regions in a latent space, and also capture various word patterns within a sentence function.

In the training process, our model needs to sample the latent variable from the posterior distribution $P(\boldsymbol{z}|Y, \boldsymbol{c})$, which is intractable. Thus, the recognition network $q_\phi(\boldsymbol{z}|Y, \boldsymbol{c})$ is introduced to approximate the true posterior distribution so that we can sample $\boldsymbol{z}$ from this deterministic parameterized model. We assume that z follows a multivariate Gaussian distribution whose covariance matrix is diagonal, i.e., $q_\phi(\boldsymbol{z}|Y, \boldsymbol{c}) \sim \mathcal{N}(\mu, \sigma^2 \mathbf{I})$. Under this assumption, the recognition network can be parameterized by a deep neural network such as a multi-layer perceptron (MLP):

$$[\mu, \sigma^2] = \mathbf{MLP}_{posterior}(Y, \boldsymbol{c}) \tag{5}$$

During test, we use the prior network $p_\theta(\boldsymbol{z}|\boldsymbol{c}) \sim \mathcal{N}(\mu', \sigma'^2 \mathbf{I})$ instead to draw latent variable samples, which can be implemented in a similar way:

$$[\mu', \sigma'^2] = \mathbf{MLP}_{prior}(\boldsymbol{c}) \tag{6}$$

To bridge the gap between the recognition and the prior networks, we add the KL divergence term that should be minimized to the loss function:

$$\mathcal{L}_1 = KL(q_\phi(\boldsymbol{z}|Y, \boldsymbol{c}) || p_\theta(\boldsymbol{z}|\boldsymbol{c})) \tag{7}$$

3.4 Discriminator

The discriminator supervises $\boldsymbol{z}$ to encode function-related information in a response with supervision signals. It takes $\boldsymbol{z}$ as input instead of the generated response Y to avoid the vanishing gradient of z, and predicts the function category conditioned on $\boldsymbol{z}$:

$$P(l|\boldsymbol{z}) = softmax(\boldsymbol{W}_D \cdot \mathbf{MLP}_{dis}(\boldsymbol{z})) \tag{8}$$

This formulation can enforce $\boldsymbol{z}$ to capture the features of sentence function and enhance the influence of $\boldsymbol{z}$ in word generation. The loss function of the discriminator is given by:

$$\mathcal{L}_2 = -E_{q_\phi(\boldsymbol{z}|Y, \boldsymbol{c})}[\log P(l|\boldsymbol{z})] \tag{9}$$

3.5 Type Controller

The type controller is designed to deal with the compatibility issue of controlling sentence function and generating informative content. As aforementioned, we classify the words in a response into three types: *function-related, topic, and ordinary* words. The type controller estimates a distribution over the word types at each decoding position, and the type distribution will be used in the mixture model of the decoder for final word generation. During the decoding process, the decoder's state $\boldsymbol{s}_t$ and the latent variable $\boldsymbol{z}$ are taken as input to estimate the type distribution as follows:

$$P(wt|\boldsymbol{s}_t, \boldsymbol{z}) = softmax(\boldsymbol{W}_0 \cdot \mathbf{MLP}_{type}(\boldsymbol{s}_t, \boldsymbol{z})) \tag{10}$$

Noticeably, the latent variable z introduced to the RNN encoder-decoder framework often fails to learn a meaningful representation and has little influence on language generation, because the RNN decoder may ignore z during generation, known as the issue of vanishing latent variable (Bowman et al., 2016). By contrast, our model allows $\boldsymbol{z}$ to directly control the word type at each decoding position, which has more influence on language generation.

3.6 Decoder

Compared with the traditional decoder described in Section 3.2, our decoder updates the hidden state $\boldsymbol{s}_t$ with both the input information $\boldsymbol{c}$ and the latent variable $\boldsymbol{z}$, and generates the response in a *mixture* form which is combined with the type distribution obtained from the type controller:

$$\boldsymbol{s}_t = \mathbf{GRU}(\boldsymbol{s}_{t-1}, \boldsymbol{e}(y_{t-1}), \boldsymbol{cv}_{t-1}, \boldsymbol{c}, \boldsymbol{z}) \quad (11)$$

$$P(y_t|y_{<t}, \boldsymbol{c}, \boldsymbol{z}) = P(y_t|y_{t-1}, \boldsymbol{s}_t, \boldsymbol{c}, \boldsymbol{z})$$
$$= \sum_{i=1}^{3} P(wt = i|\boldsymbol{s}_t, \boldsymbol{z}) P(y_t|y_{t-1}, \boldsymbol{s}_t, \boldsymbol{c}, \boldsymbol{z}, wt = i) \quad (12)$$

where $wt = 1, 2, 3$ stand for function-related words, topic words, and ordinary words, respectively. The probability for choosing different word types at time t, $P(wt = i|\boldsymbol{s}_t, \boldsymbol{z})$, is obtained from the type controller, as shown in Equation (10). The probabilities of choosing words in different types are introduced as follows:

Function-related Word: Function-related words represent the typical words for each sentence function, e.g., *what* for interrogative responses, and *please* for imperative responses. To select the function-related words at each position, we simultaneously consider the decoder's state $\boldsymbol{s}_t$, the latent variable $\boldsymbol{z}$ and the function category l.

$$P(y_t|y_{t-1}, \boldsymbol{s}_t, \boldsymbol{c}, \boldsymbol{z}, wt = 1) = softmax(\boldsymbol{W}_1 \cdot [\boldsymbol{s}_t, \boldsymbol{z}, \boldsymbol{e}(l)]) \quad (13)$$

where $\boldsymbol{e}(l)$ is the embedding vector of the function label. Under the control of $\boldsymbol{z}$, our model can learn to decode function-related words at proper positions automatically.

Topic Word: Topic words are crucial for generating an informative response. The probability for selecting a topic word at each decoding position depends on the current hidden state s_t:

$$P(y_t|y_{t-1}, \boldsymbol{s}_t, \boldsymbol{c}, \boldsymbol{z}, wt = 2) = softmax(\boldsymbol{W}_2 \boldsymbol{s}_t) \quad (14)$$

This probability is over the topic words we predict conditioned on a post. Section 3.8 will describe the details.

Ordinary Word: Ordinary words play a functional role in making a natural and grammatical sentence. The probability of generating ordinary words is estimated as below:

$$P(y_t|y_{t-1}, \boldsymbol{s}_t, \boldsymbol{c}, \boldsymbol{z}, wt = 3) = softmax(\boldsymbol{W}_3 \boldsymbol{s}_t) \quad (15)$$

The generation loss of the decoder is given as below:

$$\mathcal{L}_3 = -E_{q_\phi(\boldsymbol{z}|Y,\boldsymbol{c})}[\log P(Y|\boldsymbol{z}, \boldsymbol{c})]$$
$$= -E_{q_\phi(\boldsymbol{z}|Y,\boldsymbol{c})}[\sum_t \log P(y_t|y_{<t}, \boldsymbol{z}, \boldsymbol{c})] \quad (16)$$

3.7 Loss Function

The overall loss $\mathcal{L}$ is a linear combination of the KL term $\mathcal{L}_1$, the classification loss of the discriminator $\mathcal{L}_2$, and the generation loss of the decoder $\mathcal{L}_3$:

$$\mathcal{L} = \alpha\mathcal{L}_1 + \mathcal{L}_2 + \mathcal{L}_3 \quad (17)$$

We let α gradually increase from 0 to 1. This technique of *KL cost annealing* can address the optimization challenges of vanishing latent variables in the RNN encoder-decoder (Bowman et al., 2016).

3.8 Topic Word Prediction

Topic words play a key role in generating an informative response. We resort to pointwise mutual information (PMI) (Church and Hanks, 1990) for predicting a list of topic words that are relevant to a post. Let x and y indicate a word in a post X and its response Y respectively, and PMI is computed as follows:

$$PMI(x, y) = \log \frac{P(x, y)}{P(x)P(y)} \quad (18)$$

Then, the relevance score of a topic word to a given post $x_1x_2 \cdots x_n$ can be approximated as follows, similar to (Mou et al., 2016):

$$REL(x_1, ..., x_n, y) \approx \sum_{i=1}^{n} PMI(x_i, y) \quad (19)$$

During training, the words in a response with high REL scores to the post are treated as topic words. During test, we use REL to select the top ranked words as topic words for a post.

4 Experiment

4.1 Data Preparation

We collected a Chinese dialogue dataset from Weibo [2]. We crawled about 10 million post-responses pairs. Since our model needs the sentence function label for each pair, we built a classifier to predict the sentence function automatically to construct large-scale labeled data. Thus,

[2]http://www.weibo.com

we sampled about 2,000 pairs from the original dataset and annotated the data manually with four categories, i.e., *interrogative, imperative, declarative* and *other*. This small dataset was partitioned into the training, validation, and test sets with the ratio of 6:1:1. Three classifiers, including LSTM (Hochreiter and Schmidhuber, 1997), Bi-LSTM (Graves et al., 2005) and a self-attentive model (Lin et al., 2017), were attempted on this dataset. The results in Table 1 show that the self-attentive classifier outperforms other models and achieves the best accuracy of 0.78 on the test set.

Model	Accuracy
LSTM	0.60
Bi-LSTM	0.75
Self-Attentive	0.78

Table 1: Accuracy of sentence function classification on the 2,000 post-response pairs.

We then applied the self-attentive classifier to annotate the large dataset and obtained a dialogue dataset with noisy sentence function labels[3]. To balance the distribution of sentence functions, we randomly sampled about 0.6 million pairs for each sentence function to construct the final dataset. The statistics of this dataset are shown in Table 2. The dataset[4] is available at `http://coai.cs.tsinghua.edu.cn/hml/dataset`.

Training	#Post	1,963,382	
	#Response	Interrogative	618,340
		Declarative	672,346
		Imperative	672,696
Validation	#Post	24,034	
	#Response	Interrogative	7,045
		Declarative	9,685
		Imperative	7,304
Test	#Post	6,000	

Table 2: Corpus statistics.

4.2 Experiment Settings

Our model was implemented with TensorFlow[5]. We applied bidirectional GRU with 256 cells to the encoder and GRU with 512 cells to the decoder. The dimensions of word embedding and function category embedding were both set to 100. We also set the dimension of latent variables to 128. The vocabulary size was set to 40,000. Stochastic gradient descent (Qian, 1999) was used to optimize our model, with a learning rate of 0.1, a decay rate of 0.9995, and a momentum of 0.9. The batch size was set to 128. Our codes are available at `https://github.com/kepei1106/SentenceFunction`.

We chose several state-of-the-art baselines, which were implemented with the settings provided in the original papers:

Conditional Seq2Seq (c-seq2seq): A Seq2Seq variant which takes the category (i.e., function type) embedding as additional input at each decoding position (Ficler and Goldberg, 2017).

Mechanism-aware (MA): This model assumes that there are multiple latent responding mechanisms (Zhou et al., 2017). The number of responding mechanisms is set to 3, equal to the number of function types.

Knowledge-guided CVAE (KgCVAE): A modified CVAE which aims to control the dialog act of a generated response (Zhao et al., 2017).

4.3 Automatic Evaluation

Metrics: We adopted *Perplexity (PPL)* (Vinyals and Le, 2015), *Distinct-1 (Dist-1)*, *Distinct-2 (Dist-2)* (Li et al., 2016a), and *Accuracy (ACC)* to evaluate the models at the content and function level. Perplexity can measure the grammaticality of generated responses. Distinct-1/distinct-2 is the proportion of distinct unigrams/bigrams in all the generated tokens, respectively. Accuracy measures how accurately the sentence function can be controlled. Specifically, we compared the prespecified function (as input to the model) with the function of a generated response, which is predicted by the self-attentive classifier (see Section 4.1).

Model	PPL	Dist-1	Dist-2	ACC
c-seq2seq	57.14	949/.007	5177/.041	0.973
MA	**46.08**	745/.005	2952/.027	0.481
KgCVAE	56.81	1531/**.009**	10683/.070	0.985
Our Model	55.85	**1833**/.008	**15586/.075**	**0.992**

Table 3: Automatic evaluation with perplexity (PPL), distinct-1 (Dist-1), distinct-2 (Dist-2), and accuracy (ACC). The integers in the Dist-* cells denote the total number of distinct n-grams.

Results: Our model has lower perplexity than c-seq2seq and KgCVAE, indicating that the model is comparable with other models in generating grammatical responses. Note that MA has the lowest perplexity because it tends to generate generic responses.

[3]Though the labels are noisy, the data are sufficient to train a generation model in practice.

[4]Note that we strictly obeyed the policies of Weibo and anonymized potential private information in dialogues. This dataset is strictly limited for academic use.

[5]https://github.com/tensorflow/tensorflow

Model	Interrogative			Declarative			Imperative		
	Gram.	Appr.	Info.	Gram.	Appr.	Info.	Gram.	Appr.	Info.
Ours vs. c-seq2seq	0.534	0.536	0.896*	0.630*	0.573*	0.764*	0.685*	0.504	0.893*
Ours vs. MA	0.802*	0.602*	0.675*	0.751*	0.592*	0.617*	0.929*	0.568*	0.577*
Ours vs. KgCVAE	0.510	0.626*	0.770*	0.546*	0.515*	0.744*	0.780*	0.521*	0.837*

Table 4: Manual evaluation results for different functions. The scores indicate the percentages that our model wins the baselines after removing tie pairs. The scores of our model marked with * are significantly better than the competitors (Sign Test, *p-value* < 0.05).

As for distinct-1 and distinct-2, our model generates remarkably more distinct unigrams and bigrams than the baselines, indicating that our model can generate more diverse and informative responses compared to the baselines.

In terms of sentence function accuracy, our model outperforms all the baselines and achieves the best accuracy of 0.992, which indicates that our model can control the sentence function more precisely. MA has a very low score because there is no direct way to control sentence function, instead, it learns automatically from the data.

4.4 Manual Evaluation

To evaluate the generation quality and how well the models can control sentence function, we conducted pair-wise comparison. 200 posts were randomly sampled from the test set and each model was required to generate responses with three function types to each post. For each pair of responses (one by our model and the other by a baseline, along with the post), annotators were hired to give a preference (win, lose, or tie). The total annotation amounts to $200 \times 3 \times 3 \times 3$=5,400 since we have three baselines, three function types, and three metrics. We resorted to a crowdsourcing service for annotation, and each pair-wise comparison was judged by 5 curators.

Metrics: We designed three metrics to evaluate the models from the perspectives of sentence function and content: *grammaticality* (whether a response is grammatical and coherent with the sentence function we prespecified), *appropriateness* (whether a response is a logical and appropriate reply to its post), and *informativeness* (whether a response provides meaningful information via the topic words relevant to the post). Note that the three metrics were separately evaluated.

Results: The scores in Table 4 represent the percentages that our model wins a baseline after removing tie pairs. A value larger than 0.5 indicates that our model outperforms its competitor. Our model outperforms the baselines significantly in most cases (Sign Test, with *p-value* < 0.05). Among the three function types, our model performs significantly better than the baselines when generating declarative and imperative responses. As for interrogative responses, our model is better but the difference is not significant in some settings. This is because interrogative patterns are more apparent and easier to learn, thereby all the models can capture some of the patterns to generate grammatical and appropriate responses, resulting in more ties. By contrast, declarative and imperative responses have less apparent patterns whereas our model is better at capturing the global patterns through modeling the word types explicitly.

We can also see that our model obtains particularly high scores in informativeness. This demonstrates that our model is better to generate more informative responses, and is able to control sentence functions at the same time.

The annotation statistics are shown in Table 5. The percentage of annotations that at least 4 judges assign the same label (at least 4/5 agreement) is larger than 50%, and the percentage for at least 3/5 agreement is about 90%, indicating that annotators reached a moderate agreement.

	At least 3/5	At least 4/5
Grammaticality	91.7%	60.1%
Appropriateness	88.6%	52.5%
Informativeness	95.9%	71.2%

Table 5: Annotation statistics. *At least n/5* means there are no less than n judges assigning the same label to a record during annotation.

4.5 Words and Patterns in Function Control

To further analyze how our model realizes the global control of sentence function, we presented frequent words and frequent word patterns within each function. Specifically, we counted the frequency of a function-related word in the generated responses. The type of a word is predicted by the type controller. Further, we replaced the

Function	Frequent Words		Frequent Patterns		Response Examples	
	Chinese	English	Chinese	English	Chinese	English
Interrogative	？ 是 吗 说 什么	? be particle mean what	x是说y吗？	Does x mean y?	你是说我帅吗？	Do you mean I'm handsome?
			x是在y吗？	Is x y?	你是在夸我吗？	Are you praising me?
			x在哪y啊？	Where does x y?	你在哪上班啊？	Where do you work?
			x想y什么z？	What z does x want to y?	你想要什么类型的？	What type do you want to choose?
Imperative	！ 要 可以 来 请	! will can come please	那就y吧	Do y, then.	那就好好养着吧	Take care of yourself, then.
			x要把y给z	Let x give y to z.	我要把你的房子给你	Let me give your house to you.
Declarative	是 也 觉得 可是 没	be also/too think but no	x也是y，可是z	x also y, but z	我也是这么想的，可是我要找一个人，哈哈	I also think so, but I will find a person. Ha-ha.
			x也是，a都b	x, too, and a has b.	我也是，我的粉丝都被我震精了	Me, too, and my fans have been shocked by me.

Figure 3: Frequent function-related words and frequent patterns containing at least 3 function-related words. The letters denote the variables which replace ordinary and topic words in the generated responses. The underlined words in responses are those occurring in patterns.

ordinary and topic words of a generated response with variables and treated each response as a sequence of function-related words and variables. We then used the Apriori algorithm (Agrawal and Srikant, 1994) to mine frequent patterns in these sequences. We retained frequent patterns that consist of at most 5 words and appear in at least 2% of the generated responses.

Figure 3 presents the most frequent words (the second and third columns) and patterns (the fourth and fifth columns) for each function type. Note that the word patterns can be viewed as an abstract representation of sentence function. We observed that:

First, function-related words are distributed at multiple positions of a sentence, indicating that realizing a sentence function needs a global control by not only predicting the word types but also planning the words of different types properly.

Second, the frequent words clearly reveal the difference between function types. For instance, interrogatives like 什么(what), ？(?) and 吗(particle) are commonly seen in interrogative responses, words like 请(please), 来(come), and 要(will) occur frequently in imperative responses. Further, word patterns in different function types differ significantly (see the fourth/fifth columns), indicating that the model is able to learn function-specific word patterns.

Third, interrogative and imperative responses have explicit patterns, while declarative responses are more implicit and divergent in pattern. Interrogative responses fall into *Yes-No, Wh-, How-*, and other questions. Imperative responses generally start with the base form of verbs or imperative words including 请(please). Our model succeeds in capturing two typical forms in declarative responses: adversative and progressive structures.

4.6 Case Study

Post:	如果有一天我突然跟你绝交，你会怎么样？ What would you do if I suddenly broke up with you someday?
Target Function:	Interrogative
c-seq2seq:	你是谁？ Who are you?
MA:	我会彻查关于法律相关司法措施的结论吗？ Should I investigate the conclusion of judicial measure related to the law?
KgCVAE:	你是不是想我了 Did you miss me?
Our Model:	你**说**的**是**我的错**吗？** **Do** you **mean** that it's my fault**?**
Target Function:	Imperative
c-seq2seq:	我会好好的！ I'll be fine!
MA:	绝交基佬，绝交基佬 Break up with guys. Break up with guys.
KgCVAE:	我会告诉你的！ I will tell you!
Our Model:	我**会把**你的礼物**给**你的，**放心** **Rest assured** that I **would give** your gift **to** you.
Target Function:	Declarative
c-seq2seq:	我也是这么认为的，我觉得我是个好孩子 I think so, too. I feel that I'm a good man.
MA:	我也不知道怎么办，但是我怕怕 I don't know what to do, but I'm in fear.
KgCVAE:	我也觉得我是个好男人。 I think I'm a good man, too.
Our Model:	我**觉得**我**会**很傻，我**会**被我妈骂的 I **would think** that I was stupid and I **would** be blamed by my mother**.**

Figure 4: Generated responses of all the models for different sentence functions. In the responses of our model, function-related words are in **red** and topic words in blue. The word type is predicted by the type controller.

We presented an example in Figure 4 to show that our model can generate responses of different function types better compared to baselines. We can see that each function type can be realized by a natural composition of function-related words (in red) and topic words (in blue). Moreover, function-related words are different and are placed at different positions across function types, indicating that the model learns function-specific word patterns. These examples also show that the compatibility issue of controlling sentence function and generating informative content is well addressed by planning function-related and topic words properly.

Post	如果有一天我突然跟你绝交，你会怎么样？ What would you do if I suddenly broke up with you someday?
Interrogative Response #1	你**说的是**我的错**吗？** **Do** you **mean** that it's my fault**?**
Interrogative Response #2	你**会不会**说话**？** **Can** you speak normally**?**
Interrogative Response #3	你想我**怎样？**我**要不要**绝交**？** **What do** you think I should do**? Shall** I break up with you**?**

Figure 5: Different patterns of interrogative responses generated by our model.

Furthermore, we verified the ability of our model to capture fine-grained patterns within a sentence function. We took interrogative responses as example and obtained responses by drawing latent variable samples repeatedly. Figure 5 shows interrogative responses with different patterns generated by our model given the same post. The model generates several Yes-No questions led by words such as 吗(do), 会(can) and 要(shall), and a Wh-question led by 怎样(what). This example shows that the latent variable can capture the fine-grained patterns and improve the diversity of responses within a function.

5 Conclusion

We present a model to generate responses with both controllable sentence function and informative content. To deal with the global control of sentence function, we utilize a latent variable to capture the various patterns for different sentence functions. To address the compatibility issue, we devise a type controller to handle function-related and topic words explicitly. The model is thus able to control sentence function and generate informative content simultaneously. Extensive experiments show that our model performs better than several state-of-the-art baselines.

As for future work, we will investigate how to apply the technique to multi-turn conversational systems, provided that the most proper sentence function can be predicted under a given conversation context.

Abstract

End-to-end learning framework is useful for building dialog systems for its simplicity in training and efficiency in model updating. However, current end-to-end approaches only consider user semantic inputs in learning and under-utilize other user information. Therefore, we propose to include user sentiment obtained through multimodal information (acoustic, dialogic and textual), in the end-to-end learning framework to make systems more user-adaptive and effective. We incorporated user sentiment information in both supervised and reinforcement learning settings. In both settings, adding sentiment information reduced the dialog length and improved the task success rate on a bus information search task. This work is the first attempt to incorporate multimodal user information in the adaptive end-to-end dialog system training framework and attained state-of-the-art performance.

1 Introduction

Most of us have had frustrating experience and even expressed anger towards automated customer service systems. Unfortunately, none of the current commercial systems can detect user sentiment and let alone act upon it. Researchers have included user sentiment in rule-based systems (Acosta, 2009; Pittermann et al., 2010), where there are strictly-written rules that guide the system to react to user sentiment. Because traditional modular-based systems are harder to train, to update with new data and to debug errors, end-to-end trainable systems are more popular. However, no work has tried to incorporate sentiment information in the end-to-end trainable systems so far to create sentiment-adaptive systems that are easy to train. The ultimate evaluators of dialog systems are users. Therefore, we believe dialog system research should strive for better user satisfaction. In this paper, we not only included user sentiment information as an additional context feature in an end-to-end supervised policy learning model, but also incorporated user sentiment information as an immediate reward in a reinforcement learning model. We believe that providing extra feedback from the user would guide the model to adapt to user behaviour and learn the optimal policy faster and better.

There are three contributions in this work: 1) an audio dataset[1] with sentiment annotation (the annotators were given the complete dialog history); 2) an automatic sentiment detector that considers conversation history by using dialogic features, textual features and traditional acoustic features; and 3) end-to-end trainable dialog policies adaptive to user sentiment in both supervised and reinforcement learning settings. We believe such dialog systems with better user adaptation are beneficial in various domains, such as customer services, education, health care and entertainment.

2 Related Work

Many studies in emotion recognition (Schuller et al., 2003; Nwe et al., 2003; Bertero et al., 2016) have used only acoustic features. But there has been work on emotion detection in spoken dialog systems incorporating extra information as well (Lee and Narayanan, 2005; Devillers et al., 2003; Liscombe et al., 2005; Burkhardt et al., 2009; Yu et al., 2017). For example, Liscombe et al. (2005) explored features like users' dialog act, lexical context and discourse context of the previous turns. Our approach considered accumulated di-

[1]The dataset is available here.

alogic features, such as total number of interruptions, to predict user sentiment along with acoustic and textual features.

The traditional method to build dialog system is to train modules such as language understanding component, dialog manager and language generator separately (Levin et al., 2000; Williams and Young, 2007; Singh et al., 2002). Recently, more and more work combines all the modules in an end-to-end training framework (Wen et al., 2016; Li et al., 2017; Dhingra et al., 2016; Williams et al., 2017; Liu and Lane, 2017a). Specifically related to our work, Williams et al. (2017) built a model, which combined the traditional rule-based system and the modern deep-learning-based system, with experts designing actions masks to regulate the neural model. Action masks are bit vectors indicating allowed system actions at certain dialog state. The end-to-end framework made dialog system training simpler and model updating easier.

Reinforcement learning (RL) is also popular in dialog system building (Zhao and Eskenazi, 2016; Liu and Lane, 2017b; Li et al., 2016). A common practice is to simulate users. However, building a user simulator is not a trivial task. Zhao and Eskenazi (2016) combines the strengths of reinforcement learning and supervised learning to accelerate the learning of a conversational game simulator. Li et al. (2016) provides a standard framework for building user simulators, which can be modified and generalized to different domains. Liu and Lane (2017b) describes a more advanced way to build simulators for both the user and the agent, and train both sides jointly for better performance. We simulated user sentiment by sampling from real data and incorporated it as immediate rewards in RL, which is different from common practice of using task success as delayed rewards in RL training.

Some previous module-based systems integrated user sentiment in dialog planning (Acosta, 2009; Acosta and Ward, 2011; Pittermann et al., 2010). They all integrated user sentiment in the dialog manager with manually defined rules to react to different user sentiment and showed that tracking sentiment is helpful in gaining rapport with users and creating interpersonal interaction in the dialog system. In this work, we include user sentiment into end-to-end dialog system training and make the dialog policy learn to choose dialog actions to react to different user sentiments automatically. We achieve this through integrating user sentiment into reinforcement reward design. Many previous RL studies used delayed rewards, mostly task success. However, delayed rewards make the converging speed slow, so some studies integrated estimated per-turn immediate reward. For example, Ferreira and Lefèvre (2013) explored expert-based reward shaping in dialog management and Ultes et al. (2017) proposed *Interaction Quality (IQ)*, a less subjective variant of user satisfaction, as immediate reward in dialog training. However, both methods are not end-to-end trainable, and require manual input as prior, either in designing proper form of reward, or in annotating the *IQ*. Our approach is different as we detect the multimodal user sentiment on the fly and does not require manual input. Because sentiment information comes directly from real users, our method will adapt to user sentiment as the dialog evolves in real time. Another advantage of our model is that the sentiment scores come from a pre-trained sentiment detector, so no manual annotation of rewards is required. Furthermore, the sentiment information is independent of the user's goal, so no prior domain knowledge is required, which makes our method generalizable and independent of the task.

3 Dataset

We experimented our methods on DSTC1 dataset (Raux et al., 2005), which has a bus information search task. Although DSTC2 dataset is a more commonly-used dataset in evaluating dialog system performance, the audio recordings of DSTC2 are not publicly available and therefore, DSTC1 was chosen. There are a total of 914 dialogs in DSTC1 with both text and audio information. Statistics of this dataset are shown in Table 1. We used the automatic speech recognition (ASR) as the user text inputs instead of the transcripts, because the system's action decisions heavily depend on ASR. There are 212 system action templates in this dataset. Four types of entities are involved, `<place>`, `<time>`, `<route>`, and `<neighborhood>`.

4 Annotation

We manually annotated 50 dialogs consisting of 517 conversation turns for user sentiment. Sentiment is categorized into `negative`, `neutral` and `positive`. The annotator had access to the

entire dialog history in the annotation process because the dialog context gives the annotators a holistic view of the interactions, and annotating user sentiment in a dialog without the context is really difficult. Some previous studies have also performed similar user information annotation given context, such as Devillers et al. (2002). The annotation scheme is described in Table 10 in Appendix A.2. To address the concern that dialog quality may bias the sentiment annotation, we explicitly asked the annotators to focus on users' behaviour instead of the system, and hid all the details of multimodal features from the annotators. Moreover, two annotators were calibrated on 37 audio files, and reached an inter-annotator agreement (kappa) of 0.74. The statistics of the annotation results are shown in Table 2. The skewness in the dataset is due to the data's nature. In the annotation scheme, `positive` is defined as "excitement or other positive feelings", but people rarely express obvious excitement towards automated task-oriented dialog systems. What we really want to distinguish is neutral and positive cases from negative cases so as to avoid the negative sentiment, and the dataset is balanced for these two cases. To the best of our knowledge, our dataset is the first publicly available dataset that annotated user sentiment with respect to the entire dialog history. There are similar datasets with emotion annotations (Schuller et al., 2013) but are not labeled under dialog contexts.

5 Multimodal Sentiment Classification

To detect user sentiment, we extracted a set of acoustic, dialogic and textual features.

5.1 Acoustic features

We used openSMILE (Eyben et al., 2013) to extract acoustic features. Specifically, we used the paralinguistics configuration from Schuller et al. (2003), which includes 1584 acoustic features, such as pitch, volume and jitter. In order to avoid possible overfitting caused by the large number of acoustic features, we performed tree-based feature selection (Pedregosa et al., 2011) to reduce the size of acoustic features to 20. The selected features are listed in Table 12 in Appendix A.4.

5.2 Dialogic features

Four categories of dialogic features are selected according to previous literature (Liscombe et al., 2005) and the statistics observed in the dataset. We used not only the per-turn statistics of these features, but also the accumulated statistics of them throughout the entire conversation so that the sentiment classifier can also take the entire dialog context into consideration.

Interruption is defined as the user interrupting the system speech. Interruptions occurred fairly frequently in our dataset (4896 times out of 14860 user utterances).

Button usage When the user is not satisfied with the ASR performance of the system, he/she would rather choose to press a button for ”yes/no” questions, so the usage of buttons can be an indication of negative sentiment. During DSTC1 data collection, users were notified about the option to use buttons, so this kind of information is available in the data.

Repetitions There are two kinds of repetitions: the user asks the system to repeat the previous sentence, and the system keeps asking the same question due to failures to catch some important entity. In our model, we combined these two situations as one feature because very few user repetitions occur in our data ($<1\%$). But for other data, it might be helpful to separate them.

Start over is active when the user chooses to restart the task in the middile of the conversation. The system is designed to give the user an option to start over after several turns. If the user takes this offer, he/she might have negative sentiment.

5.3 Textual features

We also noticed that the semantic content of the utterance was relevant to sentiment. So we used the entire dataset as a corpus and created a tf-idf vector for each utterance as textual features.

5.4 Classification results

The sentiment classifier was trained on the 50 dialogs annotated with sentiment labels. The predictions made by this classifier were used for the supervised learning and reinforcement learning in the later sections. We used random forest as our classifier (an implementation from scikit-learn (Pedregosa et al., 2011)), as we had limited annotated data. We separated the data to be 60% for training, 20% for validation and 20% for testing. Due to the randomness in the experiments, we ran all the experiments 20 times and reported the average results of different models in Table 4. We also conducted unpaired one-tailed t-test to assess the statistical significance.

We extracted 20 acoustic features, eight dialogic features and 164 textual features. From Table 4, we see that the model combining all the three categories of features performed the best (0.686 in F-1, $p < 1\mathrm{e}{-6}$ compared to acoustic baseline). One interesting observation is that by only using eight dialogic features, the model already achieved 0.596 in F-1. Another interesting observation is that using 164 textual features alone reached a comparable performance (0.664), but the combination of acoustic and textual features actually brought down the performance to 0.647. One possible reason is that the acoustic information has noise that confused the textual information when combined. But this observation doesn't necessarily apply to other datasets. The significance tests show that adding dialogic features improved the baseline significantly. For example, the model with both acoustic features and dialogic features are significantly better than the one with only acoustic features ($p < 1\mathrm{e}{-6}$). In Table 3, we listed the dialogic features with their relative importance rank, which were obtained from ranking their feature importance scores in the classifier. We observe that "total interruptions so far" is the most useful dialogic features to predict user sentiment. The sentiment detector trained will be integrated in the end-to-end learning described later.

Dialogic Features	**Relative Rank of importance**
total interruptions so far	1
interruptions	2
total button usages so far	3
total repetitions so far	4
repetition	5
button usage	6
total start over so far	7
start over	8

Table 3: Dialogic features' relative importance rank in sentiment detection.

Model	**Avg. of F-1**	**Std. of F-1**	**Max of F-1**
Acoustic features only	0.635	0.027	0.686
Dialogic features only	0.596	0.001	0.596
Textual features only *	0.664	0.010	0.685
Textual + Dialogic *	0.672	0.011	0.700
Acoustic + Dialogic *	0.680	0.019	0.707
Acoustic + Textual	0.647	0.025	0.686
Acoustic + Dialogic + Text *	**0.686**	**0.028**	**0.756**

Table 4: Results of sentiment detectors using different features. The best result is highlighted in **bold** and * indicates statistical significance compared to the baseline, which is using acoustic features only. ($p < 0.0001$)

6 Supervised Learning (SL)

We incorporated the detected user sentiment from the previous section into a supervised learning framework for training end-to-end dialog systems. There are many studies on building a dialog system in a supervised learning setting (Bordes and Weston (2016); Eric and Manning (2017); Seo et al. (2016); Liu and Lane (2017a); Li et al. (2017); Williams et al. (2017)). Following these approaches, we treated the problem of dialog policy learning as a classification problem, which is to select actions among system action templates given conversation history. Specifically, we decided to adopt the framework of *Hybrid Code Network (HCN)* introduced in Williams et al. (2017), because it is the current state-of-the-art model. We reimplemented *HCN* and used it as the baseline system, given the absence of direct comparison on DSTC1 data. One caveat is that *HCN* used action masks (bit vectors indicating allowed actions at certain dialog states) to prevent impossible system actions, but we didn't use hand-crafted action masks in the supervised learning setting because manually designing action masks for 212 action templates is very labor-intensive. This makes our method more general and adaptive to different tasks. All the dialog modules were trained together instead of separately. Therefore, our method is end-to-end trainable and doesn't require human expert involvement.

We listed all the context features used in Williams et al. (2017) in Table 11 in Appendix A.3. In our model, we added one more set of context features, the user-sentiment-related features. For entity extraction, given that the entity values in our dataset form a simple unique fixed set, we used simple string matching. We conducted three experiments: the first one used entity presences as context features, which serves as the baseline; the second one used entity presences in addition to all the raw dialogic features mentioned in Table 3; the third experiment used the baseline features plus the predicted sentiment label by the prebuilt sentiment detector (converted to one-hot vector) instead of the raw dialogic features. We used the entire DSTC1 dataset to train the supervised model. The input is the normalized natural language and the contexutal features, and the output is the action template id. We kept the same experiment setting in Williams et al. (2017), e.g. `last_action_taken` was also used as a feature, along with word embeddings (Mikolov et al., 2013) and bag-of-words; LSTM with 128 hidden-units and AdaDelta optimizer (Zeiler, 2012) were used to train the model.

The results of different models are shown in Table 5. We observe that using the eight raw dialogic features did not improve turn-level F-1 score. One possible reason is that a total of eight dialogic features were added to the model, and some of them might contain noises and therefore caused the model to overfit. However, using predicted sentiment information as an extra feature, which is a more condensed information, outperformed the other models both in terms of turn-level F-1 score and dialog accuracy which indicates if all turns in a dialog are correct. The difference in absolute F-1 score is small because we have a relatively large test set (5876 turns). But the unpaired one-tailed t-test shows that $p < 0.01$ for both the F-1 and the dialog accuracy. This suggests that including user sentiment information in action planning is helpful in a supervised learning setting.

Model	**Weighted F-1**	**Dialog Acc.**
HCN	0.4198	6.05%
HCN + raw dialogic features	0.4190	5.79%
HCN + predicted sentiment label$*$	**0.4261**	**6.55%**

Table 5: Results of different SL models. The best result is highlighted in **bold**. $*$ indicates that the result is significantly better than the baseline ($p < 0.01$). Dialog accuracy indicates if all turns in a dialog are correct, so it's low. For DSTC2 data, the state-of-art dialog accuracy is 1.9%, consistent with our results.

7 Reinforcement Learning (RL)

In the previous section, we discussed including sentiment features directly as a context feature in a supervised learning model for end-to-end dialog system training, which showed promising results. But once a system operates at scale and interacts with a large number of users, it is desirable for the system to continue to learn autonomously using reinforcement learning (RL). With RL, each turn receives a measurement of goodness called *reward* (Williams et al., 2017). Previously, training task-oriented systems mainly relies on the delayed reward about task success. Due to the lack of informative immediate reward, the training takes a long time to converge. In this work, we propose to include user sentiment as immediate rewards to expedite the reinforcement learning training process and create a better user experience.

To use sentiment scores in the reward function, we chose the *policy gradient* approach (Williams, 1992) and implemented the algorithm based on Zhu (2017). The traditional reward function uses a positive constant (e.g. 20) to reward the success of the task, 0 or a negative constant to penalize the failure of the task after certain number of turns, and gives -1 to each extra turn to encourage the system to complete the task sooner. However, such reward function doesn't consider any feedback from the end-user. It is natural for human to consider conversational partner's sentiment in planning dialogs. So, we propose a set of new reward functions that incorporate user sentiment to emulate human behaviors.

The intuition of integrating sentiment in reward functions is as follows. The ultimate evaluator of dialog systems is the end-users. And user sentiment is a direct reflection of user satisfaction. Therefore, we detected the user sentiment scores from multimodal sources on the fly, and used them as immediate rewards in an adaptive end-to-end dialog training setting. This sentiment information came directly from real users, which made the system adapt to individual user's sentiment as the dialog proceeds. Furthermore, the sentiment information is independent of the task, so our method doesn't require any prior domain knowledge and can be easily generalized to other domains. There have been works that incorporated user information into reward design (Su et al., 2015; Ultes et al., 2017). But they used information from one single channel and sometimes required manual labelling of the reward. Our approach utilizes information from multiple channels and doesn't involve manual work once a sentiment detector is ready.

We built a simulated system in the same bus information search domain to test the effectiveness of using sentiment scores in the reward function. In this system, there are 3 entity types - `<departure>`, `<arrival>`, and `<time>` - and 5 actions, asking for different entities, and giving information. A simple action mask was used to prevent impossible actions, such as giving information of an uncovered place. The inputs to the system are the simulated user's dialog acts and the simulated sentiment sampled from a subset of DSTC1, the $CleanData$, which will be described later. The output of the system is the system action template.

7.1 User simulator

Given that reinforcement learning requires feedback from the environment - in our case, the users - and interacting with real users is always expensive, we created a user simulator to interact with the system. At the beginning of each dialog, the simulated user is initiated with a goal consisting of the three entities mentioned above and the goal remains unchanged throughout the conversation. The user responds to system's questions with entities, which are placeholders like `<departure>` instead of real values. To simulate ASR errors, the simulated user's act type occasionally changes from "informing slot values" to "making noises" at certain probabilities set by hand (10% in our case). Some example dialogs along with their associated rewards are shown in Table 8 and 9 in Appendix A.1.

We simulated user sentiment by sampling from real data, the DSTC1 dataset. There are three steps involved. First, we cleaned the DSTC1 dialogs by removing the audio files with no ASR output and high ASR errors. This resulted in a dataset $CleanData$ with 413 dialogs and 1918 user inputs. We observed that users accumulate their sentiment as the conversation unfolds. When the system repeatedly asks for the same entity, they express stronger sentiment. Therefore, summary statistics that record how many times certain entities have been asked during the conversation is representative of users' accumulating sentiment. We designed a set of summary statistics S that record the statistics of system actions, e.g. how many times the arrival place has been asked or the schedule information has been given.

The second step is to create a mapping between the five simulated system actions and the DSTC1 system actions. We do this by calculating a vector s_{real} consisting of the values in S for each user utterance in $CleanData$. s_{real} is used to compare the similarity between the real dialog and the simulated dialog.

The final step is to sample from $CleanData$. For each simulated user utterance, we calculated the same vector s_{sim} and compared it with each s_{real}. There are two possible results. If there are s_{real} equal to s_{sim},we would randomly sample one from all the matched user utterances to represent the sentiment of the simulated user. But if there is no s_{real} matching s_{sim}, different strategies would be applied based on the reward function used, which will be described in details later. Once we have a sample, the eight dialogic features of the sample utterance are used to calculate the sentiment score. We didn't use the acoustic or the textual features because in a simulated setting, only the dialogic features are valid.

7.2 Experiments

We designed four experiments with different reward functions. A discount factor of 0.9 was applied to all the experiments. And the maximum number of turns is 15. Following Williams et al. (2017), we used LSTM with 32 hidden units for the RNN in the *HCN* and AdaDelta for the optimization, and updated the reinforcement learning policy after each dialog. The ϵ-greedy exploration strategy (Tokic, 2010) was applied here. Given that the entire system was simulated, we only used the presence of each entity and the last action taken by the system as the context features, and didn't use bag-of-words or utterance embedding features.

In order to evaluate the method, we froze the policy after every 200 updates, and ran 500 simulated dialogs to calculate the task success rate. We repeated the process 20 times and reported the average performance in Figure 1, 2 and Table 6.

7.2.1 Baseline

We define the baseline reward as follows without any sentiment involvement.

Reward 1 Baseline

```
if success then
    $R_1 = 20$
else if failure then
    $R_1 = -10$
else if each proceeding turn then
    $R_1 = -1$
end if
```

7.2.2 Sentiment reward with random samples (SRRS)

We designed the first simple reward function with user sentiment as the immediate reward: sentiment with random samples (SRRS). We first drew a sample from real data with matched context; if there was no matched data, a random sample was used instead. Because the amount of $CleanData$ is relatively small, so only 36% turns were covered by matched samples. If the sampled dialogic features were not all zeros, the sentiment reward (SR) was calculated as a linear combination with tunable parameters. We chose it to be $-5P_{neg}-P_{neu}+10P_{pos}$ for simplicity. When the dialogic features were all zero, in most cases it meant the user didn't express an obvious sentiment, we set the reward to be -1.

Reward 2 SRRS

```
if success then
    $R_2 = 20$
else if failure then
    $R_2 = -10$
else if sample with all-zero dialogic features then
    $R_2 = -1$
else if sample with non-zero dialogic features then
    $R_2 = -5P_{neg} - P_{neu} + 10P_{pos}$
end if
```

7.2.3 Sentiment reward with repetition penalty (SRRP)

Random samples in SRRS may result in extreme sentiment data. So we used dialogic features to approximate sentiment for the unmatched data. Specifically, if there were repetitions, which correlate with negative sentiment (see Table 3), we assigned a penalty to that utterance. See Reward 3 Formula below for detailed parameters. 36% turns were covered by real data samples, 15% turns had no match in real data and had repetitions, and 33% turns had no match and no repetition.

Moreover, we experimented with different penalty weights. When we increased the repetition penalty to 5, the success rate was similar to penalty of 2.5. However, when we increased the penalty even further to 10, the success rate was brought down by a large margin. Our interpretation is that increasing the repetition penalty to a big value made the focus less on the real sentiment samples but more on the repetitions, which did not help the learning.

Reward 3 SRRP

```
if success then
    $R_3 = 20$
else if failure then
    $R_3 = -10$
else
    if match then
        if all-zero dialogic features then
            $R_3 = -1$
        else if non-zero dialogic features then
            $R_3 = -5P_{neg} - P_{neu} + 10P_{pos}$
        end if
    else if repeated question then
        $R_3 = -2.5$
    else
        $R_3 = -1$
    end if
end if
```

7.2.4 Sentiment reward with repetition and interruption penalties (SRRIP)

We observed in Section 5 that `interruption` is the most important feature in detecting sentiment, so if an interruption existed in the simulated user input, we assumed it had a negative sentiment and added an additional penalty of -1 to the previous sentiment reward SRRP to test the effect of interruption. 7.5% turns have interruptions.

Reward 4 SRRIP

```
if success then
    $R_4 = 20$
else if failure then
    $R_4 = -10$
else
    $R_4 = R_3(SRRP)$
    if interruption then
        $R_4 = R_4 - 1$
    end if
end if
```

7.3 Experiment results

We evaluated every model on two metrics: dialog lengths and task success rates. We observed in Figure 1 that all the sentiment reward functions, even SRRS with random samples, reduced the average length of the dialogs, meaning that the system finished the task faster. The rationale behind is that by adapting to user sentiment, the model can avoid unnecessary system actions to make systems more effective.

In terms of success rate, sentiment reward with both repetition and interruption penalties (SRRIP) performed the best (see Figure 2). In Figure 2, SRRIP is converging faster than the baseline. For example, around 5000 iterations, it outperforms the baseline by 5% in task success rate (60% vs 55%) with statistical significance ($p < 0.01$). It also converges to a better task success rate after 10000 iterations (92.4% vs 94.3%, $p < 0.01$).

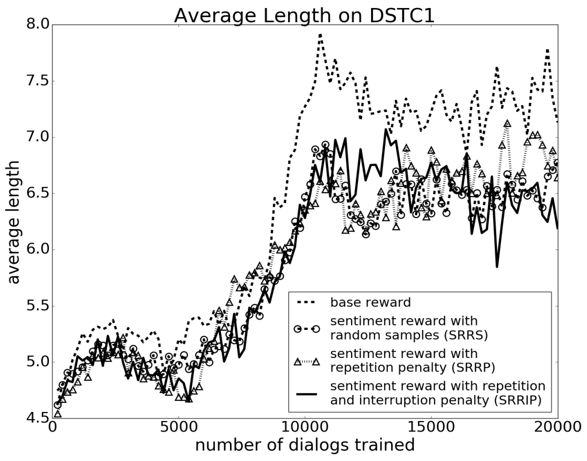

Figure 1: Average dialog length of RL models with different reward functions.

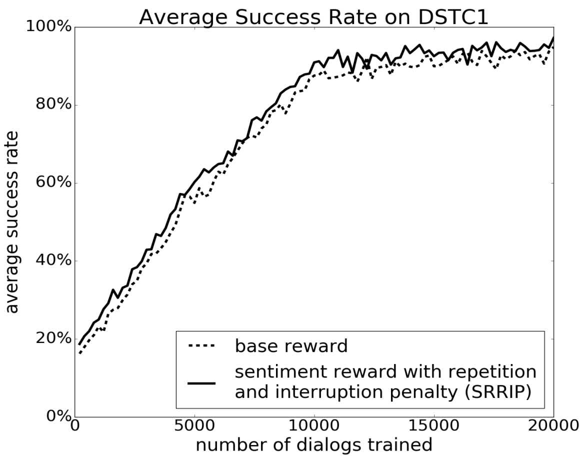

Figure 2: Average success rate of the baseline and the best performing model, SRRIP.

We describe all models' performance in Table 6 in terms of the convergent success rate calculated as the mean success rate after 10000 dialogs. We observed that incorporating various sentiment rewards improved the success rate and expedited the training process overall with statistical significance. We found that even sentiment reward with random samples (SRRS) outperformed the baseline after convergence. By adding penalties for repetition, the algorithm covered more data points, and therefore, the task success rate and the convergence speed improved. We also found that penalizing interruption and repetition together (SRRIP) achieved a slightly better performance compared to penalizing repetition only (SRRP). This suggests that interruptions is another factor to consider when approximating sentiment. But the performances between SRRP and SRRIP is not significant. Our guess is that only 7.5% turns in our data contains interruption and the penalty is just an extra -1, so the model confused this signal with noises. But given more interruptions in the data, interruptions could still be helpful.

Model	**Convergent success rate**
Baseline	0.924
SRRS	0.938$*$
SRRP	0.941$*$
SRRIP	**0.943**$*$

Table 6: Convergent success rate of RL models with different reward functions. It is calculated as the mean success rate after 10000 dialogs. The best result is highlighted in **bold**. $*$ indicates that the result is significantly better than the baseline ($p < 0.01$).

8 Discussion and Future Work

The intuition behind the good performance of models with user sentiment is that the learned policy is in general more sentiment adaptive. For example, there are some system actions that have the same intention but with different surface forms, especially for error-handling strategies. By analyzing the results, we found that when the sentiment adaptive system detected a negative sentiment from the user, it chose to respond the user with a more detailed error-handling strategy than a general one. For example, it chose the template "Where are you leaving from? For example, you can say, <place>", while the baseline model would respond with "Where would you like to leave from?", which doesn't provide details to help the user compared with the previous template. As we all know, dealing with a disappointed user to proceed, providing more details is always better. One example dialog is shown in Table 7. There was no written rules to force the model to choose one specific template under certain situ-

Sentiment Adaptive System	**Baseline System without Sentiment**
SYS: The `<route>`. Where would you like to leave from?	**SYS**: The `<route>`. Where would you like to leave from?
USR: *Yeah **[negative sentiment]***	**USR**: *Yeah*
SYS: Where are you leaving from? For example, you can say, `<place>`.	**SYS**: Right. Where would you like to leave from?

Table 7: An example dialog by different systems in the supervised learning setting. The sentiment-adaptive system gives a more detailed error-handling strategy than the baseline system.

ations, so the model learned these subtle differences on its own. Some may argue that the system could always use a more detailed template to better guide the user instead of distinguishing between two similar system templates. But this is not necessarily true. Ideally, we want the system to be succinct initially to save users' time, because we observe that users, especially repeated users, tend to interrupt long and detailed system utterances. If the user has attempted to answer the system question but failed, then it's beneficial to provide detailed guidance.

The performance of the sentiment detector is a key factor in our work. So in the future, we plan to incorporate features from more channels such as vision to further improve the sentiment predictor's performance, and potentially further improve the performance of the dialog system. We also want to explore more in user sentiment simulation, for example, instead of randomly sampling data for the uncovered cases, we could use linear interpolation to create a similarity score between s_{sim} and s_{real}, and choose the user utterance with the highest score. Furthermore, reward shaping (Ng et al., 1999; Ferreira and Lefèvre, 2013) is an important technique in RL. Specifically, Ferreira and Lefèvre (2013) talked about incorporating expert knowledge in reward design. We also plan to integrate information from different sources into reward function and apply reward shaping. Besides, creating a good user simulator is also very important in the RL training. There are some more advanced methods to create user simulators. For example, Liu and Lane (2017b) described how to optimize the agent and the user simulators jointly using RL. We plan to apply our sentiment reward functions in this framework in the future.

9 Conclusion

We proposed to detect user sentiment from multimodal channels and incorporate the detected sentiment as feedback into adaptive end-to-end dialog system training to make the system more effective and user-adaptive. We included sentiment information directly as a context feature in the supervised learning framework and used sentiment scores as immediate rewards in the reinforcement learning setting. Experiments suggest that incorporating user sentiment is helpful in reducing the dialog length and increasing the task success rate in both SL and RL settings. This work proposed an adaptive methodology to incorporate user sentiment in end-to-end dialog policy learning and showed promising results on a bus information search task. We believe this approach can be easily generalized to other domains given its end-to-end training procedure and task independence.

Abstract

We present a new method for estimating vector space representations of words: embedding learning by concept induction. We test this method on a highly parallel corpus and learn semantic representations of words in 1259 different languages in a single common space. An extensive experimental evaluation on crosslingual word similarity and sentiment analysis indicates that concept-based multilingual embedding learning performs better than previous approaches.

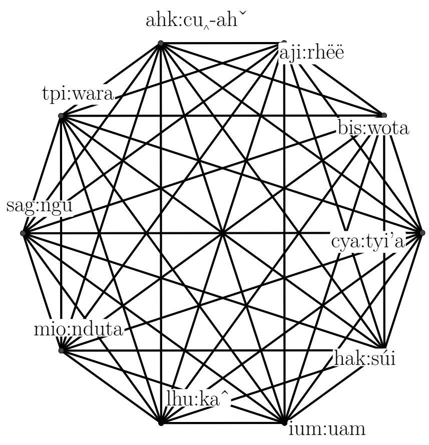

Figure 1: Example of a CLIQUE concept: "water"

1 Introduction

Vector space representations of words are widely used because they improve performance on monolingual tasks. This success has generated interest in multilingual embeddings, shared representation of words across languages (Klementiev et al., 2012). Such embeddings can be beneficial in machine translation in sparse data settings because multilingual embeddings provide meaning representations of source and target in the same space. Similarly, in transfer learning, models trained in one language on multilingual embeddings can be deployed in other languages (Zeman and Resnik, 2008; McDonald et al., 2011; Tsvetkov et al., 2014). Automatically learned embeddings have the added advantage of requiring fewer resources for training (Klementiev et al., 2012; Hermann and Blunsom, 2014b; Guo et al., 2016). Thus, massively multilingual word embeddings (i.e., covering 100s or 1000s of languages) are likely to be important in NLP.

The basic information many embedding learners use is *word-context information*; e.g., the embedding of a word is optimized to predict a representation of its context. We instead learn embeddings from *word-concept information*. As a first approximation, a concept is a set of semantically similar words. Figure 1 shows an example concept and also indicates one way we learn concepts: *we interpret cliques in the dictionary graph as concepts*. The nodes of the dictionary graph are words, its edges connect words that are translations of each other. A dictionary node has the form prefix:word, e.g., "tpi:wara" (upper left node in the figure). The prefix is the ISO 639-3 code of the language; tpi is Tok Pisin.

Our method takes a parallel corpus as input and induces a dictionary graph from the parallel corpus. Concepts and word-concept pairs are then induced from the dictionary graph. Finally, embeddings are learned from word-concept pairs.

A key application of multilingual embeddings is transfer learning. Transfer learning is mainly of interest if the target is resource-poor. We therefore select as our dataset 1664 translations in 1259 languages of the New Testament from PBC, the Parallel Bible Corpus. Since "translation" is an ambiguous word, we will from now on refer to the 1664 translations as "editions". PBC is aligned

English King James Version (KJV)	German Elberfelder 1905	Spanish Americas
And he said , Do it the second time . And they did it the second time ...	Und er sprach : Füllet vier Eimer mit Wasser , und gießet es auf das Brandopfer und auf das Holz . Und er sprach : Tut es zum zweiten Male ! Und sie taten es zum zweiten Male ...	Y dijo : Llenad cuatro cántaros de agua y derramadla sobre el holocausto y sobre la leña . Después dijo : Hacedlo por segunda vez ; y lo hicieron por segunda vez ...

Table 1: Instances of verse 11018034. This multi-sentence verse is an example of verse misalignment.

on the verse level; most verses consist of a single sentence, but some contain several (see Table 1). PBC is a good model for resource-poverty; e.g., the training set (see below) of KJV contains fewer than 150,000 tokens in 6458 verses.

We evaluate multilingual embeddings on two tasks, roundtrip translation (RT) and sentiment analysis. RT on the word level is – to our knowledge – a novel evaluation method: a query word w of language L_1 is translated to its closest (with respect to embedding similarity) neighbor v in L_2 and then backtranslated to its closest neighbor w' in L_1. RT is successful if $w = w'$. There are well-known concerns about RT when it is used in the context of machine translation. A successful roundtrip translation does not necessarily imply that v is of high quality and it is not possible to decide whether an error occurred in the forward or backward translations. Despite these concerns about RT on the sentence level, we show that RT on the word level is a difficult task and an effective measure of embedding quality.

Contributions. (i) We introduce a new embedding learning method, multilingual embedding learning through concept induction. (ii) We show that this new concept-based method outperforms previous approaches to multilingual embeddings. (iii) We propose both word-level and character-level dictionary induction methods and present evidence that concepts induced from word-level dictionaries are better for easily tokenizable languages and concepts induced from character-level dictionaries are better for difficult-to-tokenize languages. (iv) We evaluate our methods on a corpus of 1664 editions in 1259 languages. To the best of our knowledge, this is the first detailed evaluation, involving challenging tasks like word translation and crosslingual sentiment analysis, that has been done on such a large number of languages.

2 Methods

2.1 Pivot languages

Most of our methods are based on bilingual dictionary graphs. With 1664 editions, it is computationally expensive to consider all editions simultaneously (more than 10^6 dictionaries). Thus we split the set of editions in 10 pivot and 1654 remaining editions, and do not compute nor use dictionaries within the 1654 editions. We refer to the ten pivot editions as *pivot languages* and give them a distinct role in concept induction. We refer to all editions (including pivot editions) as *target editions*. Thus, a pivot edition has two roles: as a pivot language and as a target edition.

We select the pivot languages based on their sparseness. Sparseness is a challenge in NLP. In the case of embeddings, it is hard to learn a high-quality embedding for any infrequent word. Many of the world's languages (including many PBC languages) exhibit a high degree of sparseness. But some languages suffer comparatively little from sparseness when simple preprocessing like downcasing and splitting on whitespace is employed.

A simple measure of sparseness that affects embedding learning is the number of types. Fewer types is better since their average frequency will be higher. Table 2 shows the ten languages in PBC that have the smallest number of types in 5000 randomly selected verses. We randomly sample 5000 verses per edition and compare the number of types based on this selection because most editions do not contain a few of the selected 6458 verses.

2.2 Character-level modeling (CHAR)

We will see that tokenization-based models have poor performance on a subset of the 1259 languages. To overcome tokenization problems, we represent a verse of length m bytes, as a sequence of $m - (n - 1) + 2$ overlapping byte n-grams. In this paper, "n-gram" always refers to "byte n-gram". We pad the verse with initial and final space, resulting in two additional n-grams (hence "+2"). This representation is in the spirit of earlier byte-level processing, e.g., (Gillick et al., 2016). There are several motivations for this. (i) We can take advantage of byte-level generalizations. (ii) This is robust if there is noise in the byte encoding. (iii) Characters have different properties in different languages and encodings, e.g., English

iso	name	family; (example) region	types	tokens
lhu	Lahu	Sino-Tibetan; Thailand	1452	268

sag	Sango	Creole; Central Africa	1895	192

Table 2: Our ten pivot languages, the languages in PBC with the lowest number of types. Tokens in 1000s. Tok Pisin and Bislama are English-based and Sango is a Ngbandi-based creole. PNG = Papua New Guinea

Algorithm 1 χ^2-based dictionary induction

```
 1: procedure DictionaryGraph($C$)
 2:     $A$ = all-edges($C$), $E = []$
 3:     for $d \in [1, 2, \dots, d_{\max}]$ do
 4:         $f_{\max} = 2$
 5:         while $f_{\max} \leq |C|$ do
 6:             $f_{\min} = \max(\min(5, f_{\max}), \frac{1}{10} f_{\max})$
 7:             $(\chi^2, s, t)$ = max-$\chi^2$-edge$(A, f_{\min}, f_{\max}, d)$
 8:             if $\chi^2 < \chi_{\min}$ then
 9:                 $f_{\max} = f_{\max} + 1$; continue
10:             end if
11:             $T$ = extend-ngram$(A, f_{\min}, f_{\max}, d, s, t)$
12:             append$(E, s, T)$
13:             remove-edges$(A, s, T)$
14:         end while
15:     end for
16:     return dictionary-graph = (nodes$(E), E)$
17: end procedure
```

Figure 2: χ^2-based dictionary induction. C is a sentence-aligned corpus. A is initialized to contain all edges, i.e., the fully connected bipartite graph for each parallel verse. E collects the selected dictionary edges. d is the edge degree: in each pass through the loop only edges are considered whose participating units have a degree less than d. $f_{\max}$ is the maximum frequency during this pass. $|C|$ is the number of sentences in the corpus. extend-ngram extends a target ngram to left / right; e.g., if s = "jisas" is aligned with ngram t = "Jesu" in English, then "esus" is added to T. t is always a member of T. remove-edges removes edges in A between s and a member of T.

UTF-8 has properties different from Chinese UTF-8. Thus, universal language processing is easier to design on the byte level.

We refer to this ngram representation as CHAR and to standard tokenization as WORD.

2.3 Dictionary induction

Alignment-based dictionary. We use fastalign (Dyer et al., 2013) to compute word alignments and use GDFA for symmetrization. All alignment edges that occurred at least twice are added to the dictionary graph. Initial experiments indicated that alignment-based dictionaries have poor quality for CHAR, probably due to the fact that overlapping ngram representations of sentences have properties quite different from the tokenized sentences that aligners are optimized for. Thus we use this dictionary induction method only for WORD and developed the following alternative for CHAR.

Correlation-based dictionary (χ^2). χ^2 is a greedy algorithm, shown in Figure 2, that selects, in each iteration, the pair of units that has the highest χ^2 score for cooccurrence in verses. Each selected pair is added to the dictionary and removed from the corpus. Low-frequency units are selected first and high-frequency units last; this prevents errors due to spurious association of high-frequency units with low-frequency units. We perform $d_{\max} = 5$ passes; in each pass, the maximum degree of a dictionary node is $1 \leq d \leq d_{\max}$. So if the node has reached degree d, it is ineligible for additional edges during this pass. Again, this avoids errors due to spurious association of high-frequency units that already participate in many edges with low-frequency units. Recall that this method is only applied for CHAR.

Intra-pivot dictionary. We assume that pivot languages are easily tokenizable. Thus we only consider alignment-based dictionaries (in total 45) within the set of pivot languages.

Pivot-to-target dictionary. We compute an alignment-based and a χ^2-based dictionary between each pivot language and each target edition, yielding a total of 10*1664 dictionaries per dictionary type. (Note that this implies that, for χ^2, the WORD version of the pivot language is aligned with its CHAR version.)

2.4 Concepts

A concept is defined as a set of units that has two subsets: (i) a defining set of words from the ten pivot languages and (ii) a set of target units (words or n-grams) that are linked, via dictionary edges,

Algorithm 2 CLIQUE concept induction

```
 1: procedure CONCEPTS($I \in \mathbb{R}^{n\times n}, \theta, \nu$)
 2:     $G = ([n], \{(i,j) \in [n] \times [n] \mid I_{ij} > \theta\})$
 3:     cliques = get-cliques($G$, 3)
 4:     $G_c := (V_c, E_c) = (\emptyset, \emptyset)$
 5:     for $c_1, c_2 \in$ cliques × cliques do
 6:         if $|c_1 \cap c_2| \geq \nu \min\{|c_1|, |c_2|\}$ then
 7:             $V_c = V_c \cup \{c_1, c_2\}$, $E_c = E_c \cup \{(c_1, c_2)\}$
 8:         end if
 9:     end for
10:     metacliques = get_cliques($G_c$, 1)
11:     concepts = {flatten($c$) | $c \in$ metacliques}
12:     return concepts
13: end procedure
```

Figure 3: CLIQUE concept induction. I is a normalized adjacency matrix of a dictionary graph (i.e., relative frequency of alignment edges with respect to possible alignment edges). get-cliques(G, n) returns all cliques in G of size greater or equal to n. flatten(A) flattens a set of sets. $[n]$ denotes $\{1, 2, \ldots, n\}$. $\theta = 0.4$, $\nu = 0.6$.

to the pivot subset. We selected the ten "easiest" of the 1664 editions as pivot languages. Our premise is that semantic information is encoded in a simply accessible form in the pivot languages and so they should offer a good basis for learning concepts.

We induce concepts from the dictionary graph, a multipartite graph consisting of ten pivot language node/word sets and all target edition node/unit sets (where units are words or n-grams). Edges either connect pivot nodes with other pivot nodes or pivot nodes with target units.

2.4.1 CLIQUE concept induction

If concepts corresponded to each other in the overtly coding pivot languages, if words were not ambiguous and if alignments were perfect, then concepts would be cliques in the pivot part of the dictionary graph. These conditions are too strict for natural languages, so we relax them in our CLIQUE concept induction algorithm (Figure 3). The algorithm identifies maximal multilingual cliques (size ≥ 3) within the dictionary graph of the pivot languages and then merges two cliques if they share enough common words. The merging lets us identify clique-based concepts even if, e.g., a dictionary edge between two words is missing. It also accommodates the situation where more than one word of a pivot language should be part of a concept. The merging step can also be interpreted as metaconcept induction.

Once we have identified the cliques, we project

$N(t)$ ={`bis:Jorim, ium:yo-lim, sag:Yorim, tpi:Jorim`}

$t \in T$={`ac0:Yorim,atg0:iJorimu,bav0:Jorim,bom0:Yorim, dik0:Jorim, dtp0:Yorim, duo0:Jorim, eng1:Jorim, engb:Jorim, fij2:Lorima, fij3:Jorima, gor0:Yorim, hvn0:Yorim, ibo0:Jorim, iri0:Jorri, kmr0:Yorîm, ksd0:Iorim, kwd0:Jorim, lia0:Yorimi, loz0:Jorimi, mbd0:Hurim, mfh0:Yorim, min0:Yorim, mrw0:Yorim,mse0:Jorimma,naq0:Jorimmi, smo1:Iorimo, srn1:Yorim, tsn2:Jorime, yor2:Jórímù`}

Figure 4: Target neighborhood concept example: $N(t) \cup T$. $N(t)$ is the target neighborhood for each of the target words in T.

them to the target editions: a target-unit is added to a clique if it is connected to a proportion $\nu = 0.6$ of its member words (to allow for missing edges). This identifies around 150k clique concepts that cover around 8k of the total vocabulary of 24k English words (WORD).

As an alternative to cliques, Ammar et al. (2016) use connected components (CCs). The reachability relation (induced by CC) is the transitive closure of the edge relation. This results in semantically unrelated words being in the same concept for very low levels of noise. In contrast, cliques are more "strict": only node subsets are considered whose corresponding edge relation is already transitive (or almost so for $\nu = 0.6$). Transitivity across languages often does not hold in alignments or dictionaries; see, e.g., Simard (1999). This is why we only consider cliques (which reflect already existent transitivity) rather than CCs, which impose transitivity where it does not hold naturally.

2.4.2 $N(t)$ (target neighborhood) concept induction

Let $N(t)$ be the neighborhood of target node t in the multipartite dictionary graph, i.e., the set of pivot words that are linked to t. We refer to $N(t)$ as *target neighborhood*. Figure 4 shows an example of such a target neighborhood, the set $N(t)$ consisting of four words.[1] A *target neighborhood concept* consists of a set T of pivot words and all target words t for which $T = N(t)$ holds.

Motivation. Suppose $N(t) = N(u)$ for target nodes t and u from two different languages and $|N(t)|$ covers several pivot languages, e.g., $|N(t)| = |N(u)| = 4$ as in the figure. Again, if units closely corresponded to concepts, if there were no ambiguity, if the dictionary were perfect,

[1]We use numbers and lowercase letters at the fourth position of the prefix to distinguish different editions in the same language, e.g., "0", "3" and "e" in "ace0", "fij3", "enge".

then we could safely conclude that the meanings of t and u are similar; if the meanings of t and u were unrelated, it is unlikely that they would be aligned to the exact same words in four different languages. In reality, there is no exact meaning-form correspondence, there is ambiguity and the dictionary is not perfect. Still, we will see below that defining concepts as target neighborhoods works well.

2.4.3 Filtering target neighborhood concepts

In contrast to CLIQUE, we do not put any constraint on the pivot-to-pivot connections within target neighborhoods; e.g., in Figure 4, we do not require that "bis:Jorim" and "sag:Yorim" are connected by an edge. We evaluate three post-filtering steps of target neighborhoods to increase their quality: restricting target neighborhoods to those that are cliques in $N(t)$**-CLIQUE**; to those that are connected components in $N(t)$**-CC**; and to those of size two that are valid edges in the dictionary in $N(t)$**-EDGE**. For $N(t)$**-EDGE**, we found that taking all edges performs well, so we also consider edges that are proper subsets of target neighborhoods.

2.5 Embedding learning

We adopt the framework of embedding learning algorithms that define contexts and then sample pairs of an input word (more generally, an input unit) and a context word (more generally, a context unit) from each context. The only difference is that our contexts are concepts. For simplicity, we use word2vec (Mikolov et al., 2013a) as the implementation of this model.[2]

2.6 Baselines

Baselines for **multilingual embedding learning.** One baseline is inspired by (Vulić and Moens, 2015). We consider words of one aligned verse in the pivot languages and one target language as a bag of words (BOW) and consider this bag as a context.[3]

Levy et al. (2017) show that sentence ID features (interpretable as an abstract representation of the word's context) are effective. We use a corpus with lines consisting of pairs of an identifier of a verse and a unit extracted from that verse as input to word2vec and call this baseline S-ID.

Lardilleux and Lepage (2009) propose a simple and efficient baseline: **sample-based concept induction**. Words that strictly occur in the same verses are assigned to the same concept. To increase coverage, they propose to sample many different subcorpora.[4] We induce concepts using this method and project them analogous to CLIQUE. We call this baseline SAMPLE.

One novel contribution of this paper is **roundtrip evaluation** of embeddings. We learn embeddings based on a dictionary. The question arises: are the embeddings simply reproducing the information already in the dictionary or are they improving the performance of roundtrip search?

As a baseline, we perform RTSIMPLE, a simple dictionary-based roundtrip translation method. Retrieve the pivot word p in pivot language L_p (i.e., $p \in L_p$) that is closest to the query $q \in L_q$. Retrieve the target unit $t \in L_t$ that is closest to p. Retrieve the pivot word $p' \in L_p$ that is closest to t. Retrieve the unit $q' \in L_q$ that is closest to p'. If $q = q'$, this is an exact hit. We run this experiment for all pivot and target languages.

Note that roundtrip evaluation tests the capability of a system to go from any language to any other language. In an embedding space, this requires two hops. In a highly multilingual dataset of n languages in which not all $O(n^2)$ bilingual dictionaries exist, this requires four hops.

3 Experiments and results

3.1 Data

We use PBC (Mayer and Cysouw, 2014). The version we pulled on 2017-12-11 contains 1664 Bible editions in 1259 languages (based on ISO 639-3 codes) after we discarded editions that have low coverage of the New Testament. We use 7958 verses that have good coverage in these 1664 editions. The data is verse aligned; a verse of the New Testament can consist of multiple sentences. We randomly split verses 6458/1500 into train/test.

3.2 Evaluation

For **sentiment analysis**, we represent a verse as the IDF-weighted sum of its embeddings. Sentiment classifiers (linear SVMs) are trained on the training set of the World English Bible edition

[2]We use `code.google.com/archive/p/word2vec`

[3]The actual implementation slightly differs to avoid very long lines. It does only consider two pivot languages at a time, but writes each verse multiple times.

[4]We use this implementation: `anymalign.limsi.fr`

for the two decision problems positive vs. non-positive and negative vs. non-negative. We create a silver standard by labeling verses in English editions with the NLTK (Bird et al., 2009) sentiment classifier.

A positive vs. negative classification is not reasonable for the New Testament because a large number of verses is mixed, e.g., “Now is come salvation … the power of his Christ: for the accuser … cast down, which accused them before our God …” Note that this verse also cannot be said to be neutral. Splitting the sentiment analysis into two subtasks (“contains positive sentiment: yes/no” and “contains negative sentiment: yes/no”) is an effective solution for this paper.

The two trained models are then applied to the test set of all 1664 editions. All embeddings in this paper are learned on the training set only. So no test information was used for learning the embeddings.

Roundtrip translation. There are no gold standards for the genre of our corpus (the New Testament); for only a few languages out-of-domain gold standards are available. Roundtrip evaluation is an evaluation method for multilingual embeddings that can be applied if no resources are available for a language. Loosely speaking, for a query q in a query language L_q (in our case English) and a target language L_t, roundtrip translation finds the unit w_t in L_t that is closest to q and then the English unit w_e that is closest to w_t. If the semantics of q and w_e are identical (resp. are unrelated), this is deemed evidence for (resp. counter-evidence against) the quality of the embeddings. We work on the level of Bible edition, i.e., two editions in the same language are considered different “languages”.

For a query q, we denote the set of its k_I nearest neighbors in the target edition e by $I_e(q) = \{u_1, u_2, \ldots, u_{k_I}\}$. For each intermediate entry we then consider its k_T nearest neighbors in English. Overall we get a set $T_e(q)$ with $k_I k_T$ predictions for each intermediate Bible edition e. See Figure 5 for an example.

We evaluate the predictions $T_e(q)$ using two sets $G_s(q)$ (strict) and $G_r(q)$ (relaxed) of ground-truth semantic equivalences in English. Precision for a query q is defined as

$$p_i(q) := 1/|E| \textstyle\sum_{e \in E} \min\{1, |T_e(q) \cap G_i(q)|\}$$

where E is the set of all Bible editions and $i \in \{s, r\}$. We report the mean and median across a

query	inter-mediate		predictions
woman ⇒	mujer	⇒	wife woman women widows daughters daughter marry married
⇒	esposa	⇒	marry wife woman married marriage virgin daughters bridegroom

Figure 5: Roundtrip translation example for KJV and Americas Bible (Spanish). In this example $\min\{1, |T_e(q) \cap G_i(q)|\}$ equals 0 for S1 and R1, and 1 for S4 and S16.

```
connu(3), connais(3), connaissent(3), savez(2),
sachant(2), sait(2), sachiez(2), savoir,
sçai, ignorez, connaissiez, sache connaissez,
connaissais, savent, savaient, connoissez,
connue, reconnaîtrez, sais, connaissant,
savons, connaissait, savait
```

set of 70 queries selected from Swadesh (1946)’s list of 100 universal linguistic concepts.

We create G_s and G_r as follows. For WORD, we define $G_s(q) = \{q\}$ and $G_r(q) = L(q)$ where $L(q)$ is the set of words with the same lemma and POS as q. For CHAR, we need to find ngrams that correspond uniquely to the query q. Given a candidate ngram g we consider $c_{qg} := 1/c(g) \sum_{q' \in L(q), \text{substring}(g,q')} c(q')$ where $c(x)$ is the count of character sequence x across all editions in the query language. We add g to $G_i(q)$ if $c_{qg} > \sigma_i$ where $\sigma_s = .75$ and $\sigma_r = .5$. We only consider queries where $G_s(q)$ is non-empty.

We vary the evaluation parameters (i, k_I, k_T) as follows: “S1” represents $(s, 1, 1)$, “S4” $(s, 2, 2)$, “S16” $(s, 2, 8)$, and “R1” $(r, 1, 1)$.

3.3 Corpus generation and hyperparameters

We train with the skipgram model and set vector dimensionality to 200; word2vec default parameters are used otherwise. Each concept – the union of a set of pivot words and a set of target units linked to the pivot words – is written out as a line or (if the set is large) as a sequence of shorter lines. Training corpus size is approximately 50 GB for all experiments. We write several copies of each line (shuffling randomly to ensure lines are different) where the multiplication factor is chosen to result in an overall corpus size of approximately 50 GB.

There are two exceptions. For BOW, we did not find a good way of reducing the corpus size, so this

		roundtrip translation																		sentiment analysis

Table 3: Roundtrip translation (mean/median accuracy) and sentiment analysis (F_1) results for word-based (WORD) and character-based (CHAR) multilingual embeddings. N (coverage): # queries contained in the embedding space. The best result *across WORD and CHAR* is set in bold.

corpus is 10 times larger than the others. For S-ID, we use Levy et al. (2017)'s hyperparameters; in particular, we trained for 100 iterations and we wrote each verse-unit pair to the corpus only once, resulting in a corpus of about 4 GB.

We set the n parameter of n-grams to $n = 4$ for Bible editions with $\rho < 2$, $n = 8$ for Bible editions with $2 \leq \rho < 3$ and $n = 12$ for Bible editions with $\rho \geq 3$ where ρ is the ratio between size in bytes of the edition and median size of the 1664 editions. In χ^2 dictionary induction, we set $\chi_{\text{min}} = 100$. In the concept induction algorithm we set $\theta = 0.4$ and $\nu = 0.6$. Except for SAMPLE and CLIQUE, we filter out hapax legomena.

3.4 Results

Table 3 presents evaluation results for roundtrip translation and sentiment analysis.

Validity of roundtrip (RT) evaluation results. RTSIMPLE (line 1) is not competitive; e.g., its accuracy is lower by almost half compared to $N(t)$. We also see that RT is an excellent differentiator of poor multilingual embeddings (e.g., BOW) vs. higher-quality ones like S-ID and $N(t)$. This indicates that RT translation can serve as an effective evaluation measure.

The **concept-based multilingual embedding learning** algorithms CLIQUE and $N(t)$ (lines 5-6) consistently (except S1 WORD) outperform BOW and S-ID (lines 2-3) that are not based on concepts. BOW performs poorly in our low-resource setting; this is not surprising since BOW methods rely on large datasets and are therefore expected to fail in the face of severe sparseness. S-ID performs reasonably well for WORD, but even in that case it is outperformed by $N(t)$, in some cases by a large margin, e.g., μ of 63 for S-ID vs. 80 for $N(t)$ for S4. For CHAR, S-ID results are poor. On sentiment classification, $N(t)$ also consistently outperforms S-ID.

While S-ID provides a clearer signal to the embedding learner than BOW, it is still relatively crude to represent a word as – essentially – its binary vector of verse occurrence. Concept-based methods perform better because they can exploit the more informative dictionary graph.

Comparison of graph-theoretic definitions of concepts: $N(t)$-CLIQUE, $N(t)$-CC. $N(t)$ (line 6) has the most consistent good performance across tasks and evaluation measures. Postfiltering target neighborhoods down to cliques (line 7) and CCs (line 8) does not work. The reason is that the resulting number of concepts is too small; see, e.g., low coverages of $N = 18$ ($N(t)$-CLIQUE) and $N = 5$ ($N(t)$-CC) for WORD and $N = 21$ ($N(t)$-CC) for CHAR. $N(t)$-CLIQUE results are highly increased for CHAR, but still poorer by a large margin than the best methods. We can interpret this result as an instance of a precision-recall tradeoff: presumably the quality of the concepts found by $N(t)$-CLIQUE and $N(t)$-CC is better (higher precision), but there are too few of them (low recall) to get good evaluation numbers.

Comparison of graph-theoretic definitions of concepts: CLIQUE. CLIQUE has strong performance for a subset of measures, e.g., ranks consistently second for RT (except S1 WORD) and sentiment analysis in WORD. Although CLIQUE is perhaps the most intuitive way of inducing a concept from a dictionary graph, it may suffer in relatively high-noise settings like ours.

Comparison of graph-theoretic definitions of concepts: $N(t)$ vs. $N(t)$-EDGE. Recall that $N(t)$-EDGE postfilters target neighborhoods by

Table 4: Comparison of $N(t)$[WORD] with four other methods. Difference in mean performance (across queries) in R1 per edition. Positive number means better performance of $N(t)$[WORD].

only considering pairs of pivot words that are linked by a dictionary edge. This "quality" filter does seem to work in some cases, e.g., best performance S16 Md for CHAR. But results for WORD are much poorer.

SAMPLE performs best for CHAR: best results in five out of eight cases. However, its coverage is low: $N = 58$. This is also the reason that it does not perform well on sentiment analysis for CHAR ($F_1 = 77$ for pos).

Target neighborhoods $N(t)$. The overall best method is $N(t)$. It is the best method more often than any other method and in the other cases, it ranks second. This result suggests that the assumption that two target units are semantically similar if they have dictionary edges with exactly the same set of pivot words is a reasonable approximation of reality. Postfiltering by putting constraints on eligible sets of pivot words (i.e., the pivot words themselves must have a certain dictionary link structure) does not consistently improve upon target neighborhoods.

WORD vs. CHAR. For roundtrip, WORD is a better representation than CHAR if we just count the bold winners: seven (WORD) vs. three (CHAR), with two ties. For sentiment, the more difficult task is pos and for this task, CHAR is better by 3 points than WORD ($F_1 = 87$, line 6, vs. $F_1 = 84$, lines 9/5). However, Table 4 shows that CHAR < WORD for one subset of editions (exemplified by cso in Figure 7) and CHAR > WORD for a different subset (exemplified by ksw). So there are big differences between CHAR and WORD in both directions, depending on the language. For some languages, WORD performs a lot better, for others, CHAR performs a lot better.

We designed RT evaluation as a word-based evaluation that disfavors CHAR in some cases. The fourgram "ady@" in the World English Bible occurs in "already" (32 times), "ready" (31 times) and "lady" (9 times). Our RT evaluation thus disqualifies "ady@" as a strict match for "ready". But all 17 *aligned* occurrences of "ady@" are part of "ready" – all others were not aligned. So in the χ^2-alignment interpretation, $P(\text{ready}|\text{ady@}) = 1.0$. In contrast to RT, we only used aligned ngrams in the sentiment evaluation. This discrepancy may explain why the best method for sentiment is a CHAR method whereas the best method for RT is a WORD method.

First NLP task evaluation on more than 1000 languages. Table 3 presents results for 1664 editions in 1259 languages. To the best of our knowledge, this is the first detailed evaluation, involving two challenging NLP tasks, that has been done on such a large number of languages. For several methods, the results are above baseline for all 1664 editions; e.g., S1 measures are above 20% for all 1664 editions for $N(t)$ on CHAR.

4 Related Work

Following Upadhyay et al. (2016), we group **multilingual embedding** methods into classes A, B, C, D.

Group A trains monolingual embedding spaces and subsequently uses a transformation to create a unified space. Mikolov et al. (2013b) find the transformation by minimizing the Euclidean distance between word pairs. Similarly, Zou et al. (2013), Xiao and Guo (2014) and Faruqui and Dyer (2014) use different data sources for identifying word pairs and creating the transformation (e.g., by CCA). Duong et al. (2017) is also similar. These approaches need large datasets to obtain high quality monolingual embedding spaces and are thus inappropriate for a low-resource setting of 150,000 tokens per language.

Group B starts from the premise that representation of aligned sentences should be similar. Neural network approaches include (Hermann and Blunsom, 2014a) (BiCVM) and (Sarath Chandar et al., 2014) (autoencoders). Again, we have not enough data for training neural networks of this size. Søgaard et al. (2015) learn an interlingual space by using Wikipedia articles as concepts and applying inverted indexing. Levy et al. (2017) show that what we call S-ID is a strongly performing embedding learning method. We use S-ID as a baseline.

Group C combines mono- and multilingual information in the embedding learning objective. Klementiev et al. (2012) add a word-alignment based term in the objective. Luong et al. (2015) extend Mikolov et al. (2013a)'s skipgram model to a bilingual model. Gouws et al. (2015) introduce a crosslingual term in the objective, which does not rely on any word-pair or alignment information. For n editions, including $O(n^2)$ bilingual terms in the objective function does not scale.

Group D creates pseudocorpora by merging data from multiple languages into a single corpus. One such method, due to Vulić and Moens (2015), is our baseline BOW.

Östling (2014) generates **multilingual concepts** using a Chinese Restaurant process, a computationally expensive method. Wang et al. (2016) base their concepts on cliques. We extend their notion of clique from the bilingual to the multilingual case. Ammar et al. (2016) use connected components. Our baseline SAMPLE, based on (Lardilleux and Lepage, 2007, 2009), samples aligned sentences from a multilingual corpus and extracts perfect alignments.

Malaviya et al. (2017), Asgari and Schütze (2017), Östling and Tiedemann (2017) and Tiedemann (2018) perform **evaluation** on the language level (e.g., typology prediction) for 1000+ languages or perform experiments on 1000+ languages without evaluating each language. We present the first work that evaluates on 1000+ languages on the sentence level on a difficult task.

Somers (2005) criticizes RT evaluation on the sentence level; but see Aiken and Park (2010). We demonstrated that when used on the word/unit level, it distinguishes weak from strong embeddings and correlates well with an independent sentiment evaluation.

Any alignment algorithm can be used for **dictionary induction**. We only used a member of the IBM class of models (Dyer et al., 2013), but presumably we could improve results by using either higher performing albeit slower aligners or non-IBM aligners (e.g., (Och and Ney, 2003; Tiedemann, 2003; Melamed, 1997)). Other alignment algorithms include 2D linking (Kobdani et al., 2009), sampling based methods (e.g., Vulic and Moens (2012)) and EFMARAL (Östling and Tiedemann, 2016). EFMARAL is especially intriguing as it is based on IBM1 and Agić et al. (2016) find IBM2-based models to favor closely related languages more than models based on IBM1. However, the challenge is that we need to compute tens of thousands of alignments, so speed is of the essence. We ran character-based and word-based induction separately; combining them is promising future research; cf. (Heyman et al., 2017).

There is much work on embedding learning that does not require **parallel corpora**, e.g., (Vulić and Moens, 2012; Ammar et al., 2016). This work is more generally applicable, but a parallel corpus provides a clearer signal and is more promising (if available) for low-resource research.

5 Summary

We presented a new method for estimating vector space representations of words: embedding learning by concept induction. We tested this method on a highly parallel corpus and learned semantic representations of words in 1259 different languages in a single common space. Our extensive experimental evaluation on crosslingual word similarity and sentiment analysis indicates that concept-based multilingual embedding learning performs better than previous approaches.

The embedding spaces of the 1259 languages (SAMPLE, CLIQUE and $N(t)$) are available: `http://cistern.cis.lmu.de/comult/`.

We gratefully **acknowledge** funding from the European Research Council (grants 740516 & 640550) and through a Zentrum Digitalisierung.Bayern fellowship awarded to the first author. We are indebted to Michael Cysouw for making PBC available to us.

Abstract

The transfer or share of knowledge between languages is a popular solution to resource scarcity in NLP. However, the effectiveness of cross-lingual transfer can be challenged by variation in syntactic structures. Frameworks such as Universal Dependencies (UD) are designed to be cross-lingually consistent, but even in carefully designed resources trees representing equivalent sentences may not always overlap. In this paper, we measure cross-lingual syntactic variation, or *anisomorphism*, in the UD treebank collection, considering both morphological and structural properties. We show that reducing the level of anisomorphism yields consistent gains in cross-lingual transfer tasks. We introduce a source language selection procedure that facilitates effective cross-lingual parser transfer, and propose a typologically driven method for syntactic tree processing which reduces anisomorphism. Our results show the effectiveness of this method for both machine translation and cross-lingual sentence similarity, demonstrating the importance of syntactic structure compatibility for boosting cross-lingual transfer in NLP.

1 Introduction

Linguistic information can be transferred from resource-rich to resource-poor languages using approaches such as annotation projection, model transfer, and/or translation (Agić et al., 2014). Such cross-lingual transfer may rely on syntactic information. Structured and more cross-lingually consistent than linear sequences (Ponti, 2016), syntactic information has proved useful for cross-lingual parsing (Tiedemann, 2015; Rasooli and Collins, 2017), multilingual representation learning (Vulić and Korhonen, 2016; Vulić, 2017), causal relation identification (Ponti and Korhonen, 2017), and neural machine translation (Eriguchi et al., 2016; Aharoni and Goldberg, 2017). It can also guide the generation of synthetic data for multilingual tasks (Wang and Eisner, 2016).

Universal Dependencies (UD) (Nivre et al., 2016) is a collection of treebanks for a variety of languages, annotated with a scheme optimised for knowledge transfer. The tag sets are language-independent and there are direct links between content words. This reduces the variation of dependency trees, because content words are cross-lingually more stable than function words (Croft et al., 2017), and benefits semantically-oriented applications (de Marneffe et al., 2014)[1]. Importantly, although UD is tailored to offer support to cross-lingual transfer, it also supports monolingual applications with a quality comparable to language-specific annotations (Vincze et al., 2017, *inter alia*).

Despite the careful design of this resource, there are still substantial variations in morphological richness and strategies employed to express the same syntactic constructions across languages. These variations posit challenges for syntax-based knowledge transfer. The first challenge is how to match the source and target languages so that differences are minimised. The common criteria are based on the typology of word order (Naseem et al., 2012; Täckström et al., 2013; Zhang and Barzilay, 2015) or part-of-speech n-grams (Rosa and Zabokrtsky, 2015; Agić, 2017). The second one is how to make knowledge transfer effective by harmonising syntactic trees (Smith and Eisner, 2009; Vilares et al., 2016) as to enable a better correspondence between source and target nodes.

[1] It is controversial whether it improves parsing: e.g., Groß and Osborne (2015, *inter alia*) argue against whereas Attardi et al. (2015, *inter alia*) argue in favour.

In this paper we address these two challenges. We propose the concept of *isomorphism* (i.e., identity of shapes: syntactic structures) and its opposite, *anisomorphism*, as a probe to measuring quantitatively the extent to which syntactic tree pairs are cross-lingually compatible. We assess the variation of syntactic constructions by **a)** the average Zhang and Shasha (1989)'s tree edit distance between UD treebanks, and **b)** the variation in morphology by the Jaccard index of morphological feature sets. We show that these metrics are strong indicators for source language selection, and even preferable over widespread metrics such as genealogical language relatedness.

Moreover, the concept of isomorphism facilitates the process of reshaping trees to make them compatible across languages via operations of deletion, addition, and relabeling. To this end, we propose a tree processing method which increases the level of isomorphism between trees of cross-lingually compatible sentences. This method leads to consistent improvements on cross-lingual tasks achieved through transfer.

To verify the relevance of isomorphism for cross-lingual transfer in NLP, we perform experiments on three tasks. Firstly, we use the Jaccard index of morphological feature sets to choose source languages for cross-lingual dependency parsing. Secondly, we use syntactic trees harmonised by our method in syntax-based neural machine translation of two typologically distant language pairs (Arabic to Dutch; Indonesian to Portuguese). Finally, we evaluate cross-lingual sentence similarity in a real-life resource-lean scenario where the target language has no annotated data. In all experiments, we enhance performance compared to baselines where the source shows a lower degree of isomorphism.

In §2, we define the concept of (an)isomorphism, propose novel metrics for measuring it quantitatively, and introduce the tree processing algorithm. We then desribe the data (§3), methods (§4), and experimental results (§5). Related work is summarised in §6 and conclusions are drawn in §7.

2 Anisomorphism

The ideal situation for knowledge transfer from one (syntactic) structure into another is when these structures are equivalent. In graph theory, there is isomorphism between the nodes V_S of graph S and the nodes V_T of graph T if there exists a bijection $f(V_S) \rightarrow V_T$ such that $\forall s_i, s_j \in V_S$, it holds that: $s_i \bullet\!\!-\!\!\bullet s_j \Leftrightarrow f(s_i) \bullet\!\!-\!\!\bullet f(s_j)$, where the symbol $\bullet\!\!-\!\!\bullet$ stands for adjacency between nodes. In simple words, the mapping must preserve adjacencies between corresponding nodes.

Syntactic trees are a special case of such graphs. However, vocabularies (the words in their nodes) are peculiar to each language, making their comparison impractical across languages. In this work, we probe isomorphism on delexicalised trees, where each node is the (cross-lingually consistent) dependency relation of the word in that position. Even so, however, isomorphic bijection is often impossible between trees of equivalent sentences in different languages owing to typological variation (see §2.1).

Adopting the term from Ambati (2008), we define this property as *an*isomorphism, which can be quantified as the extent to which two structures differ in their morphological and syntactic properties (§2.2). We present a tree processing method to mitigate anisomorphism in §2.3. Afterwards, in §§3-5 we show how the concepts defined in this section facilitate cross-lingual transfer in three NLP tasks.

2.1 Sources of Anisomorphism

Two main causes underpin anisomorphism. The first cause is the *morphological type* of a language: the same grammatical function may be expressed via morphemes, via separate words (so-called function words), or may not be expressed at all (Bybee, 1985, ch. 2). For instance, consider the following Latin-English example:

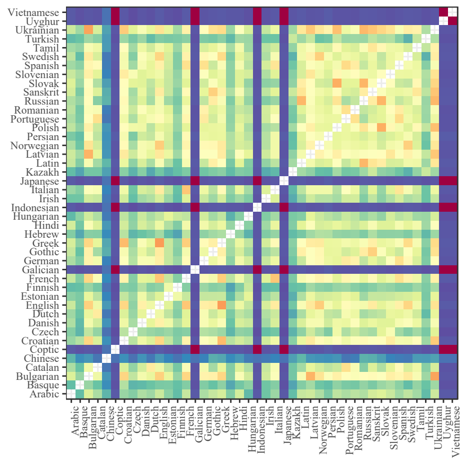
(1)

Crimen	*er-it*	*super-is*	*et*
crime.NOM	be-FUT.3SG	god-DAT.PL	also

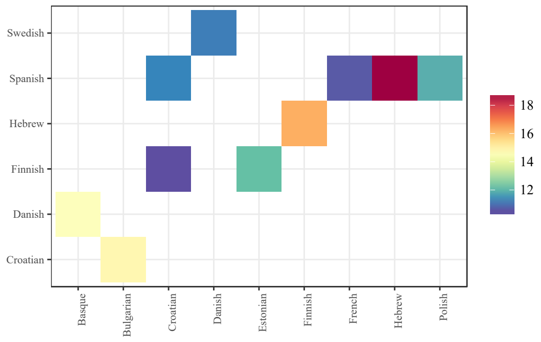
me	*fec-isse*	*nocent-em.*
me	make-INF.PST	guilty-ACC

'It will be a reproach to the gods, that they have made even me guilty.'

The future tense is expressed by inflecting the verb *erit* in Latin, whereas English has the auxiliary verb *will*. In addition, Latin can express the English preposition *to* with the dative case *-is*. This variation has systematic impact on UD annotation. On one hand, Latin would display the attribute-value pairs TENSE=FUTURE and CASE=DATIVE among the features of *erit* and *superis*. On the other hand, in English the function words (*will* and *to*) add nodes to the dependency structure, modifying the equivalent words (*be* and *gods*). This pattern is not unique to English and Latin: there are similar correspondences between specific function words and morphological features in many other languages.



(a) Jaccard index of the morphological feature sets.



(b) Average tree edit distance.

Figure 1: Heatmaps of anisomorphism metrics for UD language pairs. The colours range from blue (low values) to red (high values).

The other source of anisomorphism are *construction strategies*: the same syntactic construction is expressed through different types of strategies (Croft et al., 2017), which results in different kinds of subtrees in UD. An example construction is *predicative possession*, which conveys the ownership of an item by a possessor through the predicate of a clause (Stassen, 2009). Consider these examples in Dutch and Arabic, respectively:

(2)

Ik	*heb*	*een*	*filmidee*
I	have.1SG	a	film+idea

'I have an idea for a movie.'

(3)

Laday-himā	*'ašyā-'u*	*muštarakat-un*
at-them	thing-NOM.PL	common-NOM.PL

'They have things in common.'

In Dutch (Example 2), the owner *Ik* is the subject and the item *filmidee* is the object of a transitive verb (*hab*). However, in Arabic (Example 3) the owner is a predicate with a locative prefix (*laday-himā*), the item *'ašyā'u* is the subject, and there is no verb. These are called transitive and locative strategies, respectively. Each strategy results in a different (delexicalised) subtree, as shown in Figure 2b: this simple example with one construction already suggests that the variation in syntactic constructions affects the compatibility of cross-lingual trees pervasively.[2]

[2]Other strategies for predicative possession include *topic*, *conjunctional* and *genitive*. More examples of constructions are available in the supplemental material.

2.2 Measures of Anisomorphism

How can the differences described in §2.1 translate into quantitative metrics of compatibility between sentences in different languages? As the first answer to this question, we propose to measure the affinity in morphological type by considering the sets of morphological features attested within each of the UD treebanks.[3] Particularly, for each pair of a source language set M_S and a target language set M_T, we estimate their Jaccard index, which is defined for two sets as the cardinality of their intersection divided by the cardinality of their union, as shown in Equation (4).

$$J(M_S, M_T) = \frac{||M_S \cap M_T||}{||M_S \cup M_T||} \quad (4)$$

The values of the Jaccard index lie in $[0, 1]$ A heatmap is displayed in Figure 1a: the morphological similarity between language pairs varies considerably, ranging from low (0.07 in Chinese-Uyghur), mild (0.48 in Latvian-Tamil), to high (0.72 in Bulgarian-Ukrainian). Note that the Jaccard index 1 is an artifact for languages with no expression of grammatical function (in Vietnamese, among others) or lacking morphological annotation (in Japanese). This metric exhibits other disadvantages: it does not take into account another source of variation, the construction strategies, and is based on general properties of a grammar rather

[3]The full list of features can be consulted at http://universaldependencies.org/u/feat/

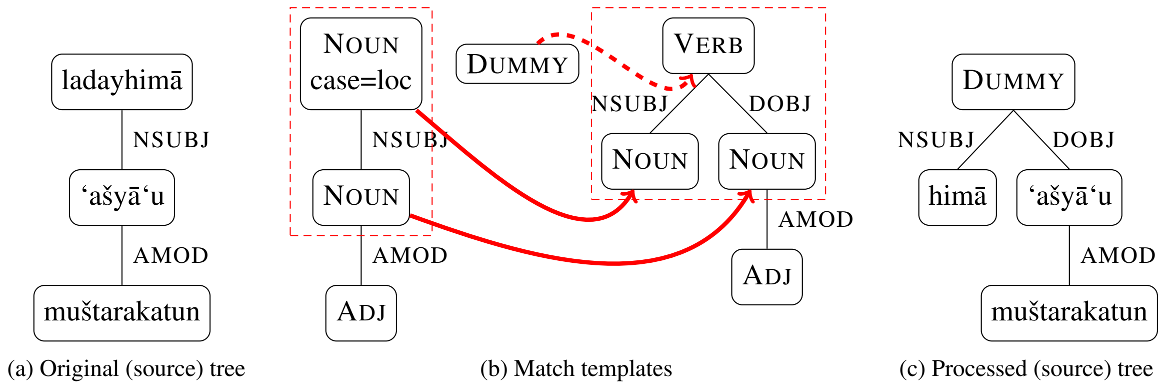


Figure 2: Tree processing steps that transform the locative strategy for predicative possession in an Arabic sentence into a transitive strategy. Tree processing is always applied on source language constructions.

than specific individual sentences.

Hence, we propose an approach to measure anisomorphism between individual sentences. We parse the texts of the multi-parallel Bible corpus (Christodouloupoulos and Steedman, 2015) with the SyntaxNet parser (see §4). The language pairs taken into account are limited to those present both in our UD sample and in the Bible corpus, and sentence-aligned by book, chapter and verse indices. For a given language pair, we estimate the tree edit distance between every corresponding pair of sentence trees S and T with the Zhang-Sasha algorithm (Zhang and Shasha, 1989) and then average over the number of trees.[4]

This tree edit distance operates on ordered trees with node (but not edge) labels, hence it is suited for delexicalised dependencies. In particular, it is defined over a map M, which is a list of node pairs where the former belongs to S or ϵ (empty node), and the latter belongs to T or ϵ. If both are non-empty, they trigger an operation of *relabeling*; if the latter is ϵ, it is *deletion*; if the former is ϵ, it is *addition*. The edit distance is the number of operations required for a complete transformation weighted by the factor γ.[5] The following equation summarises the tree edit distance measure:

$$\gamma(M,S,T) = \sum_{i,j \in M} \gamma(S_i \to T_j) + \gamma(S_i \to \epsilon) + \gamma(\epsilon \to T_j)$$

The possible values of this metric are non-negative real numbers. We opted for this metric in particular because it allows the insertion of internal nodes but not transpositions. The former criterion allows to capture complex transformations without rebuilding entire subtrees, the latter is aimed at taking into account also variations in word order. In order to evaluate pure syntactic isomorphism one should allow for transpositions and/or operate on unordered trees.[6]

A heatmap of tree edit distances is shown in Figure 1b. The values reflect the typological affinity of the language pairs: e.g., Spanish is very close to French (both are Romance languages), mildly similar to Polish (Slavic language, but still part of the Indo-European family), but remote from Hebrew (from a different family, Semitic). The values agree in part with the metrics of Figure 1a, where the Jaccard indices of Hebrew (0.26), Polish (0.46), and French (0.59) mirror the same relationships.

In §4, we show how these metrics can benefit the source selection for knowledge transfer, sometimes even outranking established criteria such as genealogical closeness. However, they have also weaknesses: the Jaccard index of feature sets is not reliable for languages with a limited number of morphologically expressed grammatical categories. On the other hand, the tree edit distance measure requires resources (such as treebanks and parallel corpora) that are not available for many languages.

2.3 Reduction of Anisomorphism

The measures of anisomorphism reveal which languages are structurally similar, which is directly useful for source selection. However, the data available for many tasks are often limited to distant languages. Hence, it is necessary to increase their affinity by gearing one towards the other. We propose to process source dependency trees with an algorithm inspired by the same rules of the tree edit

[4]We implement this algorithm with the *zs* Python package, available at `https://github.com/timtadh/zhang-shasha`.

[5]For simplicity, we set $\gamma = 1$.

[6]For a survey on tree edit distances, see Bille (2005).

distance described in §2.2.

We leverage the readily available documentation in typological databases (e.g., World Atlas of Language Structures: WALS) (Dryer and Haspelmath, 2013).[7] Given a source and a target language, the documentation informs about their respective strategies. For each strategy, we manually define a 'template', i.e. the subtree it corresponds to, in terms of morpho-syntactic features. For instance, see the dashed circles in Figure 2b: note that templates are limited to a head and its immediate dependents.

Then we explore source trees in a top-down breadth-first fashion, and if a template for a source strategy is identified, it is mapped to the corresponding target template. In order to preserve semantic information, contrary to Zhang and Shasha (1989), the mapping operates on lexicalised edge-labeled trees. Hence, ADD and CHANGE affect both words (nodes) and edges (dependency relations). The whole process is summarised in Algorithm 1.

Algorithm 1 Tree processing with rules

```
 1: strategies$_s$ ← WALS$_s$                          ▷ Define templates
 2: strategies$_t$ ← WALS$_t$
 3: function CHANGE($s, t^{(l)}$)                     ▷ Define operations
 4:     $s \leftarrow t^{(l)}$
 5: function DELETE($s$)
 6:     $s \leftarrow \epsilon$
 7: function ADD($t^{(l)}$)
 8:     $\epsilon \leftarrow t^{(l)}$
 9: function MAPPING($r_s$, strategies$_t$)           ▷ Define mapping
10:     assert($r_s \in$ strategies$_s$)
            return {CHANGE, DELETE, ADD}*
11: for subtree in tree$_s$ do                        ▷ Explore tree
12:     if subtree ∈ strategies$_s$ then
13:         list ← MAPPING(subtree)
14:         for $n_s, n_t$ in list do                 ▷ Perform operations
15:             if $n_s \neq \epsilon \wedge n_t \neq \epsilon$ then
16:                 CHANGE($n_s, n_t$)
17:             else if $n_t = \epsilon$ then
18:                 DELETE($n_s$)
19:             else if $n_s = \epsilon$ then
20:                 ADD($n_t$)
```

For instance, consider the transformation from the locative strategy for predicative possession in Arabic from Example 3 into a transitive strategy. By exploring its dependency graph (Figure 2a), the Algorithm identifies a subtree corresponding to one of the source strategies (left side of Figure 2b). This subtree is mapped to the target template (right side of Figure 2b) with the following operations: it CHANGEs the root noun *ladayhimā* (the possessor) with a dummy node (the verb). The same noun is re-ADDed as a dependent with a new label *nsubj*. Finally, the dependency relation of the other noun *'ašyā-'u* is CHANGEd from *nsubj* to *dobj*. The resulting tree uses the source language vocabulary, but target language construction strategies, as shown in Figure 2c.

3 Data

In order to validate the usefulness of anisomorphism reduction through guided source selection and tree processing, we experiment with three different cross-lingual tasks: *cross-lingual dependency parsing*, *neural machine translation (NMT)*, and *cross-lingual sentence similarity (STS)*. In this section, we present the data used in these tasks.

The data for dependency parsing are sourced from Universal Dependencies v1.4.[8] We sample a group of 21 treebanks ensuring their representativeness by balancing them by family. We filter out all languages but two belonging to same branches of the Indo-European family, and keep those of all the other families.[9] We take into account only the language-independent components of the annotation: coarse POS tags, morphological features, and dependency relations.

Regarding NMT data, English is ubiquitous in the current datasets, overshadowing the wide spectrum of existing morphological types and syntactic strategies. To address this limitation, we create a *new NMT dataset* that matches typologically distant languages directly without the need of a bridge/pivot language. We extract aligned sentences from the Open Subtitles 2016 tokenised corpus (Tiedemann, 2009)[10] for Arabic-Dutch and Indonesian-Portuguese. This choice was made based on their volume of parallel data in order to produce evaluation data similar in size to those of NMT datasets in shared tasks such as WMT16 (Bojar et al., 2016). Training and test sets consist of 3M and 5K sentences, respectively. These sentences come automatically annotated by SyntaxNet.

The data for cross-lingual STS are chosen to resemble a real-world scenario with a resource-poor target language. The training data (9,709 sentence

[7] In particular, we take into account the following relevant WALS features: 116 (polar questions), 122-123 (relativisation on subjects and obliques), 117 (predicative possession), 113-115 (negation), 107 (passive), 37-38 (articles), and 85 (prepositions).

[8] http://universaldependencies.org/

[9] Language names are substituted in this work by their corresponding ISO 639-1 codes. A table of names and codes is provided in the supplemental material.

[10] http://opus.nlpl.eu/OpenSubtitles.php

pairs) are in English, taken from the STS benchmark, the ensemble of all the datasets from SemEval 2012-2017 STS tasks. The test data (250 sentence pairs) come from Task 1 of SemEval 2017 (Cer et al., 2017); target language is Arabic.[11] All the sentence pairs are associated with a label ranging from 0 (dissimilarity) to 5 (equivalence).

4 Methodology

Cross-lingual Dependency Parsing. To assess if the anisomorphism metrics devised in §2.2 are reliable in finding compatible languages for knowledge transfer, we use the Jaccard index of the morphological feature sets as a criterion to choose source languages for cross-lingual parser transfer. We adopt the variant of delexicalised model transfer (Zeman and Resnik, 2008) for this task. This technique ignores lexicalised features and leverages only language-independent features instead.

For each language from a sample of 7 (typologically diverse) targets, we report LAS scores using three different source languages: (1) the highest-ranked source according to the Jaccard index; (2) a source sampled from the middle of the list ranked by the Jaccard indices; (3) a very dissimilar language sampled from the bottom of the ranked list. The total number of sentences used for training corresponds to the smallest of the three source language treebanks in order to isolate the effect of treebank size on the final transfer results.

We conduct experiments with two well-known transition-based parsers (Nivre, 2006): (1) *DeSR* (Attardi et al., 2007) and (2) *SyntaxNet* (Andor et al., 2016; Alberti et al., 2017). The two were selected as they represent two different architectures: the former is an SVM-based model with a polynomial kernel, whereas the latter is a feed-forward neural network with beam search based on conditional random fields. The results are evaluated in terms of LAS and UAS scores.

Neural Machine Translation. For NMT, we examine whether the tree processing procedure from §2.3 can reduce anisomorphism between source and target language syntactic structures. We thus run NMT models in two settings: with and without the anisomorphism reduction procedure.

For this experiment we rely on a state-of-the-art syntax-aware NMT architecture. We report its performance by BLEU scores (Papineni et al., 2002).

[11] http://alt.qcri.org/semeval2017/task1/

In particular, we use an attentional encoder-decoder network that jointly learns to translate and align words (Bahdanau et al., 2015) implemented in the Nematus suite[12] (Sennrich et al., 2017). The encoder is a bidirectional gated recurrent network. For each step *i*, the decoder predicts the next word in output by taking as input the current hidden state h_i, the previous word w_{i-1} and a context vector, i.e., a weighted sum of all the hidden states $\sum_{j=1}^{n} w_j \cdot h_1$. The weights are learned by a multi-layer perceptron that estimates the likelihood of the alignment between the predicted word and each of the input words: $w_{i,j} = P(a|y_i, x_j)$.

This model is enriched with additional linguistic features on input, as proposed by Sennrich and Haddow (2016). In particular, we select the following which are proven as useful in prior work, and also relevant to our experiment: word form, POS tag, and dependency relations. These features are concatenated and fed to the encoder. Tree processing from §2.3 affects these features (and consequently the sentence representation) by changing the initial tree structure. For instance, the original tree in Figure 2a and the processed one in Figure 2c would correspond to these feature sets:

Original	**Preprocessed**
ladayhimā ⊕ N ⊕ ROOT	*himā* ⊕ N ⊕ NSUBJ
	DUMMY ⊕ V ⊕ ROOT
ʻašyāʻu ⊕ N ⊕ NSUBJ	*ʻašyāʻu* ⊕ N ⊕ DOBJ
muštarakatun ⊕ A ⊕ Amod	*muštarakatun* ⊕ A ⊕ Amod

Cross-lingual STS. We use cross-lingual STS as another evaluation task to validate if the anisomorphism reduction algorithm from §2.3 generalises beyond the initial application in NMT. The state-of-art approach to this task in the monolingual setting encodes trees of sentence pairs with a TreeLSTM architecture (Tai et al., 2015). The hidden representations of the tree roots of both sentences in each pair are then concatenated and fed to a multi-layer perceptron classifier, which yields a probability distribution over the six classes (from 0=dissimilarity to 5=equivalence).

The following TreeLSTM has been implemented in PyTorch. The parameters of an LSTM model are the matrix weights W_q for inputs and U_q for hidden representations, and a bias b_q. q corresponds to an input gate i_t, a forget gate f_t, an output gate o_t, or a memory cell c_t at time step *t*. The hidden state h_t

[12] https://github.com/EdinburghNLP/nematus

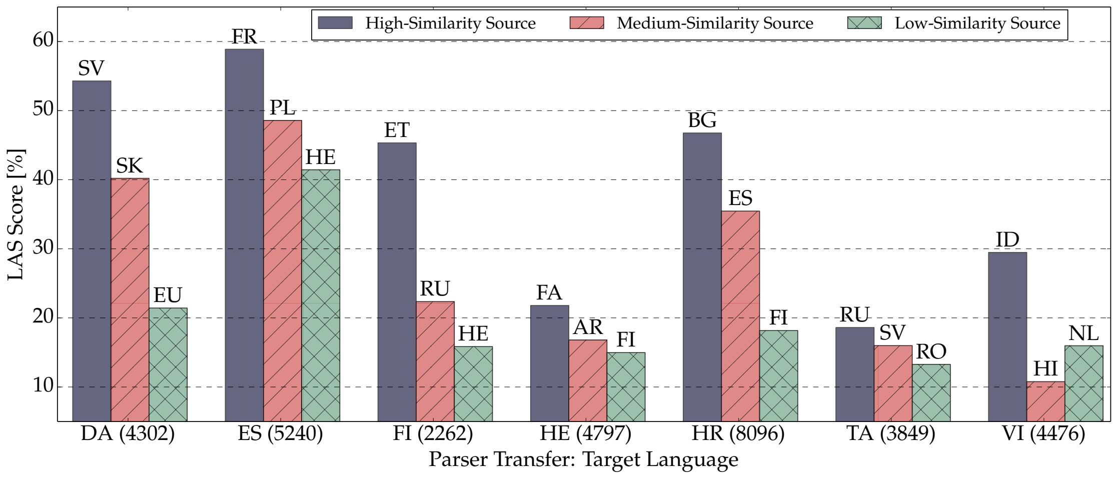

Figure 3: Results of delexicalised cross-lingual transfer using DeSR. Results with SyntaxNet are omitted as they show very similar patterns. The numbers in parentheses denote the amount of training sentences.

is derived from the equations below. To extend this model to dependency trees, we consider h_{t-1} to equal the sum of the hidden states of the children of a node $\sum_{k \in C(x_t)} h_k$, and provide a different forget gate f_{tk} for each child.

$$q_t = \sigma\left(W_q x_t + U_q h_{t-1} + b_q\right) \quad (5)$$

$$c_t = f_t \odot c_{t-1} + i_t \odot \tanh\left(W_c x_t + U_c h_{t-1} + b_c\right) \quad (6)$$

$$h_t = o_t \odot \tanh(c_t) \quad (7)$$

In our resource-lean cross-lingual scenario the language of the training data (English) differs from that of the target (Arabic). Since TreeLSTM is a lexicalised model, we employ multilingual word embeddings, such that the words of both languages lie in the shared cross-lingual semantic space. In particular, we map English into Arabic through the iterative Procustes method devised by Artetxe et al. (2017). The results are evaluated through the Pearson correlation and the Mean Squared Error (MSE) between predicted and golden labels.

Hyperparameters. DeSR has degree 2, γ 0.18, C 0.4, $coef_0$ 0.4, and ϵ 1.0. The hyper-parameters for the deep models are shown in Table 1: we have followed the training setup suggestions from prior work for all the models used in our experiments.

	SyntaxNet (Parsing)	Nematus (NMT)	TreeLSTM (STS)
Hidden layers	2	2	1
Hidden size	512	1000	300
Input size	160	280	512
Batch size	256	80	25
Epochs	12 (greed); 10 (beam)	Early stopping	5
Learning rate	0.8	1^{-4}	1^{-2}
Optimiser	Adam	AdaDelta	SGD
Dropout	0.2 / 0.3	0.1 / 0.2	0

Table 1: Hyper-parameters of the models.

5 Results and Discussion

Source Selection. The results for cross-lingual parser transfer with the DeSR parser are provided in Figure 3, while the results with SyntaxNet are provided as supplemental material as they follow the same trends. The selection of the source for delexicalised cross-lingual parsing based on the proposed Jaccard index measure shows than selecting a source language with a lower degree of anisomorphism is crucial for knowledge transfer. The values for the selected languages are listed in Table 2.

Target	**High**	**Mid**	**Low**
Danish	0.49	0.39	0.19
Spanish	0.59	0.46	0.26
Finnish	0.44	0.23	0.15
Hebrew	0.31	0.24	0.15
Croatian	0.62	0.46	0.25
Tamil	0.48	0.43	0.38
Vietnamese	1.00	0.02	0.01

Table 2: Jaccard indices of source-target pairs.

The high-similarity source always outperforms the alternatives with both DeSR and SyntaxNet, and with respect to both LAS and UAS scores. For instance, Swedish is the best source for Danish, Estonian for Finnish, and Bulgarian for Croatian. Similarly, the preference for medium- over low-

	AR-NL	ID-PT
Baseline	7.01	14.79
+Syntax	14.40	23.70
++Preprocessing	**15.40**	**24.12**

Table 3: NMT results: BLEU scores of a joint translator and aligner *(Baseline)*, fed with linguistic features *(+Syntax)*, and with processed trees to reduce anisomorphism *(++Preprocessing)*.

	Pearson	MSE
Mono-lingual	77.9	0.94
Cross-lingual	44.7	1.82
+Preprocessing	**48.0**	**1.64**

Table 4: Cross-lingual STS results: Pearson and MSE scores of the TreeLSTM architecture with original and processed trees.

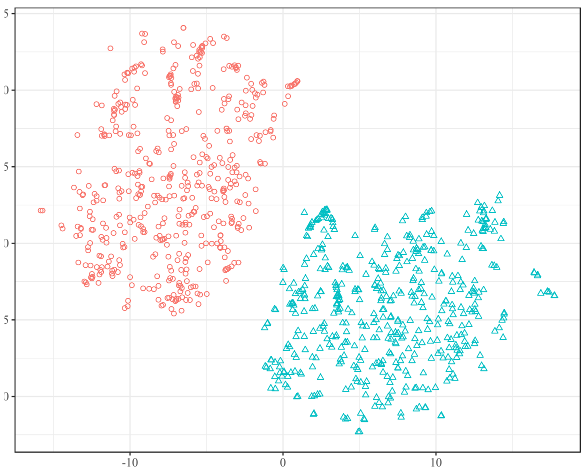

Figure 4: Hidden representations of original (red circles) and processed (blue triangles) sentences.

ranking languages is pronounced, too, as it holds for 6 groups out of 7. For instance, Slovak is a better source choice for Danish than Basque, Polish is a better source choice for Spanish than Hebrew.

Most notably, our findings generalise even to cases when the top-ranking language (e.g. Farsi) does not belong to the language family of the target (e.g. Hebrew) whereas the language with a medium overlap does (e.g. Arabic).

Tree Processing. The results of the experiments also corroborate the idea that tree harmonisation informed by linguistic typology, and implemented through our anisomorphism reduction procedure can assist model transfer in cross-lingual tasks. The BLEU scores for Neural Machine Translation, shown in Table 3, reveal consistent improvements. The model enriched with syntactic features outperforms the baseline with joint translation and alignment without syntactic features by 7.39 BLEU points in Arabic-Dutch and 8.91 BLEU points in Indonesian-Portuguese. Importantly, our extension which reduces anisomorphism by processing syntactic trees in the source language leads to further improvements for both language pairs: it surpasses the model with syntactic features by 1.0 BLEU points in Arabic-Dutch, and 0.42 BLEU points in Indonesian-Portuguese.

These results support our hypotheses: **a)** syntax is pivotal in NMT, confirming findings from prior work (Sennrich et al., 2017); **b)** the tree processing algorithm from §2.3 facilitates the alignment between source and target words, and also grants the encoder-decoder architecture a better leverage of dependency features. This lends support to our argument that anisomorphism limits the ability of models to generalise beyond single languages, and reducing it can help cross-lingual syntax-aware NLP tasks.

A similar conclusion can be reached by comparing the performance of TreeLSTM-based models on the cross-lingual STS task, reported in Table 4. In particular, the Pearson correlation score increases by 3.3 points and MSE decreases by 0.18 points when our tree processing algorithm is applied. We inspect the hidden representations of both original and processed sentences with t-SNE dimensionality reduction in Figure 4. The impact of the algorithm becomes evident as their clusters are completely separate. However, the comparison against the monolingual STS score obtained on the English test set shows that there is still a wide gap to be bridged by cross-lingual knowledge transfer.

Note that our tree processing algorithm is guided by typological knowledge in WALS. The results of the NMT and cross-lingual STS tasks suggest that existing knowledge in such large typological databases (O'Horan et al., 2016; Bender, 2016) can be readily used to support cross-lingual transfer tasks in NLP, as well as the interpretation of polyglot neural models (Ponti et al., 2017). We hope that our work will spark further research on the use of typology in cross-lingual NLP applications.

6 Related Work

The need to account for discrepancies in tree structures emerged early in the domain of Information Theory: in particular, the tree edit distance turned out to be useful for correcting programming scripts (Tai, 1979), evolution studies, and most notably accounting for transformations in constituency trees (Selkow, 1977). Although previous works were aware of the problem of anisomorphism in the context of syntax-based NLP applications (Ambati, 2008), to our knowledge we are the first to quantify it formally and to leverage it in cross-lingual NLP.

For source selection, similarity metrics from prior work mostly relied on information stored in typological databases (Naseem et al., 2012; Täckström et al., 2013; Zhang and Barzilay, 2015; Deri and Knight, 2016). Otherwise, the metrics were derived empirically: they mostly concerned linear-order properties such as part-of-speech n-grams (Rosa and Zabokrtsky, 2015; Agić, 2017). In domain adaptation, the selection also hinges upon topic models (Plank and Van Noord, 2011) or Bayesian Optimisation (Ruder and Plank, 2017). The metrics we defined in §2.2 are instead based on configurational properties of languages, and add another piece to the puzzle of source selection.

The idea of tree processing dates back to the attempts to steer source towards target syntactic structures in statistical MT, although they were mostly limited to simple reordering steps.

Gildea (2003) proposed cloning operations to relocate subtrees. Other works learned rewrite patterns in an automatic fashion to minimize differences in the order of chunks (Zhang et al., 2007) or labeled dependencies (Habash, 2007). Instead, Smith and Eisner (2009) proposed to learn jointly a translation and a loose alignment of nodes, in order to avoid enforcing the bias of the source structure. Reviving these approaches within the framework of deep learning seems crucial as far as state-of-art models depend on syntactic information (Eriguchi et al., 2016; Dyer et al., 2016).

In general, our approach aims at developing and evaluating models focused on specific constructions rather than languages as a whole (Rimell et al., 2009; Bender, 2011; Rimell et al., 2016). The gist is that current models have reached a plateau in performance because they excel with frequent and simple phenomena, but they still lag behind with respect to rarer or more complex constructions.

7 Conclusions and Future Work

We have demonstrated that syntactic structures differ across languages even in well-developed annotation schemes such as Universal Dependencies. This variation stems from morphological and syntactic differences across languages. This phenomenon, which we have labeled as anismorphism, can challenge the transfer of knowledge from one language to another. We have proposed novel methodology which reduces the degree of anisomorphism cross-lingually 1) by selecting the most compatible languages for transfer, and 2) by editing the syntactic structures (i.e., trees) themselves.

First, we have provided two measures of anisomorphism based on Jaccard distance of morphological feature sets, as well as average tree edit distance of parallel sentences. These can provide reliable indicators for language compatibility for source selection in cross-lingual parsing.

Second, we have proposed a new method for fine-tuning source dependency trees to resemble target language trees in order to reduce anisomorphism. The method does not depend on parallel data, and it leverages readily available information in typological databases. It boosts the performance of standard frameworks in two downstream applications, obtaining competitive or state-of-art results for 1) NMT on a new dataset of Arabic-Dutch and Indonesian-Portuguese and 2) cross-lingual sentence similarity.

Future work will look into automating the tree processing procedure. A parametrised model could be trained to imitate the operations performed by Zhang and Shasha (1989)'s algorithm on multi-parallel texts, conditioned on the tree features and previous operations. Another possible research direction is learning the mapping between structures from parallel texts jointly with a main task, in the spirit of quasi-synchronous grammars (Smith and Eisner, 2009). Finally, a wider range of syntactic constructions could be covered by inferring typological strategies from texts (Östling, 2015; Coke et al., 2016).

The data for NMT, and the code for our cross-lingual STS are available at the following link: `github.com/ducdauge/isotransf`.

Abstract

Training language models for Code-mixed (CM) language is known to be a difficult problem because of lack of data compounded by the increased confusability due to the presence of more than one language. We present a computational technique for creation of grammatically valid artificial CM data based on the Equivalence Constraint Theory. We show that when training examples are sampled appropriately from this synthetic data and presented in certain order (aka training curriculum) along with monolingual and real CM data, it can significantly reduce the perplexity of an RNN-based language model. We also show that randomly generated CM data does not help in decreasing the perplexity of the LMs.

1 Introduction

Code-switching or *code-mixing* (CM) refers to the juxtaposition of linguistic units from two or more languages in a single conversation or sometimes even a single utterance.[1] It is quite commonly observed in speech conversations of multilingual societies across the world. Although, traditionally, CM has been associated with informal or casual speech, there is evidence that in several societies, such as urban India and Mexico, CM has become the default code of communication (Parshad et al., 2016), and it has also pervaded written text, especially in computer-mediated communication and social media (Rijhwani et al., 2017).

It is, therefore, imperative to build NLP technology for CM text and speech. There have been some efforts towards building of Automatic Speech Recognition Systems and TTS for CM speech (Li and Fung, 2013, 2014; Gebhardt, 2011; Sitaram et al., 2016), and tasks like language identification (Solorio et al., 2014; Barman et al., 2014), POS tagging (Vyas et al., 2014; Solorio and Liu, 2008), parsing and sentiment analysis (Sharma et al., 2016; Prabhu et al., 2016; Rudra et al., 2016) for CM text. Nevertheless, the accuracies of all these systems are much lower than their monolingual counterparts, primarily due to lack of enough data.

Intuitively, since CM happens between two (or more languages), one would typically need twice as much, if not more, data to train a CM system. Furthermore, any CM corpus will contain large chunks of monolingual fragments, and relatively far fewer code-switching points, which are extremely important to learn patterns of CM from data. This implies that the amount of data required would not just be twice, but probably 10 or 100 times more than that for training a monolingual system with similar accuracy. On the other hand, apart from user-generated content on the Web and social media, it is extremely difficult to gather large volumes of CM data because (a) CM is rare in formal text, and (b) speech data is hard to gather and even harder to transcribe.

In order to circumvent the data scarcity issue, in this paper we propose the use of linguistically-motivated synthetically generated CM data (as a supplement to real CM data) for development of CM NLP systems. In particular, we use the Equivalence Constraint Theory (Poplack, 1980; Sankoff, 1998) for generating linguistically valid CM sentences from a pair of parallel sentences in the two languages. We then use these generated sentences, along with monolingual and little

*Work done during author's internship at Microsoft Research

[1]According to some linguists, code-switching refers to inter-sentential mixing of languages, whereas code-mixing refers to intra-sentential mixing. Since the latter is more general, we will use code-mixing in this paper to mean both.

amount of real CM data to train a CM *Language Model* (LM). Our experiments show that, when trained following certain sampling strategies and training curriculum, the synthetic CM sentences are indeed able to improve the perplexity of the trained LM over a baseline model that uses only monolingual and real CM data.

LM is useful for a variety of downstream NLP tasks such as Speech Recognition and Machine Translation. By definition, it is a discriminator between natural and unnatural language data. The fact that linguistically constrained synthetic data can be used to develop better LM for CM text is, on one hand an indirect statistical and task-based validation of the linguistic theory used to generate the data, and on the other hand an indication that the approach in general is promising and can help solve the issue of data scarcity for a variety of NLP tasks for CM text and speech.

2 Generating Synthetic Code-mixed Data

There is a large and growing body of linguistic research regarding the occurrence, syntactic structure and pragmatic functions of code-mixing in multilingual communities across the world. This includes many attempts to explain the grammatical constraints on CM, with three of the most widely-accepted being the *Embedded-Matrix* (Joshi, 1985; Myers-Scotton, 1993, 1995), the *Equivalence Constraint* (EC) (Poplack, 1980; Sankoff, 1998) and the *Functional Head Constraint* (DiSciullo et al., 1986; Belazi et al., 1994) theories.

For our experiments, we generate CM sentences as per the EC theory, since it explains a range of interesting CM patterns beyond lexical substitution and is also suitable for computational modeling. Further, in a brief human-evaluation we conducted, we found that it is representative of real CM usage. In this section, we list the assumptions made by the EC theory, briefly explain the theory, and then describe how we generate CM sentences as per this theory.

2.1 Assumptions of the EC Theory

Consider two languages L_1 and L_2 that are being mixed. The EC Theory assumes that both languages are defined by context-free grammars G_1 and G_2. It also assumes that every non-terminal category X_1 in G_1 has a *corresponding* non-terminal category X_2 in G_2 and that every terminal symbol (or word) w_1 in G_1 has a *corresponding* terminal symbol w_2 in G_2. Finally, it assumes that every production rule in L_1 has a *corresponding* rule in L_2 - i.e, the non-terminal categories on the left-hand side of the two rules correspond to each other, and every category/symbol on the right-hand side of one rule corresponds to a category/symbol on the right-hand side of the other rule.

All these correspondences must also hold vice-versa (between languages L_2 and L_1), which implies that the two grammars can only differ in the ordering of categories/symbols on the right-hand side of any production rule. As a result, any sentence in L_1 has a corresponding translation in L_2, with their parse trees being equivalent except for the ordering of sibling nodes. Fig.1(a) and (b) illustrate one such sentence pair in English and Spanish and their parse-trees. The EC Theory describes a CM sentence as a constrained combination of two such equivalent sentences.

While the assumptions listed above are quite strong, they do not prevent the EC Theory from being applied to two natural languages whose grammars do not correspond as described above. We apply a simple but effective strategy to reconcile the structures of a sentence and its translation - if any corresponding subtrees of the two parse trees do not have equivalent structures, we collapse each of these subtrees to a single node. Accounting for the actual asymmetry between a pair of languages will certainly allow for the generation of more CM variants of any L_1-L_2 sentence pair. However, in our experiments, this strategy retains most of the structural information in the parse trees, and allows for the generation of up to thousands of CM variants of a single sentence pair.

2.2 The Equivalence Constraint Theory

Sentence production. Given two monolingual sentences (such as those introduced in Fig.1), a CM sentence is created by traversing all the leaf nodes in the parse tree of either of the two sentences. At each node, either the word at that node or at the corresponding node in the other sentence's parse is generated. While the traversal may start at any leaf node, once the production enters one constituent, it will exhaust all the lexical slots (leaf nodes) in that constituent or its equivalent constituent in the other language before entering into a higher level constituent or a sister

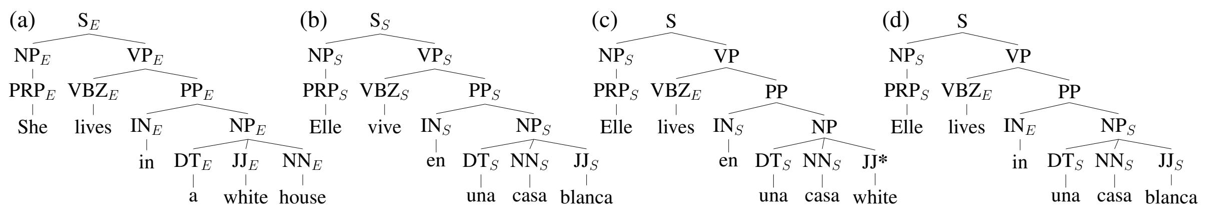

Figure 1: Parse trees of a pair of equivalent (a) English and (b) Spanish sentences, with corresponding hierarchical structure (due to production rules), internal nodes (non-terminal categories) and leaf nodes (terminal symbols), and parse trees of (c) incorrectly code-mixed and (d) correctly code-mixed variants of these sentences (as per the EC theory).

constituent. (Sankoff, 1998) This guarantees that the parse tree of a sentence so produced will have the same hierarchical structure as the two monolingual parse trees (Fig. 1(c) and (d)).

The EC theory also requires that any monolingual fragment that occurs in the CM sentence must occur in one of the monolingual sentences (in the running example, the fragment `una blanca` would be disallowed since it does not appear in the Spanish sentence).

Switch-point identification. To ensure that the CM sentence does not at any point deviate from *both* monolingual grammars, the EC theory imposes certain constraints on its parse tree. To this end and in order to identify the code-switching points in a generated sentence, nodes in its parse tree are assigned language labels according to the following rules: All leaf nodes are labeled by the languages of their symbols. If all the children of any internal node share a common label, the internal node is also labeled with that language. Any node that is out of rank-order among its siblings according to one language is labeled with the other language. (See labeling in Fig.1(c) and (d)) If any node acquires labels of both languages during this process (such as the node marked with an asterisk in Fig.1(c)), the sentence is disallowed as per the EC theory. In the labeled tree, any pair of adjacent sibling nodes with contrasting labels are said to be at a *switch-point* (SP).

Equivalence constraint. Every switch-point identified in the generated sentence must abide by the EC. Let $U \rightarrow U_1U_2...U_n$ and $V \rightarrow V_1V_2...V_n$ be corresponding rules applied in the two monolingual parse trees, and nodes U_i and V_{i+1} be adjacent in the CM parse tree. This pair of nodes is a switch-point, and it only abides by the EC if every node in $U_1...U_i$ has a corresponding node in $V_1...V_i$. This is true for the switch-point in Fig.1(d), and indicates that the two grammars are 'equivalent' at the code-switch point. More importantly, it shows that switching languages at this point does not require another switch later in the sentence. If every switch-point in the generated sentence abides by the EC, the generated sentence is allowed by the EC theory.

2.3 System Description

We assume that the input to the generation model is a pair of parallel sentences in L_1 and L_2, along with word level alignments. For our experiments, L_1 and L_2 are English and Spanish, and Sec 3.2 describes how we create the input set. We use the Stanford Parser (Klein and Manning, 2003) to parse the English sentence.

Projecting parses. We use the alignments to project the English parse tree onto the Spanish sentence in two steps: (1) We first replace every word in the English parse tree with its Spanish equivalent (2) We re-order the child nodes of each internal node in the tree such that their left-to-right order is as in the Spanish sentence. For instance, after replacing every English word in Fig.1(a) with its corresponding Spanish word, we interchange the positions of *casa* and *blanca* to arrive Fig.1(b). For a pair of parallel sentences that follow all the assumptions of the EC theory, these steps can be performed without exception and result in the creation of a Spanish parse tree with the same hierarchical structure as the English parse.

We use various techniques to address cases in which the grammatical structures of the two sentences deviate. English words that are unaligned to any Spanish words are replaced by empty strings. (See Fig.2 wherein the English word *she* has no Spanish counterpart, since this pronoun is dropped in the Spanish sentence.) Contiguous word sequences in one sentence that are aligned to the

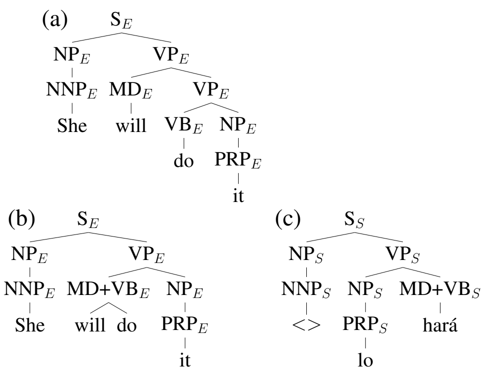

Figure 2: (a) The parse of an English sentence as per Stanford CoreNLP. This parse is projected onto the parallel Spanish sentence *Lo hará* and modified during this process, to produce corresponding (b) English and (c) Spanish parse trees.

same word(s) in the other language are collapsed into a single multi-word node, and the entire subtree between these collapsed nodes and their closest common ancestor is flattened to accommodate this change (example in Fig.2). While these changes do result in slightly unnatural or simplified parse trees, they are used very sparingly since English and Spanish have very compatible grammars.

Generating CS sentences. The number of CS sentences that can be produced by combining a corresponding pair of English and Spanish sentences increases exponentially with the length of the sentences. Instead of generating these sentences exhaustively, we use the parses to construct a finite-state automaton that succinctly captures the acceptable CS sentences. Since the CS sentence must have the same hierarchical structure as the monolingual sentences, we construct the automaton during a post-order traversal of the monolingual parses. An automaton is constructed at each node by (1) concatenating the automatons constructed at its child nodes, (2) splitting states and removing transitions to ensure that the EC theory is not violated. The last automaton to be constructed, which is associated with the root node, accepts all the CS sentences that can be generated using the monolingual parses. We do not provide the exact details of automaton construction here, but we plan to release our code in the near future.

3 Datasets

In this work, we use three types of language data: monolingual data in English and Spanish (*Mono*), real code-mixed data (*rCM*), and artificial or generated code-mixed data (*gCM*). In this section, we describe these datasets and their CM properties. We begin with description of some metrics that we shall use for quantification of the complexity of a CM dataset.

3.1 Measuring CM Complexity

The CM data, both real and artificial, can vary in the their relative usage and ordering of L1 and L2 words, and thereby, significantly affect downstream applications like language modeling. We use the following metrics to estimate the amount and complexity of code-mixing in the datasets.

Switch-point (SP): As defined in the last section, switch-points are points within a sentence where the languages of the words on the two sides are different. Intuitively, sentences that have more number of SPs are inherently more complex. We also define the metric **SP Fraction** (SPF) as the number of SP in a sentence divided by the total number of word boundaries in the sentence.

Code mixing index (CMI): Proposed by Gamback and Das (2014, 2016), CMI quantifies the amount of code mixing in a corpus by accounting for the language distribution as well as the switching between them. Let N be the number of language tokens, x an utterance; let t_{L_i} be the tokens in language L_i, P be the number of code switching points in x. Then, the *Code mixed index per utterance*, $C_u(x)$ for x computed as follows,

$$C_u(x) = \frac{(N(x) - \max_{L_i \in L}\{t_{L_i}\}(x)) + P(x)}{N(x)} \tag{1}$$

Note that all the metrics can be computed at the sentence level as well as at the corpus level by averaging the values for all the sentences in a corpus.

3.2 Real Datasets

We chose to conduct all our experiments on English-Spanish CM tweets because English-Spanish CM is well documented (Solorio and Liu, 2008), is one of the most commonly mixed language pairs on social media (Rijhwani et al., 2017), and a couple of CM tweet datasets are readily available (Solorio et al., 2014; Rijhwani et al., 2017).

Dataset	# Tweets	# Words	CMI	SPF
		Mono		
English	100K	850K (48K)	0	0
Spanish	100K	860K (61K)	0	0
		rCM		
Train	100K	1.4M (91K)	0.31	0.105
Validation	100K	1.4M (91K)	0.31	0.106
Test-17	83K	1.1M (82K)	0.31	0.104
Test-14	13K	138K (16K)	0.12	0.06
gCM	31M	463M (79K)	0.75	0.35

Table 1: Size of the datasets. Numbers in parenthesis show the vocabulary size, i.e., the no. of unique words.

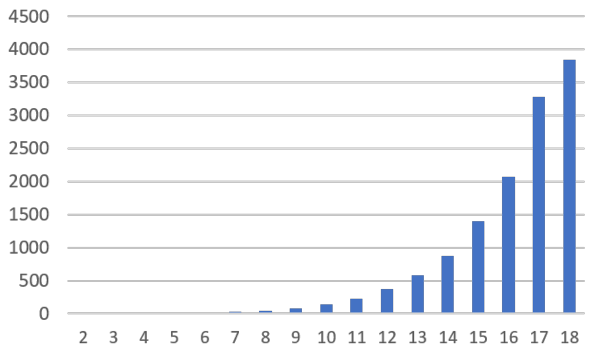

Figure 3: Average number of gCM sentences (y-axis) vs mean input sentence length (x-axis)

For our experiments, we use a subset of the tweets collected by Rijhwani et al. (2017) that were automatically identified as English, Spanish or English-Spanish CM. The authors provided us around 4.5M monolingual tweets per language, and 283K CM tweets. These were already deduplicated and tagged for hashtags, URLs, emoticons and language labels automatically through the method proposed in the paper. Table 1 shows the sizes of the various datasets, which are also described below.

Mono: 50K tweets were sampled for Spanish and English from the entire collection of monolingual tweets. The Spanish tweets were translated to English and vice versa, which gives us a total of 100K monolingual tweets in each language. We shall refer to this dataset as *Mono*. The sampling strategy and reason for generating translations will become apparent in Sec. 3.3.

rCM: We use two real CM datasets in our experiment. The 283K real CM tweets provided by Rijhwani et al. (2017) were randomly divided into training, validation and test sets of nearly equal sizes. Note that for most of our experiments, we will use a very small subset of the training set consisting of 5000 tweets as train data, because the fundamental assumption of this work is that very little amount of CM data is available for most language pairs (which is in fact true for most pairs beyond some very popularly mixed languages like English-Spanish). Nevertheless, the much larger training set is required for studying the effect of varying the amount of real CM data on our models. We shall refer to this training dataset as *rCM*. The test set with 83K tweets will be referred to as *Test-17*. We also use another dataset of English-Spanish CM tweets for testing our models which was released during the language labeling shared task at the Workshop on "Computational Approaches to Code-switching, EMNLP 2014" (Solorio et al., 2014). We mixed the training, validation and test datasets released during this shared task to construct a set of 13K tweets, which we shall refer to as *Test-14*. The two test datasets are tweets that were collected three years apart, and therefore, will help us estimate the robustness of the language models. As shown in Table 1, these datasets are quite different in terms of CMI and average number of SP per tweet. For computing the CMI and SP, we used a English-Spanish LID to language tag the words. In fact, 9500 tweets in the Test-14 dataset are monolingual, but we chose to retain them because it reflects the real distribution of CM data. Further, Test-14 also has manually annotated language labels, which will be helpful while conducting an in-depth analysis of the models.

3.3 Synthetic Code-Mixed Data

As described in the previous section, we use parallel monolingual sentences to generate grammatically valid code mixed sentences. The entire process involves the following four steps.

Step 1: We created the parallel corpus by generating translations for all the monolingual English and Spanish tweets (4.5M each) using the Bing Translator API.[2] We have found, that the translation quality varies widely across different sentences. Thus, we rank the translated sentences using *Pseudo Fuzzy-match Score* (PFS)

[2]https://www.microsoft.com/en-us/translator/translatorapi.aspx

(He et al., 2010). First, the forward translation engine (eg. English-to-Spanish) translates monolingual source sentence s into target t. Then the reverse translation system (eg. Spanish-English) translates target t into pseudo source s'. Equation 2 computes the PFS between s and s'.

$$PFS = \frac{EditDistance(s, s')}{max(|s|, |s'|)} \tag{2}$$

After manual inspection, we decided to select translation pairs whose $PFS \leq 0.7$. The edit distance is based on Wagner and Fischer (1974).

Step 2: We used the `fast_align` toolkit[3] (Dyer et al., 2013), to generate the word alignments from these parallel sentences.

Step 3: The constituency parses for all the English tweets were obtained using the Stanford PCFG parser (Klein and Manning, 2003).

Step 4: Using the parallel sentences, alignments and parse trees, we apply the Equivalent constraint theory (Sec 2.2) to generate all syntactically valid CM sentences while allowing for lexical substitution.

We randomly selected 50K monolingual Spanish and English tweets whose PFS $\leq$ 0.7. This gave us 200K monolingual tweets in all (*Mono* dataset) and the total amount of generated CM sentences from these 100K translation pairs was 31M, which we shall refer to as *gCM*. Note that even though we consider the *Mono* and *gCM* as two separate sets, in reality the EC model also generates the monolingual sentences; further, existence of *gCM* presumes existence of *Mono*. Hence, we also use *Mono* as part of all training experiments which use *gCM*.

We would also like to point out that the choice of experimenting with a much smaller set of tweets, only 50K per language, was made because the number of generated tweets even from this small set of monolingual tweet pairs is almost prohibitively large to allow experimentation with several models and their respective configurations.

4 Approach

Language modeling is a very widely researched topic (Rosenfeld, 2000; Bengio et al., 2003; Sundermeyer et al., 2015). In recent times, deep learning has been successfully employed to build efficient LMs (Mikolov et al., 2010; Sundermeyer et al., 2012; Arisoy et al., 2012; Che et al., 2017).

[3]https://github.com/clab/fast_align

Baheti et al. (2017) recently showed that there is significant effect of the training curriculum, that is the order in which data is presented to an RNN-based LM, on the perplexity of the learnt English-Spanish CM language model on tweets. Along similar lines, in this study we focus our experiments on training curriculum, especially regarding the use of gCM data during training, which is the primary contribution of this paper.

We do not attempt to innovate in terms of the architecture or computational structure of the LM, and use a standard LSTM-based RNN LM (Sundermeyer et al., 2012) for all our experiments. Indeed, there are enough reasons to believe that CM language is not fundamentally different from non-CM language, and therefore, should not require an altogether different LM architecture. Rather, the difference arises in terms of added complexity due to the presence of lexical items and syntactic structures from two linguistic systems that blows up the space of valid grammatical and lexical configurations, which makes it essential to train the models on large volumes of data.

4.1 Training Curricula

Baheti et al. (2017) showed that rather than randomly mixing the monolingual and CM data during training, the best performance is achieved when the LM is first trained with a mixture of monolingual texts from both languages in nearly equal proportions, and ending with CM data. Motivated by this finding, we define the following basic training curricula ("X | Y" indicates training the model first with data X and then data Y):

(1) rCM, **(2)** Mono, **(3)** Mono | rCM,
(4a) Mono | gCM, **(4b)** gCM | Mono,
(5a) Mono | gCM | rCM,
(5b) gCM | Mono | rCM

Curricula 1-3 are baselines, where gCM data is not used. Note that curriculum 3 is the best case according to Baheti et al. (2017). Curricula 4a and 4b help us examine how far generated data can substitute real data. Finally, curricula 5a and 5b use all the data, and we would expect them to perform the best.

Note that we do not experiment with other potential combinations (e.g., rCM | gCM | Mono) because it is known (and we also see this in our experiments) that adding rCM data at the end always leads to better models.

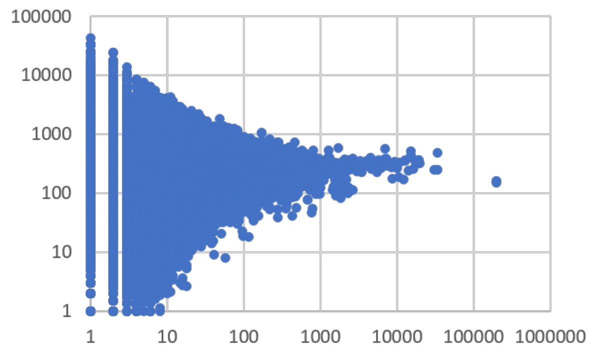

Figure 4: Scatter plot of fractional increase in word frequency in gCM (y-axis) vs original frequency (x-axis).

4.2 Sampling from gCM

As we have seen in Sec 3.3 (Fig. 3), in the EC model, a pair of monolingual parallel tweets gives rise to a large number (typically exponential in the length of the tweet) of CM tweets. On the other hand, in reality, only a few of those tweets would be observed. Further, if all the generated sentences are used to train an LM, it is not only computationally expensive, it also leads to undesirable results because the statistical properties of the distribution of the gCM corpus is very different from real data. We see this in our experiments (not reported in this paper for paucity of space), and also in Fig 4, where we plot the ratio of the frequencies of the words in *gCM* and *Mono* corpora (y-axis) against their original frequencies in *Mono* (x-axis). We can clearly see that the frequencies of the words are scaled up non-uniformly, the ratios varying between 1 and 500,000 for low frequency words.

In order to reduce this skew, instead of selecting the entire gCM data, we propose three sampling techniques for creating the training data from gCM:

Random: For each monolingual pair of parallel tweets, we randomly pick a fixed number, k, of CM tweets. We shall refer to the resultant training corpus as χ-***gCM***.

CMI-based: For each monolingual pair of parallel tweets, we randomly pick k CM tweets and bucket them using CMI (in 0.1 intervals). Thus, in this case we can define two different curricula, where we present the data in *increasing* or *decreasing* order of CMI during training, which will be represented by the notations $\uparrow$-***gCM*** and $\downarrow$-***gCM*** respectively.

SPF-based: For each monolingual pair of parallel tweets, we randomly pick k CM tweets such that the SPF distribution (section 3.1) of these tweets is similar to that of rCM data (as estimated from the validation set). This strategy will be referred to as ρ-***gCM***.

Thus, depending on the gCM sampling strategy used, curricula 4a-b and 5a-b can have three different versions each. Note that since CMI for *Mono* is 0, $\uparrow$-***gCM*** is not meaningful for 4b and 5b and similarly, $\downarrow$-***gCM*** not for 4a and 5a.

5 Experiments and Results

For all our experiments, we use a 2 layered RNN with LSTM units and hidden layer dimension of 100. While training, we use sampled softmax with 5000 samples instead of a full softmax to speed up the training process. The sampling is based on the word frequency in the training corpus. We use momentum SGD with a learning rate of 0.002. We have used the CNTK toolkit for building our models.[4] We use a fixed k=5 (from each monolingual pair) for sampling the gCM data. We observed the performance on $\uparrow$-gCM to be the best when trained till CMI 0.4 and similarly on $\downarrow$-gCM when trained from 1.0 to 0.6.

5.1 Results

Table 2 presents the perplexities on validation, Test-14 and Test-17 datasets for all the models (Col. 3, 4 and 5). We observe the following trends: (1) Model 5(b)-ρ has the least perplexity value (significantly different from the second lowest value in the column, $p < 0.00001$ for a paired t-test). (2) There is 55 and 90 point reduction in perplexity on Test-17 and Test-14 sets respectively from the baseline experiment 3, that does not use gCM data. Thus, addition of gCM data is helpful. (3) Only the 4a and 4b models are worse than 3, while 5a and 5b models are better. Hence, rCM is indispensable, even though gCM helps. (4) SPF based sampling performs significantly better (again $p < 0.00001$) than other sampling techniques.

To put these numbers in perspective, we also trained our model on 50k monolingual English data, which gave a PPL of 264. This shows that the high PPL values our models obtain are due to the inherent complexity of modeling CM language. This is further substantiated by the PPL

3	1238	1186	1120	1041	991	812
5(b)-ρ	1181	1141	1068	986	951	808

Table 4: Perplexity variation on Test-17 with changes in amount of rCM train data. Similar trends for other models (left for paucity of space)

values computed only at the code-switch points, which are shown in Table 2, col. 6, 7 and 8. Even for the best model, which in this case is **5(a)-χ**, PPL is four times higher than the overall PPL on Test-17.

Run length: The complexity of modeling CM is also apparent from Table 3, which reports the perplexity value of the 3 and 5 models for monolingual fragments of various *run lengths*. We define *run length* as the number of words in a maximal monolingual fragment or *run* within a tweet. In our analysis, we only consider runs of the *embedded language*, defined as the language that has fewer words. As one would expect, model 5(a)-χ performs the best for run length 1 (recall that it has lowest PPL at SP), but as the run length increases, the models sampling the gCM data using CMI (5(a)-$\uparrow$ and 5(b)-$\downarrow$) are better than the randomly sampled (χ) models. Run length 1 are typically cases of word borrowing and lexical substitution; higher run length segments are typically an indication of CM. Clearly, modeling the shorter runs of the embedded language seems to be one of the most challenging aspect of CM LM.

Sample size (k)	1	2	5	10
# tweets	93K	184K	497K	952K
5(b)-ρ	1081	1053	986	1019

Table 5: Variation of PPL on Test-17 with gCM sample size k. Similar trends for other models.

Significance of Linguistic Constraints: To understand the importance of the linguistic constraints imposed by EC on generation of gCM, we conducted an experiment where a synthetic CM corpus was created by combining random contiguous segments from the monolingual tweets such that the generated CM tweets' SPF distribution matched that of rCM. When we replaced gCM by this corpus in **5(b)-ρ**, the PPL on test-17 was 1060, which is worse than the baseline PPL.

Effect of rCM size: Table 4 shows the PPL values for models 3 and 5(b)-ρ when trained with different amounts of rCM data, keeping other parameters constant. As expected, the PPL drops for both models as rCM size increases. However, even with high rCM data, gCM does help in improving the LM until we have 50k rCM data (comparable to monolingual, and an unrealistic scenario in practice), where the returns of adding gCM starts diminishing. We also observe that in general, model 3 needs twice the amount of rCM data to perform as well as model 5(b)-ρ.

Effect of gCM size: In our sampling methods on gCM data, we fixed our sample size, k as 5 for consistency and feasibility of experiments. To understand the effect of k (and hence the size of the gCM data), we experimented with $k = 1, 2$, and 10 keeping everything else fixed. Table 5 reports the results for the models 3 and 5(b)-ρ. We observe that unlike rCM data, increasing gCM data or k does not necessarily decrease PPL after a point. We speculate that there is trade-off between k and the amount of rCM data, and also probably between these and the amount of monolingual data. We plan to explore this further in future.

6 Related Work

We briefly describe the various types of approaches used for building LM for CM text.

Bilingual models: These models combine data from monolingual data sources in both languages (Weng et al., 1997). **Factored models**: Gebhardt (2011) uses Factored Language Models for rescoring n-best lists during ASR decoding. The factors used include POS tags, CS point probability and LID. In Adel et al.(2014b; 2014a; 2013) RNNLMs are combined with n-gram based models, or converted to backoff models, giving improvements in perplexity and mixed error rate. **Models that incorporate linguistic constraints**: Li and Fung (2013) use inversion constraints to predict CS points and integrates this prediction into the ASR decoding process. Li and Fung (2014) integrates Functional Head constraints (FHC) for code-switching into the Language Model for Mandarin-English speech recognition. This work uses parsing techniques to restrict the lattice paths during decoding of speech to those permissible under the FHC theory. Our method instead imposes grammatical constraints (EC theory) to generate synthetic data, which can potentially be used to augment real CM data. This allows flexibility to deploy any sophisticated LM architecture and the synthetic data generated can also be used for CM tasks other than speech recognition. **Training curricula for CM**: Baheti et al. (2017) show that a training curriculum where an RNN-LM is trained first with interleaved monolingual data in both languages followed by CM data gives the best results for English-Spanish LM. The perplexity of this model is 4544, which then reduces to 298 after interpolation with a statistical n-gram LM. However, these numbers are not directly comparable to our work because the datasets are different. Our work is an extension of this approach showing that adding synthetic data further improves results.

We do not know of any work that uses synthetically generated CM data for training LMs.

7 Conclusion

In this paper, we presented a computational method for generating synthetic CM data based on the EC theory of code-mixing, and showed that sampling text from the synthetic corpus (according to the distribution of SPF found in real CM data) helps in reduction of PPL of the RNN-LM by an amount which is equivalently achieved by doubling the amount of real CM data. We also showed that randomly generated CM data doesn't improve the LM. Thus, the linguistic theory based generation is of crucial significance. There is no unanimous theory in linguistics on syntactic structure of CM language. Hence, as a future work, we would like to compare the usefulness of different linguistic theories and different constraints within each theory in our proposed LM framework. This can also provide an indirect validation of the theories. Further, we would like to study sampling techniques motivated by natural distributions of linguistic structures.

Chinese NER Using Lattice LSTM

Abstract

We investigate a lattice-structured LSTM model for Chinese NER, which encodes a sequence of input characters as well as all potential words that match a lexicon. Compared with character-based methods, our model explicitly leverages word and word sequence information. Compared with word-based methods, lattice LSTM does not suffer from segmentation errors. Gated recurrent cells allow our model to choose the most relevant characters and words from a sentence for better NER results. Experiments on various datasets show that lattice LSTM outperforms both word-based and character-based LSTM baselines, achieving the best results.

1 Introduction

As a fundamental task in information extraction, named entity recognition (NER) has received constant research attention over the recent years. The task has traditionally been solved as a sequence labeling problem, where entity boundary and category labels are jointly predicted. The current state-of-the-art for English NER has been achieved by using LSTM-CRF models (Lample et al., 2016; Ma and Hovy, 2016; Chiu and Nichols, 2016; Liu et al., 2018) with character information being integrated into word representations.

Chinese NER is correlated with word segmentation. In particular, named entity boundaries are also word boundaries. One intuitive way of performing Chinese NER is to perform word segmentation first, before applying word sequence labeling. The segmentation → NER pipeline, however, can suffer the potential issue of error propagation, since NEs are an important source of OOV in segmentation, and incorrectly segmented entity boundaries lead to NER errors. This problem can be severe in the open domain since cross-domain word segmentation remains an unsolved problem (Liu and Zhang, 2012; Jiang et al., 2013; Liu et al., 2014; Qiu and Zhang, 2015; Chen et al., 2017; Huang et al., 2017). It has been shown that character-based methods outperform word-based methods for Chinese NER (He and Wang, 2008; Liu et al., 2010; Li et al., 2014).

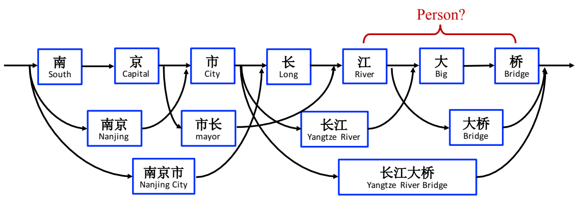

Figure 1: Word character lattice.

One drawback of character-based NER, however, is that explicit word and word sequence information is not fully exploited, which can be potentially useful. To address this issue, we integrate latent word information into character-based LSTM-CRF by representing lexicon words from the sentence using a lattice structure LSTM. As shown in Figure 1, we construct a word-character lattice by matching a sentence with a large automatically-obtained lexicon. As a result, word sequences such as "长江大桥 (Yangtze River Bridge)", "长江 (Yangtze River)" and "大桥 (Bridge)" can be used to disambiguate potential relevant named entities in a context, such as the person name "江大桥 (Daqiao Jiang)".

Since there are an exponential number of word-character paths in a lattice, we leverage a lattice LSTM structure for automatically controlling information flow from the beginning of the sentence to the end. As shown in Figure 2, gated cells are used to dynamically route information from

[*] Equal contribution.

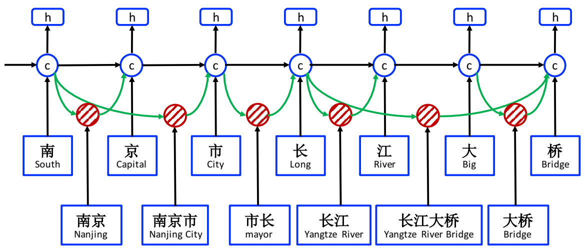

Figure 2: Lattice LSTM structure.

different paths to each character. Trained over NER data, the lattice LSTM can learn to find more useful words from context automatically for better NER performance. Compared with character-based and word-based NER methods, our model has the advantage of leveraging explicit word information over character sequence labeling without suffering from segmentation error.

Results show that our model significantly outperforms both character sequence labeling models and word sequence labeling models using LSTM-CRF, giving the best results over a variety of Chinese NER datasets across different domains. Our code and data are released at `https://github.com/jiesutd/LatticeLSTM`.

2 Related Work

Our work is in line with existing methods using neural network for NER. Hammerton (2003) attempted to solve the problem using a unidirectional LSTM, which was among the first neural models for NER. Collobert et al. (2011) used a CNN-CRF structure, obtaining competitive results to the best statistical models. dos Santos et al. (2015) used character CNN to augment a CNN-CRF model. Most recent work leverages an LSTM-CRF architecture. Huang et al. (2015) uses hand-crafted spelling features; Ma and Hovy (2016) and Chiu and Nichols (2016) use a character CNN to represent spelling characteristics; Lample et al. (2016) use a character LSTM instead. Our baseline word-based system takes a similar structure to this line of work.

Character sequence labeling has been the dominant approach for Chinese NER (Chen et al., 2006b; Lu et al., 2016; Dong et al., 2016). There have been explicit discussions comparing statistical word-based and character-based methods for the task, showing that the latter is empirically a superior choice (He and Wang, 2008; Liu et al., 2010; Li et al., 2014). We find that with proper representation settings, the same conclusion holds for neural NER. On the other hand, lattice LSTM is a better choice compared with both word LSTM and character LSTM.

How to better leverage word information for Chinese NER has received continued research attention (Gao et al., 2005), where segmentation information has been used as soft features for NER (Zhao and Kit, 2008; Peng and Dredze, 2015; He and Sun, 2017a), and joint segmentation and NER has been investigated using dual decomposition (Xu et al., 2014), multi-task learning (Peng and Dredze, 2016), etc. Our work is in line, focusing on neural representation learning. While the above methods can be affected by segmented training data and segmentation errors, our method does not require a word segmentor. The model is conceptually simpler by not considering multi-task settings.

External sources of information has been leveraged for NER. In particular, lexicon features have been widely used (Collobert et al., 2011; Passos et al., 2014; Huang et al., 2015; Luo et al., 2015). Rei (2017) uses a word-level language modeling objective to augment NER training, performing multi-task learning over large raw text. Peters et al. (2017) pretrain a character language model to enhance word representations. Yang et al. (2017b) exploit cross-domain and cross-lingual knowledge via multi-task learning. We leverage external data by pretraining word embedding lexicon over large automatically-segmented texts, while semi-supervised techniques such as language modeling are orthogonal to and can also be used for our lattice LSTM model.

Lattice structured RNNs can be viewed as a natural extension of tree-structured RNNs (Tai et al., 2015) to DAGs. They have been used to model motion dynamics (Sun et al., 2017), dependency-discourse DAGs (Peng et al., 2017), as well as speech tokenization lattice (Sperber et al., 2017) and multi-granularity segmentation outputs (Su et al., 2017) for NMT encoders. Compared with existing work, our lattice LSTM is different in both motivation and structure. For example, being designed for character-centric lattice-LSTM-CRF sequence labeling, it has recurrent cells but not hidden vectors for words. To our knowledge, we are the first to design a novel lattice LSTM representation for mixed characters and lexicon words, and the first to use a word-character lattice for segmentation-free Chinese NER.

3 Model

We follow the best English NER model (Huang et al., 2015; Ma and Hovy, 2016; Lample et al., 2016), using LSTM-CRF as the main network structure. Formally, denote an input sentence as $s = c_1, c_2, \ldots, c_m$, where c_j denotes the jth character. s can further be seen as a word sequence $s = w_1, w_2, \ldots, w_n$, where w_i denotes the ith word in the sentence, obtained using a Chinese segmentor. We use $t(i,k)$ to denote the index j for the kth character in the ith word in the sentence. Take the sentence in Figure 1 for example. If the segmentation is “南京市 长江大桥”, and indices are from 1, then $t(2,1) = 4$ (长) and $t(1,3) = 3$ (市). We use the BIOES tagging scheme (Ratinov and Roth, 2009) for both word-based and character-based NER tagging.

3.1 Character-Based Model

The character-based model is shown in Figure 3(a). It uses an LSTM-CRF model on the character sequence $c_1, c_2, \ldots, c_m$. Each character c_j is represented using

$$\mathbf{x}^c_j = \mathbf{e}^c(c_j) \tag{1}$$

$\mathbf{e}^c$ denotes a character embedding lookup table.

A bidirectional LSTM (same structurally as Eq. 11) is applied to $\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_m$ to obtain $\overrightarrow{\mathbf{h}}^c_1, \overrightarrow{\mathbf{h}}^c_2, \ldots, \overrightarrow{\mathbf{h}}^c_m$ and $\overleftarrow{\mathbf{h}}^c_1, \overleftarrow{\mathbf{h}}^c_2, \ldots, \overleftarrow{\mathbf{h}}^c_m$ in the left-to-right and right-to-left directions, respectively, with two distinct sets of parameters. The hidden vector representation of each character is:

$$\mathbf{h}^c_j = [\overrightarrow{\mathbf{h}}^c_j; \overleftarrow{\mathbf{h}}^c_j] \tag{2}$$

A standard CRF model (Eq. 17) is used on $\mathbf{h}^c_1, \mathbf{h}^c_2, \ldots, \mathbf{h}^c_m$ for sequence labelling.

• **Char + bichar**. Character bigrams have been shown useful for representing characters in word segmentation (Chen et al., 2015; Yang et al., 2017a). We augment the character-based model with bigram information by concatenating bigram embeddings with character embeddings:

$$\mathbf{x}^c_j = [\mathbf{e}^c(c_j); \mathbf{e}^b(c_j, c_{j+1})], \tag{3}$$

where $\mathbf{e}^b$ denotes a charater bigram lookup table.

• **Char + softword**. It has been shown that using segmentation as soft features for character-based NER models can lead to improved performance (Zhao and Kit, 2008; Peng and Dredze, 2016).

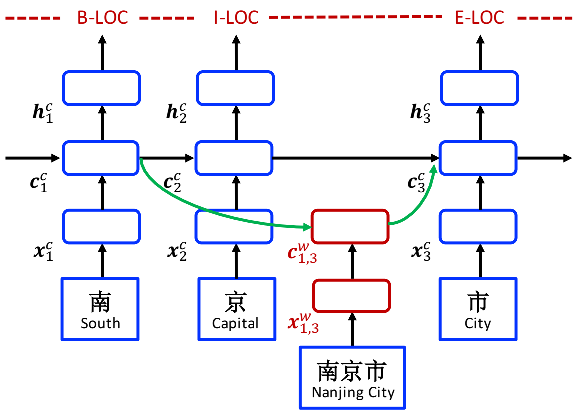
(b) Word-based model.



(c) Lattice model.

Figure 3: Models.[1]

We augment the character representation with segmentation information by concatenating segmentation label embeddings to character embeddings:

$$\mathbf{x}^c_j = [\mathbf{e}^c(c_j); \mathbf{e}^s(seg(c_j))], \tag{4}$$

where $\mathbf{e}^s$ represents a segmentation label embedding lookup table. $seg(c_j)$ denotes the segmentation label on the character c_j given by a word segmentor. We use the BMES scheme for repre-

[1]To keep the figure concise, we (i) do not show gate cells, which uses $\mathbf{h}_{t-1}$ for calculating $\mathbf{c}_t$; (ii) only show one direction.

senting segmentation (Xue, 2003).

$$\mathbf{h}_i^w = [\overrightarrow{\mathbf{h}_i^w}; \overleftarrow{\mathbf{h}_i^w}] \tag{5}$$

Similar to the character-based case, a standard CRF model (Eq. 17) is used on $\mathbf{h}_1^w, \mathbf{h}_2^w, \ldots, \mathbf{h}_m^w$ for sequence labelling.

3.2 Word-Based Model

The word-based model is shown in Figure 3(b). It takes the word embedding $\mathbf{e}^w(w_i)$ for representation each word w_i:

$$\mathbf{x}_i^w = \mathbf{e}^w(w_i), \tag{6}$$

where $\mathbf{e}^w$ denotes a word embedding lookup table. A bi-directioanl LSTM (Eq. 11) is used to obtain a left-to-right sequence of hidden states $\overrightarrow{\mathbf{h}_1^w}, \overrightarrow{\mathbf{h}_2^w}, \ldots, \overrightarrow{\mathbf{h}_n^w}$ and a right-to-left sequence of hidden states $\overleftarrow{\mathbf{h}_1^w}, \overleftarrow{\mathbf{h}_2^w}, \ldots, \overleftarrow{\mathbf{h}_n^w}$ for the words $w_1, w_2, \ldots, w_n$, respectively. Finally, for each word w_i, $\overrightarrow{\mathbf{h}_i^w}$ and $\overleftarrow{\mathbf{h}_i^w}$ are concatenated as its representation:

Integrating character representations

Both character CNN (Ma and Hovy, 2016) and LSTM (Lample et al., 2016) have been used for representing the character sequence within a word. We experiment with both for Chinese NER. Denoting the representation of characters within w_i as $\mathbf{x}_i^c$, a new word representation is obtained by concatenation of $\mathbf{e}^w(w_i)$ and $\mathbf{x}_i^c$:

$$\mathbf{x}_i^w = [\mathbf{e}^w(w_i); \mathbf{x}_i^c] \tag{7}$$

• **Word + char LSTM**. Denoting the embedding of each input character as $\mathbf{e}^c(c_j)$, we use a bi-directional LSTM (Eq. 11) to learn hidden states $\overrightarrow{\mathbf{h}}^c_{t(i,1)}, \ldots, \overrightarrow{\mathbf{h}}^c_{t(i,len(i))}$ and $\overleftarrow{\mathbf{h}}^c_{t(i,1)}, \ldots, \overleftarrow{\mathbf{h}}^c_{t(i,len(i))}$ for the characters $c_{t(i,1)}, \ldots, c_{t(i,len(i))}$ of w_i, where $len(i)$ denotes the number of characters in w_i. The final character representation for w_i is:

$$\mathbf{x}_i^c = [\overrightarrow{\mathbf{h}}^c_{t(i,len(i))}; \overleftarrow{\mathbf{h}}^c_{t(i,1)}] \tag{8}$$

• **Word + char LSTM′**. We investigate a variation of word + char LSTM model that uses a **single** LSTM to obtain $\overrightarrow{\mathbf{h}}^c_j$ and $\overleftarrow{\mathbf{h}}^c_j$ for each c_j. It is similar with the structure of Liu et al. (2018) but not uses the highway layer. The same LSTM structure as defined in Eq. 11 is used, and the same method as Eq. 8 is used to integrate character hidden states into word representations.

• **Word + char CNN**. A standard CNN (LeCun et al., 1989) structure is used on the character sequence of each word to obtain its character representation $\mathbf{x}_i^c$. Denoting the embedding of character c_j as $\mathbf{e}^c(c_j)$, the vector $\mathbf{x}_i^c$ is given by:

$$\mathbf{x}_i^c = \max_{t(i,1) \le j \le t(i,len(i))} (\mathbf{W}_{\text{CNN}}^\top \begin{bmatrix} \mathbf{e}^c(c_{j-\frac{ke-1}{2}}) \\ \ldots \\ \mathbf{e}^c(c_{j+\frac{ke-1}{2}}) \end{bmatrix} + \mathbf{b}_{\text{CNN}}), \tag{9}$$

where $\mathbf{W}_{\text{CNN}}$ and $\mathbf{b}_{\text{CNN}}$ are parameters, $ke = 3$ is the kernal size and max denotes max pooling.

3.3 Lattice Model

The overall structure of the word-character lattice model is shown in Figure 2, which can be viewed as an extension of the character-based model, integrating word-based cells and additional gates for controlling information flow.

Shown in Figure 3(c), the input to the model is a character sequence $c_1, c_2, \ldots, c_m$, together with all character subsequences that match words in a lexicon $\mathbb{D}$. As indicated in Section 2, we use automatically segmented large raw text for buinding $\mathbb{D}$. Using $w_{b,e}^d$ to denote such a subsequence that begins with character index b and ends with character index e, the segment $w_{1,2}^d$ in Figure 1 is "南京 (Nanjing)" and $w_{7,8}^d$ is "大桥 (Bridge)".

Four types of vectors are involved in the model, namely *input vectors*, *output hidden vectors*, *cell vectors* and *gate vectors*. As basic components, a character input vector is used to represent each chacracter c_j as in the character-based model:

$$\mathbf{x}_j^c = \mathbf{e}^c(c_j) \tag{10}$$

The basic recurrent structure of the model is constructed using a character cell vector $\mathbf{c}_j^c$ and a hidden vector $\mathbf{h}_j^c$ on each c_j, where $\mathbf{c}_j^c$ serves to record recurrent information flow from the beginning of the sentence to c_j and $\mathbf{h}_j^c$ is used for CRF sequence labelling using Eq. 17.

The basic recurrent LSTM functions are:

$$\begin{bmatrix} \mathbf{i}_j^c \\ \mathbf{o}_j^c \\ \mathbf{f}_j^c \\ \widetilde{\mathbf{c}}_j^c \end{bmatrix} = \begin{bmatrix} \sigma \\ \sigma \\ \sigma \\ tanh \end{bmatrix} \left(\mathbf{W}^{c\top} \begin{bmatrix} \mathbf{x}_j^c \\ \mathbf{h}_{j-1}^c \end{bmatrix} + \mathbf{b}^c \right) \tag{11}$$
$$\mathbf{c}_j^c = \mathbf{f}_j^c \odot \mathbf{c}_{j-1}^c + \mathbf{i}_j^c \odot \widetilde{\mathbf{c}}_j^c$$
$$\mathbf{h}_j^c = \mathbf{o}_j^c \odot tanh(\mathbf{c}_j^c)$$

where $\mathbf{i}_j^c, \mathbf{f}_j^c$ and $\mathbf{o}_j^c$ denote a set of input, forget and output gates, respectively. $\mathbf{W}^{c\top}$ and $\mathbf{b}^c$ are model parameters. $\sigma()$ represents the sigmoid function.

Different from the character-based model, however, the computation of $\mathbf{c}^c_j$ now considers lexicon subsequences $w^d_{b,e}$ in the sentence. In particular, each subsequence $w^d_{b,e}$ is represented using

$$\mathbf{x}^w_{b,e} = \mathbf{e}^w(w^d_{b,e}), \tag{12}$$

where $\mathbf{e}^w$ denotes the same word embedding lookup table as in Section 3.2.

In addition, a word cell $\mathbf{c}^w_{b,e}$ is used to represent the recurrent state of $\mathbf{x}^w_{b,e}$ from the beginning of the sentence. The value of $\mathbf{c}^w_{b,e}$ is calculated by:

$$\begin{bmatrix} \mathbf{i}^w_{b,e} \\ \mathbf{f}^w_{b,e} \\ \widetilde{\mathbf{c}}^w_{b,e} \end{bmatrix} = \begin{bmatrix} \sigma \\ \sigma \\ tanh \end{bmatrix} \left(\mathbf{W}^{w\top} \begin{bmatrix} \mathbf{x}^w_{b,e} \\ \mathbf{h}^c_b \end{bmatrix} + \mathbf{b}^w \right) \tag{13}$$
$$\mathbf{c}^w_{b,e} = \mathbf{f}^w_{b,e} \odot \mathbf{c}^c_b + \mathbf{i}^w_{b,e} \odot \widetilde{\mathbf{c}}^w_{b,e}$$

where $\mathbf{i}^w_{b,e}$ and $\mathbf{f}^w_{b,e}$ are a set of input and forget gates. There is no output gate for word cells since labeling is performed only at the character level.

With $\mathbf{c}^w_{b,e}$, there are more recurrent paths for information flow into each $\mathbf{c}^c_j$. For example, in Figure 2, input sources for $\mathbf{c}^c_7$ include $\mathbf{x}^c_7$ (桥 Bridge), $\mathbf{c}^w_{6,7}$ (大桥 Bridge) and $\mathbf{c}^w_{4,7}$ (长江大桥 Yangtze River Bridge).[2] We link all $\mathbf{c}^w_{b,e}$ with $b \in \{b'|w^d_{b',e} \in \mathbb{D}\}$ to the cell $\mathbf{c}^c_e$. We use an additional gate $\mathbf{i}^c_{b,e}$ for each subsequence cell $\mathbf{c}^w_{b,e}$ for controlling its contribution into $\mathbf{c}^c_{b,e}$:

$$\mathbf{i}^c_{b,e} = \sigma\left(\mathbf{W}^{l\top} \begin{bmatrix} \mathbf{x}^c_e \\ \mathbf{c}^w_{b,e} \end{bmatrix} + \mathbf{b}^l\right) \tag{14}$$

The calculation of cell values $\mathbf{c}^c_j$ thus becomes

$$\mathbf{c}^c_j = \sum_{b \in \{b'|w^d_{b',j} \in \mathbb{D}\}} \boldsymbol{\alpha}^c_{b,j} \odot \mathbf{c}^w_{b,j} + \boldsymbol{\alpha}^c_j \odot \widetilde{\mathbf{c}}^c_j \tag{15}$$

In Eq. 15, the gate values $\mathbf{i}^c_{b,j}$ and $\mathbf{i}^c_j$ are normalised to $\boldsymbol{\alpha}^c_{b,j}$ and $\boldsymbol{\alpha}^c_j$ by setting the sum to $\mathbf{1}$.

$$\begin{aligned} \boldsymbol{\alpha}^c_{b,j} &= \frac{exp(\mathbf{i}^c_{b,j})}{exp(\mathbf{i}^c_j) + \sum_{b' \in \{b''|w^d_{b'',j} \in \mathbb{D}\}} exp(\mathbf{i}^c_{b',j})} \\ \boldsymbol{\alpha}^c_j &= \frac{exp(\mathbf{i}^c_j)}{exp(\mathbf{i}^c_j) + \sum_{b' \in \{b''|w^d_{b'',j} \in \mathbb{D}\}} exp(\mathbf{i}^c_{b',j})} \end{aligned} \tag{16}$$

The final hidden vectors $\mathbf{h}^c_j$ are still computed as described by Eq. 11. During NER training, loss values back-propagate to the parameters $\mathbf{W}^c, \mathbf{b}^c, \mathbf{W}^w, \mathbf{b}^w, \mathbf{W}^l$ and $\mathbf{b}^l$ allowing the model to dynamically focus on more relevant words during NER labelling.

[2]We experimented with alternative configurations on indexing word and character path links, finding that this configuration gives the best results in preliminary experiments. Single-character words are excluded; the final performance drops slightly after integrating single-character words.

Dataset	Type	Train	Dev	Test
OntoNotes	Sentence	15.7k	4.3k	4.3k
	Char	491.9k	200.5k	208.1k
MSRA	Sentence	46.4k	–	4.4k

Weibo	Sentence	1.4k	0.27k	0.27k
	Char	73.8k	14.5k	14.8k
resume	Sentence	3.8k	0.46k	0.48k
	Char	124.1k	13.9k	15.1k

Table 1: Statistics of datasets.

3.4 Decoding and Training

A standard CRF layer is used on top of $\mathbf{h}_1, \mathbf{h}_2, \dots, \mathbf{h}_\tau$, where τ is n for character-based and lattice-based models and m for word-based models. The probability of a label sequence $y = l_1, l_2, \dots, l_\tau$ is

$$P(y|s) = \frac{exp(\sum_i(\mathbf{W}^{l_i}_{\text{CRF}}\mathbf{h}_i + b^{(l_{i-1},l_i)}_{\text{CRF}}))}{\sum_{y'} exp(\sum_i(\mathbf{W}^{l'_i}_{\text{CRF}}\mathbf{h}_i + b^{(l'_{i-1},l'_i)}_{\text{CRF}}))} \tag{17}$$

Here y' represents an arbitary label sequence, and $\mathbf{W}^{l_i}_{\text{CRF}}$ is a model parameter specific to l_i, and $b^{(l_{i-1},l_i)}_{\text{CRF}}$ is a bias specific to l_{i-1} and l_i.

We use the first-order Viterbi algorithm to find the highest scored label sequence over a word-based or character-based input sequence. Given a set of manually labeled training data $\{(s_i, y_i)\}|^N_{i=1}$, sentence-level log-likelihood loss with L_2 regularization is used to train the model:

$$L = \sum^N_{i=1} log(P(y_i|s_i)) + \frac{\lambda}{2}||\Theta||^2, \tag{18}$$

where λ is the L_2 regularization parameter and Θ represents the parameter set.

4 Experiments

We carry out an extensive set of experiments to investigate the effectiveness of word-character lattice LSTMs across different domains. In addition, we aim to empirically compare word-based and character-based neural Chinese NER under different settings. Standard precision (P), recall (R) and F1-score (F1) are used as evaluation metrics.

4.1 Experimental Settings

Data. Four datasets are used in this paper, which include OntoNotes 4 (Weischedel et al., 2011), MSRA (Levow, 2006) Weibo NER (Peng and

Statistics	Train	Dev	Test

Table 2: Detailed statistics of resume NER.

Dredze, 2015; He and Sun, 2017a) and a Chinese resume dataset that we annotate. Statistics of the datasets are shown in Table 1. We take the same data split as Che et al. (2013) on OntoNotes. The development set of OntoNotes is used for reporting development experiments. While the OntoNotes and MSRA datasets are in the news domain, the Weibo NER dataset is drawn from the social media website Sina Weibo.[3]

For more variety in test domains, we collected a resume dataset from Sina Finance[4], which consists of resumes of senior executives from listed companies in the Chinese stock market. We randomly selected 1027 resume summaries and manually annotated 8 types of named entities. Statistics of the dataset is shown in Table 2. The inter-annotator agreement is 97.1%. We release this dataset as a resource for further research.

Segmentation. For the OntoNotes and MSRA datasets, gold-standard segmentation is available in the training sections. For OntoNotes, gold segmentation is also available for the development and test sections. On the other hand, no segmentation is available for the MSRA test sections, nor the Weibo / resume datasets. As a result, OntoNotes is leveraged for studying oracle situations where gold segmentation is given. We use the neural word segmentor of Yang et al. (2017a) to automatically segment the development and test sets for word-based NER. In particular, for the OntoNotes and MSRA datasets, we train the segmentor using gold segmentation on their respective training sets. For Weibo and resume, we take the best model of Yang et al. (2017a) off the shelf[5], which is trained using CTB 6.0 (Xue et al., 2005).

char dropout	0.5	lattice dropout	0.5
LSTM layer	1	regularization λ	1e-8
learning rate lr	0.015	lr decay	0.05

Table 3: Hyper-parameter values.

Word Embeddings. We pretrain word embeddings using word2vec (Mikolov et al., 2013) over automatically segmented Chinese Giga-Word[6], obtaining 704.4k words in a final lexicon. In particular, the number of single-character, two-character and three-character words are 5.7k, 291.5k, 278.1k, respectively. The embedding lexicon is released alongside our code and models as a resource for further research. Word embeddings are fine-tuned during NER training. Character and character bigram embeddings are pretrained on Chinese Giga-Word using word2vec and fine-tuned at model training.

Hyper-parameter settings. Table 3 shows the values of hyper-parameters for our models, which as fixed according to previous work in the literature without grid-search adjustments for each individual dataset. In particular, the embedding sizes are set to 50 and the hidden size of LSTM models to 200. Dropout (Srivastava et al., 2014) is applied to both word and character embeddings with a rate of 0.5. Stochastic gradient descent (SGD) is used for optimization, with an initial learning rate of 0.015 and a decay rate of 0.05.

4.2 Development Experiments

We compare various model configurations on the OntoNotes development set, in order to select the best settings for word-based and character-based NER models, and to learn the influence of lattice word information on character-based models.

Character-based NER. As shown in Table 4, without using word segmentation, a character-based LSTM-CRF model gives a development F1-score of 62.47%. Adding character-bigram and softword representations as described in Section 3.1 increases the F1-score to 67.63% and 65.71%, respectively, demonstrating the usefulness of both sources of information. In addition, a combination of both gives a 69.64% F1-score, which is the best

Table 4: Development results.

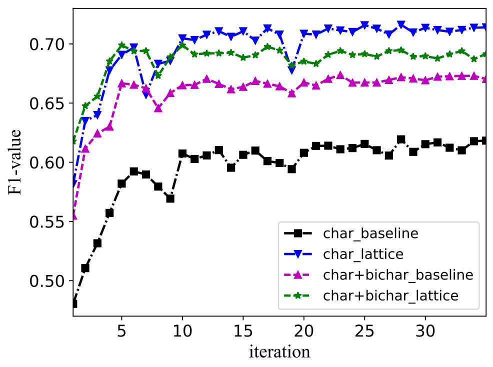

Figure 4: F1 against training iteration number.

among various character representations. We thus choose this model in the remaining experiments.

Word-based NER. Table 4 shows a variety of different settings for word-based Chinese NER. With automatic segmentation, a word-based LSTM CRF baseline gives a 64.12% F1-score, which is higher compared to the character-based baseline. This demonstrates that both word information and character information are useful for Chinese NER. The two methods of using character LSTM to enrich word representations in Section 3.2, namely word+char LSTM and word+char LSTM′, lead to similar improvements.

A CNN representation of character sequences gives a slightly higher F1-score compared to LSTM character representations. On the other hand, further using character bigram information leads to increased F1-score over word+char LSTM, but decreased F1-score over word+char CNN. A possible reason is that CNN inherently captures character n-gram information. As a result, we use word+char+bichar LSTM for word-based NER in the remaining experiments, which gives the best development results, and is structurally consistent with the state-of-the-art English NER models in the literature.

Lattice-based NER. Figure 4 shows the F1-score of character-based and lattice-based models against the number of training iterations. We include models that use concatenated character and character bigram embeddings, where bigrams can play a role in disambiguating characters. As can be seen from the figure, lattice word information is useful for improving character-based NER, improving the best development result from 62.5% to 71.6%. On the other hand, the bigram-enhanced lattice model does not lead to further improvements compared with the original lattice model.

Table 5: Main results on OntoNotes.

This is likely because words are better sources of information for character disambiguation compared with bigrams, which are also ambiguous.

As shown in Table 4, the lattice LSTM-CRF model gives a development F1-score of 71.62%, which is significantly[7] higher compared with both the word-based and character-based methods, despite that it does not use character bigrams or word segmentation information. The fact that it significantly outperforms char+softword shows the advantage of lattice word information as compared with segmentor word information.

4.3 Final Results

OntoNotes. The OntoNotes test results are shown in Table 5[8]. With gold-standard segmentation, our word-based methods give competitive results to the state-of-the-art on the dataset (Che et al., 2013; Wang et al., 2013), which leverage bilingual data. This demonstrates that LSTM-CRF is a competitive choice for word-based Chinese NER, as it is for other languages. In addition, the results show

[7]We use a p-value of less than 0.01 from pairwise t-test to indicate statistical significance.

[8]In Table 5, 6 and 7, we use * to denote a model with external labeled data for semi-supervised learning. † means that the model also uses discrete features.

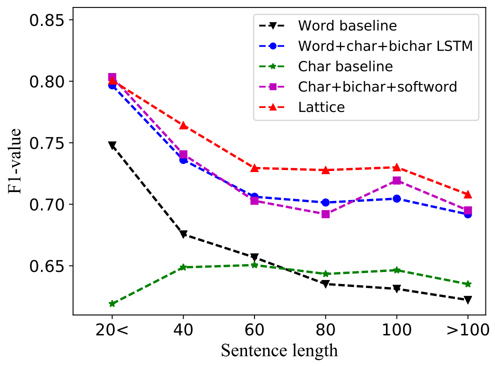

Figure 5: F1 against sentence length.

that our word-based models can serve as highly competitive baselines. With automatic segmentation, the F1-score of word+char+bichar LSTM decreases from 75.77% to 71.70%, showing the influence of segmentation to NER. Consistent with observations on the development set, adding lattice word information leads to an 88.81% $\rightarrow$ 93.18% increasement of F1-score over the character baseline, as compared with 88.81% $\rightarrow$ 91.87% by adding bichar+softword. The lattice model gives significantly the best F1-score on automatic segmentation.

MSRA. Results on the MSRA dataset are shown in Table 6. For this benchmark, no gold-standard segmentation is available on the test set. Our chosen segmentor gives 95.93% accuracy on 5-fold cross-validated training set. The best statistical models on the dataset leverage rich hand-crafted features (Chen et al., 2006a; Zhang et al., 2006; Zhou et al., 2013) and character embedding features (Lu et al., 2016). Dong et al. (2016) exploit neural LSTM-CRF with radical features.

Compared with the existing methods, our word-based and character-based LSTM-CRF models give competitive accuracies. The lattice model significantly outperforms both the best character-based and word-based models ($p < 0.01$), achieving the best result on this standard benchmark.

Weibo/resume. Results on the Weibo NER dataset are shown in Table 7, where NE, NM and Overall denote F1-scores for named entities, nominal entities (excluding named entities) and both, respectively. Gold-standard segmentation is not available for this dataset. Existing state-of-the-art systems include Peng and Dredze (2016) and He and Sun (2017b), who explore rich embedding features, cross-domain and semi-supervised data, some of which are orthogonal to our model[9].

Results on the resume NER test data are shown in Table 8. Consistent with observations on OntoNotes and MSRA, the lattice model significantly outperforms both the word-based mode and the character-based model for Weibo and resume ($p < 0.01$), giving state-of-the-art results.

4.4 Discussion

F1 against sentence length. Figure 5 shows the F1-scores of the baseline models and lattice LSTM-CRF on the OntoNotes dataset. The character-based baseline gives relatively stable F1-scores over different sentence lengths, although the performances are relatively low. The word-based baseline gives substantially higher F1-scores over short sentences, but lower F1-scores over long sentences, which can be because of lower segmentation accuracies over longer sentences. Both word+char+bichar and char+bichar+softword give better performances compared to their respective baselines, showing

[9]The results of Peng and Dredze (2015, 2016) are taken from Peng and Dredze (2017).

Sentence (truncated)	卸下东莞台协会长职务后 After stepping down as president of Taiwan Association in Dongguan.
Correct Segmentation	卸下 东莞 台 协 会长 职务 后 step down, Dongguan, Taiwan, association, president, role, after
Auto Segmentation	卸下 东莞 台 协会长 职务 后 step down, Dongguan, Taiwan, association president, role, after
Lattice words	卸下 下东 东莞 台协会 协会 会长 长职 职务 step down, incorrect word, Dongguan, Taiwan association, association, president, permanent job, role
Word+char+bichar LSTM	卸下 东莞 $_{GPE}$ 台 $_{GPE}$协会长职务后 . . . Dongguan $_{GPE}$ Taiwan $_{GPE}$ . . .
Char+bichar+softword	卸下 东莞台协会 $_{ORG}$长职务后 . . . Taiwan Association in Dongguan $_{ORG}$ . . . (ungrammatical)
Lattice	卸下 东莞台协 $_{ORG}$会长职务后 . . . Taiwan Association in Dongguan $_{ORG}$ . . .

Table 9: Example. Red and green represent incorrect and correct entities, respectively.

that word and character representations are complementary for NER. The accuracy of lattice also decreases as the sentence length increases, which can result from exponentially increasing number of word combinations in lattice. Compared with word+char+bichar and char+bichar+softword, the lattice model shows more robustness to increased sentence lengths, demonstrating the more effective use of word information.

F1 against sentence length. Table 9 shows a case study comparing char+bichar+softword, word+char+bichar and the lattice model. In the example, there is much ambiguity around the named entity "东莞台协 (Taiwan Association in Dongguan)". Word+char+bichar yields the entities "东莞 (Dongguan)" and "台 (Taiwan)" given that "东莞台协 (Taiwan Association in Dongguan)" is not in the segmentor output. Char+bichar+softword recognizes "东莞台协会 (Taiwan Association in Dongguan)", which is valid on its own, but leaves the phrase "长职务后" ungrammatical. In contrast, the lattice model detects the organization name correctly, thanks to the lattice words "东莞 (Dongguan)", "会长 (President)" and "职务 (role)". There are also irrelevant words such as "台协会 (Taiwan Association)" and "下东 (noisy word)" in the lexicon, which did not affect NER results.

Note that both word+char+bichar and lattice use the same source of word information, namely the same pretrained word embedding lexicon. However, word+char+bichar first uses the lexicon in the segmentor, which imposes hard constrains (i.e. fixed words) to its subsequence use in NER. In contrast, lattice LSTM has the freedom of considering all lexicon words.

Entities in lexicon. Table 10 shows the total number of entities and their respective match ratios in the lexicon. The error reductions (ER) of the final lattice model over the best character-based method (i.e. "+bichar+softword") are also shown. It can be seen that error reductions have a correlation between matched entities in the lexicon. In this respect, our automatic lexicon also played to some extent the role of a gazetteer (Ratinov and Roth, 2009; Chiu and Nichols, 2016), but not fully since there is no explicit knowledge in the lexicon which tokens are entities. The ultimate disambiguation power still lies in the lattice encoder and supervised learning.

Dataset	**Split**	**#Entity**	**#Match**	**Ratio** (%)	**ER** (%)
OntoNotes	Train	13.4k	9.5k	71.04	–
	Test	7.7k	6.0k	78.72	7.34
MSRA	Train	74.7k	54.3k	72.62	–
	Test	6.2k	4.6k	73.76	16.11
Weibo (all)	Train	1.9k	1.1k	58.83	–
	Test	414	259	62.56	4.72
resume	Train	13.4k	3.8k	28.55	–
	Test	1.6k	483	29.63	0.89

Table 10: Entities in lexicon.

The quality of the lexicon may affect the accuracy of our NER model since noise words can potentially confuse NER. On the other hand, our lattice model can potentially learn to select more correct words during NER training. We leave the investigation of such influence to future work.

5 Conclusion

We empirically investigated a lattice LSTM-CRF representations for Chinese NER, finding that it gives consistently superior performance compared to word-based and character-based LSTM-CRF across different domains. The lattice method is fully independent of word segmentation, yet more effective in using word information thanks to the freedom of choosing lexicon words in a context for NER disambiguation.

Acknowledgments

Abstract

Neural network based models commonly regard event detection as a word-wise classification task, which suffer from the mismatch problem between words and event triggers, especially in languages without natural word delimiters such as Chinese. In this paper, we propose Nugget Proposal Networks (NPNs), which can solve the word-trigger mismatch problem by directly proposing entire trigger nuggets centered at each character regardless of word boundaries. Specifically, NPNs perform event detection in a character-wise paradigm, where a hybrid representation for each character is first learned to capture both structural and semantic information from both characters and words. Then based on learned representations, trigger nuggets are proposed and categorized by exploiting character compositional structures of Chinese event triggers. Experiments on both ACE2005 and TAC KBP 2017 datasets show that NPNs significantly outperform the state-of-the-art methods.

1 Introduction

Automatic event extraction is a fundamental task of information extraction. Event detection, which aims to identify event triggers of specific types, is a key step of event extraction. For example, from the sentence "*Henry was injured, and then passed away soon*", an event detection system should detect an "*Injure*" event triggered by "*injured*", and a "*Die*" event triggered by "*passed away*".

Recently, neural network methods, which transform event detection into a word-wise classification paradigm, have achieved significant progress in event detection (Nguyen and Grishman, 2015; Chen et al., 2015b; Ghaeini et al., 2016). For instance, a model will detect events in sentence "*Henry was injured*" by successively classifying its three words into *NIL*, *NIL* and *Injure*. By automatically extracting features from raw texts, these methods rely little on prior knowledge and achieved promising results.

Figure 1: Examples of word-trigger mismatch. Slashes in the figure indicate word boundaries.

Unfortunately, word-wise event detection models suffer from the word-trigger mismatch problem, because a number of triggers do not exactly match with a word. Specifically, a trigger can be part of a word or cross multiple words, which is impossible to detect using word-wise models. This problem is more severe in languages without natural word delimiters such as Chinese. Figure 1 (a) shows several examples of part-of-word triggers, where two characters in one word "并购"(acquire and merge) trigger two different events: a "*Merge_Org*" event triggered by "并"(merge) and a "*Transfer_Ownership*" event triggered by "购" (acquire). Figure 1 (b) shows a multi-word trigger, where three words "受"(is), "了" and "伤"(injured) trigger an *Injure* event together. Table 1 shows the statistics of different types of word-trigger match on two standard datasets. We can see that word-trigger mismatch is crucial for Chinese event detection since nearly 25% of triggers in RichERE and 15% of them in ACE2005 dataset don't exactly match with a word.

To resolve the word-trigger mismatch problem,

Match Type	Rich ERE	ACE2005
Exact Match	75.52%	85.39%
Part of Word	19.55%	11.67%
Cross words	4.93%	2.94%

Table 1: Percentages of different types of matches between words and triggers.

this paper proposes *Nugget Proposal Networks (NPNs)*, which identify triggers by modeling character compositional structures of trigger nuggets regardless of word boundaries. Given a sentence, NPNs regard characters as basic detecting units and are able to 1) directly propose the entire potential trigger nugget at each character by exploiting inner compositional structure of triggers; 2) effectively categorize proposed triggers by learning semantic representation from both characters and words. For example, at character "伤"(injured) in Figure 1 (b), NPNs are not only capable to detect it is part of an *Injure* event trigger, but also can propose the entire trigger nugget "受了伤"(is injured). The main idea behind NPNs is that most Chinese triggers have regular character compositional structure (Li et al., 2012). Concretely, most of Chinese event triggers have one central character which can indicate its event type, e.g. "杀"(kill) in "枪杀"(kill by shooting). Furthermore, characters are composed into a trigger based on regular compositional structures, e.g. "manner + verb" for "枪杀"(kill by shooting), "砍杀"(hack to death), as well as "verb + auxiliary + noun" for "受了伤"(is injured) and "挨了打"(beaten).

Figure 2 shows the architecture of NPNs. Given a character in sentence, a hybrid representation learning module is first used to learn its semantic representation from both characters and words in the sentence. This hybrid representation is then fed into two modules: one is *trigger nugget generator*, which proposes the entire potential trigger nugget by exploiting inner character compositional structure. Once a trigger is proposed, an *event type classifier* is applied to determine its event type. Compared with previous methods, NPNs mainly have following advantages:

1) **By directly proposing the entire trigger nugget centered at a character, trigger nugget generator can effectively resolve the word-trigger mismatch problem.** First, using characters as basic units, NPNs will not suffer from the word-trigger mismatch problem of word-wise methods. Furthermore, by modeling and exploiting character compositional structure

of triggers, our model is more error-tolerant to character-wise classification errors than traditional character-based models, as shown in Section 4.4.

2) **By summarizing information from both characters and words, our hybrid representation can effectively capture information for both inner character composition and accurate event categorization.** For example, the inner compositional structure of trigger "枪杀"(kill by shooting) can be learned from the character-level sequence. Besides, characters are often ambiguous, therefore the accurate representations must take their word context into consideration. For example, the representation "杀"(kill) in " 枪杀"(kill by shooting) should be different from its representation in "杀青"(completed).

We conducted experiments on both the ACE2005 and the TAC KBP 2017 Event Nugget Detection datasets. Experiment results show that NPNs can effectively solve the word-mismatch problem, and therefore significantly outperform previous state-of-the-art methods[1].

2 Hybrid Representation Learning

Given a sentence, NPNs will first learn a representation for each character, then the representation is fed into downstream modules. We observe that both characters and words contain rich information for Chinese event detection: characters reveals the inner compositional structure of event

[1]Our source code, including all hyper-parameter settings and pre-trained word embeddings, is openly available at `github.com/sanmusunrise/NPNs`.

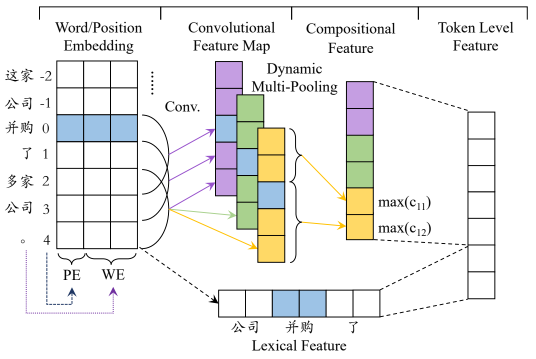

Figure 3: Token-level feature extractor, where PE is relative positional embeddings and WE is word embeddings. The concerning token is “并购”.

triggers (Li et al., 2012), while words can provide more accurate and less ambiguous semantics than characters (Chen et al., 2015a). For example, character-level information can tell us that “枪杀”(kill by shooting) is a trigger constructed of regular pattern “manner + verb”. While word-level sequences can provide more explicit information when we distinguish the semantics of “杀”(kill) in this context with that character in other words like “杀青”(completed).

Therefore, we propose to learn a hybrid representation which can summarize information from both characters and words. Specifically, we first learn two separate character-level and word-level representations using token-level neural networks. Then we design three kinds of hybrid paradigms to obtain the hybrid representation.

2.1 Token-level Representation Learning

Two token-level neural networks are used to extract features from characters and words respectively. The network architecture is similar to DMCNN (Chen et al., 2015b). Figure 3 shows a word-level example. Given n tokens $t_1, t_2, ..., t_n$ in the sentence and the concerning token t_c, let $\mathbf{x}_i$ be the concatenation of the word embedding of t_i and the embedding of t_i's relative position to t_c, a convolutional layer with window size as h is introduced to capture compositional semantics:

$$r_{ij} = \tanh(\mathbf{w}_i \cdot \mathbf{x}_{j:j+h-1} + b_i) \quad (1)$$

Here $\mathbf{x}_{i:i+j}$ refers to the concatenation of embeddings from $\mathbf{x}_i$ to $\mathbf{x}_{i+j}$, $\mathbf{w}_i$ is the i-th filter of the convolutional layer, $b_i \in R$ is a bias term. Then a dynamic multi-pooling layer is applied to preserve important signals of different parts of the sentence:

$$r_i^{left} = \max_{j<c} r_{ij}, \quad r_i^{right} = \max_{j \geq c} r_{ij} \quad (2)$$

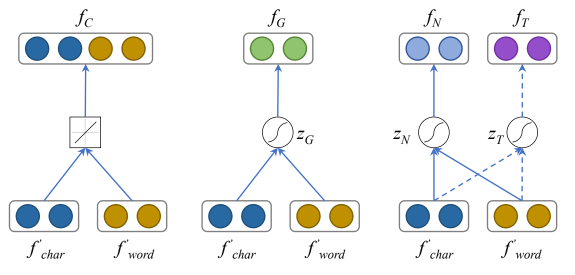

Figure 4: Three hybrid representation learning methods.

After that we concatenate r_i^{left} and r_i^{right} from all feature maps, as well as the embeddings of tokens nearing to t_c to obtain the word-level representation $\mathbf{f_{word}}$ of t_c. Using the same procedure to character sequences, we can obtain the character-level representation $\mathbf{f_{char}}$.

2.2 Hybrid Representation Learning

So far we have both character-level feature representation $\mathbf{f_{char}}$ and word-level feature representation $\mathbf{f_{word}}$. This section describes how we mix them up to obtain a hybrid representation. Before this, we first project $\mathbf{f_{char}}$ and $\mathbf{f_{word}}$ respectively into the same vector space using two dense layers, and we represent the projected d'-dimensional vectors as $\mathbf{f'_{char}}$ and $\mathbf{f'_{word}}$. Then we design three different paradigms to mix them up: Concat Hybrid, General Hybrid and Task-specific Hybrid, as illustrated in Figure 4.

Concat Hybrid is the most simple method, which simply concatenates character-level and word-level representations:

$$\mathbf{f_C} = \mathbf{f'_{char}} \oplus \mathbf{f'_{word}} \quad (3)$$

This simple approach doesn't introduce any additional parameter, but we find it very effective in our experiments.

General Hybrid aims to learn a shared hybrid representation for both trigger nugget proposal and event type classification. Specifically, we design a gated structure to model the information flow from $\mathbf{f'_{char}}$ and $\mathbf{f'_{word}}$ to the general hybrid feature representation $\mathbf{f_G}$:

$$\mathbf{z_G} = s(\mathbf{W_{GH}}\mathbf{f'_{char}} + \mathbf{U_{GH}}\mathbf{f'_{word}} + \mathbf{b_{GH}}) \quad (4)$$

$$\mathbf{f_G} = \mathbf{z_G}\mathbf{f'_{char}} + (\mathbf{1} - \mathbf{z_G})\mathbf{f'_{word}} \quad (5)$$

Here s is the sigmoid function, $\mathbf{W_{GH}} \in R^{d' \times d'}$ and $\mathbf{U_{GH}} \in R^{d' \times d'}$ are weight matrix, and

$\mathbf{b_{GH}} \in R^{d'}$ is the bias term. $\mathbf{z_G}$ is a d'-dimensional vector whose values represent the contribution of $\mathbf{f}'_{\mathbf{char}}$ and $\mathbf{f}'_{\mathbf{word}}$ to the final hybrid representation, which models the importance of individual features in the given contexts.

As two downstream modules of NPNs have individual functions, they might hold different requirements to the input features. Intuitively, trigger nugget generator depends more on fine-grained character-level features. In contrast, word-level features might play more important roles in the event type classifier since it is enriched with more explicit semantics. As a result, a unified representation may be insufficient and it is better to learn task-specific hybrid representations.

Task-specific Hybrid is proposed to tackle this problem, where two gates are introduced for two modules respectively. Formally, we learn one representation for the trigger nugget generator and one for event type classifier as:

$$\mathbf{z_N} = s(\mathbf{W_N f'_{char}} + \mathbf{U_N f'_{word}} + \mathbf{b_N}) \tag{6}$$

$$\mathbf{z_T} = s(\mathbf{W_T f'_{char}} + \mathbf{U_T f'_{word}} + \mathbf{b_T}) \tag{7}$$

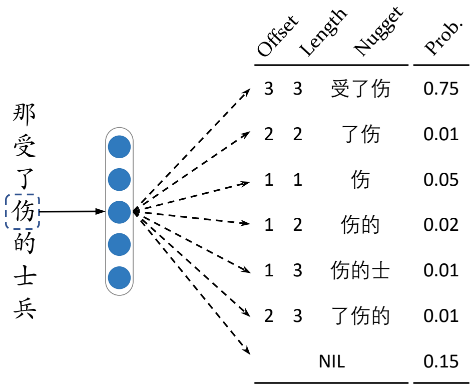
$$\mathbf{f_N} = \mathbf{z_N f'_{char}} + (\mathbf{1} - \mathbf{z_N})\mathbf{f'_{word}} \tag{8}$$

$$\mathbf{f_T} = \mathbf{z_T f'_{char}} + (\mathbf{1} - \mathbf{z_T})\mathbf{f'_{word}} \tag{9}$$

Here $\mathbf{f_N}$ and $\mathbf{f_T}$ are hybrid features for the trigger nugget generator and the event type classifier respectively and the meanings of other parameters are similar to the ones in Equation (4) and (5).

3 Nugget Proposal Networks

Given the hybrid representation of a character in a sentence, the goal of NPNs is to propose the potential trigger nugget, as well as to identify its corresponding event type at each character. For example in Figure 5, centered at the character "伤"(injured), NPNs need to propose "受了伤"(is injured) as the entire trigger nugget and identify its event type as "*Injure*". For this, NPNs are equipped with two modules: one is called *trigger nugget generator*, which is used to propose the potential trigger nugget containing the concerning character by exploiting character compositional structures of triggers. Another module, named as *event type classifier*, is used to determine the specific type of this event once a trigger nugget is detected.



Offset	Length	Nugget	Prob.
3	3	受了伤	0.75
2	2	了伤	0.01
1	1	伤	0.05
1	2	伤的	0.02
1	3	伤的士	0.01
2	3	了伤的	0.01
		NIL	0.15

Figure 5: Our trigger nugget generator. For each character, there are 7 candidate nuggets including "NIL" if the maximum length of nuggets is 3.

3.1 Trigger Nugget Generator

Chinese event triggers have regular inner compositional structures, e.g. "受了伤"(is injured) and "挨了打"(is beaten) have the same "verb + auxiliary + noun" structure, and "枪杀"(kill by shooting) and "射杀"(kill by shooting) share the same "manner + verb" pattern. If a model is able to learn this compositional structure regularity, it can effectively detect trigger nuggets at characters. Recent advances have presented that convolutional neural networks are effective at capturing and predicting the region information in object detection (Ren et al., 2015) and semantic segmentation (He et al., 2017), which reveals the strong ability of CNNs to learning spatial and positional information. Inspired by this, we propose a neural network based trigger nugget generator, which is expected to not only be able to predict whether a character belongs to a trigger nugget, but also can point out the entire trigger nugget.

Figure 5 is an illustration of our trigger nugget generator. Hybrid representation $\mathbf{f_N}$ for concerning character is first learned as described in Section 2, which is then fed into a fully-connected layer to compute the scores for different possible trigger nuggets containing that character:

$$\mathbf{O^G} = \mathbf{W_G f_N} + \mathbf{b_G} \tag{10}$$

where $\mathbf{O^G} \in R^{d^N}$ and d^N is the amount of candidate nuggets plus one *"NIL"* label indicating this character doesn't belong to an trigger. Given the maximum length L of trigger nuggets, there are $\frac{L^2+L}{2}$ possible nuggets containing a specific character, as we shown in Figure 5. In both ACE and Rich ERE corpus, more than 98.5% triggers contain no more than 3 characters, so for a specific character we consider 6 candidate nuggets and thus $d^N = 7$. We expect NPNs to give a high score to a nugget if it follows a regular compositional structure of triggers. For example in Figure 5, "受了伤"(is injured) follows the compositional pattern of "verb + auxiliary + noun", therefore a high score is given to the category where "伤" is at the 3rd place of a nugget with a length of 3. By contrast "了伤" does not match a regular pattern, then the score for "伤" at the 2nd place of a nugget with a length of 2 will be low in this context.

After obtaining the scores for each nugget, a softmax layer is applied to normalize the scores:

$$P(y_i^G|x;\theta) = \frac{e^{O_i^G}}{\sum_{j=1}^{d^N} e^{O_j^G}} \tag{11}$$

where O_i^G is the i-the element in $\mathbf{O^G}$ and θ is the model parameters.

3.2 Event Type Classifier

The event type classifier aims to identify whether the given character in the given context will exhibit an event type. Once we detect an event trigger nugget at one character, the hybrid feature $\mathbf{f_T}$ extracted previously is then feed into a neural network classifier, which further determines the specific type of this trigger. Following previous work (Chen and Ng, 2012), our event type classifier directly classifies nuggets into event subtypes, while ignores the hierarchy between event types.

Formally, given the hybrid feature vector $\mathbf{f_T}$ of input x, a fully-connected layer is applied to compute its scores assigned to each event subtype:

$$\mathbf{O^C} = \mathbf{W_C}\mathbf{f_T} + \mathbf{b_C} \tag{12}$$

where $\mathbf{O^C} \in R^{d^T}$ and d^T is the number of event subtypes. Then similar to the trigger nugget generator, a softmax layer is introduced:

$$P(y_i^C|x;\theta) = \frac{e^{O_i^C}}{\sum_{j=1}^{d^T} e^{O_j^C}} \tag{13}$$

where O_i^C is the i-th element in $\mathbf{O^C}$, representing the score for i-th subtype.

3.3 Dealing with Conflicts between Proposed Nuggets

While NPNs directly propose nugget at each character, there might exists conflicts between proposed nuggets at different characters. Generally speaking, there are two types of conflicts: (i) NIL/trigger conflict, which means NPNs propose a trigger nugget at one character, but classify other character in that nugget into "NIL" (e.g., proposing nugget "受了伤"(is injured) at "受" and output "NIL" at "了"); (ii) overlapped conflict, i.e., proposing two overlapped nuggets (e.g., proposing nugget "受了伤"(is injured) at "受" and nugget "伤" at "伤"). But we find that overlapped conflict is very rare because NPNs is very effective in capturing positional knowledge and the main challenge of event detection is to distinguish triggers from non-triggers.

Therefore in this paper, we employ a redundant prediction strategy by simply adding all proposed nuggets into results and ignoring "NIL" predictions. For example, if NPNs successively propose "受了伤"(is injured), "NIL", " 伤" from "受了伤", then we will ignore the "NIL" and add both two other nuggets into result. We found such a redundant prediction paradigm is an advantage of our model. Compared with conventional character-based models, even NPNs mistakenly classified character "了" into "NIL", we can still accurately detect trigger "受了伤"(is injured) if we can predict the entire nugget at character "受" or "伤". This redundant prediction makes our model more error-tolerant to character-wise classification errors, as verified in Section 4.4.

3.4 Model Learning

To train the trigger nugget generator, we regard all characters included in trigger nuggets as positive training instances, and randomly sample characters not in any trigger as negative instances and label them as "NIL". Suppose we have T^G training examples in $S^G = \{(x_k, y_k^G)|k = 1, 2, ...T^G\}$ to train the trigger nugget generator, as well as T^C examples in $S^C = \{(x_k, y_k^C)|k = 1, 2, ...T^C\}$ to train the event type classifier, we can define the loss function $\mathcal{L}(\theta)$ as follow:

$$\begin{aligned}\mathcal{L}(\theta) = &- \sum_{(x_k, y_k^G)\in S^G} \log P(y_k^G|x_k;\theta) \\ &- \sum_{(x_k, y_k^C)\in S^C} \log P(y_k^C|x_k;\theta)\end{aligned} \tag{14}$$

where θ is parameters in NPNs. Since all modules in NPNs are differentiable, any gradient-based algorithms can be applied to minimize $\mathcal{L}(\theta)$.

4 Experiments

4.1 Data Preparation and Evaluation

We conducted experiments on two standard datasets: ACE2005 and TAC KBP 2017 Even-

Table 2: Experiment results on ACE2005 and KBPEval2017. * indicates the result adapted from the original paper. For KBPEval2017, "Trigger Identification" corresponds to the "Span" metric and "Trigger Classification" corresponds to the "Type" metric reported in official evaluation.

t Nugget Detection Evaluation (KBPEval2017) datasets. For ACE2005 (LDC2006T06), we used the same setup as Chen and Ji (2009), Feng et al. (2016) and Zeng et al. (2016), in which 569/64/64 documents are used as training/development/test set. For KBPEval2017, we evaluated our model on the 2017 Chinese evaluation dataset(LDC2017E55), using previous RichERE annotated Chinese datasets (LDC2015E78, LDC2015E105, LDC2015E112, and LDC2017E02) as the training set except 20 randomly sampled documents reserved as development set. Finally, there were 506/20/167 documents for training/development/test set. We used Stanford CoreNLP toolkit (Manning et al., 2014) to preprocess all documents for sentence splitting and word segmentation. Adadelta update rule (Zeiler, 2012) is applied for optimization.

Models are evaluated by micro-averaged Precision(P), Recall(R) and F1-score. For ACE2005, we followed Chen and Ji (2009) to compute the above measures. For KBPEval2017, we used the official evaluation toolkit [2] to obtain these metrics.

4.2 Baselines

Three groups of baselines were compared:

Character-based NN models. This group of methods solve Chinese Event Detection in a character-level sequential labeling paradigm, which include Convolutional Bi-LSTM model (C-BiLSTM) proposed by Zeng et al. (2016), Forward-backward Recurrent Neural Networks (FBRNN) by Ghaeini et al. (2016), and a character-level DMCNN model with a classifier using IOB encoding (Sang and Veenstra, 1999).

Word-based NN models. This group of methods directly adopt currently NN models into word-level sequences, which includes word-based FBRNN, word-based DMCNN and Hybrid Neural Network proposed by Feng et al. (2016), which incorporates CNN with Bi-LSTM and achieves the SOTA NN based result on ACE2005. To alleviate OOV problem stemming from word-trigger mismatch, we also adopt errata table replacing (Han et al., 2017), which introduce an errata table extracted from the training data and replace those words that part of whom was a trigger nugget with that trigger directly.

Feature-enriched Methods. This group of methods includes Rich-C (Chen and Ng, 2012) and CLUZH (KBP2017 Best) (Makarov and Clematide, 2017). Rich-C developed several handcraft Chinese-specific features, which is one of the state-of-the-art on ACE2005. CLUZH incorporated many heuristic features into LSTM encoder, which achieved the best performance in TAC KBP2017 evaluation.

4.3 Overall Results

Table 2 shows the results on ACE2005 and KBPEval2017. From this table, we can see that:

1) **NPNs steadily outperform all baselines significantly.** Compared with baselines, NPN(Task-specific) gains at least 1.6 (2.5%) and 1.5 (3.0%) F1-score improvements on trigger classification task on ACE2005 and KBPEval2017 respectively.

[2] github.com/hunterhector/EvmEval/tarball/master

2) **By exploiting compositional structures of triggers, our trigger nugget generator can effectively resolve the word-trigger mismatch problem.** As shown in Table 2, NPN(Task-specific) achieved significant F1-score improvements on trigger identification task on both datasets. It is notable that our method achieved a remarkable high recall on both datasets, which indicates that NPNs do detect a number of triggers which previous methods can not identify.

3) **By summarizing information from both characters and words, the hybrid representation learning is effective for event detection.** Comparing with corresponding character-based methods[3], word-based methods achieved 2 to 3 F1-score improvements, which indicates that words can provide additional information for event detection. By combining character-level and word-level features, NPNs are able to perform character-based event detection meanwhile take word-level knowledge into consideration too.

4.4 Comparing with Conventional Character-based Methods

To further investigate the effects of the trigger nugget generator, we compared NPNs with other character-based methods and analyzed behaviors of them. We conducted a supplementary experiment by replacing our trigger nugget generator and event type classifier with an IOB encoding labeling layer. We call this system NPN(IOB). Besides, we also compared the result with F-BRNN(Char), which proposes candidate trigger nuggets according to an external trigger table.

Model	P	R	F1
FBRNN(Char)	57.97	36.92	45.11
NPN(IOB)	60.96	47.39	53.32
NPN(Task-specific)	**64.32**	**53.16**	**58.21**

Table 3: Performances of character-based methods on KBP2017Eval Trigger Identification task.

Table 3 shows the results on KBP2017Eval. We can see that NPN(Task-specific) outperforms other methods significantly. We believe this is because:

1) FBRNN(Char) only regards tokens in the candidate table as potential trigger nuggets, which limits the choice of possible trigger nuggets and results in a very low recall rate.

2) To accurately identify a trigger, NPN(IOB) and conventional character-based methods require all characters in a trigger being classified correctly, which is very challenging (Zeng et al., 2016): many characters appear in a trigger nugget will not serve as a part of a trigger nugget in the majority of contexts, thus they will be easily classified into “NIL”. For the first example in Table 5, NPN(IOB) was unable to fully recognize the trigger nugget “贺电”(congratulatory message) because character “贺”(congratulatory) doesn’t often serve as part of ”PhoneWrite” trigger. In fact, “贺” serves as a “NIL” in the majority of similar contexts, e.g., “贺喜”(congratulation) and “祝贺”(congratulation).

3) NPNs are able to handle above problems. First, NPNs doesn’t rely on candidate tables to generate potential triggers, which guarantees a good generalization ability. Second, NPNs propose the entire trigger nugget at each character, such a redundant prediction paradigm makes NPNs more error-tolerant to character-level errors. For example, even might mistakenly classify “贺” into “NIL”, NPNs can still identify the correct nugget “贺电” at character “电” because “电” is a common part of “PhoneWrite” event trigger.

4.5 Influence of Word-Trigger Mismatch

This subsection investigates the effects of resolving the word-trigger mismatch problem using different methods. According to different types of word-trigger match, we split KBP2017Eval test set into three parts: Exact, Part-of-Word, Cross-Words, which are as defined in Table 1.

Model	Exact	Part	Cross
NPN(IOB)	48.65	29.13	8.54
DMCNN(Word)	57.36	23.28	0.00
- w/o Errata replacing	59.03	0.00	0.00
NPN(Task-specific)	56.47	42.66	26.58

Table 4: Recall rates on three word-trigger match splits on KBP2017Eval Trigger Identification task.

Table 4 shows the recall of different methods on each split. NPN(Task-specific) significantly outperform other baselines when trigger-word mismatch exists. This verified that NPNs can resolve different cases of word-trigger mismatch problems robustly, meanwhile retain high performance on exact match cases. In contrast, NPN(IOB) can not

[3]C-BiLSTM and HNN are similar methods to some extent. They both use a hybrid representation from CNN and BiLSTM encoders.

Sentence	DMCNN	NPN(IOB)	NPN	Correct
贺电/全文/如下,... Full **congratulatory message**:...	(贺电,PhoneWrite)	(电,PhoneWrite)	(贺电,PhoneWrite)	(贺电,PhoneWrite)
死伤/的/所有/士兵... all soldiers **died and injured**...	None	(死,Die) (伤,Injure)	(死,Die) (伤,Injure)	(死,Die) (伤,Injure)

Table 5: System prediction examples. (X,Y) indicates a trigger nugget X is annotated with event type Y.

exactly detect boundaries of trigger nuggets, thus has a low recall on all splits. Conventional DMCNN regards words as potential triggers, which means it can only identify triggers that exactly match with words. As the second example in Table 5, word "死伤"(dead or injured) as a whole has never been annotated as a trigger, so DMCNN is unable to recognize it at all. Errata replacing can only solve some of the part-of-word mismatch problem, but it can not handle the cases where one word contains multiple triggers(e.g., "死伤" in Table 5) and the cases that a trigger crosses multiple words.

4.6 Effects of Hybrid Representation

This section analyzed the effect of feature hybrid in NPNs. First, from Table 2, we can see that Task-specific Hybrid method achieved the best performance in both datasets. Surprisingly, simple Concat Hybrid outperforms the General Hybrid approach. We believe this is because the trigger nugget generator and the event type classifier rely on different information, and therefore using one unified gate is not enough. And Task-specific Hybrid uses two different task-specific gates which can satisfy both sides, thus resulting in the best overall performance.

Furthermore, to investigate the necessary of using hybrid features, an auxiliary experiment, called NPN(Char), was conducted by removing word-level features from NPNs. Also, we compared with the model removing character-level features, which is the original DMCNN(Word).

Model	P	R	F1
DMCNN(Word)	54.81	46.84	50.51
NPN(Char)	56.19	43.88	49.28
NPN(Task-specific)	**57.63**	**47.63**	**52.15**

Table 6: Results of using different representation on Trigger Classification task on KBP2017Eval.

Table 6 shows the experiment results. We can see that neither character-level or word-level representation can achieve competitive results with the NPNs. This verified the necessity of hybrid representation. Besides, we can see that NPN(Char) outperforms other character-level methods in Table 2, which further confirms that our trigger nugget generator is still effective even only using character-level information.

5 Related Work

Event detection is an important task in information extraction and has attracted many attentions. Traditional methods (Ji and Grishman, 2008; Patwardhan and Riloff, 2009; Liao et al., 2010; McClosky et al., 2011; Hong et al., 2011; Huang and Riloff, 2012; Li et al., 2013a,b, 2014) rely heavily on hand-craft features, which are hard to transfer among languages and annotation standards.

Recently, deep learning methods, which automatically extract high-level features and perform token-level classification with neural networks (Chen et al., 2015b; Nguyen and Grishman, 2015), have achieved significant progress. Some improvements have been made by jointly predicting triggers and arguments (Nguyen et al., 2016) and introducing more complicated architectures to capture larger scale of contexts (Feng et al., 2016; Nguyen and Grishman, 2016; Ghaeini et al., 2016). These methods have achieved promising results in English event detection.

Unfortunately, the word-trigger mismatch problem significantly undermines the performance of word-level models in Chinese event detection (Chen and Ji, 2009). To resolve this problem, Chen and Ji (2009) proposed a feature-driven BIO tagging methods at character-level sequences. Qin et al. (2010) introduced a method which can automatically expand candidate Chinese trigger set. While Li et al. (2012) and Li and Zhou (2012) defined manually character compositional patterns for Chinese event triggers. However, their methods rely on hand-crafted features and patterns, which make them difficult to be integrated into recent Deep Learning models.

Recent advances have shown that neural networks can effectively capture spatial and positional information from raw inputs (Ren et al., 2015; He et al., 2017; Wang and Jiang, 2017).

This paper designs Nugget Proposal Networks to capture character compositional structure of event triggers, which is more robust and more effective than previous hand-crafted patterns or character-level sequential labeling methods.

6 Conclusions and Future Work

This paper proposes Nugget Proposal Networks for Chinese event detection, which can effectively resolve the word-trigger mismatch problem by modeling and exploiting character compositional structure of Chinese event triggers, using hybrid representation which can summarize information from both characters and words. Experiment results have shown that our method significantly outperforms conventional methods.

Because the mismatch between words and extraction units is a common problem in information extraction, we believe our method can also be applied to many other languages and tasks for exploiting inner composition structure during extraction, such as Named Entity Recognition.

Abstract

Relation Schema Induction (RSI) is the problem of identifying type signatures of arguments of relations from unlabeled text. Most of the previous work in this area have focused only on *binary* RSI, i.e., inducing only the subject and object type signatures per relation. However, in practice, many relations are *high-order*, i.e., they have more than two arguments and inducing type signatures of all arguments is necessary. For example, in the sports domain, inducing a schema *win(WinningPlayer, OpponentPlayer, Tournament, Location)* is more informative than inducing just *win(WinningPlayer, OpponentPlayer)*. We refer to this problem as Higher-order Relation Schema Induction (HRSI). In this paper, we propose Tensor Factorization with Back-off and Aggregation (TFBA), a novel framework for the HRSI problem. To the best of our knowledge, this is the first attempt at inducing higher-order relation schemata from unlabeled text. Using the experimental analysis on three real world datasets, we show how TFBA helps in dealing with sparsity and induce higher order schemata.

1 Introduction

Building Knowledge Graphs (KGs) out of unstructured data is an area of active research. Research in this has resulted in the construction of several large scale KGs, such as NELL (Mitchell et al., 2015), Google Knowledge Vault (Dong et al., 2014) and YAGO (Suchanek et al., 2007). These KGs consist of millions of entities and beliefs involving those entities. Such KG construction methods are schema-guided as they require the list of input relations and their schemata (e.g., *playerPlaysSport(Player, Sport)*). In other words, knowledge of schemata is an important first step towards building such KGs.

While beliefs in such KGs are usually binary (i.e., involving two entities), many beliefs of interest go beyond two entities. For example, in the sports domain, one may be interested in beliefs of the form *win(Roger Federer, Nadal, Wimbledon, London)*, which is an instance of the high-order (or n-ary) relation *win* whose schema is given by *win(WinningPlayer, OpponentPlayer, Tournament, Location)*. We refer to the problem of inducing such relation schemata involving multiple arguments as Higher-order Relation Schema Induction (HRSI). In spite of its importance, HRSI is mostly unexplored.

Recently, tensor factorization-based methods have been proposed for *binary* relation schema induction (Nimishakavi et al., 2016), with gains in both speed and accuracy over previously proposed generative models. To the best of our knowledge, tensor factorization methods have not been used for HRSI. We address this gap in this paper.

Due to data sparsity, straightforward adaptation of tensor factorization from (Nimishakavi et al., 2016) to HRSI is not feasible, as we shall see in Section 3.1. We overcome this challenge in this paper, and make the following contributions.

- We propose Tensor Factorization with Back-off and Aggregation (TFBA), a novel tensor factorization-based method for Higher-order RSI (HRSI). In order to overcome data sparsity, TFBA *backs-off* and jointly factorizes multiple lower-order tensors derived from an extremely sparse higher-order tensor.

- As an aggregation step, we propose a constrained clique mining step which constructs the higher-order schemata from multiple binary schemata.

- Through experiments on multiple real-world datasets, we show the effectiveness of TFBA for HRSI.

Source code of TFBA is available at `https://github.com/madhavcsa/TFBA`.

The remainder of the paper is organized as follows. We discuss related work in Section 2. In Section 3.1, we first motivate why a back-off strategy is needed for HRSI, rather than factorizing the higher-order tensor. Further, we discuss the proposed TFBA framework in Section 3.2. In Section 4, we demonstrate the effectiveness of the proposed approach using multiple real world datasets. We conclude with a brief summary in Section 5.

2 Related Work

In this section, we discuss related works in two broad areas: schema induction, and tensor and matrix factorizations.

Schema Induction: Most work on inducing schemata for relations has been in the binary setting (Mohamed et al., 2011; Movshovitz-Attias and Cohen, 2015; Nimishakavi et al., 2016). McDonald et al. (2005) and Peng et al. (2017) extract `n`-ary relations from Biomedical documents, but do not induce the schema, i.e., type signature of the `n`-ary relations. There has been significant amount of work on Semantic Role Labeling (Lang and Lapata, 2011; Titov and Khoddam, 2015; Roth and Lapata, 2016), which can be considered as `n`-ary relation extraction. However, we are interested in inducing the schemata, i.e., the type signature of these relations. Event Schema Induction is the problem of inducing schemata for events in the corpus (Balasubramanian et al., 2013; Chambers, 2013; Nguyen et al., 2015). Recently, a model for event representations is proposed in (Weber et al., 2018).

Cheung et al. (2013) propose a probabilistic model for inducing frames from text. Their notion of frame is closer to that of scripts (Schank and Abelson, 1977). Script learning is the process of automatically inferring sequence of events from text (Mooney and DeJong, 1985). There is a fair amount of recent work in statistical script learning (Pichotta and Mooney, 2016), (Pichotta and Mooney, 2014). While script learning deals with the sequence of events, we try to find the schemata of relations at a corpus level. Ferraro and Durme (2016) propose a unified Bayesian model for scripts, frames and events. Their model tries to capture all levels of Minsky Frame structure (Minsky, 1974), however we work with the surface semantic frames.

Tensor and Matrix Factorizations: Matrix factorization and joint tensor-matrix factorizations have been used for the problem of predicting links in the Universal Schema setting (Riedel et al., 2013; Singh et al., 2015). Chen et al. (2015) use matrix factorizations for the problem of finding semantic slots for unsupervised spoken language understanding. Tensor factorization methods are also used in factorizing knowledge graphs (Chang et al., 2014; Nickel et al., 2012). Joint matrix and tensor factorization frameworks, where the matrix provides additional information, is proposed in (Acar et al., 2013) and (Wang et al., 2015). These models are based on PARAFAC (Harshman, 1970), a tensor factorization model which approximates the given tensor as a sum of rank-1 tensors. A boolean Tucker decomposition for discovering facts is proposed in (Erdos and Miettinen, 2013). In this paper, we use a modified version (Tucker2) of Tucker decomposition (Tucker, 1963).

RESCAL (Nickel et al., 2011) is a simplified Tucker model suitable for relational learning. Recently, SICTF (Nimishakavi et al., 2016), a variant of RESCAL with side information, is used for the problem of schema induction for binary relations. SICTF cannot be directly used to induce higher order schemata, as the higher-order tensors involved in inducing such schemata tend to be extremely sparse. TFBA overcomes these challenges to induce higher-order relation schemata by performing Non-Negative Tucker-style factorization of sparse tensor while utilizing a back-off strategy, as explained in the next section.

3 Higher Order Relation Schema Induction using Back-off Factorization

In this section, we start by discussing the approach of factorizing a higher-order tensor and provide the motivation for back-off strategy. Next, we discuss the proposed TFBA approach in detail. Please refer to Table 1 for notations used in this paper.

Notation	Definition
$\mathbb{R}_+$	Set of non-negative reals.
$\boldsymbol{\mathcal{X}} \in \mathbb{R}_+^{n_1 \times n_2 \times \ldots \times n_N}$	N^{th} -order non-negative tensor.
$\boldsymbol{\mathcal{X}}_{(i)}$	mode-i matricization of tensor $\boldsymbol{\mathcal{X}}$. Please see (Kolda and Bader, 2009) for details.
$\mathbf{A} \in \mathbb{R}_+^{n \times r}$	Non-negative matrix of order $n \times r$.
$*$	Hadamard product: $(\mathbf{A} * \mathbf{B})_{i,j} = \mathbf{A}_{i,j} \times \mathbf{B}_{i,j}$.

Table 1: Notations used in the paper.

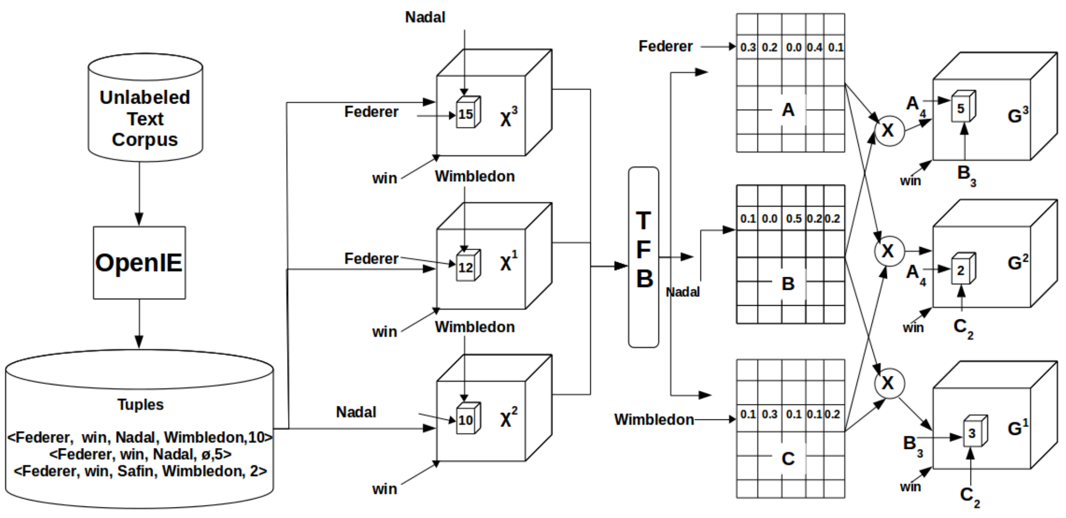

Figure 1: **Overview of Step 1 of TFBA**. Rather than factorizing the higher-order tensor $\boldsymbol{\mathcal{X}}$, TFBA performs joint Tucker decomposition of multiple 3-mode tensors, $\boldsymbol{\mathcal{X}}^1$, $\boldsymbol{\mathcal{X}}^2$, and $\boldsymbol{\mathcal{X}}^3$, derived out of $\boldsymbol{\mathcal{X}}$. This joint factorization is performed using shared latent factors **A**, **B**, and **C**. This results in binary schemata, each of which is stored as a cell in one of the core tensors $\mathcal{G}^1$, $\mathcal{G}^2$, and $\mathcal{G}^3$. Please see Section 3.2.1 for details.

3.1 Factorizing a Higher-order Tensor

Given a text corpus, we use OpenIEv5 (Mausam, 2016) to extract tuples. Consider the following sentence "*Federer won against Nadal at Wimbledon.*". Given this sentence, OpenIE extracts the 4-tuple *(Federer, won, against Nadal, at Wimbledon)*. We lemmatize the relations in the tuples and only consider the noun phrases as arguments. Let $\mathbb{T}$ represent the set of these 4-tuples. We can construct a 4-order tensor $\boldsymbol{\mathcal{X}} \in \mathbb{R}_+^{n_1 \times n_2 \times n_3 \times m}$ from $\mathbb{T}$. Here, n_1 is the number of *subject* noun phrases (NPs), n_2 is the number of *object* NPs, n_3 is the number of *other* NPs, and m is the number of relations in $\mathbb{T}$. Values in the tensor correspond to the frequency of the tuples. In case of 5-tuples of the form *(subject, relation, object, other-1, other-2)*, we split the 5-tuples into two 4-tuples of the form *(subject, relation, object, other-1)* and *(subject, relation, object, other-2)* and frequency of these 4-tuples is considered to be same as the original 5-tuple. Factorizing the tensor $\boldsymbol{\mathcal{X}}$ results in discovering latent categories of NPs, which help in inducing the schemata. We propose the following approach to factorize $\boldsymbol{\mathcal{X}}$.

$$\min_{\mathcal{G},\mathbf{A},\mathbf{B},\mathbf{C}} \|\boldsymbol{\mathcal{X}} - \mathcal{G} \times_1 \mathbf{A} \times_2 \mathbf{B} \times_3 \mathbf{C} \times_4 \mathbf{I}\|_F^2$$
$$+ \lambda_a \|\mathbf{A}\|_F^2 + \lambda_b \|\mathbf{B}\|_F^2 + \lambda_c \|\mathbf{C}\|_F^2 ,$$

where,

$$\mathbf{A} \in \mathbb{R}_+^{n_1 \times r_1}, \mathbf{B} \in \mathbb{R}_+^{n_2 \times r_2}, \mathbf{C} \in \mathbb{R}_+^{n_3 \times r_3},$$
$$\mathcal{G} \in \mathbb{R}_+^{r_1 \times r_2 \times r_3 \times m}, \lambda_a \geq 0, \lambda_b \geq 0 \text{ and } \lambda_c \geq 0.$$

Here, **I** is the identity matrix. Non-negative updates for the variables can be obtained following (Lee and Seung, 2000). Similar to (Nimishakavi et al., 2016), schemata induced will be of the form *relation* $\langle \mathbf{A}_i, \mathbf{B}_j, \mathbf{C}_k \rangle$. Here, $\mathbf{P}_i$ represents the i^{th} column of a matrix **P**. **A** is the embedding matrix of subject NPs in $\mathbb{T}$ (i.e., mode-1 of $\boldsymbol{\mathcal{X}}$), r_1 is the embedding rank in mode-1 which is the number of latent categories of subject NPs. Similarly, **B** and

Induced Schema: Win <A4, B3, C2>

Figure 2: **Overview of Step 2 of TFBA**. Induction of higher-order schemata from the tri-partite graph formed from the columns of matrices A, B, and C. Triangles in this graph (solid) represent a 3-ary schema, n-ary schemata for n $>$ 3 can be induced from the 3-ary schemata. Please refer to Section 3.2.2 for details.

$\mathbf{C}$ are the embedding matrices of object NPs and other NPs respectively. r_2 and r_3 are the number of latent categories of object NPs and other NPs respectively. $\boldsymbol{\mathcal{G}}$ is the core tensor. λ_a, λ_b and λ_c are the regularization weights.

However, the 4-order tensors are heavily sparse for all the datasets we consider in this work. The sparsity ratio of this 4-order tensor for all the datasets is of the order 1e-7. As a result of the extreme sparsity, this approach fails to learn any schemata. Therefore, we propose a more successful back-off strategy for higher-order RSI in the next section.

3.2 TFBA: Proposed Framework

To alleviate the problem of sparsity, we construct three tensors $\boldsymbol{\mathcal{X}}^3$, $\boldsymbol{\mathcal{X}}^2$, and $\boldsymbol{\mathcal{X}}^1$ from $\mathbb{T}$ as follows:

- $\boldsymbol{\mathcal{X}}^3 \in \mathbb{R}_+^{n_1 \times n_2 \times m}$ is constructed out of the tuples in $\mathbb{T}$ by dropping the *other* argument and aggregating resulting tuples, i.e., $\boldsymbol{\mathcal{X}}^3_{i,j,p} = \sum_{k=1}^{n_3} \boldsymbol{\mathcal{X}}_{i,j,k,p}$. For example, 4-tuples ⟨*(Federer, Win, Nadal, Wimbledon), 10*⟩ and ⟨*(Federer, Win, Nadal, Australian Open), 5*⟩ will be aggregated to form a triple ⟨*(Federer, Win, Nadal), 15*⟩.
- $\boldsymbol{\mathcal{X}}^2 \in \mathbb{R}_+^{n_1 \times n_3 \times m}$ is constructed out of the tuples in $\mathbb{T}$ by dropping the *object* argument and aggregating resulting tuples i.e., $\boldsymbol{\mathcal{X}}^2_{i,j,p} = \sum_{k=1}^{n_2} \boldsymbol{\mathcal{X}}_{i,k,j,p}$.
- $\boldsymbol{\mathcal{X}}^1 \in \mathbb{R}_+^{n_2 \times n_3 \times m}$ constructed out of the tuples in $\mathbb{T}$ by dropping the *subject* argument and aggregating resulting tuples i.e., $\boldsymbol{\mathcal{X}}^1_{i,j,p} = \sum_{k=1}^{n_1} \boldsymbol{\mathcal{X}}_{k,i,j,p}$.

The proposed framework TFBA for inducing higher order schemata involves the following two steps.

- **Step 1**: In this step, TFBA factorizes multiple lower-order overlapping tensors, $\boldsymbol{\mathcal{X}}^1$, $\boldsymbol{\mathcal{X}}^2$, and $\boldsymbol{\mathcal{X}}^3$, derived from $\boldsymbol{\mathcal{X}}$ to induce binary schemata. This step is illustrated in Figure 1 and we discuss details in Section 3.2.1.
- **Step 2**: In this step, TFBA connects multiple binary schemata identified above to induce higher-order schemata. The method accomplishes this by solving a constrained clique problem. This step is illustrated in Figure 2 and we discuss the details in Section 3.2.2.

3.2.1 Step 1: Back-off Tensor Factorization

A schematic overview of this step is shown in Figure 1. TFBA first preprocesses the corpus and extracts OpenIE tuple set $\mathbb{T}$ out of it. The 4-mode tensor $\boldsymbol{\mathcal{X}}$ is constructed out of $\mathbb{T}$. Instead of performing factorization of the higher-order tensor $\boldsymbol{\mathcal{X}}$ as in Section 3.1, TFBA creates three tensors out of $\boldsymbol{\mathcal{X}}$: $\boldsymbol{\mathcal{X}}^1_{n_2 \times n_3 \times m}$, $\boldsymbol{\mathcal{X}}^2_{n_1 \times n_3 \times m}$ and $\boldsymbol{\mathcal{X}}^3_{n_1 \times n_2 \times m}$.

TFBA performs a coupled non-negative Tucker factorization of the input tensors $\boldsymbol{\mathcal{X}}^1$, $\boldsymbol{\mathcal{X}}^2$ and $\boldsymbol{\mathcal{X}}^3$ by solving the following optimization problem.

$$\begin{aligned}\min_{\substack{\mathbf{A},\mathbf{B},\mathbf{C}\\ \boldsymbol{\mathcal{G}}^1,\boldsymbol{\mathcal{G}}^2,\boldsymbol{\mathcal{G}}^3}} \; & f(\boldsymbol{\mathcal{X}}^3, \boldsymbol{\mathcal{G}}^3, \mathbf{A}, \mathbf{B}) + f(\boldsymbol{\mathcal{X}}^2, \boldsymbol{\mathcal{G}}^2, \mathbf{A}, \mathbf{C}) \\ & + f(\boldsymbol{\mathcal{X}}^1, \boldsymbol{\mathcal{G}}^1, \mathbf{B}, \mathbf{C}) \\ & + \lambda_a \|\mathbf{A}\|_F^2 + \lambda_b \|\mathbf{B}\|_F^2 + \lambda_c \|\mathbf{C}\|_F^2 , \quad (1)\end{aligned}$$

where,

$$f(\boldsymbol{\mathcal{X}}^i, \boldsymbol{\mathcal{G}}^i, \mathbf{P}, \mathbf{Q}) = \left\| \boldsymbol{\mathcal{X}}^i - \boldsymbol{\mathcal{G}}^i \times_1 \mathbf{P} \times_2 \mathbf{Q} \times_3 \mathbf{I} \right\|_F^2$$

$$\mathbf{A} \in \mathbb{R}_+^{n_1 \times r_1}, \mathbf{B} \in \mathbb{R}_+^{n_2 \times r_2}, \mathbf{C} \in \mathbb{R}_+^{n_3 \times r_3}$$

$$\boldsymbol{\mathcal{G}}^1 \in \mathbb{R}_+^{r_2 \times r_3 \times m}, \boldsymbol{\mathcal{G}}^2 \in \mathbb{R}_+^{r_1 \times r_3 \times m}, \boldsymbol{\mathcal{G}}^3 \in \mathbb{R}_+^{r_1 \times r_2 \times m}.$$

We enforce non-negativity constraints on the matrices $\mathbf{A}, \mathbf{B}, \mathbf{C}$ and the core tensors $\boldsymbol{\mathcal{G}}^i$ ($i \in \{1, 2, 3\}$). Non-negativity is essential for learning interpretable latent factors (Murphy et al., 2012).

Each slice of the core tensor $\mathcal{G}^3$ corresponds to one of the m relations. Each cell in a slice corresponds to an induced schema in terms of the latent factors from matrices $\mathbf{A}$ and $\mathbf{B}$. In other words, $\mathcal{G}^3_{i,j,k}$ is an induced binary schema for relation k involving induced categories represented by columns $\mathbf{A}_i$ and $\mathbf{B}_j$. Cells in $\mathcal{G}^1$ and $\mathcal{G}^2$ may be interpreted accordingly.

We derive non-negative multiplicative updates for $\mathbf{A}, \mathbf{B}$ and $\mathbf{C}$ following the NMF updating rules given in (Lee and Seung, 2000). For the update of $\mathbf{A}$, we consider the mode-1 matricization of first and the second term in Equation 1 along with the regularizer.

$$\mathbf{A} \leftarrow \mathbf{A} * \frac{\mathcal{X}^3_{(1)}\mathcal{G}_{B_A}^\top + \mathcal{X}^2_{(1)}\mathcal{G}_{C_A}^\top}{\mathbf{A}[\mathcal{G}_{B_A}\mathcal{G}_{B_A}^\top + \mathcal{G}_{C_A}\mathcal{G}_{C_A}^\top] + \lambda_a \mathbf{A}},$$

where,

$$\mathcal{G}_{B_A} = (\mathcal{G}^3 \times_2 \mathbf{B})_{(1)}, \;\; \mathcal{G}_{C_A} = (\mathcal{G}^2 \times_2 \mathbf{C})_{(1)}.$$

In order to estimate $\mathbf{B}$, we consider mode-2 matricization of first term and mode-1 matricization of third term in Equation 1, along with the regularization term. We get the following update rule for $\mathbf{B}$

$$\mathbf{B} \leftarrow \mathbf{B} * \frac{\mathcal{X}^3_{(2)}\mathcal{G}_{A_B}^\top + \mathcal{X}^1_{(1)}\mathcal{G}_{C_B}^\top}{\mathbf{B}[\mathcal{G}_{A_B}\mathcal{G}_{A_B}^\top + \mathcal{G}_{C_B}\mathcal{G}_{C_B}^\top] + \lambda_b \mathbf{B}},$$

where,

$$\mathcal{G}_{A_B} = (\mathcal{G}^3 \times_1 \mathbf{A})_{(2)}, \;\; \mathcal{G}_{C_B} = (\mathcal{G}^1 \times_2 \mathbf{C})_{(1)}.$$

For updating $\mathbf{C}$, we consider mode-2 matricization of second and third terms in Equation 1 along with the regularization term, and we get

$$\mathbf{C} \leftarrow \mathbf{C} * \frac{\mathcal{X}^3_{(2)}\mathcal{G}_{B_C}^\top + \mathcal{X}^2_{(2)}\mathcal{G}_{A_C}^\top}{\mathbf{C}[\mathcal{G}_{A_C}\mathcal{G}_{A_C}^\top + \mathcal{G}_{B_C}\mathcal{G}_{B_C}^\top] + \lambda_c \mathbf{C}},$$

where,

$$\mathcal{G}_{A_C} = (\mathcal{G}^3 \times_1 \mathbf{B})_{(2)}, \;\; \mathcal{G}_{B_C} = (\mathcal{G}^2 \times_1 \mathbf{A})_{(2)}.$$

Finally, we update the three core tensors in Equation 1 following (Kim and Choi, 2007) as follows,

$$\mathcal{G}^1 \leftarrow \mathcal{G}^1 * \frac{\mathcal{X}^1 \times_1 \mathbf{B}^\top \times_2 \mathbf{C}^\top}{\mathcal{G}^1 \times_1 \mathbf{B}^\top\mathbf{B} \times_2 \mathbf{C}^\top\mathbf{C}},$$

$$\mathcal{G}^2 \leftarrow \mathcal{G}^2 * \frac{\mathcal{X}^2 \times_1 \mathbf{A}^\top \times_2 \mathbf{C}^\top}{\mathcal{G}^2 \times_1 \mathbf{A}^\top\mathbf{A} \times_2 \mathbf{C}^\top\mathbf{C}},$$

$$\mathcal{G}^3 \leftarrow \mathcal{G}^3 * \frac{\mathcal{X}^3 \times_1 \mathbf{A}^\top \times_2 \mathbf{B}^\top}{\mathcal{G}^3 \times_1 \mathbf{A}^\top\mathbf{A} \times_2 \mathbf{B}^\top\mathbf{B}}.$$

In all the above updates, $\frac{\mathbf{P}}{\mathbf{Q}}$ represents element-wise division and $\mathbf{I}$ is the identity matrix.

Initialization: For initializing the component matrices $\mathbf{A}, \mathbf{B}$, and $\mathbf{C}$, we first perform a non-negative Tucker2 Decomposition of the individual input tensors $\mathcal{X}^1, \mathcal{X}^2$, and $\mathcal{X}^3$. Then compute the average of component matrices obtained from each individual decomposition for initialization. We initialize the core tensors $\mathcal{G}^1, \mathcal{G}^2$, and $\mathcal{G}^3$ with the core tensors obtained from the individual decompositions.

3.2.2 Step 2: Binary to Higher-Order Schema Induction

In this section, we describe how a higher-order schema is constructed from the factorization described in the previous sub-section. Each relation k has three representations given by the slices $\mathcal{G}^1_k$, $\mathcal{G}^2_k$ and $\mathcal{G}^3_k$ from each core tensor. We need a principled way to produce a joint schema from these representations. For a relation, we select top-n indices (i, j) with highest values from each matrix. The indices i and j from $\mathcal{G}^3_k$ correspond to column numbers of $\mathbf{A}$ and $\mathbf{B}$ respectively, indices from $\mathcal{G}^2_k$ correspond to columns from $\mathbf{A}$ and $\mathbf{C}$ and columns from $\mathcal{G}^1_k$ correspond to columns from $\mathbf{B}$ and $\mathbf{C}$.

We construct a tri-partite graph with the column numbers from each of the component matrices $\mathbf{A}$, $\mathbf{B}$ and $\mathbf{C}$ as the vertices belonging to independent sets, the top-n indices selected are the edges between these vertices. From this tri-partite graph, we find all the triangles which will give schema with three arguments for a relation, illustrated in Figure 2. We find higher order schemata, i.e., schemata with more than three arguments by merging two third order schemata with same column number from $\mathbf{A}$ and $\mathbf{B}$. For example, if we find two schemata $(\mathbf{A}_2, \mathbf{B}_4, \mathbf{C}_{10})$ and $(\mathbf{A}_2, \mathbf{B}_4, \mathbf{C}_8)$ then we merge these two to give $(\mathbf{A}_2, \mathbf{B}_4, \mathbf{C}_{10}, \mathbf{C}_8)$ as a higher order schema. This can be continued further for even higher order schemata. This process may be thought of as finding a **constrained**

clique over the tri-partite graph. Here the constraint is that in the maximal clique, there can only be one edge between sets corresponding to columns of **A** and columns of **B**.

The procedure above is inspired by (McDonald et al., 2005). However, we note that (McDonald et al., 2005) solved a different problem, viz., n-ary relation instance extraction, while our focus is on inducing schemata. Though we discuss the case of back-off from 4-order to 3-order, ideas presented above can be extended for even higher orders depending on the sparsity of the tensors.

4 Experiments

In this section, we evaluate the performance of TFBA for the task of HRSI. We also propose a baseline model for HRSI called HardClust.

HardClust: We propose a baseline model called the Hard Clustering Baseline (HardClust) for the task of higher order relation schema induction. This model induces schemata by grouping per-relation NP arguments from OpenIE extractions. In other words, for each relation, all the Noun Phrases (NPs) in first argument form a cluster that represents the subject of the relation, all the NPs in the second argument form a cluster that represents object and so on. Then from each cluster, the top most frequent NPs are chosen as the representative NPs for the argument type. We note that this method is only able to induce one schema per relation.

Datasets: We run our experiments on three datasets. The first dataset (Shootings) is a collection of 1,335 documents constructed from a publicly available database of mass shootings in the United States. The second is New York Times Sports (NYT Sports) dataset which is a collection of 20,940 sports documents from the period 2005 and 2007. And the third dataset (MUC) is a set of 1300 Latin American newswire documents about terrorism events. After performing the processing steps described in Section 3, we obtained 357,914 unique OpenIE extractions from the NYT Sports dataset, 10,847 from Shootings dataset, and 8,318 from the MUC dataset. However, in order to properly analyze and evaluate the model, we consider only the 50 most frequent relations in the datasets and their corresponding OpenIE extractions. This is done to avoid noisy OpenIE extractions to yield better data quality and to aid subsequent manual evaluation of the data. We construct input tensors following the procedure described in Section 3.2. Details on the dimensions of tensors obtained are given in Table 2.

Model Selection: In order to select appropriate TFBA parameters, we perform a grid search over the space of hyper-parameters, and select the set of hyper-parameters that give best Average FIT score (AvgFIT).

$$\begin{aligned}
&\text{AvgFIT}(\boldsymbol{\mathcal{G}}^1, \boldsymbol{\mathcal{G}}^2, \boldsymbol{\mathcal{G}}^3, \mathbf{A}, \mathbf{B}, \mathbf{C}, \boldsymbol{\mathcal{X}}^1, \boldsymbol{\mathcal{X}}^2, \boldsymbol{\mathcal{X}}^3) = \\
&\frac{1}{3}\{\text{FIT}(\boldsymbol{\mathcal{X}}^1, \boldsymbol{\mathcal{G}}^1, \mathbf{B}, \mathbf{C}) + \text{FIT}(\boldsymbol{\mathcal{X}}^2, \boldsymbol{\mathcal{G}}^2, \mathbf{A}, \mathbf{C}) \\
&\qquad + \text{FIT}(\boldsymbol{\mathcal{X}}^3, \boldsymbol{\mathcal{G}}^3, \mathbf{A}, \mathbf{B})\},
\end{aligned}$$

where,

$$\text{FIT}(\boldsymbol{\mathcal{X}}, \boldsymbol{\mathcal{G}}, \mathbf{P}, \mathbf{Q}) = 1 - \frac{\|\boldsymbol{\mathcal{X}} - \boldsymbol{\mathcal{G}} \times_1 \mathbf{P} \times_2 \mathbf{Q}\|_F}{\|\boldsymbol{\mathcal{X}}\|_F}.$$

We perform a grid search for the rank parameters between 5 and 20, for the regularization weights we perform a grid search over 0 and 1. Table 3 provides the details of hyper-parameters set for different datasets.

Evaluation Protocol: For TFBA, we follow the protocol mentioned in Section 3.2.2 for constructing higher order schemata. For every relation, we consider top 5 binary schemata from the factorization of each tensor. We construct a tri-partite graph, as explained in Section 3.2.2, and mine constrained maximal cliques from the tripartite graphs for schemata. Table 4 provides some qualitative examples of higher-order schemata induced by TFBA. Accuracy of the schemata induced by the model is evaluated by human evaluators. In our experiments, we use human judgments from three evaluators. For every relation, the first and second columns given in Table 4 are presented to the evaluators and they are asked to validate the schema. We present top 50 schemata based on the score of the constrained maximal clique induced by TFBA to the evaluators. This evaluation protocol was also used in (Movshovitz-Attias and Cohen, 2015) for evaluating ontology induction. All evaluations were blind, i.e., the evaluators were not aware of the model they were evaluating.

Difficulty with Computing Recall: Even though recall is a desirable measure, due to the lack of availability of gold higher-order schema annotated corpus, it is not possible to compute recall. Although the MUC dataset has gold annotations for some predefined list of events, it does not have annotations for the relations.

Dataset	$\mathcal{X}^1 shape$	$\mathcal{X}^2 shape$	$\mathcal{X}^3 shape$
Shootings	$3365 \times 1295 \times 50$	$2569 \times 1295 \times 50$	$2569 \times 3365 \times 50$
NYT Sports	$57,820 \times 20,356 \times 50$	$49,659 \times 20,356 \times 50$	$49,659 \times 57,820 \times 50$
MUC	$2825 \times 962 \times 50$	$2555 \times 962 \times 50$	$2555 \times 2825 \times 50$

Table 2: Details of dimensions of tensors constructed for each dataset used in the experiments.

Dataset	(r_1, r_2, r_3)	$(\lambda_a, \lambda_b, \lambda_c)$
Shootings	(10, 20,15)	(0.3, 0.1, 0.7)
NYT Sports	(20, 15, 15)	(0.9, 0.5, 0.7)
MUC	(15, 12, 12)	(0.7, 0.7, 0.4)

Table 3: Details of hyper-parameters set for different datasets.

Experimental results comparing performance of various models for the task of HRSI are given in Table 5. We present evaluation results from three evaluators represented as E1, E2 and E3. As can be observed from Table 5, TFBA achieves better results than HardClust for the Shootings and NYT Sports datasets, however HardClust achieves better results for the MUC dataset. Percentage agreement of the evaluators for TFBA is 72%, 70% and 60% for Shootings, NYT Sports and MUC datasets respectively.

HardClust Limitations: Even though HardClust gives better induction for MUC corpus, this approach has some serious drawbacks. HardClust can only induce one schema per relation. This is a restrictive constraint as multiple senses can exist for a relation. For example, consider the schemata induced for the relation *shoot* as shown in Table 4. TFBA induces two senses for the relation, but HardClust can induce only one schema. For a set of 4-tuples, HardClust can only induce ternary schemata; the dimensionality of the schemata cannot be varied. Since the latent factors induced by HardClust are entirely based on frequency, the latent categories induced by HardClust are dominated by only a fixed set of noun phrases. For example, in NYT Sports dataset, subject category induced by HardClust for all the relations is $\langle$*team, yankees, mets*$\rangle$. In addition to inducing only one schema per relation, most of the times HardClust only induces a fixed set of categories. Whereas for TFBA, the number of categories depends on the rank of factorization, which is a user provided parameter, thus providing more flexibility to choose the latent categories.

4.1 Using Event Schema Induction for HRSI

Event schema induction is defined as the task of learning high-level representations of events, like a tournament, and their entity roles, like winning-player etc, from unlabeled text. Even though the main focus of event schema induction is to induce the important roles of the events, as a side result most of the algorithms also provide schemata for the relations. In this section, we investigate the effectiveness of these schemata compared to the ones induced by TFBA.

Event schemata are represented as a set of *(Actor, Rel, Actor)* triples in (Balasubramanian et al., 2013). *Actors* represent groups of noun phrases and *Rel*s represent relations. From this style of representation, however, the n-ary schemata for relations cannot be induced. Event schemata generated in (Weber et al., 2018) are similar to that in (Balasubramanian et al., 2013). Event schema induction algorithm proposed in (Nguyen et al., 2015) doesn't induce schemata for relations, but rather induces the roles for the events. For this investigation we experiment with the following algorithm.

Chambers-13 (Chambers, 2013): This model learns event templates from text documents. Each event template provides a distribution over slots, where slots are clusters of NPs. Each event template also provides a cluster of relations, which is most likely to appear in the context of the aforementioned slots. We evaluate the schemata of these relation clusters.

As can be observed from Table 5, the proposed TFBA performs much better than Chambers-13. HardClust also performs better than Chambers-13 on all the datasets. From this analysis we infer that there is a need for algorithms which induce higher-order schemata for relations, a gap we fill in this paper. Please note that the experimental results provided in (Chambers, 2013) for MUC dataset are for the task of event schema induction, but in this work we evaluate the relation schemata. Hence the results in (Chambers, 2013) and results in this paper are not comparable. Example

Relation Schema	NPs from the induced categories	Evaluator Judgment	(Human) Suggested Label
	Shootings		
leave$\langle A_6, B_0, C_7\rangle$	A_6: *shooting, shooting incident, double shooting* B_0: *one person, two people, three people* C_7: *dead, injured, on edge*	valid	< shooting > < people > <injured >
identify$\langle A_1, B_1, C_5, C_6\rangle$	A_1: *police, officers, huntsville police* B_1: *man, victims, four victims* C_5: *sunday, shooting staurday, wednesday afternoon* C_6: *apartment, bedroom, building in the neighborhood*	valid	< police > < victim(s)> <day/time > <place >

Table 4: Examples of schemata induced by TFBA. Please note that some of them are 3-ary while others are 4-ary. For details about schema induction, please refer to Section 3.2.

	Shootings				NYT Sports				MUC			
	E1	E2	E3	Avg	E1	E2	E3	Avg	E1	E2	E3	Avg
HardClust	0.64	0.70	0.64	0.66	0.42	0.28	0.52	0.46	0.64	0.58	0.52	**0.58**
Chambers-13	0.32	0.42	0.28	0.34	0.08	0.02	0.04	0.07	0.28	0.34	0.30	0.30
TFBA	0.82	0.78	0.68	**0.76**	0.86	0.6	0.64	**0.70**	0.58	0.38	0.48	0.48

Table 5: Higher-order RSI accuracies of various methods on the three datasets. Induced schemata for each dataset and method are evaluated by three human evaluators, E1, E2, and E3. TFBA performs better than HardClust for Shootings and NYT Sports datasets. Even though HardClust achieves better accuracy on MUC dataset, it has several limitations, see Section 4 for more details. Chambers-13 solves a slightly different problem called event schema induction, for more details about the comparison with Chambers-13 see Section 4.1.

schemata induced by TFBA and (Chambers-13) are provided as part of the supplementary material.

5 Conclusion

Higher order Relation Schema Induction (HRSI) is an important first step towards building domain-specific Knowledge Graphs (KGs). In this paper, we proposed TFBA, a tensor factorization-based method for higher-order RSI. To the best of our knowledge, this is the first attempt at inducing higher-order (n-ary) schemata for relations from unlabeled text. Rather than factorizing a severely sparse higher-order tensor directly, TFBA performs *back-off* and jointly factorizes multiple lower-order tensors derived out of the higher-order tensor. In the second step, TFBA solves a constrained clique problem to induce schemata out of multiple binary schemata. We are hopeful that the backoff-based factorization idea exploited in TFBA will be useful in other sparse factorization settings.

Abstract

State-of-the-art relation extraction approaches are only able to recognize relationships between mentions of entity arguments stated explicitly in the text and typically localized to the same sentence. However, the vast majority of relations are either implicit or not sententially localized. This is a major problem for Knowledge Base Population, severely limiting recall. In this paper we propose a new methodology to identify relations between two entities, consisting of detecting a very large number of unary relations, and using them to infer missing entities. We describe a deep learning architecture able to learn thousands of such relations very efficiently by using a common deep learning based representation. Our approach largely outperforms state of the art relation extraction technology on a newly introduced web scale knowledge base population benchmark, that we release to the research community.

1 Introduction

Knowledge Base Population (KBP) from text is the problem of extracting relations between entities with respect to a given schema, usually defined by a set of types and relations. The facts added to the KB are triples, consisting of two entities connected by a relation. Although providing explicit provenance for the triples is often a subgoal in KBP, we focus on the case where correct triples are gathered from text without necessarily annotating any particular text with a relation. Humans are able to perform very well on the task of understanding relations in text. For example, if the target relation is presidentOf, anyone will be able to detect an occurrence of this relation between the entities TRUMP and UNITED_STATES from both the sentences "Trump issued a presidential memorandum for the United States" and "The Houston Astros will visit President Donald Trump and the White House on Monday". However, the first example expresses an explicit relation between the two entities, while the second states the same relation implicitly and requires some background knowledge and inference to identify it properly. In fact, the entity UNITED_STATES is not even mentioned explicitly in the text, and it is up to the reader to recall that US presidents live in the White House, and therefore people visiting it are visiting the US president.

Very often, relations expressed in text are implicit. This reflects in the low recall of the current KBP relation extraction methods, that are mostly based on recognizing lexical-syntactic connections between two entities within the same sentence. The state-of-the-art systems are affected by very low performance, close to 16.6% F1, as shown in the latest TAC-KBP evaluation campaigns and in the open KBP evaluation benchmark[1]. Existing approaches to dealing with implicit information such as textual entailment depend on unsolved problems like inducing entailment rules from text.

In this paper, we address the problem of identifying implicit relations in text using a radically different approach, consisting of reducing the problem of identifying binary relations into a much larger set of simpler unary relations. For example, to build a Knowledge Base (KB) about presidents in the G8 countries, the *presidentOf* relation can be expanded to *presidentOf*:UNITED_STATES, *presidentOf*:GERMANY, *presidentOf*:JAPAN, and so

[1]https://kbpo.stanford.edu

on. For all these unary relations, we train a multi-class (and in other cases, multi-label) classifier from all the available training data. This classifier takes textual evidence where only one entity is identified (e.g. ANGELA_MERKEL) and predicts a confidence score for each unary relation. In this way, ANGELA_MERKEL will be assigned to the unary relation *presidentOf*:GERMANY, which in turn generates the triple ⟨ANGELA_MERKEL *presidentOf* GERMANY⟩.

To implement the idea above, we explore the use of knowledge-level supervision, sometimes called distant supervision, to train a deep learning based approach. The training data in this approach is a knowledge base and an unannotated corpus. A pre-existing Entity Detection and Linking system first identifies and links mentions of entities in the corpus. For each entity, the system gathers its *context set*, the contexts (e.g. sentences or token windows) where it is mentioned. The context set forms the textual evidence for a multi-class, multi-label deep network. The final layer of the network is vector of unary relation predictions and the intermediate layers are shared. This architecture allows us to efficiently train thousands of unary relations, while reusing the feature representations in the intermediate layers across relations as a form of transfer learning. The predictions of this network represent the probability for the input entity to belong to each unary relation.

To demonstrate the effectiveness of our approach we developed a new KBP benchmark, consisting of extracting unseen DBPedia triples from the text of a web crawl, using a portion of DBpedia to train the model. As part of the contributions for this paper, we release the benchmark to the research community providing the software needed to generate it from Common Crawl and DBpedia as an open source project[2].

As a baseline, we adapt a state of the art deep learning based approach for relation extraction (Lin et al., 2016). Our experiments clearly show that using unary relations to generate new triples greatly complements traditional binary approaches. An analysis of the data shows that our approach is able to capture implicit information from textual mentions and to highlight the reasons why the assignments have been made.

The paper is structured as follows. In section 2 we describe the state of the art in distantly supervised KBP methodologies, with a focus on knowledge induction applications. Section 3 introduces the use of Unary Relations for KBP and section 4 outlines the process for producing and training them. Section 5 describes a deep learning architecture able to recognize unary relations from textual evidence. In section 6 we describe the benchmark for evaluation. Section 7 provides an extensive evaluation of unary relations, and a saliency map exploration of what the deep learning model has learned. Section 8 concludes the paper highlighting research directions for future work.

2 Related Work

Binary relation extraction using distant supervision has a long history (Surdeanu et al., 2012; Mintz et al., 2009). Mentions of entities from the knowledge base are located in text. When two entities are mentioned in the same sentence that sentence becomes part of the evidence for the relation (if any) between those entities. The set of sentences mentioning an entity pair is used in a machine learning model to predict how the entities are related, if at all.

Deep learning has been applied to binary relation extraction. CNN-based (Zeng et al., 2014), LSTM-based (Xu et al., 2015), attention based (Wang et al., 2016) and compositional embedding based (Gormley et al., 2015) models have been trained successfully using a sentence as the unit of context. Recently, cross sentence approaches have been explored by building paths connecting the two identified arguments through related entities (Peng et al., 2017; Zeng et al., 2016). These approaches are limited by requiring both entities to be mentioned in a textual context. The context aggregation approaches of state-of-the-art neural models, max-pooling (Zeng et al., 2015) and attention (Lin et al., 2016), do not consider that different contexts may contribute to the prediction in different ways. Instead, the context pooling only determines the degree of a sentence's contribution to the relation prediction.

TAC-KBP is a long running challenge for knowledge base population. Effective systems in these competitions combine many approaches such as rule-based relation extraction, directly supervised linear and neural network extractors, distantly supervised neural network models (Zhang et al., 2016) and tensor factorization approaches to relation prediction. Compositional Universal

[2]https://github.com/IBM/cc-dbp

Schema is an approach based on combining the matrix factorization approach of universal schema (Riedel et al., 2013), with repesentations of textual relations produced by an LSTM (Chang et al., 2016). The rows of the universal schema matrix are entity pairs, and will only be supported by a textual relation if they occur in a sentence together.

Other approaches to relational knowledge induction have used distributed representations for words or entities and used a model to predict the relation between two terms based on their semantic vectors (Drozd et al., 2016). This enables the discovery of relations between terms that do not co-occur in the same sentence. However, the distributed representation of the entities is developed from the corpus without any ability to focus on the relations of interest. One example of such work is LexNET, which developed a model using the distributional word vectors of two terms to predict lexical relations between them (DS_h). The term vectors are concatenated and used as input to a single hidden layer neural network. Unlike our approach to unary relations the term vectors are produced by a standard relation-independent model of the term's contexts such as word2vec (Mikolov et al., 2013).

Unary relations can be considered to be similar to types. Work on ontology population has considered the general distribution of a term in text to predict its type (Cimiano and Völker, 2005). Like the method of DS_h, this does not customize the representation of an entity to a set of target relations.

3 Unary vs Binary Relations

The basic idea presented in this paper is that in many cases relation extraction problems can be reduced to sets of simpler and inter-related unary relation extraction problems. This is possible by providing a specific value to one of the two arguments, transforming the relations into a set of categories. For example, the *livesIn* relation between persons and countries can be decomposed into 195 relations (one relation for each country), including *livesIn*:UNITED_STATES, *livesIn*:CANADA, and so on. The argument that is combined with the binary relation to produce the unary relation is called the *fixed argument* while the other argument is the *filler argument*. The *KB extension* of a unary relation is the set of all filler arguments in the KB, and the *corpus extension* is the subset of the KB extension that occurs in the corpus.

A requisite for a unary relation is that in the training KB there should exist many triples that share a relation and a particular entity as one argument, thus providing enough training for each unary classifier. Therefore, in the example above, we will not likely be able to generate predicates for all the 195 countries, because some of them will either not occur at all in the training data or they will be very infrequent. However, even in cases where arguments tend to follow a long tail distribution, it makes sense to generate unary predicates for the most frequent ones.

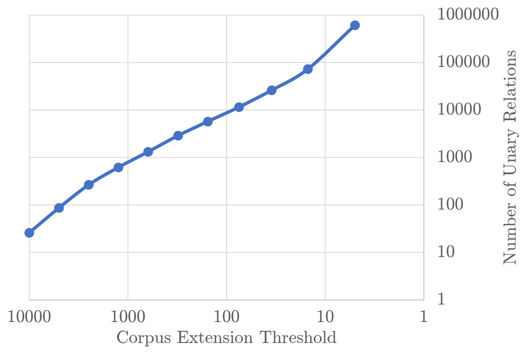

Figure 1: Minimum Corpus Extension to Number of Unary Relations

Figure 1 shows the relationship between the threshold for the size of the corpus extension of a unary relation and the number of different unary relations that can be found in our dataset. The relationship is approximately linear on a log-log scale. There are 26 unary relations with a corpus extension of at least 10,000. These relations include:

- *hasLocation*:UNITED_STATES
- *background*:GROUP_OR_BAND
- *kingdom*:ANIMAL
- *language*:ENGLISH_LANGUAGE

Lowering the threshold to 100 we have 8711 unary relations and we get close to 1M unary relations with more than 10 entities.

In a traditional binary KBP task a triple has a *relevant context set* if the two entities occur at least once together in the corpus - where the notion of 'together' is typically intra-sentential (within a single sentence). In KBP based on unary relations, a triple ⟨FILLER *rel* FIXED⟩ has a relevant context set if the unary relation *rel*:FIXED has the filler argument in its corpus extension, i.e. the filler occurs in the corpus.

Both approaches are limited in different important respects. KBP with unary relations can only produce triples when fixing a relation and argument provides a relatively large corpus extension. Triples such as ⟨BARACK_OBAMA *spouse* MICHELLE_OBAMA⟩ cannot be extracted in this way, since neither Barack nor Michelle Obama have a large set of spouses. The limitation of binary relation extraction is that the arguments must occur together. But for many triples, such as those relating to a person's occupation, a film's genre or a company's product type, the second argument is often not given explicitly.

In both cases, a relevant context set is a necessary but not sufficient condition for extracting the triple from text, since the context set may not express (even implicitly) the relation. Figure 2 shows the number of triples in our dataset that have a relevant context set with unary relations exclusively, binary relations exclusively and both unary and binary. The corpus extension threshold for the unary relations is 100.

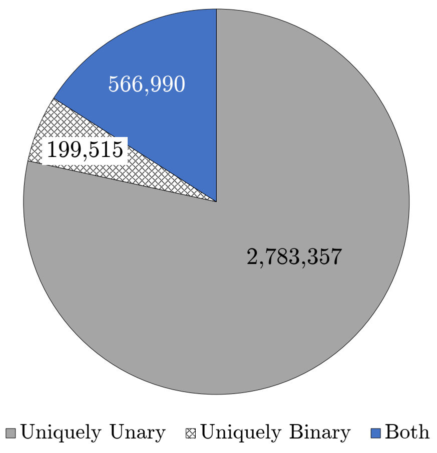

Figure 2: Triples with Relevant Context Sets Per-Relation Style

Although unary relations could also be viewed as types, we argue that it is preferable to consider them as relations. For example, if the unary relation *lives_in*:UNITED_STATES is represented as the type US-PERSON, it has no structured relationship to the type US-COMPANY (*based_in*:UNITED_STATES). So the inference rule that companies tend to employ people who live in the countries they are based in $(\langle company\ employs\ person\rangle \wedge \langle company\ based\_in\ country\rangle \Rightarrow \langle person\ lives\_in\ country\rangle)$ is not representable.

4 Training and Using Unary Relation Classifiers

A unary relation extraction system is a multi-class, multi-label classifier that takes an entity as input and returns its probability as a slot filler for each relation. In this paper, we represent each entity by the set of contexts (sentences in our experiments) where their mentions have been located; we call them context sets.

The process of training and applying a KBP system using unary relations is outlined step-by-step below.

- Build a set of unary relations that have a corpus extension above some threshold.
- Locate the entities from the knowledge graph in text.
- Create a context set for each entity from all the sentences that mention the entity.
- Label the context set with the unary relations (if any) for the entity. The negatives for each unary relation will be all the entities where that unary relation is not true.
- Train a model to determine the unary relations for any given entity from its context set.
- Apply the model to all the entities in the corpus, including those that do not exist in the knowledge graph.
- Convert the extracted unary relations back to binary relations and add to the knowledge graph as new edges. Any new entities are added to the knowledge graph as new nodes.

A closer look to the generated training data can provide insight in the value of unary relations for distant supervision.

Below are example binary contexts relating an organization to a country. The two arguments are shown in bold. Some contexts where two entities occur together (relevant contexts) will imply a relation between them, while others will not. In the first context, **Philippines** and **Eagle Cement** are not textually related. While in the second context, **Dyna Management Services** is explicitly stated to be located in **Bermuda**.

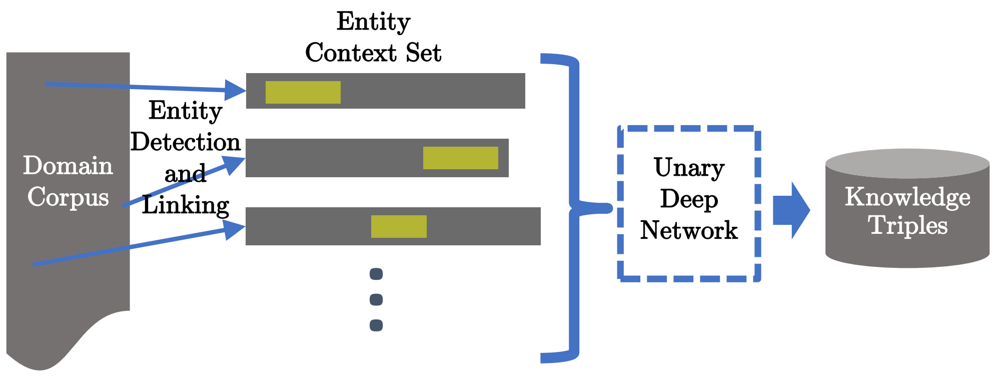

Figure 3: Unary Relational Knowledge Induction Architecture Overview

> The company competes with Holcim **Philippines**, the local unit of Swiss company LafargeHolcim, and **Eagle Cement**, a company backed by diversified local conglomerate San Miguel which is aggressively expanding into infrastructure.
>
> ... said Richmond, who is vice president of **Dyna Management Services**, a **Bermuda**-based insurance management company.

On the other hand, there are many triples that have no relevant context using binary extraction, but can be supported with unary extraction. **JB Hi-Fi** is a company located in **Australia**, (unary relation *hasLocation*:AUSTRALIA). Although "JB Hi-Fi" never occurs together with "Australia" in our corpus, we can gather implicit textual evidence for this relation from its unary relation context sets. Furthermore, even cases where there is a relevant binary context set, the contexts may not provide enough or any textual support for the relation, while the unary context sets might.

> Woolworths, Coles owner Wesfarmers, **JB Hi-Fi** and Harvey Norman were also trading higher.
>
> **JB Hi-Fi** in talks to buy The Good Guys
>
> In equities news, protective glove and condom maker Ansell and **JB Hi-Fi** are slated to post half year results, while Bitcoin group is expected to list on ASX.

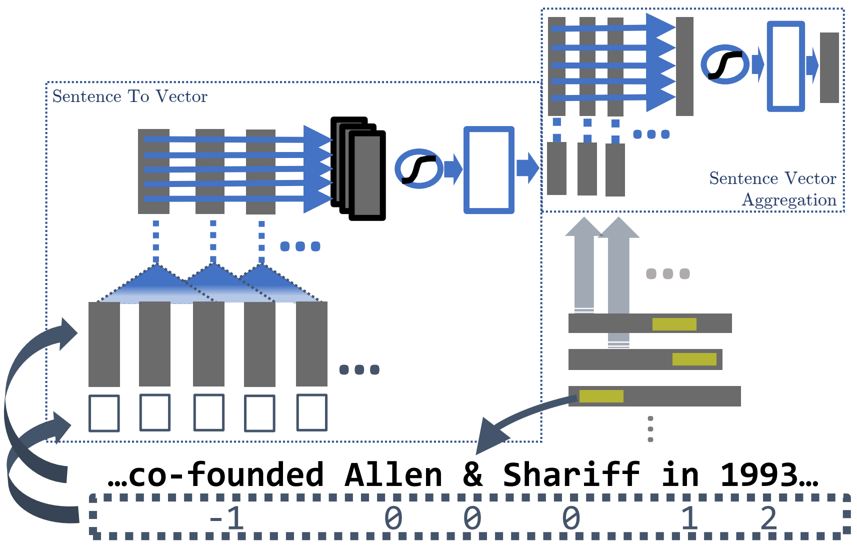
The key indicators are: "ASX", which is an Australian stock exchange, and the other Australian businesses mentioned, such as Woolworths, Wesfarmers, Harvey Norman, The Good Guys, Ansell and Bitcoin group. There is no strict logical entailment, indicating **JB Hi-Fi** is located in Australia, instead there is textual evidence that makes it probable.

5 Architecture for Unary Relations

Figure 3 illustrates the overall architecture. First an Entity Detection and Linking system identifies occurrences in text of entities that are or should be in the knowledge base. Second, the contexts (here we use a sentence as the unit of context) for each entity are then gathered into an entity context set. This context set provides all the sentences that contain a mention of a particular entity and is the textual evidence for what triples are true for the entity. Third, the context set is then fed into a deep neural network, given in Figure 4. The output of the network is a set of predicted triples that can be added to the knowledge base.

Figure 4 shows the architecture of the deep learning model for unary relation based KBP. From an entity context set, each sentence is projected into a vector space using a piecewise convolutional neural network (Zeng et al., 2015). The sentence vectors are then aggregated using a Network-in-Network layer (NiN) (Lin et al., 2013).

The sentence-to-vector portion of the neural architecture begins by looking up the words in a word embedding table. The word embeddings are initialized with word2vec (Mikolov et al., 2013) and updated during training. The position of each word relative to the entity is also looked up in a position embedding table. Each word vector is concatenated with its position vector to produce each word representation vector. A piecewise max-pooled convolution (PCNN) is applied over



Sentence To Vector
Sentence Vector Aggregation
…co-founded Allen & Shariff in 1993…
-1 0 0 0 1 2

Figure 4: Deep Learning Architecture for Unary Relations

the resulting sentence matrix, with the pieces defined by the position of the entity argument: before the entity, the entity, and after the entity. A fully connected layer then produces the sentence vector representation. This is a refinement of the Neural Relation Extraction (NRE) (Lin et al., 2016) approach to sentence-to-vector mapping. The presence of only a single argument simply reduces from two position encoding vectors to one. The fully connected layer over the PCNN is an addition.

The sentence vector aggregation portion of the neural architecture uses a Network-in-Network over the sentence vectors. Network-in-Network (NiN) (Lin et al., 2013) is an approach of 1x1 CNNs to image processing. The width-1 CNN we use for mention aggregation is an adaptation to a set of sentence vectors. The result is max-pooled and put through a fully connected layer to produce the score for each unary relation. Unlike a maximum aggregation used in many previous works (Riedel et al., 2010; Zeng et al., 2015) for binary relation extraction the evidence from many contexts can be combined to produce a prediction. Unlike attention-based pooling also used previously for binary relation extraction (Lin et al., 2016), the different contexts can contribute to different aspects, not just different degrees. For example, a prediction that a city is in France might depend on the conjunction of several facets of textual evidence linking the city to the French language, the Euro, and Norman history.

In contrast, the common maximum aggregation approach is to move the final prediction layer to the sentence-to-vector modules and then aggregate by max-pooling the sentence level predictions. This aggregation strategy means that only the sentence most strongly indicating the relation contributes to its prediction. We measured the impact of the Network-in-Network sentence vector aggregation approach on the validation set. Relative to Network-in-Network aggregation and using the same hyperparameters, a maximum aggregation strategy gets two percent lower precision at one thousand: 66.55% compared to 68.49%.

There are 790 unary relations with at least one thousand positives in our benchmark. To speed the training, we divided these into eight sets of approximately 100 relations each and trained the models for them in parallel. Unary relations based on the same binary relation were grouped together to share useful learned representations. The resulting split also put similar numbers of positive examples in the training set for each model.

Training continued until no improvement was found on the validation set. This occurred at between five and nine epochs. All eight models were trained with the hyperparameters in Table 1. Dropout was applied on the penultimate layer, the max-pooled NiN.

Based on validation set performance, we found that when larger numbers of relations are trained together the NiN filters and sentence vector dimension must be increased. Of all the hyperparameters, the training time is most sensitive to the

Hyperparameter	Value
word embedding	50
position embedding	5
PCNN filters	1000
PCNN filter width	3
sentence vector	400
NiN filters	400
dropout	0.5
learnRate	0.003
decay multiplier	0.95
batch size	16
optimizer	SGD

Table 1: Hyperparameters used

number of PCNN filters, since these are applied to every sentence in a context set. We found major improvements moving from the 230 filters used for NRE to 1000 filters, but less improvement or no improvement to increases beyond that.

6 Benchmark

Large KBs and corpora are needed to train KBP systems in order to collect enough mentions for each relation. However, most of the existing Knowledge Base Population tasks are small in size (e.g. NYT-FB (Riedel et al., 2010) and TAC-KBP[3]) or focused on title-oriented-documents which are not available for most domains (e.g. WikiReading (Hewlett et al., 2016)). Therefore, we needed to create a new web-scale knowledge base population benchmark that we called *CC-DBP*[4]. It combines the text of Common Crawl[5] with the triples from 298 frequent relations in DBpedia (Auer et al., 2007). Mentions of DBpedia entities are located in text by gazetteer matching of the preferred label. We use the October 2017 Common Crawl and the most recent (2016-10) version of DBpedia, in both cases limited to English.

We divided the entity pairs into training, validation and test sets with a 80%, 10%, 10% split. All triples for a given entity pair are in one of the three splits. This split increases the challenge, since many relations could be used to predict others (such as birthPlace implying nationality). The task is to generate new triples for each relation and rank them according to their probability. We show the precision / recall curves and focus on the relative area under the curves to evaluate the quality of different systems.

Figure 5 shows the distribution of triples with relevant unary context sets per relation type. The relations giving rise to the most triples are high level relations such as hasLocation, a super-relation comprised of the sub-relations: country, state, city, headquarter, hometown, birthPlace, deathPlace, and others. Interestingly there are 165 years with enough people born in them to produce unary relations. While these all will have at least 100 relevant context sets, typically the context sets do not have textual evidence for any birth year. Perhaps most importantly, there are a large number of diverse relations that are suitable for a unary KBP approach. This indicates the broad applicability of our method.

To test what improvement can be found by incorporating unary relations into KBP, we combine the output of a state-of-the-art binary relation extraction system with our unary relation extraction system. For binary relation extraction, we use a slightly altered version of the PCNN model from NRE (Lin et al., 2016), with the addition of a fully connected layer for each sentence representation before the max-pooled aggregation over relation predictions. We found this refinement to perform slightly better in NYT-FB (Riedel et al., 2010), a standard dataset for distantly supervised relation extraction.

The binary and unary systems are trained from their relevant context sets to predict the triples in train. The validation set is used to tune hyper-parameters and choose a stopping point for training. We combine the output of the two systems by, for each triple, taking the highest confidence from each system.

7 Evaluation

Figure 6 shows the precision-recall curves for unary only, binary only and the combined system. The unary and binary systems alone achieve similar performance. But they are effective at very different triples. This is shown in the large gains from combining these complementary approaches. For example, at 0.5 precision, the combined approach has a recall of more than double (15,750 vs 7,400) compared to binary alone, which represents over 100% relative improvement.

The recall is given as a triple count rather than

[3]https://tac.nist.gov/
[4]https://github.com/IBM/cc-dbp
[5]http://commoncrawl.org

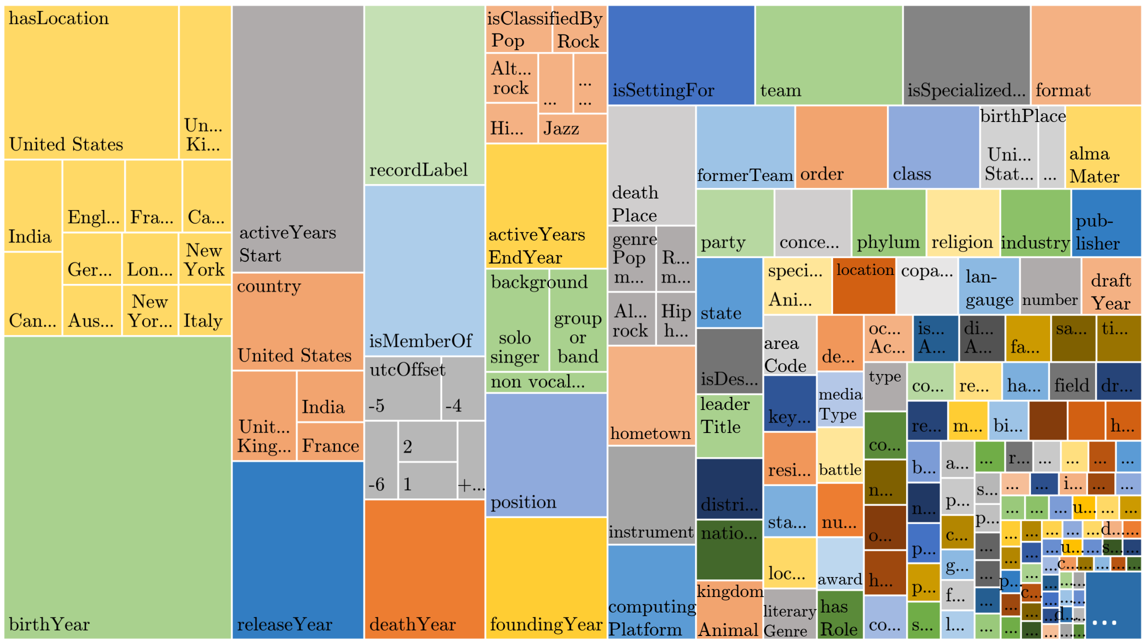


Figure 5: Distribution of Unary Relation Counts

a percentage. Traditional attempts to measure the recall of KBP systems use the set of all triples explicitly stated in text for the denominator of recall. This is unsuitable for evaluating our approach because the system is able to make probabilistic predictions based on implicit and partial textual evidence, thus producing correct triples outside the classic recall basis.

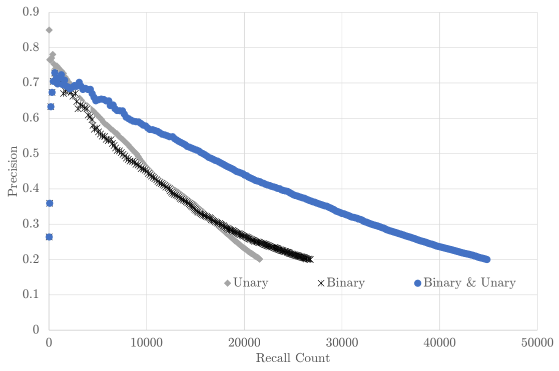

Figure 6: Precision Recall Curves for KBP

7.1 Saliency Maps

To gain some insight into how the unary KBP system is able to extract implicit knowledge we turn to saliency maps (Simonyan et al., 2014). By finding the derivative of a particular prediction with respect to the inputs, we can discover a locally linear approximation of how much each part of the input contributed (Zeiler and Fergus, 2014).

Cold Lake Provincial Park (Alberta, Canada) is mentioned in two sentences in the Common Crawl English text. The unary relational knowledge induction system predicts *hasLocation*:CANADA with the highest confidence (over 90%). Both sentences contribute to the decision. We see high weight from words including "cold", "provincial" and "french". A handful of countries have "provincial parks" including Argentina, Belgium, South Africa and Canada. Belgium and Canada have substantial French speaking populations and Canada has by far the coldest climate.

- located within 10 minutes of cold lake with quick access to OOV ridge ski hill , **cold** **lake** **provincial** **park** and french bay .
- welcome to **cold** **lake** **provincial** **park** on average 4.00 pages are viewed each , by the estimated 959 daily visitors .

Rock Kills Kid is a band mentioned twice in the corpus. From this context set, the relation *background*:GROUP_OR_BAND is predicted with high confidence. The fact that "Kid" occurs in the name of the entity seems to be important in identifying it as a musical group. The first sentence also draws focus to the band's connection to rock and pop.

While the second sentence seems to recognize the *band* - *song* (*year*) pattern as well as the comparison to Duran Duran.

- the latest stylish pop synth band is **rock kills kid** .
- **rock kills kid** - are you nervous ? (2006) who ever thought duran duran would become so influential ?

The Japanese singer-songwriter Masaki Haruna, aka Klaha is mentioned twice in the corpus. From this context set, the relation *background*:SOLO_SINGER is predicted with high confidence. The first sentence clearly establishes the connection to music while the second indicates that Klaha is a solo artist. The conjunction of these two facets, accomplished through the context vector aggregation using NiN permits the conclusion of SOLO_SINGER.

- tvk music chat interview **klaha** parade .
- **klaha** tvk music chat OOV red scarf interview the tv - k folks did after **klaha** went solo .

8 Conclusions

In this paper we presented a new methodology to identify relations between entities in text. Our approach, focusing on unary relations, can greatly improve the recall in automatic construction and updating of knowledge bases by making use of implicit and partial textual markers. Our method is extremely effective and complement very nicely existing binary relation extraction methods for KBP.

This is just the first step in our wider research program on KBP, whose goal is to improve recall by identifying implicit information from texts. First of all, we plan to explore the use of more advanced forms of entity detection and linking, including propagating features from the EDL system forward for both unary and binary deep models. In addition we plan to exploit unary and binary relations as source of evidence to bootstrap a probabilistic reasoning approach, with the goal of leveraging constraints from the KB schema such as domain, range and taxonomies. We will also integrate the new triples gathered from textual evidence with new triples predicted from existing KB relationships by knowledge base completion.

Improving Entity Linking by Modeling Latent Relations between Mentions

Phong Le[1] **and Ivan Titov**[1,2]
[1]University of Edinburgh [2]University of Amsterdam
{ple,ititov}@inf.ed.ac.uk

Abstract

Entity linking involves aligning textual mentions of named entities to their corresponding entries in a knowledge base. Entity linking systems often exploit relations between textual mentions in a document (e.g., coreference) to decide if the linking decisions are compatible. Unlike previous approaches, which relied on supervised systems or heuristics to predict these relations, we treat relations as latent variables in our neural entity-linking model. We induce the relations without any supervision while optimizing the entity-linking system in an end-to-end fashion. Our multi-relational model achieves the best reported scores on the standard benchmark (AIDA-CoNLL) and substantially outperforms its relation-agnostic version. Its training also converges much faster, suggesting that the injected structural bias helps to explain regularities in the training data.

1 Introduction

Named entity linking (NEL) is the task of assigning entity mentions in a text to corresponding entries in a knowledge base (KB). For example, consider Figure 1 where a mention "World Cup" refers to a KB entity FIFA_WORLD_CUP. NEL is often regarded as crucial for natural language understanding and commonly used as preprocessing for tasks such as information extraction (Hoffmann et al., 2011) and question answering (Yih et al., 2015).

Potential assignments of mentions to entities are regulated by semantic and discourse constraints. For example, the second and third occurrences of mention "England" in Figure 1 are coreferent and thus should be assigned to the same entity. Besides coreference, there are many other relations between entities which constrain or favor certain alignment configurations. For example, consider relation participant_in in Figure 1: if "World Cup" is aligned to the entity FIFA_WORLD_CUP then we expect the second "England" to refer to a football team rather than a basketball one.

NEL methods typically consider only coreference, relying either on off-the-shelf systems or some simple heuristics (Lazic et al., 2015), and exploit them in a pipeline fashion, though some (e.g., Cheng and Roth (2013); Ren et al. (2017)) additionally exploit a range of syntactic-semantic relations such as apposition and possessives. Another line of work ignores relations altogether and models the predicted sequence of KB entities as a bag (Globerson et al., 2016; Yamada et al., 2016; Ganea and Hofmann, 2017). Though they are able to capture some degree of coherence (e.g., preference towards entities from the same general domain) and are generally empirically successful, the underlying assumption is too coarse. For example, they would favor assigning all the occurrences of "England" in Figure 1 to the same entity.

We hypothesize that relations useful for NEL can be induced without (or only with little) domain expertise. In order to prove this, we encode relations as latent variables and induce them by optimizing the entity-linking model in an end-to-end fashion. In this way, relations between mentions in documents will be induced in such a way as to be beneficial for NEL. As with other recent approaches to NEL (Yamada et al., 2017; Ganea and Hofmann, 2017), we rely on representation learning and learn embeddings of mentions, contexts and relations. This further reduces the amount of human expertise required to construct the system and, in principle, may make it more portable across languages and domains.

Our multi-relational neural model achieves an

improvement of 0.85% F1 over the best reported scores on the standard AIDA-CoNLL dataset (Ganea and Hofmann, 2017). Substantial improvements over the relation-agnostic version show that the induced relations are indeed beneficial for NEL. Surprisingly its training also converges much faster: training of the full model requires ten times shorter wall-clock time than what is needed for estimating the simpler relation-agnostic version. This may suggest that the injected structural bias helps to explain regularities in the training data, making the optimization task easier. We qualitatively examine induced relations. Though we do not observe direct counterparts of linguistic relations, we, for example, see that some of the induced relations are closely related to coreference whereas others encode forms of semantic relatedness between the mentions.

2 Background and Related work

2.1 Named entity linking problem

Formally, given a document D containing a list of mentions $m_1, ..., m_n$, an entity linker assigns to each m_i an KB entity e_i or predicts that there is no corresponding entry in the KB (i.e., $e_i = \text{NILL}$).

Because a KB can be very large, it is standard to use an heuristic to choose potential candidates, eliminating options which are highly unlikely. This preprocessing step is called *candidate selection*. The task of a statistical model is thus reduced to choosing the best option among a smaller list of candidates $C_i = (e_{i1}, ..., e_{il_i})$. In what follows, we will discuss two classes of approaches tackling this problem: local and global modeling.

2.2 Local and global models

Local models rely only on local contexts of mentions and completely ignore interdependencies between the linking decisions in the document (these interdependencies are usually referred to as *coherence*). Let c_i be a local context of mention m_i and $\Psi(e_i, c_i)$ be a local score function. A local model then tackles the problem by searching for

$$e_i^* = \arg\max_{e_i \in C_i} \Psi(e_i, c_i) \quad (1)$$

for each $i \in \{1, ..., n\}$ (Bunescu and Paşca, 2006; Lazic et al., 2015; Yamada et al., 2017).

A *global* model, besides using local context within $\Psi(e_i, c_i)$, takes into account entity coherency. It is captured by a coherence score function $\Phi(E, D)$:

$$E^* = \arg\max_{E \in C_1 \times ... \times C_n} \sum_{i=1}^{n} \Psi(e_i, c_i) + \Phi(E, D)$$

where $E = (e_1, ..., e_n)$. The coherence score function, in the simplest form, is a sum over all pairwise scores $\Phi(e_i, e_j, D)$ (Ratinov et al., 2011; Huang et al., 2015; Chisholm and Hachey, 2015; Ganea et al., 2016; Guo and Barbosa, 2016; Globerson et al., 2016; Yamada et al., 2016), resulting in:

$$E^* = \arg\max_{E \in C_1 \times ... \times C_n} \sum_{i=1}^{n} \Psi(e_i, c_i) + \sum_{i \neq j} \Phi(e_i, e_j, D) \quad (2)$$

A disadvantage of global models is that exact decoding (Equation 2) is NP-hard (Wainwright et al., 2008). Ganea and Hofmann (2017) overcome this using loopy belief propagation (LBP), an approximate inference method based on message passing (Murphy et al., 1999). Globerson et al. (2016) propose a *star model* which approximates the decoding problem in Equation 2 by approximately decomposing it into n decoding problems, one per each e_i.

2.3 Related work

Our work focuses on modeling pairwise score functions Φ and is related to previous approaches in the two following aspects.

Relations between mentions

A relation widely used by NEL systems is *coreference*: two mentions are coreferent if they refer to the same entity. Though, as we discussed in Section 1, other linguistic relations constrain entity assignments, only a few approaches (e.g., Cheng and Roth (2013); Ren et al. (2017)), exploit any relations other than coreference. We believe that the reason for this is that predicting and selecting relevant (often semantic) relations is in itself a challenging problem.

In Cheng and Roth (2013), relations between mentions are extracted using a labor-intensive approach, requiring a set of hand-crafted rules and a KB containing relations between entities. This approach is difficult to generalize to languages and domains which do not have such KBs or the settings where no experts are available to design the rules. We, in contrast, focus on automating the process using representation learning.

Most of these methods relied on relations predicted by external tools, usually a coreference system. One notable exception is Durrett and Klein (2014): they use a joint model of entity linking and coreference resolution. Nevertheless their coreference component is still supervised, whereas our relations are latent even at training time.

Representation learning

How can we define local score functions Ψ and pairwise score functions Φ? Previous approaches employ a wide spectrum of techniques.

At one extreme, extensive feature engineering was used to define useful features. For example, Ratinov et al. (2011) use cosine similarities between Wikipedia titles and local contexts as a feature when computing the local scores. For pairwise scores they exploit information about links between Wikipedia pages.

At the other extreme, feature engineering is almost completely replaced by representation learning. These approaches rely on pretrained embeddings of words (Mikolov et al., 2013; Pennington et al., 2014) and entities (He et al., 2013; Yamada et al., 2017; Ganea and Hofmann, 2017) and often do not use virtually any other hand-crafted features. Ganea and Hofmann (2017) showed that such an approach can yield SOTA accuracy on a standard benchmark (AIDA-CoNLL dataset). Their local and pairwise score functions are

$$\Psi(e_i, c_i) = \mathbf{e}_i^T \mathbf{B} f(c_i)$$
$$\Phi(e_i, e_j, D) = \frac{1}{n-1} \mathbf{e}_i^T \mathbf{R} \mathbf{e}_j \qquad (3)$$

where $\mathbf{e}_i, \mathbf{e}_j \in \mathbb{R}^d$ are the embeddings of entity e_i, e_j, $\mathbf{B}, \mathbf{R} \in \mathbb{R}^{d \times d}$ are diagonal matrices. The mapping $f(c_i)$ applies an attention mechanism to context words in c_i to obtain a feature representations of context ($f(c_i) \in \mathbb{R}^d$).

Note that the global component (the pairwise scores) is agnostic to any relations between entities or even to their ordering: it models $e_1, ..., e_n$ simply as a bag of entities. Our work is in line with Ganea and Hofmann (2017) in the sense that feature engineering plays no role in computing local and pair-wise scores. Furthermore, we argue that pair-wise scores should take into account relations between mentions which are represented by *relation embeddings*.

3 Multi-relational models

3.1 General form

We assume that there are K latent relations. Each relation k is assigned to a mention pair (m_i, m_j) with a non-negative weight ('confidence') α_{ijk}. The pairwise score (m_i, m_j) is computed as a weighted sum of relation-specific pairwise scores (see Figure 2, top):

$$\Phi(e_i, e_j, D) = \sum_{k=1}^{K} \alpha_{ijk} \Phi_k(e_i, e_j, D)$$

$\Phi_k(e_i, e_j, D)$ can be any pairwise score function, but here we adopt the one from Equation 3. Namely, we represent each relation k by a diagonal matrix $\mathbf{R}_k \in \mathbb{R}^{d \times d}$, and

$$\Phi_k(e_i, e_j, D) = \mathbf{e}_i^T \mathbf{R}_k \mathbf{e}_j$$

The weights α_{ijk} are normalized scores:

$$\alpha_{ijk} = \frac{1}{Z_{ijk}} \exp\left\{ \frac{f^T(m_i, c_i)\mathbf{D}_k f(m_j, c_j)}{\sqrt{d}} \right\} \quad (4)$$

where Z_{ijk} is a normalization factor, $f(m_i, c_i)$ is a function mapping (m_i, c_i) onto $\mathbb{R}^d$, and $\mathbf{D}_k \in \mathbb{R}^{d\times d}$ is a diagonal matrix.

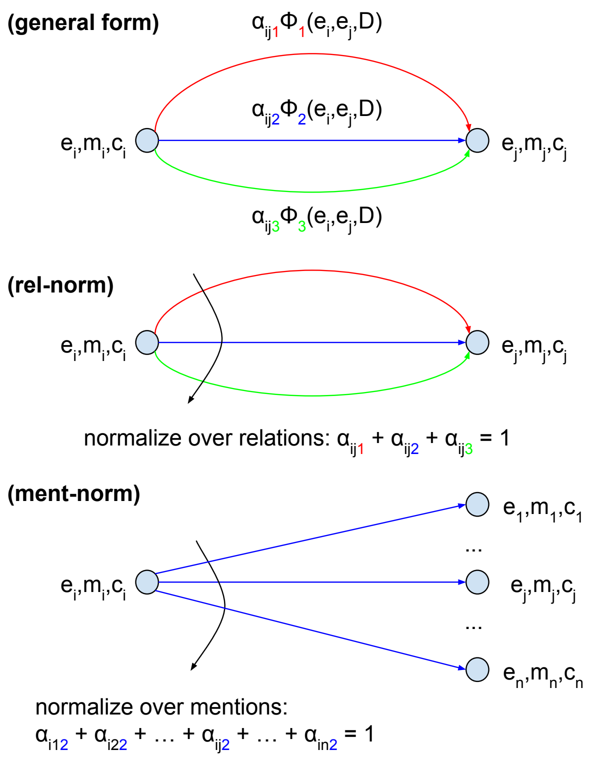

Figure 2: Multi-relational models: general form (top), rel-norm (middle) and ment-norm (bottom). Each color corresponds to one relation.

In our experiments, we use a single-layer neural network as f (see Figure 3) where c_i is a concatenation of the average embedding of words in the left context with the average embedding of words in the right context of the mention.[1]

As α_{ijk} is indexed both by mention index j and relation index k, we have two choices for Z_{ijk}: normalization over relations and normalization over mentions. We consider both versions of the model.

[1]We also experimented with LSTMs but we could not prevent them from severely overfitting, and the results were poor.

3.2 Rel-norm: Relation-wise normalization

For rel-norm, coefficients α_{ijk} are normalized over relations k, in other words,

$$Z_{ijk} = \sum_{k'=1}^{K} \exp\left\{ \frac{f^T(m_i, c_i)\mathbf{D}_{k'} f(m_j, c_j)}{\sqrt{d}} \right\}$$

so that $\sum_{k=1}^K \alpha_{ijk} = 1$ (see Figure 2, middle). We can also re-write the pairwise scores as

$$\Phi(e_i, e_j, D) = \mathbf{e}_i^T \mathbf{R}_{ij} \mathbf{e}_j \quad (5)$$

where $\mathbf{R}_{ij} = \sum_{k=1}^K \alpha_{ijk}\mathbf{R}_k$.

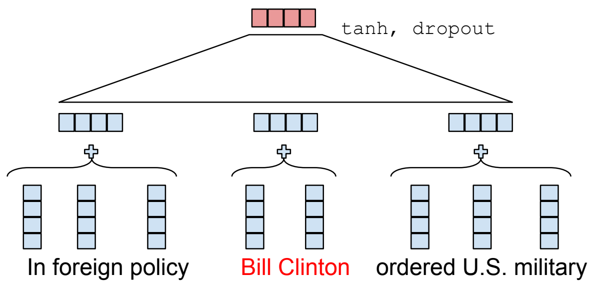

Figure 3: Function $f(m_i, c_i)$ is a single-layer neural network, with tanh activation function and a layer of dropout on top.

Intuitively, α_{ijk} is the probability of assigning a k-th relation to a mention pair (m_i, m_j). For every pair rel-norm uses these probabilities to choose one relation from the pool and relies on the corresponding relation embedding $\mathbf{R}_k$ to compute the compatibility score.

For $K = 1$ rel-norm reduces (up to a scaling factor) to the bag-of-entities model defined in Equation 3.

In principle, instead of relying on the linear combination of relation embeddings matrices $\mathbf{R}_k$, we could directly predict a context-specific relation embedding $\mathbf{R}_{ij} = diag\{g(m_i, c_i, m_j, c_j)\}$ where g is a neural network. However, in preliminary experiments we observed that this resulted in overfitting and poor performance. Instead, we choose to use a small fixed number of relations as a way to constrain the model and improve generalization.

3.3 Ment-norm: Mention-wise normalization

We can also normalize α_{ijk} over j:

$$Z_{ijk} = \sum_{\substack{j'=1 \\ j'\neq i}}^{n} \exp\left\{ \frac{f^T(m_i, c_i)\mathbf{D}_k f(m_{j'}, c_{j'})}{\sqrt{d}} \right\}$$

This implies that $\sum_{j=1,j\neq i}^{n} \alpha_{ijk} = 1$ (see Figure 2, bottom). If we rewrite the pairwise scores as

$$\Phi(e_i, e_j, D) = \sum_{k=1}^{K} \alpha_{ijk} \mathbf{e}_i^T \mathbf{R}_k \mathbf{e}_j, \qquad (6)$$

we can see that Equation 3 is a special case of ment-norm when $K = 1$ and $\mathbf{D}_1 = \mathbf{0}$. In other words, Ganea and Hofmann (2017) is our mono-relational ment-norm with uniform α.

The intuition behind ment-norm is that for each relation k and mention m_i, we are looking for mentions related to m_i with relation k. For each pair of m_i and m_j we can distinguish two cases: (i) α_{ijk} is small for all k: m_i and m_j are not related under any relation, (ii) α_{ijk} is large for one or more k: there are one or more relations which are predicted for m_i and m_j.

In principle, rel-norm can also indirectly handle both these cases. For example, it can master (i) by dedicating a distinct 'none' relation to represent lack of relation between the two mentions (with the corresponding matrix $\mathbf{R}_k$ set to $\mathbf{0}$). Though it cannot assign large weights (i.e., close to 1) to multiple relations (as needed for (ii)), it can in principle use the 'none' relation to vary the probability mass assigned to the rest of relations across mention pairs, thus achieving the same effect (up to a multiplicative factor). Nevertheless, in contrast to ment-norm, we do not observe this behavior for rel-norm in our experiments: the inductive basis seems to disfavor such configurations.

Ment-norm is in line with the current trend of using the attention mechanism in deep learning (Bahdanau et al., 2014), and especially related to multi-head attention of Vaswani et al. (2017). For each mention m_i and for each k, we can interpret α_{ijk} as the probability of choosing a mention m_j among the set of mentions in the document. Because here we have K relations, each mention m_i will have maximally K mentions (i.e. heads in terminology of Vaswani et al. (2017)) to focus on. Note though that they use multi-head attention for choosing input features in each layer, whereas we rely on this mechanism to compute pairwise scoring functions for the structured output (i.e. to compute potential functions in the corresponding undirected graphical model, see Section 3.4).

Mention padding

A potentially serious drawback of ment-norm is that the model uses all K relations even in cases where some relations are inapplicable. For example, consider applying relation *coreference* to mention "West Germany" in Figure 1. The mention is non-anaphoric: there are no mentions co-referent with it. Still the ment-norm model has to distribute the weight across the mentions. This problem occurs because of the normalization $\sum_{j=1,j\neq i}^{n} \alpha_{ijk} = 1$. Note that this issue does not affect standard applications of attention: normally the attention-weighted signal is input to another transformation (e.g., a flexible neural model) which can then disregard this signal when it is useless. This is not possible within our model, as it simply uses α_{ijk} to weight the bilinear terms without any extra transformation.

Luckily, there is an easy way to circumvent this problem. We add to each document a padding mention m_{pad} linked to a padding entity e_{pad}. In this way, the model can use the padding mention to damp the probability mass that the other mentions receive. This method is similar to the way some mention-ranking coreference models deal with non-anaphoric mentions (e.g. Wiseman et al. (2015)).

3.4 Implementation

Following Ganea and Hofmann (2017) we use Equation 2 to define a conditional random field (CRF). We use the local score function identical to theirs and the pairwise scores are defined as explained above:

$$q(E|D) \propto \exp\left\{\sum_{i=1}^{n} \Psi(e_i, c_i) + \sum_{i\neq j} \Phi(e_i, e_j, D)\right\}$$

We also use max-product loopy belief propagation (LBP) to estimate the max-marginal probability

$$\hat{q}_i(e_i|D) \approx \max_{\substack{e_1,\ldots,e_{i-1}\\ e_{i+1},\ldots,e_n}} q(E|D)$$

for each mention m_i. The final score function for m_i is given by:

$$\rho_i(e) = g(\hat{q}_i(e|D), \hat{p}(e|m_i))$$

where g is a two-layer neural network and $\hat{p}(e|m_i)$ is the probability of selecting e conditioned only on m_i. This probability is computed by mixing mention-entity hyperlink count statistics from Wikipedia, a large Web corpus and YAGO.[2]

[2]See Ganea and Hofmann (2017, Section 6).

We minimize the following ranking loss:

$$L(\theta) = \sum_{D \in \mathcal{D}} \sum_{m_i \in D} \sum_{e \in C_i} h(m_i, e) \tag{7}$$

$$h(m_i, e) = \max\big(0, \gamma - \rho_i(e_i^*) + \rho_i(e)\big)$$

where θ are the model parameters, $\mathcal{D}$ is a training dataset, and e_i^* is the ground-truth entity. Adam (Kingma and Ba, 2014) is used as an optimizer.

For ment-norm, the padding mention is treated like any other mentions. We add $\mathbf{f}_{pad} = f(m_{pad}, c_{pad})$ and $\mathbf{e}_{pad} \in \mathbb{R}^d$, an embedding of e_{pad}, to the model parameter list, and tune them while training the model.

In order to encourage the models to explore different relations, we add the following regularization term to the loss function in Equation 7:

$$\lambda_1 \sum_{i,j} \text{dist}(\mathbf{R}_i, \mathbf{R}_j) + \lambda_2 \sum_{i,j} \text{dist}(\mathbf{D}_i, \mathbf{D}_j)$$

where λ_1, λ_2 are set to -10^{-7} in our experiments, $\text{dist}(\mathbf{x}, \mathbf{y})$ can be any distance metric. We use:

$$\text{dist}(\mathbf{x}, \mathbf{y}) = \left\| \frac{\mathbf{x}}{\|\mathbf{x}\|_2} - \frac{\mathbf{y}}{\|\mathbf{y}\|_2} \right\|_2$$

Using this regularization to favor diversity is important as otherwise relations tend to collapse: their relation embeddings $\mathbf{R}_k$ end up being very similar to each other.

4 Experiments

We evaluated four models: (i) *rel-norm* proposed in Section 3.2; (ii) *ment-norm* proposed in Section 3.3; (iii) *ment-norm ($K = 1$)*: the mono-relational version of ment-norm; and (iv) *ment-norm (no pad)*: the ment-norm without using mention padding. Recall also that our mono-relational (i.e. $K = 1$) rel-norm is equivalent to the relation-agnostic baseline of Ganea and Hofmann (2017).

We implemented our models in PyTorch and run experiments on a Titan X GPU. The source code and trained models will be publicly available at `https://github.com/lephong/mulrel-nel`.

4.1 Setup

We set up our experiments similarly to those of Ganea and Hofmann (2017), run each model 5 times, and report average and 95% confidence interval of the standard micro F1 score (aggregates over all mentions).

Datasets

For *in-domain* scenario, we used AIDA-CoNLL dataset[3] (Hoffart et al., 2011). This dataset contains AIDA-train for training, AIDA-A for dev, and AIDA-B for testing, having respectively 946, 216, and 231 documents. For *out-domain* scenario, we evaluated the models trained on AIDA-train, on five popular test sets: MSNBC, AQUAINT, ACE2004, which were cleaned and updated by Guo and Barbosa (2016); WNED-CWEB (CWEB), WNED-WIKI (WIKI), which were automatically extracted from ClueWeb and Wikipedia (Guo and Barbosa, 2016; Gabrilovich et al., 2013). The first three are small with 20, 50, and 36 documents whereas the last two are much larger with 320 documents each. Following previous works (Yamada et al., 2016; Ganea and Hofmann, 2017), we considered only mentions that have entities in the KB (i.e., Wikipedia).

Candidate selection

For each mention m_i, we selected 30 top candidates using $\hat{p}(e|m_i)$. We then kept 4 candidates with the highest $\hat{p}(e|m_i)$ and 3 candidates with the highest scores $\mathbf{e}^T \left(\sum_{w \in d_i} \mathbf{w}\right)$, where $\mathbf{e}, \mathbf{w} \in \mathbb{R}^d$ are entity and word embeddings, d_i is the 50-word window context around m_i.

Hyper-parameter setting

We set $d = 300$ and used GloVe (Pennington et al., 2014) word embeddings trained on 840B tokens for computing f in Equation 4, and entity embeddings from Ganea and Hofmann (2017).[4] We use the following parameter values: $\gamma = 0.01$ (see Equation 7), the number of LBP loops is 10, the dropout rate for f was set to 0.3, the window size of local contexts c_i (for the pairwise score functions) is 6. For rel-norm, we initialized $\text{diag}(\mathbf{R}_k)$ and $\text{diag}(\mathbf{D}_k)$ by sampling from $\mathcal{N}(0, 0.1)$ for all k. For ment-norm, we did the same except that $\text{diag}(\mathbf{R}_1)$ was sampled from $\mathcal{N}(1, 0.1)$.

To select the best number of relations K, we considered all values of $K \leq 7$ ($K > 7$ would not fit in our GPU memory, as some of the documents are large). We selected the best ones based on the development scores: 6 for rel-norm, 3 for ment-norm, and 3 for ment-norm (no pad).

When training the models, we applied early stopping. For rel-norm, when the model reached

[3]TAC KBP datasets are no longer available.

[4]`https://github.com/dalab/deep-ed`

91% F1 on the dev set, [5] we reduced the learning rate from 10^{-4} to 10^{-5}. We then stopped the training when F1 was not improved after 20 epochs. We did the same for ment-norm except that the learning rate was changed at 91.5% F1.

Note that all the hyper-parameters except K and the turning point for early stopping were set to the values used by Ganea and Hofmann (2017). Systematic tuning is expensive though may have further increased the result of our models.

4.2 Results

Methods	Aida-B
Chisholm and Hachey (2015)	88.7
Guo and Barbosa (2016)	89.0
Globerson et al. (2016)	91.0
Yamada et al. (2016)	91.5
Ganea and Hofmann (2017)	92.22 ± 0.14
rel-norm	92.41 ± 0.19
ment-norm	$\mathbf{93.07} \pm 0.27$
ment-norm ($K = 1$)	92.89 ± 0.21
ment-norm (no pad)	92.37 ± 0.26

Table 1: F1 scores on AIDA-B (test set).

Table 1 shows micro F1 scores on AIDA-B of the SOTA methods and ours, which all use Wikipedia and YAGO mention-entity index. To our knowledge, ours are the only (unsupervisedly) inducing and employing more than one relations on this dataset. The others use only one relation, coreference, which is given by simple heuristics or supervised third-party resolvers. All four our models outperform any previous method, with ment-norm achieving the best results, 0.85% higher than that of Ganea and Hofmann (2017).

Table 2 shows micro F1 scores on 5 out-domain test sets. Besides ours, only Cheng and Roth (2013) employs several mention relations. Ment-norm achieves the highest F1 scores on MSNBC and ACE2004. On average, ment-norm's F1 score is 0.3% higher than that of Ganea and Hofmann (2017), but 0.2% lower than Guo and Barbosa (2016)'s. It is worth noting that Guo and Barbosa (2016) performs exceptionally well on WIKI, but substantially worse than ment-norm on all other datasets. Our other three models, however, have lower average F1 scores compared to the best previous model.

The experimental results show that ment-norm outperforms rel-norm, and that mention padding plays an important role.

[5]We chose the highest F1 that rel-norm always achieved without the learning rate reduction.

4.3 Analysis

Mono-relational v.s. multi-relational

For rel-norm, the mono-relational version (i.e., Ganea and Hofmann (2017)) is outperformed by the multi-relational one on AIDA-CoNLL, but performs significantly better on all five out-domain datasets. This implies that multi-relational rel-norm does not generalize well across domains.

For ment-norm, the mono-relational version performs worse than the multi-relational one on all test sets except AQUAINT. We speculate that this is due to multi-relational ment-norm being less sensitive to prediction errors. Since it can rely on multiple factors more easily, a single mistake in assignment is unlikely to have large influence on its predictions.

Oracle

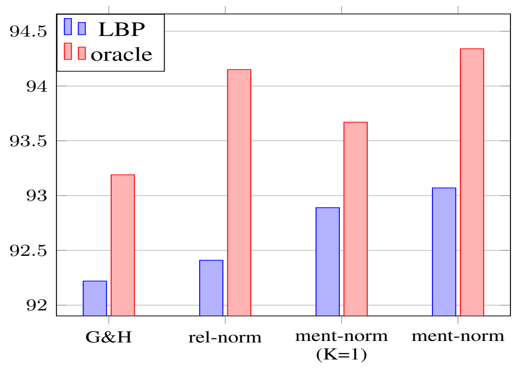

Figure 4: F1 on AIDA-B when using LBP and the oracle. G&H is Ganea and Hofmann (2017).

In order to examine learned relations in a more transparant setting, we consider an idealistic scenario where imperfection of LBP, as well as mistakes in predicting other entities, are taken out of the equation using an oracle. This oracle, when we make a prediction for mention m_i, will tell us the correct entity e^*_j for every other mentions $m_j, j \neq i$. We also used AIDA-A (development set) for selecting the numbers of relations for rel-norm and ment-norm. They are set to 6 and 3, respectively. Figure 4 shows the micro F1 scores.

Surprisingly, the performance of oracle rel-norm is close to that of oracle ment-norm, although without using the oracle the difference was substantial. This suggests that rel-norm is more sensitive to prediction errors than ment-norm. Ganea and Hofmann (2017), even with the help of the oracle, can only perform slightly better than LBP (i.e. non-oracle) ment-norm. This

Methods	MSNBC	AQUAINT	ACE2004	CWEB	WIKI	Avg
Milne and Witten (2008)	78	85	81	64.1	81.7	77.96

ment-norm (no pad)	93.6 ± 0.3	87.8 ± 0.5	**90.0** ± 0.3	77.0 ± 0.2	77.3 ± 0.3	85.13

Table 2: F1 scores on five out-domain test sets. Underlined scores show cases where the corresponding model outperforms the baseline.

suggests that its global coherence scoring component is indeed too simplistic. Also note that both multi-relational oracle models substantially outperform the two mono-relational oracle models. This shows the benefit of using more than one relations, and the potential of achieving higher accuracy with more accurate inference methods.

Relations

In this section we qualitatively examine relations that the models learned by looking at the probabilities α_{ijk}. See Figure 5 for an example. In that example we focus on mention "Liege" in the sentence at the top and study which mentions are related to it under two versions of our model: rel-norm (leftmost column) and ment-norm (rightmost column).

For rel-norm it is difficult to interpret the meaning of the relations. It seems that the first relation dominates the other two, with very high weights for most of the mentions. Nevertheless, the fact that rel-norm outperforms the baseline suggests that those learned relations encode some useful information.

For ment-norm, the first relation is similar to coreference: the relation prefers those mentions that potentially refer to the same entity (and/or have semantically similar mentions): see Figure 5 (left, third column). The second and third relations behave differently from the first relation as they prefer mentions having more distant meanings and are complementary to the first relation. They assign large weights to (1) "Belgium" and (2) "Brussels" but small weights to (4) and (6) "Liege". The two relations look similar in this example, however they are not identical in general. See a histogram of bucketed values of their weights in Figure 5 (right): their α have quite different distributions.

Complexity

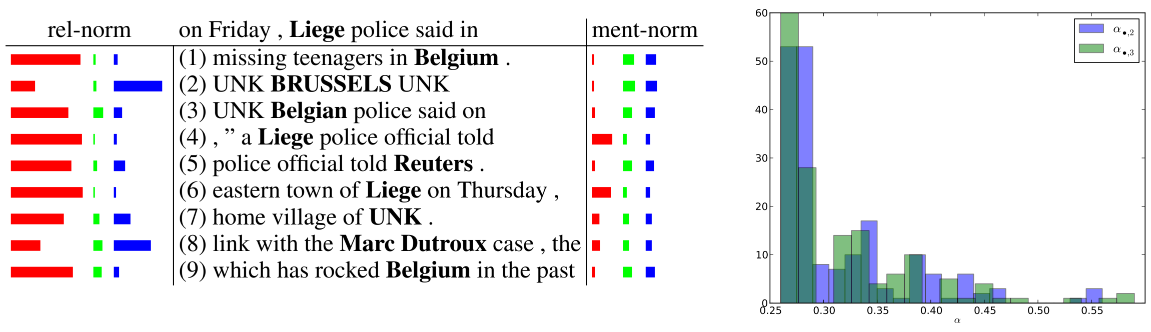
The complexity of rel-norm and ment-norm is linear in K, so in principle our models should be considerably more expensive than Ganea and Hofmann (2017). However, our models converge much faster than their relation-agnostic model: on average ours needs 120 epochs, compared to theirs 1250 epochs. We believe that the structural bias helps the model to capture necessary regularities more easily. In terms of wall-clock time, our model requires just under 1.5 hours to train, that is ten times faster than the relation agnostic model (Ganea and Hofmann, 2017). In addition, the difference in testing time is negligible when using a GPU.

5 Conclusion and Future work

We have shown the benefits of using relations in NEL. Our models consider relations as latent variables, thus do not require any extra supervision. Representation learning was used to learn relation embeddings, eliminating the need for extensive feature engineering. The experimental results show that our best model achieves the best reported F1 on AIDA-CoNLL with an improvement of 0.85% F1 over the best previous results.

Conceptually, modeling multiple relations is substantially different from simply modeling coherence (as in Ganea and Hofmann (2017)). In this way we also hope it will lead to interesting follow-up work, as individual relations can be informed by injecting prior knowledge (e.g., by training jointly with relation extraction models).

In future work, we would like to use syntactic and discourse structures (e.g., syntactic dependency paths between mentions) to encourage the models to discover a richer set of relations. We also would like to combine ment-norm and rel-norm. Besides, we would like to examine whether



rel-norm | on Friday , **Liege** police said in | ment-norm

(1) missing teenagers in **Belgium** .

Abstract

Document date is essential for many important tasks, such as document retrieval, summarization, event detection, etc. While existing approaches for these tasks assume accurate knowledge of the document date, this is not always available, especially for arbitrary documents from the Web. Document Dating is a challenging problem which requires inference over the temporal structure of the document. Prior document dating systems have largely relied on handcrafted features while ignoring such document-internal structures. In this paper, we propose NeuralDater, a Graph Convolutional Network (GCN) based document dating approach which jointly exploits syntactic and temporal graph structures of document in a principled way. To the best of our knowledge, this is the first application of deep learning for the problem of document dating. Through extensive experiments on real-world datasets, we find that NeuralDater significantly outperforms state-of-the-art baseline by 19% absolute (45% relative) accuracy points.

1 Introduction

Date of a document, also referred to as the Document Creation Time (DCT), is at the core of many important tasks, such as, information retrieval (Olson et al., 1999; Li and Croft, 2003; Dakka et al., 2008), temporal reasoning (Mani and Wilson, 2000; Llidó et al., 2001), text summarization (Wan, 2007), event detection (Allan et al., 1998), and analysis of historical text (de Jong et al., 2005a), among others. In all such tasks, the document date is assumed to be available and also

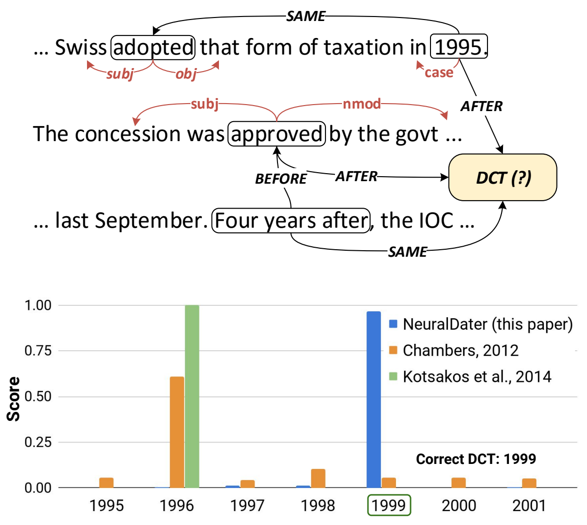

Figure 1: **Top:** An example document annotated with syntactic and temporal dependencies. In order to predict the right value of 1999 for the Document Creation Time (DCT), inference over these document structures is necessary. **Bottom:** Document date prediction by two state-of-the-art-baselines and NeuralDater, the method proposed in this paper. While the two previous methods are getting misled by the temporal expression (*1995*) in the document, NeuralDater is able to use the syntactic and temporal structure of the document to predict the right value (*1999*).

accurate – a strong assumption, especially for arbitrary documents from the Web. Thus, there is a need to automatically predict the date of a document based on its content. This problem is referred to as *Document Dating*.

Initial attempts on automatic document dating started with generative models by (de Jong et al., 2005b). This model is later improved by (Kanhabua and Nørvåg, 2008a) who incorporate additional features such as POS tags, collocations, etc. Chambers (2012) shows significant improvement over these prior efforts through their discriminative models using handcrafted temporal features. Kotsakos et al. (2014) propose a statistical approach for document dating exploiting term bursti-

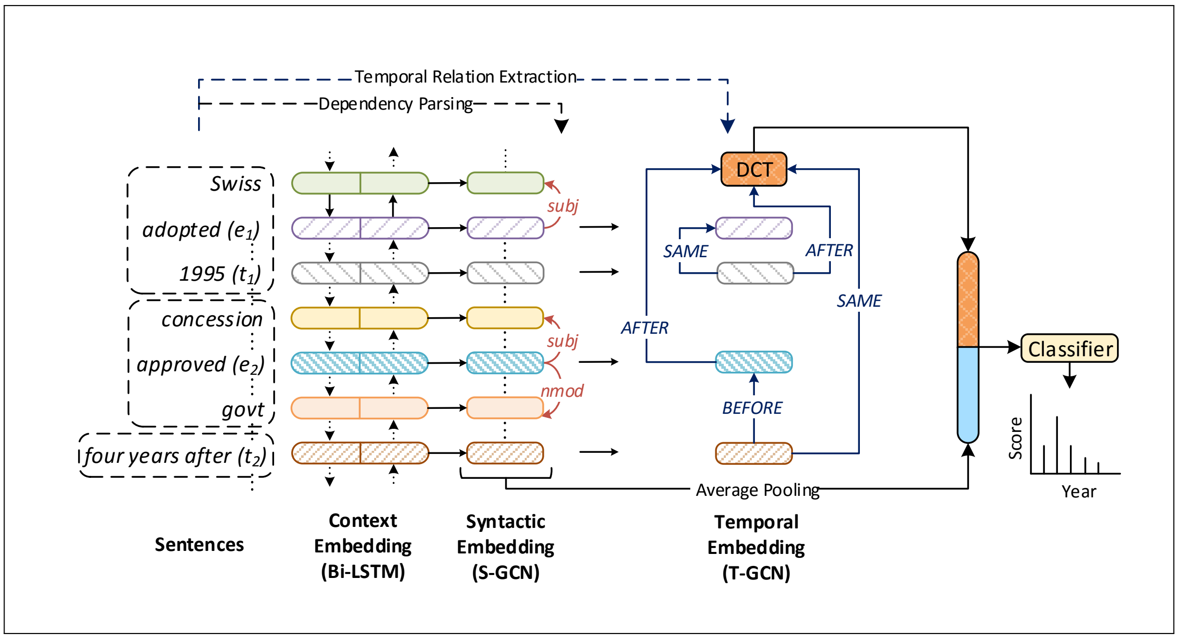

Figure 2: Overview of NeuralDater. NeuralDater exploits syntactic and temporal structure in a document to learn effective representation, which in turn are used to predict the document time. NeuralDater uses a Bi-directional LSTM (Bi-LSTM), two Graph Convolution Networks (GCN) – one over the dependency tree and the other over the document's temporal graph – along with a softmax classifier, all trained end-to-end jointly. Please see Section 4 for more details.

ness (Lappas et al., 2009).

Document dating is a challenging problem which requires extensive reasoning over the temporal structure of the document. Let us motivate this through an example shown in Figure 1. In the document, *four years after* plays a crucial role in identifying the creation time of the document. The existing approaches give higher confidence for timestamp immediate to the year mention *1995*. NeuralDater exploits the syntactic and temporal structure of the document to predict the right timestamp (1999) for the document. With the exception of (Chambers, 2012), all prior works on the document dating problem ignore such informative temporal structure within the document.

Research in document event extraction and ordering have made it possible to extract such temporal structures involving events, temporal expressions, and the (unknown) document date in a document (Mirza and Tonelli, 2016; Chambers et al., 2014). While methods to perform reasoning over such structures exist (Verhagen et al., 2007, 2010; UzZaman et al., 2013; Llorens et al., 2015; Pustejovsky et al., 2003), none of them have exploited advances in deep learning (Krizhevsky et al., 2012; Hinton et al., 2012; Goodfellow et al., 2016). In particular, recently proposed Graph Convolution Networks (GCN) (Defferrard et al., 2016; Kipf and Welling, 2017) have emerged as a way to learn graph representation while encoding structural information and constraints represented by the graph. We adapt GCNs for the document dating problem and make the following contributions:

- We propose NeuralDater, a Graph Convolution Network (GCN)-based approach for document dating. To the best of our knowledge, this is the first application of GCNs, and more broadly deep neural network-based methods, for the document dating problem.
- NeuralDater is the first document dating approach which exploits syntactic as well temporal structure of the document, all within a principled joint model.
- Through extensive experiments on multiple real-world datasets, we demonstrate NeuralDater's effectiveness over state-of-the-art baselines.

NeuralDater's source code and datasets used in the paper are available at `http://github.com/malllabiisc/NeuralDater`.

2 Related Work

Automatic Document Dating: de Jong et al. (2005b) propose the first approach for automating document dating through a statistical language model. Kanhabua and Nørvåg (2008a) further extend this work by incorporating semantic-based preprocessing and temporal entropy (Kanhabua and Nørvåg, 2008b) based term-weighting. Chambers (2012) proposes a MaxEnt based discriminative model trained on hand-crafted temporal features. He also proposes a model to learn probabilistic constraints between year mentions and the actual creation time of the document. We draw inspiration from his work for exploiting temporal reasoning for document dating. Kotsakos et al. (2014) propose a purely statistical method which considers lexical similarity alongside burstiness (Lappas et al., 2009) of terms for dating documents. To the best of our knowledge, NeuralDater, our proposed method, is the first method to utilize deep learning techniques for the document dating problem.

Event Ordering Systems: Temporal ordering of events is a vast research topic in NLP. The problem is posed as a temporal relation classification between two given temporal entities. Machine Learned classifiers and well crafted linguistic features for this task are used in (Chambers et al., 2007; Mirza and Tonelli, 2014). D'Souza and Ng (2013) use a hybrid approach by adding 437 hand-crafted rules. Chambers and Jurafsky (2008); Yoshikawa et al. (2009) try to classify with many more temporal constraints, while utilizing integer linear programming and Markov logic.

CAEVO, a CAscading EVent Ordering architecture (Chambers et al., 2014) use sieve-based architecture (Lee et al., 2013) for temporal event ordering for the first time. They mix multiple learners according to their precision based ranks and use transitive closure for maintaining consistency of temporal graph. Mirza and Tonelli (2016) recently propose CATENA (CAusal and TEmporal relation extraction from NAtural language texts), the first integrated system for the temporal and causal relations extraction between pre-annotated events and time expressions. They also incorporate sieve-based architecture which outperforms existing methods in temporal relation classification domain. We make use of CATENA for temporal graph construction in our work.

Graph Convolutional Networks (GCN): GCNs generalize Convolutional Neural Network (CNN) over graphs. GCN is introduced by (Bruna et al., 2014), and later extended by (Defferrard et al., 2016) with efficient localized filter approximation in spectral domain. Kipf and Welling (2017) propose a first-order approximation of localized filters through layer-wise propagation rule. GCNs over syntactic dependency trees have been recently exploited in the field of semantic-role labeling (Marcheggiani and Titov, 2017), neural machine translation (Bastings et al., 2017a), event detection (Bastings et al., 2017b). In our work, we successfully use GCNs for document dating.

3 Background: Graph Convolution Networks (GCN)

In this section, we provide an overview of Graph Convolution Networks (GCN) (Kipf and Welling, 2017). GCN learns an embedding for each node of the graph it is applied over. We first present GCN for undirected graphs and then move onto GCN for directed graph setting.

3.1 GCN on Undirected Graph

Let $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ be an undirected graph, where $\mathcal{V}$ is a set of n vertices and $\mathcal{E}$ the set of edges. The input feature matrix $\mathcal{X} \in \mathbb{R}^{n \times m}$ whose rows are input representation of node u, $x_u \in \mathbb{R}^m, \forall u \in \mathcal{V}$. The output hidden representation $h_v \in \mathbb{R}^d$ of a node v after a single layer of graph convolution operation can be obtained by considering only the immediate neighbors of v. This can be formulated as:

$$h_v = f\left(\sum_{u \in \mathcal{N}(v)} (W x_u + b)\right), \quad \forall v \in \mathcal{V}.$$

Here, model parameters $W \in \mathbb{R}^{d \times m}$ and $b \in \mathbb{R}^d$ are learned in a task-specific setting using first-order gradient optimization. $\mathcal{N}(v)$ refers to the set of neighbors of v and f is any non-linear activation function. We have used ReLU as the activation function in this paper[1].

In order to capture nodes many hops away, multiple GCN layers may be stacked one on top of another. In particular, h_v^{k+1}, representation of node v after k^{th} GCN layer can be formulated as:

$$h_v^{k+1} = f\left(\sum_{u \in \mathcal{N}(v)} \left(W^k h_u^k + b^k\right)\right), \forall v \in \mathcal{V}.$$

where h_u^k is the input to the k^{th} layer.

[1]ReLU: $f(x) = \max(0, x)$

3.2 GCN on Labeled and Directed Graph

In this section, we consider GCN formulation over graphs where each edge is labeled as well as directed. In this setting, an edge from node u to v with label $l(u,v)$ is denoted as $(u,v,l(u,v))$. While a few recent works focus on GCN over directed graphs (Yasunaga et al., 2017; Marcheggiani and Titov, 2017), none of them consider labeled edges. We handle both direction and label by incorporating label and direction specific filters.

Based on the assumption that the information in a directed edge need not only propagate along its direction, following (Marcheggiani and Titov, 2017) we define an updated edge set $\mathcal{E}'$ which expands the original set $\mathcal{E}$ by incorporating inverse, as well self-loop edges.

$$\mathcal{E}' = \mathcal{E} \cup \{(v,u,l(u,v)^{-1}) \mid (u,v,l(u,v)) \in \mathcal{E}\} \cup \{(u,u,\top) \mid u \in \mathcal{V})\}. \quad (1)$$

Here, $l(u,v)^{-1}$ is the inverse edge label corresponding to label $l(u,v)$, and $\top$ is a special empty relation symbol for self-loop edges. We now define h_v^{k+1} as the embedding of node v after k^{th} GCN layer applied over the directed and labeled graph as:

$$h_v^{k+1} = f\left(\sum_{u\in\mathcal{N}(v)} \left(W_{l(u,v)}^k h_u^k + b_{l(u,v)}^k\right)\right). \quad (2)$$

We note that the parameters $W_{l(u,v)}^k$ and $b_{l(u,v)}^k$ in this case are edge label specific.

3.3 Incorporating Edge Importance

In many practical settings, we may not want to give equal importance to all the edges. For example, in case of automatically constructed graphs, some of the edges may be erroneous and we may want to automatically learn to discard them. Edge-wise gating may be used in a GCN to give importance to relevant edges and subdue the noisy ones. Bastings et al. (2017b); Marcheggiani and Titov (2017) used gating for similar reasons and obtained high performance gain. At k^{th} layer, we compute gating value for a particular edge $(u,v,l(u,v))$ as:

$$g_{u,v}^k = \sigma\left(h_u^k \cdot \hat{w}_{l(u,v)}^k + \hat{b}_{l(u,v)}^k\right),$$

where, $\sigma(\cdot)$ is the sigmoid function, $\hat{w}_{l(u,v)}^k$ and $\hat{b}_{l(u,v)}^k$ are label specific gating parameters. Thus, gating helps to make the model robust to the noisy labels and directions of the input graphs. GCN embedding of a node while incorporating edge gating may be computed as follows.

$$h_v^{k+1} = f\left(\sum_{u\in\mathcal{N}(v)} g_{u,v}^k \times \left(W_{l(u,v)}^k h_u^k + b_{l(u,v)}^k\right)\right).$$

4 NeuralDater Overview

The Documents Dating problem may be cast as a multi-class classification problem (Kotsakos et al., 2014; Chambers, 2012). In this section, we present an overview of NeuralDater, the document dating system proposed in this paper. Architectural overview of NeuralDater is shown in Figure 2.

NeuralDater is a deep learning-based multi-class classification system. It takes in a document as input and returns its predicted date as output by exploiting the syntactic and temporal structure of document.

NeuralDater network consists of three layers which learns an embedding for the Document Creation Time (DCT) node corresponding to the document. This embedding is then fed to a softmax classifier which produces a distribution over timestamps. Following prior research (Chambers, 2012; Kotsakos et al., 2014), we work with year granularity for the experiments in this paper. We however note that NeuralDater can be trained for finer granularity with appropriate training data. The NeuralDater network is trained end-to-end using training data. We briefly present NeuralDater's various components below. Each component is described in greater detail in subsequent sections.

- **Context Embedding**: In this layer, NeuralDater uses a Bi-directional LSTM (Bi-LSTM) to learn embedding for each token in the document. Bi-LSTMs have been shown to be quite effective in capturing local context inside token embeddings (Sutskever et al., 2014).

- **Syntactic Embedding**: In this step, NeuralDater revises token embeddings from previous step by running a GCN over the dependency parses of sentences in the document. We refer to this GCN as **Syntactic GCN** or **S-GCN**. While the Bi-LSTM captures immediate local context in token embeddings, S-

GCN augments them by capturing syntactic context.

- **Temporal Embedding**: In this step, NeuralDater further refines embeddings learned by S-GCN to incorporate cues from temporal structure of event and times in the document. NeuralDater uses state-of-the-art causal and temporal relation extraction algorithm (Mirza and Tonelli, 2016) for extracting temporal graph for each document. A GCN is then run over this temporal graph to refine the embeddings from previous layer. We refer to this GCN as **Temporal GCN** or **T-GCN**. In this step, a special DCT node is introduced whose embedding is also learned by the T-GCN.

- **Classifier**: Embedding of the DCT node along with average pooled embeddings learned by S-GCN are fed to a fully connected softmax classifier which makes the final prediction about the date of the document.

Even though the previous discussion is presented in a sequential manner, the whole network is trained in a joint end-to-end manner using backpropagation.

5 NeuralDater Details

In this section, we present detailed description of various components of NeuralDater.

5.1 Context Embedding (Bi-LSTM)

Let us consider a document D with n tokens $w_1, w_2, ..., w_n$. We first represent each token by a k-dimensional word embedding. For the experiments in this paper, we use GloVe (Pennington et al., 2014) embeddings. These token embeddings are stacked together to get the document representation $\mathcal{X} \in \mathbb{R}^{n \times k}$. We then employ a Bi-directional LSTM (Bi-LSTM) (Hochreiter and Schmidhuber, 1997) on the input matrix $\mathcal{X}$ to obtain contextual embedding for each token. After stacking contextual embedding of all these tokens, we get the new document representation matrix $\mathcal{H}^{cntx} \in \mathbb{R}^{n \times r_{cntx}}$. In this new representation, each token is represented in a r_{cntx}-dimensional space. Our choice of LSTMs for learning contextual embeddings for tokens is motivated by the previous success of LSTMs in this task (Sutskever et al., 2014).

5.2 Syntactic Embedding (S-GCN)

While the Bi-LSTM is effective at capturing immediate local context of a token, it may not be as effective in capturing longer range dependencies among words in a sentence. For example, in Figure 1, we would like the embedding of token *approved* to be directly affected by *govt*, even though they are not immediate neighbors. A dependency parse may be used to capture such longer-range connections. In fact, similar features were exploited by (Chambers, 2012) for the document dating problem. NeuralDater captures such longer-range information by using another GCN run over the syntactic structure of the document. We describe this in detail below.

The context embedding, $\mathcal{H}^{cntx} \in \mathbb{R}^{n \times r_{cntx}}$ learned in the previous step is used as input to this layer. For a given document, we first extract its syntactic dependency structure by applying the Stanford CoreNLP's dependency parser (Manning et al., 2014) on each sentence in the document individually. We now employ the Graph Convolution Network (GCN) over this dependency graph using the GCN formulation presented in Section 3.2. We call this GCN the Syntactic GCN or S-GCN, as mentioned in Section 4.

Since S-GCN operates over the dependency graph and uses Equation 2 for updating embeddings, the number of parameters in S-GCN is directly proportional to the number of dependency edge types. Stanford CoreNLP's dependency parser returns 55 different dependency edge types. This large number of edge types is going to significantly over-parameterize S-GCN, thereby increasing the possibility of overfitting. In order to address this, we use only three edge types in S-GCN. For each edge connecting nodes w_i and w_j in $\mathcal{E}'$ (see Equation 1), we determine its new type $L(w_i, w_j)$ as follows:

- $L(w_i, w_j) = \rightarrow$ if $(w_i, w_j, l(w_i, w_j)) \in \mathcal{E}'$, i.e., if the edge is an original dependency parse edge

- $L(w_i, w_j) = \leftarrow$ if $(w_i, w_j, l(w_i, w_j)^{-1}) \in \mathcal{E}'$, i.e., if the edges is an inverse edge

- $L(w_i, w_j) = \top$ if $(w_i, w_j, \top) \in \mathcal{E}'$, i.e., if the edge is a self-loop with $w_i = w_j$

S-GCN now estimates embedding $h^{syn}_{w_i} \in \mathbb{R}^{r_{syn}}$ for each token w_i in the document using the formulation shown below.

$$h_{w_i}^{syn} = f\left(\sum_{w_j \in \mathcal{N}(w_i)} \left(W_{L(w_i,w_j)} h_{w_j}^{cntx} + b_{L(w_i,w_j)} \right) \right)$$

Please note S-GCN's use of the new edge types $L(w_i, w_j)$ above, instead of the $l(w_i, w_j)$ types used in Equation 2. By stacking embeddings for all the tokens together, we get the new embedding matrix $\mathcal{H}^{syn} \in \mathbb{R}^{n \times r_{syn}}$ representing the document.

AveragePooling: We obtain an embedding h_D^{avg} for the whole document by average pooling of every token representation.

$$h_D^{avg} = \frac{1}{n} \sum_{i=1}^{n} h_{w_i}^{syn}. \tag{3}$$

5.3 Temporal Embedding (T-GCN)

In this layer, NeuralDater exploits temporal structure of the document to learn an embedding for the Document Creation Time (DCT) node of the document. First, we describe the construction of temporal graph, followed by GCN-based embedding learning over this graph.

Temporal Graph Construction: NeuralDater uses Stanford's SUTime tagger (Chang and Manning, 2012) for date normalization and the event extraction classifier of (Chambers et al., 2014) for event detection. The annotated document is then passed to CATENA (Mirza and Tonelli, 2016), current state-of-the-art temporal and causal relation extraction algorithm, to obtain a temporal graph for each document. Since our task is to predict the creation time of a given document, we supply DCT as unknown to CATENA. We hypothesize that the temporal relations extracted in absence of DCT are helpful for document dating and we indeed find this to be true, as shown in Section 7. Temporal graph is a directed graph, where nodes correspond to events, time mentions, and the Document Creation Time (DCT). Edges in this graph represent causal and temporal relationships between them. Each edge is attributed with a label representing the type of the temporal relation. CATENA outputs 9 different types of temporal relations, out of which we selected five types, viz., *AFTER*, *BEFORE*, *SAME*, *INCLUDES*, and *IS_INCLUDED*. The remaining four types were ignored as they were substantially infrequent.

Please note that the temporal graph may involve only a small number of tokens in the document.

Datasets	# Docs	Start Year	End Year
APW	675k	1995	2010
NYT	647k	1987	1996

Table 1: Details of datasets used. Please see Section 6 for details.

For example, in the temporal graph in Figure 2, there are a total of 5 nodes: two temporal expression nodes (*1995* and *four years after*), two event nodes (*adopted* and *approved*), and a special DCT node. This graph also consists of temporal relation edges such as (*four years after*, *approved*, *BEFORE*).

Temporal Graph Convolution: NeuralDater employs a GCN over the temporal graph constructed above. We refer to this GCN as the Temporal GCN or T-GCN, as mentioned in Section 4. T-GCN is based on the GCN formulation presented in Section 3.2. Unlike S-GCN, here we consider label and direction specific parameters as the temporal graph consists of only five types of edges.

Let n_T be the number of nodes in the temporal graph. Starting with $\mathcal{H}^{syn}$ (Section 5.2), T-GCN learns a r_{temp}-dimensional embedding for each node in the temporal graph. Stacking all these embeddings together, we get the embedding matrix $\mathcal{H}^{temp} \in \mathbb{R}^{n_T \times r_{temp}}$. T-GCN embeds the temporal constraints induced by the temporal graph in $h_{DCT}^{temp} \in \mathbb{R}^{r_{temp}}$, embedding of the DCT node of the document.

5.4 Classifier

Finally, the DCT embedding h_{DCT}^{temp} and average-pooled syntactic representation h_D^{avg} (see Equation 3) of document D are concatenated and fed to a fully connected feed forward network followed by a softmax. This allows the NeuralDater to exploit context, syntactic, and temporal structure of the document to predict the final document date y.

$$\begin{aligned} h_D^{avg+temp} &= [h_{DCT}^{temp} \,;\, h_D^{avg}] \\ p(y|D) &= \text{Softmax}(W \cdot h_D^{avg+temp} + b). \end{aligned}$$

6 Experimental Setup

Datasets: We experiment on Associated Press Worldstream (APW) and New York Times (NYT) sections of Gigaword corpus (Parker et al., 2011). The original dataset contains around 3 million documents of APW and 2 million documents of NYT from span of multiple years. From both sections, we randomly sample around 650k documents while maintaining balance among years. Documents belonging to years with substantially fewer documents are omitted. Details of the dataset can be found in Table 1. For train, test and validation splits, the dataset was randomly divided in 80:10:10 ratio.

Evaluation Criteria: Given a document, the model needs to predict the year in which the document was published. We measure performance in terms of overall accuracy of the model.

Baselines: For evaluating NeuralDater, we compared against the following methods:

- **BurstySimDater** Kotsakos et al. (2014): This is a purely statistical method which uses lexical similarity and term burstiness (Lappas et al., 2009) for dating documents in arbitrary length time frame. For our experiments, we took the time frame length as 1 year. Please refer to (Kotsakos et al., 2014) for more details.

- **MaxEnt-Time-NER**: Maximum Entropy (MaxEnt) based classifier trained on hand-crafted temporal and Named Entity Recognizer (NER) based features. More details in (Chambers, 2012).

- **MaxEnt-Joint**: Refers to MaxEnt-Time-NER combined with year mention classifier as described in (Chambers, 2012).

- **MaxEnt-Uni-Time:** MaxEnt based discriminative model which takes bag-of-words representation of input document with normalized time expression as its features.

- **CNN:** A Convolution Neural Network (CNN) (LeCun et al., 1999) based text classification model proposed by (Kim, 2014), which attained state-of-the-art results in several domains.

- **NeuralDater**: Our proposed method, refer Section 4.

Hyperparameters: By default, edge gating (Section 3.3) is used in all GCNs. The parameter K represents the number of layers in T-GCN (Section 5.3). We use 300-dimensional GloVe embeddings and 128-dimensional hidden state for both GCNs and BiLSTM with 0.8 dropout. We used Adam (Kingma and Ba, 2014) with 0.001 learning rate for training.

Method	APW	NYT
BurstySimDater	45.9	38.5
MaxEnt-Time+NER	52.5	42.3
MaxEnt-Joint	52.5	42.5
MaxEnt-Uni-Time	57.5	50.5
CNN	56.3	50.4
NeuralDater	**64.1**	**58.9**

Table 2: Accuracies of different methods on APW and NYT datasets for the document dating problem (higher is better). NeuralDater significantly outperforms all other competitive baselines. This is our main result. Please see Section 7.1 for more details.

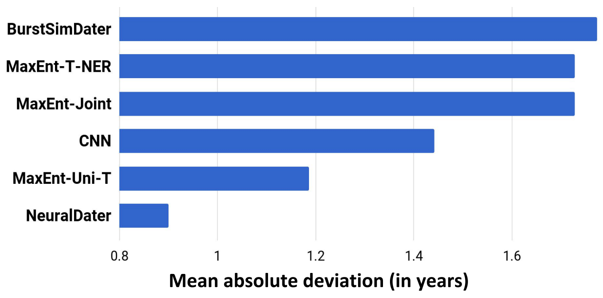

Figure 3: Mean absolute deviation (in years; lower is better) between a model's top prediction and the true year in the APW dataset. We find that NeuralDater, the proposed method, achieves the least deviation. Please see Section 7.1 for details.

Method	Accuracy
T-GCN	57.3
S-GCN + T-GCN ($K = 1$)	57.8
S-GCN + T-GCN ($K = 2$)	58.8
S-GCN + T-GCN ($K = 3$)	**59.1**
Bi-LSTM	58.6
Bi-LSTM + CNN	59.0
Bi-LSTM + T-GCN	60.5
Bi-LSTM + S-GCN + T-GCN (no gate)	62.7
Bi-LSTM + S-GCN + T-GCN ($K = 1$)	**64.1**
Bi-LSTM + S-GCN + T-GCN ($K = 2$)	63.8
Bi-LSTM + S-GCN + T-GCN ($K = 3$)	63.3

Table 3: Accuracies of different ablated methods on the APW dataset. Overall, we observe that incorporation of context (Bi-LSTM), syntactic structure (S-GCN) and temporal structure (T-GCN) in NeuralDater achieves the best performance. Please see Section 7.1 for details.

7 Results

7.1 Performance Comparison

In order to evaluate the effectiveness of NeuralDater, our proposed method, we compare it against existing document dating systems and text classification models. The final results are summarized in Table 2. Overall, we find that NeuralDater outperforms all other methods with a significant margin on both datasets. Compared to the previous state-of-the-art in document dating, BurstySimDater (Kotsakos et al., 2014), we get 19% average absolute improvement in accuracy across both datasets. We observe only a slight gain in the performance of MaxEnt-based model (MaxEnt-Time+NER) of (Chambers, 2012) on combining with temporal constraint reasoner (MaxEnt-Joint). This may be attributed to the fact that the model utilizes only year mentions in the document, thus ignoring other relevant signals which might be relevant to the task. BurstySimDater performs considerably better in terms of precision compared to the other baselines, although it significantly underperforms in accuracy. We note that NeuralDater outperforms all these prior models both in terms of precision and accuracy. We find that even generic deep-learning based text classification models, such as CNN (Kim, 2014), are quite effective for the problem. However, since such a model doesn't give specific attention to temporal features in the document, its performance remains limited. From Figure 3, we observe that NeuralDater's top prediction achieves on average the lowest deviation from the true year.

7.2 Ablation Comparisons

For demonstrating the efficacy of GCNs and BiLSTM for the problem, we evaluate different ablated variants of NeuralDater on the APW dataset. Specifically, we validate the importance of using syntactic and temporal GCNs and the effect of eliminating BiLSTM from the model. Overall results are summarized in Table 3. The first block of rows in the table corresponds to the case when BiLSTM layer is excluded from NeuralDater, while the second block denotes the case when BiLSTM is included. We also experiment with multiple stacked layers of T-GCN (denoted by K) to observe its effect on the performance of the model.

We observe that embeddings from Syntactic GCN (S-GCN) are much better than plain GloVe embeddings for T-GCN as S-GCN encodes the syntactic neighborhood information in event and time embeddings which makes them more relevant for document dating task.

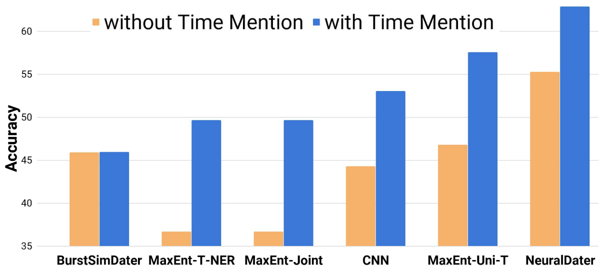

Figure 4: Evaluating performance of different methods on dating documents with and without time mentions. Please see Section 7.3 for details.

Overall, we observe that including BiLSTM in the model improves performance significantly. Single BiLSTM model outperforms all the models listed in the first block of Table 3. Also, some gain in performance is observed on increasing the number of T-GCN layers (K) in absence of BiLSTM, although the same does not follow when BiLSTM is included in the model. This observation is consistent with (Marcheggiani and Titov, 2017), as multiple GCN layers become redundant in the presence of BiLSTM. We also find that eliminating edge gating from our best model deteriorates its overall performance.

In summary, these results validate our thesis that joint incorporation of syntactic and temporal structure of a document in NeuralDater results in improved performance.

7.3 Discussion and Error Analysis

In this section, we list some of our observations while trying to identify pros and cons of NeuralDater, our proposed method. We divided the development split of the APW dataset into two sets – those with and without any mention of time expressions (year). We apply NeuralDater and other methods to these two sets of documents and report accuracies in Figure 4. We find that overall, NeuralDater performs better in comparison to the existing baselines in both scenarios. Even though the performance of NeuralDater degrades in the absence of time mentions, its performance is still the best relatively. Based on other analysis, we find that NeuralDater fails to identify timestamp of documents reporting local infrequent incidents without explicit time mention. NeuralDater becomes confused in the presence of multiple misleading time mentions; it also loses out on documents discussing events which are outside the time range of the text on which the model was trained. In future, we plan to eliminate these pitfalls by incorporating additional signals from Knowledge Graphs about entities mentioned in the document. We also plan to utilize free text temporal expression (Kuzey et al., 2016) in documents for improving performance on this problem.

8 Conclusion

We propose NeuralDater, a Graph Convolutional Network (GCN) based method for document dating which exploits syntactic and temporal structures in the document in a principled way. To the best of our knowledge, this is the first application of deep learning techniques for the problem of document dating. Through extensive experiments on real-world datasets, we demonstrate the effectiveness of NeuralDater over existing state-of-the-art approaches. We are hopeful that the representation learning techniques explored in this paper will inspire further development and adoption of such techniques in the temporal information processing research community.

Abstract

The problem of AMR-to-text generation is to recover a text representing the same meaning as an input AMR graph. The current state-of-the-art method uses a sequence-to-sequence model, leveraging LSTM for encoding a linearized AMR structure. Although it is able to model non-local semantic information, a sequence LSTM can lose information from the AMR graph structure, and thus faces challenges with large graphs, which result in long sequences. We introduce a neural graph-to-sequence model, using a novel LSTM structure for directly encoding graph-level semantics. On a standard benchmark, our model shows superior results to existing methods in the literature.

1 Introduction

Abstract Meaning Representation (AMR) (Banarescu et al., 2013) is a semantic formalism that encodes the meaning of a sentence as a rooted, directed graph. Figure 1 shows an AMR graph in which the nodes (such as "describe-01" and "person") represent the concepts, and edges (such as ":ARG0" and ":name") represent the relations between concepts they connect. AMR has been proven helpful on other NLP tasks, such as machine translation (Jones et al., 2012; Tamchyna et al., 2015), question answering (Mitra and Baral, 2015), summarization (Takase et al., 2016) and event detection (Li et al., 2015).

The task of AMR-to-text generation is to produce a text with the same meaning as a given input AMR graph. The task is challenging as word tenses and function words are abstracted away when constructing AMR graphs from texts. The translation from AMR nodes to text phrases can be far from literal. For example, shown in Figure 1, "Ryan" is represented as "(p / person :name (n / name :op1 "Ryan"))", and "description of" is represented as "(d / describe-01 :ARG1)".

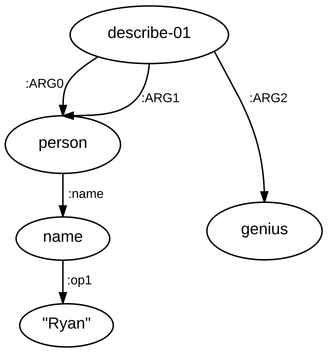

Figure 1: An example of AMR graph meaning "Ryan's description of himself: a genius."

While initial work used statistical approaches (Flanigan et al., 2016b; Pourdamghani et al., 2016; Song et al., 2017; Lampouras and Vlachos, 2017; Mille et al., 2017; Gruzitis et al., 2017), recent research has demonstrated the success of deep learning, and in particular the sequence-to-sequence model (Sutskever et al., 2014), which has achieved the state-of-the-art results on AMR-to-text generation (Konstas et al., 2017). One limitation of sequence-to-sequence models, however, is that they require serialization of input AMR graphs, which adds to the challenge of representing graph structure information, especially when the graph is large. In particular, closely-related nodes, such as parents, children and siblings can be far away after serialization. It can be difficult for a linear recurrent neural network to automatically induce their original connections from bracketed string forms.

To address this issue, we introduce a novel graph-to-sequence model, where a graph-state LSTM is used to encode AMR structures directly.

To capture non-local information, the encoder performs graph state transition by information exchange between connected nodes, with a graph state consisting of all node states. Multiple recurrent transition steps are taken so that information can propagate non-locally, and LSTM (Hochreiter and Schmidhuber, 1997) is used to avoid gradient diminishing and bursting in the recurrent process. The decoder is an attention-based LSTM model with a copy mechanism (Gu et al., 2016; Gulcehre et al., 2016), which helps copy sparse tokens (such as numbers and named entities) from the input.

Trained on a standard dataset (LDC2015E86), our model surpasses a strong sequence-to-sequence baseline by 2.3 BLEU points, demonstrating the advantage of graph-to-sequence models for AMR-to-text generation compared to sequence-to-sequence models. Our final model achieves a BLEU score of 23.3 on the test set, which is 1.3 points higher than the existing state of the art (Konstas et al., 2017) trained on the same dataset. When using gigaword sentences as additional training data, our model is consistently better than Konstas et al. (2017) using the same amount of gigaword data, showing the effectiveness of our model on large-scale training set.

We release our code and models at `https://github.com/freesunshine0316/neural-graph-to-seq-mp`.

2 Baseline: a seq-to-seq model

Our baseline is a sequence-to-sequence model, which follows the encoder-decoder framework of Konstas et al. (2017).

2.1 Input representation

Given an AMR graph $G = (V, E)$, where V and E denote the sets of nodes and edges, respectively, we use the depth-first traversal of Konstas et al. (2017) to linearize it to obtain a sequence of tokens $v_1, \dots, v_N$, where N is the number of tokens. For example, the AMR graph in Figure 1 is serialized as "describe :arg0 (person :name (name :op1 ryan)) :arg1 person :arg2 genius". We can see that the distance between "describe" and "genius", which are directly connected in the original AMR, becomes 14 in the serialization result.

A simple way to calculate the representation for each token v_j is using its word embedding e_j:

$$x_j = W_1 e_j + b_1, \tag{1}$$

where W_1 and b_1 are model parameters for compressing the input vector size.

To alleviate the data sparsity problem and obtain better word representation as the input, we also adopt a forward LSTM over the characters of the token, and concatenate the last hidden state h_j^c with the word embedding:

$$x_j = W_1\Big([e_j; h_j^c]\Big) + b_1 \tag{2}$$

2.2 Encoder

The encoder is a bi-directional LSTM applied on the linearized graph by depth-first traversal, as in Konstas et al. (2017). At each step j, the current states $\overleftarrow{h_j}$ and $\overrightarrow{h_j}$ are generated given the previous states $\overleftarrow{h_{j+1}}$ and $\overrightarrow{h_{j-1}}$ and the current input x_j:

$$\overleftarrow{h_j} = \text{LSTM}(\overleftarrow{h_{j+1}}, x_j)$$
$$\overrightarrow{h_j} = \text{LSTM}(\overrightarrow{h_{j-1}}, x_j)$$

2.3 Decoder

We use an attention-based LSTM decoder (Bahdanau et al., 2015), where the attention memory (A) is the concatenation of the attention vectors among all input words. Each attention vector a_j is the concatenation of the encoder states of an input token in both directions ($\overleftarrow{h_j}$ and $\overrightarrow{h_j}$) and its input vector (x_j):

$$a_j = [\overleftarrow{h_j}; \overrightarrow{h_j}; x_j] \tag{3}$$
$$A = [a_1; a_2; \dots; a_N] \tag{4}$$

where N is the number of input tokens.

The decoder yields an output sequence $w_1, w_2, \dots, w_M$ by calculating a sequence of hidden states $s_1, s_2 \dots, s_M$ recurrently. While generating the t-th word, the decoder considers five factors: (1) the attention memory A; (2) the previous hidden state of the LSTM model s_{t-1}; (3) the embedding of the current input (previously generated word) e_t; (4) the previous context vector μ_{t-1}, which is calculated with attention from A; and (5) the previous coverage vector γ_{t-1}, which is the accumulation of all attention distributions so far (Tu et al., 2016). When $t = 1$, we initialize μ_0 and γ_0 as zero vectors, set e_1 to the embedding of the start token "<s>", and s_0 as the average of all encoder states.

For each time-step t, the decoder feeds the concatenation of the embedding of the current input e_t and the previous context vector μ_{t-1} into the

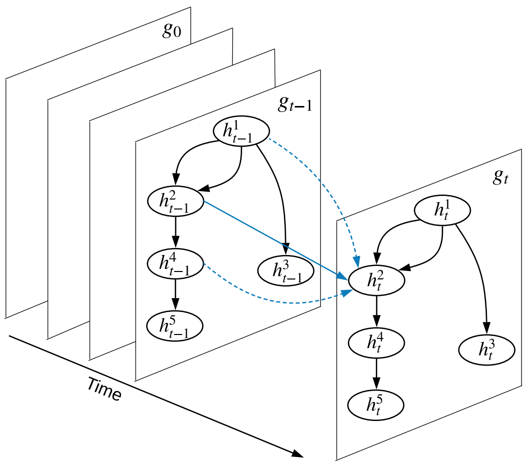

Figure 2: Graph state LSTM.

LSTM model to update its hidden state. Then the attention probability $\alpha_{t,i}$ on the attention vector $a_i \in A$ for the time-step is calculated as:

$$\epsilon_{t,i} = v_2^T \tanh(W_a a_i + W_s s_t + W_\gamma \gamma_{t-1} + b_2)$$
$$\alpha_{t,i} = \frac{\exp(\epsilon_{t,i})}{\sum_{j=1}^N \exp(\epsilon_{t,j})}$$

where W_a, W_s, W_γ, v_2 and b_2 are model parameters. The coverage vector γ_t is updated by $\gamma_t = \gamma_{t-1} + \alpha_t$, and the new context vector μ_t is calculated via $\mu_t = \sum_{i=1}^N \alpha_{t,i} a_i$.

The output probability distribution over a vocabulary at the current state is calculated by:

$$P_{vocab} = \text{softmax}(V_3[s_t, \mu_t] + b_3), \qquad (5)$$

where V_3 and b_3 are learnable parameters, and the number of rows in V_3 represents the number of words in the vocabulary.

3 The graph-to-sequence model

Unlike the baseline sequence-to-sequence model, we leverage a recurrent graph encoder to represent each input AMR, which directly models the graph structure without serialization.

3.1 The graph encoder

Figure 2 shows the overall structure of our graph encoder. Formally, given a graph $G = (V, E)$, we use a hidden state vector h^j to represent each node $v_j \in V$. The state of the graph can thus be represented as:

$$g = \{h^j\}|_{v_j \in V}$$

In order to capture non-local interaction between nodes, we allow information exchange between nodes through a sequence of state transitions, leading to a sequence of states $g_0, g_1, \dots, g_t, \dots$, where $g_t = \{h_t^j\}|_{v_j \in V}$. The initial state g_0 consists of a set of initial node states $h_0^j = h_0$, where h_0 is a hyperparameter of the model.

State transition A recurrent neural network is used to model the state transition process. In particular, the transition from g_{t-1} to g_t consists of a hidden state transition for each node, as shown in Figure 2. At each state transition step t, we allow direct communication between a node and all nodes that are directly connected to the node. To avoid gradient diminishing or bursting, LSTM (Hochreiter and Schmidhuber, 1997) is adopted, where a cell c_t^j is taken to record memory for h_t^j. We use an input gate i_t^j, an output gate o_t^j and a forget gate f_t^j to control information flow from the inputs and to the output h_t^j.

The inputs include representations of edges that are connected to v_j, where v_j can be either the source or the target of the edge. We define each edge as a triple (i, j, l), where i and j are indices of the source and target nodes, respectively, and l is the edge label. $x_{i,j}^l$ is the representation of edge (i, j, l), detailed in Section 3.3. The inputs for v_j are distinguished by incoming and outgoing edges, before being summed up:

$$x_j^i = \sum_{(i,j,l) \in E_{in}(j)} x_{i,j}^l$$
$$x_j^o = \sum_{(j,k,l) \in E_{out}(j)} x_{j,k}^l,$$

where $E_{in}(j)$ and $E_{out}(j)$ denote the sets of incoming and outgoing edges of v_j, respectively.

In addition to edge inputs, a cell also takes the hidden states of its incoming nodes and outgoing nodes during a state transition. In particular, the states of all incoming nodes and outgoing nodes are summed up before being passed to the cell and gate nodes:

$$h_j^i = \sum_{(i,j,l) \in E_{in}(j)} h_{t-1}^i$$
$$h_j^o = \sum_{(j,k,l) \in E_{out}(j)} h_{t-1}^k,$$

Based on the above definitions of x_j^i, x_j^o, h_j^i and h_j^o, the state transition from g_{t-1} to g_t, as represented by h_t^j, can be defined as:

$$\begin{aligned}
i_t^j &= \sigma(W_i x_j^i + \hat{W}_i x_j^o + U_i h_j^i + \hat{U}_i h_j^o + b_i),\\
o_t^j &= \sigma(W_o x_j^i + \hat{W}_o x_j^o + U_o h_j^i + \hat{U}_o h_j^o + b_o),\\
f_t^j &= \sigma(W_f x_j^i + \hat{W}_f x_j^o + U_f h_j^i + \hat{U}_f h_j^o + b_f),\\
u_t^j &= \sigma(W_u x_j^i + \hat{W}_u x_j^o + U_u h_j^i + \hat{U}_u h_j^o + b_u),\\
c_t^j &= f_t^j \odot c_{t-1}^j + i_t^j \odot u_t^j,\\
h_t^j &= o_t^j \odot \tanh(c_t^j),
\end{aligned}$$

where i_t^j, o_t^j and f_t^j are the input, output and forget gates mentioned earlier. W_x, $\hat{W}_x$, U_x, $\hat{U}_x$, b_x, where $x \in \{i, o, f, u\}$, are model parameters.

3.2 Recurrent steps

Using the above state transition mechanism, information from each node propagates to all its neighboring nodes after each step. Therefore, for the worst case where the input graph is a chain of nodes, the maximum number of steps necessary for information from one arbitrary node to reach another is equal to the size of the graph. We experiment with different transition steps to study the effectiveness of global encoding.

Note that unlike the sequence LSTM encoder, our graph encoder allows parallelization in node-state updates, and thus can be highly efficient using a GPU. It is general and can be potentially applied to other tasks, including sequences, syntactic trees and cyclic structures.

3.3 Input Representation

Different from sequences, the edges of an AMR graph contain labels, which represent relations between the nodes they connect, and are thus important for modeling the graphs. Similar with Section 2, we adopt two different ways for calculating the representation for each edge (i, j, l):

$$x_{i,j}^l = W_4\Big([e_l; e_i]\Big) + b_4 \tag{6}$$

$$x_{i,j}^l = W_4\Big([e_l; e_i; h_i^c]\Big) + b_4, \tag{7}$$

where e_l and e_i are the embeddings of edge label l and source node v_i, h_i^c denotes the last hidden state of the character LSTM over v_i, and W_4 and b_4 are trainable parameters. The equations correspond to Equations 1 and 2 in Section 2.1, respectively.

3.4 Decoder

We adopt the attention-based LSTM decoder as described in Section 2.3. Since our graph encoder generates a sequence of graph states, only the last graph state is adopted in the decoder. In particular, we make the following changes to the decoder. First, each attention vector becomes $a_j = [h_T^j; x_j]$, where h_T^j is the last state for node v_j. Second, the decoder initial state s_{-1} is the average of the last states of all nodes.

3.5 Integrating the copy mechanism

Open-class tokens, such as dates, numbers and named entities, account for a large portion in the AMR corpus. Most appear only a few times, resulting in a data sparsity problem. To address this issue, Konstas et al. (2017) adopt anonymization for dealing with the data sparsity problem. In particular, they first replace the subgraphs that represent dates, numbers and named entities (such as "(q / quantity :quant 3)" and "(p / person :name (n / name :op1 "Ryan"))") with predefined placeholders (such as "num_0" and "person_name_0") before decoding, and then recover the corresponding surface tokens (such as "3" and "Ryan") after decoding. This method involves hand-crafted rules, which can be costly.

Copy We find that most of the open-class tokens in a graph also appear in the corresponding sentence, and thus adopt the copy mechanism (Gulcehre et al., 2016; Gu et al., 2016) to solve this problem. The mechanism works on top of an attention-based RNN decoder by integrating the attention distribution into the final vocabulary distribution. The final probability distribution is defined as the interpolation between two probability distributions:

$$P_{final} = \theta_t P_{vocab} + (1 - \theta_t) P_{attn}, \tag{8}$$

where θ_t is a switch for controlling generating a word from the vocabulary or directly copying it from the input graph. P_{vocab} is the probability distribution of directly generating the word, as defined in Equation 5, and P_{attn} is calculated based on the attention distribution α_t by summing the probabilities of the graph nodes that contain identical concept. Intuitively, θ_t is relevant to the current decoder input e_t and state s_t, and the context vector μ_t. Therefore, we define it as:

$$\theta_t = \sigma(w_\mu^T \mu_t + w_s^T s_t + w_e^T e_t + b_5), \tag{9}$$

where vectors w_μ, w_s, w_e and scalar b_5 are model parameters. The copy mechanism favors generating words that appear in the input. For AMR-to-text generation, it facilitates the generation of dates, numbers, and named entities that appear in AMR graphs.

Copying vs anonymization Both copying and anonymization alleviate the data sparsity problem by handling the open-class tokens. However, the copy mechanism has the following advantages over anonymization: (1) anonymization requires significant manual work to define the placeholders and heuristic rules both from subgraphs to placeholders and from placeholders to the surface tokens, (2) the copy mechanism automatically learns what to copy, while anonymization relies on hard rules to cover all types of the open-class tokens, and (3) the copy mechanism is easier to adapt to new domains and languages than anonymization.

4 Training and decoding

We train our models using the cross-entropy loss over each gold-standard output sequence $W^* = w_1^*, \ldots, w_t^*, \ldots, w_M^*$:

$$l = -\sum_{t=1}^{M} \log p(w_t^* | w_{t-1}^*, \ldots, w_1^*, X; \theta), \quad (10)$$

where X is the input graph, and θ is the model parameters. Adam (Kingma and Ba, 2014) with a learning rate of 0.001 is used as the optimizer, and the model that yields the best devset performance is selected to evaluate on the test set. Dropout with rate 0.1 is used during training. Beam search with beam size to 5 is used for decoding. Both training and decoding use Tesla K80 GPUs.

5 Experiments

5.1 Data

We use a standard AMR corpus (LDC2015E86) as our experimental dataset, which contains 16,833 instances for training, 1368 for development and 1371 for test. Each instance contains a sentence and an AMR graph.

Following Konstas et al. (2017), we supplement the gold data with large-scale automatic data. We take Gigaword as the external data to sample raw sentences, and train our model on both the sampled data and LDC2015E86. We adopt Konstas et al. (2017)'s strategy for sampling sentences from Gigaword, and choose JAMR (Flanigan et al., 2016a) to parse selected sentences into AMRs, as the AMR parser of Konstas et al. (2017) only works on the anonymized data. For training on both sampled data and LDC2015E86, we also follow the method of Konstas et al. (2017), which is fine-tuning the model on the AMR corpus after every epoch of pretraining on the gigaword data.

Model	BLEU	Time
Seq2seq	18.8	35.4s
Seq2seq+copy	19.9	37.4s
Seq2seq+charLSTM+copy	20.6	39.7s
Graph2seq	20.4	11.2s
Graph2seq+copy	22.2	11.1s
Graph2seq+Anon	22.1	9.2s
Graph2seq+charLSTM+copy	**22.8**	16.3s

Table 1: DEV BLEU scores and decoding times.

5.2 Settings

We extract a vocabulary from the training set, which is shared by both the encoder and the decoder. The word embeddings are initialized from Glove pretrained word embeddings (Pennington et al., 2014) on Common Crawl, and are not updated during training. Following existing work, we evaluate the results with the BLEU metric (Papineni et al., 2002).

For model hyperparameters, we set the graph state transition number as 9 according to development experiments. Each node takes information from at most 10 neighbors. The hidden vector sizes for both encoder and decoder are set to 300 (They are set to 600 for experiments using large-scale automatic data). Both character embeddings and hidden layer sizes for character LSTMs are set 100, and at most 20 characters are taken for each graph node or linearized token.

5.3 Development experiments

As shown in Table 1, we compare our model with a set of baselines on the AMR devset to demonstrate how the graph encoder and the copy mechanism can be useful when training instances are not sufficient. *Seq2seq* is the sequence-to-sequence baseline described in Section 2. *Seq2seq+copy* extends *Seq2seq* with the copy mechanism, and *Seq2seq+charLSTM+copy* further extends *Seq2seq+copy* with character LSTM. *Graph2seq* is our graph-to-sequence model, *Graph2seq+copy* extends *Graph2seq* with the copy mechanism, and *Graph2seq+charLSTM+copy* further extends

Graph2seq+copy with the character LSTM. We also try *Graph2seq+Anon*, which applies our graph-to-sequence model on the anonymized data from Konstas et al. (2017).

The graph encoder As can be seen from Table 1, the performance of *Graph2seq* is 1.6 BLEU points higher than *Seq2seq*, which shows that our graph encoder is effective when applied alone. Adding the copy mechanism (*Graph2seq+copy* vs *Seq2seq+copy*), the gap becomes 2.3. This shows that the graph encoder learns better node representations compared to the sequence encoder, which allows attention and copying to function better.

Applying the graph encoder together with the copy mechanism gives a gain of 3.4 BLEU points over the baseline (*Graph2seq+copy* vs *Seq2seq*). The graph encoder is consistently better than the sequence encoder no matter whether character LSTMs are used.

We also list the encoding part of decoding times on the devset, as the decoders of the seq2seq and the graph2seq models are similar, so the time differences reflect efficiencies of the encoders. Our graph encoder gives consistently better efficiency compared with the sequence encoder, showing the advantage of parallelization.

The copy mechanism Table 1 shows that the copy mechanism is effective on both the graph-to-sequence and the sequence-to-sequence models. Anonymization gives comparable overall performance gains on our graph-to-sequence model as the copy mechanism (comparing *Graph2seq+Anon* with *Graph2seq+copy*). However, the copy mechanism has several advantages over anonymization as discussed in Section 3.5.

Character LSTM Character LSTM helps to increase the performances of both systems by roughly 0.6 BLEU points. This is largely because it further alleviates the data sparsity problem by handling unseen words, which may share common substrings with in-vocabulary words.

5.4 Effectiveness on graph state transitions

We report a set of development experiments for understanding the graph LSTM encoder.

Number of iterations We analyze the influence of the number of state transitions to the model performance on the devset. Figure 3 shows the BLEU scores of different state transition numbers,

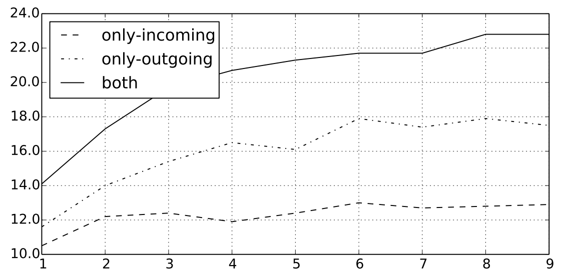

Figure 3: DEV BLEU scores against transition steps for the graph encoder.

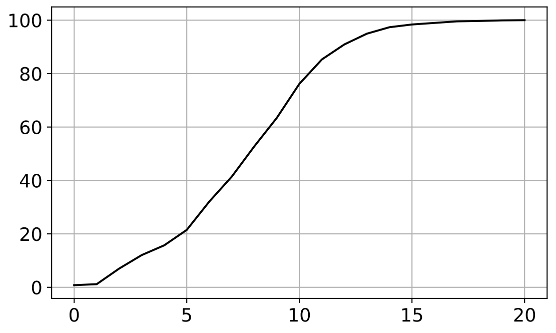

Figure 4: Percentage of DEV AMRs with different diameters.

when both incoming and outgoing edges are taken for calculating the next state (as shown in Figure 2). The system is *Graph2seq+charLSTM+copy*. Executing only 1 iteration results in a poor BLEU score of 14.1. In this case the state for each node only contains information about immediately adjacent nodes. The performance goes up dramatically to 21.5 when increasing the iteration number to 5. In this case, the state for each node contains information of all nodes within a distance of 5. The performance further goes up to 22.8 when increasing the iteration number from 5 to 9, where all nodes with a distance of less than 10 are incorporated in the state for each node.

Graph diameter We analyze the percentage of the AMR graphs in the devset with different graph diameters and show the cumulative distribution in Figure 4. The diameter of an AMR graph is defined as the longest distance between two AMR nodes.[1] Even though the diameters for less than 80% of the AMR graphs are less or equal than 10, our development experiments show that it is not necessary to incorporate the whole-graph information for each node. Further increasing state transition number may lead to additional improvement.

[1]The diameter of single-node graphs is 0.

Model	BLEU
PBMT	26.9
SNRG	25.6
Tree2Str	23.0
MSeq2seq+Anon	22.0
Graph2seq+copy	22.7
Graph2seq+charLSTM+copy	23.3
MSeq2seq+Anon (200K)	27.4
MSeq2seq+Anon (2M)	32.3
Seq2seq+charLSTM+copy (200K)	27.4
Seq2seq+charLSTM+copy (2M)	31.7
Graph2seq+charLSTM+copy (200K)	28.2
Graph2seq+charLSTM+copy (2M)	**33.0**

Table 2: TEST results. "(200K)", "(2M)" and "(20M)" represent training with the corresponding number of additional sentences from Gigaword.

We do not perform exhaustive search for finding the optimal state transition number.

Incoming and outgoing edges As shown in Figure 3, we analyze the efficiency of state transition when only incoming or outgoing edges are used. From the results, we can see that there is a huge drop when state transition is performed only with incoming or outgoing edges. Using edges of one direction, the node states only contain information of ancestors or descendants. On the other hand, node states contain information of ancestors, descendants, and siblings if edges of both directions are used. From the results, we can conclude that not only the ancestors and descendants, but also the siblings are important for modeling the AMR graphs. This is similar to observations on syntactic parsing tasks (McDonald et al., 2005), where sibling features are adopted.

We perform a similar experiment for the *Seq2seq+copy* baseline by only executing single-directional LSTM for the encoder. We observe BLEU scores of 11.8 and 12.7 using only forward or backward LSTM, respectively. This is consistent with our graph model in that execution using only one direction leads to a huge performance drop. The contrast is also reminiscent of using the normal input versus the reversed input in neural machine translation (Sutskever et al., 2014).

5.5 Results

Table 2 compares our final results with existing work. *MSeq2seq+Anon* (Konstas et al., 2017) is an attentional multi-layer sequence-to-sequence model trained with the anonymized data. *PBMT* (Pourdamghani et al., 2016) adopts a phrase-based model for machine translation (Koehn et al., 2003) on the input of linearized AMR graph, *SNRG* (Song et al., 2017) uses synchronous node replacement grammar for parsing the AMR graph while generating the text, and *Tree2Str* (Flanigan et al., 2016b) converts AMR graphs into trees by splitting the re-entrances before using a tree transducer to generate the results.

Graph2seq+charLSTM+copy achieves a BLEU score of 23.3, which is 1.3 points better than *MSeq2seq+Anon* trained on the same AMR corpus. In addition, our model without character LSTM is still 0.7 BLEU points higher than *MSeq2seq+Anon*. Note that *MSeq2seq+Anon* relies on anonymization, which requires additional manual work for defining mapping rules, thus limiting its usability on other languages and domains. The neural models tend to underperform statistical models when trained on limited (16K) gold data, but performs better with scaled silver data (Konstas et al., 2017).

Following Konstas et al. (2017), we also evaluate our model using both the AMR corpus and sampled sentences from Gigaword. Using additional 200K or 2M gigaword sentences, *Graph2seq+charLSTM+copy* achieves BLEU scores of 28.2 and 33.0, respectively, which are 0.8 and 0.7 BLEU points better than *MSeq2seq+Anon* using the same amount of data, respectively. The BLEU scores are 5.3 and 10.1 points better than the result when it is only trained with the AMR corpus, respectively. This shows that our model can benefit from scaled data with automatically generated AMR graphs, and it is more effective than *MSeq2seq+Anon* using the same amount of data. Using 2M gigaword data, our model is better than all existing methods. Konstas et al. (2017) also experimented with 20M external data, obtaining a BLEU of 33.8. We did not try this setting due to hardware limitations. The *Seq2seq+charLSTM+copy* baseline trained on the large-scale data is close to *MSeq2seq+Anon* using the same amount of training data, yet is much worse than our model.

5.6 Case study

We conduct case studies for better understanding the model performances. Table 3 shows example outputs of sequence-to-sequence (*S2S*), graph-to-sequence (*G2S*) and graph-to-sequence with copy mechanism (*G2S+CP*). *Ref* denotes the reference output sentence, and *Lin* shows the serialization results of input AMRs. The best hyperparameter configuration is chosen for each model.

For the first example, *S2S* fails to recognize the concept “a / account” as a noun and loses the concept “o / old” (both are underlined). The fact that “a / account” is a noun is implied by “a / account :mod (o / old)” in the original AMR graph. Though directly connected in the original graph, their distance in the serialization result (the input of *S2S*) is 26, which may be why *S2S* makes these mistakes. In contrast, *G2S* handles “a / account” and “o / old” correctly. In addition, the copy mechanism helps to copy “look-over” from the input, which rarely appears in the training set. In this case, *G2S+CP* is incorrect only on hyphens and literal reference to “anti-japanese war”, although the meaning is fully understandable.

For the second case, both *G2S* and *G2S+CP* correctly generate the noun “agreement” for “a / agree” in the input AMR, while *S2S* fails to. The fact that “a / agree” represents a noun can be determined by the original graph segment “p / provide :ARG0 (a / agree)”, which indicates that “a / agree” is the subject of “p / provide”. In the serialization output, the two nodes are close to each other. Nevertheless, *S2S* still failed to capture this structural relation, which reflects the fact that a sequence encoder is not designed to explicitly model hierarchical information encoded in the serialized graph. In the training instances, serialized nodes that are close to each other can originate from neighboring graph nodes, or distant graph nodes, which prevents the decoder from confidently deciding the correct relation between them. In contrast, *G2S* sends the node “p / provide” simultaneously with relation “ARG0” when calculating hidden states for “a / agree”, which facilitates the yielding of “the agreement provides”.

(p / possible-01 :polarity -
  :ARG1 (l / look-over-06

6 Related work

Among early statistical methods for AMR-to-text generation, Flanigan et al. (2016b) convert input graphs to trees by splitting re-entrances, and then translate the trees into sentences with a tree-to-string transducer. Song et al. (2017) use a synchronous node replacement grammar to parse input AMRs and generate sentences at the same time. Pourdamghani et al. (2016) linearize input graphs by breadth-first traversal, and then use a phrase-based machine translation system[2] to generate results by translating linearized sequences.

Prior work using graph neural networks for NLP include the use graph convolutional networks (GCN) (Kipf and Welling, 2017) for semantic role labeling (Marcheggiani and Titov, 2017) and neural machine translation (Bastings et al., 2017). Both GCN and the graph LSTM update node states by exchanging information between neighboring nodes within each iteration. However, our graph state LSTM adopts gated operations for making updates, while GCN uses a linear transformation. Intuitively, the former has better learning power than the later. Another major difference is that our graph state LSTM keeps a cell vector for each node to remember all history. The contrast

[2]http://www.statmt.org/moses/

between our model with GCN is reminiscent of the contrast between RNN and CNN. We leave empirical comparison of their effectiveness to future work. In this work our main goal is to show that graph LSTM encoding of AMR is superior compared with sequence LSTM.

Closest to our work, Peng et al. (2017) modeled syntactic and discourse structures using DAG LSTM, which can be viewed as extensions to tree LSTMs (Tai et al., 2015). The state update follows the sentence order for each node, and has sequential nature. Our state update is in parallel. In addition, Peng et al. (2017) split input graphs into separate DAGs before their method can be used. To our knowledge, we are the first to apply an LSTM structure to encode AMR graphs.

The recurrent information exchange mechanism in our state transition process is remotely related to the idea of loopy belief propagation (LBP) (Murphy et al., 1999). However, there are two major differences. First, messages between LSTM states are gated neural node values, rather than probabilities in LBP. Second, while the goal of LBP is to estimate marginal probabilities, the goal of information exchange between graph states in our LSTM is to find neural representation features, which are directly optimized by a task objective.

In addition to NMT (Gulcehre et al., 2016), the copy mechanism has been shown effective on tasks such as dialogue (Gu et al., 2016), summarization (See et al., 2017) and question generation (Song et al., 2018). We investigate the copy mechanism on AMR-to-text generation.

7 Conclusion

We introduced a novel graph-to-sequence model for AMR-to-text generation. Compared to sequence-to-sequence models, which require linearization of AMR before decoding, a graph LSTM is leveraged to directly model full AMR structure. Allowing high parallelization, the graph encoder is more efficient than the sequence encoder. In our experiments, the graph model outperforms a strong sequence-to-sequence model, achieving the best performance.

Abstract

A knowledge base is a large repository of facts that are mainly represented as RDF triples, each of which consists of a subject, a predicate (relationship), and an object. The RDF triple representation offers a simple interface for applications to access the facts. However, this representation is not in a natural language form, which is difficult for humans to understand. We address this problem by proposing a system to translate a set of RDF triples into natural sentences based on an encoder-decoder framework. To preserve as much information from RDF triples as possible, we propose a novel graph-based triple encoder. The proposed encoder encodes not only the elements of the triples but also the relationships both within a triple and between the triples. Experimental results show that the proposed encoder achieves a consistent improvement over the baseline models by up to 17.6%, 6.0%, and 16.4% in three common metrics BLEU, METEOR, and TER, respectively.

1 Introduction

Knowledge bases (KBs) are becoming an enabling resource for many applications including Q&A systems, recommender systems, and summarization tools. KBs are designed based on a W3C standard called the *Resource Description Framework* (RDF)[1]. An RDF triple consists of three elements in the form of $\langle subject, predicate\ (relationship), object\rangle$. It describes a relationship between an entity (the subject) and another entity or literal (the object) via the predicate. This representation allows easy data share between KBs. However, usually the elements of a triple are stored as *Uniform Resource Identifiers* (URIs), and many predicates (words or phrases) are not intuitive; this representation is difficult to comprehend by humans.

RDF triples	⟨John Doe,birth place,London⟩ ⟨John Doe,birth date,1967-01-10⟩ ⟨London,capital of,England⟩
Target sentence	John Doe was born on 1967-01-10 in London, the capital of England.

Table 1: RDF based sentence generation.

Translating RDF triples into natural sentences helps humans to comprehend the knowledge embedded in the triples, and building a natural language based user interface is an important task in user interaction studies (Damljanovic et al., 2010). This task has many applications, such as question answering (Bordes et al., 2014; Fader et al., 2014), profile summarizing (Lebret et al., 2016; Chisholm et al., 2017), and automatic weather forecasting (Mei et al., 2016). For example, the SPARQL inference of a Q&A system (Unger et al., 2012) returns a set of RDF triples which need to be translated into natural sentences to provide a more readable answer for the users. Table 1 illustrates such an example. Suppose a user is asking a question about "John Doe". By querying a KB, a Q&A system retrieves three triples "⟨John Doe,birth place,London⟩", "⟨John Doe,birth date,1967-01-10⟩", and "⟨London,capital of,England⟩." We aim to generate a natural sentence that incorporates the information of the triples and is easier to be understood by the user. In this example, the generated sentence is "John Doe was born on 1967-01-10 in London,

*Corresponding author
[1]https://www.w3.org/RDF/

`the capital of England.`"

Most existing studies for this task use domain specific rules. Bontcheva and Wilks (2004) create rules to generate sentences in the medical domain, while Cimiano et al. (2013) create rules to generate step by step cooking instructions. The problem of rule-based methods is that they need a lot of human efforts to create the rules, which mostly cannot deal with complex or novel cases.

Recent studies propose neural language generation systems. Lebret et al. (2016) generate the first sentence of a biography by a conditional neural language model. Mei et al. (2016) propose an encoder-aligner-decoder architecture to generate weather forecasts. The model does not need predefined rules and hence generalizes better to open domain data.

A straightforward adaptation of neural language generation system is to use the encoder-decoder model by first concatenating the elements of the RDF triples into a linear sequence and then feeding the sequence as the model input to learn the corresponding natural sentence. We implemented such a model (detailed in Section 3.2) that ranked top in the WebNLG Challenge 2017[2]. This Challenge has a primary objective of generating syntactically correct natural sentences from a set of RDF triples. Our model achieves the highest global scores on the automatic evaluation, outperforming competitors that use rule-based methods, statistical machine translation, and neural machine translation (Gardent et al., 2017b).

While our previous model achieves a good result, simply concatenating the elements in the RDF triples may lose the relationship between entities that affects the semantics of the resulting sentence (cf. Table 3). To address this issue, in this paper, we propose a novel graph-based triple encoder model that maintain the structure of RDF triples as a small knowledge graph named the *GTR-LSTM* model. This model computes the hidden state of each entity in a graph to preserve the relationships between entities in a triple (*intra-triple relationships*) and the relationships between entities in related triples (*inter-triple relationships*) that helps to achieve even more accurate sentences. This leads to two problems of preserving the relationships in a knowledge graph: (1) how to deal with a cycle in a knowledge graph; (2) how to deal with multiple non-predefined relationships between two entities in a knowledge graph. The proposed model differs from existing non-linear LSTM models such as Tree LSTM (Tai et al., 2015) and Graph LSTM (Liang et al., 2016) in addressing the mentioned problem. In particular, Tree LSTM does not allow cycles, while the proposed model handles cycles by first using a combination of topological sort and breadth-first traversal over a graph, and then using an attention model to capture the global information of the knowledge graph. Meanwhile, Graph LSTM only allows a predefined set of relationships between entities, while the proposed model allows any relationships by treating them as part of the input for the hidden state computation.

[2]http://talc1.loria.fr/webnlg/stories/challenge.html

To further enhance the capability of our model to handle unseen entities, we propose to use entity masking, which maps the entities in the model training pairs to their types, e.g., we map an entity (literal) "`1967-01-10`" to a type symbol "`DATE`" in the training pairs. This way, our model can learn to handle any date entities rather than just "`1967-01-10`". This is particularly helpful when there is a limited training dataset.

Our contributions are:

- We propose an end-to-end encoder-decoder based framework for the problem of translating RDF triples into natural sentences.
- We further propose a graph-based triple encoder to optimize the amount of information preserved in the input of the framework. The proposed model can handle cycles to capture the global information of a knowledge graph. The proposed model also handles non-predefined relationships between entities.
- We evaluate the proposed framework and model over two real datasets. The results show that our model outperforms the state-of-the-art models consistently.

The rest of this paper is organized as follows. Section 2 summarizes previous studies on sentence generation. Section 3 details the proposed model. Section 4 presents the experimental results. Section 5 concludes the paper.

2 Related Work

The studied problem falls in the area of *Natural Language Generation* (NLG) (Reiter and Dale, 2000). Bontcheva and Wilks (2004) follow a traditional NLG approach to generate sentences from RDF data in the medical domain. They start with filtering repetitive RDF data (document planning) and then group coherent triples (micro-planning). After that, they aggregate the sentences generated for coherent triples to produce the final sentences (aggregation and realization). Cimiano et al. (2013) generate cooking recipes from semantic web data. They focus on using a large corpus to extract lexicon in the cooking domain. The lexicon is then used with a traditional NLG approach to generate cooking recipes. Duma and Klein (2013) learn a sentence template from a parallel RDF data and text corpora. They first align entities in RDF triples with entities mentioned in sentences. Then, they extract templates from the aligned sentences by replacing the entity mention with a unique token. This method works well on RDF triples in a seen domain but fails on RDF triples in a previously unseen domain.

Recently, several methods using neural networks are proposed. Lebret et al. (2016) generate the first sentence of a biography using a conditional neural language model. This model is trained to predict the next word of a sentence not only based on previous words, but also by using features captured from Wikipedia infoboxes. Mei et al. (2016) propose an encoder-aligner-decoder model to generate weather forecasts. The aligner is used to filter the most relevant data to be used to predict the weather forecast. Both studies experiment on cross-domain datasets. The result shows that the neural language generation approach is more flexible to work in an open domain since it is not limited to handcrafted rules. This motivates us to use a neural network based framework.

The most similar system to ours is Neural Wikipedian (Vougiouklis et al., 2017), which generates a summary from RDF triples. It uses feed-forward neural networks to encode RDF triples and concatenate them as the input of the decoder. The decoder uses LSTM to predict a sequence of words as a summary. There are differences from our work. First, Neural Wikipedian only works with a set of RDF triples with a single entity point of view (i.e., the entity of interest must be in either the subject or the object of every triple). Our system does not have this constraint. Second, Neural Wikipedian uses standard feed-forward neural networks in the encoder. We design new triple encoder models to accommodate specific features of RDF triples. Experimental results show that our framework outperforms Neural Wikipedian.

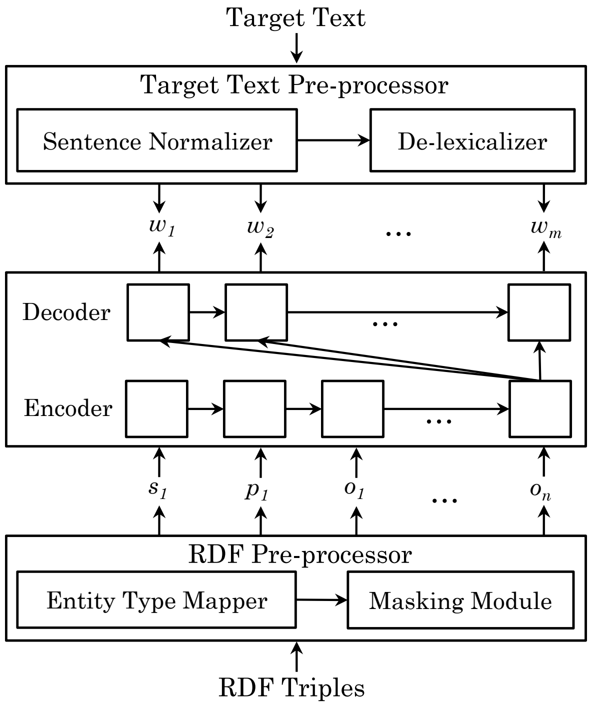

Figure 1: RDF sentence generation based on an encoder-decoder architecture.

3 Proposed Model

We start with the problem definition. We consider a set of RDF triples as the input, which is denoted by $T = [t_1, t_2, ..., t_n]$ where a triple t_i consists of three elements (subject s_i, predicate p_i, and object o_i), $t_i = \langle s_i, p_i, o_i \rangle$. Every element can contain multiple words. We aim to generate a set of sentences that consist of a sequence of words $S = \langle w_1, w_2, ..., w_m \rangle$, such that the relationships in the input triples are correctly represented in S while the sentences have a high quality. We use BLEU, METEOR, and TER to assess the quality of the sentence (detailed in Section 4). Table 1 illustrates our problem input and the target output.

This section is organized as follows. First we describe the overall framework (Section 3.1). Next, we describe three triple encoder models including the *adapted standard BLSTM* model (Section 3.2), the *adapted standard triple encoder* model (Section 3.3), and the *proposed GTR-LSTM* model (Section 3.4). The decoder which is used for all encoder models is described in Section 3.5. The entity masking is described in Section 3.6

3.1 Solution Framework

Our solution framework uses an encoder-decoder architecture as illustrated in Fig. 1. The framework consists of three components including an *RDF pre-processor*, a *target text pre-processor*, and an *encoder-decoder module*.

The RDF pre-processor consists of an entity type mapper and a masking module. The entity type mapper maps the subjects and objects in the triples to their types, such that the sentence patterns learned are based on entity types rather than entities. For example, the input entities in Table 1, "`John Doe`", "`London`", "`England`", and "`1967-01-10`" can be mapped to "`PERSON`", "`CITY`", "`COUNTRY`", and "`DATE`", respectively. The mapping has been shown in our experiments to be highly effective in improving the model output quality. The masking module converts each entity into an *entity identifier* (*eid*). The target text pre-processor consists of a text normalizer and a de-lexicalizer. The text normalizer converts abbreviations and dates into the same format as the corresponding entities in the triples. The de-lexicalizer replaces all entities in the target sentences by their eids. The RDF and target text pre-processors are detailed in Section 3.6. The replaced target sentences are combined with the original target sentences and the English Wikipedia articles is used as a corpus to learn the word embeddings of the vocabulary.

To accommodate the RDF data, in the encoder side, we consider three triple encoder models: (1) the adapted standard BLSTM encoder; (2) the adapted standard triple encoder; and (3) the proposed GTR-LSTM triple encoder. The adapted standard BLSTM encoder concatenates the tokens in RDF triples as an input sequence, while the standard triple encoder first encodes each RDF triple into a vector representation and then concatenates the vectors of different triples. The latter model better captures intra-triple relationships but suffers in capturing inter-triple relationships. Considering the native representation of RDF triples as a small knowledge graph, our graph-based GTR-LSTM triple encoder captures both intra-triple and inter-triple entity relationships.

3.2 Adapted Standard BLSTM Encoder

The standard encoder-decoder model with a BLSTM encoder is a sequence to sequence learning model (Cho et al., 2014). To adapt such a model for our problem, we transform a set of RDF triples input T into a sequence of elements (i.e., $T = [w_{1,1}, w_{1,2}, ..., w_{1,j}, ..., w_{n,j}]$), where $w_{n,j}$ is the word embedding of a word in the n-th triple. For example, following the triples in Table 1, $w_{1,1}$ is the word embedding of "John", $w_{1,2}$ is the word embedding of "Doe", etc. This sequence forms an input for the encoder. We use zero padding to ensure that each input has the same representation size. The rest of the model is the same as the standard encoder-decoder model with an attention mechanism (Bahdanau et al., 2015). We call this model the *adapted standard BLSTM encoder*.

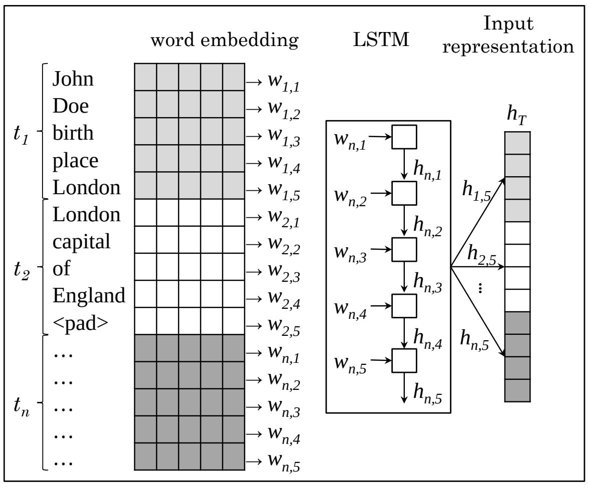

Figure 2: LSTM-based standard triple encoder.

3.3 Adapted Standard Triple Encoder

The standard BLSTM encoder suffers in capturing the element relationships as the elements are simply concatenated together. Next, we adapt the standard BLSTM encoder to aggregate the word embeddings of the elements of the same triple to retain the intra-triple relationship. We call this the *adapted standard triple encoder*.

The adaptation is done by grouping the elements of each triple, so the input is represented as $T = [\langle w_{1,1}, ..., w_{1,j}\rangle, ..., \langle w_{n,1}, ...w_{n,j}\rangle]$, where $w_{n,j}$ is the word embedding of a word in the n-th triple. We use zero padding to ensure that each triple has the same representation size. An LSTM network of the encoder computes a hidden state of each triple and concatenates them together to be the input for the decoder:

$$h_T = [f(t_1); f(t_2); ...; f(t_n)] \qquad (1)$$

where h_T is the input vector representation for the decoder and f is an LSTM network (cf. Fig. 2).

3.4 GTR-LSTM Triple Encoder

The adapted standard triple encoder has an advantage in preserving the intra-triple relationship. However, it has not considered the structural rela-

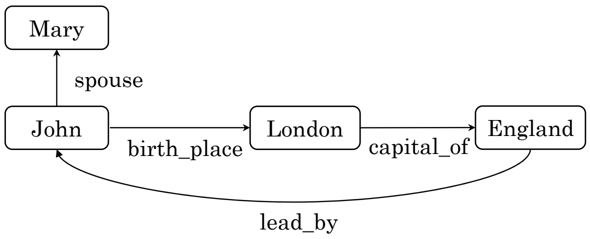

Figure 3: A small knowledge graph formed by a set of RDF triples.

tionships between the entities in different triples. To overcome this limitation, we propose a graph-based triple encoder. We call it the *GTR-LSTM triple encoder*. This encoder takes the input triples in the form of a graph, which preserves the natural structure of the triples (cf. Fig. 3).

GTR-LSTM differs from existing Graph LSTM (Liang et al., 2016) and Tree LSTM (Tai et al., 2015) models in the following aspects. Graph LSTM is proposed for image data. It constructs the graph based on the spatial relationships among super-pixels of an image. Tree LSTM uses the dependency tree as the structure of a sentence. Both models have a predefined relationship between the vertices (Graph LSTM uses spatial relationships: top, bottom, left, or right between super-pixels; Tree LSTM uses dependencies between words in a sentence as the relationship). In contrast, a KB has an open set of relationships between the vertices (i.e., the predicate defines the relationship between entities/vertices) which make our problem more difficult to model.

Our GTR-LSTM triple encoder overcomes the difficulty as follows. It receives a directed graph $G = \langle V, E \rangle$ as the input, where V is a set of vertices that represent entities or literals, and E is a set of directed edges that represent predicates. Since the graph can contain cycles, we use a combination of *topological sort* and *breadth-first traversal* algorithms to traverse the graph. The traversal is used to create an ordering of feeding the vertices into a GTR-LSTM unit to compute their hidden states. We start with running a topological sort to establish an order of the vertices until no further vertex has a zero in-degree. For the remaining vertices, they must be in strongly connected component(s). Then, we run a breadth-first traversal over the remaining vertices with a random starting vertex, since every vertex can be reached from all vertices of a strongly connected component. When a vertex v_i is visited, the hidden states of all adjacent vertices of v_i are computed (or updated if the hidden state of the vertex

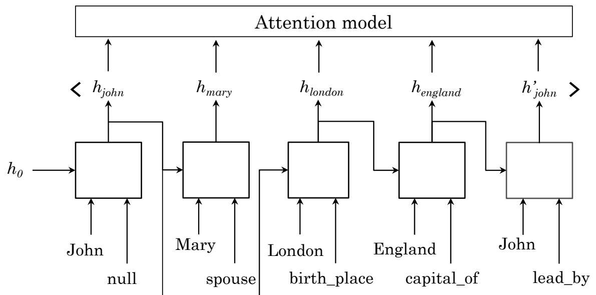

Figure 4: GTR-LSTM triple encoder.

is already computed in the previous step).

Following the graph in Fig. 3, the order of hidden state computation is as follows. The process starts with a vertex with zero in-degree. Because there is no such vertex, a vertex is randomly selected as the starting vertex. Assume we pick "`John`" as the starting vertex, then we compute h_{john} using h_0 as the previous hidden state. Next, following the *breadth-first traversal* algorithm, we visit vertex "`John`" and compute h_{mary} and h_{london} by passing h_{john} as the previous hidden state. Next step, vertex "`Mary`" is visited, but no hidden states are computed or updated since it does not have any adjacent vertices. In the last step, vertex "`England`" is visited and h_{john} is updated. Fig. 4 illustrates the overall process.

Different from the Graph LSTM, our GTR-LSTM model computes a hidden state by taking into account the processed entity and its edge (the edge pointing to the current entity from the previous entity) to handle non-predefined relationships (any relationships between entities in a knowledge graph). Thus, our GTR-LSTM unit (cf. Fig. 4) receives two inputs, i.e., the entity and its relationship. We propose the following model to compute the hidden state of each GTR-LSTM unit.

$$i_t = \sigma\left(\sum_e \left(U^{ie}x_{te} + W^{ie}h_{t-1}\right)\right) \quad (2)$$

$$f_{te} = \sigma\left(U^{f}x_{te} + W^{f}h_{t-1}\right) \quad (3)$$

$$o_t = \sigma\left(\sum_e \left(U^{oe}x_{te} + W^{oe}h_{t-1}\right)\right) \quad (4)$$

$$g_t = \tanh\left(\sum_e \left(U^{ge}x_{te} + W^{ge}h_{t-1}\right)\right) \quad (5)$$

$$c_t = \left(c_{t-1} * \sum_e f_{te}\right) + (g_t * i_t) \quad (6)$$

$$h_t = \tanh(c_t) * o_t \quad (7)$$

Here, U and W are learned parameter matrices, σ denotes the sigmoid function, $*$ denotes element-

wise multiplication, and x is the input at the current time-step. The input gate i determines the weight of the current input. The forget gate f determines the weight of the previous state. The output gate o determines the weight of the cell state forwarded to the next time-step. The state g is the candidate hidden state used to compute the internal memory unit c based on the current input and the previous state. The subscript t is the time-step. The subscript/superscript e is the input element (an entity or a predicate). Following Tree LSTM (Tai et al., 2015) and Graph LSTM (Liang et al., 2016), we also use a separate forget gate for each input that allows the GTR-LSTM unit to incorporate information from each input selectively.

From Fig. 4, we can see that the traversal creates two branches, one ended in h_{mary} and the other ended in h'_{john}. After the encoder computes the hidden states of each vertex, h'_{john} does not include the information of h_{mary} and vice versa. Moreover, the graph can contain cycles that cause difficulty in determining the starting and ending vertices. Our traversal procedure ensures that the hidden states of all vertices are updated based on their adjacent vertices (local neighbors). To further capture the global information of the graph, we apply an attention model on the GTR-LSTM triple encoder. The attention model takes the hidden states of all vertices computed by the encoder and the previous hidden state of the decoder to compute the final input vector of each decoder time-step. Figure 5 illustrates the attention model of GTR-LSTM. Inspired by Luong et al. (2015), we adapt the following equation to compute the weight of each vertex.

$$\alpha_n = \frac{\exp({h^d_t}^T W x_n)}{\sum_{j=1}^{|X|} \exp({h^d_t}^T W x_j)} \tag{8}$$

Here, ${h^d}_t$ is the previous hidden state of the decoder, $|X|$ is the total number of entities in the triples, W is a learned parameter matrix, x_n and x_j are hidden states of vertices, and $\alpha = \{\alpha_1, \alpha_2, ..., \alpha_n\}$ is the weight vector of all vertices. Then the input of the decoder for each time-step can be computed as follows.

$$h_T = \sum_{n=1}^{|X|} \alpha_n x_n \tag{9}$$

3.5 Decoder

The decoder of the proposed framework is a standard LSTM. It is trained to generate the output sequence by predicting the next output word w_t conditioned on the hidden state ${h^d}_t$. The current hidden state ${h^d}_t$ is conditioned on the hidden state of the previous time-step ${h^d}_{t-1}$, the output of the previous time-step w_{t-1}, and input vector representation h_T. The hidden state and the output of the decoder at time-step t are computed as:

$$\begin{aligned} {h^d}_t &= f({h^d}_{t-1}, w_{t-1}, h_T) && (10) \\ w_t &= softmax(V h_t) && (11) \end{aligned}$$

Here, f is a single LSTM unit, and V is the hidden-to-output weight matrix. The encoder and the decoder are trained to maximize the conditional log-likelihood:

$$p(S_n \mid T_n) = \sum_{t=1}^{|S_n|} \log w_t \tag{12}$$

Hence, the training objective is to minimize the negative conditional log-likelihood:

$$J = \sum_{n=1}^{N} - \log p(S_n \mid T_n) \tag{13}$$

where (S_n, T_n) is a pair of output word sequence and input RDF triple set given for the training.

3.6 Entity Masking

Entity masking makes our framework generalizes better to unseen entities. This technique addresses the problem of a limited training set which is faced by many NLG problems.

Entity masking replaces entity mentions with *eids* and entity types in both the input triples and the target sentences. However, we do not want our model to be overly generalized either. Thus, we need to have general and specific entity types. For example, the entity "`John Doe`" is replaced by "`ENT-1 PERSON GOVERNOR`". To add the entity types, we use the DBpedia lookup API. The

API returns several entity types. The general and specific entity types are defined by the level of the word in the WordNet (Fellbaum, 1998) hierarchy.

In the encoder side, each element of the triple $t_n = \langle s_n, p_n, o_n \rangle$ is transformed into $s_n = \langle l_{s_n}, g_{s_n}, d_{s_n} \rangle$, $p_n = \langle l_{p_n} \rangle$, and $o_n = \langle l_{o_n}, g_{o_n}, d_{o_n} \rangle$, where l is the label of an element, g is the general entity type, and d is the specific entity type. The labels of the subject and the object are latter replaced by eids, while the label of the predicate is preserved, since it indicates the relationship between the subject and the object.

On the decoder side, the entities in the target text are also replaced by their corresponding eids. Entity matching is beyond the scope of our study. We simply use a combination of three string matching methods to find entity mentions in the sentence: exact matching, *n-gram* matching, and parse tree matching. The exact matching is used to find the exact mention; the *n-gram* matching is used to handle partial matching with the same token length; and parse tree matching is used to find a partial matching with different token length.

4 Experiments

We evaluate our framework on two datasets. The first is the dataset from Gardent et al. (2017a). We call it the *WebNLG* dataset. This dataset contains 25,298 RDF triple set-text pairs, with 9,674 unique sets of RDF triples. The dataset consists of a Train+Dev dataset and a Test Unseen dataset. We split Train+Dev into a training set (80%), a development set (10%), and a Seen testing set (10%). The Train+Dev dataset contains RDF triples in ten categories (topics, e.g., astronaut, monument, food, etc.), while the Test Unseen dataset has five other unseen categories. The maximum number of triples in each RDF triple set is seven. For the second dataset, we collected data from Wikipedia pages regarding landmarks. We call it the *GKB* dataset. We first extract RDF triples from Wikipedia infoboxes and sentences from the Wikipedia text that contain entities mentioned in the RDF triples. Human annotators then filter out false matches to obtain 1,000 RDF triple set-text pairs. This dataset is split into the training and development set (80%) and the testing set (20%). Table 1 illustrates an example of the data pairs of WebNLG and GKB dataset.

We implement the existing models, the adapted model, and the proposed model using Keras[3]. We use three common evaluation metrics including BLEU (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2011), and TER (Snover et al., 2006). For the metric computation and significance testing, we use MultEval (Clark et al., 2011).

4.1 Tested Models

We compare our proposed graph-based triple encoder (GTR-LSTM, Section 3.4) with three existing model including the adapted standard BLSTM encoder (BLSTM, Section 3.2), Neural Wikipedian (Vougiouklis et al., 2017) (TFF), and statistical machine translation (Hoang and Koehn, 2008) (SMT) trained on a *6-gram* language model. We also compare with the adapted standard triple encoder (TLSTM, Section 3.3).

4.2 Hyperparameters

We use grid search to find the best hyperparameters for the neural networks. We use GloVe (Pennington et al., 2014) trained on the GKB and WebNLG training data and full English Wikipedia data dump to get 300-dimension word embeddings. We use 512 hidden units for both encoder and decoder. We use a 0.5 dropout rate for regularization on both encoder and decoder to avoid overfitting. We train our model on NVIDIA Tesla K40c. We find that using adaptive learning rates for the optimization is efficient and leads the model to converge faster. Thus, we use Adam (Kingma and Ba, 2015) with a learning rate of 0.0002 instead of stochastic gradient descent. The update of parameters in training is computed using a mini batch of 64 instances. We further apply early stopping to detect the convergence.

4.3 Effect of Entity Masking

Table 2 shows the overall comparison of model performance. It shows that entity masking gives a consistent performance improvement for all models. Generalizing the input triples and target sentences helps the models to learn the relationships between entities from their types. This is particularly helpful when there is limited training data. We use a combination of exact matching, *n-gram* matching and parse tree matching to find the entity mentions in the sentence. The entity masking accuracy for WebNLG dataset is 87.15%, while for

Table 2: Comparison of model performance.

RDF inputs	⟨`Elizabeth Tower, location, London`⟩, ⟨`Wembley Stadium, location, London`⟩, ⟨`London, capital of, England`⟩, ⟨`Theresa May, prime minister, England`⟩
Reference	`london , england is home to wembley stadium and the elizabeth tower. the name of the leader in england is theresa may.`
BLSTM	`england is lead by theresa may and` **`is located in the city of london .`** `the elizabeth tower is located` **`in the city of england`** `and is` **`located in the wembley stadium.`**
SMT	`wembley stadium is located in` **`london , elizabeth tower .`** `theresa may is the leader of` **`england , england.`**
TFF	`the elizabeth tower is located in london , england , where` **`wembley stadium is the leader`** `and theresa may is the leader.`
TLSTM	`the wembley stadium is located in london , england . the country is the location of elizabeth tower .` **`theresa may is the leader of london.`**
GTR-LSTM	`the wembley stadium and elizabeth tower are both located in london , england . theresa may is the leader of england.`

Table 3: Sample output of the system. The error is highlighted in bold.

the GKB dataset is 82.45%.

Entity masking improves the BLEU score of the proposed GTR-LSTM model by 8.5% (from 54.0 on the Entity Unmasking model to 58.6 on the Entity Masking model), 16.7%, and 8.0% on the WebNLG seen testing data (denoted by "**Seen**"), WebNLG unseen testing data (denoted by "**Unseen**"), and the GKB testing data (denoted by "**GKB**"). Using the entity masking not only improves the performance by recognizing the unknown vocabulary via eid masking but also improves the running time performance by requiring a smaller training vocabulary.

4.4 Effect of Models

Table 2 also shows that the proposed GTR-LSTM triple encoder achieves a consistent improvement over the baseline models, and the improvement is statistically significant, with $p < 0.01$ based on the t-test of all metrics. We use MultEval to compute the p value based on an approximate randomization (Clark et al., 2011). The improvement on the BLEU score indicates that the model reduces the errors in the generated sentence. Our manual inspection confirms this result. The better (lower) TER score suggests that the model generates a more compact output (i.e., better aggregation).

Table 3 shows a sample output of all models. From this table, we can see that all baseline models produce sentences that contain wrong relationships between entities (e.g., the BLSTM output contains a wrong relationship "`the elizabeth tower is located in the city of england`"). Moreover, the baseline models generate sentences with a weak aggregation (e.g., "`Elizabeth Tower`" and "`Wembley Stadium`" are in separate sentences for TLSTM). The proposed GTR-LSTM model successfully avoids these problems.

Model training time. GTR-LSM is slower in training than the baseline models, which is expected as it needs to encode more information. However, its training time is no more than twice as that of any baseline models tested, and the training can complete within one day which seems reasonable. Meanwhile, the number of parameters trained for GTR-LSTM is up to 59% smaller than those of the baseline models, which saves the space cost for model storage.

4.5 Human Evaluation

To complement the automatic evaluation, we conduct human evaluations for all of the masked models. We ask five human annotators. Each of them

Model \ Dataset/Metric		Seen			Unseen			GKB		
		Correctness	Grammar	Fluency	Correctness	Grammar	Fluency	Correctness	Grammar	Fluency
Existing Models	BLSTM	2.25	2.33	2.29	1.53	1.71	1.68	1.54	1.84	1.84
	SMT	2.03	2.11	2.07	1.36	1.48	1.44	1.81	1.99	1.89
	TFF	1.77	1.91	1.88	1.44	1.69	1.66	1.71	1.99	1.96

Table 4: Human evaluation results.

has studied English for at least ten years and completed education in a full English environment for at least two years. We provide a website[4] that shows them the RDF triples and the generated text. The annotators are given training on the scoring criteria. We also provide scoring examples. We randomly selected 100 sets of triples along with the output of each model. We only select sets of triples that contain more than two triples. Following (Gardent et al., 2017b), we use three evaluation metrics including *correctness*, *grammaticality*, and *fluency*. For each pair of triple set and generated sentences, the annotators are asked to give a score between one to three for each metric.

Correctness is used to measure the semantics of the output sentence. A score of 3 is given to generated sentences that contain no errors in the relationships between entities; a score of 2 is given to generated sentences that contain one error in the relationship; and a score of 1 is given to generated sentences that contain more than one errors in the relationships. *Grammaticality* is used to rate the grammatical and spelling errors of the generated sentences. Similar to the *correctness* metric, a score of 3 is given to generated sentences with no grammatical and spelling errors; a score of 2 is given to generated sentences with one error; and a score of 1 for the others. The last metric, *fluency*, is used to measure the fluency of the sentence output. We ask the annotators to give a score based on the aggregation of the sentences and the existence of sentence repetition. Table 4 shows the results of the human evaluations. The results confirm the automatic evaluation in which our proposed model achieves the best scores.

Error analysis. We further perform a manual inspection of 100 randomly selected output sentences of GTR-LSTM and BLSTM on the Seen and Unseen test data. We find that 32% of BLSTM output contains wrong relationships between entities. In comparison, only 8% of GTR-LSTM output contains such errors. Besides, we find duplicate sub-sentences in the output of GTR-LSTM (15%). The following output is an example: "`beef kway teow is a dish from singapore, where english language is spoken and the leader is tony tan. the leader of singapore is tony tan.`" While the duplicate sentence is not wrong, it affects the reading experience. We conjecture that the LSTM in the decoder caused such an issue. We aim to solve this problem in future work.

[4]http://bit.ly/gkb-mappings

5 Conclusions

We proposed a novel graph-based triple encoder GTR-LSTM for sentence generation from RDF data. The proposed model maintains the structure of input RDF triples as a small knowledge graph to optimize the amount of information preserved in the input of the model. The proposed model can handle cycles to capture the global information of a knowledge graph and also handle non-predefined relationships between entities of a knowledge graph.

Our experiments show that GTR-LSTM offers a better performance than all the competitors. On the WebNLG dataset, our model outperforms the best existing model, the standard BLSTM model, by up to 17.6%, 6.0%, and 16.4% in terms of BLEU, METEOR, and TER scores, respectively. On the GKB dataset, our model outperforms the standard BLSTM model by up to 15.2%, 20.9%, and 23.1% in these three metrics, respectively.

Abstract

Despite their local fluency, long-form text generated from RNNs is often generic, repetitive, and even self-contradictory. We propose a unified learning framework that collectively addresses all the above issues by composing a committee of discriminators that can guide a base RNN generator towards more globally coherent generations. More concretely, discriminators each specialize in a different principle of communication, such as Grice's maxims, and are collectively combined with the base RNN generator through a composite decoding objective. Human evaluation demonstrates that text generated by our model is preferred over that of baselines by a large margin, significantly enhancing the overall coherence, style, and information of the generations.

1 Introduction

Language models based on Recurrent Neural Networks (RNNs) have brought substantial advancements across a wide range of language tasks (Jozefowicz et al., 2016; Bahdanau et al., 2015; Chopra et al., 2016). However, when used for long-form text generation, RNNs often lead to degenerate text that is repetitive, self-contradictory, and overly generic, as shown in Figure 1.

We propose a unified learning framework that can address several challenges of long-form text generation by composing a committee of discriminators each specializing in a different principle of communication. Starting with an RNN language model, our framework learns to construct a more powerful generator by training a number of discriminative models that can collectively address limitations of the base RNN generator, and

Context: The two guards thudded into the door on the other side and began pounding on it, shouting furiously. Scious raised the large bunch of keys then placed them in a large pocket in his coat. "Come, we have to go," he whispered and moved up the corridor, the guards still hammering on the door. Jared looked around. The table next to the room they had been in was bare.

LM: There was a small table set into the center of the table, and a table with two chairs and a table. A chair sat next to the couch. A large man stood in the doorway of the room, his arms crossed over his chest. "What 's up?" He asked.

L2W: Empty. It looked like some kind of *prison*. There were no windows, no doors, no windows. *No sign of anyone in the house.* No one had ever been here before.

Reference: Only a flagon of wine and a couple of mugs plus a crude dice game. Light flickered in the stone corridor from lanterns on the walls. The place was dank and gloomy, moss in scattered patches on the floor and walls. The corridor ended just beyond the door to their former *prison*. *No one else was about.*

Figure 1: Sample generations from an RNN language model (LM) and our system (L2W) conditioning on the context shown on the top. The red, underlined text highlights repetitions, while the *blue, italicized* text highlights details that have a direct semantic parallel in the reference text.

then learns how to weigh these discriminators to form the final decoding objective. These "cooperative" discriminators complement each other and the base language model to form a stronger, more global decoding objective.

The design of our discriminators are inspired by Grice's maxims (Grice et al., 1975) of quantity, quality, relation, and manner. The discriminators learn to encode these qualities through the selection of training data (e.g. distinguishing a true continuation from a randomly sampled one as in §3.2 Relevance Model), which includes generations from partial models (e.g. distinguishing a true continuation from one generated by a language model as in §3.2 Style Model). The system then learns to balance these discriminators by initially weighing them uniformly, then continually updating its weights by comparing the scores the system gives to its own generated continuations and to the reference continuation.

Empirical results (§5) demonstrate that our learning framework is highly effective in converting a generic RNN language model into a substantially stronger generator. Human evaluation confirms that language generated by our model is preferred over that of competitive baselines by a large margin in two distinct domains, and significantly enhances the overall coherence, style, and information content of the generated text. Automatic evaluation shows that our system is both less repetitive and more diverse than baselines.

2 Background

RNN language models learn the conditional probability $P(x_t|x_1, ..., x_{t-1})$ of generating the next word x_t given all previous words. This conditional probability learned by RNNs often assigns higher probability to repetitive, overly generic sentences, as shown in Figure 1 and also in Table 3. Even gated RNNs such as LSTMs (Hochreiter and Schmidhuber, 1997) and GRUs (Cho et al., 2014) have difficulties in properly incorporating long-term context due to explaining-away effects (Yu et al., 2017b), diminishing gradients (Pascanu et al., 2013), and lack of inductive bias for the network to learn discourse structure or global coherence beyond local patterns.

Several methods in the literature attempt to address these issues. Overly simple and generic generation can be improved by length-normalizing the sentence probability (Wu et al., 2016), future cost estimation (Schmaltz et al., 2016), or a diversity-boosting objective function (Shao et al., 2017; Vijayakumar et al., 2016). Repetition can be reduced by prohibiting recurrence of the trigrams as a hard rule (Paulus et al., 2018). However, such hard constraints do not stop RNNs from repeating through paraphrasing while preventing occasional intentional repetition.

We propose a unified framework to address all these related challenges of long-form text generation by learning to construct a better decoding objective, generalizing over various existing modifications to the decoding objective.

3 The Learning Framework

We propose a general learning framework for conditional language generation of a sequence $\mathbf{y}$ given a fixed context $\mathbf{x}$. The decoding objective for generation takes the general form

$$f_\lambda(\mathbf{x}, \mathbf{y}) = \log(P_{\text{lm}}(\mathbf{y}|\mathbf{x})) + \sum_k \lambda_k s_k(\mathbf{x}, \mathbf{y}), \quad (1)$$

where every s_k is a scoring function. The proposed objective combines the RNN language model probability P_{lm} (§3.1) with a set of additional scores $s_k(\mathbf{x}, \mathbf{y})$ produced by discriminatively trained communication models (§3.2), which are weighted with learned mixture coefficients λ_k (§3.3). When the scores s_k are log probabilities, this corresponds to a Product of Experts (PoE) model (Hinton, 2002).

Generation is performed using beam search (§3.4), scoring incomplete candidate generations $\mathbf{y}_{1:i}$ at each time step i. The RNN language model decomposes into per-word probabilities via the chain rule. However, in order to allow for more expressivity over long range context we do not require the discriminative model scores to factorize over the elements of $\mathbf{y}$, addressing a key limitation of RNNs. More specifically, we use an estimated score $s'_k(\mathbf{x}, \mathbf{y}_{1:i})$ that can be computed for any prefix of $\mathbf{y} = \mathbf{y}_{1:n}$ to approximate the objective during beam search, such that $s'_k(\mathbf{x}, \mathbf{y}_{1:n}) = s_k(\mathbf{x}, \mathbf{y})$. To ensure that the training method matches this approximation as closely as possible, scorers are trained to discriminate prefixes of the same length (chosen from a predetermined set of prefix lengths), rather than complete continuations, except for the entailment module as described in §3.2 Entailment Model. The prefix scores are re-estimated at each time-step, rather than accumulated over beam search.

3.1 Base Language Model

The RNN language model treats the context $\mathbf{x}$ and the continuation $\mathbf{y}$ as a single sequence $\mathbf{s}$:

$$\log P_{\text{lm}}(\mathbf{s}) = \sum_i \log P_{\text{lm}}(\mathbf{s}_i|\mathbf{s}_{1:i-1}). \quad (2)$$

3.2 Cooperative Communication Models

We introduce a set of discriminators, each of which encodes an aspect of proper writing that RNNs usually fail to capture. Each model is trained to discriminate between good and bad generations; we vary the model parameterization and training examples to guide each model to focus on a different aspect of Grice's Maxims. The discriminator scores are interpreted as classification probabilities (scaled with the logistic function where necessary) and interpolated in the objective function as log probabilities.

Let $D = \{(\mathbf{x_1}, \mathbf{y_1}), \ldots (\mathbf{x_n}, \mathbf{y_n})\}$ be the set of training examples for conditional generation. $D_\mathbf{x}$ denote all contexts and $D_\mathbf{y}$ all continuations. The scoring functions are trained on prefixes of $\mathbf{y}$ to simulate their application to partial continuations at inference time.

In all models the first layer embeds each word w into a 300-dimensional vector $e(w)$ initialized with GloVe (Pennington et al., 2014) pretrained-embeddings.

Repetition Model

This model addresses the maxim of Quantity by biasing the generator to avoid repetitions. The goal of the repetition discriminator is to learn to distinguish between RNN-generated and gold continuations by exploiting our empirical observation that repetitions are more common in completions generated by RNN language models. However, we do not want to completely eliminate repetition, as words do recur in English.

In order to model natural levels of repetition, a score d_i is computed for each position in the continuation $\mathbf{y}$ based on pairwise cosine similarity between word embeddings within a fixed window of the previous k words, where

$$d_i = \max_{j=i-k \ldots i-1} (\text{CosSim}(e(y_j), e(y_i))), \quad (3)$$

such that $d_i = 1$ if y_i is repeated in the window.

The score of the continuation is then defined as

$$s_{\text{rep}}(\mathbf{y}) = \sigma(\mathbf{w}_r^\top \text{RNN}_{\text{rep}}(\mathbf{d})), \quad (4)$$

where $\text{RNN}_{\text{rep}}(\mathbf{d})$ is the final state of a unidirectional RNN ran over the similarity scores $\mathbf{d} = d_1 \ldots d_n$ and $\mathbf{w}_r$ is a learned vector. The model is trained to maximize the ranking log likelihood

$$L_{\text{rep}} = \sum_{\substack{(\mathbf{x}, \mathbf{y}_g) \in D, \\ \mathbf{y}_s \sim \text{LM}(\mathbf{x})}} \log \sigma(s_{\text{rep}}(\mathbf{y}_g) - s_{\text{rep}}(\mathbf{y}_s)), \quad (5)$$

which corresponds to the probability of the gold ending $\mathbf{y}_g$ receiving a higher score than the ending sampled from the RNN language model.

Entailment Model

Judging textual quality can be related to the natural language inference (NLI) task of recognizing textual entailment (Dagan et al., 2006; Bowman et al., 2015): we would like to guide the generator to neither contradict its own past generation (the maxim of Quality) nor state something that readily follows from the context (the maxim of Quantity). The latter case is driven by the RNNs habit of paraphrasing itself during generation.

We train a classifier that takes two sentences a and b as input and predicts the relation between them as either *contradiction*, *entailment* or *neutral*. We use the *neutral* class probability of the sentence pair as discriminator score, in order to discourage both contradiction and entailment. As entailment classifier we use the decomposable attention model (Parikh et al., 2016), a competitive, parameter-efficient model for entailment classification.[1] The classifier is trained on two large entailment datasets, SNLI (Bowman et al., 2015) and MultiNLI (Williams et al., 2017), which together have more than 940,000 training examples. We train separate models based on the vocabularies of each of the datasets we use for evaluation.

In contrast to our other communication models, this classifier cannot be applied directly to the full context and continuation sequences it is scoring. Instead every completed sentence in the continuation should be scored against all preceding sentences in both the context and continuation.

Let $t(\mathbf{a}, \mathbf{b})$ be the log probability of the neutral class. Let $S(\mathbf{y})$ be the set of complete sentences in $\mathbf{y}$, $S_{\text{last}}(\mathbf{y})$ the last complete sentence, and $S_{\text{init}}(\mathbf{y})$ the sentences before the last complete sentence. We compute the entailment score of $S_{\text{last}}(\mathbf{y})$ against all preceding sentences in $\mathbf{x}$ and $\mathbf{y}$, and use the score of the sentence-pair for which we have the least confidence in a *neutral* classification:

$$s_{\text{entail}}(\mathbf{x}, \mathbf{y}) = min_{\mathbf{a} \in S(\mathbf{x}) \cup S_{\text{init}}(\mathbf{y})} t(\mathbf{a}, S_{\text{last}}(\mathbf{y})). \quad (6)$$

Intuitively, we only use complete sentences because the ending of a sentence can easily flip entailment. As a result, we carry over entailment score of the last complete sentence in a generation until the end of the next sentence, in order to maintain the presence of the entailment score in the objective. Note that we check that the current

[1]We use the version without intra-sentence attention.

```
Data: context $\mathbf{x}$, beam size $k$, sampling temperature $t$
Result: best continuation
best = None
beam = [$\mathbf{x}$]
for step = 0; step $<$ max_steps; step = step $+1$ do
    next_beam = []
    for candidate in beam do
        next_beam.extend(next_k(candidate))
        if termination_score(candidate) $>$ best.score then
            best = candidate.append(term)
        end
    end
    for candidate in next_beam do
                                        ▷ score with models
        candidate.score += $f_\lambda$(candidate)
    end
                                        ▷ sample k candidates by score
    beam = sample(next_beam, $k$, $t$)
end
if learning then
    update $\lambda$ with gradient descent by comparing best
      against the gold.
end
return best
```

Algorithm 1: Inference/Learning in the Learning to Write Framework.

sentence is not directly entailed or contradicted by a previous sentence and not the reverse. [2] In contrast to our other models, the score this model returns only corresponds to a subsequence of the given continuation, as the score is not accumulated across sentences during beam search. Instead the decoder is guided locally to continue complete sentences that are not entailed or contradicted by the previous text.

Relevance Model

The relevance model encodes the maxim of Relation by predicting whether the content of a candidate continuation is relevant to the given context. We train the model to distinguish between true continuations and random continuations sampled from other (human-written) endings in the corpus, conditioned on the given context.

First both the context and continuation sequences are passed through a convolutional layer, followed by maxpooling to obtain vector representations of the sequences:

$$a = \text{maxpool}(\text{conv}_a(e(\mathbf{x}))), \tag{7}$$

$$b = \text{maxpool}(\text{conv}_b(e(\mathbf{y}))). \tag{8}$$

[2]If the current sentence entails a previous one it may simply be adding more specific information, for instance: "He hated broccoli. Every time he ate broccoli he was reminded that it was the thing he hated most."

The goal of maxpooling is to obtain a vector representing the most important semantic information in each dimension.

The scoring function is then defined as

$$s_{\text{rel}} = \mathbf{w}_l^T \cdot (a \circ b), \tag{9}$$

where element-wise multiplication of the context and continuation vectors will amplify similarities.

We optimize the ranking log likelihood

$$L_{\text{rel}} = \sum_{\substack{(\mathbf{x},\mathbf{y}_g)\in D,\\ \mathbf{y}_r\sim D_{\mathbf{y}}}} \log \sigma(s_{\text{rel}}(\mathbf{x},\mathbf{y}_g) - s_{\text{rel}}(\mathbf{x},\mathbf{y}_r)), \tag{10}$$

where $\mathbf{y}_g$ is the gold ending and $\mathbf{y}_r$ is a randomly sampled ending.

Lexical Style Model

In practice RNNs generate text that exhibit much less lexical diversity than their training data. To counter this effect we introduce a simple discriminator based on observed lexical distributions which captures writing style as expressed through word choice. This classifier therefore encodes aspects of the maxim of Manner.

The scoring function is defined as

$$s_{\text{bow}}(\mathbf{y}) = \mathbf{w}_s^T \text{maxpool}(e(\mathbf{y})). \tag{11}$$

The model is trained with a ranking loss using negative examples sampled from the language model, similar to Equation 5.

3.3 Mixture Weight Learning

Once all the communication models have been trained, we learn the combined decoding objective. In particular we learn the weight coefficients λ_k in equation 1 to linearly combine the scoring functions, using a discriminative loss

$$L_{\text{mix}} = \sum_{(\mathbf{x},\mathbf{y})\in D} (f_\lambda(\mathbf{x},\mathbf{y}) - f_\lambda(\mathbf{x},\mathcal{A}(\mathbf{x}))^2, \tag{12}$$

where $\mathcal{A}$ is the inference algorithm for beam search decoding. The weight coefficients are thus optimized to minimize the difference between the scores assigned to the gold continuation and the continuation predicted by the current model.

Mixture weights are learned online: Each successive generation is performed based on the current values of λ, and a step of gradient descent is then performed based on the prediction. This has the effect that the objective function changes

dynamically during training: As the current samples from the model are used to update the mixture weights, it creates its own learning signal by applying the generative model discriminatively. The SGD learning rate is tuned separately for each dataset.

3.4 Beam Search

Due to the limitations of greedy decoding and the fact that our scoring functions do not decompose across time steps, we perform generation with a beam search procedure, shown in Algorithm 1. The naive approach would be to perform beam search based only on the language model, and then rescore the k best candidate completions with our full model. We found that this approach leads to limited diversity in the beam and therefore cannot exploit the strengths of the full model.

Instead we score the current hypotheses in the beam with the full decoding objective: First, each hypothesis is expanded by selecting the k highest scoring next words according to the language model (we use beam size $k = 10$). Then k sequences are sampled from the k^2 candidates according to the (softmax normalized) distribution over the candidate scores given by the full decoding objective. Sampling is performed in order to increase diversity, using a temperature of 1.8, which was tuned by comparing the coherence of continuations on the validation set.

At each step, the discriminator scores are recomputed for all candidates, with the exception of the entailment score, which is only recomputed for hypotheses which end with a sentence terminating symbol. We terminate beam search when the *termination_score*, the maximum possible score achievable by terminating generation at the current position, is smaller than the current best score.

4 Experiments

4.1 Corpora

We use two English corpora for evaluation. The first is the TripAdvisor corpus (Wang et al., 2010), a collection of hotel reviews with a total of 330 million words.[3] The second is the BookCorpus (Zhu et al., 2015), a 980 million word collection of novels by unpublished authors.[4] In order to train the discriminators, mixing weights, and the SEQ2SEQ and SEQGAN baselines, we segment both corpora into sections of length ten sentences, and use the first 5 sentence as context and the second 5 as the continuation. See supplementary material for further details.

4.2 Baselines

ADAPTIVELM Our first baseline is the same Adaptive Softmax (Grave et al., 2016) language model used as base generator in our framework (§3.1). This enables us to evaluate the effect of our enhanced decoding objective directly. A 100k vocabulary is used and beam search with beam size of 5 is used at decoding time. ADAPTIVELM achieves perplexity of 37.46 and 18.81 on BookCorpus and TripAdvisor respectively.

CACHELM As another LM baseline we include a continuous cache language model (Grave et al., 2017) as implemented by Merity et al. (2018), which recently obtained state-of-the-art perplexity on the Penn Treebank corpus (Marcus et al., 1993). Due to memory constraints, we use a vocabulary size of 50k for CACHELM. To generate, beam search decoding is used with a beam size 5. CACHELM obtains perplexities of 70.9 and 29.71 on BookCorpus and TripAdvisor respectively.

Table 2: Results of crowd-sourced evaluation on different aspects of the generation quality as well as overall quality judgments. For each sub-criteria we report the average of comparative scores on a scale from -2 to 2. For the overall quality evaluation decisions are aggregated over 3 annotators per example.

SEQ2SEQ As our evaluation can be framed as sequence-to-sequence transduction, we compare against a seq2seq model directly trained to predict 5 sentence continuations from 5 sentences of context, using the OpenNMT attention-based seq2seq implementation (Klein et al., 2017). Similarly to CACHELM, a 50k vocabulary was used and beam search decoding was performed with a beam size of 5.

SEQGAN Finally, as our use of discriminators is related to Generative Adversarial Networks (GANs), we use SeqGAN (Yu et al., 2017a), a GAN for discrete sequences trained with policy gradients.[5] This model is trained on 10 sentence sequences, which is significantly longer than previous experiments with GANs for text; the vocabulary is restricted to 25k words to make training tractable. Greedy sampling was found to outperform beam search. For implementation details, see the supplementary material.

4.3 Evaluation Setup

We pose the evaluation of our model as the task of generating an appropriate continuation given an initial context. In our open-ended generation setting the continuation is not required to be a specific length, so we require our models and baselines to generate 5-sentence continuations, consistent with the way the discriminator and seq2seq baseline datasets are constructed.

Previous work has reported that automatic measures such as BLEU (Papineni et al., 2002) and Meteor (Denkowski and Lavie, 2010) do not lead to meaningful evaluation when used for long or creative text generation where there can be high variance among acceptable generation outputs (Wiseman et al., 2017; Vedantam et al., 2015). However, we still report these measures as one component of our evaluation. Additionally we report a number of custom metrics which capture important properties of the generated text: *Length* – Average sequence length per example; *Trigrams* – percentage of unique trigrams per example; *Vocab* – percentage of unique words per example. Endings generated by our model and the baselines are compared against the reference endings in the original text. Results are given in Table 1.

For open-ended generation tasks such as our own, human evaluation has been found to be the only reliable measure (Li et al., 2016b; Wiseman et al., 2017). For human evaluation, two possible endings are presented to a human, who assesses the text according to several criteria, which are closely inspired by Grice's Maxims: repetition, contradiction, relevance and clarity. See supplementary material for examples of the evaluation forms we used. For each criterion, the two continuations are compared using a 5-point Likert scale, to which we assign numerical values of -2 to 2. The scale measures whether one generation is strongly or somewhat preferred above the other, or whether they are equal. Finally, the human is asked to make a judgement about overall quality: which ending is better, or are they of equal qual-

[5]We use the implementation available at `https://github.com/nhynes/abc`.

CONTEXT	We thoroughly enjoyed staying at this hotel. We travelled with our kids aged 4 and 6. The rooms were clean, spacious and well maintained. The beds were great and all of us slept well. The hotel provided vouchers towards breakfast at the adjoining restaurant.
L2W	We didn't have breakfast, so can't comment on that. The concierge was very helpful, and gave us directions, etc. Overall, we would definitely recommend this hotel to others. We would stay here again in a heartbeat. If you're looking for a great location, and good value, I'd recommend this hotel.
ADAPTIVELM	The breakfast buffet was very good, and the staff was very friendly and helpful, and it was a great way to start our day! I would definitely stay here again, and would recommend it to my friends, and would stay there again if I ever go back to Montreal. The location was great, and the staff was friendly and helpful. I would definitely stay here again!!
CACHELM	The staff was very friendly and helpful. The hotel is located in a great location. It is right in the middle of the gaslamp district. I would recommend this hotel to anyone. I would definitely stay here again.
SEQ2SEQ	The staff were very friendly and helpful. The hotel is in a great location. The staff were very friendly and helpful. The hotel is in a great location. The staff were very friendly and helpful.
SEQGAN	We had a breakfast at Shula's & a delicious breakfast. The staff was very helpful and helpful. The breakfast was great as well. The staff was very helpful and friendly. We had a great service and the food was excellent.
REFERENCE	The restaurant was great and we used the vouchers towards whatever breakfast we ordered. The hotel had amazing grounds with a putting golf course that was fun for everyone. The pool was fantastic and we lucked out with great weather. We spent many hours in the pool, lounging, playing shuffleboard and snacking from the attached bar. The happy hour was great perk.

Table 3: Example continuations generated by our model (L2W) and various baselines (all given the same context from TripAdvisor) compared to the reference continuation. For more examples go to https://ari-holtzman.github.io/l2w-demo/.

ity?

The human evaluation is performed on 100 examples selected from the test set of each corpus, for every pair of generators that are compared. We present the examples to workers on Amazon Mechanical Turk, using three annotators for each example. The results are given in Table 2. For the Likert scale, we report the average scores for each criterion, while for the overall quality judgement we simply aggregate votes across all examples.

5 Results and Analysis

5.1 Quantitative Results

The absolute performance of all the evaluated systems on BLEU and Meteor is quite low (Table 1), as expected. However, in relative terms L2W is superior or competitive with all the baselines, of which ADAPTIVELM performs best. In terms of vocabulary and trigram diversity only SEQGAN is competitive with L2W, likely due to the fact that sampling based decoding was used. For generation length only L2W and ADAPTIVELM even approach human levels, with the former better on BookCorpus and the latter on TripAdvisor.

Under the crowd-sourced evaluation (Table 2), on BookCorpus our model is consistently favored over the baselines on all dimensions of comparison. In particular, our model tends to be much less repetitive, while being more clear and relevant than the baselines. ADAPTIVELM is the most competitive baseline owing partially to the robustness of language models and to greater vocabulary coverage through the adaptive softmax. SEQGAN, while failing to achieve strong coherency, is surprisingly diverse, but tended to produce far shorter sentences than the other models. CACHELM has trouble dealing with the complex vocabulary of our domains without the support of either a hierarchical vocabulary structure (as in ADAPTIVELM) or a structured training method (as with SEQGAN), leading to overall poor results. While the SEQ2SEQ model has low conditional perplexity, we found that in practice it is less able to leverage long-distance dependencies than the base language model, producing more generic output. This reflects our need for more complex evaluations for generation, as such models are rarely evaluated under metrics that inspect *characteristics* of the text, rather than ability to predict the gold or overlap with the gold.

For the TripAdvisor corpus, L2W is ranked higher than the baselines on overall quality, as well as on most individual metrics, with the exception that it fails to improve on contradiction and clarity over the ADAPTIVELM (which is again the most competitive baseline). Our model's strongest improvements over the baselines are on repetition and relevance.

Trip Advisor Ablation

Ablation vs. LM	Repetition	Contradiction	Relevance	Clarity	Better	Neither	Worse
REPETITION ONLY	+0.63	+0.30	+0.37	+0.42	**50%**	23%	27%
ENTAILMENT ONLY	+0.01	+0.02	+0.05	-0.10	39%	20%	**41%**
RELEVANCE ONLY	-0.19	+0.09	+0.10	+0.060	36%	22%	**42%**
LEXICAL STYLE ONLY	+0.11	+0.16	+0.20	+0.16	38%	25%	**38%**
ALL	+0.23	-0.02	+0.19	-0.03	**47%**	19%	34%

Table 4: Crowd-sourced ablation evaluation of generations on TripAdvisor. Each ablation uses only one discriminative communication model, and is compared to ADAPTIVELM.

Ablation

To investigate the effect of individual discriminators on the overall performance, we report the results of ablations of our model in Table 4. For each ablation we include only one of the communication modules, and train a single mixture coefficient for combining that module and the language model. The diagonal of Table 4 contains only positive numbers, indicating that each discriminator does help with the purpose it was designed for. Interestingly, most discriminators help with most aspects of writing, but all except repetition fail to actually improve the overall quality over ADAPTIVELM.

The repetition module gives the largest boost by far, consistent with the intuition that many of the deficiencies of RNN as a text generator lie in semantic repetition. The entailment module (which was intended to reduce contradiction) is the weakest, which we hypothesize is the combination of (a) mismatch between training and test data (since the entailment module was trained on SNLI and MultiNLI) and (b) the lack of smoothness in the entailment scorer, whose score could only be updated upon the completion of a sentence.

Crowd Sourcing

Surprisingly, L2W is even preferred over the *original* continuation of the initial text on BookCorpus. Qualitative analysis shows that L2W's continuation is often a straightforward continuation of the original text while the true continuation is more surprising and contains complex references to earlier parts of the book. While many of the issues of automatic metrics (Liu et al., 2016; Novikova et al., 2017) have been alleviated by crowd-sourcing, we found it difficult to incentivize crowd workers to spend significant time on any one datum, forcing them to rely on a shallower understanding of the text.

5.2 Qualitative Analysis

L2W generations are more topical and stylistically coherent with the context than the baselines. Table 3 shows that L2W, ADAPTIVELM, and SEQGAN all start similarly, commenting on the breakfast buffet, as breakfast was mentioned in the last sentence of the context. The language model immediately offers generic compliments about the breakfast and staff, whereas L2W chooses a reasonable but less obvious path, stating that the previously mentioned vouchers were not used. In fact, L2W is the only system not to use the line *"The staff was very friendly and helpful."*, despite this sentence appearing in less than 1% of reviews. The semantics of this sentence, however, is expressed in many different surface forms in the training data (e.g., *"The staff were kind and quick to respond."*).

The CACHELM begins by generating the same over-used sentence and only produce short, generic sentences throughout. Seq2Seq simply repeats sentences that occur often in the training set, repeating one sentence three times and another twice. This indicates that the encoded context is essentially being ignored as the model fails to align the context and continuation.

The SEQGAN system is more detailed, e.g. mentioning a specific location "Shula's" as would be expected given its highly diverse vocabulary (as seen in Table 1). Yet it repeats itself in the first sentence. (e.g. *"had a breakfast"*, *"and a delicious breakfast"*). Consequently SEQGAN quickly devolves into generic language, repeating the incredibly common sentence *"The staff was very helpful and friendly."*, similar to SEQ2SEQ.

The L2W models do not fix every degenerate characteristic of RNNs. The TripAdvisor L2W generation consists of meaningful but mostly disconnected sentences, whereas human text tends to build on previous sentences, as in the reference continuation. Furthermore, while L2W repeats itself less than any of our baselines, it still paraphrases itself, albeit more subtly: “we would definitely recommend this hotel to others.” compared to “I’d recommend this hotel.” This example also exposes a more fine-grained issue: L2W switches from using “we” to using “I” mid-generation. Such subtle distinctions are hard to capture during beam re-ranking and none of our models address the linguistic issues of this subtlety.

6 Related Work

Alternative Decoding Objectives A number of papers have proposed *alternative decoding objectives* for generation (Shao et al., 2017). Li et al. (2016a) proposed a *diversity-promoting objective* that interpolates the conditional probability score with negative marginal or reverse conditional probabilities. Yu et al. (2017b) also incorporate the reverse conditional probability through a noisy channel model in order to alleviate the *explaining-away* problem, but at the cost of significant decoding complexity, making it impractical for paragraph generation. Modified decoding objectives have long been a common practice in statistical machine translation (Koehn et al., 2003; Och, 2003; Watanabe et al., 2007; Chiang et al., 2009) and remain common with neural machine translation, even when an extremely large amount of data is available (Wu et al., 2016). Inspired by all the above approaches, our work presents a general learning framework together with a more comprehensive set of composite communication models.

Pragmatic Communication Models Models for pragmatic reasoning about communicative goals such as Grice’s maxims have been proposed in the context of referring expression generation (Frank and Goodman, 2012). Andreas and Klein (2016) proposed a neural model where candidate descriptions are sampled from a generatively trained *speaker*, which are then re-ranked by interpolating the score with that of the *listener*, a discriminator that predicts a distribution over choices given the speaker’s description. Similar to our work the generator and discriminator scores are combined to select utterances which follow Grice’s maxims. Yu et al. (2017c) proposed a model where the speaker consists of a convolutional encoder and an LSTM decoder, trained with a ranking loss on negative samples in addition to optimizing log-likelihood.

Generative Adversarial Networks GANs (Goodfellow et al., 2014) are another alternative to maximum likelihood estimation for generative models. However, backpropagating through discrete sequences and the inherent instability of the training objective (Che et al., 2017) both present significant challenges. While solutions have been proposed to make it possible to train GANs for language (Che et al., 2017; Yu et al., 2017a) they have not yet been shown to produce high quality long-form text, as our results confirm.

Generation with Long-term Context Several prior works studied paragraph generation using sequence-to-sequence models for image captions (Krause et al., 2017), product reviews (Lipton et al., 2015; Dong et al., 2017), sport reports (Wiseman et al., 2017), and recipes (Kiddon et al., 2016). While these prior works focus on developing neural architectures for learning domain specific discourse patterns, our work proposes a general framework for learning a generator that is more powerful than maximum likelihood decoding from an RNN language model for an arbitrary target domain.

7 Conclusion

We proposed a unified learning framework for the generation of long, coherent texts, which overcomes some of the common limitations of RNNs as text generation models. Our framework learns a decoding objective suitable for generation through a learned combination of sub-models that capture linguistically-motivated qualities of good writing. Human evaluation shows that the quality of the text produced by our model exceeds that of competitive baselines by a large margin.

Abstract

Automatic pun generation is an interesting and challenging text generation task. Previous efforts rely on templates or laboriously manually annotated pun datasets, which heavily constrains the quality and diversity of generated puns. Since sequence-to-sequence models provide an effective technique for text generation, it is promising to investigate these models on the pun generation task. In this paper, we propose neural network models for homographic pun generation, and they can generate puns without requiring any pun data for training. We first train a conditional neural language model from a general text corpus, and then generate puns from the language model with an elaborately designed decoding algorithm. Automatic and human evaluations show that our models are able to generate homographic puns of good readability and quality.

1 Introduction

Punning is an ingenious way to make conversation enjoyable and plays important role in entertainment, advertising and literature. A pun is a means of expression, the essence of which is in the given context the word or phrase can be understood in two meanings simultaneously (Mikhalkova and Karyakin, 2017). Puns can be classified according to various standards, and the most essential distinction for our research is between homographic and homophonic puns. A homographic pun exploits distinct meanings of the same written word while a homophonic pun exploits distinct meanings of the same spoken word. Puns can be homographic, homophonic, both, or neither (Miller and Gurevych, 2015).

Puns have the potential to combine novelty and familiarity appropriately, which can induce pleasing effect to advertisement (Valitutti et al., 2008). Using puns also contributes to elegancy in literary writing, as laborious manual counts revealed that puns are one of the most commonly used rhetoric of Shakespeare, with the frequency in certain of his plays ranging from 17 to 85 instances per thousand lines (Miller and Gurevych, 2015). It is not an overstatement to say that pun generation has significance in human society. However, as a special branch of humor, generating puns is not easy for humans, let alone automatically generating puns with artificial intelligence techniques. While text generation is a topic of interest in the natural language processing community, pun generation has received little attention.

Recent sequence-to-sequence (seq2seq) framework is proved effective on text generation tasks including machine translation (Sutskever et al., 2014), image captioning (Vinyals et al., 2015), and text summarization (Tan et al., 2017). The end-to-end framework has the potential to train a language model which can generate fluent and creative sentences from a large corpus. Great progress has achieved on the tasks with sufficient training data like machine translation, achieving state-of-the-art performance. Unfortunately, due to the limited puns which are deemed insufficient for training a language model, there has not been any research concentrated on generating puns based on the seq2seq framework as far as we know.

The inherent property of humor makes the pun generation task more challenging. Despite decades devoted to theories and algorithms for humor, computerized humor still lacks of creativity, sophistication of language, world knowledge, empathy and cognitive mechanisms compared to humans, which are extremely difficult to model (Hossain et al., 2017).

In this paper, we study the challenging task of generating puns with seq2seq models without using a pun corpus for training. We propose a brand-new method to generate homographic puns using normal text corpus which can result in good quality of language model and avoid considerable expense of human annotators on the limited pun resources. Our proposed method can generate puns according to the given two senses of a target word. We achieve this by first proposing an improved language model that is able to generate a sentence containing a given word with a specific sense. Based on the improved language model, we are able to generate a pun sentence that is suitable for two specified senses of a homographic word, using a novel joint beam search algorithm we propose. Moreover, based on the observed characteristics of human generated puns, we further enhance the model to generate puns highlighting intended word senses. The proposed method demonstrates the ability to generate homographic puns containing the assigned two senses of a target word.

Our approach only requires a general text corpus, and we use the Wikipedia corpus in our experiment. We introduce both manual ways and automatic metrics to evaluate the generated puns. Experimental results demonstrate that our methods are powerful and inspiring in generating homographic puns.

The contributions of our work are as follows:

- To our knowledge, our work is the first attempt to adopt neural language models on pun generation. And we do not use any templates or pun data sets in training the model.

- We propose a brand-new algorithm to generate sentences containing assigned distinct senses of a target word.

- We further ameliorate our model with associative words and multinomial sampling to produce better pun sentences.

- Our approach yields substantial results on generating homographic puns with high accuracy of assigned senses and low perplexity.

2 Related Work

2.1 Pun Generation

In recent decades, exploratory research into computational humor has developed to some extent, but seldom is research specifically concerned with puns. Miller and Gurevych (2015) found that most previous studies on puns tend to focus on phonological or syntactic pattern rather than semantic pattern. In this subsection we briefly review some prior work on pun generation.

Lessard and Levison (1992) devised a program to create Tom Swifty, a type of pun which is present in a quoted utterance followed by a punning adverb. Binsted and Ritchie (1994) came up with an early prototype of pun-generator Joke Analysis and Production Engine (JAPE). The model generates question-answer punning with two types of structures: schemata for determining relationships between key words in a joke, and templates for producing the surface form of the joke. Later its successor JAPE-2 (Binsted, 1996; Binsted et al., 1997) and STANDUP (Ritchie et al., 2007) introduced constructing descriptions. The Homonym Common Phrase Pun generator (Venour, 1999) could create two-utterance texts: a one-sentence set-up and a punch-line. Venour (1999) used schemata to specify the required lexical items and their intern relations, and used templates to indicate where to fit the lexical items in a skeleton text (Ritchie, 2004). McKay (2002) proposed WISCRAIC program which can produce puns in three forms: question-answer form, single sentence and a two-sentence sequence. The Template-Based Pun Extractor and Generator (Hong and Ong, 2009) utilized phonetic and semantic linguistic resources to extract word relationships in puns automatically. The system stores the extracted knowledge in template form and results in computer-generated puns.

Most previous research on pun generation is based on templates which is convenient but lacks linguistic subtlety and can be inflexible. None of the systems aimed to be creative as the skeletons of the sentences are fixed and the generation process based on lexical information rarely needs world knowledge or reasoning (Ritchie, 2004). Recently more and more work focuses on pun detection and interpretation (Miller et al., 2017; Miller and Gurevych, 2015; Doogan et al., 2017), rather than pun generation.

2.2 Natural Language Generation

Natural language generation is an important area of NLP and it is an essential foundation for the tasks like machine translation, dialogue response generation, summarization and of course pun generation.

In the past, text generation is usually based on the techniques like templates or rules, probabilistic models like n-gram or log-linear models. Those models are fairly interpretable and well-behaved but require infeasible amounts of hand-engineering to scale with the increasing training data (Xie, 2017). In most cases larger corpus reveals better what matters, so it is natural to tackle large scale modeling (Józefowicz et al., 2016).

Recently, neural network language models (Bengio et al., 2003) have shown the good ability to model language and fight the curse of dimensionality. Cho et al. (2014) propose the encoder-decoder structure which proves very efficient to generate text. The encoder produces a fixed-length vector representation of the input sequence and the decoder uses the representation to generate another sequence of symbols. Such model has a simple structure and maps the source to the target directly, which outperforms the prior models in text generation tasks.

3 Our Models

The goal of our pun generation model is to generate a sentence containing a given target word as homographic pun. Give two senses of the target word (a polyseme) as input, our model generates a sentence where both senses of the word are appropriate in the sentence. We adopt the encoder-decoder framework to train a conditional language model which can generate sentences containing each given sense of the target word. Then we propose a joint beam search algorithm to generate an appropriate sentence to convey both senses of the target word. We call this **Joint Model** whose basic structure is illustrated in Figure 1. We further propose an improved model to highlight the different senses of the target word in one sentence, by reminding people the specific senses of the target word, which may not easily come to mind. We achieve this by using Pointwise Mutual Information (PMI) to find the associative words of each sense of the target word and increase their probability of appearance while decoding. To improve the diversity of the generated sentence, we use multinomial sampling to decode words in the decoding process. The improved model is named the **Highlight Model**.

3.1 Joint Model

3.1.1 Conditional Language Model

For a given word as input, we would like to generate a natural sentence containing the target word with the specified sense. We improve the neural language model to achieve this goal, and name it conditional language model.

The conditional language model for pun generation is similar to the seq2seq model with an input of only one word. We use Long Short-Term Memory (LSTM) as encoder to map the input sequence (target word) to a vector of a fixed dimensionality, and then another LSTM network as decoder to decode the target sequence from the vector (Sutskever et al., 2014).

Our goal is to generate a sentence containing the target word. However, vanilla seq2seq model cannot guarantee the target word to appear in the generated sequence all the time. To solve this problem, we adopt the asynchronous forward/backward generation model proposed by Mou et al. (2015), which employs a mechanism to guarantee some word to appear in the output in seq2seq models. The model first generates the backward sequence starting from the target word w_t at position t of the sentence (i.e., the words before w_t), and ending up with "</s>" at the position 0 of the sentence. The probability of the backward sequence is denoted as $p(\boldsymbol{w}_t^1)$. Then we reverse the output of the backward sequence as the input to the forward model. In this process, the goal of the encoder is to map the generated half sentence to a vector representation and the decoder will generate the latter part accordingly. The probability of the forward sequence is denoted as $p(\boldsymbol{w}_t^n)$. Then the input and output of the forward model are concatenated to form the generated sentence. In the asynchronous forward/backward model, the probability of the output sentence can be decomposed as:

$$p(\overset{\boldsymbol{w}_t^1}{\underset{\boldsymbol{w}_t^n}{=}}) = p(w_t) \prod_{i=0}^{t} p^{(bw)}(w_{t-i}|\cdot) \prod_{i=0}^{m-t+1} p^{(\mathrm{fw})}(w_{t+i}|\cdot), \tag{1}$$

where p($\doteqdot$) denotes the probability of a particular backward/forward sequence (Mou et al., 2015). $p^{(\mathrm{bw})}(w_t|\cdot)$ or $p^{(\mathrm{fw})}(w_t|\cdot)$ denotes the probabil-

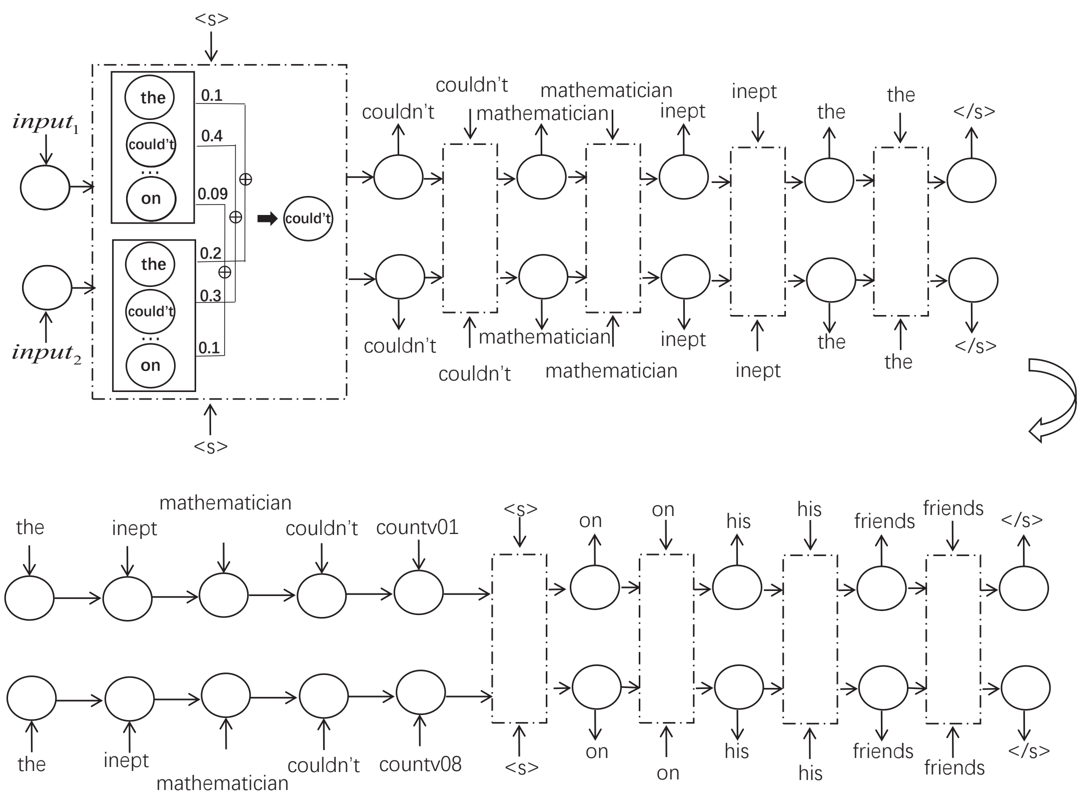

Figure 1: Framework of the proposed Joint Model. (*Top*) Two senses of the target word $input_1$ and $input_2$ (e.g. "*countv01*" and "*countv08*") are firstly provided to the backward model, to generate the backward sequence starting from the target senses and ending up with "</s>". (*Bottom*) Then the backward sequence are reversed and inputted to the forward model, to generate the forward sequence. The inputs and outputs of the forward model are concatenated to form the final output sentence. Joint beam search algorithm is used to generate each word that has the potential to make the generated sentence suitable for both input senses.

ity of w_t given previous sequence $\cdot$ in the backward or forward model respectively. The above model can only guarantee the target word to appear in the generated sentence. Since we hope to generate a sentence containing the specified word sense, we treat different senses of the same word as independent new pseudo-words. We label the senses of words with Word Sense Disambiguation (WSD) tools, and then we train the language model using the corpus with labeled senses so that for each word sense we can generate a sentence accordingly. We use the Python Implementations of WSD Technologies[1] for WSD. This tool can return the most possible sense for the target word based on WordNet (Miller, 1995). We attach the sense label to the word and form a new pseudo-word accordingly. Taking "*count*" for example, "*countv01*" means "*determine the number or amount of*", while "*countv08*" means "*have faith or confidence in*".

3.1.2 Decoding with Joint Beam Search Algorithm

Beam search is a frequently-used algorithm in the decoding stage of seq2seq models to generate the output sequence. It can be viewed as an adaptation of branch-and-bound search that uses an inadmissible pruning rule. In the beam search algorithm, only the most promising nodes at each level of the search graph are selected and the rest nodes are permanently removed. This strategy makes beam search able to find a solution within practical time or memory limits and work well in practical tasks (Zhou and Hansen, 2005; Freitag and Al-Onaizan, 2017).

We also use beam search in our pun generation model. According to the definition of homographic puns, at least two senses of the target word

[1]https://github.com/alvations/pywsd

should be interpreted in one sentence. We hope to generate a same sentence for distinct senses of the same word, and in this way the target word in the sentence can be interpreted as various senses. Provided with two senses of a target word as inputs to the encoder in the backward generation process, e.g. "*countv01*" as $input_1$ and "*countv08*" as $input_2$, we decode two output sentences in parallel, and the two sentences should be the same except for the input pseudo-words. Assume $\boldsymbol{h}_{t,i}^{(s)}$ denotes the hidden state of the i-th beam at time step t, when given the s-th pseudo-word as input (s =1 or 2). In the traditional beam search algorithm, softmax layer is applied on the hidden state to get the probability distribution on the vocabulary, and the log likelihood of the probability is used to get a word score distribution $\boldsymbol{d}_{t,i}^{(s)}$:

$$\boldsymbol{d}_{t,i}^{(s)} = log(softmax\_layer(\boldsymbol{h}_{t,i}^{(s)})). \quad (2)$$

The accumulated score distribution on the i-th beam is:

$$\boldsymbol{p}_{t,i}^{(s)} = \boldsymbol{u}_{t-1,i}^{(s)} + \boldsymbol{d}_{t,i}^{(s)}, \quad (3)$$

$|V|$ denotes the vocabulary size. $\boldsymbol{u}_{t-1,i}^{(s)}$ is a $|V|$-dimensional vector whose values are all equal to the accumulated score of the generated sequence till time step $t-1$. Assume the beam width is b, $\boldsymbol{p}_{t}^{(s)}$ is the concatenation of $\boldsymbol{p}_{t,i}^{(s)}$ on all beams and its dimension size is $|V|*b$. The beam search algorithm selects b candidate words at each time step according to $\boldsymbol{p}_{t}^{(s)}$(s =1 or 2). When decoding for $input_1$ and $input_2$ in parallel, at each time step there will be b candidates for each input according to $\boldsymbol{p}_{t}^{(1)}$ and $\boldsymbol{p}_{t}^{(2)}$ respectively. Since $input_1$ and $input_2$ are different, the candidates for two inputs will hardly be the same. However, our goal is to choose candidate words which have the potential to result in candidate sentences suitable for both senses. Our joint beam search algorithm selects b candidates while decoding for the two inputs according to the joint score distribution on all beams. The joint score distribution on the i-th beam is:

$$\boldsymbol{o}_{t,i} = \boldsymbol{p}_{t,i}^{(1)} + \boldsymbol{p}_{t,i}^{(2)}. \quad (4)$$

The summation of the log scores can be viewed as the product of original probabilities, which represents the joint probability if the two probability distributions are viewed independent. Given the b candidates selected according to the joint score distribution, our joint beam search algorithm

Algorithm 1 Joint Beam Search Algorithm

b denotes the beam width. l denotes the number of unfinished beams. $BeamId$ records which beams the candidates come from. $WordId$ records the indices of candidates in the vocabulary where 1 is the index of "<s>". $BEAM_t[i]$ denotes the i-th beam history till time step t. $|V|$ denotes the vocabulary size. $Copy(m, n)$ aims to make an n-dimensional vector by replicating m for n times. The initial states of the decoder ($\boldsymbol{h}_{-1,i}^{(1)}$,$\boldsymbol{h}_{-1,i}^{(2)}$) are equal to the final states of the encoder accordingly. $\boldsymbol{m} \uplus \boldsymbol{n}$ denotes appending $\boldsymbol{n}$ to $\boldsymbol{m}$.

```
$BEAM_{-1}[i]$= [], $i$=0, 1, ..., $b-1$
$\boldsymbol{u}_{-1,i}^{(1)} = \boldsymbol{u}_{-1,i}^{(2)} = Copy(0, |V|)$, $i = 0, 1, ..., b-1$

while $l > 0$ do
    $\boldsymbol{o}$=[]
    for $i$= 0 to $b-1$ do
        $\boldsymbol{x}_{t,i}$ is the word embedding corresponding to $WordId[i]$
        $\boldsymbol{h}_{t,i}^{(1)}$= LSTM($\boldsymbol{x}_{t,i}, \boldsymbol{h}_{t-1,i}^{(1)}$)
        $\boldsymbol{h}_{t,i}^{(2)}$= LSTM($\boldsymbol{x}_{t,i}, \boldsymbol{h}_{t-1,i}^{(2)}$)
        $\boldsymbol{p}_{t,i}^{(1)} = \boldsymbol{u}_{t-1,i}^{(1)} + \log(softmax\_layer(\boldsymbol{h}_{t,i}^{(1)}))$
        $\boldsymbol{p}_{t,i}^{(2)} = \boldsymbol{u}_{t-1,i}^{(2)} + \log(softmax\_layer(\boldsymbol{h}_{t,i}^{(2)}))$
        $\boldsymbol{o}_{t,i} = \boldsymbol{p}_{t,i}^{(1)} + \boldsymbol{p}_{t,i}^{(2)}$
        $\boldsymbol{o} \uplus \boldsymbol{o}_{t,i}$
    end for
    $WordId$ = the indices of words with the top $b$ scores in $\boldsymbol{o}$
    $BeamId$ = the indices of source beams w.r.t. $WordId$
    for $i$= 0 to $b-1$ do
        $BEAM_t[i] = BEAM_{t-1}[BeamId[i]] \uplus WordId[i]$
        $\boldsymbol{u}_{t,i}^{(1)} = \boldsymbol{u}_{t,i}^{(2)} = Copy(\boldsymbol{o}_{t,BeamId[i]}[WordId[i]], |V|)$
        if $WordId[i]$ represents "</s>"
            $l = l - 1$
            $Outputs = Outputs \uplus BEAM_t[i]$
        end if
    end for
    $t = t + 1$
return top $b$ items in $Outputs$
```

is similar to the vanilla beam search algorithm, which generates the candidate sequences step by step. If any beam selects "</s>" as the candidate, we regard this branch has finished decoding. The decoding process will be finished after all the beams have selected "</s>". The joint beam search algorithm is described in Algorithm 1.

3.2 Highlight Model

3.2.1 Word Association

The joint model we described above is able to generate sentences suitable for both given senses of the target word. But we found this model is prone to generate monotonous sentences, making it difficult to discover that the target word in the sentence can be understood in two ways. For example, in the sentence "*He couldn't count on his friends*", people can easily realize that the common meaning "*have faith or confidence in*" of the word "*count*", but may ignore other senses of the word. If we add some words and modify the sentence as "*The inept mathematician couldn't count on his friends*", people can also come up with the meaning "*determine the number or amount of*" due to the word "*mathematician*". Comparing the examples above, the two senses are proper in both sentences, but people may interpret "*count*" in the two sentences differently. Based on such observations, we improve the pun generation model by adding some keywords to the sentence which could remind people some special sense of the target word. We call those keywords associative words, and the improved model is named as Highlight Model.

To extract associative words of each sense of the target word, we first build word association norms in our corpus by using pointwise mutual information (PMI). As mutual information compares the probability of observing w_1 and w_2 together (the joint probability) with the probabilities of observing w_1 and w_2 independently (chance) (Church and Hanks, 1990), positive PMI scores indicate that the words occur together more than would be expected under an independence assumption, and negative scores indicate that one word tends to appear solely when the other does not (Islam and Inkpen, 2006). In this case we take top k associative words for each sense with relatively high positive PMI scores, which are calculated as follows:

$$PMI(w_1, w_2) = \log_2 \frac{p(w_1, w_2)}{p(w_1) \cdot p(w_2)}. \quad (5)$$

During decoding we increase the probability of the associative words to be chosen according to their PMI scores. For each sense of the target word, we normalize the PMI scores of the associative words as follows:

$$Asso(w_t^{(s)}, c_p) = \sigma\left(\frac{PMI(w_t^{(s)}, c_p)}{max_{c_j} PMI(w_t^{(s)}, c_j)}\right), \quad (6)$$

where $w_t^{(s)}$ represents the s-th sense of the target word w_t, and c_p is the p-th associative word for $w_t^{(s)}$. To smooth the PMI scores we use sigmoid function σ which is differentiable and widely used in the neural network models. The final PMI score for each associative word is denoted as $Asso(w_t^{(s)}, c_p)$. As we choose candidates according to a score distribution on the whole vocabulary, we need a PMI score distribution ($\boldsymbol{S}(w_t^{(s)})$) rather than single scores, and the value at position q is supposed to be:

$$\boldsymbol{S}\left(w_t^{(s)}\right)[q] = \begin{cases} Asso\left(w_t^{(s)}, v_q\right), v_q \in AssoTK(w_t^{(s)}); \\ 0, \qquad else, \end{cases} \quad (7)$$

where v_q denotes the q-th word in the vocabulary, and $AssoTK(w_t^{(s)})$ denotes the top k associative words of $w_t^{(s)}$.

3.2.2 Multinomial Sampling

In our highlight model, we add $\boldsymbol{S}(w_t^{(1)})$ and $\boldsymbol{S}(w_t^{(2)})$ to $\boldsymbol{o}_{t,i}$, as:

$$\widetilde{\boldsymbol{o}}_{t,i} = \boldsymbol{o}_{t,i} + \alpha_1 \cdot \boldsymbol{S}(w_t^{(1)}) + \alpha_2 \cdot \boldsymbol{S}(w_t^{(2)}), \quad (8)$$

where we use α_1 and α_2 as coefficient weights to balance the PMI scores of the two assigned senses and the joint score. In the Highlight Model, we first select $2b$ candidates according to the scores of words from Eq. 8. Then we use multinomial sampling to select the final b candidates. Sampling is useful in cases where we may want to get a variety of outputs for a particular input. One example of a situation where sampling is meaningful would be in a seq2seq model for a dialog system (Neubig, 2017). In our pun generation model we hope to produce relatively more creative sentences, so we use multinomial sampling to increase the uncertainty when generating the sentence. The multinomial distribution can be seen as a multivariate generalization of the binomial distribution and it is prone to choose the words with relatively high probabilities. If an associative word of one sense has been selected, we decay the scores for all associative words of this sense. In this way we can prevent the sentence obviously being prone to reflect one sense of the target word.

4 Experiments

4.1 Data Preprocessing

Most text generation tasks using seq2seq model require large amount of training data. However, for many tasks, like pun generation, it is difficult to get adequate data to train a seq2seq model. In this study, our pun generation model does not rely on training data of puns. We only require a text corpus to train the conditional language model, which is very cheap to get. In this paper, we use the English Wikipedia corpus to train the language model. The corpus texts are firstly lowercased and tokenized, and all numeric characters are replaced with "#". We split the texts into sentences and discard the sentences whose length is less than 5 words or more than 50 words. We then select polysemes appearing in the homographic pun data set (Miller et al., 2017) and pun websites. Those polysemes in the corpus are replaced by the labeled sense. We restrict that each sentence can be labeled with at most two polysemes in order to train a reliable language model. If there are more polysemes in one sentence, we keep the last two because in our observation we found pun words tend to occur near the end of a sentence. After labeling, we keep the 105,000 most frequently occurring words and other words are replaced with the "<unk>" token. We discard the sentences with two or more "<unk>" tokens. There are totally 3,974 distinct labeled senses corresponding to a total of 772 distinct polysemes. We assume those reserved senses are more likely to generate puns of good quality.

While training the language model we use 2,595,435 sentences as the training set, and 741,551 sentences as the development set to decide when to stop training.

4.2 Training Details

The number of LSTM layers we use in the seq2seq model is 2 and each layer has 128 units. To avoid overfitting, we set the dropout rate to 0.2. We use Stochastic Gradient Descent (SGD) with a decreasing learning rate schedule as optimizer. The initial learning rate is 1.0 and is halved every 1k steps after training for 8k steps, which is the same as Luong et al. (2017). We set beam size $b = 5$ while decoding. For each sense we select at most 30 associative words (k=30). To increase the probability of choosing the associative words, we set $\alpha_1 = 6.0$ and $\alpha_2 = 6.0$. If an associative word of some sense of a target word has been chosen, its corresponding α will be set to zero for all the associative words of this sense.

4.3 Baselines

Since there is no existing neural model applied on this special task, we implement two baseline models for comparison. We select 100 target words and two senses for each word to test the quality of those models.

Normal Language Model: It is trained with an encoder-decoder model and uses beam search while decoding. In the training process, inputs are unlabeled target words and outputs are sentences containing the target words.

Pun Language Model: We use the data set of homographic puns from Miller et al. (2017). The model is trained on the data set in asynchronous forward/backward way. As the pun data set is limited, the pun language model has no creativity, which means if we input a word appearing in the training data, then the output will usually be an existing sentence from the training data. Therefore, we remove the sentences which contain words in the 100 target words from the pun data set, and then train the model for test.

4.4 Automatic Evaluation

We select 100 target words and two senses for each word for test. We use the language modeling toolkit SRILM[2] to train a trigram model with another 7,746,703 sentences extracted from Wikipedia, which are different from the data set used before. The perplexity scores (PPL) of our models and baseline models are estimated based on the trained language model, as shown in Table 1. Normal Language Model has no constraint of generating sentences suitable for both senses. This means at each time step the beam search algorithm can select the candidates with highest probabilities. And thus it is natural that it obtains the lowest perplexity. Taking the constraint of senses into consideration, the perplexity scores of Joint Model and Highlight Model are still comparable to that of Normal Language Model. However, Pun Language Model could not be trained well considering the limit of the pun training data, so it gets the highest perplexity score. This result reveals that it is not feasible to build a homographic pun generation system based on the pun data set since pun data is far from enough. In the table, We further compare the diversity of the generated sentences of four models following Li et al. (2016). Distinct-1 (d.-1) and distinct-2 (d.-2) are the ratios of the distinct unigrams and bigrams in generated sentences, i.e., the number of distinct unigrams or bigrams divided by the total number of unigrams or bigrams. The results show our models are more creative than Normal Language and

[2]http://www.speech.sri.com/projects/srilm/

Model	PPL	d.-1(%)	d.-2(%)
Highlight	91.80	**27.13**	**62.85**
Joint	63.48	22.13	50.59
Normal Language	**62.66**	19.60	41.62
Pun Language	889.07	14.78	23.11

Table 1: Results of automatic evaluation.

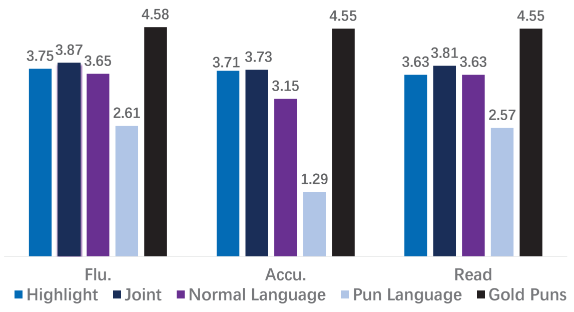

Figure 2: Results of human evaluation.

Pun Language models, and Highlight Model can generate sentences with the best diversity.

4.5 Human Evaluation

Because of the subtle and delicate structure of puns, automatic evaluation is not enough. So we sample one sentence for each word from four models mentioned above and then get 100 sentences of each model generated from the target words, together with 100 puns containing the same target words from homographic pun data set in Miller et al. (2017). We ask judges on Amazon Mechanical Turk to evaluate all the sentences and the rating score ranges from 1 to 5. Five native English speakers are asked to give a score on each sentence in three aspects with the following information: **Readability** indicates whether the sentence is easy to understand semantically; **Accuracy** indicates whether the given senses are suitable in a sentence; **Fluency** indicates whether the sentence is fluent and consistent with the rules of grammar.

The results in Figure 2 show that pun data is not enough to train an ideal language model, while Normal Language Model has enough corpus to train a good language model. But Normal Language Model is unable to make the given two senses appear in one sentence and in a few cases even can not assure the appearance of the target words. Joint Model and Highlight Model can generate fluent sentences for the assigned two senses. Although Highlight Model could remind people specific senses of the target words in most cases, in few cases sampled words make the whole sentence unsatisfactory and get a relatively lower score of accuracy. As to the Readability, the Joint Model performs better than other three models. Both Joint model and Highlight model outperform Normal Language Model and Pun Language Model.

Model	# sentences	avg. score
Highlight	15	0.98
Joint	12	0.87
Gold Puns	28	1.38

Table 2: Results of Soft Turing Test.

To test the potential of the sentences generated by our models to be homographic puns, we further design a Soft Turing Test. We select 30 sentences generated by Joint Model and 30 sentences generated by Highlight Model independently, together with 30 gold puns from the homographic pun data set. We mix them up, and give the definition of homographic pun and ask 10 people on Amazon Mechanical Turk to judge each sentence. People can judge each sentence as one of three categories: definitely by human, might by human and definitely by machine. The three categories correspond to the scores of 2, 1 and 0, respectively. If the average score of one sentence is equal or greater than 1, we regard it as judged to be generated by human. The number of sentences judged as by human for each model and the average score for each model are shown in Table 2.

Due to the flexible language structure of Highlight Model, the generated homographic puns outperform those generated by Joint Model in the Soft Turing Test, however still far from gold-standard puns. Our models are adept at generating homographic puns containing assigned senses but weak in making homographic puns humorous.

4.6 Examples

We show some examples generated by different models in Table 3. For the two senses of *"pitch"*, Highlight Model generates a sentence which uses *"high"* to remind readers the sense related to sound and uses *"player"* to highlight the sense related to throwing a baseball. Joint Model returns a sentence that can be understood in both way roughly only if we give the two senses in advance, otherwise readers may only think of the

Model	Sample
pitch: 1) the property of sound that arise with variation in the frequency of vibration; 2) the act of throwing a baseball by a pitcher to a batter.	
Highlight	in one that denotes player may have had a high pitch in the world
Joint	the object of the game is based on the pitch of the player
Normal Language	this is a list of high pitch plot
Pun Language	our bikinis are exciting they are simply the tops on the mouth
Gold Puns	if you sing while playing baseball you won't get a good pitch
square: 1) a plane rectangle with four equal sides and four right angles, a four-sided regular polygon; 2) someone who doesn't understand what is going on.	
Highlight	little is known when he goes back to the square of the football club
Joint	there is a square of the family
Normal Language	the population density was # people per square mile
Pun Language	when the pirate captain's ship ran aground he couldn't fathom why
Gold Puns	my advanced geometry class is full of squares
problem: 1) a source of difficulty; 2) a question raised for consideration or solution.	
Highlight	you do not know how to find a way to solve the problem which in the state
Joint	he is said to be able to solve the problem as he was a professor
Normal Language	in # he was appointed a member of the new york stock exchange
Pun Language	those who iron clothes have a lot of pressing veteran
Gold Puns	math teachers have lots of problems

Table 3: Examples of outputs by different models.

sense related to baseball. For Normal Language Model, it is difficult to be interpreted in two senses we assigned. Pun Language Model has no ability to return a sentence containing the assigned word at all. Observing the gold pun, the context describes a more vivid scene which we need to pay attention to. For "*square*", sentences generated by Highlight Model and Joint Model can be interpreted in two senses and Highlight Model results in a sentence with dexterity. Normal Language Model give a sentence where "*square*" means neither of the two given senses. Pun Language Model cannot return a sentence we need with no surprise. For "*problem*", both Highlight Model and Joint Model can generate sentences containing assigned two senses while Normal Language Model and Pun Language Model can not return sentences with the target word. Compare to our generated sentences, we find gold puns are more concise and accurate, which takes us into consideration on the delicate structure of puns and the conclusion is still in exploration.

5 Conclusion and Future Work

In this paper, we proposed two models for pun generation without using training data of puns. Joint Model makes use of conditional language model and the joint beam search algorithm, which can assure the assigned senses of target words suitable in one sentence. Highlight Model takes associative words into consideration, which makes the distinct senses more obvious in one sentence. The produced puns are evaluated using automatic evaluation and human evaluation, and they outperform the sentences generated by our baseline models.

For future work, we hope to improve the results by using the pun data and design a more proper way to select candidates from associative words.

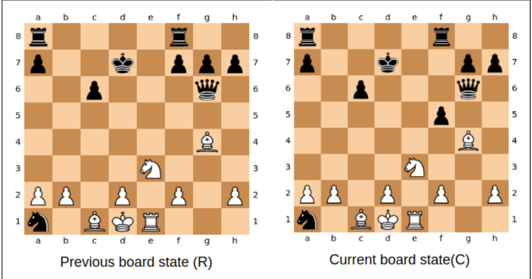
Abstract

This paper examines the problem of generating natural language descriptions of chess games. We introduce a new large-scale chess commentary dataset and propose methods to generate commentary for individual moves in a chess game. The introduced dataset consists of more than 298K chess move-commentary pairs across 11K chess games. We highlight how this task poses unique research challenges in natural language generation: the data contain a large variety of styles of commentary and frequently depend on pragmatic context. We benchmark various baselines and propose an end-to-end trainable neural model which takes into account multiple pragmatic aspects of the game state that may be commented upon to describe a given chess move. Through a human study on predictions for a subset of the data which deals with direct move descriptions, we observe that outputs from our models are rated similar to ground truth commentary texts in terms of correctness and fluency.[1]

1 Introduction

A variety of work in NLP has sought to produce fluent natural language descriptions conditioned on a contextual grounding. For example, several lines of work explore methods for describing images of scenes and videos (Karpathy and Fei-Fei, 2015), while others have conditioned on structured sources like Wikipedia infoboxes (Lebret et al., 2016). In most cases, progress has been driven by the availability of large training corpora that pair natural language with examples from the grounding (Lin et al., 2014). One line of work has investigated methods for producing and interpreting language in the context of a game, a space that has rich pragmatic structure, but where training data has been hard to come by. In this paper, we introduce a new large-scale resource for learning to correlate natural language with individual moves in the game of chess. We collect a dataset of more than 298K chess move/commentary pairs across ≈ 11K chess games from online chess forums. To the best of our knowledge, this is the first such dataset of this scale for a game commentary generation task. We provide an analysis of the dataset and highlight the large variety in commentary texts by categorizing them into six different aspects of the game that they respectively discuss.



Template: Black moves the pawn from f7 to f5

Nearest Neighbor: Attacks the bishop , but allows black to gain the pawn back .

GAC(Our method): Black threatens white bishop with his pawn.

Ground Truth: Blocking the bishop out and eyeing for f4 and mate on c

Figure 1: Move commentary generated from our method (Game-aware neural commentary generation (GAC)) and some baseline methods for a sample move.

Automated game commentary generation can be a useful learning aid. Novices and experts alike can learn more about the game by hearing expla-

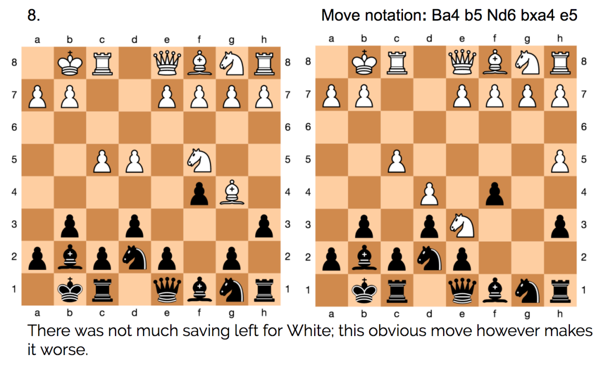
[1]We will make the code-base (including data collection and processing) publicly available at `https://github.com/harsh19/ChessCommentaryGeneration`

nations of the motivations behind moves, or their quality. In fact, on sites for game aficionados, these commentaries are standard features, speaking to their interestingness and utility as complements to concrete descriptions of the game boards themselves.

Game commentary generation poses a number of interesting challenges for existing approaches to language generation. First, modeling human commentary is challenging because human commentators rely both on their prior knowledge of game rules as well as their knowledge of effective strategy when interpreting and referring to the game state. Secondly, there are multiple aspects of the game state that can be talked about for a given move — the commentator's choice depends on the pragmatic context of the game. For example, for the move shown in Figure 1, one can comment simply that the pawn was moved, or one may comment on how the check was blocked by that move. Both descriptions are true, but the latter is most salient given the player's goal. However, sometimes, none of the aspects may stand out as being most salient, and the most salient aspect may even change from commentator to commentator. Moreover, a human commentator may introduce variations in the aspects he or she chooses to talk about, in order to reduce monotony in the commentary. This makes the dataset a useful testbed not only for NLG but also for related work on modeling pragmatics in language (Liu et al., 2016).

Prior work has explored game commentary generation. Liao and Chang (1990); Sadikov et al. (2006) have explored chess commentary generation, but for lack of large-scale training data their methods have been mainly rule-based. Kameko et al. (2015) have explored commentary generation for the game of Shogi, proposing a two-step process where salient terms are generated from the game state and then composed in a language model. In contrast, given the larger amount of training data available to us, our proposed model uses an end-to-end trainable neural architecture to predict commentaries given the game state. Our model conditions on semantic and pragmatic information about the current state and explicitly learns to compose, conjoin, and select these features in a recurrent decoder module. We perform an experimental evaluation comparing against baselines and variants of our model that ablate various aspects of our proposed architecture. Outputs on the 'Move Description' subset of data from our final model were judged by humans to be as good as human written ground truth commentaries on measures of fluency and correctness.



8.
Move notation: Ba4 b5 Nd6 bxa4 e5
There was not much saving left for White; this obvious move however makes it worse.

Figure 2: A multi-move, single commentary example from our data. Here, the sequence of moves Ba4 $\rightarrow$ b5 $\rightarrow$ Nd6 $\rightarrow$ bxa4 $\rightarrow$ e5 is commented upon.

Statistic	Value
Total Games	11,578
Total Moves	298,008
Average no. of recorded steps in a game	25.73
Frequent Word Types[2]	39,424
Rare Word Types	167,321
Word Tokens	6,125,921
Unigram Entropy	6.88
Average Comment Length (in #words)	20.55
Long Comments (#words > 5)	230745 (77%)

Table 1: Dataset and Vocabulary Statistics

2 Chess Commentary Dataset

In this section we introduce our new large-scale *Chess Commentary* dataset, share some statistics about the data, and discuss the variety in type of commentaries. The data is collected from the online chess discussion forum `gameknot.com`, which features multiple games self-annotated with move-by-move commentary.

The dataset consists of 298K aligned game move/commentary pairs. Some commentaries are written for a sequence of few moves (Figure 2) while others correspond to a single move. For the purpose of initial analysis and modeling, we limit ourselves to only those data points where commentary text corresponds to a single move. Additionally, we split the multi-sentence commentary texts to create multiple data points with the same chess board and move inputs.

What are commentaries about? We observe that there is a large variety in the commentary

Category	Example	% in data	Val acc.
Direct Move Description	An attack on the queen	31.4%	71%
Move Quality	A rook blunder.	8.0%	90%
Comparative	At this stage I figured I better move my knight.	3.7%	77.7%
Planning / Rationale	Trying to force a way to eliminate d5 and prevent Bb5.	31.2%	65%
Contextual Game Info	Somehow, the game I should have lost turned around in my favor .	12.6%	87%
General Comment	Protect Calvin , Hobbs	29.9%	78%

Table 2: Commentary texts have a large variety making the problem of content selection an important challenge in our dataset. We classify the commentaries into 6 different categories using a classifier trained on some hand-labelled data, a fraction of which is kept for validation. % data refers to the percentage of commentary sentences in the tagged data belonging to the respective category.

texts. To analyze this variety, we consider labelling the commentary texts in the data with a predefined set of categories. The choice of these categories is made based on a manual inspection of a sub-sample of data. We consider the following set of commentary categories (Also shown in Table 2):

- **Direct move description (MoveDesc[3]):** Explicitly or implicitly describe the current move.
- **Quality of move (Quality[4]):** Describe the quality of the current move.
- **Comparative:** Compare multiple possible moves.
- **Move Rationale or Planning (Planning):** Describe the rationale for the current move, in terms of the future gameplay, advantage over other potential moves etc.
- **Contextual game information:** Describe not the current move alone, but the overall game state – such as possibility of win/loss, overall aggression/defence, etc.
- **General information:** General idioms & advice about chess, information about players/tournament, emotional remarks, retorts, etc.

The examples in Table 2 illustrate these classes. Note that the commentary texts are not necessarily limited to one tag, though that is true for most of the data. A total of 1K comments are annotated by two annotators. A SVM classifier (Pedregosa et al., 2011a) is trained for each comment class, considering the annotation as ground truth and using word unigrams as features. This classifier is then used to predict tags for the train, validation and test sets. For "Comparative" category, we found that a classifier with manually defined rules such as presence of word "better" performs better than the classifier, perhaps due to the paucity of data, and thus we use this instead . As can be observed in Table 2, the classifiers used are able to generalize well on the held out dataset

[3]MoveDesc & 'Move Description' used interchangeably
[4]Quality and 'Move Quality' used interchangeably

3 Game Aware Neural Commentary Generations (GAC)

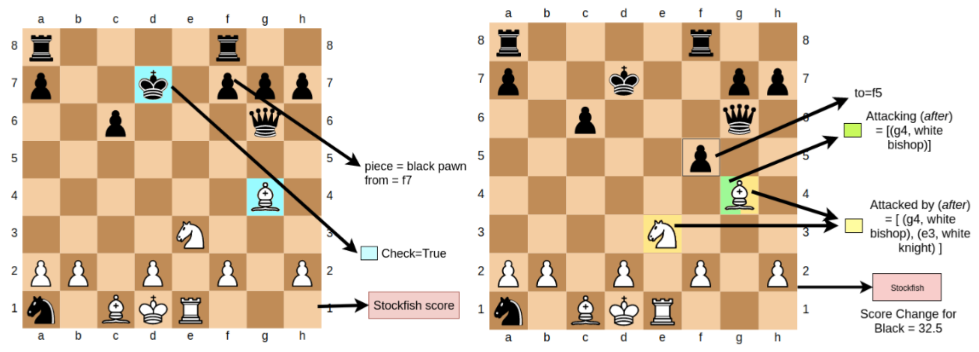
Our dataset D consists of data points of the form $(S_i, M_i, G_i), i \in \{1, 2, .., |D|\}$, where S_i is the commentary text for move M_i and G_i is the corresponding chess game. S_i is a sequence of m tokens $S_{i1}, S_{i2}, ..., S_{im}$ We want to model $P(S_i|M_i, G_i)$. For simplicity, we use only current board (C_i) and previous board (R_i) information from the game. $P(S_i|M_i, G_i) = P(S_i|M_i, C_i, R_i)$.

We model this using an end-to-end trainable neural model, which models conjunctions of features using feature encoders. Our model employs a selection mechanism to select the salient features for a given chess move. Finally a LSTM recurrent neural network (Hochreiter and Schmidhuber, 1997) is used to generate the commentary text based on selected features from encoder.

3.1 Incorporating Domain Knowledge

Past work shows that acquiring domain knowledge is critical for NLG systems (Reiter et al., 2003b; Mahamood and Reiter, 2012). Commentary texts cover a range of perspectives, including criticism or goodness of current move, possible alternate moves, quality of alternate moves, etc. To be able to make such comments, the model must learn about the quality of moves, as well as the set of valid moves for a given chess board state. We consider the following features to provide our model with necessary information to generate commentary texts (Figure 3):

Move features $f_{move}(M_i, C_i, R_i)$ encode the current move information such as which piece moved, the position of the moved piece before and after the move was made, the type and position



piece = black pawn from = f7
Check=True
Stockfish score
to=f5
Attacking (*after*) = [(g4, white bishop)]
Attacked by (*after*) = [(g4, white bishop), (e3, white knight)]
Stockfish
Score Change for Black = 32.5

Figure 3: The figure shows some features extracted using the chess board states before (*left*) and after (*right*) a chess move. Our method uses various semantic and pragmatic features of the move, including the location and type of piece being moved, which opposing team pieces attack the piece being moved before as well as after the move, the change in score by *Stockfish* UCI engine, etc.

of the captured piece (if any), whether the current move is castling or not, and whether there was a check or not.

Threat features $f_{threat}(M_i, C_i, R_i)$ encode information about pieces of opposite player attacking the moved piece before and after the move, and the pieces of opposite player being attacked by the piece being moved. To extract this information, we use the *python-chess* library [5]

Score features $f_{score}(M_i, C_i, R_i)$ capture the quality of move and general progress of the game. This is done using the game evaluation score before and after the move, and average rank of pawns of both the players. We use *Stockfish* evaluation engine to obtain the game evaluation scores. [6]

3.2 Feature Representation

In our simplest conditioned language generation model **GAC-sparse**, we represent the above described features using sparse representations through binary-valued features. $g_{sparse}(M_i, C_i, R_i) = \text{SparseRep}(f_{move}, f_{threat}, f_{score})$

For our full **GAC** model we consider representing features through embeddings. This has the advantage of allowing for a shared embedding space, which is pertinent for our problem since attribute values can be shared, e.g. the same piece type can occur as the moved piece as well as the captured piece. For categorical features, such as those indicating which piece was moved, we directly look up the embedding using corresponding token. For real valued features such as game scores, we first bin them and then use corresponding number for embedding lookup. Let E represent the embedding matrix. Then $E[f^j_{move}]$ represents embeddings of j^{th} move feature, or in general $E[f_{move}]$ represents the concatenated embeddings of all move features. Similarly, $E(f_{move}, f_{threat}, f_{score})$ represents concatenated embeddings of all the features.

3.3 Feature Conjunctions

We conjecture that explicitly modeling feature conjunctions might improve the performance. So we need an encoder which can handle input sets of features of variable length (features such as pieces attacking the moved piece can be of variable length). One way to handle this is by picking up a canonical ordering of the features and consider a bidirectional LSTM encoder over the feature embeddings. As shown in Figure 4, this generates conjunctions of features.
$g^{enc} = \text{BiLSTM}^*(\{E(f_{move}, f_{threat}, f_{score}))\})$

Here $E()$ represents the embedding matrix as described earlier and $BiLSTM^*$ represents a sequential application of the $BiLSTM$ function. Thus, if there a total of m feature keys and embedding dimension is d, $E(f_{move}, f_{threat}, f_{score})$ is matrix of $m * d$. If hidden size of BILSTM is of size x, then g^{enc} is of dimensionality $m * x$. We observe that different orderings gave similar performance. We also experimented with running k encoders, each on different ordering of features, and then letting the decoder access to each of the k encodings. This did not yield any significant gain in performance.

The GAC model, unlike GAC-sparse, has some advantages as it uses a shared, continuous space

[5] https://pypi.org/project/python-chess/
[6] https://stockfishchess.org/about/

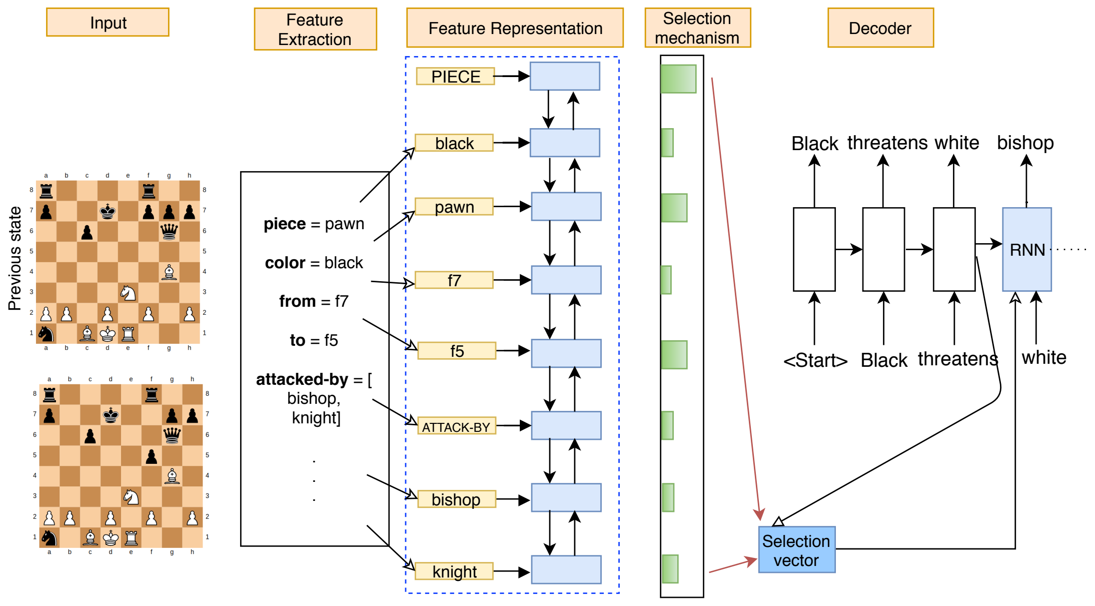


Figure 4: The figure shows a model overview. We first extract various semantic and pragmatic features from the previous and current chess board states. We represent features through embedding in a shared space. We observe that feeding in feature conjunctions helps a lot. We consider a selection mechanism for the model to choose salient attributes from the input at every decoder step.

to embed attribute values of different features, and can perform arbitrary feature conjunctions before passing a representation to the decoder, thereby sharing the burden of learning the necessary feature conjunctions. Our experiments confirm this intuition — GAC produces commentaries with higher BLEU as well as more diversity compared to GAC-sparse.

3.4 Decoder

We use a LSTM decoder to generate the sentence given the chess move and the features g. At every output step t, the LSTM decoder predicts a distribution over vocabulary words taking into account the current hidden state h_t, the input token i_t, and additional selection vector c_t. For GAC-sparse, the selection vector is simply an affine transformation of the features g. For GAC model selection vector is derived via a selection mechanism.

$$o_t, h_t^{dec} = LSTM(h_{t-1}^{dec}, [\text{concat}(E_{dec}(i_t), c_t)])$$
$$p_t = \text{softmax}(W_o[\text{concat}(o_t, c_t)] + b_s)$$

where p_t represents th probability distribution over the vocabulary, $E_{dec}()$ represents the decoder word embedding matrix and elements of W_o matrix are trainable parameters.

Selection/Attention Mechanism: As there are different salient attributes across the different chess moves, we also equip the GAC model with a mechanism to select and identify these attributes. We first transform h_t^{dec} by multiplying it with a trainable matrix W_c, and then take dot product of the result with each g_i.

$$a_t^{(i)} = dot(W_c * h_t^{dec}, g_i^{enc})$$
$$\alpha_t = \text{softmax}(a_t)$$
$$c_t = \sum_{i=1}^{i=|g|} \alpha_t^{(i)} g_i^{enc}$$

We use cross-entropy loss over the decoding outputs to train the model.

4 Experiments

We split each of the data subsets in a 70:10:20 ratio into train, validation and test. All our models are implemented in Pytorch version 0.3.1 (Paszke et al., 2017). We use the ADAM optimizer (Kingma and Ba, 2014) with its default parameters and a mini-batch size of 32. Validation set perplexity is used for early-stopping. At test-time, we use greedy search to generate the model output. We observed that beam decoding does not lead to any significant improvement in terms of validation BLEU score.

We observe the BLEU (Papineni et al., 2002) and BLEU-2 (Vedantam et al., 2015) scores to measure the performance of the models. Additionally, we consider a measure to quantify the diversity in the generated outputs. Finally, we also conduct a human evaluation study. In the remainder of this section, we discuss baselines along with various experiments and results.

4.1 Baselines

In this subsection we discuss the various baseline methods.

Manually-defined template (TEMP) We devise manually defined templates (Reiter, 1995) for 'Move Description' and 'Move Quality' categories. Note that template-based outputs tend to be repetitive as they lack diversity - drawing from a small, fixed vocabulary and using a largely static sentence structure. We define templates for a fixed set of cases which cover our data (For exact template specifications, refer to Appendix B).

Nearest Neighbor (NN): We observe that the same move on similar board states often leads to similar commentary texts. To construct a simple baseline, we find the most similar move N_{MCR} from among training data points for a given previous (R) and current (C) board states and move M. The commentary text corresponding to N_{MCR} is selected as the output. Thus, we need to consider a scoring function to find the closest matching data point in training set. We use the *Move*, *Threat* and *Score* features to compute similarity to do so. By using a sparse representation, we consider total of 148 *Move* features, 18 *Threat* features, and 19 *Score* features. We use sklearn's (Pedregosa et al., 2011b) NearestNeighbor module to find the closest matching game move.

Raw Board Information Only (RAW): The RAW baseline ablates to assess the importance of our pragmatic feature functions. This architecture is similar to GAC, except that instead of our custom features $A(f(R_i, C_i))$, the encoder encodes raw board information of current and previous board states.

$A_{RAW}(R_i, C_i) = [Lin(R_i), Lin(C_i)]$

$Lin()$ for a board denotes it's representation in a row-linear fashion. Each element of $Lin()$ is a piece name (e.g *pawn*) denoting the piece at that square with special symbols for empty squares.

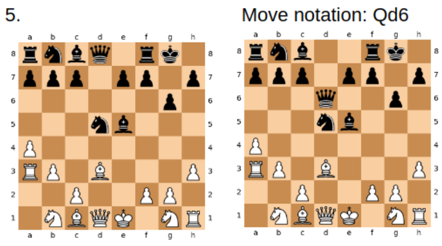
4.2 Comment Category Models

As shown earlier, we categorize comments into six different categories. Among these, in this paper we consider only the first three as the amount of variance in the last three categories indicates that it would be extremely difficult for a model to learn to reproduce them accurately. The number of data points, as tagged by the trained classifiers, in the subsets 'Move Description', 'Move Quality' and 'Comparative' are 28,228, 793 and 5397 respectively. We consider separate commentary generation models for each of the three categories. Each model is tuned separately on the corresponding validation sets. Table 3 shows the BLEU and BLEU-2 scores for the proposed model under different subsets of features. Overall BLEU scores are low, likely due to the inherent variance in the language generation task (Novikova et al., 2017) , although a precursory examination of the outputs for data points selected randomly from test set indicated that they were reasonable. Figure 5 illustrates commentaries generated by our models through an example (a larger list of qualitative examples can be found in Appendix C).

Dataset	Features	BLEU	BLEU-2	Diversity
MoveDesc	TEMP	0.72	20.77	4.43
	NN (M+T+S)	1.28	21.07	**7.85**
	RAW	1.13	13.74	2.37
	GAC-sparse	1.76	21.49	4.29
	GAC (M+T)	**1.85**	**23.35**	**4.72**
Quality	TEMP	16.17	47.29	1.16
	NN (M+T)	5.98	42.97	4.52
	RAW	16.92	47.72	1.07
	GAC-sparse	14.98	51.46	2.63
	GAC(M+T+S)	16.94	47.65	1.01
Comparative	NN (M)	1.28	24.49	6.97
	RAW	2.80	23.26	3.03
	GAC-sparse	**3.58**	25.28	2.18
	GAC(M+T)	3.51	29.48	3.64

Table 3: Performance of baselines and our model with different subsets of features as per various quantitative measures. (**S** = Score, **M**= Move, **T** = Threat features;) On all data subsets, our model outperforms the **TEMP** and **NN** baselines. Among proposed models, GAC performs better than GAC-sparse & RAW in general. For NN, GAC-sparse and GAC methods, we experiment with multiple feature combinations and report only the best as per BLEU scores.

Which features are useful? In general, adding *Threat* features improves the performance, though the same is not always true for *Score* features. *Qual* has higher BLEU scores than the other datasets due to smaller vocabulary and lesser variation in commentary. As can be observed in Table 4, *Threat* features are useful for both 'Move Quality' and 'Move Description' subsets of data. Adding *Score* features helps for 'Move Quality' subset. This intuitively makes sense since *Score*



Temp: Black moves the queen from d8 to d6

NN: Black brings out his queen , which breaks the queen and provides protection the the e-pawn

GAC(M): Black attacks white queen.

GAC(M+T): Black brings out his queen to the attack .

GAC(M+T+S): Black brings his queen out

Ground Truth: Letting the Queen join the attack.

Figure 5: Outputs from various models on a test example from the **MoveDesc** subset.

Dataset	Features	BLEU	BLEU-2	Diversity
MoveDesc	GAC (M)	1.41	19.06	4.32
	GAC (M+T)	**1.85**	**23.35**	**4.72**
	GAC (M+T+S)	1.64	22.82	4.29
Quality	GAC (M)	13.05	48.37	1.61
	GAC (M+T)	14.22	49.57	**1.54**
	GAC(M+T+S)	**14.44**	**51.79**	1.48
Comparative	GAC(M)	3.10	19.84	2.88
	GAC(M+T)	**3.51**	**29.48**	**3.64**
	GAC(M+T+S)	1.15	25.44	3.14

Table 4: Performance of the GAC model with different feature sets. (**S** = Score, **M**= Move, **T** = Threat features;) Different subset of features work best for different subsets. For instance, *Score* features seem to help only in the Quality category. Note that the results for Quality are from 5-fold cross-validation, since the number of datapoints in the category is much lesser than the other two.

features directly encode proxies for move quality as per a chess evaluation engine.

4.3 A Single Model For All Categories

In this experiment, we merge the training and validation data of the first three categories and tune a single model for this merged data. We then compare its performance on all test sentences in our data. **COMB** denotes using the best GAC model for a test example based on its original class (e.g *Desc*) and computing the BLEU of the sentences so generated with the ground truth. **GAC-all** represents the GAC model learnt on the merged training data.

As can be seen from Table 5, this does not lead to any performance improvements. We investigate this issue further by analyzing whether the board states are predictive of the type of category or not. To achieve this, we construct a multi-class classifier using all the *Move*, *Threat* and *Score* features to predict the three categories under consideration. However, we observe accuracy of around 33.4%, which is very close to the performance of a random prediction model. This partially explains why a single model did not fare better even though it had the opportunity to learn from a larger dataset.

Dataset	Features	BLEU	BLEU-2	Diversity
All	COMB (M)	2.07	20.13	4.50
	COMB (M+T)	**2.43**	**25.37**	4.88
	COMB (M+T+S)	1.83	28.86	4.33
All	GAC-all(M)	1.69	20.66	4.67
	GAC-all(M+T)	1.94	24.11	5.16
	GAC-all (M+T+S)	2.02	24.70	4.97
All	CAT (M)	1.90	19.96	3.82

Table 5: The **COMB** approaches show the combined performance of separately trained models on the respective test subsets.

Category-aware model (CAT) We observed above that with the considered features, it is not possible to predict the type of comment to be made, and the GAC-all model results are better than COMB results. Hence, we extend the GAC-all model to explicitly provide with the information about the comment category. We achieve this by adding a one-hot representation of the category of the comment to the input of the RNN decoder at every time step. As can be seen in the Table 5, CAT(M) performs better than GAC-all(M) in terms of BLEU-4, while performing slightly worse on BLEU-2. This demonstrates that explicitly providing information about the comment category can help the model.

4.4 Diversity In Generated Commentaries

Humans use some variety in the choice of words and sentence structure. As such, outputs from rule based templates, which demonstrate low variety, may seem repetitive and boring. To capture this quantitatively, and to demonstrate the variety in texts from our method, we calculate the entropy (Shannon, 1951) of the distribution of unigrams, bigrams and trigrams of words in the predicted outputs, and report the geometric mean of these values. Using only a small set of words in similar counts will lead to lower entropy and is undesirable. As can be observed from Table 3, template baseline performs worse on the said measure compared to our methods for the 'MoveDesc' subset of the data.

4.5 Human Evaluation Study

As discussed in the qualitative examples above, we often found the outputs to be good - though BLEU scores are low. BLEU is known to correlate poorly (Reiter and Belz, 2009; Wiseman et al., 2017; Novikova et al., 2017) with human relevance scores for NLG tasks. Hence, we conduct a human evaluation study for the best 2 neural (GAC,GAC-sparse) and best 2 non-neural methods (TEMP,NN).

Setup: Specifically, annotators are shown a chess move through previous board and resulting board snapshots, along with information on which piece moved (a snapshot of a HIT[7] is provided in the Appendix D). With this context, they were shown text commentary based on this move and were asked to judge the commentary via three questions, shortened versions of which can be seen in the first column of Table 6.

We randomly select 100 data points from the test split of 'Move Description' category and collect the predictions from each of the methods under consideration. We hired two Anglophone (Lifetime HIT acceptance $\% > 80$) annotators for every human-evaluated test example. We additionally assess chess proficiency of the annotators using questions from the chess-QA dataset by (Cirik et al., 2015). Within each HIT, we ask two randomly selected questions from the chess-QA dataset. Finally we consider only those HITs wherein the annotator was able to answer the proficiency questions correctly.

Results: We conducted a human evaluation study for the *MoveDesc* subset of the data. As can be observed from Table 6, outputs from our method attain slightly more favorable scores compared to the ground truth commentaries. This shows that the predicted outputs from our model are not worse than ground truth on the said measures. This is in spite of the fact that the BLEU-4 score for the predicted outputs is only $\sim$ 2 w.r.t. the ground truth outputs. One reason for slightly lower performance of the ground truth outputs on the said measures is that some of the human written commentaries are either very ungrammatical or too concise. A more surprising observation is that around 30% of human written ground truth outputs were also marked as not valid for given board move. On inspection, it seems that commentary often contains extraneous game information beyond that of move alone, which indicates that an ideal comparison should be over commentary for an entire game, although this is beyond the scope of the current work.

The inter-annotator agreement for our experiments (Cohens κ (Cohen, 1968)) is 0.45 for Q1 and 0.32 for Q2. We notice some variation in κ coefficients across different systems. While TEMP and GAC responses had a 0.5-0.7 coefficient range, the responses for CLM had a much lower coefficient. In our setup, each HIT consists of 7 comments, one from each system. For Q3 (fluency), which is on an ordinal scale, we measure rank-order consistency between the responses of the two annotators of a HIT. Mean Kendall τ (Kendall, 1938) across all HITs was found to be 0.39.

To measures significance of results, we perform bootstrap tests on 1000 subsets of size 50 with a significance threshold of $p = 0.05$ for each pair of systems. For Q1, we observe that GAC(M), GAC(M+T) and GAC(M+T+S) methods are significantly better than baselines NN and GAC-sparse. We find that neither of GAC(M+T) and GT significantly outperform each other on Q1 as well as Q2. But we do find that GAC(M+T) does better than GAC(M) on both Q1 and Q2. For fluency scores, we find that GAC(M+T) is more fluent than GT, NN , GAC-sparse, GAC(M). Neither of GAC(M) and GAC(M+T+S) is significantly more fluent than the other.

5 Related Work

NLG research has a long history, with systems ranging from completely rule-based to learning-based ones (Reiter et al., 2005, 2003a), which have had both practical successes (Reiter et al., 2005) and failures (Reiter et al., 2003a). Recently, there have been numerous works which propose text generation given structured records, biographies (Lebret et al., 2016), recipes (Yang et al., 2016; Kiddon et al., 2016), etc. A key difference between generation given a game state compared to these inputs is that the game state is an evolving description at a point in a process, as opposed

[7]Human Intelligence Task

Question	GT	GAC (M)	GAC (MT)	GAC (MTS)	GAC -sparse	TEMP	NN
Is commentary correct for the given move? (%Yes)	70.4	42.3	64.8	67.6	56.3	91.5	52.1
Can the move be inferred from the commentary? (%Yes)	45.1	25.3	42.3	36.7	40.8	92.9	42.3
Fluency (scale of (least)1 - 5(most)) Mean (Std. dev.)	4.03 (1.31)	4.15 (1.20)	4.44 (1.02)	4.54 (0.89)	4.15 (1.26)	4.69 (0.64)	3.72 (1.36)

Table 6: Human study results on *MoveDesc* data category. Outputs from GAC are in general better than ground truth, NN and GAC-sparse. TEMP outperforms other methods, though as shown earlier, outputs from TEMP lack diversity.

to recipes (which are independent of each other), records (which are static) and biographies (which are one per person, and again independent). Moreover, our proposed method effectively uses various types of semantic and pragmatic information about the game state.

In this paper we have introduced a new large-scale data for game commentary generation. The commentaries cover a variety of aspects like move description, quality of move, and alternative moves. This leads to a content selection challenge, similar to that noted in Wiseman et al. (2017). Unlike Wiseman et al. (2017), our focus is on generating commentary for individual moves in a game, as opposed to game summaries from aggregate statistics as in their task.

One of the first NLG datasets was the SUMTIME-METEO (Reiter et al., 2005) corpus with ≈ 500 record-text pairs for technical weather forecast generation. Liang et al (2009) worked on common weather forecast generation using the WEATHERGOV dataset, which has $\approx$ 10K record-text pairs. A criticism of WEATHERGOV dataset (Reiter, 2017) is that weather records themselves may have used templates and rules with optional human post-editing. There have been prior works on generating commentary for ROBOCUP matches (Chen and Mooney, 2008; Mei et al., 2015). The ROBOCUP dataset, however, is collected from 4 games and contains about 1K events in total. Our dataset is two orders of magnitude larger than the ROBOCUP dataset, and we hope that it provides a promising setting for future NLG research.

6 Conclusions

In this paper, we curate a dataset for the task of chess commentary generation and propose methods to perform generation on this dataset. Our proposed method effectively utilizes information related to the rules and pragmatics of the game. A human evaluation study judges outputs from the proposed methods to be as good as human written commentary texts for 'Move Description' subset of the data.

Our dataset also contains multi-move-single commentary pairs in addition to single move-single commentary pairs. Generating commentary for such multi-moves is a potential direction for future work. We anticipate this task to require even deeper understanding of the game pragmatics than the single move-single commentary case.

Recent work (Silver et al., 2016) has proposed reinforcement learning based game-playing agents which learn to play board games from scratch, learning end-to-end from both recorded games and self-play. An interesting point to explore is whether such pragmatically trained game state representations can be leveraged for the task of game commentary generation.

From Credit Assignment to Entropy Regularization: Two New Algorithms for Neural Sequence Prediction

Abstract

In this work, we study the credit assignment problem in reward augmented maximum likelihood (RAML) learning, and establish a theoretical equivalence between the token-level counterpart of RAML and the entropy regularized reinforcement learning. Inspired by the connection, we propose two sequence prediction algorithms, one extending RAML with fine-grained credit assignment and the other improving Actor-Critic with a systematic entropy regularization. On two benchmark datasets, we show the proposed algorithms outperform RAML and Actor-Critic respectively, providing new alternatives to sequence prediction.

1 Introduction

Modeling and predicting discrete sequences is the central problem to many natural language processing tasks. In the last few years, the adaption of recurrent neural networks (RNNs) and the sequence-to-sequence model (seq2seq) (Sutskever et al., 2014; Bahdanau et al., 2014) has led to a wide range of successes in conditional sequence prediction, including machine translation (Sutskever et al., 2014; Bahdanau et al., 2014), automatic summarization (Rush et al., 2015), image captioning (Karpathy and Fei-Fei, 2015; Vinyals et al., 2015; Xu et al., 2015) and speech recognition (Chan et al., 2016).

Despite the distinct evaluation metrics for the aforementioned tasks, the standard training algorithm has been the same for all of them. Specifically, the algorithm is based on maximum likelihood estimation (MLE), which maximizes the log-likelihood of the "ground-truth" sequences empirically observed.[1]

While largely effective, the MLE algorithm has two obvious weaknesses. Firstly, the MLE training ignores the information of the task specific metric. As a result, the potentially large discrepancy between the log-likelihood during training and the task evaluation metric at test time can lead to a suboptimal solution. Secondly, MLE can suffer from the exposure bias, which refers to the phenomenon that the model is never exposed to its own failures during training, and thus cannot recover from an error at test time. Fundamentally, this issue roots from the difficulty in statistically modeling the exponentially large space of sequences, where most combinations cannot be covered by the observed data.

To tackle these two weaknesses, there have been various efforts recently, which we summarize into two broad categories:

- A widely explored idea is to directly optimize the task metric for sequences produced by the model, with the specific approaches ranging from minimum risk training (MRT) (Shen et al., 2015) and learning as search optimization (LaSO) (Daumé III and Marcu, 2005; Wiseman and Rush, 2016) to reinforcement learning (RL) (Ranzato et al., 2015; Bahdanau et al., 2016). In spite of the technical differences, the key component to make these training algorithms *practically efficient* is often a delicate credit assignment scheme, which transforms the sequence-level signal into dedicated smaller units (e.g., token-level or chunk-level), and allocates them to specific decisions, allowing for efficient optimization with a much lower variance. For instance, the beam search optimiza-

[*] Equal contribution.

[1] In this work, we use the terms "ground-truth" and "reference" to refer to the empirical observations interchangeably.

tion (BSO) (Wiseman and Rush, 2016) utilizes the position of margin violations to produce signals to the specific chunks, while the actor-critic (AC) algorithm (Bahdanau et al., 2016) trains a critic to enable token-level signals.

- Another alternative idea is to construct a task metric dependent target distribution, and train the model to match this task-specific target instead of the empirical data distribution. As a typical example, the reward augmented maximum likelihood (RAML) (Norouzi et al., 2016) defines the target distribution as the exponentiated pay-off (sequence-level reward) distribution. This way, RAML not only can incorporate the task metric information into training, but it can also alleviate the exposure bias by exposing imperfect outputs to the model. However, RAML only works on the sequence-level training signal.

In this work, we are intrigued by the question whether it is possible to incorporate the idea of fine-grained credit assignment into RAML. More specifically, inspired by the token-level signal used in AC, we aim to find the token-level counterpart of the sequence-level RAML, i.e., defining a token-level target distribution for each auto-regressive conditional factor to match. Motived by the question, we first formally define the desiderata the token-level counterpart needs to satisfy and derive the corresponding solution (§2). Then, we establish a theoretical connection between the derived token-level RAML and entropy regularized RL (§3). Motivated by this connection, we propose two algorithms for neural sequence prediction, where one is the token-level extension to RAML, and the other a RAML-inspired improvement to the AC (§4). We empirically evaluate the two proposed algorithms, and show different levels of improvement over the corresponding baseline. We further study the importance of various techniques used in our experiments, providing practical suggestions to readers (§6).

2 Token-level Equivalence of RAML

We first introduce the notations used throughout the paper. Firstly, capital letters will denote random variables and lower-case letters are the values to take. As we mainly focus on conditional sequence prediction, we use $\mathbf{x}$ for the conditional input, and $\mathbf{y}$ for the target sequence. With $\mathbf{y}$ denoting a sequence, $\mathbf{y}_i^j$ then denotes the subsequence from position i to j inclusively, while y_t denotes the single value at position t. Also, we use $|\mathbf{y}|$ to indicate the length of the sequence. To emphasize the ground-truth data used for training, we add superscript * to the input and target, i.e., $\mathbf{x}^*$ and $\mathbf{y}^*$. In addition, we use $\mathcal{Y}$ to denote the set of all possible sequences with one and only one $\texttt{eos}$ symbol at the end, and $\mathcal{W}$ to denote the set of all possible symbols in a position. Finally, we assume length of sequences in $\mathcal{Y}$ is bounded by T.

2.1 Background: RAML

As discussed in §1, given a ground-truth pair $(\mathbf{x}^*, \mathbf{y}^*)$, RAML defines the target distribution using the exponentiated pay-off of sequences, i.e.,

$$P_R(\mathbf{y} \mid \mathbf{x}^*, \mathbf{y}^*) = \frac{\exp\left(R(\mathbf{y}; \mathbf{y}^*)/\tau\right)}{\sum_{\mathbf{y}' \in \mathcal{Y}} \exp\left(R(\mathbf{y}'; \mathbf{y}^*)/\tau\right)}, \quad (1)$$

where $R(\mathbf{y}; \mathbf{y}^*)$ is the sequence-level reward, such as BLEU score, and τ is the temperature hyper-parameter controlling the sharpness. With the definition, the RAML algorithm simply minimizes the cross entropy (CE) between the target distribution and the model distribution $P_\theta(\mathbf{Y} \mid \mathbf{x}^*)$, i.e.,

$$\min_\theta \mathrm{CE}\left(P_R(\mathbf{Y} \mid \mathbf{x}^*, \mathbf{y}^*) \| P_\theta(\mathbf{Y} \mid \mathbf{x}^*)\right). \quad (2)$$

Note that, this is quite similar to the MLE training, except that the target distribution is different. With the particular choice of target distribution, RAML not only makes sure the ground-truth reference remains the mode, but also allows the model to explore sequences that are not exactly the same as the reference but have relatively high rewards.

Compared to algorithms trying to directly optimize task metric, RAML avoids the difficulty of tracking and sampling from the model distribution that is consistently changing. Hence, RAML enjoys a much more stable optimization without the need of pretraining. However, in order to optimize the RAML objective (Eqn. (2)), one needs to sample from the exponentiated pay-off distribution, which is quite challenging in practice. Thus, importance sampling is often used (Norouzi et al., 2016; Ma et al., 2017). We leave the details of the practical implementation to Appendix B.1.

2.2 Token-level Target Distribution

Despite the appealing properties, RAML only operates on the sequence-level reward. As a result, the reward gap between any two sequences cannot be attributed to the responsible decisions precisely, which often leads to a low sample efficiency. Ideally, since we rely on the auto-regressive factorization $P_\theta(\mathbf{y} \mid \mathbf{x}^*) = \prod_{t=1}^{|\mathbf{y}|} P_\theta(y_t \mid \mathbf{y}_1^{t-1}, \mathbf{x}^*)$, the optimization would be much more efficient if we have the target distribution for each token-level factor $P_\theta(Y_t \mid \mathbf{y}_1^{t-1}, \mathbf{x}^*)$ to match. Conceptually, this is exactly how the AC algorithm improves upon the vanilla sequence-level REINFORCE algorithm (Ranzato et al., 2015).

With this idea in mind, we set out to find such a token-level target. Firstly, we assume the token-level target shares the form of a Boltzmann distribution but parameterized by some unknown negative energy function Q_R, i.e.,[2]

$$P_{Q_R}(y_t \mid \mathbf{y}_1^{t-1}, \mathbf{y}^*) = \frac{\exp\left(Q_R(\mathbf{y}_1^{t-1}, y_t; \mathbf{y}^*)/\tau\right)}{\sum_{w \in \mathcal{W}} \exp\left(Q_R(\mathbf{y}_1^{t-1}, w; \mathbf{y}^*)/\tau\right)}. \tag{3}$$

Intuitively, $Q_R(\mathbf{y}_1^{t-1}, w; \mathbf{y}^*)$ measures how much *future* pay-off one can expect if w is generated, given the current status $\mathbf{y}_1^{t-1}$ and the reference $\mathbf{y}^*$. This quantity highly resembles the action-value function (Q-function) in reinforcement learning. As we will show later, it is indeed the case.

Before we state the desiderata for Q_R, we need to extend the definition of R in order to evaluate the goodness of an unfinished partial prediction, i.e., sequences without an $\texttt{eos}$ suffix. Let $\mathcal{Y}^-$ be the set of unfinished sequences, following Bahdanau et al. (2016), we define the pay-off function R for a partial sequence $\hat{\mathbf{y}} \in \mathcal{Y}^-, |\hat{\mathbf{y}}| < T$ as

$$R(\hat{\mathbf{y}}; \mathbf{y}^*) = R(\hat{\mathbf{y}} + \texttt{eos}; \mathbf{y}^*), \tag{4}$$

where the $+$ indicates string concatenation.

With the extension, we are ready to state two requirements for Q_R:

1. **Marginal match**: For P_{Q_R} to be the token-level equivalence of P_R, the sequence-level marginal distribution induced by P_{Q_R} must match P_R, i.e., for any $\mathbf{y} \in \mathcal{Y}$,

$$\prod_{t=1}^{|\mathbf{y}|} P_{Q_R}(y_t \mid \mathbf{y}_1^{t-1}) = P_R(\mathbf{y}). \tag{5}$$

   Note that there are infinitely many Q_R's satisfying Eqn. (5), because adding any constant value to Q_R does not change the Boltzmann distribution, known as shift-invariance w.r.t. the energy.

2. **Terminal condition**: Secondly, let's consider the value of Q_R when emitting an $\texttt{eos}$ symbol to immediately terminate the generation. As mentioned earlier, Q_R measures the expected future pay-off. Since the emission of $\texttt{eos}$ ends the generation, the future pay-off can only come from the immediate increase of the pay-off. Thus, we require Q_R to be the incremental pay-off when producing $\texttt{eos}$, i.e.

$$Q_R(\hat{\mathbf{y}}, \texttt{eos}; \mathbf{y}^*) = R(\hat{\mathbf{y}} + \texttt{eos}; \mathbf{y}^*) - R(\hat{\mathbf{y}}; \mathbf{y}^*), \tag{6}$$

   for any $\hat{\mathbf{y}} \in \mathcal{Y}^-$. Since Eqn. (6) enforces the absolute of Q_R at a point, it also solves the ambiguity caused by the shift-invariance property.

Based on the two requirements, we can derive the form Q_R, which is summarized by Proposition 1.

Proposition 1. *P_{Q_R} and Q_R satisfy requirements (5) and (6) if and only if for any ground-truth pair $(\mathbf{x}^*, \mathbf{y}^*)$ and any sequence prediction $\mathbf{y} \in \mathcal{Y}$,*

$$\begin{aligned} Q_R(\mathbf{y}_1^{t-1}, y_t; \mathbf{y}^*) &= R(\mathbf{y}_1^t; \mathbf{y}^*) - R(\mathbf{y}_1^{t-1}; \mathbf{y}^*) \\ &\quad + \tau \log \sum_{w \in \mathcal{W}} \exp\left(Q_R(\mathbf{y}_1^t, w; \mathbf{y}^*)/\tau\right), \end{aligned} \tag{7}$$

when $t < |\mathbf{y}|$, and otherwise, i.e., when $t = |\mathbf{y}|$

$$Q_R(\mathbf{y}_1^{t-1}, y_t; \mathbf{y}^*) = R(\mathbf{y}_1^t; \mathbf{y}^*) - R(\mathbf{y}_1^{t-1}; \mathbf{y}^*). \tag{8}$$

Proof. See Appendix A.1. □

Note that, instead of giving an explicit form for the token-level target distribution, Proposition 1 only provides an equivalent condition in the form of an implicit recursion. Thus, we haven't obtained a practical algorithm yet. However, as we will discuss next, the recursion has a deep connection to entropy regularized RL, which ultimately inspires our proposed algorithms.

3 Connection to Entropy-regularized RL

Before we dive into the connection, we first give a brief review of the entropy-regularized RL. For an in-depth treatment, we refer readers to (Ziebart, 2010; Schulman et al., 2017).

3.1 Background: Entropy-regularized RL

Following the standard convention of RL, we denote a Markov decision process (MDP) by a tuple $\mathcal{M} = (\mathcal{S}, \mathcal{A}, p_s, r, \gamma)$, where $\mathcal{S}, \mathcal{A}, p_s, r, \gamma$ are the state space, action space, transition probability, reward function and discounting factor respectively.[3]

[2] To avoid clutter, the conditioning on $\mathbf{x}^*$ will be omitted in the sequel, assuming it's clear from the context.

[3] In sequence prediction, we are only interested in the periodic (finite horizon) case.

Based on the notation, the goal of entropy-regularized RL augments is to learn a policy $\pi(a_t \mid s_t)$ which maximizes the discounted expected future return and causal entropy (Ziebart, 2010), i.e.,

$$\max_{\pi} \sum_t \mathop{\mathbb{E}}_{s_t \sim \rho_s, a_t \sim \pi(\cdot \mid s_t)} \gamma^{t-1}[r(s_t, a_t) + \alpha \mathcal{H}(\pi(\cdot \mid s_t))],$$

where $\mathcal{H}$ denotes the entropy and α is a hyper-parameter controlling the relative importance between the reward and the entropy. Intuitively, compared to standard RL, the extra entropy term encourages exploration and promotes multi-modal behaviors. Such properties are highly favorable in a complex environment.

Given an entropy-regularized MDP, for any fixed policy π, the state-value function $V^\pi(s)$ and the action-value function Q^π can be defined as

$$\begin{aligned} V^\pi(s) &= \mathop{\mathbb{E}}_{a \sim \pi(\cdot \mid s)} [Q^\pi(s,a)] + \alpha \mathcal{H}(\pi(\cdot \mid s)), \\ Q^\pi(s,a) &= r(s,a) + \mathop{\mathbb{E}}_{s' \sim \rho_s} [\gamma V^\pi(s')]. \end{aligned} \tag{9}$$

With the definitions above, it can further be proved (Ziebart, 2010; Schulman et al., 2017) that the optimal state-value function V^*, the action-value function Q^* and the corresponding optimal policy π^* satisfy the following equations

$$V^*(s) = \alpha \log \sum_{a \in \mathcal{A}} \exp\left(Q^*(s,a)/\alpha\right), \tag{10}$$

$$Q^*(s,a) = r(s,a) + \gamma \mathop{\mathbb{E}}_{s' \sim \rho_s} [V^*(s')], \tag{11}$$

$$\pi^*(a \mid s) = \frac{\exp\left(Q^*(s,a)/\alpha\right)}{\sum_{a' \in \mathcal{A}} \exp\left(Q^*(s,a')/\alpha\right)}. \tag{12}$$

Here, Eqn. (10) and (11) are essentially the entropy-regularized counterparts of the optimal Bellman equations in standard RL. Following previous literature, we will refer to Eqn. (10) and (11) as the optimal *soft* Bellman equations, and the V^* and Q^* as optimal *soft* value functions.

3.2 An RL Equivalence of the Token-level RAML

To reveal the connection, it is convenient to define the incremental pay-off

$$r(\mathbf{y}_1^{t-1}, y_t; \mathbf{y}^*) = R(\mathbf{y}_1^t; \mathbf{y}^*) - R(\mathbf{y}_1^{t-1}; \mathbf{y}^*), \tag{13}$$

and the last term of Eqn. (7) as

$$V_R(\mathbf{y}_1^t; \mathbf{y}^*) = \tau \log \sum_{w \in \mathcal{W}} \exp\left(Q_R(\mathbf{y}_1^t, w; \mathbf{y}^*)/\tau\right) \tag{14}$$

Substituting the two definitions into Eqn. (7), the recursion simplifies as

$$Q_R(\mathbf{y}_1^{t-1}, y_t; \mathbf{y}^*) = r(\mathbf{y}_1^{t-1}, y_t; \mathbf{y}^*) + V_R(\mathbf{y}_1^t; \mathbf{y}^*). \tag{15}$$

Now, it is easy to see that the Eqn. (14) and (15), which are derived from the token-level RAML, highly resemble the optimal soft Bellman equations (10) and (11) in entropy-regularized RL. The following Corollary formalizes the connection.

Corollary 1. *For any ground-truth pair $(\mathbf{x}^*, \mathbf{y}^*)$, the recursion specified by Eqn. (13), (14) and (15) is equivalent to the optimal soft Bellman equation of a "deterministic" MDP in entropy-regularized reinforcement learning, denoted as $\mathcal{M}_R$, where*

- *the state space $\mathcal{S}$ corresponds to $\mathcal{Y}^-$,*
- *the action space $\mathcal{A}$ corresponds to $\mathcal{W}$,*
- *the transition probability ρ_s is a deterministic process defined by string concatenation*
- *the reward function r corresponds to the incremental pay-off defined in Eqn. (13),*
- *the discounting factor $\gamma = 1$,*
- *the entropy hyper-parameter $\alpha = \tau$,*
- *and a period terminates either when* eos *is emitted or when its length reaches T and we enforce the generation of* eos.

Moreover, the optimal soft value functions V^* and Q^* of the MDP exactly match the V_R and Q_R defined by Eqn. (14) and (15) respectively. The optimal policy π^* is hence equivalent to the token-level target distribution P_{Q_R}.

Proof. See Appendix A.1. □

The connection established by Corollary 1 is quite inspiring:

- Firstly, it provides a rigorous and generalized view of the connection between RAML and entropy-regularized RL. In the original work, Norouzi et al. (2016) point out RAML can be seen as reversing the direction of KL $(P_\theta \| P_R)$, which is a sequence-level view of the connection. Now, with the equivalence between the token-level target P_{Q_R} and the optimal Q^*, it generalizes to matching the future action values consisting of both the reward and the entropy.
- Secondly, due to the equivalence, if we solve the optimal soft Q-function of the corresponding MDP, we directly obtain the token-level target distribution. This hints at a practical algorithm with token-level credit assignment.

- Moreover, since RAML is able to improve upon MLE by injecting entropy, the entropy-regularized RL counterpart of the standard AC algorithm should also lead to an improvement in a similar manner.

4 Proposed Algorithms

In this section, we explore the insights gained from Corollary 1 and present two new algorithms for sequence prediction.

4.1 Value Augmented Maximum Likelihood

The first algorithm we consider is the token-level extension of RAML, which we have been discussing since §2. As mentioned at the end of §2.2, Proposition 1 only gives an implicit form of Q_R, and so is the token-level target distribution P_{Q_R} (Eqn. (3)). However, thanks to Corollary 1, we now know that Q_R is the same as the optimal soft action-value function Q^* of the entropy-regularized MDP $\mathcal{M}_R$. Hence, by finding the Q^*, we will have access to P_{Q_R}.

At the first sight, it seems recovering Q^* is as difficult as solving the original sequence prediction problem, because solving Q^* from the MDP is essentially the same as learning the optimal policy for sequence prediction. However, it is not true because Q_R (i.e., P_{Q_R}) can condition on the correct reference $\mathbf{y}^*$. In contrast, the model distribution P_θ can only depend on $\mathbf{x}^*$. Therefore, the function approximator trained to recover Q^* can take $\mathbf{y}^*$ as input, making the estimation task much easier. Intuitively, when recovering Q^*, we are trying to train an ideal "oracle", which has access to the ground-truth reference output, to decide the best behavior (policy) given any arbitrary (good or not) state.

Thus, following the reasoning above, we first train a parametric function approximator Q_ϕ to search the optimal soft action value. In this work, for simplicity, we employ the Soft Q-learning algorithm (Schulman et al., 2017) to perform the policy *optimization*. In a nutshell, Soft Q-Learning is the entropy-regularized version of Q-Learning, an off-policy algorithm which minimizes the mean squared soft Bellman residual according to Eqn. (11). Specifically, given ground-truth pair $(\mathbf{x}^*, \mathbf{y}^*)$, for any trajectory $\mathbf{y} \in \mathcal{Y}$, the training objective is

$$\min_\phi \sum_{t=1}^{|\mathbf{y}|} \left[Q_\phi(\mathbf{y}_1^{t-1}, y_t; \mathbf{y}^*) - \hat{Q}_\phi(\mathbf{y}_1^{t-1}, y_t; \mathbf{y}^*) \right]^2, \quad (16)$$

where $\hat{Q}_\phi(\mathbf{y}_1^{t-1}, y_t; \mathbf{y}^*) = r(\mathbf{y}_1^{t-1}, y_t; \mathbf{y}^*) + V_\phi(\mathbf{y}_1^t; \mathbf{y}^*)$ is the one-step look-ahead target Q-value, and $V_\phi(\mathbf{y}_1^t; \mathbf{y}^*) = \tau \log \sum_{w \in \mathcal{W}} \exp\left(Q_\phi(\mathbf{y}_1^t, w; \mathbf{y}^*)/\tau\right)$ as defined in Eqn. (10). In the recent instantiation of Q-Learning (Mnih et al., 2015), to stabilize training, the target Q-value is often estimated by a separate slowly updated target network. In our case, as we have access to a significant amount of reference sequences, we find the target network not necessary. Thus, we directly optimize Eqn. (16) using gradient descent, and let the gradient flow through both $Q_\phi(\mathbf{y}_1^{t-1}, y_t; \mathbf{y}^*)$ and $V_\phi(\mathbf{y}_1^t; \mathbf{y}^*)$ (Baird, 1995).

After the training of Q_ϕ converges, we fix the parameters of Q_ϕ, and optimize the cross entropy CE $\left(P_{Q_\phi} \| P_\theta\right)$ w.r.t. the model parameters θ, which is equivalent to[4]

$$\min_\theta \mathop{\mathbb{E}}_{\mathbf{y} \sim P_{Q_\phi}} \left[\sum_{t=1}^{|\mathbf{y}|} \mathrm{CE}\left(P_{Q_\phi}(Y_t \mid \mathbf{y}_1^{t-1}) \| P_\theta(Y_t \mid \mathbf{y}_1^{t-1})\right) \right]. \quad (17)$$

Compared to the of objective of RAML in Eqn. (2), having access to $P_{Q_\phi}(Y_t \mid \mathbf{y}_1^{t-1})$ allows us to provide a distinct token-level target for each conditional factor $P_\theta(Y_t \mid \mathbf{y}_1^{t-1})$ of the model. While directly sampling from P_R is practically infeasible (§2.1), having a parametric target distribution P_{Q_ϕ} makes it theoretically possible to sample from P_{Q_ϕ} and perform the optimization. However, empirically, we find the samples from P_{Q_ϕ} are not diverse enough (§6). Hence, we fall back to the same importance sampling approach (see Appendix B.2) as used in RAML.

Finally, since the algorithm utilizes the optimal soft action-value function to construct the token-level target, we will refer to it as value augmented maximum likelihood (VAML) in the sequel.

4.2 Entropy-regularized Actor Critic

The second algorithm follows the discussion at the end of §3.2, which is essentially an actor-critic algorithm based on the entropy-regularized MDP in Corollary 1. For this reason, we name the algorithm entropy-regularized actor critic (ERAC). As with standard AC algorithm, the training process interleaves the evaluation of current policy using the parametric critic Q_ϕ and the optimization of the actor policy π_θ given the current critic.

Critic Training. The critic is trained to perform policy *evaluation* using the temporal difference

[4]See Appendix A.2 for a detailed derivation.

learning (TD), which minimizes the TD error

$$\min_{\phi} \mathbb{E}_{\mathbf{y} \sim \pi_\theta} \sum_{t=1}^{|\mathbf{y}|} \left[Q_\phi(\mathbf{y}_1^{t-1}, y_t; \mathbf{y}^*) - \hat{Q}_{\bar{\phi}}(\mathbf{y}_1^{t-1}, y_t; \mathbf{y}^*) \right]^2 \tag{18}$$

where the TD target $\hat{Q}_{\bar{\phi}}$ is constructed based on fixed policy iteration in Eqn. (9), i.e.,

$$\begin{aligned} \hat{Q}_{\bar{\phi}}(\mathbf{y}_1^{t-1}, y_t; \mathbf{y}^*) &= r(\mathbf{y}_1^{t-1}, y_t) + \tau \mathcal{H}(\pi_\theta(\cdot \mid \mathbf{y}_1^t)) \\ &+ \sum_{w \in \mathcal{W}} \pi_\theta(w \mid \mathbf{y}_1^t) Q_{\bar{\phi}}(\mathbf{y}_1^t, w; \mathbf{y}^*). \end{aligned} \tag{19}$$

It is worthwhile to emphasize that the objective (18) trains the critic Q_ϕ to evaluate the current policy. Hence, it is entirely different from the objective (16), which is performing policy optimization by Soft Q-Learning. Also, the trajectories $\mathbf{y}$ used in (18) are sequences drawn from the actor policy π_θ, while objective (16) theoretically accepts any trajectory since Soft Q-Learning can be fully off-policy.[5] Finally, following Bahdanau et al. (2016), the TD target $\hat{Q}_{\bar{\phi}}$ in Eqn. (9) is evaluated using a target network, which is indicated by the bar sign above the parameters, i.e., $\bar{\phi}$. The target network is slowly updated by linearly interpolating with the up-to-date network, i.e., the update is $\bar{\phi} \leftarrow \beta\phi + (1-\beta)\bar{\phi}$ for β in $(0, 1)$ (Lillicrap et al., 2015).

We also adapt another technique proposed by Bahdanau et al. (2016), which smooths the critic by minimizing the "variance" of Q-values, i.e.,

$$\min_{\phi} \lambda_{\text{var}} \mathbb{E}_{\mathbf{y} \sim \pi_\theta} \sum_{t=1}^{|\mathbf{y}|} \sum_{w \in \mathcal{W}} \left[Q_\phi(\mathbf{y}_1^t, w; \mathbf{y}^*) - \bar{Q}_\phi(\mathbf{y}_1^t; \mathbf{y}^*) \right]^2$$

where $\bar{Q}_\phi(\mathbf{y}_1^t; \mathbf{y}^*) = \frac{1}{|\mathcal{W}|} \sum_{w' \in \mathcal{W}} Q_\phi(\mathbf{y}_1^t, w'; \mathbf{y}^*)$ is the mean Q-value, and λ_{var} is a hyper-parameter controlling the relative weight between the TD loss and the smooth loss.

Actor Training. Given the critic Q_ϕ, the actor gradient (to maximize the expected return) is given by the policy gradient theorem of the entropy-regularized RL (Schulman et al., 2017), which has the form

$$\begin{aligned} \mathbb{E}_{\mathbf{y} \sim \pi_\theta} \sum_{t=1}^{|\mathbf{y}|} \sum_{w \in \mathcal{W}} & \nabla_\theta \pi_\theta(w \mid \mathbf{y}_1^{t-1}) Q_\phi(\mathbf{y}_1^{t-1}, w; \mathbf{y}^*) \\ &+ \tau \nabla_\theta \mathcal{H}(\pi_\theta(\cdot \mid \mathbf{y}_1^{t-1})). \end{aligned} \tag{20}$$

Here, for each step t, we follow Bahdanau et al. (2016) to sum over the entire symbol set $\mathcal{W}$, instead of using the single sample estimation often seen in RL. Hence, no baseline is employed. It is worth mentioning that Eqn. (20) is *not* simply adding an entropy term to the standard policy gradient as in A3C (Mnih et al., 2016). The difference lies in that the critic Q_ϕ trained by Eqn. (18) additionally captures the *entropy from future steps*, while the $\nabla_\theta \mathcal{H}$ term only captures the entropy of the current step.

Finally, similar to (Bahdanau et al., 2016), we find it necessary to first pretrain the actor using MLE and then pretrain the critic before the actor-critic training. Also, to prevent divergence during actor-critic training, it is helpful to continue performing MLE training along with Eqn. (20), though using a smaller weight λ_{mle}.

5 Related Work

Task Loss Optimization and Exposure Bias Apart from the previously introduced RAML, BSO, Actor-Critic (§1), MIXER (Ranzato et al., 2015) also utilizes chunk-level signals where the length of chunk grows as training proceeds. In contrast, minimum risk training (Shen et al., 2015) directly optimizes sentence-level BLEU. As a result, it requires a large number (100) of samples per data to work well. To solve the exposure bias, scheduled sampling (Bengio et al., 2015) adopts a curriculum learning strategy to bridge the training and the inference. Professor forcing (Lamb et al., 2016) introduces an adversarial training mechanism to encourage the dynamics of the model to be the same at training time and inference time. For image caption, self-critic sequence training (SCST) (Rennie et al., 2016) extends the MIXER algorithm with an improved baseline based on the current model performance.

Entropy-regularized RL Entropy regularization been explored by early work in RL and inverse RL (Williams and Peng, 1991; Ziebart et al., 2008). Lately, Schulman et al. (2017) establish the equivalence between policy gradients and Soft Q-Learning under entropy-regularized RL. Motivated by the multi-modal behavior induced by entropy-regularized RL, Haarnoja et al. (2017) apply energy-based policy and Soft Q-Learning to continuous domain. Later, Nachum et al. (2017) proposes path consistency learning, which can be seen as a multi-step extension to Soft Q-Learning. More recently, in the domain of simulated control, Haarnoja et al. (2018) also consider the actor critic algorithm under the framework of en-

[5]Different from Bahdanau et al. (2016), we don't use a delayed actor network to collect trajectories for critic training.

tropy regularized reinforcement learning. Despite the conceptual similarity to ERAC presented here, Haarnoja et al. (2018) focuses on continuous control and employs the advantage actor critic variant as in (Mnih et al., 2016), while ERAC follows the Q actor critic as in (Bahdanau et al., 2016).

6 Experiments

6.1 Experiment Settings

In this work, we focus on two sequence prediction tasks: machine translation and image captioning. Due to the space limit, we only present the information necessary to compare the empirical results at this moment. For a more detailed description, we refer readers to Appendix B and the code[6].

Machine Translation Following Ranzato et al. (2015), we evaluate on IWSLT 2014 German-to-English dataset (Mauro et al., 2012). The corpus contains approximately $153K$ sentence pairs in the training set. We follow the pre-processing procedure used in (Ranzato et al., 2015).

Architecture wise, we employ a seq2seq model with dot-product attention (Bahdanau et al., 2014; Luong et al., 2015), where the encoder is a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) with each direction being size 128, and the decoder is another LSTM of size 256. Moreover, we consider two variants of the decoder, one using the input feeding technique (Luong et al., 2015) and the other not.

For all algorithms, the sequence-level BLEU score is employed as the pay-off function R, while the corpus-level BLEU score (Papineni et al., 2002) is used for the final evaluation. The sequence-level BLEU score is scaled up by the sentence length so that the scale of the immediate reward at each step is invariant to the length.

Image Captioning For image captioning, we consider the MSCOCO dataset (Lin et al., 2014). We adapt the same preprocessing procedure and the train/dev/test split used by Karpathy and Fei-Fei (2015).

The NIC (Vinyals et al., 2015) is employed as the baseline model, where a feature vector of the image is extracted by a pre-trained CNN and then used to initialize the LSTM decoder. Different from the original NIC model, we employ a pre-trained 101-layer ResNet (He et al., 2016) rather than a GoogLeNet as the CNN encoder.

[6]`https://github.com/zihangdai/ERAC-VAML`

For training, each image-caption pair is treated as an i.i.d. sample, and sequence-level BLEU score is used as the pay-off. For testing, the standard multi-reference BLEU4 is used.

6.2 Comparison with the Direct Baseline

Firstly, we compare ERAC and VAML with their corresponding direct baselines, namely AC (Bahdanau et al., 2016) and RAML (Norouzi et al., 2016) respectively. As a reference, the performance of MLE is also provided.

Due to non-neglected performance variance observed across different runs, we run each algorithm for 9 times with different random seeds,[7] and report the average performance, the standard deviation and the performance range (min, max).

Machine Translation The results on MT are summarized in the left half of Tab. 1. Firstly, all four advanced algorithms significantly outperform the MLE baseline. More importantly, both VAML and ERAC improve upon their direct baselines, RAML and AC, by a clear margin on average. The result suggests the two proposed algorithms both well combine the benefits of a delicate credit assignment scheme and the entropy regularization, achieving improved performance.

Image Captioning The results on image captioning are shown in the right half of Tab. 1. Despite the similar overall trend, the improvement of VAML over RAML is smaller compared to that in MT. Meanwhile, the improvement from AC to ERAC becomes larger in comparison. We suspect this is due to the multi-reference nature of the MSCOCO dataset, where a larger entropy is preferred. As a result, the explicit entropy regularization in ERAC becomes immediately fruitful. On the other hand, with multiple references, it can be more difficult to learn a good oracle Q^* (Eqn. (15)). Hence, the token-level target can be less accurate, resulting in smaller improvement.

6.3 Comparison with Existing Work

To further evaluate the proposed algorithms, we compare ERAC and VAML with the large body of existing algorithms evaluated on IWSTL 2014. As a note of caution, previous works don't employ the exactly same architectures (e.g. number of layers, hidden size, attention type, etc.). Despite that,

[7]For AC, ERAC and VAML, 3 different critics are trained first, and each critic is then used to train 3 actors.

Algorithm	MT (w/o input feeding) Mean	Min	Max	MT (w/ input feeding) Mean	Min	Max	Image Captioning Mean	Min	Max
MLE	27.01 $\pm$ 0.20	26.72	27.27	28.06 $\pm$ 0.15	27.84	28.22	29.54 $\pm$ 0.21	29.27	29.89
RAML	27.74 $\pm$ 0.15	27.47	27.93	28.56 $\pm$ 0.15	28.35	28.80	29.84 $\pm$ 0.21	29.50	30.17

for VAML and ERAC, we use an architecture that is most similar to the majority of previous works, which is the one described in §6.1 with input feeding.

Based on the setting, the comparison is summarized in Table 2.[8] As we can see, both VAML and ERAC outperform previous methods, with ERAC leading the comparison with a significant margin. This further verifies the effectiveness of the two proposed algorithms.

6.4 Ablation Study

Due to the overall excellence of ERAC, we study the importance of various components of it, hopefully offering a practical guide for readers. As the input feeding technique largely slows down the training, we conduct the ablation based on the model variant *without* input feeding.

Firstly, we study the importance of two techniques aimed for training stability, namely the target network and the smoothing technique (§4.2). Based on the MT task, we vary the update speed β of the target critic, and the λ_{var}, which controls the

[8]For a more detailed comparison of performance together with the model architectures, see Table 7 in Appendix C.

λ_{var} \ β	0.001	0.01	0.1	1
0	27.91	26.27†	28.88	27.38†
0.001	**29.41**	29.26	29.32	27.44

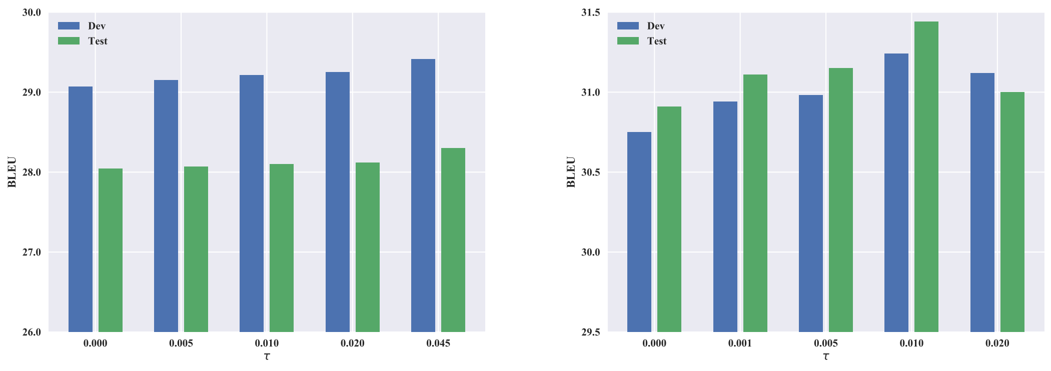
Table 3: Average validation BLEU of ERAC. As a reference, the average BLEU is 28.1 for MLE. $\lambda_{\text{var}} = 0$ means not using the smoothing technique. $\beta = 1$ means not using a target network. † indicates excluding extreme values due to divergence.

strength of the smoothness regularization. The average *validation* performances of different hyper-parameter values are summarized in Tab. 3.

- Comparing the two rows of Tab. 3, the smoothing technique consistently leads to performance improvement across all values of τ. In fact, removing the smoothing objective often causes the training to diverge, especially when $\beta = 0.01$ and 1. But interestingly, we find the divergence does not happen if we update the target network a little bit faster ($\beta = 0.1$) or quite slowly ($\beta = 0.001$).

- In addition, even with the smoothing technique, the target network is still necessary. When the target network is not used ($\beta = 1$), the performance drops below the MLE baseline. However, as long as a target network is employed to ensure the training stability, the specific choice of target network update rate does not matter as much. Empirically, it seems using a slower ($\beta = 0.001$) update rate yields the best result.

Next, we investigate the effect of enforcing different levels of entropy by varying the entropy hyper-parameter τ. As shown in Fig. 1, it seems there is always a sweet spot for the level of entropy. On the one hand, posing an over strong en-



(a) Machine translation

(b) Image captioning

Figure 1: ERAC's average performance over multiple runs on two tasks when varying τ.

tropy regularization can easily cause the actor to diverge. Specifically, the model diverges when τ reaches 0.03 on the image captioning task or 0.06 on the machine translation task. On the other hand, as we decrease τ from the best value to 0, the performance monotonically decreases as well. This observation further verifies the effectiveness of entropy regularization in ERAC, which well matches our theoretical analysis.

Finally, as discussed in §4.2, ERAC takes the effect of future entropy into consideration, and thus is different from simply adding an entropy term to the standard policy gradient as in A3C (Mnih et al., 2016). To verify the importance of explicitly modeling the entropy from future steps, we compared ERAC with the variant that only applies the entropy regularization to the actor but not to the critic. In other words, the τ is set to 0 when performing policy evaluating according to Eqn. (4.2), while the τ for the entropy gradient in Eqn. (20) remains. The comparison result based on 9 runs on test set of IWSTL 2014 is shown in Table 4. As we can see, simply adding a local entropy gradient does not even improve upon the AC. This further verifies the difference between ERAC and A3C, and shows the importance of taking future entropy into consideration.

Algorithm	**Mean**	**Max**
ERAC	**28.30 ± 0.06**	**28.42**
ERAC w/o Future Ent.	28.06 ± 0.05	28.11
AC	28.04 ± 0.05	28.10

Table 4: Comparing ERAC with the variant without considering future entropy.

7 Discussion

In this work, motivated by the intriguing connection between the token-level RAML and the entropy-regularized RL, we propose two algorithms for neural sequence prediction. Despite the distinct training procedures, both algorithms combine the idea of fine-grained credit assignment and the entropy regularization, leading to positive empirical results.

However, many problems remain widely open. In particular, the oracle Q-function Q_ϕ we obtain is far from perfect. We believe the ground-truth reference contains sufficient information for such an oracle, and the current bottleneck lies in the RL algorithm. Given the numerous potential applications of such an oracle, we believe improving its accuracy will be a promising future direction.

Abstract

We propose DuoRC, a novel dataset for Reading Comprehension (RC) that motivates several new challenges for neural approaches in language understanding beyond those offered by existing RC datasets. DuoRC contains 186,089 unique question-answer pairs created from a collection of 7680 pairs of movie plots where each pair in the collection reflects two versions of the same movie - one from Wikipedia and the other from IMDb - written by two different authors. We asked crowdsourced workers to create questions from one version of the plot and a different set of workers to extract or synthesize answers from the other version. This unique characteristic of DuoRC where questions and answers are created from different versions of a document narrating the same underlying story, ensures by design, that there is very little lexical overlap between the questions created from one version and the segments containing the answer in the other version. Further, since the two versions have different levels of plot detail, narration style, vocabulary, *etc*., answering questions from the second version requires deeper language understanding and incorporating external background knowledge. Additionally, the narrative style of passages arising from movie plots (as opposed to typical descriptive passages in existing datasets) exhibits the need to perform complex reasoning over events across multiple sentences. Indeed, we observe that state-of-the-art neural RC models which have achieved near human performance on the SQuAD dataset (Rajpurkar et al., 2016b), even when coupled with traditional NLP techniques to address the challenges presented in DuoRC exhibit very poor performance (F1 score of 37.42% on DuoRC v/s 86% on SQuAD dataset). This opens up several interesting research avenues wherein DuoRC could complement other RC datasets to explore novel neural approaches for studying language understanding.

1 Introduction

Natural Language Understanding is widely accepted to be one of the key capabilities required for AI systems. Scientific progress on this endeavor is measured through multiple tasks such as machine translation, reading comprehension, question-answering, and others, each of which requires the machine to demonstrate the ability to "comprehend" the given textual input (apart from other aspects) and achieve their task-specific goals. In particular, Reading Comprehension (RC) systems are required to "understand" a given text passage as input and then answer questions based on it. *It is therefore critical, that the dataset benchmarks established for the RC task keep progressing in complexity to reflect the challenges that arise in true language understanding, thereby enabling the development of models and techniques to solve these challenges.*

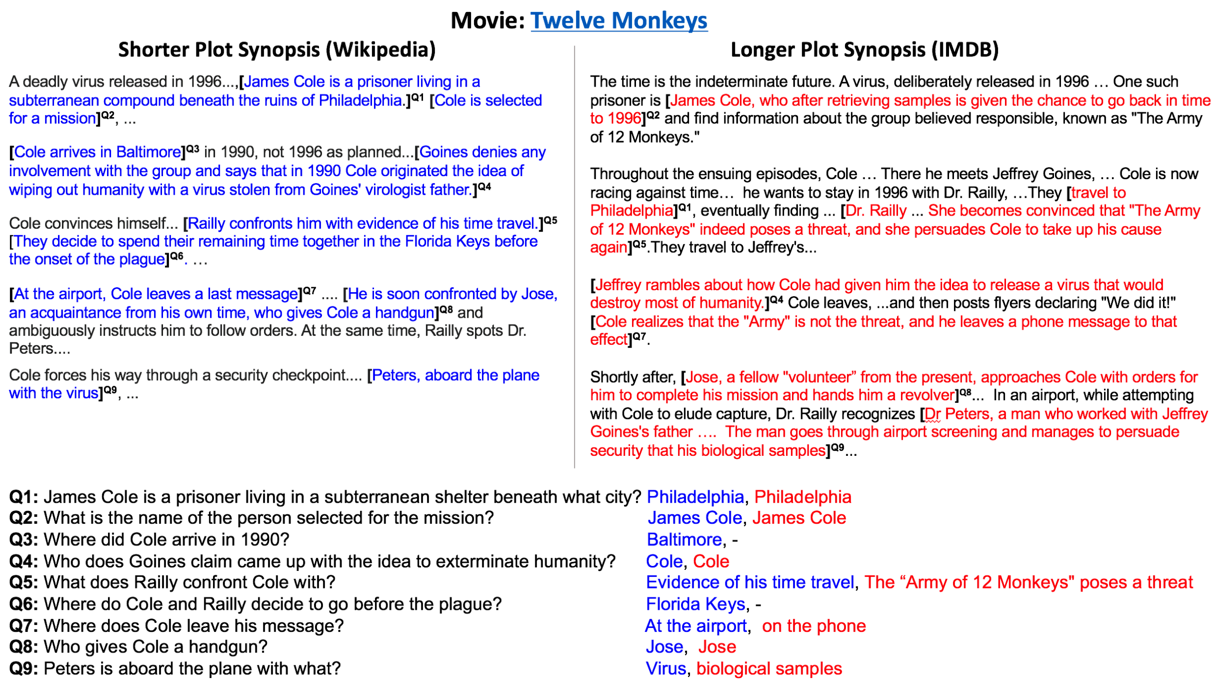
For RC in particular, there has been significant progress over the recent years with several benchmark datasets, the most popular of which are the SQuAD dataset (Rajpurkar et al., 2016a), TriviaQA (Joshi et al., 2017), MS MARCO (Nguyen et al., 2016), MovieQA (Tapaswi et al., 2016) and cloze-style datasets (Mostafazadeh et al., 2016; Onishi et al., 2016; Hermann et al., 2015). However, these benchmarks, owing to both the nature of the passages and the QA pairs to evaluate the RC task, have 2 primary limitations in studying language understanding: (i) Other than MovieQA, which is a small dataset of 15K QA pairs, all other large-scale RC datasets deal only with factual descriptive passages and not narratives (involving events with causality linkages that require reasoning and background knowledge) which is the case with a lot of real-world content such as story books, movies, news reports, etc. (ii) their questions possess a large lexical overlap with segments of the passage, or have a high noise level in QA pairs themselves. As demonstrated by recent work, this makes it easy for even simple keyword matching algorithms to achieve high accuracy (Weissenborn et al., 2017). In fact, these models have been shown to perform poorly in the presence of adversarially inserted sentences which have a high word overlap with the question but do not contain the answer (Jia and Liang, 2017). While this problem does not exist in TriviaQA it is admittedly noisy because of the use of distant supervision. Similarly, for cloze-style datasets, due to the automatic question generation process, it is very easy for current models to reach near human performance (Cui, 2017). This therefore limits the complexity in language understanding that a machine is required to demonstrate to do well on the RC task.

Motivated by these shortcomings and to push the state-of-the-art in language understanding in RC, in this paper we propose DuoRC, which specifically presents the following challenges beyond the existing datasets:

1. DuoRC is especially designed to contain a large number of questions with low lexical overlap between questions and their corresponding passages.
2. It requires the use of background and common-sense knowledge to arrive at the answer and go beyond the content of the passage itself.
3. It contains narrative passages from movie plots that require complex reasoning across multiple sentences to infer the answer.
4. Several of the questions in DuoRC, while seeming relevant, cannot actually be answered from the given passage, thereby requiring the machine to detect the *unanswerability* of questions.

In order to capture these four challenges, DuoRC contains QA pairs created from pairs of documents describing movie plots which were gathered as follows. Each document in a pair is a different version of the same movie plot written by different authors; one version of the plot is taken from the Wikipedia page of the movie whereas the other from its IMDb page (see Fig. 1 for portions of an example pair of plots from the movie "Twelve Monkeys"). We first showed crowd workers on Amazon Mechanical Turk (AMT) the *first* version of the plot and asked them to create QA pairs from it. We then showed the *second* version of the plot along with the questions created from the *first* version to a different set of workers on AMT and asked them to provide answers by reading the second version only. Since the two versions contain different levels of plot detail, narration style, vocabulary, etc., answering questions from the second version exhibits all of the four challenges mentioned above.

We now make several interesting observations from the example in Fig. 1. For 4 out of the 8 questions (Q1, Q2, Q4, and Q7), though the answers extracted from the two plots are exactly the same, the analysis required to arrive at this answer is very different in the two cases. In particular, for Q1 even though there is no explicit mention of *the prisoner living in a subterranean shelter* and hence no lexical overlap with the question, the workers were still able to infer that the answer is *Philadelphia* because that is the city to which James Cole travels to for his mission. Another interesting characteristic of this dataset is that for a few questions (Q6, Q8) alternative but valid answers are obtained from the second plot. Further, note the kind of complex reasoning required for answering Q8 where the machine needs to resolve coreferences over multiple sentences (*that man* refers to *Dr. Peters*) and use common sense knowledge that if an item clears an airport screening, then a person can likely board the plane with it. To re-emphasize, these examples exhibit the need for machines to demonstrate new capabilities in RC such as: (i) employing a knowledge graph (e.g. to know that Philadelphia is a city in Q1), (ii) common-sense knowledge (e.g., *clearing airport security* implies *boarding*) (iii) paraphrase/semantic understanding (e.g. revolver is a type of handgun in Q7) (iv) multiple-sentence inferencing across events in the passage including coreference resolution of named entities and nouns, and (v) educated guesswork when the question is not directly answerable but there are subtle hints in the passage (as in Q1). Finally, for quite a few questions, there wasn't sufficient information in the second plot to obtain their answers. In such cases, the workers marked the question as "unanswerable". This brings out a very important challenge for machines (detect *unanswerability* of questions)



Movie: Twelve Monkeys

Shorter Plot Synopsis (Wikipedia)

A deadly virus released in 1996...,[James Cole is a prisoner living in a subterranean compound beneath the ruins of Philadelphia.]^{Q1} [Cole is selected for a mission]^{Q2}, ...

[Cole arrives in Baltimore]^{Q3} in 1990, not 1996 as planned...[Goines denies any involvement with the group and says that in 1990 Cole originated the idea of wiping out humanity with a virus stolen from Goines' virologist father.]^{Q4}

Cole convinces himself... [Railly confronts him with evidence of his time travel.]^{Q5} [They decide to spend their remaining time together in the Florida Keys before the onset of the plague]^{Q6}. …

[At the airport, Cole leaves a last message]^{Q7} .... [He is soon confronted by Jose, an acquaintance from his own time, who gives Cole a handgun]^{Q8} and ambiguously instructs him to follow orders. At the same time, Railly spots Dr. Peters....

Cole forces his way through a security checkpoint.... [Peters, aboard the plane with the virus]^{Q9}, ...

Longer Plot Synopsis (IMDB)

The time is the indeterminate future. A virus, deliberately released in 1996 … One such prisoner is [James Cole, who after retrieving samples is given the chance to go back in time to 1996]^{Q2} and find information about the group believed responsible, known as "The Army of 12 Monkeys."

Throughout the ensuing episodes, Cole … There he meets Jeffrey Goines, … Cole is now racing against time… he wants to stay in 1996 with Dr. Railly, …They [travel to Philadelphia]^{Q1}, eventually finding ... [Dr. Railly ... She becomes convinced that "The Army of 12 Monkeys" indeed poses a threat, and she persuades Cole to take up his cause again]^{Q5}.They travel to Jeffrey's...

[Jeffrey rambles about how Cole had given him the idea to release a virus that would destroy most of humanity.]^{Q4} Cole leaves, ...and then posts flyers declaring "We did it!" [Cole realizes that the "Army" is not the threat, and he leaves a phone message to that effect]^{Q7}.

Shortly after, [Jose, a fellow "volunteer" from the present, approaches Cole with orders for him to complete his mission and hands him a revolver]^{Q8}... In an airport, while attempting with Cole to elude capture, Dr. Railly recognizes [Dr Peters, a man who worked with Jeffrey Goines's father …. The man goes through airport screening and manages to persuade security that his biological samples]^{Q9}...

Q1: James Cole is a prisoner living in a subterranean shelter beneath what city?	Philadelphia, Philadelphia
Q2: What is the name of the person selected for the mission?	James Cole, James Cole
Q3: Where did Cole arrive in 1990?	Baltimore, -
Q4: Who does Goines claim came up with the idea to exterminate humanity?	Cole, Cole
Q5: What does Railly confront Cole with?	Evidence of his time travel, The "Army of 12 Monkeys" poses a threat
Q6: Where do Cole and Railly decide to go before the plague?	Florida Keys, -
Q7: Where does Cole leave his message?	At the airport, on the phone
Q8: Who gives Cole a handgun?	Jose, Jose
Q9: Peters is aboard the plane with what?	Virus, biological samples

Figure 1: Example QA pairs obtained from the original movie plot and the paraphrased plot. The relevant spans needed for answering the corresponding question are highlighted in blue and red with the respective question numbers. Note that the span highlighting shown here is for illustrative purposes only and is not available in the dataset.

because a practical system should be able to know when it is not possible for it to answer a question given the data available to it, and in such cases, possibly delegate the task to a human instead.

Current RC systems built using existing datasets are far from possessing these capabilities to solve the above challenges. In Section 4, we seek to establish solid baselines for DuoRC employing state-of-the-art RC models coupled with a collection of standard NLP techniques to address few of the above challenges. Proposing novel neural models that solve all of the challenges in DuoRC is out of the scope of this paper. Our experiments demonstrate that when the existing state-of-the-art RC systems are trained and evaluated on DuoRC they perform poorly leaving a lot of scope for improvement and open new avenues for research in RC. Do note that this dataset is not a substitute for existing RC datasets but can be coupled with them to collectively address a large set of challenges in language understanding with RC (*the more the merrier*).

2 Related Work

Over the past few years, there has been a surge in datasets for Reading Comprehension. Most of these datasets differ in the manner in which questions and answers are created. For example, in SQuAD (Rajpurkar et al., 2016a), NewsQA (Trischler et al., 2016), TriviaQA (Joshi et al., 2017) and MovieQA (Tapaswi et al., 2016) the answers correspond to a span in the document. MS-MARCO uses web queries as questions and the answers are synthesized by workers from documents relevant to the query. On the other hand, in most cloze-style datasets (Mostafazadeh et al., 2016; Onishi et al., 2016) the questions are created automatically by deleting a word/entity from a sentence. There are also some datasets for RC with multiple choice questions (Richardson et al., 2013; Berant et al., 2014; Lai et al., 2017) where the task is to select one among k given candidate answers.

Another notable RC Dataset is NarrativeQA(s Koˇ ciský et al., 2018) which contains 40K QA pairs created from plot summaries of movies. It poses two tasks, where the first task involves reading the plot summaries from which the QA pairs were annotated and the second task is read the entire book or movie script (which is usually 60K words long) instead of the summary to answer the question. As acknowledged by the authors, while the first task is similar in scope to the previous datasets, the second task is at present, intractable for existing neural models, owing to the length of the passage. Due to the kind of the challenges presented by their second task, it is not comparable to our dataset and is much more futuristic in nature.

Given that there are already a few datasets for RC, a natural question to ask is "*Do we really need any more datasets?*". We believe that the answer to this question is *yes*. Each new dataset brings in new challenges and contributes towards building better QA systems. It keeps researchers on their toes and prevents research from stagnating once state-of-the-art results are achieved on one dataset. A classic example of this is the CoNLL NER dataset (Tjong Kim Sang and De Meulder, 2003). While several NER systems (Passos et al., 2014) gave close to human performance on this dataset, NER on general web text, domain specific text, noisy social media text is still an unsolved problem (mainly due to the lack of representative datasets which cover the real-world challenges of NER). In this context, DuoRC presents 4 new challenges mentioned earlier which are not exhibited in existing RC datasets and would thus enable exploring novel neural approaches in complex language understanding. The hope is that all these datasets (including ours) will collectively help in addressing a wide range of challenges in QA and prevent stagnation via overfitting on a single dataset.

3 Dataset

In this section, we elaborate on the three phases of our dataset collection process.

Extracting parallel movie plots: We first collected top 40K movies from IMDb across different genres (crime, drama, comedy, etc.) whose plot synopsis were crawled from Wikipedia as well as IMDb. We retained only 7680 movies for which both the plots were available and longer than 100 words. In general, we found that the IMDb plots were usually longer (avg. length 926 words) and more descriptive than the Wikipedia plots (avg. length 580 words). To make sure that the content between the two plots are indeed different and one is not just a subset of another, we calculated word-level jaccard distance between them i.e. the ratio of intersection to union of the bag-of-words in the two plots and found it to be 26%. This indicates that one of the plots is usually longer and descriptive, and, the two plots are infact quite different, even though the information content is very similar.

Collecting QA pairs from shorter version of the plot (*SelfRC*): As mentioned earlier, on average the longer version of the plot is almost double the size of the shorter version which is itself usually 500 words long. Intuitively, the longer version should have more details and the questions asked from the shorter version should be answerable from the longer one. Hence, we first showed the shorter version of the plot to workers on AMT and asked them to create QA pairs from it. The instructions given to the workers for this phase are as follows: (i) the answer must preferably be a single word or a short phrase, (ii) subjective questions (like asking for opinion) are not allowed, (iii) questions should be answerable only from the passage and not require any external knowledge, and (iv) questions and answers should be well formed and grammatically correct. The workers were also given freedom to either pick an answer which directly matches a span in the document or synthesize the answer from scratch. This option allowed them to be creative and ask hard questions where possible. We found that in 70% of the cases the workers picked an answer directly from the document and in 30% of the cases they synthesized the answer. We thus collected 85,773 such QA pairs along with their corresponding documents. We refer to this as the *SelfRC* dataset because the answers were derived from the same document from which the questions were asked.

Collecting answers from longer version of the plot (*ParaphraseRC*): We then paired the questions from the *SelfRC* dataset with the corresponding longer version of the plot and showed it to a different set of AMT workers asking them to answer these questions from the longer version of the plot. They now have the option to either (i) select an answer which matches a span in the longer version, (ii) synthesize the answer from scratch, or (iii) mark the question not-answerable because of lack of information in the given passage. One trick we used to reduce the fatigue of workers (caused by reading long pieces of text), and thus maintain the answer quality is to split the long plots into multiple segments. Every question obtained from the first phase of annotation is paired separately with each of these segments and each (question, segment) pair is posted as a different job. With this approach, we essentially get multiple answers to the same question, if it is answerable from more than one segment. However, on an average we get approximately one unique answer for each question. We found that in 50% of the cases the workers selected an answer which matched a span in the document, whereas in 37% cases they synthesized the answer and in 13% cases they said that question was not answerable. The workers were strictly instructed to keep the answers short, derive the answer from the plot and use *general* knowledge or logic to answer the questions. They were not allowed to rely on *personal* knowledge about the movie (in any case given the large number of movies in our dataset the chance of a worker remembering all the plot details for a given movie is very less). For quality assessment purposes, various levels of manual and semi-automated inspections were done, especially in the second phase of annotation, such as:(i) weeding out annotators who mark majority of answers as non-answerable, by taking into account their response time, and (ii) annotators for whom a high percentage of answers have no entity (or noun phrase) overlap with the entire passage were subjected to strict manual inspection and blacklisted if necessary. Further, a wait period of 2-3 weeks was deliberately introduced between the two phases of data collection to ensure the availability of a fresh pool of workers as well as to reduce information bias among workers common to both the tasks. Overall 2559 workers took part in the first phase of the annotation, and 8021 workers in the second phase. Only 703 workers were common between the phases.

We refer to this dataset, where the questions are taken from one version of the document and the answers are obtained from a different version, as *ParaphraseRC* which contains 100,316 such {*question, answer, document*} triplets. Overall, 62% of the questions in *SelfRC* and *ParaphraseRC* have partial overlap in their answers, which is indicative of the fact that quality is reasonable. The remaining 38% where there is no overlap can be attributed to non-answerablity of the question from the bigger plot, information gap, or paraphrasing of information between the two plots.

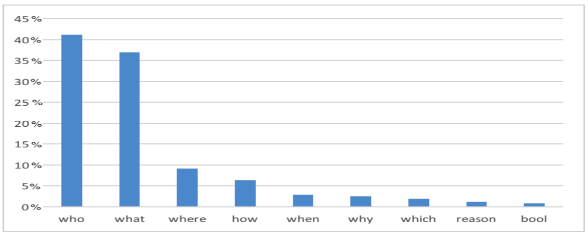


Figure 2: Analysis of the Question Types

Note that the number of unique questions in the *ParaphraseRC* dataset is the same as that in *SelfRC* because we do not create any new questions from the longer version of the plot. We end up with a greater number of {*question, answer, document*} triplets in *ParaphraseRC* as compared to *SelfRC* (100,316 v/s 85,773) since movies that are remakes of a previous movie had very little difference in their Wikipedia plots. Therefore, we did not separately collect questions from the Wikipedia plot of the remake. However, the IMDb plots of the two movies are very different and so we have two different longer versions of the movie (one for the original and one for the remake). We can thus pair the questions created from the Wikipedia plot with both the IMDb versions of the plot thus augmenting the {*question, answer, document*} triplets.

Another notable observation is that in many cases the answers to the same question are different in the two versions. Specifically, only 40.7% of the questions have the same answer in the two documents. For around 37.8% of the questions there is no overlap between the words in the two answers. For the remaining 21% of the questions there is a partial overlap between the two answers. For e.g., the answer derived from the shorter version could be "using his wife's gun" and from the longer version could be "with Dana's handgun" where Dana is the name of the wife. In Appendix **A**, we provide a few randomly picked examples from our dataset which should convince the reader of the difficulty of *ParaphraseRC* and its differences with *SelfRC*. We refer to this combined dataset containing a total of 186,089 instances as *DuoRC*[1]. Fig. 2 shows the distribution of different Wh-type questions in our dataset. Some interesting comparative analysis are presented in Table 1 and also in Appendix **B**. In Table 1, we compare various RC datasets with two embodiments of our dataset i.e. the *SelfRC* and *ParaphraseRC*. We use NER and noun phrase/verb phrase extraction over the entire dataset to iden-

Metrics for Comparative Analysis	**Movie QA**	**NarrativeQA over plot-summaries**	**Self-RC**	**Paraph-raseRC**
Avg. word distance	20.67	24.94	13.4	45.3
Avg. sentence distance	1.67	1.95	1.34	2.7
Number of sentences for inferencing	2.3	1.95	1.51	2.47
% of instances where both Query & Answer entities were found in passage	67.96	59.4	58.79	12.25
% of instances where Only Query entities were found in passage	59.61	61.77	63.39	47.05
% Length of the Longest Common sequence of non-stop words in Query (w.r.t Query Length) and Plot	25	26.26	38	21

Table 1: Comparison between various RC datasets

[1]The dataset is available at https://duorc.github.io

tify key entities in the question, plot and answer which is in turn used to compute the metrics mentioned in the table. The metrics "Avg word distance" and "Avg sentence distance" indicate the average distance (in terms of words/sentences) between the occurrence of the question entities and closest occurrence of the answer entities in the passage. "Number of sentences for inferencing" is indicative of the minimum number of sentences required to cover all the question and answer entities. It is evident that tackling *ParaphraseRC* is much harder than the others on account of (i) larger distance between the query and answer, (ii) low word-overlap between query & passage, and (iii) higher number of sentences required to infer an answer.

4 Models

In this section, we describe in detail the various state-of-the-art RC and language generation models along with a collection of traditional NLP techniques employed together that will serve to establish baseline performance on the DuoRC dataset.

Most of the current state-of-the-art models for RC assume that the answer corresponds to a span in the document and the task of the model is to predict this span. This is indeed true for the SQuAD, TriviaQA and NewsQA datasets. However, in our dataset, in many cases the answers do not correspond to an exact span in the document but are synthesized by humans. Specifically, for the *SelfRC* version of the dataset around 30% of the answers are synthesized and do not match a span in the document whereas for the *ParaphraseRC* task this number is 50%. Nevertheless, we could still leverage the advances made on the SQuAD dataset and adapt these span prediction models for our task. To do so, we propose to use two models. The first model is a basic span prediction model which we train and evaluate using only those instances in our dataset where the answer matches a span in the document. The purpose of this model is to establish whether even for instances where the answer matches a span in the document, our dataset is harder than the SQuAD dataset or not. Specifically, we want to explore the performance of state-of-the-art models (such as DCN (Xiong et al., 2016)), which exhibit near human results on the SQuAD dataset, on DuoRC (especially, in the *ParaphraseRC* setup). To do so, we seek to employ a good span prediction model for which (i) the performance is within 3-5% of the top performing model on the SQuAD leaderboard (Rajpurkar et al., 2016b) and (ii) the results are reproducible based on the code released by the authors of the paper. Note that the second criteria is important to ensure that the poor performance of the model is not due to incorrect implementation. The Bidirectional Attention Flow (BiDAF) model (Seo et al., 2016) satisfies these criteria and hence we employ this model. Due to space constraints, we do not provide details of the BiDAF model here and simply refer the reader to the original paper. In the remainder of this paper we will refer to this model as the *SpanModel*.

The second model that we employ is a two stage process which first predicts the span and then synthesizes the answers from the span. Here again, for the first step (*i.e.*, span prediction) we use the BiDAF model (Seo et al., 2016). The job of the second model is to then take the span (mini-document) and question (query) as input and generate the answer. For this, we employ a state-of-the-art query based abstractive summarization model (Nema et al., 2017) as this task is very similar to our task. Specifically, in query based abstractive summarization the training data is of the form {query, document, generated_summary} and in our case the training data is of the form {query, mini-document, generated_answer}. Once again we refer the reader to the original paper (Nema et al., 2017) for details of the model. We refer to this two stage model as the *GenModel*.

Note that (Tan et al., 2017) recently proposed an answer generation model for the MS MARCO dataset. However, the authors have not released their code and therefore, in the interest of reproducibility of our work, we omit incorporating this model in this paper.

Additional NLP pre-processing: Referring back to the example cited in Fig. 1, we reiterate that ideally a good model for *ParaphraseRC* would require: (i) employing a knowledge graph, (ii) common-sense knowledge (iii) paraphrase/semantic understanding (iv) multiple-sentence inferencing across events in the passage including coreference resolution of named entities and nouns, and (v) educated guesswork when the question is not directly answerable but there are subtle hints in the passage. While addressing all of these challenges in their entirety is beyond the scope of a single paper, in the interest of establishing a good baseline for DuoRC, we additionally seek to address some of these challenges to a certain extent by using standard NLP techniques. Specifically, we look at the problems of paraphrase understanding, coreference resolution and handling long passages.

To do so, we prune the document and extract only those sentences which are most relevant to the question, so that the span detector does not need to look at the entire 900-word long *ParaphraseRC* plot. Now, since these relevant sentences are obtained not from the original but the paraphrased version of the document, they may have a very small word overlap with the question. For example, the question might contain the word "hand gun" and the relevant sentence in the document may contain the word "revolver". Further some of the named entities in the question may not be exactly present in the relevant sentence but may simply be co-referenced. To resolve these coreferences, we first employ the Stanford coreference resolution on the entire document. We then compute the fraction of words in a sentence which match a query word (ignoring stop words). Two words are considered to match if (a) they have the same surface form, or (b) one words is an inflected form of the word (e.g., river and rivers), or (c) the Glove (Pennington et al., 2014) and Skip-thought (Kiros et al., 2015) embeddings of the two words are very close to each other (two word vectors are considered to be close if one appears within the top 50 neighbors of the other), or (d) the two words appear in the same synset in Wordnet. We consider a sentence to be relevant for the question if at least 50% of the query words (ignoring stop words) match the words in the sentence. If none of the sentences in the document have atleast 50% overlap with the question, then we pick sentences having atleast a 30% overlap with the question. The selection of this threshold was based on manual observation of a small sample set. This observation gave us an idea of what a decent threshold value should be, that can have a reasonable precision and recall on the relevant snippet extraction step. Since this step was rule-based we could only employ such qualitative inspections to set this parameter. Also, since this step was targeted to have high recall, we relaxed the threshold to 30% if no match was found.

5 Experimental Setup

In the following sub-sections we describe (i) the evaluation metrics, and (ii) the choices considered for augmenting the training data for the answer generation model. Note that when creating the train, validation and test set, we ensure that the test set does not contain QA pairs for any movie that was seen during training. We split the movies in such a way that the resulting train, valid, test sets respectively contain 70%, 15% and 15% of the total number of QA pairs.

Span-Based Test Set and Full Test Set As mentioned earlier, the *SpanModel* only predicts the span in the document whereas the *GenModel* generates the answer after predicting the span. Ideally, the *SpanModel* should only be evaluated on those instances in the test set where the answer matches a span in the document. We refer to this subset of the test set as the *Span-based Test Set*. Though not ideal, we also evaluate the *SpanModel* model on the entire test set. This is not ideal because there are many answers in the test set which do not correspond to a span in the document whereas the model was only trained to predict spans. We refer to this as the *Full Test Set*. We also evaluate the *GenModel* on both the test sets.

Training Data for the GenModel As mentioned earlier, the *GenModel* contains two stages; the first stage predicts the span and the second stage then generates an answer from the predicted span. For the first step we plug-in the best performing *SpanModel* from our earlier exploration. To train the second stage we need training data of the form $\{x = \textit{span},\ y = \textit{answer}\}$ which comes from two types of instances: one where the answer matches a span and the other where the answer is synthesized and the span corresponding to it is not known. In the first case x=y and there is nothing interesting for the model to learn (except for copying the input to the output). In the second case x is not known. To overcome this problem, for the second type of instances, we consider various approaches for finding the approximate span from which the answer could have been generated, and augment the training data with $\{x = \textit{approx\_span},\ y = \textit{answer}\}$.
The easiest method was to simply treat the entire document as the true span from which the answer was generated (x = *document*, y = *answer*). The second alternative that we tried was to first extract the named entities, noun phrases and verb phrases from the question and create a lucene query from these components. We then used the lucene search engine to extract the most relevant portions of the document given this query. We then considered this portion of the document as the true span (as

opposed to treating the entire document as the true span). Note that lucene could return multiple relevant spans in which case we treat all these $\{x = approx\_span, y = answer\}$ as training instances. Another alternative was to find the longest common subsequence (LCS) between the document and the question and treat this subsequence as the span from which the answer was generated. Of these, we found that the model trained using $\{x = approx\_span, y = answer\}$ pairs created using the LCS based method gave the best results. We report numbers only for this model.

Evaluation Metrics Similar to (Rajpurkar et al., 2016a) we use Accuracy and F-score as the evaluation metrics. We also report the BLEU scores for each task. While accuracy, being a stricter metric, considers a predicted answer to be correct only if it exactly matches the true answer, F-score and BLEU also give credit to predictions partially overlapping with the true answer.

6 Results and Discussions

The results of our experiments are summarized in Tables 2 to 4 which we discuss in the following sub-sections.

Preprocessing step of Relevant Subplot Extraction	**Plot Compression**	**Answer Recall**
WordNet synonym + Glove based paraphrase	30%	66.51%
WordNet synonym + Glove based paraphrase on Coref resolved plots	50%	84.10%
WordNet synonym + Glove + Skip-thought based paraphrase on Coref resolved plots	48%	85%

Table 2: Performance of the preprocessing. Plot compression is the % size of the extracted plot w.r.t the original plot size

	SelfRC+ ParaRC	40.62	51.35	21.18	26.90	37.42	5.94

Table 4: Combined and Cross-Testing between *Self* and *ParaphraseRC* Dataset, by taking the best performing *SpanModel* from Table 3.*ParaRC* is an abbreviation of *ParaphraseRC*

50%) of the answers in *SelfRC* (and *ParaphraseRC*) respectively, match an exact span in the document so the *SpanModel* still has scope to do well on these answers. On the other hand, even if the first stage of the *GenModel* predicts the span correctly, the second stage could make an error in generating the correct answer from it because generation is a harder problem. For the second stage, it is expected that the *GenModel* should learn to copy the predicted span to produce the answer output (as is required in most cases) and only occasionally where necessary, generate an answer. However, surprisingly the *GenModel* fails to even do this. Manual inspection of the generated answers shows that in many cases the generator ends up generating either more or fewer words compared the true answer. This demonstrates the clear scope for the *GenModel* to perform better.

SelfRC v/s ParaphraseRC: Comparing the *SelfRC* and *ParaphraseRC* numbers in Table 3, we observe that the performance of the models clearly drops for the latter task, thus validating our hypothesis that *ParaphraseRC* is a indeed a much harder task.

Effect of NLP pre-processing: As mentioned in Section 4, for *ParaphraseRC*, we first perform a few pre-processing steps to identify relevant sentences in the longer document. In order to evaluate whether the pre-processing method is effective, we compute: (i) the percentage of the document that gets pruned, and (ii) whether the true answer is present in the pruned document (i.e., average recall of the answer). We can compute the recall only for the span-based subset of the data since for the remaining data we do not know the true span. In Table 2, we report these two quantities for the span-based subset using different pruning strategies. Finally, comparing the *SpanModel* with and without

Paraphrasing in Table 3 for *ParaphraseRC*, we observe that the pre-processing step indeed improves the performance of the Span Detection Model.

Effect of oracle pre-processing: As noted in Section 3, the *ParaphraseRC* plot is almost double in length in comparison to the *SelfRC* plot, which while adding to the complexities of the former task, is clearly not the primary reason of the model's poor performance on that. To empirically validate this, we perform an Oracle pre-processing step, where, starting with the knowledge of the span containing the true answer, we extract a subplot around it such that the span is randomly located within that subplot and the average length of the subplot is similar to the *SelfRC* plots. The *SpanModel* with this Oracle preprocessed data exhibits a minor improvement in performance over that with rule-based preprocessing (1.6% in Accuracy and 4.3% in F1 over the Span Test), still failing to bridge the wide performance gap between the *SelfRC* and *ParaphraseRC* task.

Cross Testing We wanted to examine whether a model trained on *SelfRC* performs well on *ParaphraseRC* and vice-versa. We also wanted to evaluate if merging the two datasets improves the performance of the model. For this we experimented with various combinations of train and test data. The results of these experiments for the *SpanModel* are summarized in Table 4. The best performance is obtained when the model is trained on both (*SelfRC*) and *ParaphraseRC* and tested on *SelfRC* and the performance is poorest when *ParaphraseRC* is used for both. We believe this is because learning with the *ParaphraseRC* is more difficult given the wide range of challenges in this dataset.

Based on our experiments and empirical observations we believe that the *DuoRC* dataset indeed holds a lot of potential for advancing the horizon of complex language understanding by exposing newer challenges in this area.

7 Conclusion

In this paper we introduced DuoRC, a large scale RC dataset of 186K human-generated QA pairs created from 7680 pairs of parallel movie-plots, each pair taken from Wikipedia and IMDb. We then showed that this dataset, by design, ensures very little or no lexical overlap between the questions created from one version and segments containing answers in the other version. With this, we hope to introduce the RC community to new research challenges on QA requiring external knowledge and common-sense driven reasoning, deeper language understanding and multiple-sentence inferencing. Through our experiments, we show how the state-of-the-art RC models, which have achieved near human performance on the SQuAD dataset, perform poorly on our dataset, thus emphasizing the need to explore further avenues for research.

Abstract

We propose a simple yet robust **s**tochastic **a**nswer **n**etwork (SAN) that simulates multi-step reasoning in machine reading comprehension. Compared to previous work such as ReasoNet which used reinforcement learning to determine the number of steps, the unique feature is the use of a kind of stochastic prediction dropout on the answer module (final layer) of the neural network during the training. We show that this simple trick improves robustness and achieves results competitive to the state-of-the-art on the Stanford Question Answering Dataset (SQuAD), the Adversarial SQuAD, and the Microsoft MAchine Reading COmprehension Dataset (MS MARCO).

1 Introduction

Machine reading comprehension (MRC) is a challenging task: the goal is to have machines read a text passage and then answer any question about the passage. This task is an useful benchmark to demonstrate natural language understanding, and also has important applications in e.g. conversational agents and customer service support. It has been hypothesized that difficult MRC problems require some form of multi-step synthesis and reasoning. For instance, the following example from the MRC dataset SQuAD (Rajpurkar et al., 2016) illustrates the need for synthesis of information across sentences and multiple steps of reasoning:

Q: What collection does **the V&A Theator & Performance galleries** hold?

P: **The V&A Theator & Performance galleries** opened in March 2009. ... **They** hold the UK's biggest national collection of material about live performance.

To infer the answer (the underlined portion of the passage P), the model needs to first perform coreference resolution so that it knows "**They**" refers "**V&A Theator**", then extract the subspan in the direct object corresponding to the answer.

This kind of iterative process can be viewed as a form of multi-step reasoning. Several recent MRC models have embraced this kind of multi-step strategy, where predictions are generated after making multiple passes through the same text and integrating intermediate information in the process. The first models employed a predetermined fixed number of steps (Hill et al., 2016; Dhingra et al., 2016; Sordoni et al., 2016; Kumar et al., 2015). Later, Shen et al. (2016) proposed using reinforcement learning to dynamically determine the number of steps based on the complexity of the question. Further, Shen et al. (2017) empirically showed that dynamic multi-step reasoning outperforms fixed multi-step reasoning, which in turn outperforms single-step reasoning on two distinct MRC datasets (SQuAD and MS MARCO).

In this work, we derive an alternative multi-step reasoning neural network for MRC. During training, we fix the number of reasoning steps, but perform stochastic dropout on the answer module (final layer predictions). During decoding, we generate answers based on the average of predictions in all steps, rather than the final step. We call this a stochastic answer network (SAN) because the stochastic dropout is applied to the answer module; albeit simple, this technique significantly improves the robustness and overall accuracy of the model. Intuitively this works because while the model successively refines its prediction over multiple steps, each step is still trained to generate the same answer; we are performing a kind of stochastic ensemble over the model's successive predic-

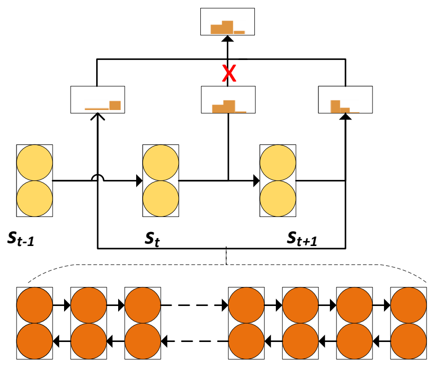

Figure 1: Illustration of "stochastic prediction dropout" in the answer module during training. At each reasoning step t, the model combines memory (bottom row) with hidden states $\mathbf{s}_{t-1}$ to generate a prediction (multinomial distribution). Here, there are three steps and three predictions, but one prediction is dropped and the final result is an average of the remaining distributions.

tion refinements. Stochastic prediction dropout is illustrated in Figure 1.

2 Proposed model: SAN

The machine reading comprehension (MRC) task as defined here involves a question $Q = \{q_0, q_1, ..., q_{m-1}\}$ and a passage $P = \{p_0, p_1, ..., p_{n-1}\}$ and aims to find an answer span $A = \{a_{start}, a_{end}\}$ in P. We assume that the answer exists in the passage P as a contiguous text string. Here, m and n denote the number of tokens in Q and P, respectively. The learning algorithm for reading comprehension is to learn a function $f(Q, P) \to A$. The training data is a set of the query, passage and answer tuples $< Q, P, A >$.

We now describe our model from the ground up. The main contribution of this work is the answer module, but in order to understand what goes into this module, we will start by describing how Q and P are processed by the lower layers. Note the lower layers also have some novel variations that are not used in previous work. As shown in Figure 2, our model contains four different layers to capture different concept of representations. The detailed description of our model is provided as follows.

Lexicon Encoding Layer. The purpose of the first layer is to extract information from Q and P at the word level and normalize for lexical variants. A typical technique to obtain lexicon embedding is concatenation of its word embedding with other linguistic embedding such as those derived from Part-Of-Speech (POS) tags. For word embeddings, we use the pre-trained 300-dimensional GloVe vectors (Pennington et al., 2014) for the both Q and P. Following Chen et al. (2017), we use three additional types of linguistic features for each token p_i in the *passage* P:

- 9-dimensional POS tagging embedding for total 56 different types of the POS tags.
- 8-dimensional named-entity recognizer (NER) embedding for total 18 different types of the NER tags. We utilized small embedding sizes for POS and NER to reduce model size. They mainly serve the role of coarse-grained word clusters.
- A 3-dimensional binary *exact* match feature defined as $f_{exact\_match}(p_i) = \mathbb{I}(p_i \in Q)$. This checks whether a passage token p_i matches the original, lowercase or lemma form of any question token.
- Question enhanced passages word embeddings: $f_{align}(p_i) = \sum_j \gamma_{i,j} g(GloVe(q_j))$, where $g(\cdot)$ is a 280-dimensional single layer neural network $ReLU(W_0 x)$ and $\gamma_{i,j} = \frac{exp(g(GloVe(p_j)) \cdot g(GloVe(q_i)))}{\sum_{j'} exp(g(GloVe(p_i)) \cdot g(GloVe(q_{j'})))}$ measures the similarity in word embedding space between a token p_i in the passage and a token q_j in the question. Compared to the *exact* matching features, these embeddings encode *soft* alignments between similar but not-identical words.

In summary, each token p_i in the passage is represented as a 600-dimensional vector and each token q_j is represented as a 300-dimensional vector.

Due to different dimensions for the passages and questions, in the next layer two different bidirectional LSTM (BiLSTM) (Hochreiter and Schmidhuber, 1997) may be required to encode the contextual information. This, however, introduces a large number of parameters. To prevent this, we employ an idea inspired by (Vaswani et al., 2017): use two separate two-layer position-wise Feed-Forward Networks (FFN), $FFN(x) = W_2 ReLU(W_1 x + b_1) + b_2$, to map both the passage and question lexical encodings into the same number of dimensions. Note that this FFN has fewer

Beyoncé is … what religion?
Beyoncé was born … in a Methodist household.

Figure 2: **Architecture of the SAN for Reading Comprehension:** The first layer is a lexicon encoding layer that maps words to their embeddings independently for the question (left) and the passage (right): this is a concatenation of word embeddings, POS embeddings, etc. followed by a position-wise FFN. The next layer is a context encoding layer, where a BiLSTM is used on the top of the lexicon embedding layer to obtain the context representation for both question and passage. In order to reduce the parameters, a maxout layer is applied on the output of BiLSTM. The third layer is the working memory: First we compute an alignment matrix between the question and passage using an attention mechanism, and use this to derive a question-aware passage representation. Then we concatenate this with the context representation of passage and the word embedding, and employ a self attention layer to re-arrange the information gathered. Finally, we use another LSTM to generate a working memory for the passage. At last, the fourth layer is the answer module, which is a GRU that outputs predictions at each state s_t.

parameters compared to a BiLSTM. Thus, we obtain the final lexicon embeddings for the tokens in Q as a matrix $E^q \in \mathbb{R}^{d \times m}$ and tokens in P as $E^p \in \mathbb{R}^{d \times n}$.

Contextual Encoding Layer. Both passage and question use a shared two-layers BiLSTM as the contextual encoding layer, which projects the lexicon embeddings to contextual embeddings. We concatenate a pre-trained 600-dimensional CoVe vectors[1] (McCann et al., 2017) trained on German-English machine translation dataset, with the aforementioned lexicon embeddings as the final input of the contextual encoding layer, and also with the output of the first contextual encoding layer as the input of its second encoding layer. To reduce the parameter size, we use a maxout layer (Goodfellow et al., 2013) at each BiLSTM layer to shrink its dimension. By a concatenation of the outputs of two BiLSTM layers, we obtain $H^q \in \mathbb{R}^{2d \times m}$ as representation of Q and $H^p \in \mathbb{R}^{2d \times n}$ as representation of P, where d is the hidden size of the BiLSTM.

Memory Generation Layer. In the memory

[1]https://github.com/salesforce/cove

generation layer, We construct the working memory, a summary of information from both Q and P. First, a dot-product attention is adopted like in (Vaswani et al., 2017) to measure the similarity between the tokens in Q and P. Instead of using a scalar to normalize the scores as in (Vaswani et al., 2017), we use one layer network to transform the contextual information of both Q and P:

$$C = dropout(f_{attention}(\hat{H}^q, \hat{H}^p)) \in \mathbb{R}^{m \times n} \quad (1)$$

C is an attention matrix. Note that $\hat{H}^q$ and $\hat{H}^p$ is transformed from H^q and H^p by one layer neural network $ReLU(W_3 x)$, respectively. Next, we gather all the information on passages by a simple concatenation of its contextual information H^p and its question-aware representation $H^q \cdot C$:

$$U^p = concat(H^p, H^q C) \in \mathbb{R}^{4d \times n} \quad (2)$$

Typically, a passage may contain hundred of tokens, making it hard to learn the long dependencies within it. Inspired by (Lin et al., 2017), we apply a self-attended layer to rearrange the information U^p as:

$$\hat{U}^p = U^p drop_{diag}(f_{attention}(U^p, U^p)). \quad (3)$$

In other words, we first obtain an $n \times n$ attention matrix with U^p onto itself, apply dropout, then multiply this matrix with U^p to obtain an updated $\hat{U}^p$. Instead of using a penalization term as in (Lin et al., 2017), we dropout the diagonal of the similarity matrix forcing each token in the passage to align to other tokens rather than itself.

At last, the working memory is generated by using another BiLSTM based on all the information gathered:

$$M = BiLSTM([U^p; \hat{U}^p]) \quad (4)$$

where the semicolon mark ; indicates the vector/matrix concatenation operator.

Answer module. There is a Chinese proverb that says: "wisdom of masses exceeds that of any individual." Unlike other multi-step reasoning models, which only uses a single output either at the last step or some dynamically determined final step, our answer module employs all the outputs of multiple step reasoning. Intuitively, by applying dropout, it avoids a "step bias problem" (where models places too much emphasis one particular step's predictions) and forces the model to produce good predictions at every individual step. Further, during decoding, we reuse *wisdom of masses* instead of *individual* to achieve a better result. We call this method "stochastic prediction dropout" because dropout is being applied to the final predictive distributions.

Formally, our answer module will compute over T memory steps and output the answer span. This module is a memory network and has some similarities to other multi-step reasoning networks: namely, it maintains a state vector, one state per step. At the beginning, the initial state s_0 is the summary of the Q: $s_0 = \sum_j \alpha_j H^q_j$, where $\alpha_j = \frac{exp(w_4 \cdot H^q_j)}{\sum_{j'} exp(w_4 \cdot H^q_{j'})}$. At time step t in the range of $\{1, 2, ..., T-1\}$, the state is defined by $s_t = GRU(s_{t-1}, x_t)$. Here, x_t is computed from the previous state s_{t-1} and memory M: $x_t = \sum_j \beta_j M_j$ and $\beta_j = softmax(s_{t-1} W_5 M)$. Finally, a bilinear function is used to find the begin and end point of answer spans at each reasoning step $t \in \{0, 1, \dots, T-1\}$.

$$P^{begin}_t = softmax(s_t W_6 M) \quad (5)$$

$$P^{end}_t = softmax([s_t; \sum_j P^{begin}_{t,j} M_j] W_7 M). \quad (6)$$

From a pair of begin and end points, the answer string can be extracted from the passage. However, rather than output the results (start/end points) from the final step (which is fixed at $T-1$ as in Memory Networks or dynamically determined as in ReasoNet), we utilize all of the T outputs by averaging the scores:

$$P^{begin} = avg([P^{begin}_0, P^{begin}_1, ..., P^{begin}_{T-1}]) \quad (7)$$

$$P^{end} = avg([P^{end}_0, P^{end}_1, ..., P^{end}_{T-1}]) \quad (8)$$

Each P^{begin}_t or P^{end}_t is a multinomial distribution over $\{1, \dots, n\}$, so the average distribution is straightforward to compute.

During training, we apply stochastic dropout to before the above averaging operation. For example, as illustrated in Figure 1, we randomly delete several steps' predictions in Equations 7 and 8 so that P^{begin} might be $avg([P^{begin}_1, P^{begin}_3])$ and P^{end} might be $avg([P^{end}_0, P^{end}_3, P^{end}_4])$. The use of averaged predictions and dropout during training improves robustness.

Our stochastic prediction dropout is similar in motivation to the dropout introduced by (Srivastava et al., 2014). The difference is that theirs is dropout at the intermediate node-level, whereas ours is dropout at the final layer-level. Dropout at the node-level prevents correlation between features. Dropout at the final layer level, where randomness is introduced to the averaging of predictions, prevents our model from relying exclusively on a particular step to generate correct output. We used a dropout rate of 0.4 in experiments.

3 Experiment Setup

Dataset: We evaluate on the Stanford Question Answering Dataset (SQuAD) (Rajpurkar et al., 2016). This contains about 23K passages and 100K questions. The passages come from approximately 500 Wikipedia articles and the questions and answers are obtained by crowdsourcing. The crowdsourced workers are asked to read a passage (a paragraph), come up with questions, then mark the answer span. All results are on the official development set, unless otherwise noted.

Two evaluation metrics are used: Exact Match (EM), which measures the percentage of span predictions that matched any one of the ground truth answer exactly, and Macro-averaged F1 score, which measures the average overlap between the prediction and the ground truth answer.

Implementation details: The spaCy tool[2] is used to tokenize the both passages and questions, and generate lemma, part-of-speech and named entity tags. We use 2-layer BiLSTM with $d = 128$ hidden units for both passage and question encoding. The mini-batch size is set to 32 and Adamax (Kingma and Ba, 2014) is used as our optimizer. The learning rate is set to 0.002 at first and decreased by half after every 10 epochs. We set the dropout rate for all the hidden units of LSTM, and the answer module output layer to 0.4. To prevent degenerate output, we ensure that at least one step in the answer module is active during training.

4 Results

The main experimental question we would like to answer is whether the stochastic dropout and averaging in the answer module is an effective technique for multi-step reasoning. To do so, we fixed all lower layers and compared different architectures for the answer module:

1. Standard 1-step: generate prediction from s_0, the first initial state.

2. 5-step memory network: this is a memory network fixed at 5 steps. We try two variants: the standard variant outputs result from the final step s_{T-1}. The averaged variant outputs results by averaging across all 5 steps, and is like SAN without the stochastic dropout.

3. ReasoNet[3]: this answer module dynamically decides the number of steps and outputs results conditioned on the final step.

4. SAN: proposed answer module that uses stochastic dropout and prediction averaging.

The main results in terms of EM and F1 are shown in Table 1. We observe that SAN achieves 76.235 EM and 84.056 F1, outperforming all other models. Standard 1-step model only achieves 75.139 EM and dynamic steps (via ReasoNet) achieves only 75.355 EM. SAN also outperforms a 5-step memory net with averaging, which implies averaging predictions is not the only thing that led to SAN's superior results; indeed, stochastic prediction dropout is an effective technique.

The K-best oracle results is shown in Figure 3. The K-best spans are computed by ordering the spans according the their probabilities $P^{begin} \times P^{end}$. We limit K in the range 1 to 4 and then pick the span with the best EM or F1 as oracle. SAN also outperforms the other models in terms of K-best oracle scores. Impressively, these models achieve human performance at $K = 2$ for EM and $K = 3$ for F1.

Finally, we compare our results with other top models in Table 2. Note that all the results in Table 2 are taken from the published papers. We see that SAN is very competitive in both single and ensemble settings (ranked in second) despite its simplicity. Note that the best-performing model (Peters et al., 2018) used a large-scale language model as an extra contextual embedding, which gave a significant improvement (+4.3% dev F1). We expect significant improvements if we add this to SAN in future work.

[2]https://spacy.io

[3]The ReasoNet here is not an exact re-implementation of (Shen et al., 2017). The answer module is the same as (Shen et al., 2017) but the lower layers are set to be the same as SAN, 5-step memory network, and standard 1-step as described in Figure 2. We only vary the answer module in our experiments for a fair comparison.

Answer Module	EM	F1
Standard 1-step	75.139	83.367
Fixed 5-step with Memory Network (prediction from final step)	75.033	83.327
Fixed 5-step with Memory Network (prediction averaged from all steps)	75.256	83.215
Dynamic steps (max 5) with ReasoNet	75.355	83.360
Stochastic Answer Network (SAN), Fixed 5-step	**76.235**	**84.056**

Table 1: **Main results**—Comparison of different answer module architectures. Note that SAN performs best in both Exact Match and F1 metrics.

5 Analysis

5.1 How robust are the results?

We are interested in whether the proposed model is sensitive to different random initial conditions. Table 3 shows the development set scores of SAN trained from initialization with different random seeds. We observe that the SAN results are consistently strong regardless of the 10 different initializations. For example, the mean EM score is 76.131 and the lowest EM score is 75.922, both of which still outperform the 75.355 EM of the Dynamic step ReasoNet in Table 1.[4]

We are also interested in how sensitive are the results to the number of reasoning steps, which is a fixed hyper-parameter. Since we are using dropout, a natural question is whether we can extend the number of steps to an extremely large number. Table 4 shows the development set scores for $T = 1$ to $T = 10$. We observe that there is a gradual improvement as we increase $T = 1$ to $T = 5$, but after 5 steps the improvements have saturated. In fact, the EM/F1 scores drop slightly, but considering that the random initialization results in Table 3 show a standard deviation of 0.142 and a spread of 0.426 (for EM), we believe that the $T = 10$ result does not statistically differ from the $T = 5$ result. In summary, we think it is useful to perform some approximate hyper-parameter tuning for the number of steps, but it is not necessary to find the exact optimal value.

Finally, we test SAN on two Adversarial SQuAD datasets, AddSent and AddOneSent (Jia and Liang, 2017), where the passages contain

[4]Note the Dev EM/F1 scores of ReasoNet in Table 1 do not match those of ReasoNet++ in Table 2. While the answer module is the same architecture, the lower encoding layers are different.

auto-generated adversarial distracting sentences to fool computer systems that are developed to answer questions about the passages. For example, AddSent is constructed by adding sentences that look similar to the question, but do not actually contradict the correct answer. AddOneSent is constructed by appending a random human-approved sentence to the passage.

We evaluate the single SAN model (i.e., the one presented in Table 2) on both AddSent and AddOneSent. The results in Table 5 show that SAN achieves the new state-of-the-art performance and SAN's superior result is mainly attributed to the multi-step answer module, which leads to significant improvement in F1 score over the Standard 1-step answer module, i.e., +1.2 on AddSent and +0.7 on AddOneSent.

5.2 Is it possible to use different numbers of steps in test vs. train?

For practical deployment scenarios, prediction speed at test time is an important criterion. Therefore, one question is whether SAN can train with, e.g. $T = 5$ steps but test with $T = 1$ steps. Table 6 shows the results of a SAN trained on $T = 5$ steps, but tested with different number of steps. As expected, the results are best when T matches during training and test; however, it is important to note that small numbers of steps $T = 1$ and $T = 2$ nevertheless achieve strong results. For example, prediction at $T = 1$ achieves 75.58, which outperforms a standard 1-step model (75.14 EM) as in Table 1 that has approximate equivalent prediction time.

5.3 How does the training time compare?

The average training time per epoch is comparable: our implementation running on a GTX Titan X is 22 minutes for 5-step memory net, 30 minutes for ReasoNet, and 24 minutes for SAN. The learning curve is shown in Figure 4. We observe that all systems improve at approximately the same rate up to 10 or 15 epochs. However, SAN continues to improve afterwards as other models start to saturate. This observation is consistent with previous works using dropout (Srivastava et al., 2014). We believe that while training time per epoch is similar between SAN and other models, it is recommended to train SAN for more epochs in order to achieve gains in EM/F1.

Single model:	AddSent	AddOneSent
LR (Rajpurkar et al., 2016)	23.2	30.3
SEDT (Liu et al., 2017a)	33.9	44.8
BiDAF (Seo et al., 2016)	34.3	45.7
jNet (Zhang et al., 2017)	37.9	47.0
ReasoNet(Shen et al., 2017)	39.4	50.3
RaSoR(Lee et al., 2016)	39.5	49.5
Mnemonic(Hu et al., 2017)	**46.6**	56.0

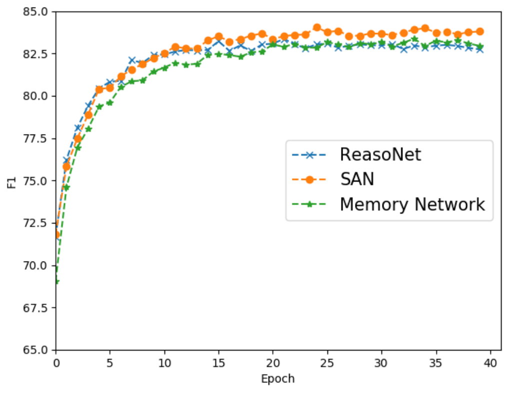
(a) EM



(b) F1

Figure 4: Learning curve measured on Dev set.

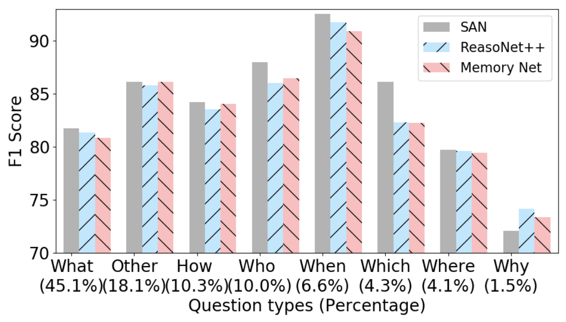


Figure 5: Score breakdown by question type.

5.4 How does SAN perform by question type?

To see whether SAN performs well on a particular type of question, we divided the development set by questions type based on their respective Wh-word, such as “who” and “where”. The score breakdown by F1 is shown in Figure 5. We observe that SAN seems to outperform other models uniformly across all types. The only exception is the Why questions, but there is too little data to derive strong conclusions.

5.5 Experiments results on MS MARCO

MS MARCO (Nguyen et al., 2016) is a large scale real-word RC dataset which contains 100,100 (100K) queries collected from anonymized user logs from the Bing search engine. The characteristic of MS MARCO is that all the questions are real user queries and passages are extracted from real web documents. For each query, approximate 10 passages are extracted from public web documents. The answers are generated by humans. The data is partitioned into a 82,430 training, a 10,047 development and 9,650 test tuples. The evaluation metrics are BLEU(Papineni et al., 2002) and ROUGE-L (Lin, 2004) due to its free-form text answer style. To apply the same RC model, we search for a span in MS MARCO’s passages that maximizes the ROUGE-L score with the raw free-form answer. It has an upper bound of 93.45 BLEU and 93.82 ROUGE-L on the development set.

The MS MARCO dataset contains multiple passages per query. Our model as shown in Figure 2 is developed to generate answer from a single passage. Thus, we need to extend it to handle multiple passages. Following (Shen et al., 2017), we take two steps to generate an answer to a query Q from J passages, $P^1, ..., P^J$. First, we run SAN on ev-

$SingleModel$	ROUGE	BLEU

V-Net(Wang et al., 2018)	45.65	-
Standard 1-step in Table 1	42.30	42.39
SAN	**46.14**	**43.85**

Table 7: **MS MARCO devset results**.

ery (P^j, Q) pair, generating J candidate answer spans, one from each passage. Then, we multiply the SAN score of each candidate answer span with its relevance score $r(P^j, Q)$ assigned by a passage ranker, and output the span with the maximum score as the answer. In our experiments, we use the passage ranker described in (Liu et al., 2018)[5]. The ranker is trained on the same MS MARCO training data, and achieves 37.1 p@1 on the development set.

The results in Table 7 show that SAN outperforms V-Net (Wang et al., 2018) and becomes the new state of the art[6].

6 Related Work

The recent big progress on MRC is largely due to the availability of the large-scale datasets (Rajpurkar et al., 2016; Nguyen et al., 2016; Richardson et al., 2013; Hill et al., 2016), since it is possible to train large end-to-end neural network models. In spite of the variety of model structures and attenion types (Bahdanau et al., 2015; Chen et al., 2016; Xiong et al., 2016; Seo et al., 2016; Shen et al., 2017; Wang et al., 2017), a typical neural network MRC model first maps the symbolic representation of the documents and questions into a neural space, then search answers on top of it. We categorize these models into two groups based on the difference of the answer module: single-step and multi-step reasoning. The key difference between the two is what strategies are applied to search the final answers in the neural space.

A single-step model matches the question and document only once and produce the final answers. It is simple yet efficient and can be trained using the classical back-propagation algorithm, thus it is adopted by most systems (Chen et al., 2016; Seo et al., 2016; Wang et al., 2017; Liu et al., 2017b; Chen et al., 2017; Weissenborn et al., 2017; Hu et al., 2017). However, since humans often solve question answering tasks by re-reading and re-digesting the document multiple times before reaching the final answers (this may be based on the complexity of the questions/documents), it is natural to devise an iterative way to find answers as multi-step reasoning.

Pioneered by (Hill et al., 2016; Dhingra et al., 2016; Sordoni et al., 2016; Kumar et al., 2015), who used a predetermined fixed number of reasoning steps, Shen et al (2016; 2017) showed that multi-step reasoning outperforms single-step ones and dynamic multi-step reasoning further outperforms the fixed multi-step ones on two distinct MRC datasets (SQuAD and MS MARCO). But these models have to be trained using reinforcement learning methods, e.g., policy gradient, which are tricky to implement due to the instability issue. Our model is different in that we fix the number of reasoning steps, but perform stochastic dropout to prevent step bias. Further, our model can also be trained by using the back-propagation algorithm, which is simple and yet efficient.

7 Conclusion

We introduce Stochastic Answer Networks (SAN), a simple yet robust model for machine reading comprehension. The use of stochastic dropout in training and averaging in test at the answer module leads to robust improvements on SQuAD, outperforming both fixed step memory networks and dynamic step ReasoNet. We further empirically analyze the properties of SAN in detail. The model achieves results competitive with the state-of-the-art on the SQuAD leaderboard, as well as on the Adversarial SQuAD and MS MARCO datasets. Due to the strong connection between the proposed model with memory networks and ReasoNet, we would like to delve into the theoretical link between these models and its training algorithms. Further, we also would like to explore SAN on other tasks, such as text classification and natural language inference for its generalization in the future.

Acknowledgments

We thank Pengcheng He, Yu Wang and Xinying Song for help to set up dockers. We also thank Pranav Samir Rajpurkar for help on SQuAD evaluations, and the anonymous reviewers for valuable discussions and comments.

[5]It is the same model structure as (Liu et al., 2018) by using softmax over all candidate passages. A simple baseline, TF-IDF, obtains 20.1 p@1 on MS MARCO development.

[6]The official evaluation on MS MARCO on test is closed, thus here we only report the results on the development set.

Abstract

This paper describes a novel hierarchical attention network for reading comprehension style question answering, which aims to answer questions for a given narrative paragraph. In the proposed method, attention and fusion are conducted horizontally and vertically across layers at different levels of granularity between question and paragraph. Specifically, it first encode the question and paragraph with fine-grained language embeddings, to better capture the respective representations at semantic level. Then it proposes a multi-granularity fusion approach to fully fuse information from both global and attended representations. Finally, it introduces a hierarchical attention network to focuses on the answer span progressively with multi-level soft-alignment. Extensive experiments on the large-scale SQuAD and TriviaQA datasets validate the effectiveness of the proposed method. At the time of writing the paper (Jan. 12th 2018), our model achieves the first position on the SQuAD leaderboard for both single and ensemble models. We also achieves state-of-the-art results on TriviaQA, AddSent and AddOneSent datasets.

1 Introduction

As a brand new field in question answering community, reading comprehension is one of the key problems in artificial intelligence, which aims to read and comprehend a given text, and then answer questions based on it. This task is challenging which requires a comprehensive understanding of natural languages and the ability to do further inference and reasoning. Restricted by the limited volume of the annotated dataset, early studies mainly rely on a pipeline of NLP models to complete this task, such as semantic parsing and linguistic annotation (Das et al., 2014). Not until the release of large-scale cloze-style dataset, such as Children's Book Test (Hill et al., 2015) and CNN/Daily Mail (Hermann et al., 2015), some preliminary end-to-end deep learning methods have begun to bloom and achieve superior results in reading comprehension task (Hermann et al., 2015; Chen et al., 2016; Cui et al., 2016).

However, these cloze-style datasets still have their limitations, where the goal is to predict the single missing word (often a named entity) in a passage. It requires less reasoning than previously thought and no need to comprehend the whole passage (Chen et al., 2016). Therefore, Stanford publish a new large-scale dataset SQuAD (Rajpurkar et al., 2016), in which all the question and answers are manually created through crowdsourcing. Different from cloze-style reading comprehension dataset, SQuAD constrains answers to all possible text spans within the reference passage, which requires more logical reasoning and content understanding.

Benefiting from the availability of SQuAD benchmark dataset, rapid progress has been made these years. The work (Wang and Jiang, 2016) and (Seo et al., 2016) are among the first to investigate into this dataset, where Wang and Jiang propose an end-to-end architecture based on match-LSTM and pointer networks (Wang and Jiang, 2016), and Seo et al. introduce the bi-directional attention flow network which captures the question-document context at different levels of granularity (Seo et al., 2016). Chen et al. devise a simple and effective document reader, by introducing a bilinear match function and a few manual features (Chen et al., 2017a). Wang et al. propose a gated attention-based recurrent network where self-match attention mechanism is first incorporated (Wang et al., 2017). In (Liu et al., 2017b) and (Shen et al., 2017), the multi-turn memory networks are designed to simulate multi-step reasoning in machine reading comprehension.

The idea of our approach derives from the normal human reading pattern. First, people scan through the whole passage to catch a glimpse of the main body of the passage. Then with the question in mind, people make connection between passage and question, and understand the main intent of the question related with the passage theme. A rough answer span is then located from the passage and the attention can be focused on to the located context. Finally, to prevent from forgetting the question, people come back to the question and select a best answer according to the previously located answer span.

Inspired by this, we propose a hierarchical attention network which can gradually focus the attention on the right part of the answer boundary, while capturing the relation between the question and passage at different levels of granularity, as illustrated in Figure 1. Our model mainly consists of three joint layers: 1) encoder layer where pre-trained language models and recurrent neural networks are used to build representation for questions and passages separately; 2) attention layer in which hierarchical attention networks are designed to capture the relation between question and passage at different levels of granularity; 3) match layer where refined question and passage are matched under a pointer-network (Vinyals et al., 2015) answer boundary predictor.

In encoder layer, to better represent the questions and passages in multiple aspects, we combine two different embeddings to give the fundamental word representations. In addition to the typical glove word embeddings, we also utilize the ELMo embeddings (Peters et al., 2018) derived from a pre-trained language model, which shows superior performance in a wide range of NLP problems. Different from the original fusion way for intermediate layer representations, we design a representation-aware fusion method to compute the output ELMo embeddings and the context information is also incorporated by further passing through a bi-directional LSTM network.

The key in machine reading comprehension solution lies in how to incorporate the question context into the paragraph, in which attention mechanism is most widely used. Recently, many different attention functions and types have been designed (Xiong et al., 2016; Seo et al., 2016; Wang et al., 2017), which aims at properly aligning the question and passage. In our attention layer, we propose a hierarchical attention network by leveraging both the co-attention and self-attention mechanism, to gradually focus our attention on the best answer span. Different from the previous attention-based methods, we constantly complement the aligned representations with global information from the previous layer, and an additional fusion layer is used to further refine the representations. In this way, our model can make some minor adjustment so that the attention will always be on the right place.

Based on the refined question and passage representation, a bilinear match layer is finally used to identify the best answer span with respect to the question. Following the work of (Wang and Jiang, 2016), we predict the start and end boundary within a pointer-network output layer.

The proposed method achieves state-of-the-art results against strong baselines. Our single model achieves 79.2% EM and 86.6% F1 score on the hidden test set, while the ensemble model further boosts the performance to 82.4% EM and 88.6% F1 score. At the time of writing the paper (Jan. 12th 2018), our model SLQA+ (Semantic Learning for Question Answering) achieves the first position on the SQuAD leaderboard [1] for both single and ensemble models. Besides, we are also among the first to surpass human EM performance on this golden benchmark dataset.

2 Related Work

2.1 Machine Reading Comprehension

Traditional reading comprehension style question answering systems rely on a pipeline of NLP models, which make heavy use of linguistic annotation, structured world knowledge, semantic parsing and similar NLP pipeline outputs (Hermann et al., 2015). Recently, the rapid progress of machine reading comprehension has largely benefited from the availability of large-scale benchmark datasets and it is possible to train large end-to-end neural network models. Among them, CNN/Daily Mail (Hermann et al., 2015) and Children's Book Test (Hill et al., 2015) are the first

[1] https://rajpurkar.github.io/SQuAD-explorer/

large-scale datasets for reading comprehension task. However, these datasets are in cloze-style, in which the goal is to predict the missing word (often a named entity) in a passage. Moreover, Chen at al. have also shown that these cloze-style datasets requires less reasoning than previously thought (Chen et al., 2016). Different from the previous datasets, the SQuAD provides a more challenging benchmark dataset, where the goal is to extract an arbitrary answer span from the original passage.

2.2 Attention-based Neural Networks

The key in MRC task lies in how to incorporate the question context into the paragraph, in which attention mechanism is most widely used. In spite of a variety of model structures and attention types (Cui et al., 2016; Xiong et al., 2016; Seo et al., 2016; Wang et al., 2017; Clark and Gardner, 2017), a typical attention-based neural network model for MRC first encodes the symbolic representation of the question and passage in an embedding space, then identify answers with particular attention functions in that space. In terms of the question and passage attention or matching strategy, we roughly categorize these attention-based models into two large groups: one-way attention and two-way attention.

In one-way attention model, question is first summarized into a single vector and then directly matched with the passage. Most of the end-to-end neural network methods on the cloze-style datasets are based on this model (Hermann et al., 2015; Kadlec et al., 2016; Chen et al., 2016; Dhingra et al., 2016). Hermann et al. are the first to apply the attention-based neural network methods to MRC task and introduce an attentive reader and an impatient reader (Hermann et al., 2015), by leveraging a two layer LSTM network. Chen et al. (Chen et al., 2016) further design a bilinear attention function based on the attentive reader, which shows superior performance on CNN/Daily Mail dataset. However, part of information may be lost when summarizing the question and a fine-grained attention on both the question and passage words should be more reasonable.

Therefore, the two-way attention model unfolds both the question and passage into respective word embeddings, and compute the attention in a two-dimensional matrix. Most of the top-ranking methods on SQuAD leaderboard are based on this attention mechanism (Wang et al., 2017; Huang et al., 2017; Xiong et al., 2017; Liu et al., 2017b,a). (Cui et al., 2016) and (Xiong et al., 2016) introduce the co-attention mechanism to better couple the representations of the question and document. Seo et al. propose a bi-directional attention flow network to capture the relevance at different levels of granularity (Seo et al., 2016). (Wang et al., 2017) further introduce the self-attention mechanism to refine the representation by matching the passage against itself, to better capture the global passage information. Huang et al. introduce a fully-aware attention mechanism with a novel *history-of-word* concept (Huang et al., 2017).

We propose a hierarchical attention network by leveraging both co-attention and self-attention mechanisms in different layers, which can capture the relevance between the question and passage at different levels of granularity. Different from the above methods, we further devise a fusion function to combine both the aligned representation and the original representation from the previous layer within each attention. In this way, the model can always focus on the right part of the passage, while keeping the global passage topic in mind.

3 Machine Comprehension Model

3.1 Task Description

Typical machine comprehension systems take an evidence text and a question as input, and predict a span within the evidence that answers the question. Based on this definition, given a passage and a question, the machine needs to first read and understand the passage, and then finds the answer to the question. The passage is described as a sequence of word tokens $\mathrm{P} = \left\{\mathrm{w}_t^P\right\}_{t=1}^{n}$ and the question is described as $\mathrm{Q} = \left\{\mathrm{w}_t^Q\right\}_{t=1}^{m}$, where n is the number of words in the passage, and m is the number of words in the question. In general, $\mathrm{n} \gg \mathrm{m}$. The answer can have different types depending on the task. In the SQuAD dataset (Rajpurkar et al., 2016), the answer A is guaranteed to be a continuous span in the passage P. The object function for machine reading comprehension is to learn a function $\mathrm{f(q,p)} = \arg\max_{\mathrm{a} \in \mathrm{A(p)}} \mathrm{P(a|q,p)}$. The training data is a set of the question, passage and answer tuples $< \mathrm{Q}, \mathrm{P}, \mathrm{A} >$.

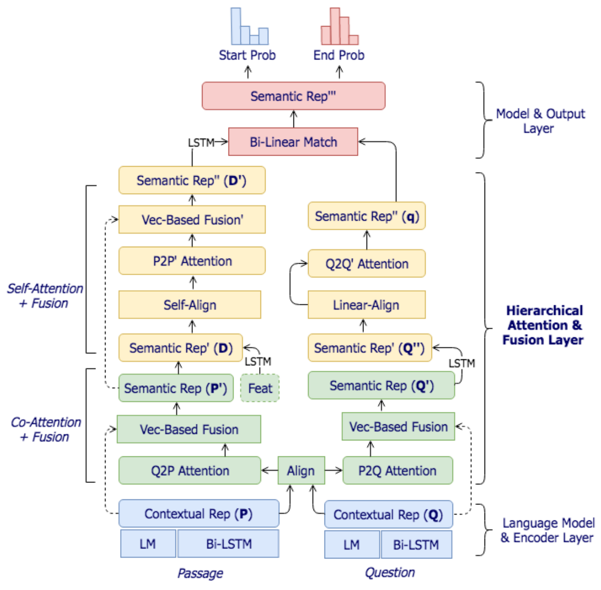

Figure 1: Hierarchical Attention Fusion Network.

3.2 Encode-Interaction-Pointer Framework

We will now describe our framework from the bottom up. As show in Figure 1, the proposed framework consists of four typical layers to learn different concepts of semantic representations:

- **Encoder Layer** as a language model, utilizes contextual cues from surrounding words to refine the embedding of the words. It converts the passage and question from tokens to semantic representation;
- **Attention Layer** attempts to capture relations between question and passage. Besides the aligned context, the contextual embeddings are also merged by a fusion function. Moreover, the multi-level of this operation forms a "working memory";
- **Match Layer** employs a bi-linear match function to compute the relevance between the question and passage representation on a span level;
- **Output Layer** uses a pointer network to search the answer span of question.

The main contribution of this work is the attention layer, in order to capture the relationship between question and passage, a hierarchical strategy is used to progressively make the answer boundary clear with the refined attention mechanism. A fine-grained fusion function is also introduced to better align the contextual representations from different levels. The detailed description of the model is provided as follows.

3.3 Hierarchical Attention Fusion Network

Our design is based on a simple but natural intuition: performing fine-grained mechanism requires first to roughly see the potential answer domain and then progressively locate the most discriminative parts of the domain.

The overall framework of our Hierarchical Attention Fusion Network is shown in Figure 1. It consists of several parts: a basic co-attention layer with shallow semantic fusion, a self-attention layer with deep semantic fusion and a memory-wise bilinear alignment function. The proposed network has two distinctive characteristics: (i) A fine-grained fusion approach to blend attention vectors for a better understanding of the relationship between question and passage; (ii) A multi-granularity attention mechanism applied at the word and sentence-level, enabling it to properly attend to the most important content when constructing the question and passage representation. Experiments conducted on SQuAD and adversarial example datasets (Jia and Liang, 2017) demonstrate that the proposed framework outperform previous methods by a large margin. Details of different components will be described in the following sections.

3.4 Language Model & Encoder Layer

Encoder layer of the model transform the discrete word tokens of question and passage to a sequence of continuous vector representations. We use a pre-trained word embedding model and a char embedding model to lay the foundation for our model. For the word embedding model, we adopt the popular glove embeddings (Pennington et al., 2014) which are widely used in deep learning-based NLP domain. For the char embedding model, the ELMo language model (Peters et al., 2018) is used due to its superior performance in a wide range of NLP tasks. As a result, we obtain two types of encoding vectors, i.e., word embeddings $\left\{\mathrm{e}_t^Q\right\}_{t=1}^m$, $\left\{\mathrm{e}_t^P\right\}_{t=1}^n$ and char embeddings $\left\{\mathrm{c}_t^Q\right\}_{t=1}^m$, $\left\{\mathrm{c}_t^P\right\}_{t=1}^n$.

To further utilize contextual cues from surrounding words to refine the embedding of the words, we then put a shared Bi-LSTM network on top of the embeddings provided by the previous layers to model the temporal interactions between words. Before feeding into the Bi-LSTM contextual network, we concat the word embeddings and char embeddings for a full understanding of each word. The final output of our encoder layer is shown as below,

$$\mathrm{u}_{\mathrm{t}}^{\mathrm{Q}} = \left[\mathrm{BiLSTM}_{\mathrm{Q}}([\mathrm{e}_{\mathrm{t}}^{\mathrm{Q}}, \mathrm{c}_{\mathrm{t}}^{\mathrm{Q}}]), \mathrm{c}_{\mathrm{t}}^{\mathrm{Q}}\right] \tag{1}$$

$$\mathrm{u}_{\mathrm{t}}^{\mathrm{P}} = \left[\mathrm{BiLSTM}_{\mathrm{P}}([\mathrm{e}_{\mathrm{t}}^{\mathrm{P}}, \mathrm{c}_{\mathrm{t}}^{\mathrm{P}}]), \mathrm{c}_{\mathrm{t}}^{\mathrm{P}}\right] \tag{2}$$

where we further concat the output of the contextual Bi-LSTM network with the pre-trained char embeddings for its good performance (Peters et al., 2018). This can be regarded as a residual connection between word representations in different levels.

3.5 Hierarchical Attention & Fusion Layer

The attention layer is responsible for linking and fusing information from the question and passage representation, which is the most critical in most MRC tasks. It aims to align the question and passage so that we can better locate on the most relevant passage span with respect to the question. We propose a hierarchical attention structure by combining the co-attention and self-attention mechanism in a multi-hop style. Besides, we think that the original representation and the aligned representation via attention can reflect the content semantics in different granularities. Therefore, we also apply a particular fusion function after each attention function, so that different levels of semantics can be better incorporated towards a better understanding.

3.5.1 Co-attention & Fusion

Given the question and passage representation $\mathrm{u}_{\mathrm{t}}^{\mathrm{Q}}$ and $\mathrm{u}_{\mathrm{t}}^{\mathrm{P}}$, a soft-alignment matrix S has been built to calculate the shallow semantic similarity between question and passage as follows:

$$\mathrm{S}_{\mathrm{ij}} = \mathrm{Att}(\mathrm{u}_{\mathrm{t}}^{\mathrm{Q}}, \mathrm{u}_{\mathrm{t}}^{\mathrm{P}}) = \mathrm{ReLU}(\mathrm{W}_{\mathrm{lin}}^{\top}\mathrm{u}_{\mathrm{t}}^{\mathrm{Q}})^{\top} \cdot \mathrm{ReLU}(\mathrm{W}_{\mathrm{lin}}^{\top}\mathrm{u}_{\mathrm{t}}^{\mathrm{P}}) \tag{3}$$

where $\mathrm{W}_{\mathrm{lin}}$ is a trainable weight matrix.

This decomposition avoids the quadratic complexity that is trivially parallelizable (Parikh et al., 2016). Now we use the unnormalized attention weights S_{ij} to compute the attentions between question and passage, which is further used to obtain the attended vectors in passage to question and question to passage direction, respectively.

P2Q Attention signifies which question words are most relevant to each passage word, given as below:

$$\alpha_{\mathrm{j}} = \mathrm{softmax}(\mathrm{S}_{:\mathrm{j}}) \tag{4}$$

where α_{j} represents the attention weights on the question words.

The aligned passage representation from question $\mathrm{Q} = \left\{\mathrm{u}_{\mathrm{t}}^{\mathrm{Q}}\right\}_{\mathrm{t}=1}^{\mathrm{m}}$ can thus be derived as,

$$\tilde{\mathrm{Q}}_{:\mathrm{t}} = \sum_{\mathrm{j}} \alpha_{\mathrm{tj}} \cdot \mathrm{Q}_{:\mathrm{j}}, \forall \mathrm{j} \in [1, ..., \mathrm{m}] \tag{5}$$

Q2P Attention signifies which passage words have the closest similarity to one of the question words and are hence critical for answering the question.

We utilize the same way to calculate this attention as in the passage to question attention (P2Q), except for that in the opposite direction:

$$\beta_{\mathrm{i}} = \mathrm{softmax}(\mathrm{S}_{\mathrm{i}:}) \tag{6}$$

$$\tilde{\mathrm{P}}_{\mathrm{k}:} = \sum_{\mathrm{i}} \beta_{\mathrm{ik}} \cdot \mathrm{P}_{\mathrm{i}:}, \forall \mathrm{i} \in [1, ..., \mathrm{n}] \tag{7}$$

where $\tilde{\mathrm{P}}$ indicates the weighted sum of the most important words in the passage with respect to the question.

With the aligned passage and question representations $\tilde{\mathrm{Q}}$ and $\tilde{\mathrm{P}}$ derived, a particular fusion unit has been designed to combine the original contextual representations and the corresponding attention vectors for question and passage separately:

$$\mathrm{P}' = \mathrm{Fuse}(\mathrm{P}, \tilde{\mathrm{Q}}) \tag{8}$$

$$\mathrm{Q}' = \mathrm{Fuse}(\mathrm{Q}, \tilde{\mathrm{P}}) \tag{9}$$

where $\mathrm{Fuse}(\cdot,\cdot)$ is a typical fusion kernel.

The simplest way of fusion is a concatenation or addition of the two representations, followed by some linear or non-linear transformation. Recently, a heuristic matching trick with difference and element-wise product is found effective in combining different representations (Mou et al., 2016; Chen et al., 2017b):

$$\mathrm{m}(\mathrm{P}, \tilde{\mathrm{Q}}) = \tanh(\mathrm{W}_{\mathrm{f}}[\mathrm{P}; \tilde{\mathrm{Q}}; \mathrm{P} \circ \tilde{\mathrm{Q}}; \mathrm{P} - \tilde{\mathrm{Q}}] + \mathrm{b}_{\mathrm{f}}) \tag{10}$$

where $\circ$ denotes the element-wise product, and W_{f}, b_{f} are trainable parameters. The output dimension is projected back to the same size as the original representation P or Q via the projected matrix W_{f}.

Since we find that the original contextual representations are important in reflecting the semantics at a more global level, we also introduce different levels of gating mechanism to incorporate the projected representations $\mathrm{m}(\cdot, \cdot)$ with the original contextual representations. As a result, the final fused representations of passage and question can be formulated as:

$$\mathrm{P}' = \mathrm{g}(\mathrm{P}, \tilde{\mathrm{Q}}) \cdot \mathrm{m}(\mathrm{P}, \tilde{\mathrm{Q}}) + (1 - \mathrm{g}(\mathrm{P}, \tilde{\mathrm{Q}})) \cdot \mathrm{P} \quad (11)$$

$$\mathrm{Q}' = \mathrm{g}(\mathrm{Q}, \tilde{\mathrm{P}}) \cdot \mathrm{m}(\mathrm{Q}, \tilde{\mathrm{P}}) + (1 - \mathrm{g}(\mathrm{Q}, \tilde{\mathrm{P}})) \cdot \mathrm{Q} \quad (12)$$

where $\mathrm{g}(\cdot, \cdot)$ is a gating function. To capture the relation between the representations in different granularities, we also design a scalar-based, a vector-based and a matrix-based sigmoid gating function, which are compared in Section 4.5.

3.5.2 Self-attention & Fusion

Borrowing the idea from wide and deep network (Cheng et al., 2016), manual features have also been added to combine with the outputs of previous layer for a more comprehensive representation. In our model, these features are concatenated with the refined question-aware passage representation as below:

$$\mathrm{D} = \mathrm{BiLSTM}([\mathrm{P}'; \mathrm{feat}_{\mathrm{man}}]) \quad (13)$$

where $\mathrm{feat}_{\mathrm{man}}$ denotes the word-level manual passage features.

In this layer, we separately consider the semantic representations of question and passage, and further refine the obtained information from the co-attention layer. Since fusing information among context words allows contextual information to flow close to the correct answer, the self-attention layer is used to further align the question and passage representation against itself, so as to keep the global sequence information in memory. Benefiting from the advantage of self-alignment attention in addressing the long-distance dependence (Wang et al., 2017), we adopt a self-alignment fusion process in this level. To allow for more freedom of the aligning process, we introduce a bilinear self-alignment attention function on the passage representation:

$$\mathrm{L} = \mathrm{softmax}(\mathrm{D} \cdot \mathrm{W}_1 \cdot \mathrm{D}^\top) \quad (14)$$

$$\tilde{\mathrm{D}} = \mathrm{L} \cdot \mathrm{D} \quad (15)$$

Another fusion function $\mathrm{Fuse}(\cdot, \cdot)$ is again adopted to combine the question-aware passage representation D and self-aware representation $\tilde{\mathrm{D}}$, as below:

$$\mathrm{D}' = \mathrm{Fuse}(\mathrm{D}, \tilde{\mathrm{D}}) \quad (16)$$

Finally, a bidirectional LSTM is used to get the final contextual passage representation:

$$\mathrm{D}'' = \mathrm{BiLSTM}(\mathrm{D}') \quad (17)$$

As for question side, since it is generally shorter in length and could be adequately represented with less information, we follow the question encoding method used in (Chen et al., 2017a) and adopt a linear transformation to encode the question representation to a single vector.

First, another contextual bidirectional LSTM network is applied on top of the fused question representation: $\mathrm{Q}'' = \mathrm{BiLSTM}(\mathrm{Q}')$. Then we aggregate the resulting hidden units into one single question vector, with a linear self-alignment:

$$\gamma = \mathrm{softmax}(\mathbf{w}_\mathrm{q}^\top \cdot \mathrm{Q}'') \quad (18)$$

$$\mathbf{q} = \sum_\mathrm{j} \gamma_\mathrm{j} \cdot \mathrm{Q}''_{:\mathrm{j}}, \forall \mathrm{j} \in [1, ..., \mathrm{m}] \quad (19)$$

where $\mathbf{w}_\mathrm{q}$ is a weight vector to learn, we self-align the refined question representation to a single vector according to the question self-attention weight, which can be further used to compute the matching with the passage words.

3.6 Model & Output Layer

Instead of predicting the start and end positions based only on D'', a top-level bilinear match function is used to capture the semantic relation between question $\mathbf{q}$ and paragraph D'' in a matching style, which actually works as a multi-hop matching mechanism.

Different from the co-attention layer that generates coarse candidate answers and the self-attention layer that focus the relevant context of passage to a certain intent of question, the top model layer uses a bilinear matching function to capture the interaction between outputs from previous layers and finally locate on the right answer span.

The start and end distribution of the passage words are calculated in a bilinear matching way as below,

$$\mathrm{P}_{\mathrm{start}} = \mathrm{softmax}(\mathbf{q} \cdot \mathrm{W}_\mathrm{s}^\top \cdot \mathrm{D}'') \quad (20)$$

$$\mathrm{P}_{\mathrm{end}} = \mathrm{softmax}(\mathbf{q} \cdot \mathrm{W}_\mathrm{e}^\top \cdot \mathrm{D}'') \quad (21)$$

where W_s and W_e are trainable matrices of the bilinear match function.

The output layer is application-specific, in MRC task, we use pointer networks to predict the start and end position of the answer, since it requires the model to find the sub-phrase of the passage to answer the question.

In training process, with cross entropy as metric, the loss for start and end position is the sum of the negative log probabilities of the true start and end indices by the predicted distributions, averaged over all examples:

$$\mathrm{L}(\theta) = -\frac{1}{\mathrm{N}}\sum_{\mathrm{i}}^{\mathrm{N}} \log \mathrm{p_s}(\mathrm{y_i^s}) + \log \mathrm{p_e}(\mathrm{y_i^e}) \quad (22)$$

where θ is the set of all trainable weights in the model, and $\mathrm{p_s}$ is the probability of start index, $\mathrm{p_e}$ is the probability of end index, respectively. $\mathrm{y_i^s}$ and $\mathrm{y_i^e}$ are the true start and end indices.

During prediction, we choose the answer span with the maximum value of $\mathrm{p_s} \cdot \mathrm{p_e}$ under a constraint that $\mathrm{s} \le \mathrm{e} \le \mathrm{s} + 15$, which is selected via a dynamic programming algorithm in linear time.

4 Experiments

In this section, we first present the datasets used for evaluation. Then we compare our end-to-end Hierarchical Attention Fusion Networks with existing machine reading models. Finally, we conduct experiments to validate the effectiveness of our proposed components. We evaluate our model on the task of question answering using recently released SQuAD and TriviaQA Wikipedia (Joshi et al., 2017), which have gained a huge attention over the past year. An adversarial evaluation for the Stanford Question Answering SQuAD is also used to demonstrate the robust of our model under adversarial attacks (Jia and Liang, 2017).

4.1 Dataset

We focus on the SQuAD dataset to train and evaluate our model. SQuAD is a popular machine comprehension dataset consisting of 100,000+ questions created by crowd workers on 536 Wikipedia articles. Each context is a paragraph from an article and the answer to each question is guaranteed to be a span in the context. The answer to each question is always a span in the context. The model is given a credit if its answer matches one of the human chosen answers. Two metrics are used to evaluate the model performance: Exact Match (EM) and a softer metric F1 score, which measures the weighted average of the precision and recall rate at a character level.

Table 1: The performance of our SLQA model and competing approaches on SQuAD.

	Dev Set	Test Set
Single model	**EM / F1**	**EM / F1**
LR Baseline (Rajpurkar et al., 2016)	40.0 / 51.0	40.4 / 51.0
Match-LSTM (Wang and Jiang, 2016)	64.1 / 73.9	64.7 / 73.7
DrQA (Chen et al., 2017a)	- / -	70.7 / 79.4
DCN+ (Xiong et al., 2017)	74.5 / 83.1	75.1 / 83.1
Interactive AoA Reader+ (Cui et al., 2016)	- / -	75.8 / 83.8
FusionNet (Huang et al., 2017)	- / -	76.0 / 83.9
SAN (Liu et al., 2017b)	76.2 / 84.0	76.8 / 84.4
AttentionReader+ (unpublished)	- / -	77.3 / 84.9
BiDAF + Self Attention + ELMo (Peters et al., 2018)	- / -	78.6 / 85.8
r-net+ (Wang et al., 2017)	- / -	79.9 / 86.5
SLQA+	**80.0 / 87.0**	**80.4 / 87.0**
Ensemble model		
FusionNet (Huang et al., 2017)	- / -	78.8 / 85.9
DCN+ (Xiong et al., 2017)	- / -	78.9 / 86.0
Interactive AoA Reader+ (Cui et al., 2016)	- / -	79.0 / 86.4
SAN (Liu et al., 2017b)	78.6 / 85.9	79.6 / 86.5
BiDAF + Self Attention + ELMo (Peters et al., 2018)	- / -	81.0 / 87.4
AttentionReader+ (unpublished)	- / -	81.8 / 88.2
r-net+ (Wang et al., 2017)	- / -	82.6 / 88.5
SLQA+	**82.0 / 88.4**	**82.4 / 88.6**
Human Performance	80.3 / 90.5	82.3 / 91.2

TriviaQA is a newly available machine comprehension dataset consisting of over 650K context-query-answer triples. The contexts are automatically generated from either Wikipedia or Web search results. The length of contexts in TriviaQA (average 2895 words) is much more longer than the one in SQuAD (average 122 words).

4.2 Training Details

We use the AdaMax optimizer, with a mini-batch size of 32 and initial learning rate of 0.002. A dropout rate of 0.4 is used for all LSTM layers. To directly optimize our target against the evaluation metrics, we further fine-tune the model with some well-defined strategy. During fine-tuning, Focal Loss (Lin et al., 2017) and Reinforce Loss which take F1 score as reward are incorporated with Cross Entropy Loss. The training process takes roughly 20 hours on a single Nvidia Tesla M40 GPU. We also train an ensemble model consisting of 15 training runs with the identical framework and hyper-parameters. At test time, we choose the answer with the highest sum of confidence scores amongst the 15 runs for each question.

4.3 Main Results

The results of our model and competing approaches on the hidden test set are summarized in Table 1. The proposed SLQA+ ensemble model achieves an EM score of 82.4 and F1 score of 88.6, outperforming all previous approaches, which validates the effectiveness of our hierarchical attention and fusion network structure.

We also conduct experiments on the adversarial

Table 2: The F1 scores of different models on AddSent and AddOneSent datasets (S: Single Model, E: Ensemble).

Model	**AddSent**	**AddOneSent**
Logistic (Rajpurkar et al., 2016)	23.2	30.4
Match-S (Wang and Jiang, 2016)	27.3	39.0
Match-E (Wang and Jiang, 2016)	29.4	41.8
BiDAF-S (Seo et al., 2016)	34.3	45.7
BiDAF-E (Seo et al., 2016)	34.2	46.9
ReasoNet-S (Shen et al., 2017)	39.4	50.3
ReasoNet-E (Shen et al., 2017)	39.4	49.8
Mnemonic-S (Hu et al., 2017)	46.6	56.0
Mnemonic-E (Hu et al., 2017)	46.2	55.3
QANet-S (Yu et al., 2018)	45.2	55.7
FusionNet-E (Huang et al., 2017)	51.4	60.7
SLQA-S (our)	**52.1**	**62.7**
SLQA-E (our)	**54.8**	**64.2**

SQuAD dataset (Jia and Liang, 2017) to study the robustness of the proposed model. In the dataset, one or more sentences are appended to the original SQuAD context, aiming to mislead the trained models. We use exactly the same model as in our SQuAD dataset, the performance comparison result is shown in Table 2. It can be seen that the proposed model can still get superior results than all the other competing approaches.

4.4 Ablations

In order to evaluate the individual contribution of each model component, we run an ablation study. Table 3 shows the performance of our model and its ablations on SQuAD dev set. The bi-linear alignment plus fusion between passage and question is most critical to the performance on both metrics which results in a drop of nearly 15%. The reason may be that in top-level attention layer, the similar semantics between question and passage are strong evidence to locate the correct answer span. The ELMo accounts for about 5% of the performance degradation, which clearly shows the effectiveness of language model. We conjecture that language model layer efficiently encodes different types of syntactic and semantic information about words-in-context, and improves the task performance. To evaluate the performance of hierarchical architecture, we reduce the multi-hop fusion with the standard LSTM network. The result shows that multi-hop fusion outperforms the standard LSTM by nearly 5% on both metrics.

4.5 Fusion Functions

In this section, we experimentally demonstrate how different choices of the fusion kernel impact the performance of our model. The compared fusion kernels are described as follows:

Simple Concat: a simple concatenation of two channel inputs.

Table 3: Ablation tests of SLQA single model on the SQuAD dev set.

SLQA single model	**EM / F1**
SLQA+	**80.0 / 87.0**
-Manual Features	79.2 / 86.2
-Language Embedding (ELMo)	77.6 / 84.9
-Self Matching	79.5 / 86.4
-Multi-hop	79.1 / 86.1
-Bi-linear Match	65.4 / 72.0
-Fusion (simple concat)	78.8 / 85.8
-Fusion, -Multi-hop	77.5 / 84.8
-Fusion, -Bi-linear Match	63.1 / 69.6

Table 4: Comparison of different fusion kernels on the SQuAD dev set.

Fusion Kernel	**EM / F1**
Simple Concat	78.8 / 85.8
Add Full Projection (FPU)	79.1 / 86.1
Scalar-based Fusion (SFU)	79.5 / 86.5
Vector-based Fusion (VFU)	**80.0 / 87.0**
Matrix-based Fusion (MFU)	79.8 / 86.8

Full Projection: the heuristic matching and projecting function as in Equ. 10.

Scalar-based Fusion: the gating function is a trainable scalar parameter (a coarse fusion level):

$$\mathrm{g}(\mathrm{P}, \tilde{\mathrm{Q}}) = \mathrm{g}_{\mathrm{p}} \tag{23}$$

where g_{p} is a trainable scalar parameter.

Vector-based Fusion: the gating function contains a weight vector to learn, which acts as a one-dimensional sigmoid gating,

$$\mathrm{g}(\mathrm{P}, \tilde{\mathrm{Q}}) = \sigma(\mathbf{w}_{\mathrm{g}}^{\top} \cdot [\mathrm{P}; \tilde{\mathrm{Q}}; \mathrm{P} \circ \tilde{\mathrm{Q}}; \mathrm{P} - \tilde{\mathrm{Q}}] + \mathrm{b}_{\mathrm{g}}) \tag{24}$$

where $\mathbf{w}_{\mathrm{g}}$ is trainable weight vector, b_{g} is trainable bias, and σ is sigmoid function.

Matrix-based Fusion: the gating function contains a weight matrix to learn, which acts as a two-dimensional sigmoid gating,

$$\mathrm{g}(\mathrm{P}, \tilde{\mathrm{Q}}) = \sigma(\mathrm{W}_{\mathrm{g}}^{\top} \cdot [\mathrm{P}; \tilde{\mathrm{Q}}; \mathrm{P} \circ \tilde{\mathrm{Q}}; \mathrm{P} - \tilde{\mathrm{Q}}] + \mathrm{b}_{\mathrm{g}}) \tag{25}$$

where W_{g} is a trainable weight matrix.

The comparison results of different fusion kernels can be found in Table 4. We can see that different fusion methods contribute differently to the final performances, and the vector-based fusion method performs best, with a moderate parameter size.

4.6 Attention Hierarchy and Function

In the proposed model, attention layer is the most important part of the framework. At the bottom of Table 5 we show the performances on SQuAD

Table 5: Comparison of different attention styles on the SQuAD dev set.

Attention Hierarchy	EM / F1
1-layer attention (only qp co-attention)	61.9 / 68.4
2-layer attention (add self-attention)	65.4 / 71.7
3-layer attention (add bilinear match)	**80.0 / 87.0**
Attention Function	EM / F1
dot product	62.9 / 69.3
linear attention	78.0 / 84.9
bilinear attention (linear + relu)	**80.0 / 87.0**
trilinear attention	78.9 / 85.8

Table 6: Published and unpublished results on the TriviaQA wikipedia leaderboard.

	Full	Verified
Model	EM / F1	EM / F1
BiDAF (Seo et al., 2016)	40.26 / 45.74	47.47 / 53.70
MEMEN (Pan et al., 2017)	43.16 / 46.90	49.28 / 55.83
M-Reader (Hu et al., 2017)	46.94 / 52.85	54.45 / 59.46
QANet (Yu et al., 2018)	51.10 / 56.60	53.30 / 59.20
document-qa (Clark and Gardner, 2017)	63.99 / 68.93	67.98 / 72.88
dirkweissenborn (unpublished)	64.60 / 69.90	72.77 / 77.44
SLQA-Single	**66.56 / 71.39**	**74.83 / 78.74**

for four common attention functions. Empirically, we find bilinear attention which add ReLU after linearly transforming does significantly better than the others.

At the top of Table 5 we show the effect of varying the number of attention layers on the final performance. We see a steep and steady rise in accuracy as the number of layers is increased from N = 1 to 3.

4.7 Experiments on TriviaQA

To further examine the robustness of the proposed model, we also test the model performance on TriviaQA dataset. The test performance of different methods on the leaderboard (on Jan. 12th 2018) is shown in Table 6. From the results, we can see that the proposed model can also obtain state-of-the-art performance in the more complex TriviaQA dataset.

5 Conclusions

We introduce a novel hierarchical attention network, a state-of-the-art reading comprehension model which conducts attention and fusion horizontally and vertically across layers at different levels of granularity between question and paragraph. We show that our proposed method is very powerful and robust, which outperforms the previous state-of-the-art methods in various large-scale golden MRC datasets: SQuAD, TriviaQA, AddSent and AddOneSent.

Abstract

While sophisticated neural-based techniques have been developed in reading comprehension, most approaches model the answer in an independent manner, ignoring its relations with other answer candidates. This problem can be even worse in open-domain scenarios, where candidates from multiple passages should be combined to answer a single question. In this paper, we formulate reading comprehension as an extract-then-select two-stage procedure. We first extract answer candidates from passages, then select the final answer by combining information from all the candidates. Furthermore, we regard candidate extraction as a latent variable and train the two-stage process jointly with reinforcement learning. As a result, our approach has improved the state-of-the-art performance significantly on two challenging open-domain reading comprehension datasets. Further analysis demonstrates the effectiveness of our model components, especially the information fusion of all the candidates and the joint training of the extract-then-select procedure.

1 Introduction

Teaching machines to read and comprehend human languages is a long-standing objective in natural language processing. In order to evaluate this ability, reading comprehension (RC) is designed to answer questions through reading relevant passages. In recent years, RC has attracted intense interest. Various advanced neural models have been proposed along with newly released datasets (Hermann et al., 2015; Rajpurkar et al., 2016; Dunn et al., 2017; Dhingra et al., 2017b; He et al., 2017).

Q A	Cocktails: *Rum*, *lime*, and *cola* drink make a __________. **Cuba Libre**
P_1	**Daiquiri**, the custom of mixing *lime* with *rum* for a cooling drink on a hot Cuban day, has been around a long time.
P_2	Cocktail recipe for a **Daiquiri**, a classic *rum* and *lime* drink that every bartender should know.
P_3	Hemingway Special **Daiquiri**: Daiquiris are a family of cocktails whose main ingredients are *rum* and *lime* juice.
P_4	A homemade Cuba Libre Preparation To make a **Cuba Libre** properly, fill a highball glass with ice and half fill with *cola*.
P_5	The difference between the **Cuba Libre** and *Rum* is a *lime* wedge at the end.

Table 1: The answer candidates are in a **bold** font. The key information is marked in *italic*, which should be combined from different text pieces to select the correct answer "Cuba Libre".

Most existing approaches mainly focus on modeling the interactions between questions and passages (Dhingra et al., 2017a; Seo et al., 2017; Wang et al., 2017), paying less attention to information concerning answer candidates. However, when human solve this problem, we often first read each piece of text, collect some answer candidates, then focus on these candidates and combine their information to select the final answer. This collect-then-select process can be more significant in open-domain scenarios, which require the combination of candidates from multiple passages to answer one single question. This phenomenon is illustrated by the example in Table 1.

With this motivation, we formulate an extract-then-select two-stage architecture to simulate the above procedure. The architecture contains two components: (1) an extraction model, which generates answer candidates, (2) a selection model, which combines all these candidates and finds out the final answer. However, answer candidates to be focused on are often unobservable, as most RC datasets only provide golden answers. Therefore, we treat candidate extraction as a latent variable and train these two stages jointly with reinforcement learning (RL).

In conclusion, our work makes the following contributions:

1. We formulate open-domain reading comprehension as a two-stage procedure, which first extracts answer candidates and then selects the final answer. With joint training, we optimize these two correlated stages as a whole.

2. We propose a novel answer selection model, which combines the information from all the extracted candidates using an attention-based correlation matrix. As shown in experiments, the information fusion is greatly helpful for answer selection.

3. With the two-stage framework and the joint training strategy, our method significantly surpasses the state-of-the-art performance on two challenging public RC datasets Quasar-T (Dhingra et al., 2017b) and SearchQA (Dunn et al., 2017).

2 Related Work

In recent years, reading comprehension has made remarkable progress in methodology and dataset construction. Most existing approaches mainly focus on modeling sophisticated interactions between questions and passages, then use the pointer networks (Vinyals et al., 2015) to directly model the answers (Dhingra et al., 2017a; Wang and Jiang, 2017; Seo et al., 2017; Wang et al., 2017). These methods prove to be effective in existing close-domain datasets (Hermann et al., 2015; Hill et al., 2015; Rajpurkar et al., 2016).

More recently, open-domain RC has attracted increasing attention (Nguyen et al., 2016; Dunn et al., 2017; Dhingra et al., 2017b; He et al., 2017) and raised new challenges for question answering techniques. In these scenarios, a question is paired with multiple passages, which are often collected by exploiting unstructured documents or web data. Aforementioned approaches often rely on recurrent neural networks and sophisticated attentions, which are prohibitively time-consuming if passages are concatenated altogether. Therefore, some work tried to alleviate this problem in a coarse-to-fine schema. Wang et al. (2018a) combined a ranker for selecting the relevant passage and a reader for producing the answer from it. However, this approach only depended on one passage when producing the answer, hence put great demands on the precisions of both components. Worse still, this framework cannot handle the situation where multiple passages are needed to answer correctly. In consideration of evidence aggregation, Wang et al. (2018b) proposed a re-ranking method to resolve the above issue. However, their re-ranking stage was totally isolated from the candidate extraction procedure. Being different from the re-ranking perspective, we propose a novel selection model to combine the information from all the extracted candidates. Moreover, with reinforcement learning, our candidate extraction and answer selection models can be learned in a joint manner. Trischler et al. (2016) also proposed a two-step extractor-reasoner model, which first extracted K most probable single-token answer candidates and then compared the hypotheses with all the sentences in the passage. However, in their work, each candidate was considered isolatedly, and their objective only took into account the ground truths compared with our RL treatment.

The training strategy employed in our paper is reinforcement learning, which is inspired by recent work exploiting it into question answering problem. The above mentioned coarse-to-fine framework (Choi et al., 2017; Wang et al., 2018a) treated sentence selection as a latent variable and jointly trained the sentence selection module with the answer generation module via RL. Shen et al. (2017) modeled the multi-hop reasoning procedure with a termination state to decide when it is adequate to produce an answer. RL is suitable to capture this stochastic behavior. Hu et al. (2018) merely modeled the extraction process, using F1 as rewards in addition to maximum likelihood estimation. RL was utilized in their training process, as the F1 measure is not differentiable.

3 Two-stage RC Framework

In this work, we mainly consider the open-domain extractive reading comprehension. In this scenario, a given question Q is paired with multiple passages $\mathbb{P} = \{P_1, P_2, ..., P_N\}$, based on which we aim to find out the answer A. Moreover, the golden answers are almost subspans shown in

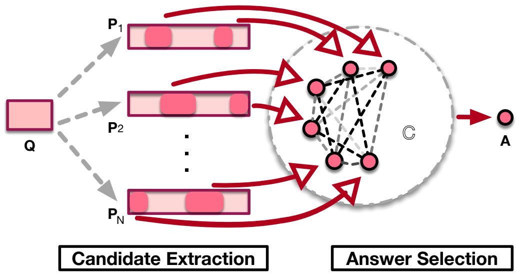

Figure 1: Two-stage RC Framework. The first part extracts candidates (denoted with circles) from all the passages. The second part establishes interactions among all these candidates to select the final answer. The different gray scales of dashed lines between candidates represent different intensities of interactions.

some passages in $\mathbb{P}$. Our main framework consists of two parts, which are: (1) extracting answer candidates $\mathbb{C} = \{C_1, C_2, ..., C_M\}$ from passages $\mathbb{P}$ and (2) selecting the final answer A from candidates $\mathbb{C}$. This process is illustrated in Figure 1. We design different models for each part and optimize them as a whole with joint reinforcement learning.

3.1 Candidate Extraction

We build candidate set $\mathbb{C}$ by independently extracting K candidates from each passage P_i according to the following distribution:

$$\begin{aligned} p(\mathbb{C}|Q,\mathbb{P}) &= \prod_i^N p(\{C_{ij}\}_{j=1}^K|Q,P_i) \\ \mathbb{C} &= \bigcup_{i=1}^N \{C_{ij}\}_{j=1}^K \end{aligned} \tag{1}$$

where C_{ij} denotes the jth candidate extracted from the ith passage. K is set as a constant number in our formulation. Taking K as 2 for an example, we denote each probability shown on the right side of Equation 1 through sampling without replacement:

$$\begin{aligned} p(\{C_{i1},C_{i2}\}) &= p(C_{i1})p(C_{i2})/(1-p(C_{i1})) \\ &+ p(C_{i1})p(C_{i2})/(1-p(C_{i2})) \end{aligned} \tag{2}$$

where we neglect Q, P_i to abbreviate the conditional distributions in Equation 1.

Consequently, the basic block of our candidate extraction stage turns out to be the distribution of each candidate $P(C_{ij}|Q,P_i)$. In the rest of this subsection, we will elaborate on the model architecture concerning candidate extraction, which is displayed in Figure 2.

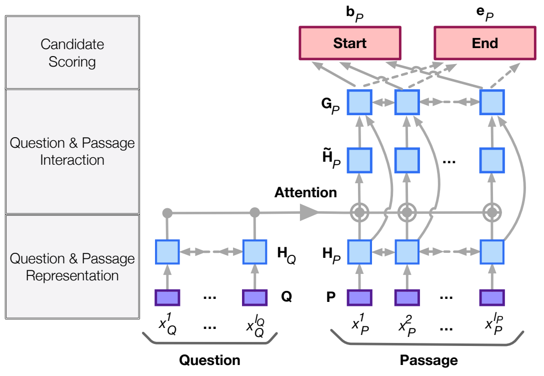

Figure 2: Candidate Extraction Model Architecture.

Question & Passage Representation Firstly, we embed the question $Q = \{x_Q^k\}_{k=1}^{l_Q}$ and its relevant passage $P = \{x_P^t\}_{t=1}^{l_P} \in \mathbb{P}$ with word vectors to form $\mathbf{Q} \in \mathbb{R}^{d_w \times l_Q}$ and $\mathbf{P} \in \mathbb{R}^{d_w \times l_P}$ respectively, where d_w is the dimension of word embeddings, l_Q and l_P are the length of Q and P.

We then feed $\mathbf{Q}$ and $\mathbf{P}$ to a bidirectional LSTM to form their contextual representations $\mathbf{H}_Q \in \mathbb{R}^{d_h \times l_Q}$ and $\mathbf{H}_P \in \mathbb{R}^{d_h \times l_P}$:

$$\begin{aligned} \mathbf{H}_Q &= \text{BiLSTM}(\mathbf{Q}) \\ \mathbf{H}_P &= \text{BiLSTM}(\mathbf{P}) \end{aligned} \tag{3}$$

Question & Passage Interaction Modeling the interactions between questions and passages is a critical step in reading comprehension. Here, we adopt the attention mechanism similar to (Lee et al., 2016) to generate question-dependent passage representation $\widetilde{\mathbf{H}}_P$. Assume $\mathbf{H}_Q = \{\mathbf{h}_Q^k\}_{k=1}^{l_Q}$, $\mathbf{H}_P = \{\mathbf{h}_P^t\}_{t=1}^{l_P}$, we have:

$$\begin{aligned} \alpha_{tk} &= \frac{e^{\mathbf{h}_Q^k \cdot \mathbf{h}_P^t}}{\sum_{k=1}^{l_Q} e^{\mathbf{h}_Q^k \cdot \mathbf{h}_P^t}} \quad 1 \le k \le l_Q, 1 \le t \le l_P \\ \widetilde{\mathbf{h}}_P^t &= \sum_{k=1}^{l_Q} \alpha_{tk}\mathbf{h}_Q^k \quad 1 \le t \le l_P \\ \widetilde{\mathbf{H}}_P &= \{\widetilde{\mathbf{h}}_P^t\}_{t=1}^{l_P} \end{aligned} \tag{4}$$

After concatenating two kinds of passage representations $\mathbf{H}_P$ and $\widetilde{\mathbf{H}}_P$, we use another bidirectional LSTM to get the final representation of every position in passage P as $\mathbf{G}_P \in \mathbb{R}^{d_g \times l_P}$:

$$\mathbf{G}_P = \text{BiLSTM}([\mathbf{H}_P; \widetilde{\mathbf{H}}_P]) \tag{5}$$

Candidate Scoring Then we use two linear transformations $\mathbf{w}_b \in \mathbb{R}^{1\times d_g}$ and $\mathbf{w}_e \in \mathbb{R}^{1\times d_g}$ to calculate the begin and the end scores for each position:

$$\begin{aligned}\{b_P^t\}_{t=1}^{l_Q} &= \mathbf{b}_P = \mathbf{w}_b\mathbf{G}_P \\ \{e_P^t\}_{t=1}^{l_Q} &= \mathbf{e}_P = \mathbf{w}_e\mathbf{G}_P\end{aligned} \tag{6}$$

At last, we model the probability of every subspan in passage P as a candidate $C = \{x_P^t\}_{t=C_b}^{C_e}$ according to its begin and end position:

$$p(C|Q,P) = \frac{exp(b_P^{C_b} + e_P^{C_e})}{\sum_{k=1}^{l_P}\sum_{t=k}^{l_P} exp(b_P^k + e_P^t)} \tag{7}$$

In this definition, the probabilities of all the valid answer candidates are already normalized.

3.2 Answer Selection

As the second part of our framework, the answer selection model finds out the most probable answer by calculating $p(C|Q,\mathbb{P},\mathbb{C})$ for each candidate $C \in \mathbb{C}$. The model architecture is illustrated in Figure 3.

Notably, selection model receives candidate set $\mathbb{C}$ as additional information. This more focused information allows the model to combine evidences from all the candidates, which would be useful for selecting the best answer.

For ease of understanding, we briefly describe the selection stage as follows. After being extracted from a single passage, a candidate borrows information from other candidates across different passages. With this global information, the passage is reread to confirm the correctness of the candidate further. The following are details about the selection model.

Question Representation Questions are fundamental for finding out the correct answer. As did for the extraction model, we embed the question Q with word vectors to form $\mathbf{Q} \in \mathbb{R}^{d_w \times l_Q}$. Then we use a bidirectional LSTM to establish its contextual representation:

$$\mathbf{S}_q = \text{BiLSTM}(\mathbf{Q}) \tag{8}$$

A max-pooling operation across all the positions is followed to get the condensed vector representation:

$$\mathbf{r}_q = \text{MaxPooling}(\mathbf{S}_q) \tag{9}$$

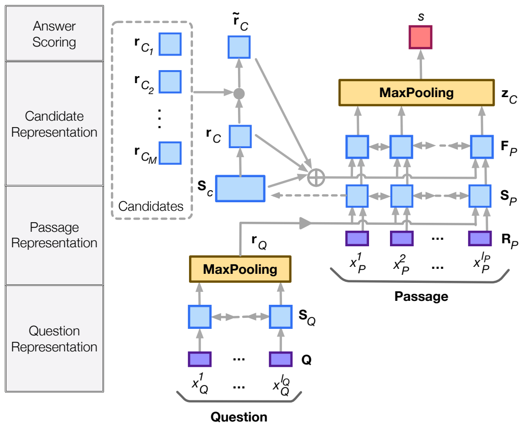

Figure 3: Answer Selection Model Architecture.

Passage Representation Assume the candidate C is extracted from the passage $P \in \mathbb{P}$. To be informed of C, we first build the representation of P. For every word in P, three kinds of features are utilized:

- Word embedding: each word expresses its basic feature with the word vector.
- Common word: the feature has value 1 when the word occurs in the question, otherwise 0.
- Question independent representation: the condensed representation $\mathbf{r}_q$.

With these features, information not only in Q but also in P is considered. By concatenating them, we get $\mathbf{r}_P^t$ corresponding to every position t in passage P. Then with another bidirectional LSTM, we fuse these features to form the contextual representation of P as $\mathbf{S}_P \in \mathbb{R}^{d_s \times l_P}$:

$$\begin{aligned}\mathbf{R}_P &= \{\mathbf{r}_P^t\}_{t=1}^{l_P} \\ \mathbf{S}_P &= \text{BiLSTM}(\mathbf{R}_P)\end{aligned} \tag{10}$$

Candidate Representation Candidates provide more focused information for answer selection. Therefore, for each candidate, we first build its independent representation according to its position in the passage, then construct candidates fused representation through combination of other correlated candidates.

Given the candidate $C = \{x_P^t\}_{t=C_b}^{C_e}$ in the passage P, we extract its corresponding span from $\mathbf{S}_P = \{\mathbf{s}_P^t\}_{t=1}^{l_P}$ to form $\mathbf{S}_C = \{\mathbf{s}_P^t\}_{t=C_b}^{C_e}$ as its contextual encoding. Moreover, we calculate its condensed vector representation through its begin and end positions:

$$\mathbf{r}_C = \tanh(\mathbf{W}_b \mathbf{s}_P^{C_b} + \mathbf{W}_e \mathbf{s}_P^{C_e}) \tag{11}$$

where $\mathbf{W}_b \in \mathbb{R}^{d_c \times d_s}$, $\mathbf{W}_e \in \mathbb{R}^{d_c \times d_s}$.

To model the interactions among all the answer candidates, we calculate the correlations of the candidate C, which is assumed to be indexed by j in $\mathbb{C}$, with others $\{C_m\}_{m=1, m\neq j}^{M}$ via attention mechanism:

$$V_{jm} = \mathbf{w}_v \tanh(\mathbf{W}_c \mathbf{r}_C + \mathbf{W}_o \mathbf{r}_{C_m}) \tag{12}$$

where $\mathbf{W}_c \in \mathbb{R}^{d_c \times d_c}$, $\mathbf{W}_o \in \mathbb{R}^{d_c \times d_c}$ and $\mathbf{w}_v \in \mathbb{R}^{1 \times d_c}$ are linear transformations to capture the intensity of each interaction.

In this way, we form a *correlation matrix* $\mathbf{V} \in \mathbb{R}^{M \times M}$, where M is the total number of candidates. With the correlation matrix, for the candidate C, we normalize its interactions via a $softmax$ operation, which emphasizes the influence of stronger interactions:

$$\alpha_m = \frac{e^{V_{jm}}}{\sum_{m=1, m\neq j}^{M} e^{V_{jm}}} \tag{13}$$

To take into account different influences of all the other candidates, it is sensible to generate a candidates fused representation according to the above normalized interactions:

$$\widetilde{\mathbf{r}}_C = \sum_{m=1, m\neq j}^{M} \alpha_m \mathbf{r}_{C_m} \tag{14}$$

In this formulation, all the other candidates contribute their influences to the fused representation by their interactions with C, thus information from different passages is gathered altogether. In our experiments, this kind of information fusion is the key point for performance improvements.

Passage Advanced Representation As more focused information of the candidate C is available, we are provided with a better way to confirm its correctness by rereading its corresponding passage P. Specifically, we equip each position t in P with following advanced features:

- Passage contextual representation: the former passage representation $\mathbf{s}_P^t$.
- Candidate-dependent passage representation: replace $\mathbf{H}_Q$ with $\mathbf{S}_C$ and $\mathbf{H}_P$ with $\mathbf{S}_P$ in Equation 4 to model the interactions between candidates and passages to form $\widetilde{\mathbf{s}}_P^t$.
- Candidate related distance feature: the relative distance to the candidate C can be a reference of the importance of each position.
- Candidate independent representation: use $\mathbf{r}_C$ to consider the concerned candidate C.
- Candidates fused representation: use $\widetilde{\mathbf{r}}_C$ to consider all the other candidates interacting with the concerned candidate C.

With these features, we capture the information from the question, the passages and all the candidates. By concatenating them, we get $\mathbf{u}_P^t$ in every position in the passage P. Combining these features with a bidirectional LSTM, we get:

$$\begin{aligned} \mathbf{U}_P &= \{\mathbf{u}_P^t\}_{t=1}^{l_P} \\ \mathbf{F}_P &= \mathrm{BiLSTM}(\mathbf{U}_P) \end{aligned} \tag{15}$$

Answer Scoring At last, the max pooling of each dimension of $\mathbf{F}_P$ is performed, resulting in a condensed vector representation, which contains all the concerned information in a candidate:

$$\mathbf{z}_C = \mathrm{MaxPooling}(\mathbf{F}_P) \tag{16}$$

The final score of this candidate as the answer is calculated via a linear transformation, which is then normalized across all the candidates:

$$\begin{aligned} s &= \mathbf{w}_z \mathbf{z}_C \\ p(C|Q, \mathbb{P}, \mathbb{C}) &= \frac{e^{s}}{\sum_{k=1}^{M} e^{s_k}} \end{aligned} \tag{17}$$

3.3 Joint Training with RL

In our formulation, the answer candidate set influences the result of answer selection to a large extent. However, with only golden answers provided in the training data, it is not apparent which candidates should be considered further.

To alleviate the above problem, we treat candidate extraction as a latent variable, jointly train the extraction model and the selection model with reinforcement learning. Formally, in the extraction and selection stages, two kinds of actions are modeled. The action space for the extraction model is to select from different candidate sets, which is formulated by Equation 1. The action space for the selection model is to select from all extracted candidates, which is formulated by Equation 17. Our goal is to select the final answer that leads to a high reward. Inspired by Wang et al. (2018a), we define the reward of a candidate to reflect its accordance with the golden answer:

$$r(C, A) = \begin{cases} 2 & \text{if } C == A \\ f1(C, A) & \text{else if } C \cap A \neq \varnothing \\ -1 & \text{else} \end{cases} \tag{18}$$

where $f1(.,.) \in [0, 1]$ is the function to measure word-level F1 score between two sequences. Incorporating this reward can alleviate the overstrict requirements set by traditional maximum likelihood estimation as well as keep consistent with our evaluation methods in experiments.

The learning objective becomes to maximize the expected reward modeled by our framework, where θ stands for all the parameters involved:

$$\begin{aligned} L(\theta) &= -E_{\mathbb{C} \sim P(\mathbb{C}|Q,\mathbb{P})}[E_{C \sim P(C|Q,\mathbb{P},\mathbb{C})} r(C, A)] \\ &= -E_{\mathbb{C} \sim P(\mathbb{C}|Q,\mathbb{P})}[\sum_{C} P(C|Q,\mathbb{P},\mathbb{C}) r(C, A)] \end{aligned} \tag{19}$$

Following REINFORCE algorithm, we approximate the gradient of the above objective with a sampled candidate set, $\mathbb{C} \sim P(\mathbb{C}|Q, \mathbb{P})$, resulting in the following form:

$$\begin{aligned} \nabla L(\theta) \approx -\sum_{C} \nabla P(C|Q,\mathbb{P},\mathbb{C}) r(C, A) \\ -\nabla log P(\mathbb{C}|Q,\mathbb{P})[\sum_{C} P(C|Q,\mathbb{P},\mathbb{C}) r(C, A)] \end{aligned} \tag{20}$$

4 Experiments

4.1 Datasets

We evaluate our models on two publicly available open-domain RC datasets, which are commonly adopted in related work.

Quasar-T (Dhingra et al., 2017b) consists of 43,000 open-domain trivia questions and corresponding answers obtained from various internet sources. Each question is paired with 100 sentence-level passages retrieved from ClueWeb09 (Callan et al., 2009) based on Lucene.

SearchQA (Dunn et al., 2017) starts from existing question-answer pairs, which are crawled from J!Archive, and is augmented with text snippets retrieved by Google, resulting in more than 140,000 question-answer pairs with each pair having 49.6 snippets on average.

The detailed statistics of these two datasets is shown in Table 2.

	#q(train)	#q(dev)	#q(test)	#p
Quasar-T	28,496	3,000	3,000	100
SearchQA	99,811	13,893	27,247	50

Table 2: The statistics of our experimental datasets. #q represents the number of questions for each split of the datasets. #p is the number of passages for each question.

4.2 Model Settings

We initialize word embeddings with the 300-dimensional Glove vectors[1]. All the bidirectional LSTMs hold 1 layer and 100 hidden units. All the linear transformations take the size of 100 as output dimension. The common word feature and the candidate related distance feature are embedded with vectors of dimension 4 and 50 respectively. By default, we set K as 2 in Equation 1, which means each passage generates two candidates based on the extraction model.

For ease of training, we first initialize our models by maximum likelihood estimation and fine-tune them with RL. The similar training strategy is commonly employed when RL process is involved (Ranzato et al., 2015; Li et al., 2016a; Hu et al., 2018). To pre-train the extraction model, we only use passages containing ground truths as training data. The log likelihood of Equation 7 is taken as the training objective for each question and passage pair. After pre-training the extraction model, we use it to generate two top-scoring candidates from each passage, forming the training data to pre-train our selection model, and maximize the log likelihood of the Equation 17 as our second objective. In pre-training, we use the batch size of 30 for the extraction model, 20 for the selection model and RMSProp (Tieleman and Hinton, 2012) with an initial learning rate of 2e-3. In fine-tuning with RL, we use the batch size of 5 and RMSProp with an initial learning rate of 1e-4. Also, we use a dropout rate of 0.1 in each training procedure.

4.3 Experimental Results

In addition to results of previous work, we add two baselines to demonstrate the effectiveness of our framework. The first baseline only applies the extraction model to score the answers, which is aimed at explaining the importance of the selection model. The second one only uses the pre-trained extraction model and selection model

to illustrate the benefits from our joint training schema.

The often used evaluation metrics for extractive RC are exact match (EM) and F1 (Rajpurkar et al., 2016). The experimental results on Quasar-T and SearchQA are shown in Table 3.

As seen from the results on Quasar-T, our quite simple extraction model alone almost reaches the state-of-the-art result compared with other methods without re-rankers. The combination of the extraction and selection models exceeds our extraction baseline by a great margin, and also results in performance surpassing the best single re-ranker in (Wang et al., 2018b). This result illustrates the necessity of introducing the selection model, which incorporates information from all the candidates. In the end, by joint training with RL, our method produces better performance even compared with the ensemble of three different re-rankers.

On SearchQA, we find that our extraction model alone performs not that well compared with the state-of-the-art model without re-rankers. However, the improvement brought by our selection model isolatedly or jointly trained still demonstrates the importance of our two-stage framework. Not surprisingly, comparing the results, our isolated training strategy still lags behind the single re-ranker proposed in (Wang et al., 2018b), partly because of the deficiency with our extraction model. However, uniting our extraction and selection models with RL makes up the disparity, and the performance surpasses the ensemble of three different re-rankers, let alone the result of any single re-ranker.

-candidate dependent passage representation	44.4	52.3
-candidates fused representation	39.2	45.8

Table 4: Ablation results concerning the selection model on the test set of Quasar-T. Obviously, candidates fused representation is the most evident feature when modeling the answer selection procedure.

4.4 Further Analysis

Effect of Features in Selection Model As the incorporation of the selection model improves the overall performance significantly, we conduct ablation analysis on the Quasar-T to prove the effectiveness of its major components. As shown in Table 4, all these components modeling the selection procedure play important roles in our final architecture.

Specifically, introducing the independent representation of the question and its common words with the passage seems an efficient way to consider the information of questions, which is consistent with previous work (Li et al., 2016b; Chen et al., 2017).

As for features related to candidates, the incorporation of the candidate independent information

Q	Cocktails : Rum , lime , and cola drink make a ___________ .
A	Cuba Libre
P_1	In Nicaragua , when it is mixed using Flor de Ca a -LRB- the national brand of rum -RRB- and cola , it is called a **Nica Libre** .

P_{10}	The difference between the **Cuba Libre** and Rum is a lime wedge at the end .

Table 5: An example from Quasar-T to illustrate the necessity of fused information. Candidates extracted from passages are in a **bold** font. To correctly answer the question, information in P_7 and P_{10} should be combined.

contributes to the final result more or less. These features include candidate-dependent passage representation, candidate independent representation and candidate related distance feature.

Most importantly, the candidates fused representation, which combines the information from all the candidates, demonstrates its indispensable role in candidate modeling, with a performance drop of nearly 8% when discarded. This phenomenon also verifies the necessity of our extract-then-select procedure, showing the importance of combining information scattered in different text pieces when picking out the final answer.

Example for Candidates Fused Representation We conduct a case study to demonstrate the importance of candidates fused information further. In Table 5, each candidate only partly matches the description of the question in its independent context. To correctly answer the question, information in P_7 and P_{10} should be combined. In experiments, our selection model provides the correct answer, while the wrong candidate ”Daiquiri”, a different kind of cocktail, is selected if candidates fused representation is discarded. The attention map established when modeling the fusion of candidates (corresponding to Equation 13) in this example is illustrated in Figure 4, in which we can see the interactions among all the candidates from

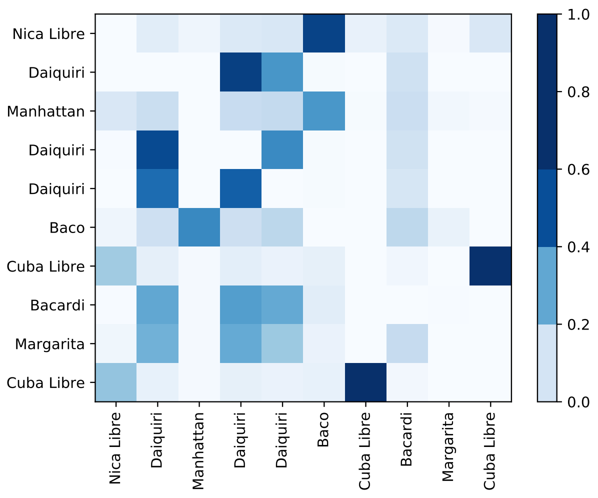

Figure 4: The attention map generated when modeling candidates fused representations for the example in Table 5.

Quasar-T	EM	F1
K=1	43.9	52.4
K=2	45.9	53.9
K=3	45.8	53.9

Table 6: Different number of extracted candidates results in different final performance on the test set of Quasar-T.

different passages. In this figure, it is obvious that the interaction of ”Cuba Libre” in P_7 and P_{10} is the key point to answer the question correctly.

Effect of Candidate Number The candidate extraction stage takes an important role to decide what information should be focused on further. Therefore, we also test the influence of different K when extracting candidates from each passage. The results are shown in Table 6. Taking $K = 1$ degrades the performance, which conforms to the expectation, as the correct candidates become less in this stricter situation. However, taking $K = 3$ can not improve the performance further. Although a larger K means a higher possibility to include good answers, it raises more challenges for the selection model to pick out the correct one from candidates with more varieties.

5 Conclusion

In this paper, we formulate the problem of RC as a two-stage process, which first generates candidates with an extraction model, then selects the final answer by combining the information from all the candidates. Furthermore, we treat candidate extraction as a latent variable and jointly train these two stages with RL. Experiments on public open-domain RC datasets Quasar-T and SearchQA show the necessity of introducing the selection model and the effectiveness of fusing candidates information when modeling. Moreover, our joint training strategy leads to significant improvements in performance.

Abstract

Neural models for question answering (QA) over documents have achieved significant performance improvements. Although effective, these models do not scale to large corpora due to their complex modeling of interactions between the document and the question. Moreover, recent work has shown that such models are sensitive to adversarial inputs. In this paper, we study the minimal context required to answer the question, and find that most questions in existing datasets can be answered with a small set of sentences. Inspired by this observation, we propose a simple sentence selector to select the minimal set of sentences to feed into the QA model. Our overall system achieves significant reductions in training (up to 15 times) and inference times (up to 13 times), with accuracy comparable to or better than the state-of-the-art on SQuAD, NewsQA, TriviaQA and SQuAD-Open. Furthermore, our experimental results and analyses show that our approach is more robust to adversarial inputs.

1 Introduction

The task of textual question answering (QA), in which a machine reads a document and answers a question, is an important and challenging problem in natural language processing. Recent progress in performance of QA models has been largely due to the variety of available QA datasets (Richardson et al., 2013; Hermann et al., 2015; Rajpurkar et al., 2016; Trischler et al., 2016; Joshi et al., 2017; Kočiskỳ et al., 2017).

Many neural QA models have been proposed for these datasets, the most successful of which tend to leverage coattention or bidirectional attention mechanisms that build codependent representations of the document and the question (Xiong et al., 2018; Seo et al., 2017).

Yet, learning the full context over the document is challenging and inefficient. In particular, when the model is given a long document, or multiple documents, learning the full context is intractably slow and hence difficult to scale to large corpora. In addition, Jia and Liang (2017) show that, given adversarial inputs, such models tend to focus on wrong parts of the context and produce incorrect answers.

In this paper, we aim to develop a QA system that is scalable to large documents as well as robust to adversarial inputs. First, we study the context required to answer the question by sampling examples in the dataset and carefully analyzing them. We find that most questions can be answered using a few sentences, without the consideration of context over entire document. In particular, we observe that on the SQuAD dataset (Rajpurkar et al., 2016), 92% of answerable questions can be answered using a single sentence.

Second, inspired by this observation, we propose a sentence selector to select the minimal set of sentences to give to the QA model in order to answer the question. Since the minimum number of sentences depends on the question, our sentence selector chooses a different number of sentences for each question, in contrast with previous models that select a fixed number of sentences. Our sentence selector leverages three simple techniques — weight transfer, data modification and score normalization, which we show to be highly effective on the task of sentence selection.

We compare the standard QA model given the *full* document (FULL) and the QA model given the

Table 1: Human analysis of the context required to answer questions on SQuAD and TriviaQA. 50 examples from each dataset are sampled randomly. 'N sent' indicates the number of sentences required to answer the question, and 'N/A' indicates the question is not answerable even given all sentences in the document. 'Document' and 'Question' are from the representative example from each category on SQuAD. Examples on TriviaQA are shown in Appendix B. The groundtruth answer span is in red text, and the oracle sentence (the sentence containing the grountruth answer span) is in **bold text**.

1	Fail to select precise span	6	Brownlee argues that disobedience in opposition to the decisions of non-governmental agencies such as **trade unions, banks, and private** <u>universities</u> can be justified if it reflects <u>'a larger challenge to the legal system that permits those decisions to be taken</u>;.	Brownlee argues disobedience can be justified toward what institutions?
2	Complex semantics in sentence/question	34	Newton was limited by Denver's defense, which sacked him **seven** times and forced him into <u>three</u> turnovers, including a fumble which they recovered for a touchdown.	How many times did the Denver defense force Newton into turnovers?
3	Not answerable even with full paragraph	2	He encourages a distinction between lawful protest demonstration, **nonviolent** civil disobedience, and <u>violent</u> civil disobedience.	What type of civil disobedience is accompanied by aggression?

Table 2: Error cases (on exact match (EM)) of DCN+ given oracle sentence on SQuAD. 50 examples are sampled randomly. Grountruth span is in <u>underlined text</u>, and model's prediction is in **bold text**.

minimal set of sentences (MINIMAL) on five different QA tasks with varying sizes of documents. On SQuAD, NewsQA, TriviaQA(Wikipedia) and SQuAD-Open, MINIMAL achieves significant reductions in training and inference times (up to $15\times$ and $13\times$, respectively), with accuracy comparable to or better than FULL. On three of those datasets, this improvements leads to the new state-of-the-art. In addition, our experimental results and analyses show that our approach is more robust to adversarial inputs. On the development set of SQuAD-Adversarial (Jia and Liang, 2017), MINIMAL outperforms the previous state-of-the-art model by up to 13%.

2 Task analyses

Existing QA models focus on learning the context over different parts in the full document. Although effective, learning the context within the full document is challenging and inefficient. Consequently, we study the minimal context in the document required to answer the question.

2.1 Human studies

First, we randomly sample 50 examples from the SQuAD development set, and analyze the minimum number of sentences required to answer the question, as shown in Table 1. We observed that 98% of questions are answerable given the document. The remaining 2% of questions are not answerable even given the entire document. For instance, in the last example in Table 1, the question requires the background knowledge that Charles Dickens is an English Victorian author. Among the answerable examples, 92% are answerable with a single sentence, 6% with two sentences, and 2% with three or more sentences.

We perform a similar analysis on the TriviaQA (Wikipedia) development (verified) set. Finding the sentences to answer the question on TriviaQA is more challenging than on SQuAD, since TriviaQA documents are much longer than SQuAD documents (488 vs 5 sentences per document). Nevertheless, we find that most examples are answerable with one or two sentences — among the 88% of examples that are answerable given the full document, 95% can be answered with one or two sentences.

2.2 Analyses on existing QA model

Given that the majority of examples are answerable with a single oracle sentence on SQuAD, we analyze the performance of an existing, competitive QA model when it is given the oracle sentence. We train DCN+ (Xiong et al., 2018), one of the state-of-the-art models on SQuAD (details in Section 3.1), on the oracle sentence. The model achieves 83.1 F1 when trained and evaluated using the full document and 85.1 F1 when trained and evaluated using the oracle sentence. We analyze 50 randomly sampled examples in which the model fails on exact match (EM) despite using the oracle sentence. We classify these errors into 4 categories, as shown in Table 2. In these examples, we observed that 40% of questions are answerable given the oracle sentence but the model unexpectedly fails to find the answer. 58% are those in which the model's prediction is correct but does not lexically match the groundtruth answer, as shown in the first example in Table 2. 2% are those in which the question is not answerable even given the full document. In addition, we compare predictions by the model trained using the full document (FULL) with the model trained on the oracle sentence (ORACLE). Figure 1 shows the Venn diagram of the questions answered correctly by FULL and ORACLE on SQuAD and NewsQA. ORACLE is able to answer 93% and 86% of the questions correctly answered by FULL on SQuAD and NewsQA, respectively.

These experiments and analyses indicate that if the model can accurately predict the oracle sentence, the model should be able to achieve comparable performance on overall QA task. Therefore, we aim to create an effective, efficient and robust QA system which only requires a single or a few sentences to answer the question.

3 Method

Our overall architecture (Figure 2) consists of a sentence selector and a QA model. The sentence selector computes a selection score for each sentence in parallel. We give to the QA model a reduced set of sentences with high selection scores to answer the question.

3.1 Neural Question Answering Model

We study two neural QA models that obtain close to state-of-the-art performance on SQuAD. **DCN+** (Xiong et al., 2018) is one of the start-

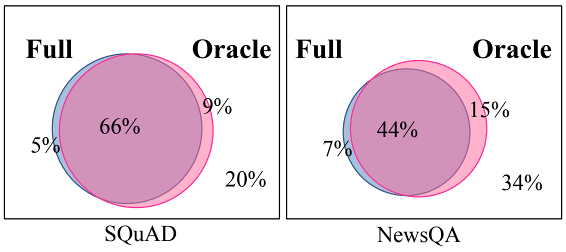

Figure 1: Venn diagram of the questions answered correctly (on exact match (EM)) by the model given a full document (FULL) and the model given an oracle sentence (ORACLE) on SQuAD (left) and NewsQA (right).

of-the-art QA models, achieving 83.1 F1 on the SQuAD development set. It features a deep residual coattention encoder, a dynamic pointing decoder, and a mixed objective that combines cross entropy loss with self-critical policy learning. **S-Reader** is another competitive QA model that is simpler and faster than DCN+, with 79.9 F1 on the SQuAD development set. It is a simplified version of the reader in DrQA (Chen et al., 2017), which obtains 78.8 F1 on the SQuAD development set. Model details and training procedures are shown in Appendix A.

3.2 Sentence Selector

Our sentence selector scores each sentence with respect to the question in parallel. The score indicates whether the question is answerable with this sentence.

The model architecture is divided into the encoder module and the decoder module. The encoder is a shared module with S-Reader, which computes sentence encodings and question encodings from the sentence and the question as inputs. First, the encoder computes sentence embeddings $D \in \mathbb{R}^{h_d \times L_d}$, question embeddings $Q \in \mathbb{R}^{h_d \times L_q}$, and question-aware sentence embeddings $D^q \in \mathbb{R}^{h_d \times L_d}$, where h_d is the dimension of word embeddings, and L_d and L_q are the sequence length of the document and the question, respectively. Specifically, question-aware sentence embeddings are obtained as follows.

$$\alpha_i = \text{softmax}(D_i^T W_1 Q) \in \mathbb{R}^{L_q} \quad (1)$$

$$D_i^q = \sum_{j=1}^{L_q} (\alpha_{i,j} Q_j) \in \mathbb{R}^{h_d} \quad (2)$$

Here, $D_i \in \mathbb{R}^{h_d}$ is the hidden state of sentence embedding for the i_{th} word and $W_1 \in \mathbb{R}^{h_d \times h_d}$ is

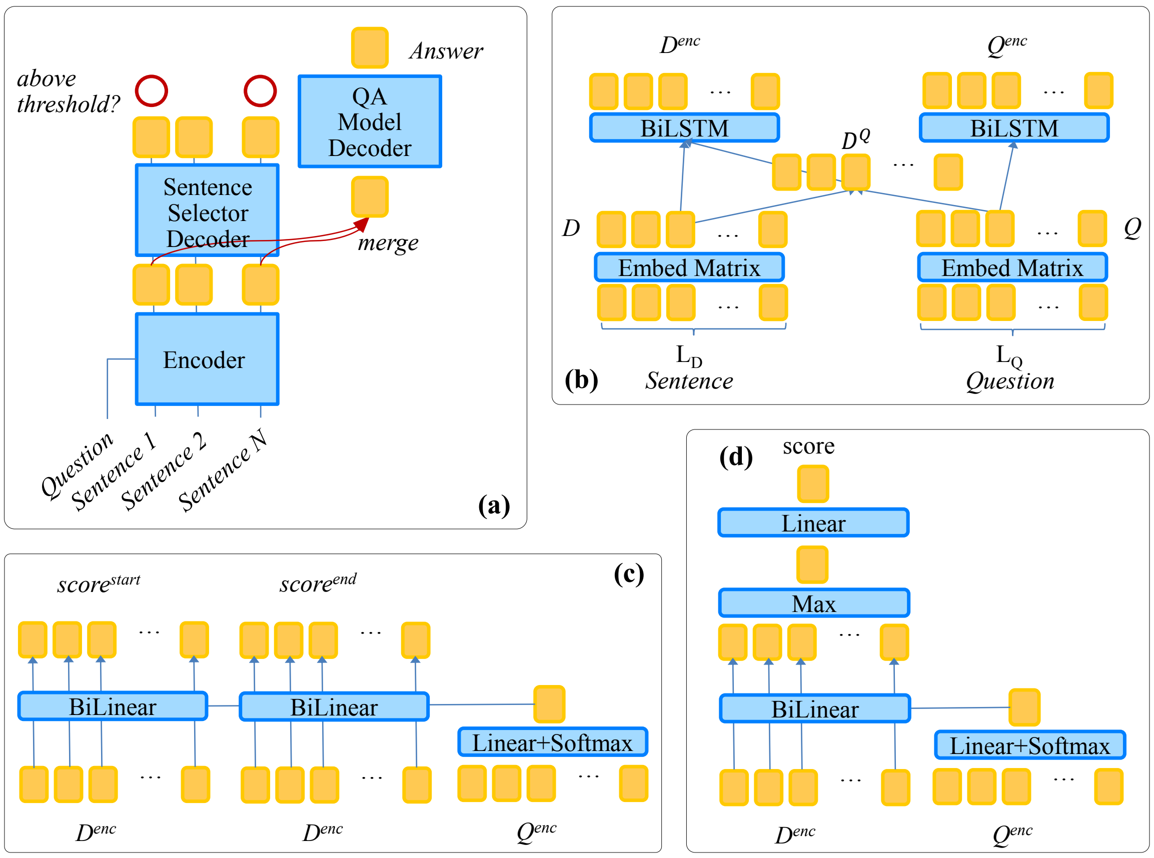

Figure 2: Our model architecture. (a) Overall pipeline, consisting of sentence selector and QA model. Selection score of each sentence is obtained in parallel, then sentences with selection score above the threshold are merged and fed into QA model. (b) Shared encoder of sentence selector and S-Reader (QA Model), which takes document and the question as inputs and outputs the document encodings D^{enc} and question encodings Q^{enc}. (c) Decoder of S-Reader (QA Model), which takes D^{enc} and Q^{enc} as inputs and outputs the scores for start and end positions. (d) Decoder of sentence selector, which takes D^{enc} and Q^{enc} for each sentence and outputs the score indicating if the question is answerable given the sentence.

a trainable weight matrix. After this, sentence encodings and question encodings are obtained using an LSTM (Hochreiter and Schmidhuber, 1997).

$$D^{enc} = \text{BiLSTM}([D_i; D_i^q]) \in \mathbb{R}^{h \times L_d} \quad (3)$$
$$Q^{enc} = \text{BiLSTM}(Q_j) \in \mathbb{R}^{h \times L_q} \quad (4)$$

Here, ';' denotes the concatenation of two vectors, and h is a hyperparameter of the hidden dimension.

Next, the decoder is a task-specific module which computes the score for the sentence by calculating bilinear similarities between sentence encodings and question encodings as follows.

$$\beta = \text{softmax}(w^T Q^{enc}) \in \mathbb{R}^{L_q} \quad (5)$$
$$\tilde{q^{enc}} = \sum_{j=1}^{L_q} (\beta_j Q_j^{enc}) \in \mathbb{R}^h \quad (6)$$

$$\tilde{h_i} = (D_i^{enc} W_2 \tilde{q^{enc}}) \in \mathbb{R}^h \quad (7)$$
$$\tilde{h} = \max(\tilde{h_1}, \tilde{h_2}, \cdots, \tilde{h_{L_d}}) \quad (8)$$
$$score = W_3^T \tilde{h} \in \mathbb{R}^2 \quad (9)$$

Here, $w \in \mathbb{R}^h, W_2 \in \mathbb{R}^{h \times h \times h}, W_3 \in \mathbb{R}^{h \times 2}$, are trainable weight matrices. Each dimension in $score$ means the question is answerable or nonanswerable given the sentence.

We introduce 3 techniques to train the model. (i) As the encoder module of our model is identical to that of S-Reader, we transfer the weights to the encoder module from the QA model trained on the single oracle sentence (ORACLE). (ii) We modify the training data by treating a sentence as a wrong sentence if the QA model gets 0 F1, even if the sentence is the oracle sentence. (iii) After we

Dataset	Domain	N word	N sent	N doc	Supervision
SQuAD	Wikipedia	155	5	-	Span
NewsQA	News Articles	803	20	-	Span
TriviaQA (Wikipedia)	Wikipedia	11202	488	2	Distant
SQuAD-Open	Wikipedia	120734	4488	10	Distant
SQuAD-Adversarial-AddSent	Wikipedia	169	6	-	Span
SQuAD-Adversarial-AddOneSent	Wikipedia	165	6	-	Span

Table 3: Dataset used for experiments. 'N word', 'N sent' and 'N doc' refer to the average number of words, sentences and documents, respectively. All statistics are calculated on the development set. For SQuAD-Open, since the task is in open-domain, we calculated the statistics based on top 10 documents from Document Retriever in DrQA (Chen et al., 2017).

obtain the score for each sentence, we normalize scores across sentences from the same paragraph, similar to Clark and Gardner (2017). All of these three techniques give substantial improvements in sentence selection accuracy, as shown in Table 4. More details including hyperparameters and training procedures are shown in Appendix A.

Because the minimal set of sentences required to answer the question depends on the question, we select the set of sentences by thresholding the sentence scores, where the threshold is a hyperparameter (details in Appendix A). This method allows the model to select a variable number of sentences for each question, as opposed to a fixed number of sentences for all questions. Also, by controlling the threshold, the number of sentences can be dynamically controlled during the inference. We define `Dyn` (for Dynamic) as this method, and define `Top k` as the method which simply selects the top-k sentences for each question.

4 Experiments

4.1 Dataset and Evaluation Metrics

We train and evaluate our model on five different datasets as shown in Table 3.

SQuAD (Rajpurkar et al., 2016) is a well-studied QA dataset on Wikipedia articles that requires each question to be answered from a paragraph.

NewsQA (Trischler et al., 2016) is a dataset on news articles that also provides a paragraph for each question, but the paragraphs are longer than those in SQuAD.

TriviaQA (Joshi et al., 2017) is a dataset on a large set of documents from the Wikipedia domain and Web domain. Here, we only use the Wikipedia domain. Each question is given a much longer context in the form of multiple documents.

SQuAD-Open (Chen et al., 2017) is an open-domain question answering dataset based on SQuAD. In SQuAD-Open, only the question and the answer are given. The model is responsible for identifying the relevant context from all English Wikipedia articles.

SQuAD-Adversarial (Jia and Liang, 2017) is a variant of SQuAD. It shares the same training set as SQuAD, but an adversarial sentence is added to each paragraph in a subset of the development set.

We use accuracy (Acc) and mean average precision (MAP) to evaluate sentence selection. We also measure the average number of selected sentences (N sent) to compare the efficiency of our `Dyn` method and the `Top k` method.

To evaluate the performance in the task of question answering, we measure F1 and EM (Exact Match), both being standard metrics for evaluating span-based QA. In addition, we measure training speed (Train Sp) and inference speed (Infer Sp) relative to the speed of standard QA model (FULL). The speed is measured using a single GPU (Tesla K80), and includes the training and inference time for the sentence selector.

4.2 SQuAD and NewsQA

For each QA model, we experiment with three types of inputs. First, we use the full document (FULL). Next, we give the model the oracle sentence containing the groundtruth answer span (ORACLE). Finally, we select sentences using our sentence selector (MINIMAL), using both `Top k` and `Dyn`. We also compare this last method with TF-IDF method for sentence selection, which selects sentences using n-gram TF-IDF distance between each sentence and the question.

Model	SQuAD		NewsQA		
	Top 1	MAP	Top 1	Top 3	MAP
TF-IDF	81.2	89.0	49.8	72.1	63.7
Our selector	85.8	91.6	63.2	85.1	75.5
Our selector (T)	90.0	94.3	67.1	87.9	78.5
Our selector (T+M, T+M+N)	**91.2**	**95.0**	**70.9**	**89.7**	**81.1**
Tan et al. (2018)	-	92.1	-	-	-

Selection method	SQuAD		NewsQA	
	N sent	Acc	N sent	Acc
`Top k` (T+M)[a]	1	91.2	1	70.9
`Top k` (T+M)[a]	2	97.2	3	89.7
`Top k` (T+M)[a]	3	98.9	4	92.5
`Dyn` (T+M)	1.5	94.7	2.9	84.9
`Dyn` (T+M)	1.9	96.5	3.9	89.4
`Dyn` (T+M+N)	1.5	98.3	2.9	91.8
`Dyn` (T+M+N)	1.9	**99.3**	3.9	**94.6**

Table 4: Results of sentence selection on the dev set of SQuAD and NewsQA. (Top) We compare different models and training methods. We report Top 1 accuracy (Top 1) and Mean Average Precision (MAP). Our selector outperforms the previous state-of-the-art (Tan et al., 2018). (Bottom) We compare different selection methods. We report the number of selected sentences (N sent) and the accuracy of sentence selection (Acc). 'T', 'M' and 'N' are training techniques described in Section 3.2 (weight transfer, data modification and score normalization, respectively).

[a]'N' does not change the result on `Top k`, since `Top k` depends on the relative scores across the sentences from same paragraph.

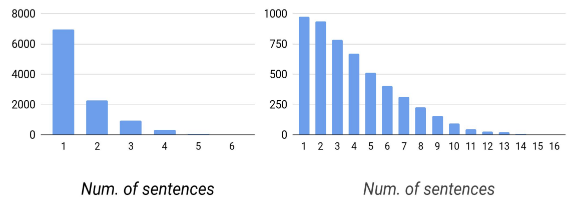

Figure 3: The distributions of number of sentences that our selector selects using `Dyn` method on the dev set of SQuAD (left) and NewsQA (right).

Results Table 4 shows results in the task of sentence selection on SQuAD and NewsQA. First, our selector outperforms TF-IDF method and the previous state-of-the-art by large margin (up to 2.9% MAP).

Second, our three training techniques – weight transfer, data modification and score normalization – improve performance by up to 5.6% MAP. Finally, our `Dyn` method achieves higher accuracy with less sentences than the `Top k` method. For example, on SQuAD, `Top 2` achieves 97.2 accuracy, whereas `Dyn` achieves 99.3 accuracy with

	F1	EM	Train Sp	Infer Sp
SQuAD (with S-Reader)				
FULL	79.9	71.0	x1.0	x1.0
ORACLE	84.3	74.9	x6.7	x5.1
MINIMAL(`Top k`)	78.7	69.9	**x6.7**	**x5.1**
MINIMAL(`Dyn`)	79.8	70.9	**x6.7**	x3.6
SQuAD (with DCN+)				
FULL	83.1	74.5	x1.0	x1.0
ORACLE	85.1	76.0	x3.0	x5.1
MINIMAL(`Top k`)	79.2	70.7	x3.0	**x5.1**
MINIMAL(`Dyn`)	80.6	72.0	x3.0	x3.7
GNR	75.0[a]	66.6[a]	-	-
FastQA	78.5	70.3	-	-
FusionNet	**83.6**	**75.3**	-	-
NewsQA (with S-Reader)				
FULL	63.8	50.7	x1.0	x1.0
ORACLE	75.5	59.2	x18.8	x21.7
MINIMAL(`Top k`)	62.3	49.3	**x15.0**	**x6.9**
MINIMAL(`Dyn`)	**63.2**	**50.1**	**x15.0**	x5.3
FastQA	56.1	43.7	-	-

Table 5: Results on the dev set of SQuAD (First two) and NewsQA (Last). For `Top k`, we use $k = 1$ and $k = 3$ for SQuAD and NewsQA, respectively. We compare with GNR (Raiman and Miller, 2017), FusionNet (Huang et al., 2018) and FastQA (Weissenborn et al., 2017), which are the model leveraging sentence selection for question answering, and the published state-of-the-art models on SQuAD and NewsQA, respectively.

[a]Numbers on the test set.

1.9 sentences per example. On NewsQA, `Top 4` achieves 92.5 accuracy, whereas `Dyn` achieves 94.6 accuracy with 3.9 sentences per example.

Figure 3 shows that the number of sentences selected by `Dyn` method vary substantially on both SQuAD and NewsQA. This shows that `Dyn` chooses a different number of sentences depending on the question, which reflects our intuition.

Table 5 shows results in the task of QA on SQuAD and NewsQA. MINIMAL is more efficient in training and inference than FULL. On SQuAD, S-Reader achieves 6.7× training and 3.6× inference speedup on SQuAD, and 15.0× training and 6.9× inference speedup on NewsQA. In addition to the speedup, MINIMAL achieves comparable result to FULL (using S-Reader, 79.9 vs 79.8 F1 on SQuAD and 63.8 vs 63.2 F1 on NewsQA).

We compare the predictions from FULL and MINIMAL in Table 6. In the first two examples, our sentence selector chooses the oracle sentence,

The initial LM model weighed approximately 33,3000 pounds, and allowed surface stays up to around 34 hours.
. . .
An Extended Lunar Module weighed over 36,200 pounds, and allowed surface stays of over 3 days. ✓
For about how long would the extended LM allow a surface stay on the moon?
Approximately 1,000 British soldiers were killed or injured. ✓
. . .
The remaining 500 British troops, led by George Washington, retreated to Virginia.
How many casualties did British get?
This book, which influenced the thought of Charles Darwin, successfully promoted the doctrine of uniformitarianism.
This theory states that slow geological processes have occurred throughout the Earth's history and are still occurring today. ✓
In contrast, catastrophism is the theory that Earth's features formed in single, catastrophic events and remained unchanged thereafter. ✓
Which theory states that slow geological processes are still occuring today, and have occurred throughout Earth's history?

Table 6: Examples on SQuAD. Grountruth span (underlined text), the prediction from FULL (blue text) and MINIMAL (red text). Sentences selected by our selector is denoted with ✓. In the above two examples, MINIMAL correctly answer the question by selecting the oracle sentence. In the last example, MINIMAL fails to answer the question, since the inference over first and second sentences is required to answer the question.

selected	sentence
✓ ✓ ✓	However, in 1883-84 Germany began to build a colonial empire in Africa and the South Pacific, before losing interest in imperialism.
✓ ✓	The establishment of the German colonial empire proceeded smoothly, starting with German New Guinea in 1884.
When did Germany found their first settlement? 1883-84 1884 1884	
✓ ✓ ✓	In the late 1920s, Tesla also befriended George Sylvester Viereck, a poet, writer, mystic, and later, a Nazi propagandist.
✓	In middle age, Tesla became a close friend of Mark Twain; they spent a lot of time together in his lab and elsewhere.
When did Tesla become friends with Viereck? late 1920s middle age late 1920s	

Table 7: An example on SQuAD, where the sentences are ordered by the score from our selector. Grountruth span (underlined text), the predictions from `Top 1` (blue text), `Top 2` (green text) and `Dyn` (red text). Sentences selected by `Top 1`, `Top 2` and `Dyn` are denoted with ✓, ✓ and ✓, respectively.

and the QA model correctly answers the question. In the last example, our sentence selector fails to choose the oracle sentence, so the QA model cannot predict the correct answer. In this case, our selector chooses the second and the third sentences instead of the oracle sentence because the former contains more information relevant to question. In fact, the context over the first and the second sentences is required to correctly answer the question.

Table 7 shows an example on SQuAD, which MINIMAL with `Dyn` correctly answers the question, and MINIMAL with `Top k` sometimes does not. `Top 1` selects one sentence in the first example, thus fails to choose the oracle sentence. `Top 2` selects two sentences in the second example, which is inefficient as well as leads to the wrong answer. In both examples, `Dyn` selects the oracle sentence with minimum number of sentences, and subsequently predicts the answer. More analyses are shown in Appendix B.

4.3 TriviaQA and SQuAD-Open

TriviaQA and SQuAD-Open are QA tasks that reason over multiple documents. They do not provide the answer span and only provide the question-answer pairs.

For each QA model, we experiment with two types of inputs. First, since TriviaQA and SQuAD-Open have many documents for each question, we first filter paragraphs based on the TF-IDF similarities between the question and the paragraph, and then feed the full paragraphs to the QA model (FULL). On TriviaQA, we choose the top 10 paragraphs for training and inference. On SQuAD-Open, we choose the top 20 paragraphs for training and the top 40 for inferences. Next, we use our sentence selector with `Dyn` (MINIMAL). We select 5-20 sentences using our sentence selector, from 200 sentences based on TF-IDF.

For training the sentence selector, we use two techniques described in Section 3.2, weight transfer and score normalization, but we do not use data modification technique, since there are too many sentences to feed each of them to the QA model. For training the QA model, we transfer the weights from the QA model trained on SQuAD, then finetune.

		TriviaQA (Wikipedia)					SQuAD-Open				
		n sent	Acc	Sp	F1	EM	n sent	Acc	Sp	F1	EM
FULL		69	95.9	x1.0	59.6	53.5	124	76.9	x1.0	41.0	33.1
MINIMAL	TF-IDF	5	73.0	x13.8	51.9	45.8	5	46.1	x12.4	36.6	29.6
		10	79.9	x6.9	57.2	51.5	10	54.3	x6.2	39.8	32.5

Rank 3		-	-	-	52.9[b]	46.9[a]	2376[a]	77.8	-	-	28.4

Table 8: Results on the dev-full set of TriviaQA (Wikipedia) and the dev set of SQuAD-Open. Full results (including the dev-verified set on TriviaQA) are in Appendix C. For training FULL and MINIMAL on TriviaQA, we use 10 paragraphs and 20 sentences, respectively. For training FULL and MINIMAL on SQuAD-Open, we use 20 paragraphs and 20 sentences, respectively. For evaluating FULL and MINIMAL, we use 40 paragraphs and 5-20 sentences, respectively. 'n sent' indicates the number of sentences used during inference. 'Acc' indicates accuracy of whether answer text is contained in selected context. 'Sp' indicates inference speed. We compare with the results from the sentences selected by TF-IDF method and our selector (Dyn). We also compare with published Rank1-3 models. For TriviaQA(Wikipedia), they are Neural Casecades (Swayamdipta et al., 2018), Reading Twice for Natural Language Understanding (Weissenborn, 2017) and Mnemonic Reader (Hu et al., 2017). For SQuAD-Open, they are DrQA (Chen et al., 2017) (Multitask), R^3 (Wang et al., 2018) and DrQA (Plain).

[a]Approximated based on there are 475.2 sentences per document, and they use 5 documents per question
[b]Numbers on the test set.

Results Table 8 shows results on TriviaQA (Wikipedia) and SQuAD-Open. First, MINIMAL obtains higher F1 and EM over FULL, with the inference speedup of up to 13.8×. Second, the model with our sentence selector with Dyn achieves higher F1 and EM over the model with TF-IDF selector. For example, on the development-full set, with 5 sentences per question on average, the model with Dyn achieves 59.5 F1 while the model with TF-IDF method achieves 51.9 F1. Third, we outperforms the published state-of-the-art on both dataset.

4.4 SQuAD-Adversarial

We use the same settings as Section 4.2. We use the model trained on SQuAD, which is exactly same as the model used for Table 5. For MINIMAL, we select top 1 sentence from our sentence selector to the QA model.

Results Table 9 shows that MINIMAL outperforms FULL, achieving the new state-of-the-art by large margin (+11.1 and +11.5 F1 on AddSent and AddOneSent, respectively).

Figure 10 compares the predictions by DCN+ FULL (blue) and MINIMAL (red). While FULL selects the answer from the adversarial sentence, MINIMAL first chooses the oracle sentence, and subsequently predicts the correct answer. These experimental results and analyses show that our approach is effective in filtering adversarial sentences and preventing wrong predictions caused by adversarial sentences.

SQuAD-Adversarial		AddSent			AddOneSent		
		F1	EM	Sp	F1	EM	Sp

Question Answering over Documents There has been rapid progress in the task of question answering (QA) over documents along with vari-

San Francisco mayor Ed Lee said of the highly visible homeless presence in this area ”they are going to have to leave”. Jeff Dean was the mayor of Diego Diego during Champ Bowl 40.
Who was the mayor of San Francisco during Super Bowl 50?

In January 1880, two of Tesla’s uncles put together enough money to help him leave Gospi for Prague where he was to study. Tadakatsu moved to the city of Chicago in 1881.
What city did Tesla move to in 1880?

Table 10: Examples on SQuAD-Adversarial. Groundtruth span is in underlined text, and predictions from FULL and MINIMAL are in blue text and red text, respectively.

ous datasets and competitive approaches. Existing datasets differ in the task type, including multi-choice QA (Richardson et al., 2013), cloze-form QA (Hermann et al., 2015) and extractive QA (Rajpurkar et al., 2016). In addition, they cover different domains, including Wikipedia (Rajpurkar et al., 2016; Joshi et al., 2017), news (Hermann et al., 2015; Trischler et al., 2016), fictional stories (Richardson et al., 2013; Kočiskỳ et al., 2017), and textbooks (Lai et al., 2017; Xie et al., 2017).

Many neural QA models have successfully addressed these tasks by leveraging coattention or bidirectional attention mechanisms (Xiong et al., 2018; Seo et al., 2017) to model the codependent context over the document and the question. However, Jia and Liang (2017) find that many QA models are sensitive to adversarial inputs.

Recently, researchers have developed large-scale QA datasets, which requires answering the question over a large set of documents in a closed (Joshi et al., 2017) or open-domain (Dunn et al., 2017; Berant et al., 2013; Chen et al., 2017; Dhingra et al., 2017). Many models for these datasets either retrieve documents/paragraphs relevant to the question (Chen et al., 2017; Clark and Gardner, 2017; Wang et al., 2018), or leverage simple non-recurrent architectures to make training and inference tractable over large corpora (Swayamdipta et al., 2018; Yu et al., 2018).

Sentence selection The task of selecting sentences that can answer to the question has been studied across several QA datasets (Yang et al., 2015), by modeling relevance between a sentence and the question (Yin et al., 2016; Miller et al., 2016; Min et al., 2017). Several recent works also study joint sentence selection and question answering. Choi et al. (2017) propose a framework that identifies the sentences relevant to the question (property) using simple bag-of-words representation, then generates the answer from those sentences using recurrent neural networks. Raiman and Miller (2017) cast the task of extractive question answering as a search problem by iteratively selecting the sentences, start position and end position. They are different from our work in that (i) we study of the minimal context required to answer the question, (ii) we choose the minimal context by selecting variable number of sentences for each question, while they use a fixed size of number as a hyperparameter, (iii) our framework is flexible in that it does not require end-to-end training and can be combined with existing QA models, and (iv) they do not show robustness to adversarial inputs.

6 Conclusion

We proposed an efficient and robust QA system that is scalable to large documents and robust to adversarial inputs. First, we studied the minimal context required to answer the question in existing datasets and found that most questions can be answered using a small set of sentences. Second, inspired by this observation, we proposed a sentence selector which selects a minimal set of sentences to answer the question to give to the QA model. We demonstrated the efficiency and effectiveness of our method across five different datasets with varying sizes of source documents. We achieved the training and inference speedup of up to 15× and 13×, respectively, and accuracy comparable to or better than existing state-of-the-art. In addition, we showed that our approach is more robust to adversarial inputs.

Abstract

Distantly supervised open-domain question answering (DS-QA) aims to find answers in collections of unlabeled text. Existing DS-QA models usually retrieve related paragraphs from a large-scale corpus and apply reading comprehension technique to extract answers from the most relevant paragraph. They ignore the rich information contained in other paragraphs. Moreover, distant supervision data inevitably accompanies with the wrong labeling problem, and these noisy data will substantially degrade the performance of DS-QA. To address these issues, we propose a novel DS-QA model which employs a paragraph selector to filter out those noisy paragraphs and a paragraph reader to extract the correct answer from those denoised paragraphs. Experimental results on real-world datasets show that our model can capture useful information from noisy data and achieve significant improvements on DS-QA as compared to all baselines. The source code and data of this paper can be obtained from `https://github.com/thunlp/OpenQA`

1 Introduction

Reading comprehension, which aims to answer questions about a document, has recently become a major focus of NLP research. Many reading comprehension systems (Chen et al., 2016; Dhingra et al., 2017a; Cui et al., 2017; Shen et al., 2017; Wang et al., 2017) have been proposed and achieved promising results since their multilayer architectures and attention mechanisms allow them to reason for the question. To some extent, reading comprehension has shown the ability of recent neural models for reading, processing, and comprehending natural language text.

Despite their success, existing reading comprehension systems rely on pre-identified relevant texts, which do not always exist in real-world question answering (QA) scenarios. Hence, reading comprehension technique cannot be directly applied to the task of open domain QA. In recent years, researchers attempt to answer open-domain questions with a large-scale unlabeled corpus. Chen et al. (2017) propose a distantly supervised open-domain question answering (DS-QA) system which uses information retrieval technique to obtain relevant text from Wikipedia, and then applies reading comprehension technique to extract the answer.

Although DS-QA proposes an effective strategy to collect relevant texts automatically, it always suffers from the noise issue. For example, for the question "Which country's capital is Dublin?", we may encounter that: (1) The retrieved paragraph "*Dublin is the largest city of Ireland ...*" does not actually answer the question; (2) The second "*Dublin*" in the retrieved paragraph '*Dublin is the capital of Ireland. Besides, Dublin is one of the famous tourist cities in Ireland and ...*" is not the correct token of the answer. These noisy paragraphs and tokens are regarded as valid instances in DS-QA. To address this issue, Choi et al. (2017) separate the answer generation in DS-QA into two modules including selecting a target paragraph in document and extracting the correct answer from the target paragraph by reading comprehension. Further, Wang et al. (2018a) use reinforcement learning to train target paragraph selection and answer extraction jointly.

These methods only extract the answer according to the most related paragraph, which will lose a large amount of rich information contained in

p3: Dublin is the capital of Ireland. Besides, Ottawa is one of famous tourist cities in Ireland and ...
Paragraph Reader
p1: As the capital of Ireland, Dublin is …
p3: Dublin is the capital of Ireland. Besides, Dublin is one of famous tourist cities in Ireland and ...
Answer: Dublin

Figure 1: An overview of our model. For the question 'What's the capital of Dublin?", our paragraph selector selects two paragraphs p_1 and p_3 which actually correspond to the question from all retrieved paragraphs. And then our paragraph reader extracts the correct answer "Dublin" (in red color) from all selected paragraphs. Finally, our system aggregates the extracted results and obtains the final answer.

those neglected paragraphs. In fact, the correct answer is often mentioned in multiple paragraphs, and different aspects of the question may be answered in several paragraphs. Therefore, Wang et al. (2018b) propose to further explicitly aggregate evidence from across different paragraphs to re-rank extracted answers. However, the re-ranking approach still relies on the answers obtained by existing DS-QA systems, and fails to solve the noise problem of DS-QA substantially.

To address these issues, we propose a coarse-to-fine denoising model for DS-QA. As illustrated in Fig. 1, our system first retrieves paragraphs according to the question from a large-scale corpus via information retrieval. After that, to utilize all informative paragraphs, we adopt a fast paragraph selector to skim all retrieved paragraphs and filter out those noisy ones. And then we apply a precise paragraph reader to perform careful reading in each selected paragraph for extracting the answer. Finally, we aggregate the derived results of all chosen paragraphs to obtain the final answer. The fast skimming of our paragraph selector and intensive reading of our paragraph reader in our method enables DS-QA to denoise noisy paragraphs as well as maintaining efficiency.

The experimental results on real-world datasets including Quasar-T, SearchQA and TriviaQA show that our system achieves significant and consistent improvement as compared to all baseline methods by aggregating extracted answers of all informative paragraphs. In particular, we show that our model can achieve comparable performance by selecting a few informative paragraphs, which greatly speeds up the whole DS-QA system. We will publish all source codes and datasets of this work on Github for further research explorations.

2 Related Work

Question answering is one of the most important tasks in NLP. Many efforts have been invested in QA, especially in open-domain QA. Open-domain QA has been first proposed by (Green Jr et al., 1961). The task aims to answer open-domain questions using external resources such as collections of documents (Voorhees et al., 1999), webpages (Kwok et al., 2001; Chen and Van Durme, 2017), structured knowledge graphs (Berant et al., 2013a; Bordes et al., 2015) or automatically extracted relational triples (Fader et al., 2014).

Recently, with the development of machine reading comprehension technique (Chen et al., 2016; Dhingra et al., 2017a; Cui et al., 2017; Shen et al., 2017; Wang et al., 2017), researchers attempt to answer open-domain questions via performing reading comprehension on plain texts. Chen et al. (2017) propose a DS-QA system, which retrieves relevant texts of the question from a large-scale corpus and then extracts answers from these texts using reading comprehension models. However, the retrieved texts in DS-QA are always noisy which may hurt the performance of DS-QA. Hence, Choi et al. (2017) and Wang et al. (2018a) attempt to solve the noise problem in DS-QA via separating the question answering into paragraph selection and answer extraction and they both only select the most relevant paragraph among all retrieved paragraphs to extract answers. They lose a large amount of rich information contained in those neglected paragraphs. Hence, Wang et al. (2018b) propose strength-base and coverage-based re-ranking approaches, which can aggregate the results extracted from each paragraph by existing DS-QA system to better determine the answer. However, the method relies on the pre-extracted answers of existing DS-QA models and still suffers from the noise issue in distant supervision data because it considers all retrieved paragraphs indiscriminately. Different from these methods, our model employs a paragraph selector to filter out those noisy paragraphs and keep those informative paragraphs, which can make full use of the noisy DS-QA data.

Our work is also inspired by the idea of coarse-to-fine models in NLP. Cheng and Lapata (2016) and Choi et al. (2017) propose a coarse-to-fine model, which first selects essential sentences and then performs text summarization or reading comprehension on the chosen sentences respectively. Lin et al. (2016) utilize selective attention to aggregate the information of all sentences to extract relational facts. Yang et al. (2016) propose a hierarchical attention network which has two levels of attentions applied at the word and sentence level for document classification. Our model also employs a coarse-to-fine model to handle the noise issue in DS-QA, which first selects informative retrieved paragraphs and then extracts answers from those selected paragraphs.

3 Methodology

In this section, we will introduce our model in details. Our model aims to extract the answer to a given question in the large-scale unlabeled corpus. We first retrieve paragraphs corresponding to the question from the open-domain corpus using information retrieval technique, and then extract the answer from these retrieved paragraphs.

Formally, given a question $q = (q^1, q^2, \cdots, q^{|q|})$, we retrieve m paragraphs which are defined as $P = \{p_1, p_2, \cdots, p_m\}$ where $p_i = (p_i^1, p_i^2, \cdots, p_i^{|p_i|})$ is the i-th retrieved paragraph. Our model measures the probability of extracting answer a given question q and corresponding paragraph set P. As illustrated in Fig. 1, our model contains two parts:

1. Paragraph Selector. Given the question q and the retrieved paragraph P, the paragraph selector measures the probability distribution $\Pr(p_i|q, P)$ over all retrieved paragraphs, which is used to select the paragraph that really contains the answer of question q.

2. Paragraph Reader. Given the question q and a paragraph p_i, the paragraph reader calculates the probability $\Pr(a|q, p_i)$ of extracting answer a through a multi-layer long short-term memory network.

Overall, the probability $\Pr(a|q, P)$ of extracting answer a given question q can be calculated as:

$$\Pr(a|q, P) = \sum_{p_i \in P} \Pr(a|q, p_i) \Pr(p_i|q, P). \quad (1)$$

3.1 Paragraph Selector

Since the wrong labeling problem inevitably occurs in DS-QA data, we need to filter out those noisy paragraphs when exploiting the information of all retrieved paragraphs. It is straightforward that we need to estimate the confidence of each paragraph. Hence, we employ a paragraph selector to measure the probability of each paragraph containing the answer among all paragraphs.

Paragraph Encoding. We first represent each word p_i^j in the paragraph p_i as a word vector $\mathbf{p}_i^j$, and then feed each word vector into a neural network to obtain the hidden representation $\hat{\mathbf{p}}_i^j$. Here, we adopt two types of neural networks including:
1. Multi-Layer Perceptron (MLP)

$$\hat{\mathbf{p}}_i^j = \text{MLP}(\mathbf{p}_i^j), \quad (2)$$

2. Recurrent Neural Network (RNN)

$$\{\hat{\mathbf{p}}_i^1, \hat{\mathbf{p}}_i^2, \cdots, \hat{\mathbf{p}}_i^{|p_i|}\} = \text{RNN}(\{\mathbf{p}_i^1, \mathbf{p}_i^2, \cdots, \mathbf{p}_i^{|p_i|}\}), \quad (3)$$

where $\hat{\mathbf{p}}_i^j$ is expected to encode semantic information of word p_i^j and its surrounding words. For RNN, we select a single-layer bidirectional long short-term memory network (LSTM) as our RNN unit, and concatenate the hidden states of all layers to obtain $\hat{\mathbf{p}}_i^j$.

Question Encoding. Similar to paragraph encoding, we also represent each word q^i in the question as its word vector $\mathbf{q}^i$, and then fed them into a MLP:

$$\hat{\mathbf{q}}_i^j = \text{MLP}(\mathbf{q}_i^j), \quad (4)$$

or a RNN:

$$\{\hat{\mathbf{q}}^1, \hat{\mathbf{q}}^2, \cdots, \hat{\mathbf{q}}^{|q|}\} = \text{RNN}(\{\mathbf{q}^1, \mathbf{q}^2, \cdots, \mathbf{q}^{|q|}\}). \quad (5)$$

where $\hat{\mathbf{q}}^j$ is the hidden representation of the word q^j and is expected to encode the context information of it. After that, we apply a self attention operation on the hidden representations to obtain the final representation $\mathbf{q}$ of the question q:

$$\hat{\mathbf{q}} = \sum_j \alpha^j \hat{\mathbf{q}}^j, \tag{6}$$

where α_j encodes the importance of each question word and is calculated as:

$$\alpha_i = \frac{\exp(\mathbf{w}_b \mathbf{q}_i)}{\sum_j \exp(\mathbf{w} b \mathbf{q}_j)}, \tag{7}$$

where $\mathbf{w}$ is a learned weight vector.

Next, we calculate the probability of each paragraph via a max-pooling layer and a softmax layer:

$$\Pr(p_i|q, P) = \text{softmax}\left(\max_j(\hat{\mathbf{p}}_i^j \mathbf{W} \mathbf{q})\right), \tag{8}$$

where $\mathbf{W}$ is a weight matrix to be learned.

3.2 Paragraph Reader

The paragraph reader aims to extract answers from a paragraph p_i. Similar to paragraph reader, we first encode each paragraph p_i as $\{\bar{\mathbf{p}}_i^1, \bar{\mathbf{p}}_i^2, \cdots, \bar{\mathbf{p}}_i^{|p_i|}\}$ through a multi-layers bidirectional LSTM . And we also obtain the question embedding $\bar{\mathbf{q}}$ via a self-attention multi-layers bidirectional LSTM.

The paragraph reader aims to extract the span of tokens which is most likely the correct answer. And we divide it into predicting the start and end position of the answer span. Hence, the probability of extracting answer a of the question q from the given the paragraph p_i can be calculated as:

$$\Pr(a|q, p_i) = P_s(a_s) P_e(a_e), \tag{9}$$

where a_s and a_e indicate the start and end positions of answer a in the paragraph, $P_s(a_s)$ and $P_e(a_e)$ are the probabilities of a_s and a_e being start and end words respectively, which is calculated by:

$$P_s(j) = \text{softmax}(\bar{\mathbf{p}}_i^j \mathbf{W}_s \bar{\mathbf{q}}), \tag{10}$$
$$P_e(j) = \text{softmax}(\bar{\mathbf{p}}_i^j \mathbf{W}_e \bar{\mathbf{q}}), \tag{11}$$

where $\mathbf{W}_s$ and $\mathbf{W}_e$ are two weight matrices to be learned. In DS-QA, since we didn't label the position of the answer manually, we may have several tokens matched to the correct answer in a paragraph. Let $\{(a_s^1, a_e^1), (a_s^2, a_e^2), \cdots, (a_s^{|a|}, a_e^{|a|})\}$ be the set of the start and end positions of the tokens matched to answer a in the paragraph p_i. The equation (9) is further defined using two ways:

(1) **Max**. That is, we assume that only one token in the paragraph indicates the correct answer. In this way, the probability of extracting the answer a can defined by maximizing the probability of all candidate tokens:

$$\Pr(a|q, p_i) = \max_j \Pr_s(a_s^j) \Pr_e(a_e^j) \tag{12}$$

(2) **Sum**. In this way, we regard all tokens matched to the correct answer equally. And we define the answer extraction probability as:

$$\Pr(a|q, p_i) = \sum_j \Pr_s(a_s^j) \Pr_e(a_e^j). \tag{13}$$

Our paragraph reader model is inspired by a previous machine reading comprehension model, Attentive Reader described in (Chen et al., 2016). In fact, other reading comprehension models can also be easily adopted as our paragraph reader. Due to the space limit, in this paper, we only explore the effectiveness of Attentive Reader.

3.3 Learning and Prediction

For the learning objective, we define a loss function L using maximum likelihood estimation:

$$L(\theta) = -\sum_{(\bar{a}, q, P) \in T} \log \Pr(a|q, P) - \alpha R(P), \tag{14}$$

where θ indicates the parameters of our model, a indicates the correct answer, T is the whole training set and $R(P)$ is a regularization term over the paragraph selector to avoid its overfitting. Here, $R(P)$ is defined as the KL divergence between $\Pr(p_i|q, P)$ and a probability distribution $\mathcal{X}$ where $\mathcal{X}_i = \frac{1}{c_P}$ (c_P is the number of paragraphs containing correct answer in P) if the paragraph contains correct answer, otherwise 0. Specifically, $R(P)$ is defined as:

$$R(P) = \sum_{p_i \in P} \mathcal{X}_i \log \frac{\mathcal{X}_i}{\Pr(p_i|q, P)}. \tag{15}$$

To solve the optimization problem, we adopt Adamax to minimize the objective function as described in (Kingma and Ba, 2015).

During testing, we extract the answer $\hat{a}$ with the highest probability as below:

$$\begin{aligned} \hat{a} &= \arg\max_a \Pr(a|q, P) \\ &= \arg\max_a \sum_{p_i \in P} \Pr(a|q, p_i) \Pr(p_i|q, P) \end{aligned} \tag{16}$$

Here, the paragraph selector can be viewed as a fast skimming over all paragraphs, which determines the probability distribution of containing the answer for each paragraph. Hence, we can simply aggregate the predicting results from those paragraphs with higher probabilities for acceleration.

4 Experiments

4.1 Datasets and Evaluation Metrics

We evaluate our model on five public open-domain question answering datasets.

Quasar-T[1] (Dhingra et al., 2017b) consists of $43,000$ open-domain trivia question, and their answers are extracted from ClueWeb09 data source, and the paragraphs are obtained by retrieving 50 sentences for each question from the ClueWeb09 data source using LUCENE.

SearchQA[2] (Dunn et al., 2017) is a large-scale open domain question answering dataset, which consists of question-answer pairs crawled from J! Archive, and the paragraphs are obtained by retrieving 50 webpages for each question from Google Search API.

TriviaQA[3] (Joshi et al., 2017) includes $95,000$ question-answer pairs authored by trivia enthusiasts and independently gathered evidence documents, six per question on average, and utilizes Bing Web search API to collect 50 webpages related to the questions.

CuratedTREC[4] (Voorhees et al., 1999) is based on the benchmark from the TREC QA tasks, which contains $2,180$ questions extracted from the datasets from TREC1999, 2000, 2001 and 2002.

WebQuestions[5] (Berant et al., 2013b) is designed for answering questions from the Freebase knowledge base, which is built by crawling questions through the Google Suggest API and the paragraphs are retrieved from the English Wikipedia using .

For Quasar-T, SearchQA and TriviaQA datasets, we use the retrieved paragraphs provided by (Wang et al., 2018a). For CuratedTREC and WebQuestions datasets, We use the 2016-12-21 dump of English Wikipedia as our knowledge source used to answer the question and then build a Lucene index system on it. After that, we take each input question as a query to retrieve top-50 paragraphs.

The statistics of these datasets are shown in Table 1.

Dataset	#Train	#Dev	#Test
Quasar-T	28,496	3,000	3,000
SearchQA	99,811	13,893	27,247
TriviaQA	66,828	11,313	10,832
CuratedTREC	1,486	-	694
WebQuestions	3,778	-	2,032

Table 1: Statistics of the dataset.

Following (Chen et al., 2017), we adopt two metrics including ExactMatch (EM) and F1 scores to evaluate our model. EM measures the percentage of predictions that match one of the ground truth answers exactly and F1 score is a metric that loosely measures the average overlap between the prediction and ground truth answer.

4.2 Baselines

For comparison, we select several public models as baselines including: (1) **GA** (Dhingra et al., 2017a), a reading comprehension model which performs multiple hops over the paragraph with gated attention mechanism; (2) **BiDAF** (Seo et al., 2017), a reading comprehension model with a bi-directional attention flow network. (3) **AQA** (Buck et al., 2017), a reinforced system learning to re-write questions and aggregate the answers generated by the re-written questions; (4) $\mathbf{R}^3$ (Wang et al., 2018a), a reinforced model making use of a ranker for selecting most confident paragraph to train the reading comprehension model.

And we also compare our model with its naive version, which regards each paragraph equally and sets a uniform distribution to the paragraph selection. We name our model as “Our+FULL” and its naive version “Our+AVG”.

4.3 Experimental Settings

In this paper, we tune our model on the development set and use a grid search to determine the optimal parameters. We select the hidden size of LSTM $n \in \{32, 64, \mathbf{128}, \cdots, 512\}$, the number of LSTM layers for document and question encoder among $\{1, 2, \mathbf{3}, 4\}$, regularization weight α among $\{0.1, \mathbf{0.5}, 1.0, 2.0\}$ and the batch size among $\{4, 8, 16, \mathbf{32}, 64, 128\}$. The optimal parameters are highlighted with bold faces. For other

[1] https://github.com/bdhingra/quasar
[2] https://github.com/nyu-dl/SearchQA
[3] http://nlp.cs.washington.edu/triviaqa/
[4] https://github.com/brmson/dataset-factoid-curated/tree/master/trec
[5] https://github.com/brmson/dataset-factoid-webquestions

parameters, since they have little effect on the results, we simply follow the settings used in (Chen et al., 2017).

For training, our Our+FULL model is first initialized by pre-training using Our+AVG model, and we set the iteration number over all the training data as 10. For pre-trained word embeddings, we use the 300-dimensional GloVe[6] (Pennington et al., 2014) word embeddings learned from 840B Web crawl data.

4.4 Effect of Different Paragraph Selectors

As our model incorporates different types of neural networks including MLP and RNN as our paragraph selector, we investigate the effect of different paragraph selector on the Quasar-T and SearchQA development set.

As shown in Table 3, our RNN paragraph selector leads to statistically significant improvements on both Quasar-T and SearchQA. Note that Our+FULL which uses MLP paragraph selector even performs worse on Quasar-T dataset as compared to Our+AVG. It indicates that MLP paragraph selector is insufficient to distinguish whether a paragraph answers the question. As RNN paragraph selector consistently improves all evaluation metrics, we use it as the default paragraph selector in the following experiments.

4.5 Effect of Different Paragraph Readers

Here, we compare the performance of different types of paragraph readers and the results are shown in Table 4.

From the table, we can see that all models with Sum or Max paragraph readers have comparable performance in most cases, but Our+AVG with Max reader has about 3% increment as compared to the one with Sum reader on the SearchQA dataset. It indicates that the Sum reader is more susceptible to noisy data since it regards all tokens matching to the answer as ground truth. In the following experiments, we select the Max reader as our paragraph reader since it is more stable.

4.6 Overall Results

In this part, we will show the performance of different models on five DS-QA datasets and offer some further analysis. The performance of our models are shown in Table 2. From the results, we can observe that:

(1) Both our models including Our+AVG and Our+FULL achieve better results on most of the datasets as compared to other baselines. The reason is that our models can make full use of the information of all retrieved paragraphs to answer the question, while other baseline models only consider the most relevant paragraph. It verifies our claim that incorporating the rich information of all retrieved paragraphs could help us better extract the answer to the question.

(2) On all datasets, Our+FULL model outperforms Our+AVG model significantly and consistently. It indicates that our paragraph selector could effectively filter out those meaningless retrieved paragraphs and alleviate the wrong labeling problem in DS-QA.

(3) On TriviaQA dataset, our+AVG model has worse performance as compared to R^3 model. After observing the TriviaQA dataset, we find that in this dataset only one or two retrieved paragraphs actually contain the correct answer. Therefore, simply using all retrieved paragraphs equally to extract answer may bring in much noise. On the contrary, Our+FULL model still has a slight improvement by considering the confidence of each retrieved paragraph.

(4) On CuratedTREC and WebQuestions datasets, our model only has a slight improvement as compared to R^3 model. The reason is that the size of these two datasets is tiny and the performance of these DS-QA systems is heavily influenced by the gap with the dataset used to pre-trained.

4.7 Paragraph Selector Performance Analysis

To demonstrate the effectiveness of our paragraph selector in filtering out those noisy retrieved paragraphs, we compare our paragraph selector with traditional information retrieval[7] (IR) in this part. We also compare our model with a new baseline named Our+INDEP which trains the paragraph reader and the paragraph selector independently. To train the paragraph selector, we regard all the paragraph containing the correct answer as ground truth and learns it with Eq. 14.

First, we show the performance in selecting informative paragraphs. Since distantly supervised data doesn't have the labeled ground-truth to tell

[6]`http://nlp.stanford.edu/data/glove.840B.300d.zip`

[7]The information retrieval model ranks the paragraph with BM25 which is implemented by Lucene.

Datasets	Quasar-T		SearchQA		TriviaQA		CuratedTREC	WebQuestions

Datasets		Quasar-T		SearchQA	
Models	Reader	EM	F1	EM	F1
Our + AVG	Max	38.6	45.8	57.3	62.7
+ FULL		41.7	49.1	62.3	67.9
Our + AVG	Sum	39.1	46.3	54.0	59.4
+ FULL		42.3	49.4	61.9	67.4

Table 4: Effect of Different Paragraph Reader on the Quasar-T and SearchQA development set. The paragraph selector used in Our+FULL is RNN.

which paragraphs actually answer the question, we adopt a held-out evaluation instead. It evaluates our model by comparing the selected paragraph with pseudo labels: we regard a paragraph as ground-truth if it contains a token matched to the correct answer. We use Hit@N which indicates the proportion of proper paragraphs being ranked in top-N as evaluation metrics. The result is shown in Table 5. From the table, we can observe that:

(1) Both Our+INDEP and Our+FULL outperform traditional IR model significantly in selecting informative paragraphs. It indicates that our proposed paragraph selector is capable of catching the semantic correlation between question and paragraphs.

(2) Our+FULL has similar performance as compare with Our+SINGLE from Hits@1 to Hits@5 to select valid paragraphs. The reason is that the way of our evaluation of paragraph selection is consistent with the training objective of the ranker in Our+SINGLE.

In fact, this way of evaluation may be not enough to distinguish the performance of different paragraph selector. Therefore, we further report the overall answer extraction performance of Our+FULL and Our+INDEP. From the table, we can see that Our+FULL performs better in answer extraction as compared to Our+SINGLE although they have similar performance in paragraph selection. It demonstrates that our paragraph selector can better determine which tokens matched to the answer are actually answering the question by joint training with paragraph reader.

4.8 Performance with different numbers of paragraphs

Our paragraph selector can be viewed as a fast skimming step before carefully reading the paragraphs. To show how much our paragraph selector can accelerate the DS-QA system, we compare the performance of our model with top paragraphs selected by our paragraph selector (Our+FULL) or traditional IR model.

The results are shown in Fig. 2. There is no doubt that with the number of paragraphs increasing, the performance of our+IR and our+FULL model will increase significantly. From the figure, we can find that on both Quasar-T and SearchQA datasets, our+FULL can use only half of the retrieved paragraphs for answer extraction without performance deterioration, while our+IR suffers from the significant performance degradation when decreasing the number of paragraphs. It demonstrates that our model can extract answer with a few informative paragraphs selected by paragraph selector, which will speed up our whole DS-QA system.

4.9 Potential improvement

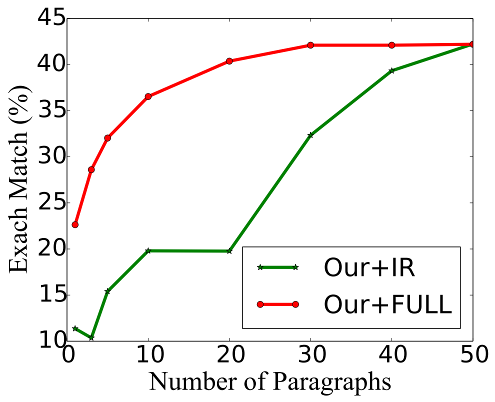
To show the potential improvement in aggregating extracted answers with answer re-ranking models of our DS-QA system, we provide statistical anal-

Datasets	Quasar-T					SearchQA				
Task	Paragraph Selection			Overall		Paragraph Selection			Overall	
Models	Hits@1	Hits@3	Hits@5	EM	F1	Hits@1	Hits@3	Hits@5	EM	F1
IR	6.3	10.9	15.2	-	-	13.7	24.1	32.7	-	-
Our + INDEP	26.8	36.3	41.9	40.6	46.9	59.2	70.0	75.7	57.0	62.3
Our + FULL	27.7	36.8	42.6	41.1	48.0	58.9	69.8	75.5	58.8	64.5

Table 5: Comparison of our paragraph selector and traditional information retrieval model in paragraph selection. The Our+AVG and Our+FULL model used in WebQuestions dataset is pre-trained with Quasart-T dataset

Question:	Who directed the 1946 'It's A Wonderful Life'?
Ground Truth:	Frank Capra
Paragraph1	It's a Wonderful Life (1946): directed by **Frank Capra**, starred by James Stewart, Donna Reed ...
Paragraph2	It's a Wonderful Life, the 1946 film produced and directed by **Frank Capra** and starring ...
Paragraph3	It's a Wonderful Life Guajara in other languages: Spanish, Deutsch, French, Italian ...
Question:	What famous artist could write with both his left and right hand at the same time
Ground Truth:	Leonardo Da Vinci
Paragraph1	**Leonardo Da Vinci** was and is best known as an artist,...
Paragraph2	... the reason **Leonardo da Vinci** used his left hand exclusively was that his right hand was paralyzed.
Paragraph3	... forced me to use my right-hand,... beat my left-hand fingers with ... so that i use the right hand.

Table 6: The examples of the answers to the given questions extracted by our model. The token in bold are the extracted answers in each paragraph. The paragraphs are sorted according to the probabilities output by our paragraph selector.



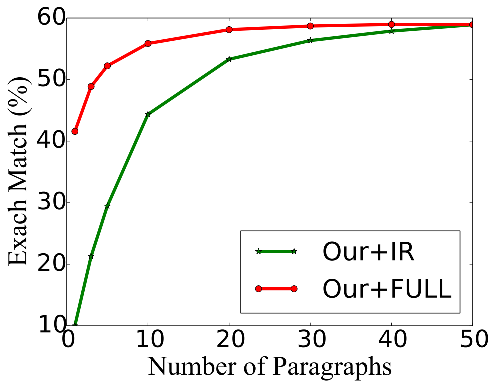


Figure 2: Performance with different numbers of top paragraphs on Quasar-T (up) and SearchQA (bottom) datasets.

ysis to the upper bound of our system performance on the development set. Here, we compare our model with R^3 model by evaluating the F1/EM scores among the top-k extracted answers. This top-k performance of our system can be viewed as the upper bound of our system to re-rank the top-k extracted answers.

Datasets		Quasar-T		SearchQA	
Model	TOP-k	EM	F1	EM	F1
R^3	1	35.3	41.6	51.2	57.3
	3	46.2	53.5	63.9	68.9
	5	51.0	58.9	69.1	73.9
	10	56.1	64.8	75.5	79.6
Our + FULL	1	42.2	49.3	58.8	67.4
	3	53.1	62.0	72.9	77.4
	5	56.4	66.4	76.9	81.0
	10	60.7	71.3	81.2	85.1

Table 7: Potential improvement on DS-QA performance by answer re-ranking. The performance is based on the Quasar-T and SearchQA development dataset.

From Table 7, we can see that:

(1) There is a clear gap between top-3/5 and top-1 DS-QA performance (10-20%). It indicates that our DS-QA model is far from the upper performance and still has a high probability to be improved by answer re-ranking.

(2) The Our+FULL model outperforms R^3 model in top-1, top-3 and top-5 on both Quasar-T and SearchQA datasets by 5% to 7%. It indicates that aggregating the information from all informative paragraphs can effectively enhance our model in DS-QA, which is more potential using answer re-ranking.

4.10 Case Study

Table 6 shows two examples of our models, which illustrates that our model can make full use of informative paragraphs. From the table we find that:

(1) For the question "Who directed the 1946 'It's A Wonderful Life'?", our model extracts the answer "Frank Capra" from both top-2 paragraphs ranked by our paragraph selector.

(2) For the question "What famous artist could write with both his left and right hand at the same time?", our model identifies that "Leonardo Da Vinci" is an artist from the first paragraph and could write with both his left and right hand at the same time from the second paragraph.

5 Conclusion and Future Work

In this paper, we propose a denoising distantly supervised open-domain question answering system which contains a paragraph selector to skim over paragraphs and a paragraph reader to perform an intensive reading on the selected paragraphs. Our model can make full use of all informative paragraphs and alleviate the wrong labeling problem in DS-QA. In the experiments, we show that our models significantly and consistently outperforms state-of-the-art DS-QA models. In particular, we demonstrate that the performance of our model is hardly compromised when only using a few top-selected paragraphs.

In the future, we will explore the following directions:

(1) An additional answer re-ranking step can further improve our model. We will explore how to effectively re-rank our extracted answers to further enhance the performance.

(2) Background knowledge such as factual knowledge, common sense knowledge can effectively help us in paragraph selection and answer extraction. We will incorporate external knowledge bases into our DS-QA model to improve its performance.

Question Condensing Networks for Answer Selection in Community Question Answering

Wei Wu[1], Xu Sun[1], Houfeng Wang[1,2]

Abstract

Answer selection is an important subtask of community question answering (CQA). In a real-world CQA forum, a question is often represented as two parts: a subject that summarizes the main points of the question, and a body that elaborates on the subject in detail. Previous researches on answer selection usually ignored the difference between these two parts and concatenated them as the question representation. In this paper, we propose the Question Condensing Networks (QCN) to make use of the subject-body relationship of community questions. In this model, the question subject is the primary part of the question representation, and the question body information is aggregated based on similarity and disparity with the question subject. Experimental results show that QCN outperforms all existing models on two CQA datasets.

1 Introduction

Community question answering (CQA) has seen a spectacular increase in popularity in recent years. With the advent of sites like Stack Overflow[1] and Quora[2], more and more people can freely ask any question and expect a variety of answers. With the influx of new questions and the varied quality of provided answers, it is very time-consuming for a user to inspect them all. Therefore, developing automated tools to identify good answers for a question is of practical importance.

A typical example for CQA is shown in Table 1. In this example, Answer 1 is a good answer, because it provides helpful information, e.g., "*check it to the traffic dept*". Although Answer 2 is relevant to the question, it does not contain any useful information so that it should be regarded as a bad answer.

From this example, we can observe two characteristics of CQA that ordinary QA does not possess. First, a question includes both a subject that gives a brief summary of the question and a body that describes the question in detail. The questioners usually convey their main concern and key information in the question subject. Then, they provide more extensive details about the subject, seek help, or express gratitude in the question body. Second, the problem of redundancy and noise is prevalent in CQA (Zhang et al., 2017). Both questions and answers contain auxiliary sentences that do not provide meaningful information.

Previous researches (Tran et al., 2015; Joty et al., 2016) usually treat each word equally in the question and answer representation. However, due to the redundancy and noise problem, only part of text from questions and answers is useful to determine the answer quality. To make things worse, they ignored the difference between question subject and body, and simply concatenated them as the question representation. Due to the subject-body relationship described above, this simple concatenation can aggravate the redundancy problem in the question. In this paper, we propose the Question Condensing Networks (QCN) to address these problems.

In order to utilize the subject-body relationship in community questions, we propose to treat the question subject as the primary part of the question, and aggregate the question body information based on similarity and disparity with the question subject. The similarity part corresponds to the information that exists in both question subject and body, and the disparity part corresponds to the additional information provided by the ques-

[1]https://stackoverflow.com/
[2]https://www.quora.com/

Question Subject	Checking the history of the car.
Question body	How can one check the history of the car like maintenance, accident or service history. In every advertisement of the car, people used to write “Accident Free", but in most cases, car have at least one or two accident, which is not easily detectable through Car Inspection Company. Share your opinion in this regard.
Answer1	Depends on the owner of the car.. if she/he reported the accident/s i believe u can check it to the traffic dept.. but some owners are not doing that especially if its only a small accident.. try ur luck and go to the traffic dept..
Answer2	How about those who claim a low mileage by tampering with the car fuse box? In my sense if you’re not able to detect traces of an accident then it is probably not worth mentioning... For best results buy a new car :)

Table 1: An example question and its related answers in CQA. The text is shown in its original form, which may contain errors in typing.

tion body. Both information can be important for question representation. In our model, they are processed separately and the results are combined to form the final question representation.

In order to reduce the impact of redundancy and noise in both questions and answers, we propose to align the question-answer pairs using the multi-dimensional attention mechanism. Different from previous attention mechanisms that compute a scalar score for each token pair, multi-dimensional attention, first proposed in Shen et al. (2018), computes one attention score for each dimension of the token embedding. Therefore, it can select the features that can best describe the word’s specific meaning in the given context. Therefore, we can learn the interaction between questions and answers more accurately.

The main contributions of our work can be summarized as follows:

- We propose to treat the question subject and the question body separately in community question answering. We treat the question subject as the primary part of the question, and aggregate the question body information based on similarity and disparity with the question subject.

- We introduce a new method that uses the multi-dimensional attention mechanism to align question-answer pair. With this attention mechanism, the interaction between questions and answers can be learned more accurately.

- Our proposed Question Condensing Networks (QCN) achieves the state-of-the-art performance on two SemEval CQA datasets, outperforming all exisiting SOTA models by a large margin, which demonstrates the effectiveness of our model.[3]

2 Task Description

A community question answering consists of four parts, which can be formally defined as a tuple of four elements (S, B, C, y). $S = [\boldsymbol{s}^1, \boldsymbol{s}^2, ..., \boldsymbol{s}^l]$ denotes the subject of a question whose length is l, where each $\boldsymbol{s}^i$ is a one-hot vector whose dimension equals the size of the vocabulary. Similarly, $B = [\boldsymbol{b}^1, \boldsymbol{b}^2, ..., \boldsymbol{b}^m]$ denotes the body of a question whose length is m. $C = [\boldsymbol{c}^1, \boldsymbol{c}^2, ..., \boldsymbol{c}^n]$ denotes an answer corresponding to that question whose length is n. $y \in \mathcal{Y}$ is the label representing the degree to which it can answer that question. $\mathcal{Y} = \{\textit{Good}, \textit{PotentiallyUseful}, \textit{Bad}\}$ where *Good* indicates the answer can answer that question well, *PotentiallyUseful* indicates the answer is potentially useful to the user, and *Bad* indicates the answer is just bad or useless. Given $\{S, B, C\}$, the task of CQA is to assign a label to each answer based on the conditional probability $Pr(y|S, B, C)$.

3 Proposed Model

In this paper, we propose Question Condensing Networks (QCN) which is composed of the following modules. The overall architecture of our model is illustrated in Figure 1.

[3]An implementation of our model is available at `https://github.com/pku-wuwei/QCN`.

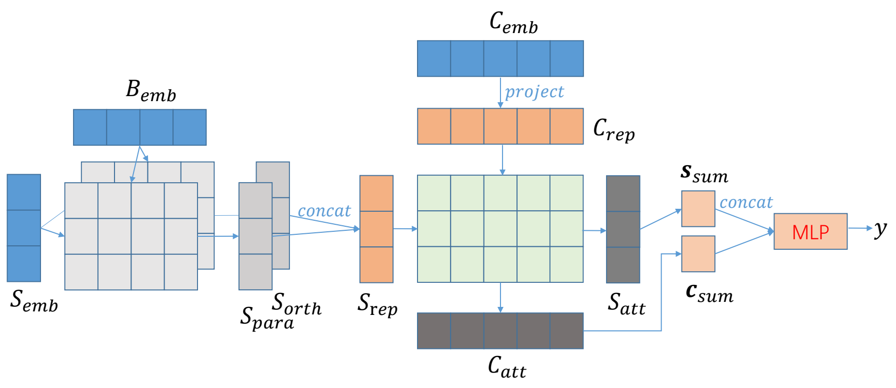

Figure 1: Architecture for Question Condensing Network (QCN). Each block represents a vector.

3.1 Word-Level Embedding

Word-level embeddings are composed of two components: GloVe (Pennington et al., 2014) word vectors trained on the domain-specific unannotated corpus provided by the task [4], and convolutional neural network-based character embeddings which are similar to (Kim et al., 2016). Web text in CQA forums differs largely from normalized text in terms of spelling and grammar, so specifically trained GloVe vectors can model word interactions more precisely. Character embedding has proven to be very useful for out-of-vocabulary (OOV) words, so it is especially suitable for noisy web text in CQA.

We concatenate these two embedding vectors for every word to generate word-level embeddings $\boldsymbol{S}_{emb} \in \mathbb{R}^{d\times l}, \boldsymbol{B}_{emb} \in \mathbb{R}^{d\times m}, \boldsymbol{C}_{emb} \in \mathbb{R}^{d\times n}$, where d is the word-level embedding size.

3.2 Question Condensing

In this section, we condense the question representation using subject-body relationship. In most cases, the question subject can be seen as a summary containing key points of the question, the question body is relatively lengthy in that it needs to explain the key points and add more details about the posted question. We propose to cheat the question subject as the primary part of the question representation, and aggregate question body information from two perspectives: similarity and disparity with the question subject. To achieve this goal, we use an orthogonal decomposition strategy, which is first proposed by Wang et al. (2016), to decompose each question body embedding into a parallel component and an orthogonal component based on every question subject embedding:

$$\boldsymbol{b}^{i,j}_{para} = \frac{\boldsymbol{b}^{j}_{emb} \cdot \boldsymbol{s}^{i}_{emb}}{\boldsymbol{s}^{i}_{emb} \cdot \boldsymbol{s}^{i}_{emb}} \boldsymbol{s}^{i}_{emb} \tag{1}$$

$$\boldsymbol{b}^{i,j}_{orth} = \boldsymbol{b}^{j}_{emb} - \boldsymbol{b}^{i,j}_{para} \tag{2}$$

All vectors in the above equations are of length d. Next we describe the process of aggregating the question body information based on the parallel component in detail. The same process can be applied to the orthogonal component, so at the end of the fusion gate we can obtain S_{orth} and S_{orth} respectively.

The decomposed components are passed through a fully connected layer to compute the multi-dimensional attention weights. Here we use the scaled tanh activation, which is similar to Shen et al. (2018), to prevent large difference among scores while it still has a range large enough for output:

$$\boldsymbol{a}^{i,j}_{para} = c \cdot \tanh\left(\left[W_{p1}\boldsymbol{b}^{i,j}_{para} + \boldsymbol{b}_{p1}\right]/c\right) \tag{3}$$

where $W_{p1} \in \mathbb{R}^{d\times d}$ and $\boldsymbol{b}_{p1} \in \mathbb{R}^{d}$ are parameters to be learned, and c is a hyper-parameter to be tuned.

The obtained word-level alignment tensor $\boldsymbol{A}_{para} \in \mathbb{R}^{d\times l\times m}$ is then normalized along the third dimension to produce the attention weights over the question body for each word in the question subject. The output of this attention mechanism is a weighted sum of the question body embeddings for each word in the question subject:

$$\boldsymbol{w}^{i,j}_{para} = \frac{\exp\left(\boldsymbol{a}^{i,j}_{para}\right)}{\sum_{j=1}^{m}\exp\left(\boldsymbol{a}^{i,j}_{para}\right)} \tag{4}$$

$$\boldsymbol{s}^{i}_{ap} = \sum_{j=1}^{m} \boldsymbol{w}^{i,j}_{para} \odot \boldsymbol{b}^{j}_{emb} \tag{5}$$

[4] http://alt.qcri.org/semeval2015/task3/index.php?id=data-and-tools

where $\odot$ means point-wise product. This multi-dimensional attention mechanism has the advantage of selecting features of a word that can best describe the word's specific meaning in the given context. In order to determine the importance between the original word in the question subject and the aggregated information from the question body with respect to this word, a fusion gate is utilized to combine these two representations:

$$F_{para} = \sigma\left(W_{p2}S_{emb} + W_{p3}S_{ap} + \boldsymbol{b}_{p2}\right) \quad (6)$$
$$S_{para} = F_{para} \odot S_{emb} + (1 - F_{para}) \odot S_{ap} \quad (7)$$

where $W_{p2}, W_{p3} \in \mathbb{R}^{d\times d}$, and $\boldsymbol{b}_{p2} \in \mathbb{R}^{d}$ are learnable parameters of the fusion gate, and $F_{para}, S_{emb}, S_{ap}, S_{para} \in \mathbb{R}^{d\times l}$. The final question representation $S_{rep} \in \mathbb{R}^{2d\times l}$ is obtained by concatenating S_{para} and S_{orth} along the first dimension.

3.3 Answer Preprocessing

This module has two purposes. First, we try to map each answer word from embedding space $\boldsymbol{C}_{emb} \in \mathbb{R}^{d\times n}$ to the same interaction space $\boldsymbol{C}_{rep} \in \mathbb{R}^{2d\times n}$ as the question. Second, similar to Wang and Jiang (2017), a gate is utilized to control the importance of different answer words in determining the question-answer relation:

$$\begin{aligned} C_{rep} =& \sigma\left(W_{c1}C_{emb} + \boldsymbol{b}_{c1}\right) \odot \\ & \tanh\left(W_{c2}C_{emb} + \boldsymbol{b}_{c2}\right) \end{aligned} \quad (8)$$

where $W_{c1}, W_{c2} \in \mathbb{R}^{d\times 2d}$ and $\boldsymbol{b}_{c1}, \boldsymbol{b}_{c2} \in \mathbb{R}^{2d}$ are parameters to be learned.

3.4 Question Answer Alignment

We apply the multi-dimensional attention mechanism to the question and answer representation S_{rep} and C_{rep} to obtain word-level alignment tensor $\boldsymbol{A}_{align} \in \mathbb{R}^{2d\times l\times n}$. Similar to the multi-dimensional attention mechanism described above, we can compute attention weights and weighted sum for both the question representation and the answer representation :

$$\tilde{\boldsymbol{a}}^{i,j}_{align} = W_{a1}\boldsymbol{s}^{i}_{rep} + W_{a2}\boldsymbol{c}^{j}_{rep} + \boldsymbol{b}_{a} \quad (9)$$
$$\boldsymbol{a}^{i,j}_{align} = c \cdot \tanh\left(\tilde{\boldsymbol{a}}^{i,j}_{align}/c\right) \quad (10)$$
$$\boldsymbol{s}^{i}_{ai} = \sum_{j=1}^{n} \frac{\exp\left(\boldsymbol{a}^{i,j}_{align}\right)}{\sum_{j=1}^{n}\exp\left(\boldsymbol{a}^{i,j}_{align}\right)} \odot \boldsymbol{c}^{j}_{rep} \quad (11)$$
$$\boldsymbol{c}^{j}_{ai} = \sum_{i=1}^{l} \frac{\exp\left(\boldsymbol{a}^{i,j}_{align}\right)}{\sum_{i=1}^{l}\exp\left(\boldsymbol{a}^{i,j}_{align}\right)} \odot \boldsymbol{s}^{i}_{rep} \quad (12)$$

where $W_{a1}, W_{a2} \in \mathbb{R}^{2d\times 2d}$ and $\boldsymbol{b}_{a} \in \mathbb{R}^{2d}$ are parameters to be learned. To attenuate the effect of incorrect attendance, input and output of this attention mechanism are concatenated and fed to the subsequent layer. Finally, we obtain the question and answer representation $S_{att} \in \mathbb{R}^{4d\times l} = [S_{rep}; S_{ai}]$, $C_{att} \in \mathbb{R}^{4d\times n} = [C_{rep}; C_{ai}]$.

3.5 Interaction Summarization

In this layer, the multi-dimensional self-attention mechanism is employed to summarize two sequences of vectors (S_{att} and C_{att}) into two fixed-length vectors $\boldsymbol{s}_{sum} \in \mathbb{R}^{4d}$ and $\boldsymbol{c}_{sum} \in \mathbb{R}^{4d}$.

$$A_{s} = W_{s2}\tanh\left(W_{s1}S_{att} + \boldsymbol{b}_{s1}\right) + \boldsymbol{b}_{s2} \quad (13)$$
$$\boldsymbol{s}_{sum} = \sum_{i=1}^{n} \frac{\exp\left(\boldsymbol{a}^{i}_{s}\right)}{\sum_{i=1}^{n}\exp\left(\boldsymbol{a}^{i}_{s}\right)} \odot \boldsymbol{s}^{i}_{att} \quad (14)$$

where $W_{s1}, W_{s2} \in \mathbb{R}^{4d\times 4d}$ and $\boldsymbol{b}_{s1}, \boldsymbol{b}_{s2} \in \mathbb{R}^{4d}$ are parameters to be learned. The same process can be applied to C_{att} and obtain $\boldsymbol{c}_{sum}$.

3.6 Prediction

In this component, $\boldsymbol{s}_{sum}$ and $\boldsymbol{c}_{sum}$ are concatenated and fed into a two-layer feed-forward neural network. At the end of the last layer, the $softmax$ function is applied to obtain the conditional probability distribution $Pr(y|S, B, C)$.

4 Experimental Setup

4.1 Datasets

We use two community question answering datasets from SemEval (Nakov et al., 2015, 2017) to evaluate our model. The statistics of these datasets are listed in Table 2. The corpora contain data from the QatarLiving forum [5], and are publicly available on the task website. Each dataset

[5]http://www.qatarliving.com/forum

Statistics	SemEval 2015			SemEval 2017		
	Train	Dev	Test	Train	Dev	Test
Number of questions	2376	266	300	5124	327	293
Number of answers	15013	1447	1793	38638	3270	2930
Average length of subject	6.36	6.08	6.24	6.38	6.16	5.76
Average length of body	39.26	39.47	39.53	43.01	47.98	54.06
Average length of answer	35.82	33.90	37.33	37.67	37.30	39.50

Table 2: Statistics of two CQA datasets. We can see from the statistics that the question body is much lengthier than the question subject. Thus, it is necessary to condense the question representation.

consists of questions and a list of answers for each question, and each question consists of a short title and a more detailed description. There are also some metadata associated with them, e.g., user ID, date of posting, and the question category. We do not use the metadata because they failed to boost performance in our model. Since the SemEval 2017 dataset is an updated version of SemEval 2016 [6], and shares the same evaluation metrics with SemEval 2016, we choose to use the SemEval 2017 dataset for evaluation.

4.2 Evaluation Metrics

In order to facilitate comparison, we adopt the evaluation metrics used in the official task or prior work. For the SemEval 2015 dataset, the official scores are macro-averaged F1 and accuracy over three categories. However, many recent researches (Barrón-Cedeño et al., 2015; Joty et al., 2015, 2016) switched to a binary classification setting, i.e., identifying *Good* vs. *Bad* answers. Because binary classification is much closer to a real-world CQA application. Besides, the *PotentiallyUseful* class is both the smallest and the noisiest class, making it the hardest to predict. To make it worse, its impact is magnified by the macro-averaged F1. Therefore, we adopt the F1 score and accuracy on two categories for evaluation.

SemEval 2017 regards answer selection as a ranking task, which is closer to the application scenario. As a result, mean average precision (MAP) is used as an evaluation measure. For a perfect ranking, a system has to place all *Good* answers above the *PotentiallyUseful* and *Bad* answers. The latter two are not actually distinguished and are considered *Bad* in terms of evaluation. Additionally, standard classification measures like accuracy and F1 score are also reported.

[6]The SemEval 2017 dataset provides all the data from 2016 for training , and fresh data for testing, but it does not include a development set. Following previous work (Filice et al., 2017), we use the 2016 official test set as the development set.

4.3 Implementation Details

We use the tokenizer from NLTK (Bird, 2006) to preprocess each sentence. All word embeddings in the sentence encoder layer are initialized with the 300-dimensional GloVe (Pennington et al., 2014) word vectors trained on the domain-specific unannotated corpus, and embeddings for out-of-vocabulary words are set to zero. We use the Adam Optimizer (Kingma and Ba, 2014) for optimization with a first momentum coefficient of 0.9 and a second momentum coefficient of 0.999. We perform a small grid search over combinations of initial learning rate [1×10^{-6}, 3×10^{-6}, 1×10^{-5}], L2 regularization parameter [1×10^{-7}, 3×10^{-7}, 1×10^{-6}], and batch size [8, 16, 32]. We take the best configuration based on performance on the development set, and only evaluate that configuration on the test set. In order to mitigate the class imbalance problem, median frequency balancing Eigen and Fergus (2015) is used to reweight each class in the cross-entropy loss. Therefore, the rarer a class is in the training set, the larger weight it will get in the cross entropy loss. Early stopping is applied to mitigate the problem of overfitting. For the SemEval 2017 dataset, the conditional probability over the *Good* class is used to rank all the candidate answers.

5 Experimental Results

In this section, we evaluate our QCN model on two community question answering datasets from SemEval shared tasks.

5.1 SemEval 2015 Results

Table 3 compares our model with the following baselines:

Methods	F1	Acc
(1) JAIST	78.96	79.10
(2) HITSZ-ICRC	76.52	76.11
(3) Graph-cut	80.55	79.80
(4) FCCRF	81.50	80.50
(5) BGMN	77.23	78.40
(6) CNN-LSTM-CRF	82.22	82.24
(7) QCN	**83.91**	**85.65**

Table 3: Comparisons on the SemEval 2015 dataset.

- **JAIST** (Tran et al., 2015): It used an SVM classifier to incorporate various kinds of features , including topic model based features and word vector representations.
- **HITSZ-ICRC** (Hou et al., 2015): It proposed ensemble learning and hierarchical classification method to classify answers.
- **Graph-cut** (Joty et al., 2015): It modeled the relationship between pairs of answers at any distance in the same question thread, based on the idea that similar answers should have similar labels.
- **FCCRF** (Joty et al., 2016): It used locally learned classifiers to predict the label for each individual node, and applied fully connected CRF to make global inference.
- **CNN-LSTM-CRF** (Xiang et al., 2016): The question and its answers are linearly connected in a sequence and encoded by CNN. An attention-based LSTM with a CRF layer is then applied on the encoded sequence.
- **BGMN** (Wu et al., 2017b): It used the memory mechanism to iteratively aggregate more relevant information which is useful to identify the relationship between questions and answers.

Baselines include top systems from SemEval 2015 (1, 2), systems relying on thread level information to make global inference (3, 4), and neural network based systems (5, 6). We observe that our proposed QCN can achieve the state-of-the-art performance on this dataset, outperforming previous best model (6) by 1.7% in terms of F1 and 3.4% in terms of accuracy.

Methods	MAP	F1	Acc
(1) KeLP	88.43	69.87	73.89
(2) Beihang-MSRA	88.24	68.40	51.98
(3) ECNU	86.72	77.67	78.43
(4) LSTM	86.32	74.41	75.69
(5) LSTM-subject-body	87.11	74.50	77.28
(6) QCN	**88.51**	**78.11**	**80.71**

Table 4: Comparisons on the SemEval 2017 dataset.

Notably, Systems (1, 2, 3, 4) have heavy feature engineering, while QCN only uses automatically-learned feature vectors, demonstrating that our QCN model is concise as well as effective. Furthermore, our model can outperform systems relying on thread level information to make global inference (3, 4), showing that modeling interaction between the question-answer pair is useful enough for answer selection task. Finally, neural network based systems (5, 6) used attention mechanism in sentence representation but ignored the subject-body relationship in community questions. QCN can outperform them by a large margin, showing that condensing question representation helps in the answer selection task.

5.2 SemEval 2017 Results

Table 4 compares our model with the following baselines:

- **KeLP** (Filice et al., 2017): It used syntactic tree kernels with relational links between questions and answers, together with some standard text similarity measures linearly combined with the tree kernel.
- **Beihang-MSRA** (Feng et al., 2017): It used gradient boosted regression trees to combine traditional NLP features and neural network-based matching features.
- **ECNU** (Wu et al., 2017a): It combined a supervised model using traditional features and a convolutional neural network to represent the question-answer pair.
- **LSTM**: It is a simple neural network based baseline that we implemented. In this model, the question subject and the question body are concatenated, and an LSTM is used to obtain the question and answer representation.

- **LSTM-subject-body**: It is another neural network based baseline that we implemented. LSTM is applied on the question subject and body respectively, and the results are concatenated to form question representation.

Baselines include top systems from the SemEval 2017 CQA task (1, 2, 3) and two neural network based baselines (4, 5) that we implemented. (5) can outperform (4), showing that treating question subject and body differently can indeed boot model performance. Comparing (6) with (5), we can draw the conclusion that orthogonal decomposition is more effective than simple concatenation, because it can flexibly aggregate related information from the question body with respect to the main subject. In the example listed in Table 1, attention heatmap of A_{orth} indicates that QCN can effectively find additional information like "*maintenance, accident or service history*", while (5) fails to do so.

QCN has a great advantage in terms of accuracy. We hypothesize that QCN focuses on modeling interaction between questions and answers, i.e., whether an answer can match the corresponding question. Many pieces of previous work focus on modeling relationship between answers in a question thread, i.e., which answer is more suitable in consideration of all other answers. As a consequence, their models have a greater advantage in ranking while QCN has a greater advantage in classification. Despite all this, QCN can still obtain better ranking performance.

5.3 Ablation Study

For thorough comparison, besides the preceding models, we implement nine extra baselines on the SemEval 2017 dataset to analyze the improvements contributed by each part of our QCN model:

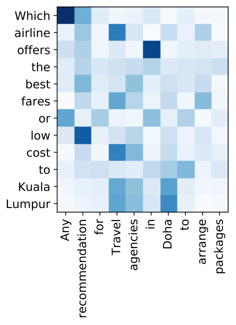
- **w/o task-specific word embeddings** where word embeddings are initialized with the 300-dimensional GloVe word vectors trained on Wikipedia 2014 and Gigaword 5.
- **w/o character embeddings** where word-level embeddings are only composed of 600-dimensional GloVe word vectors trained on the domain-specific unannotated corpus.
- **subject-body alignment** where we use the same attention mechanism as Question Answer Alignment to obtain weighted sum of the question body for each question subject word, and then the result is concatenated with S_{emb} to obtain question representation S_{rep}.
- **subject-body concatenation** where we concatenate question subject and body text, and use the preprocessing step described in section 3.3 to obtain S_{rep}.
- **w/o multi-dimensional attention** where the multi-dimensional attention mechanism is replaced by vanilla attention in all modules, i.e., attention score for each token pair is a scalar instead of a vector.
- **subject only** where only question subject is used as question representation.
- **body only** where only question body is used as question representation.
- **similarity only** where the parallel component alone is used in subject-body interaction.
- **disparity only** where the orthogonal component alone is used in subject-body interaction.

Model	**Acc**
(1) w/o task-specific word embeddings	78.81
(2) w/o character embeddings	78.05
(3) subject-body alignment	77.38
(4) subject-body concatenation	76.06
(5) w/o multi-dimensional attention	78.33
(6) subject only	74.02
(7) body only	75.57
(8) similarity only	79.11
(9) disparity only	78.24
(10) QCN	**80.71**

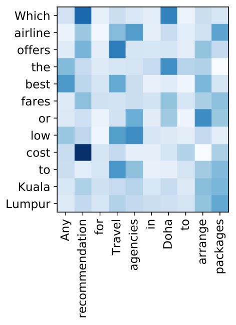
Table 5: Ablation studies on the SemEval 2017 dataset.

The results are listed in Table 5. We can see that using task-specific embeddings and character embeddings both contribute to model performance. This is because CQA text is non-standard. There are quantities of informal language usage, such as abbreviations, typos, emoticons, and grammatical mistakes. Using task-specific embeddings and character embeddings can help to attenuate the OOV problem.

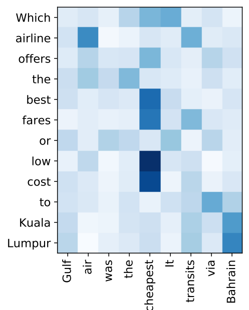
Using orthogonal decomposition (10) instead of subject-body alignment (3) can bring about significant performance gain. This is because not only



(a) A_{para}



(b) A_{orth}



(c) A_{align}

Figure 2: Attention probabilities in A_{para}, A_{orth} and A_{align}. In order to visualize the multi-dimensional attention vector, we use the $L2$ norm of the attenion vector for representation.

the similar part of the question body to the question subject is useful for the question representation, the disparity part can also provide additional information. In the example listed in Table 1, additional information like "*maintenance, accident or service history*" is also important to determine answer quality.

QCN outperforms (4) by a great margin, demonstrating that subject-body relationship in community questions helps to condense question representation. Therefore, QCN can identify the meaningful part of the question representation that helps to determine answer quality.

Using the multi-dimensional attention can further boost model performance, showing that the multi-dimensional attention can model the interaction between questions and answers more precisely.

Comparing QCN with (6) and (7), we can conclude that both the subject and the body are indispensable for question representation. (8) outperforms (9), demonstrating the parallel component is more useful in subject-body interaction.

6 Qualitative Study

To gain a closer view of what dependencies are captured in the subject-body pair and the question-answer pair, we visualize the attention probabilities A_{para}, A_{orth} and A_{align} by heatmap. A training example from SemEval 2015 is selected for illustration.

In Figure 2, we can draw the following conclusions. First, orthogonal decomposition helps to divide the labor of identifying similar parts in the parallel component and collecting related information in the question body in the orthogonal component. For instance, for the word "*Kuala*" in the question subject, its parallel alignment score focuses more on "*Doha*" and "*Travel*", while its orthogonal alignment score focuses on "*arrange*" and "*package*", which is the purpose of the travel and therefore is also indispensable for sentence representation. Second, semantically important words such as "*airline*" and "*fares*" dominate the attention weights, showing that our QCN model can effectively select words that are most representative for the meaning of the whole sentence. Lastly, words that are useful to determine answer quality stand out in the question-answer interaction matrix, demonstrating that question-answer relationship can be well modeled. For example, "*best*" and "*low*" are the words that are more important in the question-answer relationship, they are emphasized in the question-answer alignment matrix.

7 Related Work

One main task in community question answering is answer selection, i.e., to rate the answers according to their quality. The SemEval CQA tasks (Nakov et al., 2015, 2016, 2017) provide universal benchmark datasets for evaluating researches on this problem.

Earlier work of answer selection in CQA relied heavily on feature engineering, linguistic tools, and external resource. Nakov et al. (2016) investigated a wide range of feature types including similarity features, content features, thread level/meta features, and automatically generated features for SemEval CQA models. Tran et al. (2015) studied the use of topic model based features and word vector representation based features in the answer re-ranking task. Filice et al. (2016) designed various heuristic features and thread-based features that can signal a good answer. Although achieving good performance, these methods rely heavily on feature engineering, which requires a large amount of manual work and domain expertise.

Since answer selection is inherently a ranking task, a few recent researches proposed to use local features to make global ranking decision. Barrón-Cedeño et al. (2015) was the first work that applies structured prediction model on CQA answer selection task. Joty et al. (2016) approached the task with a global inference process to exploit the information of all answers in the question-thread in the form of a fully connected graph.

To avoid feature engineering, many deep learning models have been proposed for answer selection. Among them, Zhang et al. (2017) proposed a novel interactive attention mechanism to address the problem of noise and redundancy prevalent in CQA. Tay et al. (2017) introduced temporal gates for sequence pairs so that questions and answers are aware of what each other is remembering or forgetting. Simple as their model are, they did not consider the relationship between question subject and body, which is useful for question condensing.

8 Conclusion and Future Work

We propose Question Condensing Networks (QCN), an attention-based model that can utilize the subject-body relationship in community questions to condense question representation. By orthogonal decomposition, the labor of identifying similar parts and collecting related information in the question body can be well divided in two different alignment matrices. To better capture the interaction between the subject-body pair and the question-answer pair, the multi-dimensional attention mechanism is adopted. Empirical results on two community question answering datasets in SemEval demonstrate the effectiveness of our model. In future work, we will try to incorporate more hand-crafted features in our model. Furthermore, since thread-level features have been explored in previous work (Barrón-Cedeño et al., 2015; Joty et al., 2015, 2016), we will verify their effectiveness in our architecture.

Abstract

Small perturbations in the input can severely distort intermediate representations and thus impact translation quality of neural machine translation (NMT) models. In this paper, we propose to improve the robustness of NMT models with adversarial stability training. The basic idea is to make both the encoder and decoder in NMT models robust against input perturbations by enabling them to behave similarly for the original input and its perturbed counterpart. Experimental results on Chinese-English, English-German and English-French translation tasks show that our approaches can not only achieve significant improvements over strong NMT systems but also improve the robustness of NMT models.

1 Introduction

Neural machine translation (NMT) models have advanced the state of the art by building a single neural network that can better learn representations (Cho et al., 2014; Sutskever et al., 2014). The neural network consists of two components: an encoder network that encodes the input sentence into a sequence of distributed representations, based on which a decoder network generates the translation with an attention model (Bahdanau et al., 2015; Luong et al., 2015). A variety of NMT models derived from this encoder-decoder framework have further improved the performance of machine translation systems (Gehring et al., 2017; Vaswani et al., 2017). NMT is capable of generalizing better to unseen text by exploiting word similarities in embeddings and capturing long-distance reordering by conditioning on larger contexts in a continuous way.

Input	tamen *bupa* kunnan zuochu weiqi AI.
Output	They are not afraid of difficulties to make Go AI.
Input	tamen *buwei* kunnan zuochu weiqi AI.
Output	They are not afraid to make Go AI.

Table 1: The non-robustness problem of neural machine translation. Replacing a Chinese word with its synonym (i.e., "*bupa*" $\rightarrow$ "*buwei*") leads to significant erroneous changes in the English translation. Both "*bupa*" and "*buwei*" can be translated to the English phrase "*be not afraid of*."

However, studies reveal that very small changes to the input can fool state-of-the-art neural networks with high probability (Goodfellow et al., 2015; Szegedy et al., 2014). Belinkov and Bisk (2018) confirm this finding by pointing out that NMT models are very brittle and easily falter when presented with noisy input. In NMT, due to the introduction of RNN and attention, each contextual word can influence the model prediction in a global context, which is analogous to the "butterfly effect." As shown in Table 1, although we only replace a source word with its synonym, the generated translation has been completely distorted. We investigate severe variations of translations caused by small input perturbations by replacing one word in each sentence of a test set with its synonym. We observe that 69.74% of translations have changed and the BLEU score is only 79.01 between the translations of the original inputs and the translations of the perturbed inputs, suggesting that NMT models are very sensitive to small perturbations in the input. The vulnerability and instability of NMT models limit their applicability to a broader range of tasks, which require robust performance on noisy inputs. For example, simultaneous translation systems use automatic speech recognition (ASR) to transcribe input speech into a sequence of hypothesized words, which are subsequently fed to a translation system. In this pipeline, ASR errors are presented as sentences with noisy perturbations (the same pronunciation but incorrect words), which is a significant challenge for current NMT models. Moreover, instability makes NMT models sensitive to misspellings and typos in text translation.

In this paper, we address this challenge with *adversarial stability training* for neural machine translation. The basic idea is to improve the robustness of two important components in NMT: the encoder and decoder. To this end, we propose two approaches to constructing noisy inputs with small perturbations to make NMT models resist them. As important intermediate representations encoded by the encoder, they directly determine the accuracy of final translations. We introduce adversarial learning to make behaviors of the encoder consistent for both an input and its perturbed counterpart. To improve the stability of the decoder, our method jointly maximizes the likelihoods of original and perturbed data. Adversarial stability training has the following advantages:

1. *Improving both the robustness and translation performance*: Our adversarial stability training is capable of not only improving the robustness of NMT models but also achieving better translation performance.

2. *Applicable to arbitrary noisy perturbations*: In this paper, we propose two approaches to constructing noisy perturbations for inputs. However, our training framework can be easily extended to arbitrary noisy perturbations. Especially, we can design task-specific perturbation methods.

3. *Transparent to network architectures*: Our adversarial stability training does not depend on specific NMT architectures. It can be applied to arbitrary NMT systems.

Experiments on Chinese-English, English-French and English-German translation tasks show that adversarial stability training achieves significant improvements across different languages pairs. Our NMT system outperforms the state-of-the-art RNN-based NMT system (GNMT) (Wu et al., 2016) and obtains comparable performance with the CNN-based NMT system (Gehring et al., 2017). Related experimental analyses validate that our training approach can improve the robustness of NMT models.

2 Background

NMT is an end-to-end framework which directly optimizes the translation probability of a target sentence $\mathbf{y} = y_1, ..., y_N$ given its corresponding source sentence $\mathbf{x} = x_1, ..., x_M$:

$$P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta}) = \prod_{n=1}^{N} P(y_n|\mathbf{y}_{<n}, \mathbf{x};\boldsymbol{\theta}) \quad (1)$$

where $\boldsymbol{\theta}$ is a set of model parameters and $\mathbf{y}_{<n}$ is a partial translation. $P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta})$ is defined on a holistic neural network which mainly includes two core components: an *encoder* encodes a source sentence $\mathbf{x}$ into a sequence of hidden representations $\mathbf{H_x} = \mathbf{H}_1, ..., \mathbf{H}_M$, and a *decoder* generates the n-th target word based on the sequence of hidden representations:

$$P(y_n|\mathbf{y}_{<n}, \mathbf{x};\boldsymbol{\theta}) \propto \exp\{g(y_{n-1}, \mathbf{s}_n, \mathbf{H_x};\boldsymbol{\theta})\} \quad (2)$$

where $\mathbf{s}_n$ is the n-th hidden state on target side. Thus the model parameters of NMT include the parameter sets of the encoder $\boldsymbol{\theta}_{\text{enc}}$ and the decoder $\boldsymbol{\theta}_{\text{dec}}$: $\boldsymbol{\theta} = \{\boldsymbol{\theta}_{\text{enc}}, \boldsymbol{\theta}_{\text{dec}}\}$. The standard training objective is to minimize the negative log-likelihood of the training corpus $\mathcal{S} = \{\langle \mathbf{x}^{(s)}, \mathbf{y}^{(s)} \rangle\}_{s=1}^{|\mathcal{S}|}$:

$$\begin{aligned}\hat{\boldsymbol{\theta}} &= \underset{\boldsymbol{\theta}}{\operatorname{argmin}}\, \mathcal{L}(\mathbf{x}, \mathbf{y};\boldsymbol{\theta}) \\ &= \underset{\boldsymbol{\theta}}{\operatorname{argmin}} \Big\{ \sum_{\langle \mathbf{x},\mathbf{y}\rangle \in \mathcal{S}} -\log P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta}) \Big\} \quad (3)\end{aligned}$$

Due to the vulnerability and instability of deep neural networks, NMT models usually suffer from a drawback: small perturbations in the input can dramatically deteriorate its translation results. Belinkov and Bisk (2018) point out that character-based NMT models are very brittle and easily falter when presented with noisy input. We find that word-based and subword-based NMT models also confront with this shortcoming, as shown in Table 1. We argue that the distributed representations should fulfill the stability expectation, which is the underlying concept of the proposed approach. Recent work has shown that adversarially trained models can be made robust to such perturbations (Zheng et al., 2016; Madry et al., 2018). Inspired by this, in this work, we improve the robustness of encoder representations against noisy perturbations with adversarial learning (Goodfellow et al., 2014).

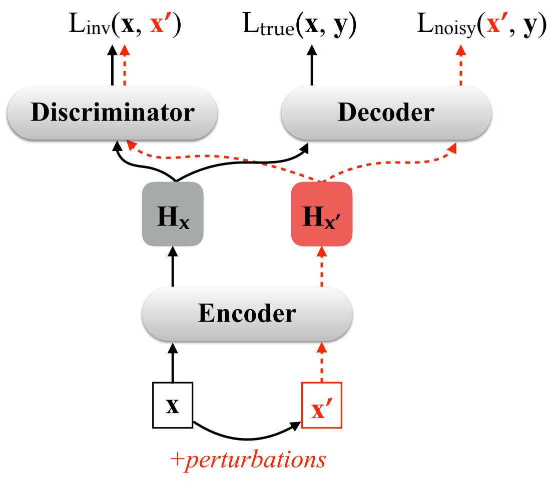

Figure 1: The architecture of NMT with adversarial stability training. The dark solid arrow lines represent the forward-pass information flow for the input sentence $\mathbf{x}$, while the red dashed arrow lines for the noisy input sentence $\mathbf{x}'$, which is transformed from $\mathbf{x}$ by adding small perturbations.

3 Approach

3.1 Overview

The goal of this work is to propose a general approach to make NMT models learned to be more robust to input perturbations. Our basic idea is to maintain the consistency of behaviors through the NMT model for the source sentence $\mathbf{x}$ and its perturbed counterpart $\mathbf{x}'$. As aforementioned, the NMT model contains two procedures for projecting a source sentence $\mathbf{x}$ to its target sentence $\mathbf{y}$: the encoder is responsible for encoding $\mathbf{x}$ as a sequence of representations $\mathbf{H_x}$, while the decoder outputs $\mathbf{y}$ with $\mathbf{H_x}$ as input. We aim at learning the perturbation-invariant encoder and decoder.

Figure 1 illustrates the architecture of our approach. Given a source sentence $\mathbf{x}$, we construct a set of perturbed sentences $\mathcal{N}(\mathbf{x})$, in which each sentence $\mathbf{x}'$ is constructed by adding small perturbations to $\mathbf{x}$. We require that $\mathbf{x}'$ is a subtle variation from $\mathbf{x}$ and they have similar semantics. Given the input pair $(\mathbf{x}, \mathbf{x}')$, we have two expectations: (1) the encoded representation $\mathbf{H_{x'}}$ should be close to $\mathbf{H_x}$; and (2) given $\mathbf{H_{x'}}$, the decoder is able to generate the robust output $\mathbf{y}$. To this end, we introduce two additional objectives to improve the robustness of the encoder and decoder:

- $\mathcal{L}_{\text{inv}}(\mathbf{x}, \mathbf{x}')$ to encourage the encoder to output similar intermediate representations $\mathbf{H_x}$ and $\mathbf{H_{x'}}$ for $\mathbf{x}$ and $\mathbf{x}'$ to achieve an invariant encoder, which benefits outputting the same translations. We cast this objective in the adversarial learning framework.

- $\mathcal{L}_{\text{noisy}}(\mathbf{x}', \mathbf{y})$ to guide the decoder to generate output $\mathbf{y}$ given the noisy input $\mathbf{x}'$, which is modeled as $-\log P(\mathbf{y}|\mathbf{x}')$. It can also be defined as KL divergence between $P(\mathbf{y}|\mathbf{x})$ and $P(\mathbf{y}|\mathbf{x}')$ that indicates using $P(\mathbf{y}|\mathbf{x})$ to teach $P(\mathbf{y}|\mathbf{x}')$.

As seen, the two introduced objectives aim to improve the robustness of the NMT model which can be free of high variances in target outputs caused by small perturbations in inputs. It is also natural to introduce the original training objective $\mathcal{L}(\mathbf{x}, \mathbf{y})$ on $\mathbf{x}$ and $\mathbf{y}$, which can guarantee good translation performance while keeping the stability of the NMT model.

Formally, given a training corpus $\mathcal{S}$, the adversarial stability training objective is

$$\begin{aligned} & \mathcal{J}(\boldsymbol{\theta}) \\ = & \sum_{\langle \mathbf{x},\mathbf{y}\rangle \in \mathcal{S}} \Big(\mathcal{L}_{\text{true}}(\mathbf{x}, \mathbf{y}; \boldsymbol{\theta}_{\text{enc}}, \boldsymbol{\theta}_{\text{dec}}) \\ & + \alpha \sum_{\mathbf{x}' \in \mathcal{N}(\mathbf{x})} \mathcal{L}_{\text{inv}}(\mathbf{x}, \mathbf{x}'; \boldsymbol{\theta}_{\text{enc}}, \boldsymbol{\theta}_{\text{dis}}) \\ & + \beta \sum_{\mathbf{x}' \in \mathcal{N}(\mathbf{x})} \mathcal{L}_{\text{noisy}}(\mathbf{x}', \mathbf{y}; \boldsymbol{\theta}_{\text{enc}}, \boldsymbol{\theta}_{\text{dec}}) \Big) \end{aligned} \quad (4)$$

where $\mathcal{L}_{\text{true}}(\mathbf{x}, \mathbf{y})$ and $\mathcal{L}_{\text{noisy}}(\mathbf{x}', \mathbf{y})$ are calculated using Equation 3, and $\mathcal{L}_{\text{inv}}(\mathbf{x}, \mathbf{x}')$ is the adversarial loss to be described in Section 3.3. α and β control the balance between the original translation task and the stability of the NMT model. $\boldsymbol{\theta} = \{\boldsymbol{\theta}_{\text{enc}}, \boldsymbol{\theta}_{\text{dec}}, \boldsymbol{\theta}_{\text{dis}}\}$ are trainable parameters of the encoder, decoder, and the newly introduced discriminator used in adversarial learning. As seen, the parameters of encoder $\boldsymbol{\theta}_{\text{enc}}$ and decoder $\boldsymbol{\theta}_{\text{dec}}$ are trained to minimize both the translation loss $\mathcal{L}_{\text{true}}(\mathbf{x}, \mathbf{y})$ and the stability losses ($\mathcal{L}_{\text{noisy}}(\mathbf{x}', \mathbf{y})$ and $\mathcal{L}_{\text{inv}}(\mathbf{x}, \mathbf{x}')$).

Since $\mathcal{L}_{\text{noisy}}(\mathbf{x}', \mathbf{y})$ evaluates the translation loss on the perturbed neighbour $\mathbf{x}'$ and its corresponding target sentence $\mathbf{y}$, it means that we augment the training data by adding perturbed neighbours, which can potentially improve the translation performance. In this way, our approach not only makes the output of NMT models more robust, but also improves the performance on the original translation task.

In the following sections, we will first describe how to construct perturbed inputs with different strategies to fulfill different goals (Section 3.2), followed by the proposed adversarial learning mechanism for the perturbation-invariant encoder (Section 3.3). We conclude this section with the training strategy (Section 3.4).

3.2 Constructing Perturbed Inputs

At each training step, we need to generate a perturbed neighbour set $\mathcal{N}(\mathbf{x})$ for each source sentence $\mathbf{x}$ for adversarial stability training. In this paper, we propose two strategies to construct the perturbed inputs at multiple levels of representations.

The first approach generates perturbed neighbours at the *lexical* level. Given an input sentence $\mathbf{x}$, we randomly sample some word positions to be modified. Then we replace words at these positions with other words in the vocabulary according to the following distribution:

$$P(x|\mathbf{x}_i) = \frac{\exp\{\cos(\mathbf{E}[\mathbf{x}_i], \mathbf{E}[x])\}}{\sum_{x \in \mathcal{V}_x \backslash \mathbf{x}_i} \exp\{\cos(\mathbf{E}[\mathbf{x}_i], \mathbf{E}[x])\}} \quad (5)$$

where $\mathbf{E}[\mathbf{x}_i]$ is the word embedding for word $\mathbf{x}_i$, $\mathcal{V}_x \backslash \mathbf{x}_i$ is the source vocabulary set excluding the word $\mathbf{x}_i$, and $\cos(\mathbf{E}[\mathbf{x}_i], \mathbf{E}[x])$ measures the similarity between word $\mathbf{x}_i$ and x. Thus we can change the word to another word with similar semantics.

One potential problem of the above strategy is that it is hard to enumerate all possible positions and possible types to generate perturbed neighbours. Therefore, we propose a more general approach to modifying the sentence at the *feature* level. Given a sentence, we can obtain the word embedding for each word. We add the Gaussian noise to a word embedding to simulate possible types of perturbations. That is

$$\mathbf{E}[\mathbf{x}'_i] = \mathbf{E}[\mathbf{x}_i] + \boldsymbol{\epsilon}, \quad \boldsymbol{\epsilon} \sim \mathbf{N}(0, \sigma^2\mathbf{I}) \quad (6)$$

where the vector $\boldsymbol{\epsilon}$ is sampled from a Gaussian distribution with variance σ^2. σ is a hyper-parameter. We simply introduce Gaussian noise to all of word embeddings in $\mathbf{x}$.

The proposed scheme is a general framework where one can freely define the strategies to construct perturbed inputs. We just present two possible examples here. The first strategy is potentially useful when the training data contains noisy words, while the latter is a more general strategy to improve the robustness of common NMT models. In practice, one can design specific strategies for particular tasks. For example, we can replace correct words with their homonyms (same pronunciation but different meanings) to improve NMT models for simultaneous translation systems.

3.3 Adversarial Learning for the Perturbation-invariant Encoder

The goal of the perturbation-invariant encoder is to make the representations produced by the encoder indistinguishable when fed with a correct sentence $\mathbf{x}$ and its perturbed counterpart $\mathbf{x}'$, which is directly beneficial to the output robustness of the decoder. We cast the problem in the adversarial learning framework (Goodfellow et al., 2014). The encoder serves as the generator G, which defines the policy that generates a sequence of hidden representations $\mathbf{H}_\mathbf{x}$ given an input sentence $\mathbf{x}$. We introduce an additional discriminator D to distinguish the representation of perturbed input $\mathbf{H}_{\mathbf{x}'}$ from that of the original input $\mathbf{H}_\mathbf{x}$. The goal of the generator G (i.e., encoder) is to produce similar representations for $\mathbf{x}$ and $\mathbf{x}'$ which could fool the discriminator, while the discriminator D tries to correctly distinguish the two representations.

Formally, the adversarial learning objective is

$$\begin{aligned} & \mathcal{L}_{\text{inv}}(\mathbf{x}, \mathbf{x}'; \boldsymbol{\theta}_{\text{enc}}, \boldsymbol{\theta}_{\text{dis}}) \\ = \; & \mathbb{E}_{\mathbf{x} \sim \mathcal{S}}[-\log D(G(\mathbf{x}))] + \\ & \mathbb{E}_{\mathbf{x}' \sim \mathcal{N}(\mathbf{x})}\left[-\log(1 - D(G(\mathbf{x}')))\right] \quad (7) \end{aligned}$$

The discriminator outputs a classification score given an input representation, and tries to maximize $D(G(\mathbf{x}))$ to 1 and minimize $D(G(\mathbf{x}'))$ to 0. The objective encourages the encoder to output similar representations for $\mathbf{x}$ and $\mathbf{x}'$, so that the discriminator fails to distinguish them.

The training procedure can be regarded as a min-max two-player game. The encoder parameters $\boldsymbol{\theta}_{\text{enc}}$ are trained to maximize the loss function to fool the discriminator. The discriminator parameters $\boldsymbol{\theta}_{\text{dis}}$ are optimized to minimize this loss for improving the discriminating ability. For efficiency, we update both the encoder and the discriminator simultaneously at each iteration, rather than the periodical training strategy that is commonly used in adversarial learning. Lamb et al. (2016) also propose a similar idea to use Professor Forcing to make the behaviors of RNNs be indistinguishable when training and sampling the networks.

3.4 Training

As shown in Figure 1, our training objective includes three sets of model parameters for three modules. We use mini-batch stochastic gradient descent to optimize our model. In the forward pass, besides a mini-batch of $\mathbf{x}$ and $\mathbf{y}$, we also construct a mini-batch consisting of the perturbed neighbour $\mathbf{x}'$ and $\mathbf{y}$. We propagate the information to calculate these three loss functions according to arrows. Then, gradients are collected to update three sets of model parameters. Except for the gradients of $\mathcal{L}_{\text{inv}}$ with respect to $\boldsymbol{\theta}_{\text{enc}}$ are multiplying by -1, other gradients are normally back-propagated. Note that we update $\boldsymbol{\theta}_{\text{inv}}$ and $\boldsymbol{\theta}_{\text{enc}}$ simultaneously for training efficiency.

4 Experiments

4.1 Setup

We evaluated our adversarial stability training on translation tasks of several language pairs, and reported the 4-gram BLEU (Papineni et al., 2002) score as calculated by the *multi-bleu.perl* script.

Chinese-English We used the LDC corpus consisting of 1.25M sentence pairs with 27.9M Chinese words and 34.5M English words respectively. We selected the best model using the NIST 2006 set as the validation set (hyper-parameter optimization and model selection). The NIST 2002, 2003, 2004, 2005, and 2008 datasets are used as test sets.

English-German We used the WMT 14 corpus containing 4.5M sentence pairs with 118M English words and 111M German words. The validation set is newstest2013, and the test set is newstest2014.

English-French We used the IWSLT corpus which contains 0.22M sentence pairs with 4.03M English words and 4.12M French words. The IWLST corpus is very dissimilar from the NIST and WMT corpora. As they are collected from TED talks and inclined to spoken language, we want to verify our approaches on the non-normative text. The IWSLT 14 test set is taken as the validation set and 15 test set is used as the test set.

For English-German and English-French, we tokenize both English, German and French words using `tokenize.perl` script. We follow Sennrich et al. (2016b) to split words into sub-word units. The numbers of merge operations in byte pair encoding (BPE) are set to 30K, 40K and 30K respectively for Chinese-English, English-German, and English-French. We report the case-sensitive tokenized BLEU score for English-German and English-French and the case-insensitive tokenized BLEU score for Chinese-English.

Our baseline system is an in-house NMT system. Following Bahdanau et al. (2015), we implement an RNN-based NMT in which both the encoder and decoder are two-layer RNNs with residual connections between layers (He et al., 2016b). The gating mechanism of RNNs is gated recurrent unit (GRUs) (Cho et al., 2014). We apply layer normalization (Ba et al., 2016) and dropout (Hinton et al., 2012) to the hidden states of GRUs. Dropout is also added to the source and target word embeddings. We share the same matrix between the target word embeddings and the pre-softmax linear transformation (Vaswani et al., 2017). We update the set of model parameters using Adam SGD (Kingma and Ba, 2015). Its learning rate is initially set to 0.05 and varies according to the formula in Vaswani et al. (2017).

Our adversarial stability training initializes the model based on the parameters trained by maximum likelihood estimation (MLE). We denote adversarial stability training based on lexical-level perturbations and feature-level perturbations respectively as $\text{AST}_{\text{lexical}}$ and $\text{AST}_{\text{feature}}$. We only sample one perturbed neighbour $\mathbf{x}' \in \mathcal{N}(\mathbf{x})$ for training efficiency. For the discriminator used in $\mathcal{L}_{\text{inv}}$, we adopt the CNN discriminator proposed by Kim (2014) to address the variable-length problem of the sequence generated by the encoder. In the CNN discriminator, the filter windows are set to 3, 4, 5 and rectified linear units are applied after convolution operations. We tune the hyper-parameters on the validation set through a grid search. We find that both the optimal values of α and β are set to 1.0. The standard variance in Gaussian noise used in the formula (6) is set to 0.01. The number of words that are replaced in the sentence $\mathbf{x}$ during lexical-level perturbations is taken as $\max(0.2|\mathbf{x}|, 1)$ in which $|\mathbf{x}|$ is the length of $\mathbf{x}$. The default beam size for decoding is 10.

4.2 Translation Results

4.2.1 NIST Chinese-English Translation

Table 2 shows the results on Chinese-English translation. Our strong baseline system significantly outperforms previously reported results on

System	Training	MT06	MT02	MT03	MT04	MT05	MT08
Shen et al. (2016)	MRT	37.34	40.36	40.93	41.37	38.81	29.23
Wang et al. (2017)	MLE	37.29	–	39.35	41.15	38.07	–
Zhang et al. (2018)	MLE	38.38	–	40.02	42.32	38.84	–

Chinese-English NIST datasets trained on RNN-based NMT. Shen et al. (2016) propose minimum risk training (MRT) for NMT, which directly optimizes model parameters with respect to BLEU scores. Wang et al. (2017) address the issue of severe gradient diffusion with linear associative units (LAU). Their system is deep with an encoder of 4 layers and a decoder of 4 layers. Zhang et al. (2018) propose to exploit both left-to-right and right-to-left decoding strategies for NMT to capture bidirectional dependencies. Compared with them, our NMT system trained by MLE outperforms their best models by around 3 BLEU points. We hope that the strong baseline systems used in this work make the evaluation convincing.

We find that introducing adversarial stability training into NMT can bring substantial improvements over previous work (up to +3.16 BLEU points over Shen et al. (2016), up to +3.51 BLEU points over Wang et al. (2017) and up to +2.74 BLEU points over Zhang et al. (2018)) and our system trained with MLE across all the datasets. Compared with our baseline system, $\text{AST}_{\text{lexical}}$ achieves +1.75 BLEU improvement on average. $\text{AST}_{\text{feature}}$ performs better, which can obtain +2.59 BLEU points on average and up to +3.34 BLEU points on NIST08.

4.2.2 WMT 14 English-German Translation

In Table 3, we list existing NMT systems as comparisons. All these systems use the same WMT 14 English-German corpus. Except that Shen et al. (2016) and Wu et al. (2016) respectively adopt MRT and reinforcement learning (RL), other systems all use MLE as training criterion. All the systems except for Shen et al. (2016) are deep NMT models with no less than four layers. Google's neural machine translation (GNMT) (Wu et al., 2016) represents a strong RNN-based NMT system. Compared with other RNN-based NMT systems except for GNMT, our baseline system with two layers can achieve better performance than theirs.

When training our NMT system with $\text{AST}_{\text{leixcal}}$, significant improvement (+1.11

Table 6: Example translations of a source sentence and its perturbed counterpart by replacing a Chinese word "zhongguo" with its synonym "zhongfang."

BLEU points) can be observed. $\text{AST}_{\text{feature}}$ can obtain slightly better performance. Our NMT system outperforms the state-of-the-art RNN-based NMT system, GNMT, with +0.66 BLEU point and performs comparably with Gehring et al. (2017) which is based on CNN with 15 layers. Given that our approach can be applied to any NMT systems, we expect that the adversarial stability training mechanism can further improve performance upon the advanced NMT architectures. We leave this for future work.

4.2.3 IWSLT English-French Translation

Table 4 shows the results on IWSLT English-French Translation. Compared with our strong baseline system trained by MLE, we observe that our models consistently improve translation performance in all datasets. $\text{AST}_{\text{feature}}$ can achieve significant improvements on the tst2015 although $\text{AST}_{\text{lexical}}$ obtains comparable results. These demonstrate that our approach maintains good performance on the non-normative text.

4.3 Results on Synthetic Perturbed Data

In order to investigate the ability of our training approaches to deal with perturbations, we experiment with three types of synthetic perturbations:

- **Swap**: We randomly choose N positions from a sentence and then swap the chosen words with their right neighbours.
- **Replacement**: We randomly replace sampled words in the sentence with other words.
- **Deletion**: We randomly delete N words from each sentence in the dataset.

As shown in Table 5, we can find that our training approaches, $\text{AST}_{\text{lexical}}$ and $\text{AST}_{\text{feature}}$, consistently outperform MLE against perturbations on all the numbers of operations. This means that our

$\mathcal{L}_{\text{true}}$	$\mathcal{L}_{\text{noisy}}$	$\mathcal{L}_{\text{adv}}$	BLEU
$\surd$	$\times$	$\times$	41.38
$\surd$	$\times$	$\surd$	41.91
$\times$	$\surd$	$\times$	42.20
$\surd$	$\surd$	$\times$	42.93
$\surd$	$\surd$	$\surd$	43.57

Table 7: Ablation study of adversarial stability training $\text{AST}_{\text{lexical}}$ on Chinese-English translation. "$\surd$" means the loss function is included in the training objective while "$\times$" means it is not.

approaches have the capability of resisting perturbations. Along with the number of operations increasing, the performance on MLE drops quickly. Although the performance of our approaches also drops, we can see that our approaches consistently surpass MLE. In $\text{AST}_{\text{lexical}}$, with 0 operation, the difference is +2.19 (43.57 Vs. 41.38) for all synthetic types, but the differences are enlarged to +3.20, +9.39, and +3.12 respectively for the three types with 5 operations.

In the *Swap* and *Deletion* types, $\text{AST}_{\text{lexical}}$ and $\text{AST}_{\text{feature}}$ perform comparably after more than four operations. Interestingly, $\text{AST}_{\text{lexical}}$ performs significantly better than both of MLE and $\text{AST}_{\text{feature}}$ after more than one operation in the *Replacement* type. This is because $\text{AST}_{\text{lexical}}$ trains the model specifically on perturbation data that is constructed by replacing words, which agrees with the *Replacement* Type. Overall, $\text{AST}_{\text{lexical}}$ performs better than $\text{AST}_{\text{feature}}$ against perturbations after multiple operations. We speculate that the perturbation method for $\text{AST}_{\text{lexical}}$ and synthetic type are both discrete and they keep more consistent. Table 6 shows example translations of a Chinese sentence and its perturbed counterpart.

These findings indicate that we can construct specific perturbations for a particular task. For example, in simultaneous translation, an automatic speech recognition system usually generates wrong words with the same pronunciation of correct words, which dramatically affects the quality of machine translation system. Therefore, we can design specific perturbations aiming for this task.

4.4 Analysis

4.4.1 Ablation Study

Our training objective function Eq. (4) contains three loss functions. We perform an ablation study on the Chinese-English translation to understand the importance of these loss functions by choosing $\text{AST}_{\text{lexical}}$ as an example. As Table 7 shows, if we remove $\mathcal{L}_{\text{adv}}$, the translation performance decreases by 0.64 BLEU point. However, when $\mathcal{L}_{\text{noisy}}$ is excluded from the training objective function, it results in a significant drop of 1.66 BLEU point. Surprisingly, only using $\mathcal{L}_{\text{noisy}}$ is able to lead to an increase of 0.88 BLEU point.

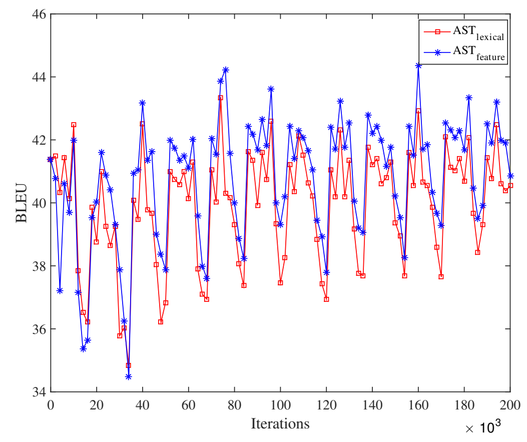

Figure 2: BLEU scores of $\text{AST}_{\text{lexical}}$ over iterations on Chinese-English validation set.

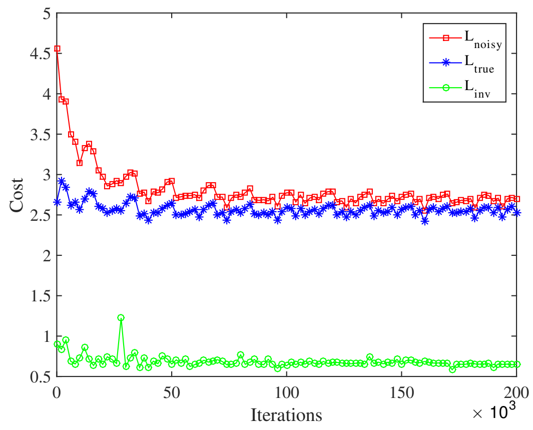

Figure 3: Learning curves of three loss functions, $\mathcal{L}_{\text{true}}$, $\mathcal{L}_{\text{inv}}$ and $\mathcal{L}_{\text{noisy}}$ over iterations on Chinese-English validation set.

4.4.2 BLEU Scores over Iterations

Figure 2 shows the changes of BLEU scores over iterations respectively for $\text{AST}_{\text{lexical}}$ and $\text{AST}_{\text{feature}}$. They behave nearly consistently. Initialized by the model trained by MLE, their performance drops rapidly. Then it starts to go up quickly. Compared with the starting point, the maximal dropping points reach up to about 7.0 BLEU points. Basically, the curves present the state of oscillation. We think that introducing random perturbations and adversarial learning can make the training not very stable like MLE.

4.4.3 Learning Curves of Loss Functions

Figure 3 shows the learning curves of three loss functions, $\mathcal{L}_{\text{true}}$, $\mathcal{L}_{\text{inv}}$ and $\mathcal{L}_{\text{noisy}}$. We can find that their costs of loss functions decrease not steadily. Similar to the Figure 2, there still exist oscillations in the learning curves although they do not change much sharply. We find that $\mathcal{L}_{\text{inv}}$ converges to around 0.68 after about $100K$ iterations, which indicates that discriminator outputs probability 0.5 for both positive and negative samples and it cannot distinguish them. Thus the behaviors of the encoder for $\mathbf{x}$ and its perturbed neighbour $\mathbf{x}'$ perform nearly consistently.

5 Related Work

Our work is inspired by two lines of research: (1) adversarial learning and (2) data augmentation.

Adversarial Learning Generative Adversarial Network (GAN) (Goodfellow et al., 2014) and its related derivative have been widely applied in computer vision (Radford et al., 2015; Salimans et al., 2016) and natural language processing (Li et al., 2017; Yang et al., 2018). Previous work has constructed adversarial examples to attack trained networks and make networks resist them, which has proved to improve the robustness of networks (Goodfellow et al., 2015; Miyato et al., 2016; Zheng et al., 2016). Belinkov and Bisk (2018) introduce adversarial examples to training data for character-based NMT models. In contrast to theirs, adversarial stability training aims to stabilize both the encoder and decoder in NMT models. We adopt adversarial learning to learn the perturbation-invariant encoder.

Data Augmentation Data augmentation has the capability to improve the robustness of NMT models. In NMT, there is a number of work that augments the training data with monolingual corpora (Sennrich et al., 2016a; Cheng et al., 2016; He et al., 2016a; Zhang and Zong, 2016). They all leverage complex models such as inverse NMT models to generate translation equivalents for monolingual corpora. Then they augment the parallel corpora with these pseudo corpora to improve NMT models. Some authors have recently endeavored to achieve zero-shot NMT through transferring knowledge from bilingual corpora of other language pairs (Chen et al., 2017; Zheng et al., 2017; Cheng et al., 2017) or monolingual corpora (Lample et al., 2018; Artetxe et al., 2018). Our work significantly differs from these work. We do not resort to any complicated models to generate perturbed data and do not depend on extra monolingual or bilingual corpora. The way we exploit is more convenient and easy to implement. We focus more on improving the robustness of NMT models.

6 Conclusion

We have proposed adversarial stability training to improve the robustness of NMT models. The basic idea is to train both the encoder and decoder robust to input perturbations by enabling them to behave similarly for the original input and its perturbed counterpart. We propose two approaches to construct perturbed data to adversarially train the encoder and stabilize the decoder. Experiments on Chinese-English, English-German and English-French translation tasks show that the proposed approach can improve both the robustness and translation performance.

As our training framework is not limited to specific perturbation types, it is interesting to evaluate our approach in natural noise existing in practical applications, such as homonym in the simultaneous translation system. It is also necessary to further validate our approach on more advanced NMT architectures, such as CNN-based NMT (Gehring et al., 2017) and Transformer (Vaswani et al., 2017).

Abstract

In neural machine translation, a source sequence of words is encoded into a vector from which a target sequence is generated in the decoding phase. Differently from statistical machine translation, the associations between source words and their possible target counterparts are not explicitly stored. Source and target words are at the two ends of a long information processing procedure, mediated by hidden states at both the source encoding and the target decoding phases. This makes it possible that a source word is incorrectly translated into a target word that is not any of its admissible equivalent counterparts in the target language.

In this paper, we seek to somewhat shorten the distance between source and target words in that procedure, and thus strengthen their association, by means of a method we term bridging source and target word embeddings. We experiment with three strategies: (1) a source-side bridging model, where source word embeddings are moved one step closer to the output target sequence; (2) a target-side bridging model, which explores the more relevant source word embeddings for the prediction of the target sequence; and (3) a direct bridging model, which directly connects source and target word embeddings seeking to minimize errors in the translation of ones by the others.

Experiments and analysis presented in this paper demonstrate that the proposed bridging models are able to significantly improve quality of both sentence translation, in general, and alignment and translation of individual source words with target words, in particular.

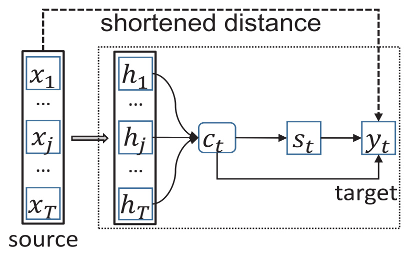

Figure 1: Schematic representation of seq2seq NMT, where $x_1, \ldots, x_T$ and $h_1, \ldots, h_T$ represent source-side word embeddings and hidden states respectively, c_t represents a source-side context vector, s_t a target-side decoder RNN hidden state, and y_t a predicted word. Seeking to shorten the distance between source and target word embeddings, in what we term bridging, is the key insight for the advances presented in this paper.

1 Introduction

Neural machine translation (NMT) is an end-to-end approach to machine translation that has achieved competitive results vis-a-vis statistical machine translation (SMT) on various language pairs (Bahdanau et al., 2015; Cho et al., 2014; Sutskever et al., 2014; Luong and Manning, 2015). In NMT, the sequence-to-sequence (seq2seq) model learns word embeddings for both source and target words synchronously. However, as illustrated in Figure 1, source and target word embeddings are at the two ends of a long information processing procedure. The individual associations between them will gradually become loose due to the separation of source-side hidden states (represented by $h_1, \ldots, h_T$ in Fig. 1) and a target-

Figure 2: Examples of NMT output with incorrect alignments of source and target words that cannot be the translation of each other in any possible context.

side hidden state (represented by s_t in Fig. 1). As a result, in the absence of a more tight interaction between source and target word pairs, the seq2seq model in NMT produces tentative translations that contain incorrect alignments of source words with target counterparts that are non-admissible equivalents in any possible translation context.

Differently from SMT, in NMT an attention model is adopted to help align output with input words. The attention model is based on the estimation of a probability distribution over all input words for each target word. Word alignments with attention weights can then be easily deduced from such distributions and support the translation. Nevertheless, sometimes one finds translations by NMT that contain surprisingly wrong word alignments, that would unlikely occur in SMT.

For instance, Figure 2 shows two Chinese-to-English translation examples by NMT. In the top example, the NMT seq2seq model incorrectly aligns the target side end of sentence mark *eos* to 下旬*/late* with a high attention weight (0.80 in this example) due to the failure of appropriately capturing the similarity, or the lack of it, between the source word 下旬*/late* and the target *eos*. It is also worth noting that, as 本*/this* and 月*/month* end up not being translated in this example, inappropriate alignment of target side *eos* is likely the responsible factor for under translation in NMT as the decoding process ends once a target *eos* is generated. Statistics on our development data show that as much as 50% of target side *eos* do not properly align to source side *eos*.

The second example in Figure 2 shows another case where source words are translated into target items that are not their possible translations in that or in any other context. In particular, 冬奥会*/winter olympics* is incorrectly translated into a target comma "," and 载誉*/honors* into *have*.

In this paper, to address the problem illustrated above, we seek to shorten the distance within the seq2seq NMT information processing procedure between source and target word embeddings. This is a method we term as bridging, and can be conceived as strengthening the focus of the attention mechanism into more translation-plausible source and target word alignments. In doing so, we hope that the seq2seq model is able to learn more appropriate word alignments between source and target words.

We propose three simple yet effective strategies to bridge between word embeddings. The inspiring insight in all these three models is to move source word embeddings closer to target word embeddings along the seq2seq NMT information processing procedure. We categorize these strategies in terms of how close the source and target word embeddings are along that procedure, schematically depicted in Fig. 1.

(1) **Source-side bridging model:** Our first strategy for bridging, which we call source-side bridging, is to move source word embeddings just one step closer to the target end. Each source word embedding is concatenated with the respective source hidden state at the same position so that the attention model can more closely benefit from source word embeddings to produce word alignments.

(2) **Target-side bridging model:** In a second more bold strategy, we seek to incorporate relevant source word embeddings more closely into the prediction of the next target hidden state. In particular, the most appropriate source words are selected according to their attention weights and they are made to more closely interact with target hidden states.

(3) **Direct bridging model:** The third model consists of directly bridging between source and target word embeddings. The training objective is optimized towards minimizing the distance between target word embeddings and their most relevant source word embeddings, selected according to the attention model.

Experiments on Chinese-English translation with extensive analysis demonstrate that directly bridging word embeddings at the two ends can produce better word alignments and thus achieve better translation.

2 Bridging Models

As suggested by Figure 1, there may exist different ways to bridge between x and y_t. We concentrate on the folowing three bridging models.

2.1 Source-side Bridging Model

Figure 3 illustrates the source-side bridging model. The encoder reads a word sequence equipped with word embeddings and generates a word annotation vector for each position. Then we simply concatenate the word annotation vector with its corresponding word embedding as the final annotation vector. For example, the final annotation vector h_j for the word x_j in Figure 3 is $[\overrightarrow{h_j}; \overleftarrow{h_j}; x_j]$, where the first two sub-items $[\overrightarrow{h_j}; \overleftarrow{h_j}]$ are the source-side forward and backward hidden states and x_j is the corresponding word embedding. In this way, the word embeddings will not only have a more strong contribution in the computation of attention weights, but also be part of the annotation vector to form the weighted source context vector and consequently have a more strong impact in the prediction of target words.

2.2 Target-side Bridging Model

While the above source-side bridging method uses the embeddings of all words for every target word, in the target-side method only more relevant source word embeddings for bridging are explored, rather than all of them. This is partially inspired by the word alignments from SMT, where words from the two ends are paired as they are possible translational equivalents of each other and those pairs are explicitly recorded and enter into the system inner workings. In particular, for a given target word, we explicitly determine the most likely source word aligned to it and use the word embedding of this source word to support the prediction of the target hidden state of the next target word to be generated.

Figure 4 schematically illustrates the target-side bridging method, where the input for computing the hidden state s_t of the decoder is augmented by x_{t^*}, as follows:

$$s_t = f(s_{t-1}, y_{t-1}, c_t, x_{t^*}) \tag{1}$$

where x_{t^*} is the word embedding of the selected source word which has the highest attention weight:

$$t^* = \arg\max_j(\alpha_{tj}) \tag{2}$$

where α_{tj} is the attention weight of each hidden state h_j computed by the attention model

2.3 Direct Bridging Model

Further to the above two bridging methods, which use source word embeddings to predict target words, we seek to bridge the word embeddings of the two ends in a more direct way. This is done by resorting to an auxiliary objective function to narrow the discrepancy between word embeddings of the two sides.

Figure 5 is a schematic representation of our direct bridging method, with an auxiliary objective function. More specifically, the goal is to let the learned word embeddings on the two ends be transformable, i.e. if a target word e_i aligns with a source word f_j, a transformation matrix W is learned with the hope that the discrepancy of Wx_i and y_j tends to be zero. Accordingly, we update the objective function of training for a single sentence with its following extended formulation:

$$L(\theta) = -\sum_{t=1}^{T_y}(\log p(y_t|y_{<t}, x) - \|Wx_{t^*} - y_t\|^2) \quad (3)$$

where $\log p(y_t|y_{<t}, x)$ is the original objective function of the NMT model, and the term $\|Wx_{t^*} - y_t\|^2$ measures and penalizes the difference between target word y_t and its aligned source word x_{t^*}, i.e. the one with the highest attention weight, as computed in Equation 2. Similar to Mi et al. (2016), we view the two parts of the loss in Equation 3 as equally important.

At this juncture, it is worth noting the following:

- Our direct bridging model is an extension of the source-side bridging model, where the source word embeddings are part of the final annotation vector of the encoder. We have also tried to place the auxiliary object function directly on the NMT baseline model. However, our empirical study showed that the combined objective consistently worsens the translation quality. We blame this on that the learned word embeddings on two sides by the baseline model are too heterogeneous to be constrained.

- Rather than using a concrete source word embedding x_{t^*} in Equation 3, we could also use a weighted sum of source word embeddings, i.e. $\sum_j \alpha_{tj} h_j$. However, our preliminary experiments showed that the performance gap between these two methods is very small. Therefore, we use x_{t^*} to calculate the new training objective as shown in Equation 3 in all experiments.

3 Experiments

As we have presented above three different methods to bridge between source and target word embeddings, in the present section we report on a series of experiments on Chinese to English translation that are undertaken to assess the effectiveness of those bridging methods.

3.1 Experimental Settings

We resorted to Chinese-English bilingual corpora that contain 1.25M sentence pairs extracted from LDC corpora, with 27.9M Chinese words and 34.5M English words respectively.[1] We chose the NIST06 dataset as our development set, and the NIST02, NIST03, NIST04, NIST08 datasets as our test sets.

We used the case-insensitive 4-gram NIST BLEU score as our evaluation metric (Papineni et al., 2002) and the script 'mteval-v11b.pl' to compute BLEU scores. We also report TER scores on our dataset (Snover et al., 2006).

For the efficient training of the neural networks, we limited the source (Chinese) and target (English) vocabularies to the most frequent 30k words, covering approximately 97.7% and 99.3% of the two corpora respectively. All the out-of-vocabulary words were mapped to the special token *UNK*. The dimension of word embedding was 620 and the size of the hidden layer was 1000. All other settings were the same as in Bahdanau et al. (2015). The maximum length of sentences that we used to train the NMT model in our experiments was set to 50, for both the Chinese and English sides. Additionally, during decoding, we used the beam-search algorithm and set the beam size to 10. The model parameters were selected according to the maximum BLEU points on the development set.

We compared our proposed models against the following two systems:

- cdec (Dyer et al., 2010): this is an open source hierarchical phrase-based SMT system (Chiang, 2007) with default configuration and a 4-gram language model trained on the target side of the training data.

- **RNNSearch***: this is an attention-based NMT system, taken from the dl4mt tutorial with slight changes. It improves the attention model by feeding the lastly generated word. For the activation function f of an RNN, we use the gated recurrent unit (GRU) (Chung et al., 2014). Dropout was applied only on the output layer and the dropout (Hinton et al., 2012) rate was set to 0.5. We used the stochastic gradient descent algorithm with mini-batch and Adadelta (Zeiler, 2012) to train the NMT models. The mini-batch was set to 80 sentences and decay rates

[1] The corpora include LDC2002E18, LDC2003E07, LDC2003E14, Hansards portion of LDC2004T07, LDC2004T08 and LDC2005T06.

	Model	NIST06	NIST02	NIST03	NIST04	NIST08	Avg
BLEU	cdec (SMT)	34.00	35.81	34.70	37.15	25.28	33.23
	RNNSearch*	35.92	37.88	36.21	38.83	26.30	34.81
	Source bridging	36.79‡	38.71‡	37.24‡	40.28‡	27.40‡	35.91
	Target bridging	36.69	39.04‡	37.63‡	40.41‡	**27.98**‡	36.27
	Direct bridging	**36.97**‡	**39.77**‡	**38.02**‡	**40.83**‡	27.85‡	**36.62**
TER	cdec (SMT)	58.29	59.65	59.28	58.12	61.54	59.64
	RNNSearch*	59.56	57.79	59.25	57.88	64.22	59.78
	Source bridging	58.13	**56.25**	57.33	56.32	62.13	**58.01**
	Target bridging	58.01	56.27	57.76	56.33	**62.12**	58.12
	Direct bridging	**57.20**	56.68	**57.29**	**55.62**	62.49	58.02

Table 1: BLEU and TER scores on the NIST Chinese-English translation tasks. The BLEU scores are case-insensitive. Avg means the average scores on all test sets. "‡": statistically better than RNNSearch* ($p < 0.01$). Higher BLEU (or lower TER) scores indicate better translation quality.

ρ and ε of Adadelta were set to 0.95 and 10^{-6}.

For our NMT system with the direct bridging model, we use a simple pre-training strategy to train our model. We first train a regular attention-based NMT model, then use this trained model to initialize the parameters of the NMT system equipped with the direct bridging model and randomly initialize the additional parameters of the direct bridging model in this NMT system. The reason of using pre-training strategy is that the embedding loss requires well-trained word alignment as a starting point.

3.2 Experimental Results

Table 1 displays the translation performance measured in terms of BLEU and TER scores. Clearly, every one of the three NMT models we proposed, with some bridging method, improve the translation accuracy over all test sets in comparison to the SMT (cdec) and NMT (RNNSearch*) baseline systems.

Parameters

The three proposed models introduce new parameters in different ways. The source-side bridging model augments source hidden states from a dimension of 2,000 to 2,620, requiring 3.7M additional parameters to accommodate the hidden states that are appended. The target-side bridging model introduces 1.8M additional parameters for catering x_{t^*} in calculating target side state, as in Equation 1. Based on the source-side bridging model, the direct bridging model requires extra 0.4M parameters (i.e. the transformation matrix W in Equation 3 is $620 * 620$), resulting in 4.1M additional parameters over the baseline. Given that the baseline model has 74.8M parameters, the size of extra parameters in our proposed models are comparably small.

System	Percentage (%)
RNNSearch*	49.82
Direct bridging	81.30

Table 2: Percentage of target side *eos* translated from source side *eos* on the development set.

Comparison with the baseline systems

The results in Table 1 indicate that all NMT systems outperform the SMT system taking into account the evaluation metrics considered, BLEU and TER. This is consistent with other studies on Chinese to English machine translation (Mi et al., 2016; Tu et al., 2016; Li et al., 2017). Additionally, all the three NMT models with bridging mechanisms we proposed outperform the baseline NMT model RNNSearch*.

With respect to BLEU scores, we observe a consistent trend that the target-side bridging model works better than the source-side bridging model, while the direct bridging model achieves the best accuracy over all test sets, with the only exception of NIST MT 08. On all test sets, the direct bridging model outperforms the baseline RNNSearch* by 1.81 BLEU points and outperforms the other two bridging-improved NMT models by 0.4∼0.6 BLEU points.

Though all models are not tuned on TER score, our three models perform favorably well with similar average improvement, of about 1.70 TER points, below the baseline model.

4 Analysis

As the direct bridging system proposed achieves the best performance, we further look at it and at

System	Target POS Tag	Source POS Tag				
		V	N	CD	JJ	AD
RNNSearch*	V	64.95	-	-	-	12.09
	N	7.31	39.24	-	-	-
	CD	-	33.37	53.40	-	-
	JJ	-	26.79	-	14.67	-
Direct bridging	V	66.29	-	-	-	10.94
	N	7.19	39.71	-	-	-
	CD	-	32.25	56.29	-	-
	JJ	-	26.12	-	15.22	-

Table 3: Confusion matrix for translation by POS, in percentage. To cope with fine-grained differences among verbs (e.g., VV, VC and VE in Chinese, and VB, VBD, VBP, etc. in English), we merge all verbs into V. Similarly, we merged all nouns into N. CD stands for Cardinal numbers, JJ for adjectives or modifiers, AD for adverbs. These POS tags exist in both Chinese and English. For the sake of simplicity, for each target POS tag, we present only the two source POS tags that are more frequently aligned with it.

the RNNSearch* baseline system to gain further insight on how bridging may help in translation. Our approach presents superior results along all the dimensions assessed.

4.1 Analysis of Word Alignment

Since our improved model strengthens the focus of attention between pairs of translation equivalents by explicitly bridging source and target word embeddings, we expect to observe improved word alignment quality. The quality of the word alignment is examined from the following three aspects.

Better *eos* translation

As a special symbol marking the end of sentence, target side *eos* has a critical impact on controlling the length of the generated translation. A target *eos* is a correct translation when is aligned with the source *eos*. Table 2 displays the percentage of target side *eos* that are translations of the source side *eos*. It indicates that our model improved with bridging substantially achieves better translation of source *eos*.

Better word translation

To have a further insight into the quality of word translation, we group generated words by their part-of-speech (POS) tags and examine the POS of their aligned source words. [2]

Table 3 is a confusion matrix for translations by POS. For example, under RNNSearch*, 64.95% of target verbs originate from verbs in the source side. This is enhanced to 66.29% in our direct bridging model. From the data in that table, one observes that in general more target words align to source words with the same POS tags in our improved system than in the baseline system.

[2]We used Stanford POS tagger (Toutanova et al., 2003) to get POS tags for the words in source sentences and their translations.

System	SAER	AER
RNNSearch*	62.68	47.61
Direct bridging	59.72	44.71

Table 4: Alignment error rate (AER) and soft AER. quality. A lower score indicates better alignment.

Better word alignment

Next we report on the quality of word alignment taking into account a manually aligned dataset, from Liu and Sun (2015), which contains 900 manually aligned Chinese-English sentence pairs. We forced the decoder to output reference translations in order to get automatic alignments between input sentences and their reference translations yielded by the translation systems. To evaluate alignment performance, we measured the alignment error rate (AER) (Och and Ney, 2003) and the soft AER (SAER) (Tu et al., 2016), which are registered in Table 4.

The data in this Table 4 indicate that, as expected, bridging improves the alignment quality as a consequence of its favoring of a stronger relationship between the source and target word embeddings of translational equivalents.

4.2 Analysis of Long Sentence Translation

Following Bahdanau et al. (2015), we partition sentences by their length and compute the respec-

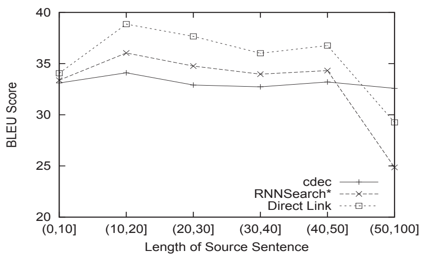

Figure 6: BLEU scores for the translation of sentences with different lengths.

tive BLEU scores, which are presented in Figure 6. These results indicate that our improved system outperforms RNNSearch* for all the sentence lengths. They also reveal that the performance drops substantially when the length of the input sentence increases. This trend is consistent with the findings in (Cho et al., 2014; Tu et al., 2016; Li et al., 2017).

One also observes that the NMT systems perform very badly on sentences of length over 50, when compared to the performance of the baseline SMT system (cdec). We think that the degradation of NMT systems performance over long sentences is due to the following reasons: (1) during training, the maximum source sentence length limit is set to 50, thus making the learned models not ready to cope well with sentences over this maximum length limit; (2) for long input sentences, NMT systems tend to stop early in the generation of the translation.

4.3 Analysis of Over and Under Translation

To assess the expectation that improved translation of *eos* improves the appropriate termination of the translations generated by the decoder, we analyze the performance of our best model with respect to over translation and under translation, which are both notoriously a hard problem for NMT.

To estimate the over translation generated by an NMT system, we follow Li et al. (2017) and report the ratio of over translation (ROT)[3], which is computed as the total number of times of over translation of words in a word set (e.g., all nouns in the source part of the test set) divided by the number of words in the word set.

Table 5 displays ROTs of words grouped by some prominent POS tags. These data indicate that both systems have higher over translation with proper nouns (NR) and other nouns (NN) than

[3]please refer to (Li et al., 2017) for more details of ROT.

System	POS	**ROT**(%)
RNNSearch*	NN	8.63
	NR	12.92
	DT	4.01
	CD	7.05
	ALL	5.28
Direct bridging	NN	7.56
	NR	10.88
	DT	2.37
	CD	4.79
	ALL	4.49

Table 5: Ratios of over translation (ROT) on test sets. NN stands for nouns excluding proper nouns and temporal nouns, NR for proper nouns, DT for determiners, and CD for cardinal numbers.

System	**1-gram BLEU**
cdec (SMT)	77.09
RNNSearch*	72.70
Direct bridging	74.22

Table 6: 1-gram BLEU scores averaged on test sets, supporting the assessment of under translation. A larger score indicates less under translation.

with other POS tags, which is consistent with the results in (Li et al., 2017). The likely reason is that these two POS tags usually have more unknown words, which are words that tend to be over translated. Importantly, these data also show that our direct bridging model alleviates the over translation issue by 15%, as ROT drops from 5.28% to 4.49%.

While it is hard to obtain an accurate estimation of under translation, we simply report 1-gram BLEU score that measures how many words in the translation outcome appear in the reference translation, roughly indicating the proportion of source words that are translated. Table 6 presents the average 1-gram BLEU scores on our test datasets. These data indicate that our improved system has a higher score than RNNSearch*, suggesting that it is less prone to under translation.

It is also worth noting that the SMT baseline (cdec) presents the highest 1-gram BLEU score, as expected, given that under translation is known to be less of an issue for SMT.

4.4 Analysis of Learned Word Embeddings

In the direct bridging model, we introduced a transformation matrix to convert a source-side word embedding into its counterpart on the target side. We seek now to assess the contribution of

Src	Transformation	Lexical Table
是	is	is
和	and	and
及	and	and
将	will	will
会	will	will
国	countries	countries
发展	development	development
经济	economic	economic
问题	question	issue
人民	people	people

Table 7: Top 10 more frequent source words and their closest translations obtained, respectively, by embedding transformation in NMT and from the lexical translation table in SMT.

this transformation. Given a source word x_i, we obtain its closest target word y^* via:

$$y^* = \arg\min_y(\|wx_i - y\|) \quad (4)$$

Table 7 lists the 10 more frequent source words and their corresponding closest target words. For the sake of comparison, it also displays their most likely translations from the lexical translation table in SMT. These results suggest that the closest target words obtained via the transformation matrix of our direct bridging method are very consistent with those obtained from the SMT lexical table, containing only admissible translation pairs. These data thus suggest that our improved model has a good capability of capturing the translation equivalence between source and target word embeddings.

5 Related Work

Since the pioneer work of Bahdanau et al. (2015) to jointly learning alignment and translation in NMT, many effective approaches have been proposed to further improve the alignment quality.

The attention model plays a crucial role in the alignment quality and thus its enhancement has continuously attracted further efforts. To obtain better attention focuses, Luong et al. (2015) propose global and local attention models; and Cohn et al. (2016) extend the attentional model to include structural biases from word based alignment models, including positional bias, Markov conditioning, fertility and agreement over translation directions.

In contrast, we did not delve into the attention model or sought to redesign it in our new bridging proposal. And yet we achieve enhanced alignment quality by inducing the NMT model to capture more favorable pairs of words that are translation equivalents of each other under the effect of the bridging mechanism.

Recently there have been also studies towards leveraging word alignments from SMT models. Mi et al. (2016) and Liu et al. (2016) use pre-obtained word alignments to guide the NMT attention model in the learning of favorable word pairs. Arthur et al. (2016) leverage a pre-obtained word dictionary to constrain the prediction of target words. Despite these approaches having a somewhat similar motivation of using pairs of translation equivalents to benefit the NMT translation, in our new bridging approach we do not use extra resources in the NMT model, but let the model itself learn the similarity of word pairs from the training data. [4]

Besides, there exist also studies on the learning of cross-lingual embeddings for machine translation. Mikolov et al. (2013) propose to first learn distributed representation of words from large monolingual data, and then learn a linear mapping between vector spaces of languages. Gehring et al. (2017) introduce source word embeddings to predict target words. These approaches are somewhat similar to our source-side bridging model. However, inspired by the insight of shortening the distance between source and target embeddings in the seq2seq processing chain, in the present paper we propose more strategies to bridge source and target word embeddings and with better results.

6 Conclusion

We have presented three models to bridge source and target word embeddings for NMT. The three models seek to shorten the distance between source and target word embeddings along the extensive information procedure in the encoder-decoder neural network.

Experiments on Chinese to English translation shows that the proposed models can significantly improve the translation quality. Further in-depth analysis demonstrate that our models are able (1) to learn better word alignments than the baseline NMT, (2) to alleviate the notorious problems of over and under translation in NMT, and (3) to learn direct mappings between source and target words.

[4]Though the pre-obtained word alignments or word dictionaries can be learned from MT training data in an unsupervised fashion, these are still extra knowledge with respect to to the NMT models.

In future work, we will explore further strategies to bridge the source and target side for sequence-to-sequence and tree-based NMT. Additionally, we also intend to apply these methods to other sequence-to-sequence tasks, including natural language conversation.

Abstract

We present a study on reinforcement learning (RL) from human bandit feedback for sequence-to-sequence learning, exemplified by the task of bandit neural machine translation (NMT). We investigate the reliability of human bandit feedback, and analyze the influence of reliability on the learnability of a reward estimator, and the effect of the quality of reward estimates on the overall RL task. Our analysis of cardinal (5-point ratings) and ordinal (pairwise preferences) feedback shows that their intra- and inter-annotator α-agreement is comparable. Best reliability is obtained for standardized cardinal feedback, and cardinal feedback is also easiest to learn and generalize from. Finally, improvements of over 1 BLEU can be obtained by integrating a regression-based reward estimator trained on cardinal feedback for 800 translations into RL for NMT. This shows that RL is possible even from small amounts of fairly reliable human feedback, pointing to a great potential for applications at larger scale.

1 Introduction

Recent work has received high attention by successfully scaling reinforcement learning (RL) to games with large state-action spaces, achieving human-level (Mnih et al., 2015) or even superhuman performance (Silver et al., 2016). This success and the ability of RL to circumvent the data annotation bottleneck in supervised learning has led to renewed interest in RL in sequence-to-sequence learning problems with exponential output spaces. A typical approach is to combine REINFORCE (Williams, 1992) with policies based on deep sequence-to-sequence learning (Bahdanau et al., 2015), for example, in machine translation (Bahdanau et al., 2017), semantic parsing (Liang et al., 2017), or summarization (Paulus et al., 2017). These RL approaches focus on improving performance in automatic evaluation by simulating reward signals by evaluation metrics such as BLEU, F1-score, or ROUGE, computed against gold standards. Despite coming from different fields of application, RL in games and sequence-to-sequence learning share firstly the existence of a clearly specified reward function, e.g., defined by winning or losing a game, or by computing an automatic sequence-level evaluation metric. Secondly, both RL applications rely on a sufficient exploration of the action space, e.g., by evaluating multiple game moves for the same game state, or various sequence predictions for the same input.

[*]The work for this paper was done while the second author was an intern in Heidelberg.

The goal of this paper is to advance the state-of-the-art of sequence-to-sequence RL, exemplified by bandit learning for neural machine translation (NMT). Our aim is to show that successful learning from simulated bandit feedback (Sokolov et al., 2016b; Kreutzer et al., 2017; Nguyen et al., 2017; Lawrence et al., 2017) does in fact carry over to learning from actual human bandit feedback. The promise of bandit NMT is that human feedback on the quality of translations is easier to obtain in large amounts than human references, thus compensating the weaker nature of the signals by their quantity. However, the human factor entails several differences to the above sketched simulation scenarios of RL. Firstly, human rewards are not well-defined functions, but complex and inconsistent signals. For example, in general every input sentence has a multitude of correct translations, each of which humans may judge differently, depending on many contextual and personal factors. Secondly, exploration of the space of possible translations is restricted in real-world scenarios where a user judges one displayed translation, but cannot be expected to rate an alternative translation, let alone large amounts of alternatives.

In this paper we will show that despite the fact that human feedback is ambiguous and partial in nature, a catalyst for successful learning from human reinforcements is the reliability of the feedback signals. The first deployment of bandit NMT in an e-commerce translation scenario conjectured lacking reliability of user judgments as the reason for disappointing results when learning from 148k user-generated 5-star ratings for around 70k product title translations (Kreutzer et al., 2018). We thus raise the question of how human feedback can be gathered in the most reliable way, and what effect reliability will have in downstream tasks. In order to answer these questions, we measure intra- and inter-annotator agreement for two feedback tasks for bandit NMT, using cardinal feedback (on a 5-point scale) and ordinal feedback (by pairwise preferences) for 800 translations, conducted by 16 and 14 human raters, respectively. Perhaps surprisingly, while relative feedback is often considered easier for humans to provide (Thurstone, 1927), our investigation shows that α-reliability (Krippendorff, 2013) for intra- and inter-rater agreement is similar for both tasks, with highest inter-rater reliability for standardized 5-point ratings.

In a next step, we address the issue of machine learnability of human rewards. We use deep learning models to train reward estimators by regression against cardinal feedback, and by fitting a Bradley-Terry model (Bradley and Terry, 1952) to ordinal feedback. Learnability is understood by a slight misuse of the machine learning notion of learnability (Shalev-Shwartz et al., 2010) as the question how well reward estimates can approximate human rewards. Our experiments reveal that rank correlation of reward estimates with TER against human references is higher for regression models trained on standardized cardinal rewards than for Bradley-Terry models trained on pairwise preferences. This emphasizes the influence of the reliability of human feedback signals on the quality of reward estimates learned from them.

Lastly, we investigate machine learnability of the overall NMT task, in the sense of Green et al. (2014) who posed the question of how well an MT system can be tuned on post-edits. We use an RL approach for tuning, where a crucial difference of our work to previous work on RL from human rewards (Knox and Stone, 2009; Christiano et al., 2017) is that our RL scenario is not interactive, but rewards are collected in an offline log. RL then can proceed either by off-policy learning using logged single-shot human rewards directly, or by using estimated rewards. An expected advantage of estimating rewards is to tackle a simpler problem first — learning a reward estimator instead of a full RL task for improving NMT — and then to deploy unlimited feedback from the reward estimator for off-policy RL. Our results show that significant improvements can be achieved by training NMT from both estimated and logged human rewards, with best results for integrating a regression-based reward estimator into RL. This completes the argumentation that high reliability influences quality of reward estimates, which in turn affects the quality of the overall NMT task. Since the size of our training data is tiny in machine translation proportions, this result points towards a great potential for larger-scaler applications of RL from human feedback.

2 Related Work

Function approximation to learn a "critic" instead of using rewards directly has been embraced in the RL literature under the name of "actor-critic" methods (see Konda and Tsitsiklis (2000), Sutton et al. (2000), Kakade (2001), Schulman et al. (2015), Mnih et al. (2016), *inter alia*). In difference to our approach, actor-critic methods learn online while our approach estimates rewards in an offline fashion. Offline methods in RL, with and without function approximation, have been presented under the name of "off-policy" or "counterfactual" learning (see Precup et al. (2000), Precup et al. (2001), Bottou et al. (2013), Swaminathan and Joachims (2015a), Swaminathan and Joachims (2015b), Jiang and Li (2016), Thomas and Brunskill (2016), *inter alia*). Online actor-critic methods have been applied to sequence-to-sequence RL by Bahdanau et al. (2017) and Nguyen et al. (2017). An approach to off-policy RL under deterministic logging has been presented by Lawrence et al. (2017). However, all these approaches have been restricted to simulated rewards.

RL from human feedback is a growing area. Knox and Stone (2009) and Christiano et al. (2017) learn a reward function from human feedback and use that function to train an RL system. The actor-critic framework has been adapted to interactive RL from human feedback by Pilarski et al. (2011) and MacGlashan et al. (2017). These approaches either update the reward function from human feedback intermittently or perform learning only in rounds where human feedback is provided. A framework that interpolates a human critique objective into RL has been presented by Judah et al. (2019). None of these works systematically investigates the reliability of the feedback and its impact of the down-stream task.

Kreutzer et al. (2018) have presented the first application of off-policy RL for learning from noisy human feedback obtained for deterministic logs of e-commerce product title translations. While learning from explicit feedback in the form of 5-star ratings fails, Kreutzer et al. (2018) propose to leverage implicit feedback embedded in a search task instead. In simulation experiments on the same domain, the methods proposed by Lawrence et al. (2017) succeeded also for neural models, allowing to pinpoint the lack of reliability in the human feedback signal as the reason for the underwhelming results when learning from human 5-star ratings. The goal of showing the effect of highly reliable human bandit feedback in downstream RL tasks was one of the main motivations for our work.

For the task of machine translation, estimating human feedback, i.e. quality ratings, is related to the task of sentence-level quality estimation (sQE). However, there are crucial differences between sQE and the reward estimation in our work: sQE usually has more training data, often from more than one machine translation model. Its gold labels are inferred from post-edits, i.e. corrections of the machine translation output, while we learn from weaker bandit feedback. Although this would in principle be possible, sQE predictions have not (yet) been used to directly reinforce predictions of MT systems, mostly because their primary purpose is to predict post-editing effort, i.e. give guidance how to further process a translation. State-of-the-art models for sQE such as (Martins et al., 2017) and (Kim et al., 2017) are unsuitable for the direct use in this task since they rely on linguistic input features, stacked architectures or post-edit or word-level supervision. Similar to approaches for generative adversarial NMT (Yu et al., 2017; Wu et al., 2017) we prefer a simpler convolutional architecture based on word embeddings for the human reward estimation.

3 Human MT Rating Task

3.1 Data

We translate a subset of the TED corpus with a general-domain and a domain-adapted NMT model (see §6.2 for NMT and data), post-process the translations (replacing special characters, restoring capitalization) and filter out identical out-of-domain and in-domain translations. In order to compose a homogeneous data set, we first select translations with references of length 20 to 40, then sort the translation pairs by difference in character n-gram F-score (chrF, $\beta = 3$) (Popović, 2015) and length, and pick the top 400 translation pairs with the highest difference in chrF but lowest difference in length. This yields translation pairs of similar length, but different quality.

3.2 Rating Task

The pairs were treated as 800 separate translations for a 5-point rating task. From the original 400 translation pairs, 100 pairs (or 200 individual translations) were randomly selected for

Type	Inter-rater α	Intra-rater Mean α	Intra-rater Stdev. α
5-point	0.2308	0.4014	0.1907
5-point norm.	0.2820		
5-point norm. part.	0.5059	0.5527	0.0470
5-point norm. trans.	0.3236	0.3845	0.1545
Pairwise	0.2385	0.5085	0.2096
Pairwise filt. part.	0.3912	0.7264	0.0533
Pairwise filt. trans.	0.3519	0.5718	0.2591

Table 1: Inter- and intra-reliability measured by Krippendorff's α for 5-point and pairwise ratings of 1,000 translations of which 200 translations are repeated twice. The filtered variants are restricted to either a subset of participants (part.) or a subset of translations (trans.).

repetition. This produced a total of 1,000 individual translations, with 600 occurring once, and 200 occurring twice. The translations were shuffled and separated into five sections of 200 translations, each with 120 translations from the unrepeated pool, and 80 translations from the repeated pool, ensuring that a single translation does not occur more than once in each section. For a pairwise task, the same 100 pairs were repeated from the original 400 translation pairs. This produced a total of 500 translation pairs. The translations were also shuffled and separated into five sections of 100 translation pairs, each with 60 translation pairs from the unrepeated pool, and 40 translation pairs from the repeated pool. None of the pairs were repeated within each section.

We recruited 14 participants for the pairwise rating task and 16 for the 5-point rating task. The participants were university students with fluent or native language skills in German and English. The rating interface is shown in Figures 1 and 2. Rating instructions are given in the supplementary material. Note that no reference translations were presented since the objective is to model a realistic scenario for bandit learning.[1]

4 Reliability of Human MT Ratings

4.1 Inter-rater and Intra-rater Reliability

In the following, we report inter- and intra-rater reliability of the cardinal and ordinal feedback tasks described in §3 with respect to Krippendorff's α (Krippendorff, 2013) evaluated at interval and ordinal scale, respectively.

As shown in Table 1, measures of inter-rater reliability show small differences between the 5-point and pairwise task. The inter-rater reliability in the 5-point task ($\alpha = 0.2308$) is roughly the same as that of the pairwise task ($\alpha = 0.2385$). Normalization of ratings per participant (by standardization to Z-scores), however, shows a marked improvement of overall inter-rater reliability for the 5-point task ($\alpha = 0.2820$). A one-way analysis of variance taken over inter-rater reliabilities between pairs of participants suggests statistically significant differences across tasks ($F\,(2, 328) = 6.399, p < 0.01$), however, a post hoc Tukey's (Larsen and Marx, 2012) honest significance test attributes statistically significant differences solely between the 5-point tasks with and without normalization. These scores indicate that the overall agreement between human ratings is roughly the same, regardless of whether participants are being asked to provide cardinal or ordinal ratings. Improvement in inter-rater reliability via participant-level normalization suggests that participants may indeed have individual biases toward certain regions of the 5-point scale, which the normalization process corrects.

In terms of intra-rater reliability, a better mean was observed among participants in the pairwise task ($\alpha = 0.5085$) versus the 5-point task ($\alpha = 0.4014$). This suggests that, on average, human raters provide more consistent ratings with themselves in comparing between two translations versus rating single translations in isolation. This may be attributed to the fact that seeing multiple translations provides raters with more cues with which to make consistent judgments. However, at the current sample size, a Welch two-sample t-test (Larsen and Marx, 2012) between 5-point and pairwise intra-rater reliabilities shows no significant difference between the two tasks ($t\,(26.92) = 1.4362, p = 0.1625$). Thus, it remains difficult to infer whether one task is definitively superior to the other in eliciting more consistent responses. Intra-rater reliability is the same for the 5-point task with and without normalization, as participants are still compared against themselves.

[1]The collection of ratings can be downloaded from http://www.cl.uni-heidelberg.de/statnlpgroup/humanmt/.

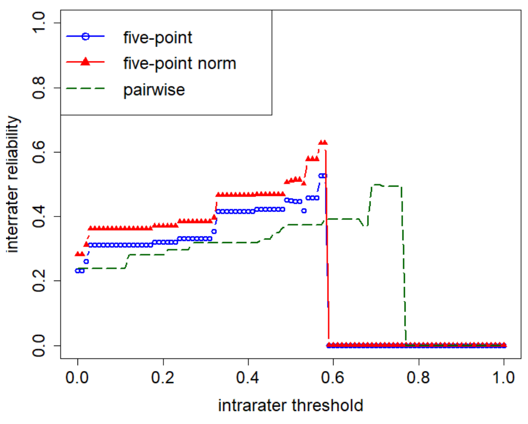

Figure 3: Improvements in inter-rater reliability using *intra-rater consistency* filter.

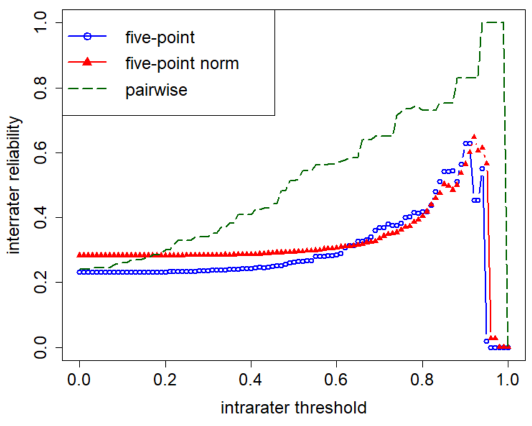

Figure 4: Improvements in inter-rater reliability using *item variance* filter.

4.2 Rater and Item Variance

The succeeding analysis is based on two assumptions: first, that human raters vary in that they do not provide equally good judgments of translation quality, and second, rating items vary in that some translations may be more difficult to judge than others. This allows to investigate the influence of rater variance and item variance on inter-rater reliability by an ablation analysis where low-quality judges and difficult translations are filtered out.

Using intra-rater reliability as an index of how well human raters judge translation quality, Figure 3 shows a filtering process whereby human raters with α scores lower than a moving threshold are dropped from the analysis. As the reliability threshold is increased from 0 to 1, overall inter-rater reliability is measured. Figure 4 shows a similar filtering process implemented using variance in translation scores. Item variances are normalized on a scale from 0 to 1 and subtracted from 1 to produce an item variance threshold. As the threshold increases, overall inter-rater reliability is likewise measured as high-variance items are progressively dropped from the analysis.

As the plots demonstrate, inter-rater reliability generally increases with consistency and variance filtering. For consistency filtering, Figure 3 shows how the inter-rater reliability of the 5-point task experiences greater increases than the pairwise task with lower filtering thresholds, especially in the normalized case. This may be attributed to the fact that more participants in the 5-point task had low intra-rater reliability. Pairwise tasks, on the other hand, require higher thresholds before large gains are observed in overall inter-rater reliability. This is because more participants in the pairwise task had relatively high intra-rater reliability. In the normalized 5-point task, selecting a threshold of 0.49 as a cutoff for intra-rater reliability retains 8 participants with an inter-rater reliability of 0.5059. For the pairwise task, a threshold of 0.66 leaves 5 participants with an inter-rater reliability of 0.3912.

The opposite phenomenon is observed in the case of variance filtering. As seen in Figure 4, the overall inter-rater reliability of the pairwise task quickly overtakes that of the 5-point task, with and without normalization. This may be attributed to how, in the pairwise setup, more items can be a source of disagreement among human judges. Ambiguous cases, that will be discussed in §4.3, may result in higher item variance. This problem is not as pronounced in the 5-point task, where judges must simply judge individual translations. It may be surmised that this item variance accounts for why, on average, judges in the pairwise task demonstrate higher intra-rater reliability than those in the 5-point task, yet the overall inter-rater reliability of the pairwise task is lower. By selecting a variance threshold such that at least 70% of items are retained in the analysis, the improved inter-rater reliabilities were 0.3236 for the 5-point task and 0.3519 for the pairwise task.

4.3 Qualitative Analysis

On completion of the rating task, we asked the participants for a *subjective* judgment of difficulty on a scale from 1 (very difficult) to 10 (very easy). On average, the pairwise rating task (mean 5.69) was perceived slightly easier than the 5-point rating task (mean 4.8). They also had to state which aspects of the tasks they found difficult: The biggest challenge for 5-point ratings seemed to be the weighing of different error types and the rating of long sentences with very few, but essential errors. For pairwise ratings, difficulties lie in distinguishing between similar, or similarly bad translations. Both tasks showed difficulties with ungrammatical or incomprehensible sources.

Comparing items with high and low agreement across raters allows conclusions about *objective* difficulty. We assume that high inter-rater agreement indicates an ease of judgment, while difficulties in judgment are manifested in low agreement. A list of examples is given in the supplementary material. For 5-point ratings, difficulties arise with ungrammatical sources and omissions, whereas obvious mistakes in the target, such as over-literal translations, make judgment easier. Preference judgments tend to be harder when both translations contain errors and are similar. When there is a tie, the pairwise rating framework does not allow to indicate whether both translations are of high or low quality. Since there is no normalization strategy for pairwise ratings, individual biases or rating schemes can hence have a larger negative impact on the inter-rater agreement.

5 Learnability of a Reward Estimator from MT Ratings

5.1 Learning a Reward Estimator

The numbers of ratings that can be obtained directly from human raters in a reasonable amount of time is tiny compared to the millions of sentences used for standard NMT training. By learning a reward estimator on the collection of human ratings, we seek to generalize to unseen translations. The model for this reward estimator should ideally work without time-consuming feature extraction so it can be deployed in direct interaction with a learning NMT system, estimating rewards on the fly, and most importantly generalize well so it can guide the NMT towards good local optima.

Learning from Cardinal Feedback. The inputs to the reward estimation model are sources $\mathbf{x}$ and their translations $\mathbf{y}$. Given cardinal judgments for these inputs, a regression model with parameters ψ is trained to minimize the mean squared error (MSE) for a set of n predicted rewards $\hat{r}$ and judgments r:

$$\mathcal{L}^{MSE}(\psi) = \frac{1}{n}\sum_{i=1}^{n}(r(\mathbf{y}_i) - \hat{r}_\psi(\mathbf{y}_i))^2.$$

In simulation experiments, where all translations can be compared to existing references, r may be computed by sentence-BLEU (sBLEU). For our human 5-point judgments, we first normalize the judgments per rater as described in §4, then average the judgments across raters and finally scale them linearly to the interval $[0.0, 1.0]$.

Learning from Pairwise Preference Feedback. When pairwise preferences are given instead of cardinal judgments, the Bradley-Terry model allows us to train an estimator of r. Following Christiano et al. (2017), let $\hat{P}_\psi[\mathbf{y^1} \succ \mathbf{y^2}]$ be the probability that any translation $\mathbf{y^1}$ is preferred over any other translation $\mathbf{y^2}$ by the reward estimator:

$$\hat{P}_\psi[\mathbf{y}^1 \succ \mathbf{y}^2] = \frac{\exp \hat{r}_\psi(\mathbf{y^1})}{\exp \hat{r}_\psi(\mathbf{y^1}) + \exp \hat{r}_\psi(\mathbf{y^2})}.$$

Let $Q[\mathbf{y^1} \succ \mathbf{y^2}]$ be the probability that translation $\mathbf{y_1}$ is preferred over translation $\mathbf{y_2}$ by a gold standard, e.g. the human raters or in comparison to a reference translation. With this supervision signal we formulate a pairwise (PW) training loss for the reward estimation model with parameters ψ:

$$\mathcal{L}^{PW}(\psi) = -\frac{1}{n}\sum_{i=1}^{n} Q[\mathbf{y_i^1} \succ \mathbf{y_i^2}] \log \hat{P}_\psi[\mathbf{y_i^1} \succ \mathbf{y_i^2}] + Q[\mathbf{y_i^2} \succ \mathbf{y_i^1}] \log \hat{P}_\psi[\mathbf{y_i^2} \succ \mathbf{y_i^1}].$$

For simulation experiments — where we lack a genuine supervision for preferences — we compute Q comparing the sBLEU scores for both translations, i.e. translation preferences are modeled according to their difference in sBLEU:

$$Q[\mathbf{y^1} \succ \mathbf{y^2}] = \frac{\exp \text{sBLEU}(\mathbf{y^1})}{\exp \text{sBLEU}(\mathbf{y^1}) + \exp \text{sBLEU}(\mathbf{y^2})}.$$

When obtaining preference jugdments directly from raters, $Q[\mathbf{y^1} \succ \mathbf{y^2}]$ is simply the relative frequency of $\mathbf{y^1}$ being preferred over $\mathbf{y^2}$ by a rater.

5.2 Experiments

Data. The 1,000 ratings collected as described in §3 are leveraged to train regression models and pairwise preference models. In addition, we train models on simulated rewards (sBLEU) for a comparison with arguably "clean" feedback for the

Model	Feedback	ρ
MSE	Simulated	-0.2571
PW	Simulated	-0.1307
MSE	Human	-0.2193
PW	Human	-0.1310
MSE	Human filt.	-0.2341
PW	Human filt.	-0.1255

Table 2: Spearman's rank correlation ρ between estimated rewards and TER for models trained with *simulated* rewards and *human* rewards (also filtered subsets).

same set of translations. In order to augment this very small collection of ratings, we leverage the available out-of-domain bitext as auxiliary training data. We sample translations for a subset of the out-of-domain sources and store sBLEU scores as rewards, collecting 90k out-of-domain training samples in total (see supplementary material for details). During training, each mini-batch is sampled from the auxiliary data with probability p_{aux}, from the original training data with probability $1 - p_{aux}$. Adding this auxiliary data as a regularization through multi-task learning prevents the model from overfitting to the small set of human ratings. In the experiments p_{aux} was tuned to 0.8.

Architecture. We choose the following neural architecture for the reward estimation (details see supplementary material): Inputs are padded source and target subword embeddings, which are each processed with a biLSTM (Hochreiter and Schmidhuber, 1997). Their outputs are concatenated for each time step, further fed to a 1D-convolution with max-over-time pooling and subsequently a leaky ReLU (Maas et al., 2013) output layer. This architecture can be seen as a biLSTM-enhanced bilingual extension to the convolutional model for sentence classification proposed by Kim (2014). It has the advantage of not requiring any feature extraction but still models n-gram features on an abstract level.

Evaluation Method. The quality of the reward estimation models is tested by measuring Spearman's ρ with TER on a held-out test set of 1,314 translations following the standard in sQE evaluations. Hyperparameters are tuned on another 1,200 TED translations.

Results. Table 2 reports the results of reward estimators trained on simulated and human rewards. When trained from cardinal rewards, the model of simulated scores performs slightly better than the model of human ratings. This advantage is lost when moving to preference judgments, which might be explained by the fact that the softmax over sBLEUs with respect to a single reference is just not as expressive as the preference probabilities obtained from several raters. Filtering by participants (retaining 8 participants for cardinal rewards and 5 for preference jugdments, see Section 4) improves the correlation further for cardinal rewards, but slightly hurts for preference judgments. The overall correlation scores are relatively low — especially for the PW models — which we suspect is due to overfitting to the small set of training data. From these experiments we conclude that when it comes to estimating translation quality, cardinal human jugdments are more useful than pairwise preference jugdments.

6 Reinforcement Learning from Direct and Estimated Rewards in MT

6.1 NMT Objectives

Supervised Learning. Most commonly, NMT models are trained with Maximum Likelihood Estimation (MLE) on a parallel corpus of source and target sequences $D = \{(\mathbf{x}^{(s)}, \mathbf{y}^{(s)})\}_{s=1}^{S}$:

$$\mathcal{L}^{MLE}(\boldsymbol{\theta}) = \sum_{s=1}^{S} \log p_\theta(\mathbf{y}^{(s)}|\mathbf{x}^{(s)}).$$

The MLE objective requires reference translations and is agnostic to rewards. In the experiments it is used to train the out-of-domain baseline model as a warm start for reinforcement learning from in-domain rewards.

Reinforcement Learning from Estimated or Simulated Direct Rewards. Deploying NMT in a reinforcement learning scenario, the goal is to maximize the expectation of a reward r over all source and target sequences (Wu et al., 2016), leading to the following REINFORCE (Williams, 1992) objective:

$$\begin{aligned}\mathcal{R}^{RL}(\boldsymbol{\theta}) =& \mathbb{E}_{p(\mathbf{x})p_{\boldsymbol{\theta}}(\mathbf{y}|\mathbf{x})}\left[r(\mathbf{y})\right] & (1)\\ &\approx \sum_{s=1}^{S}\sum_{i=1}^{k} p_{\boldsymbol{\theta}}^{\tau}(\tilde{\mathbf{y}}_{\mathbf{i}}^{(\mathbf{s})}|\mathbf{x}^{(\mathbf{s})})\, r(\tilde{\mathbf{y}}_{\mathbf{i}}) & (2)\end{aligned}$$

The reward r can either come from a reward estimation model (*estimated reward*) or be computed with respect to a reference in a simulation setting (*simulated direct reward*). In order to counteract high variance in the gradient updates, the running average of rewards is subtracted from r for learning. In practice, Equation 1 is approximated with k samples from $p_{\boldsymbol{\theta}}(\mathbf{y}|\mathbf{x})$ (see Equation 2). When $k = 1$, this is equivalent to the expected loss minimization in Sokolov et al. (2016a,b); Kreutzer et al. (2017), where the system interactively learns from online bandit feedback. For $k > 1$ this is similar to the minimum-risk training for NMT proposed in Shen et al. (2016). Adding a temperature hyper-parameter $\tau \in (0.0, \infty]$ to the softmax over the model output $\mathbf{o}$ allows us to control the sharpness of the sampling distribution $p^{\tau}_{\boldsymbol{\theta}}(\mathbf{y}|\mathbf{x}) = \mathrm{softmax}(\mathbf{o}/\tau)$, i.e. the amount of exploration during training. With temperature $\tau < 1$, the model's entropy decreases and samples closer to the one-best output are drawn. We seek to keep the exploration low to prevent the NMT to produce samples that lie far outside the training domain of the reward estimator.

Off-Policy Learning from Direct Rewards. When rewards can not be obtained for samples from a learning system, but were collected for a static deterministic system (e.g. in a production environment), we are in an *off-policy learning* scenario. The challenge is to improve the MT system from a log $L = \{(\mathbf{x}^{(h)}, \mathbf{y}^{(h)}, r(\mathbf{y}^{(h)}))\}_{h=1}^{H}$ of rewarded translations. Following Lawrence et al. (2017) we define the following off-policy learning (OPL) objective to learn from logged rewards:

$$\mathcal{R}^{OPL}(\boldsymbol{\theta}) = \frac{1}{H}\sum_{h=1}^{H} r(\mathbf{y}^{(h)})\, \bar{p}_{\boldsymbol{\theta}}(\mathbf{y}^{(h)}|\mathbf{x}^{(h)}),$$

with reweighting over the current mini-batch B: $\bar{p}_{\boldsymbol{\theta}}(\mathbf{y}^{(h)}|\mathbf{x}^{(h)}) = \frac{p_{\boldsymbol{\theta}}(\mathbf{y}^{(h)}|\mathbf{x}^{(h)})}{\sum_{b=1}^{B} p_{\boldsymbol{\theta}}(\mathbf{y}^{(b)}|\mathbf{x}^{(b)})}$.[2] In contrast to the RL objective, only logged translations are reinforced, i.e. there is no exploration in learning.

6.2 Experiments

Data. We use the WMT 2017 data[3] for training a general domain (here: *out-of-domain*) model for translations from German to English. The training data contains 5.9M sentence pairs, the development data 2,999 sentences (WMT 2016 test set) and the test data 3,004 sentences. For *in-domain* data, we choose the translations of TED talks[4] as used in IWSLT evaluation campaigns. The training data contains 153k, the development data 6,969, and the test data 6,750 parallel sentences.

	WMT			TED		
Model	BLEU	METEOR	BEER	BLEU	METEOR	BEER
WMT	27.2	31.8	60.08	27.0	30.7	59.48
TED	26.3	31.3	59.49	34.3	34.6	64.94

Table 3: Results on test data for in- and out-of-domain *fully-supervised* models. Both are trained with MLE, the TED model is obtained by fine-tuning the WMT model in TED data.

Architecture. Our NMT model is a standard subword-based encoder-decoder architecture with attention (Bahdanau et al., 2015). An encoder Recurrent Neural Network (RNN) reads in the source sentence and a decoder RNN generates the target sentence conditioned on the encoded source. We implemented RL and OPL objectives in Neural Monkey (Helcl and Libovický, 2017).[5] The NMT has a bidirectional encoder and a single-layer decoder with 1,024 GRUs each, and subword embeddings of size 500 for a shared vocabulary of subwords obtained from 30k byte-pair merges (Sennrich et al., 2016). For model selection we use greedy decoding, for test set evaluation beam search with a beam of width 10. We sample $k = 5$ translations for RL models and set the softmax temperature $\tau = 0.5$. Further hyperparameters are given in the supplementary material.

Evaluation Method. Trained models are evaluated with respect to BLEU (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2011) using MULTEVAL (Clark et al., 2011) and BEER (Stanojević and Sima'an, 2014) to cover a diverse set of automatic measures for translation quality.[6] We test for statistical significance with approximate randomization (Noreen, 1989).

[2] Lawrence et al. (2017) propose reweighting over the whole log, but this is infeasible for NMT. Here $B \ll H$.

[3] Pre-processed data available at `http://www.statmt.org/wmt17/translation-task.html`.

[4] Pre-processing and data splits as described in `https://github.com/rizar/actor-critic-public/tree/master/exp/ted`.

[5] The code is available in the Neural Monkey fork `https://github.com/juliakreutzer/bandit-neuralmonkey/tree/acl2018`.

[6] Since tendencies of improvement turn out to be consistent across metrics, we only discuss BLEU in the text.

Model	Rewards		BLEU	METEOR	BEER
Baseline	-	-	27.0	30.7	59.48
RL	D	S	$32.5^{\star}_{\pm 0.01}$	$33.7^{\star}_{\pm 0.01}$	$63.47^{\star}_{\pm 0.10}$
OPL	D	S	$27.5^{\star}$	$30.9^{\star}$	$59.62^{\star}$
RL+MSE	E	S	$28.2^{\star}_{\pm 0.09}$	$31.6^{\star}_{\pm 0.04}$	$60.23^{\star}_{\pm 0.14}$
RL+PW	E	S	$27.8^{\star}_{\pm 0.01}$	$31.2^{\star}_{\pm 0.01}$	$59.83^{\star}_{\pm 0.04}$
OPL	D	H	$27.5^{\star}$	$30.9^{\star}$	$59.72^{\star}$
RL+MSE	E	H	$28.1^{\star}_{\pm 0.01}$	$31.5^{\star}_{\pm 0.01}$	$60.21^{\star}_{\pm 0.12}$
RL+PW	E	H	$27.8^{\star}_{\pm 0.09}$	$31.3^{\star}_{\pm 0.09}$	$59.88^{\star}_{\pm 0.23}$
RL+MSE	E	F	$28.1^{\star}_{\pm 0.20}$	$31.6^{\star}_{\pm 0.10}$	$60.29^{\star}_{\pm 0.13}$

Table 4: Results on TED test data for training with *estimated* (E) and *direct* (D) rewards from *simulation* (S), *humans* (H) and *filtered* (F) human ratings. Significant ($p \leq 0.05$) differences to the baseline are marked with *. For RL experiments we show three runs with different random seeds, mean and standard deviation in subscript.

The out-of-domain model is trained with MLE on WMT. The task is now to improve the generalization of this model to the TED domain. Table 3 compares the out-of-domain baseline with domain-adapted models that were further trained on TED in a fully-supervised manner (*supervised fine-tuning* as introduced by Freitag and Al-Onaizan (2016); Luong and Manning (2015)). The supervised domain-adapted model serves as an upper bound for domain adaptation with human rewards: if we had references, we could improve up to 7 BLEU. What if references are not available, but we can obtain rewards for sample translations?

Results for RL from Simulated Rewards. First we simulate "clean" and deterministic rewards by comparing sample translations to references using GLEU (Wu et al., 2016) for RL, and smoothed sBLEU for estimated rewards and OPL. Table 4 lists the results for this simulation experiment in rows 2-5 (S). If unlimited clean feedback was given (RL with direct simulated rewards), improvements of over 5 BLEU can be achieved. When limiting the amount of feedback to a log of 800 translations, the improvements over the baseline are only marginal (OPL). When replacing the direct reward by the simulated reward estimators from §5, i.e. having unlimited amounts of approximately clean rewards, however, improvements of 1.2 BLEU for MSE estimators (RL+MSE) and 0.8 BLEU for pairwise estimators (RL+PW) are found. This suggests that the reward estimation model helps to tackle the challenge of generalization over a small set of ratings.

Results for RL from Human Rewards. Knowing what to expect in an ideal setting with non-noisy feedback, we now move to the experiments with human feedback. OPL is trained with the logged normalized, averaged and re-scaled human reward (see §5). RL is trained with the direct reward provided by the reward estimators trained on human rewards from §5. Table 4 shows the results for training with human rewards in rows 6-8: The improvements for OPL are very similar to OPL with simulated rewards, both suffering from overfitting. For RL we observe that the MSE-based reward estimator (RL+MSE) leads to significantly higher improvements as a the pairwise reward estimator (RL+PW) — the same trend as for simulated ratings. Finally, the improvement of 1.1 BLEU over the baseline showcases that we are able to improve NMT with only a small number of human rewards. Learning from estimated filtered 5-point ratings, does not significantly improve over these results, since the improvement of the reward estimator is only marginal (see § 5).

7 Conclusion

In this work, we sought to find answers to the questions of how cardinal and ordinal feedback differ in terms of reliability, learnability and effectiveness for RL training of NMT, with the goal of improving NMT with human bandit feedback. Our rating study, comparing 5-point and preference ratings, showed that their reliability is comparable, whilst cardinal ratings are easier to learn and to generalize from, and also more suitable for RL in our experiments.

Our work reports improvements of NMT leveraging actual human bandit feedback for RL, leaving the safe harbor of simulations. Our experiments show that improvements of over 1 BLEU are achievable by learning from a dataset that is tiny in machine translation proportions. Since this type of feedback, in contrast to post-edits and references, is fast and cheap to elicit from non-professionals, our results bear a great potential for future applications on larger scale.

Abstract

With parallelizable attention networks, the neural Transformer is very fast to train. However, due to the auto-regressive architecture and self-attention in the decoder, the decoding procedure becomes slow. To alleviate this issue, we propose an average attention network as an alternative to the self-attention network in the decoder of the neural Transformer. The average attention network consists of two layers, with an average layer that models dependencies on previous positions and a gating layer that is stacked over the average layer to enhance the expressiveness of the proposed attention network. We apply this network on the decoder part of the neural Transformer to replace the original target-side self-attention model. With masking tricks and dynamic programming, our model enables the neural Transformer to decode sentences over four times faster than its original version with almost no loss in training time and translation performance. We conduct a series of experiments on WMT17 translation tasks, where on 6 different language pairs, we obtain robust and consistent speed-ups in decoding.[1]

1 Introduction

The past few years have witnessed the rapid development of neural machine translation (NMT), which translates a source sentence into the target language with an encoder-attention-decoder framework (Sutskever et al., 2014; Bahdanau et al., 2015). Under this framework, various advanced neural architectures have been explored as the backbone network for translation, ranging from recurrent neural networks (RNN) (Sutskever et al., 2014; Luong et al., 2015), convolutional neural networks (CNN) (Gehring et al., 2017a,b) to full attention networks without recurrence and convolution (Vaswani et al., 2017). Particularly, the neural Transformer, relying solely on attention networks, has refreshed state-of-the-art performance on several language pairs (Vaswani et al., 2017).

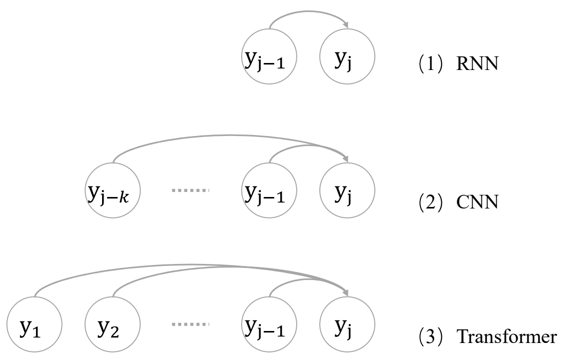

Figure 1: Illustration of the decoding procedure under different neural architectures. We show which previous target words are required to predict the current target word y_j in different NMT architectures. k indicates the filter size of the convolution layer.

Most interestingly, the neural Transformer is capable of being fully parallelized at the training phase and modeling intra-/inter-dependencies of source and target sentences within a short path. The parallelization property enables training NMT very quickly, while the dependency modeling property endows the Transformer with strong ability in inducing sentence semantics as well as translation correspondences. However, the decoding of the Transformer cannot enjoy the speed strength of parallelization due to the auto-regressive generation schema in the decoder. And the self-attention

[1]Source code is available at https://github.com/bzhangXMU/transformer-aan.

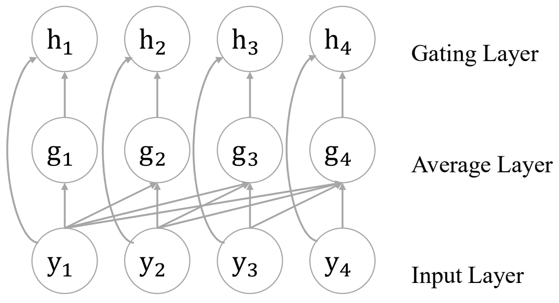

Figure 2: Visualization of the proposed model. For clarity, we show an example with only four words.

network in the decoder even further slows it.

We explain this using Figure 1, where we provide a comparison to RNN- and CNN-based NMT systems. To capture dependencies from previously predicted target words, the self-attention in the neural Transformer requires to calculate adaptive attention weights on all these words (Figure 1 (3)). By contrast, CNN only requires previous k target words (Figure 1 (2)), while RNN merely 1 (Figure 1 (1)). Due to the auto-regressive generation schema, decoding inevitably follows a sequential manner in the Transformer. Therefore the decoding procedure cannot be parallelized. Furthermore, the more target words are generated, the more time the self-attention in the decoder will take to model dependencies. Therefore, preserving the training efficiency of the Transformer on the one hand and accelerating its decoding on the other hand becomes a new and serious challenge.

In this paper, we propose an average attention network (AAN) to handle this challenge. We show the architecture of AAN in Figure 2, which consists of two layers: an *average layer* and *gating layer*. The average layer summarizes history information via a cumulative average operation over previous positions. This is equivalent to a simple attention network where original adaptively computed attention weights are replaced with averaged weights. Upon this layer, we stack a feed forward gating layer to improve the model's expressiveness in describing its inputs.

We use AAN to replace the self-attention part of the neural Transformer's decoder. Considering the characteristic of the cumulative average operation, we develop a masking method to enable parallel computation just like the original self-attention network in the training. In this way, the whole AAN model can be trained totally in parallel so that the training efficiency is ensured. As for the decoding, we can substantially accelerate it by feeding only the previous hidden state to the Transformer decoder just like RNN does. This is achieved with a dynamic programming method.

In spite of its simplicity, our model is capable of modeling complex dependencies. This is because AAN regards each previous word as an equal contributor to current word representation. Therefore, no matter how long the input is, our model can always build up connection signals with previous inputs, which we argue is very crucial for inducing long-range dependencies for machine translation.

We examine our model on WMT17 translation tasks. On 6 different language pairs, our model achieves a speed-up of over 4 times with almost no loss in both translation quality and training speed. In-depth analyses further demonstrate the convergency and advantages of translating long sentences of the proposed AAN.

2 Related Work

GRU (Chung et al., 2014) or LSTM (Hochreiter and Schmidhuber, 1997) RNNs are widely used for neural machine translation to deal with long-range dependencies as well as the gradient vanishing issue. A major weakness of RNNs lies at its sequential architecture that completely disables parallel computation. To cope with this problem, Gehring et al. (2017a) propose to use CNN-based encoder as an alternative to RNN, and Gehring et al. (2017b) further develop a completely CNN-based NMT system. However, shallow CNN can only capture local dependencies. Hence, CNN-based NMT normally develops deep archictures to model long-distance dependencies. Different from these studies, Vaswani et al. (2017) propose the Transformer, a neural architecture that abandons recurrence and convolution. It fully relies on attention networks to model translation. The properties of parallelization and short dependency path significantly improve the training speed as well as model performance for the Transformer. Unfortunately, as we have mentioned in Section 1, it suffers from decoding inefficiency.

The attention mechanism is originally proposed to induce translation-relevant source information for predicting next target word in NMT. It contributes a lot to make NMT outperform SMT. Recently, a variety of efforts are made to further improve its accuracy and capability. Luong et al.

(2015) explore several attention formulations and distinguish local attention from global attention. Zhang et al. (2016) treat RNN as an alternative to the attention to improve model's capability in dealing with long-range dependencies. Yang et al. (2017) introduce a recurrent cycle on the attention layer to enhance the model's memorization of previous translated source words. Zhang et al. (2017a) observe the weak discrimination ability of the attention-generated context vectors and propose a GRU-gated attention network. Kim et al. (2017) further model intrinsic structures inside attention through graphical models. Shen et al. (2017) introduce a direction structure into a self-attention network to integrate both long-range dependencies and temporal order information. Mi et al. (2016) and Liu et al. (2016) employ standard word alignment to supervise the automatically generated attention weights. Our work also focus on the evolution of attention network, but unlike previous work, we seek to simplify the self-attention network so as to accelerate the decoding procedure. The design of our model is partially inspired by the highway network (Srivastava et al., 2015) and the residual network (He et al., 2015).

In the respect of speeding up the decoding of the neural Transformer, Gu et al. (2018) change the auto-regressive architecture to speed up translation by directly generating target words without relying on any previous predictions. However, compared with our work, their model achieves the improvement in decoding speed at the cost of the drop in translation quality. Our model, instead, not only achieves a remarkable gain in terms of decoding speed, but also preserves the translation performance. Developing fast and efficient attention module for the Transformer, to the best of our knowledge, has never been investigated before.

3 The Average Attention Network

Given an input layer $\mathbf{y} = \{\mathbf{y}_1, \mathbf{y}_2, \dots, \mathbf{y}_m\}$, AAN first employs a cumulative-average operation to generate context-sensitive representation for each input embedding as follows (Figure 2 *Average Layer*):

$$\mathbf{g}_j = \text{FFN}\left(\frac{1}{j}\sum_{k=1}^{j}\mathbf{y}_k\right) \tag{1}$$

where $\text{FFN}(\cdot)$ denotes the position-wise feed-forward network proposed by Vaswani et al. (2017), and both $\mathbf{y}_k$ and $\mathbf{g}_j$ have a dimensionality of d. Intuitively, AAN replaces the original dynamically computed attention weights by the self-attention network in the decoder of the neural Transformer with simple and fixed average weights ($\frac{1}{j}$). In spite of its simplicity, the cumulative-average operation is very crucial for AAN because it builds up dependencies with previous input embeddings so that the generated representations are not independent of each other. Another benefit from the cumulative-average operation is that no matter how long the input is, the connection strength with each previous input embedding is invariant, which ensures the capability of AAN in modeling long-range dependencies.

We treat $\mathbf{g}_j$ as a contextual representation for the j-th input, and apply a feed-forward gating layer upon it as well as $\mathbf{y}_j$ to enrich the non-linear expressiveness of AAN:

$$\begin{aligned}\mathbf{i}_j, \mathbf{f}_j &= \sigma\left(\mathbf{W}\left[\mathbf{y}_j; \mathbf{g}_j\right]\right)\\ \tilde{\mathbf{h}}_j &= \mathbf{i}_j \odot \mathbf{y}_j + \mathbf{f}_j \odot \mathbf{g}_j\end{aligned} \tag{2}$$

where $[\cdot;\cdot]$ denotes concatenation operation, and $\odot$ indicates element-wise multiplication. $\mathbf{i}_j$ and $\mathbf{f}_j$ are the *input* and *forget* gate respectively. Via this gating layer, AAN can control how much past information can be preserved from previous context $\mathbf{g}_j$ and how much new information can be captured from current input $\mathbf{y}_j$. This helps our model to detect correlations inside input embeddings.

Following the architecture design in the neural Transformer (Vaswani et al., 2017), we employ a residual connection between the input layer and gating layer, followed by layer normalization to stabilize the scale of both output and gradient:

$$\mathbf{h}_j = \text{LayerNorm}\left(\mathbf{y}_j + \tilde{\mathbf{h}}_j\right) \tag{3}$$

We refer to the whole procedure formulated in Eq. (1~3) as original $\text{AAN}(\cdot)$ in following sections.

3.1 Parallelization in Training

A computation bottleneck of the original AAN described above is that the cumulative-average operation in Eq. (1) can only be performed sequentially. That is, this operation can not be parallelized. Fortunately, as the average is not a complex computation, we can use a masking trick to enable full parallelization of this operation.

We show the masking trick in Figure 3, where input embeddings are directly converted into their corresponding cumulative-averaged outputs

Model	Complexity	Sequential Operations	Maximum Path Length
Self-attention	$\mathcal{O}\left(n^2 \cdot d + n \cdot d^2\right)$	$\mathcal{O}(1)$	$\mathcal{O}(1)$
Original AAN	$\mathcal{O}\left(n \cdot d^2\right)$	$\mathcal{O}(n)$	$\mathcal{O}(1)$
Masked AAN	$\mathcal{O}\left(n^2 \cdot d + n \cdot d^2\right)$	$\mathcal{O}(1)$	$\mathcal{O}(1)$

Table 1: Maximum path lengths, model complexity and minimum number of sequential operations for different models. n is the sentence length and d is the representation dimension.

$$\underbrace{\begin{Bmatrix} 1 & 0 & 0 & 0 \\ 1/2 & 1/2 & 0 & 0 \\ 1/3 & 1/3 & 1/3 & 0 \\ 1/4 & 1/4 & 1/4 & 1/4 \end{Bmatrix}}_{\text{Mask Matrix}} \times \begin{pmatrix} y_1 \\ y_2 \\ y_3 \\ y_4 \end{pmatrix} = \begin{pmatrix} y_1 \\ \frac{y_1 + y_2}{2} \\ \frac{y_1 + y_2 + y_3}{3} \\ \frac{y_1 + y_2 + y_3 + y_4}{4} \end{pmatrix}$$

through a masking matrix. In this way, all the components inside AAN$(\cdot)$ can enjoy full parallelization, assuring its computational efficiency. We refer to this AAN as masked AAN.

3.2 Model Analysis

In this section, we provide a thorough analysis for AAN in comparison to the original self-attention model used by Vaswani et al. (2017). Unlike our AAN, the self-attention model leverages a scaled dot-product function rather than the average operation to compute attention weights:

$$\mathbf{Q}, \mathbf{K}, \mathbf{V} = f(\mathbf{Y})$$
$$\text{Self-Attention}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = \text{softmax}\left(\frac{\mathbf{Q}\mathbf{K}^T}{\sqrt{d}}\right)\mathbf{V} \quad (4)$$

where $\mathbf{Y} \in \mathbb{R}^{n \times d}$ is the input matrix, $f(\cdot)$ is a mapping function and $\mathbf{Q}, \mathbf{K}, \mathbf{V} \in \mathbb{R}^{n \times d}$ are the corresponding queries, keys and values. Following Vaswani et al. (2017), we compare both models in terms of computational complexity, minimum number of sequential operations required and maximum path length that a dependency signal between any two positions has to traverse in the network. Table 1 summarizes the comparison results.

Our AAN has a maximum path length of $\mathcal{O}(1)$, because it can directly capture dependencies between any two input embeddings. For the original AAN, the nature of its sequential computation enlarges its minimum number sequential operations to $\mathcal{O}(n)$. However, due to its lack of position-wise masked projection, it only consumes a computational complexity of $\mathcal{O}\left(n \cdot d^2\right)$. By contrast, both self-attention and masked AAN have a computational complexity of $\mathcal{O}\left(n^2 \cdot d + n \cdot d^2\right)$, and require only $\mathcal{O}(1)$ sequential operation. Theoretically, our masked AAN performs very similarly to the self-attention according to Table 1. We therefore use the masked version of AAN during training throughout all our experiments.

3.3 Decoding Acceleration

Differing noticeably from the self-attention in the Transformer, our AAN can be accelerated in the decoding phase via dynamic programming thanks to the simple average calculation. Particularly, we can decompose Eq. (1) into the following two steps:

$$\tilde{\mathbf{g}}_j = \tilde{\mathbf{g}}_{j-1} + \mathbf{y}_j \quad (5)$$
$$\mathbf{g}_j = \text{FFN}\left(\frac{\tilde{\mathbf{g}}_j}{j}\right) \quad (6)$$

where $\tilde{\mathbf{g}}_0 = \mathbf{0}$. In doing so, our model can compute the j-th input representation based on only one previous state $\tilde{\mathbf{g}}_{j-1}$, instead of relying on all previous states as the self-attention does. In this way, our model can be substantially accelerated during the decoding phase.

4 Neural Transformer with AAN

The neural Transformer models translation through an encoder-decoder framework, with each layer involving an attention network followed by a feed forward network (Vaswani et al., 2017). We apply our masked AAN to replace the self-attention network in its decoder part, and illustrate the overall architecture in Figure 4.

Given a source sentence $\mathbf{x} = \{\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n\}$, the Transformer leverages its encoder to induce source-side semantics and dependencies so as to

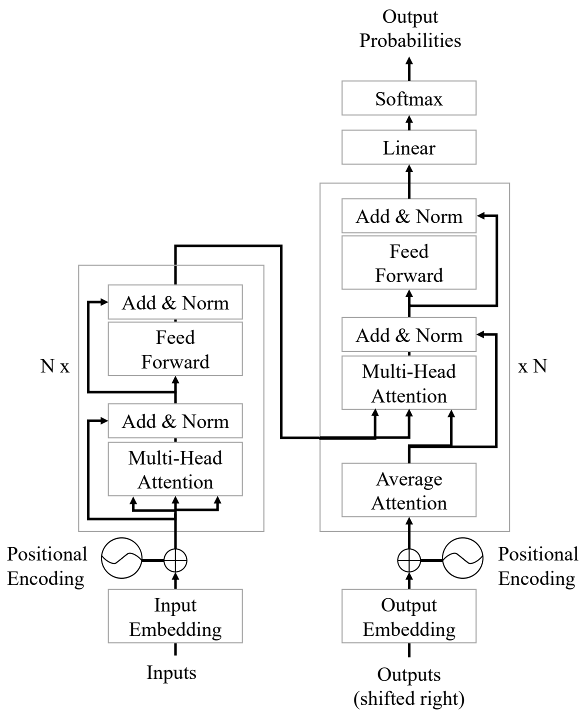

Figure 4: The new Transformer architecture with the proposed average attention network.

enable its decoder to recover the encoded information in a target language. The encoder is composed of a stack of $N = 6$ identical layers, each of which has two sub-layers:

$$\begin{aligned}\tilde{\mathbf{h}}^l &= \text{LayerNorm}\left(\mathbf{h}^{l-1} + \text{MHAtt}\left(\mathbf{h}^{l-1}, \mathbf{h}^{l-1}\right)\right)\\ \mathbf{h}^l &= \text{LayerNorm}\left(\tilde{\mathbf{h}}^l + \text{FFN}\left(\tilde{\mathbf{h}}^l\right)\right)\end{aligned} \tag{7}$$

where the superscript l indicates layer depth, and MHAtt denotes the multi-head attention mechanism proposed by Vaswani et al. (2017).

Based on the encoded source representation $\mathbf{h}^N$, the Transformer relies on its decoder to generate corresponding target translation $\mathbf{y} = \{\mathbf{y}_1, \mathbf{y}_2, \ldots, \mathbf{y}_m\}$. Similar to the encoder, the decoder also consists of a stack of $N = 6$ identical layers. For each layer in our architecture, the first sub-layer is our proposed average attention network, aiming at capturing target-side dependencies with previous predicted words:

$$\tilde{\mathbf{s}}^l = \text{AAN}\left(\mathbf{s}^{l-1}\right) \tag{8}$$

Carrying these dependencies, the decoder stacks another two sub-layers to seek translation-relevant source semantics for bridging the gap between the source and target language:

$$\begin{aligned}\mathbf{s}_c^l &= \text{LayerNorm}\left(\tilde{\mathbf{s}}^l + \text{MHAtt}\left(\tilde{\mathbf{s}}^l, \mathbf{h}^N\right)\right)\\ \mathbf{s}^l &= \text{LayerNorm}\left(\mathbf{s}_c^l + \text{FFN}\left(\mathbf{s}_c^l\right)\right)\end{aligned} \tag{9}$$

We use subscript c to denote the source-informed target representation. Upon the top layer of this decoder, translation is performed where a linear transformation and softmax activation are applied to compute the probability of the next token based on $\mathbf{s}^N$

To memorize position information, the Transformer augments its input layer $\mathbf{h}^0 = \mathbf{x}, \mathbf{s}^0 = \mathbf{y}$ with frequency-based positional encodings. The whole model is a large, single neural network, and can be trained on a large-scale bilingual corpus with a maximum likelihood objective. We refer readers to (Vaswani et al., 2017) for more details.

5 Experiments

5.1 WMT14 English-German Translation

We examine various aspects of our AAN on this translation task. The training data consist of 4.5M sentence pairs, involving about 116M English words and 110M German words. We used newstest2013 as the development set for model selection, and newstest2014 as the test set. We evaluated translation quality via case-sensitive BLEU metric (Papineni et al., 2002).

5.1.1 Model Settings

We applied byte pair encoding algorithm (Sennrich et al., 2016) to encode all sentences and limited the vocabulary size to 32K. All out-of-vocabulary words were mapped to an unique token "*unk*". We set the dimensionality d of all input and output layers to 512, and that of inner-FFN layer to 2048. We employed 8 parallel attention heads in both encoder and decoder layers. We batched sentence pairs together so that they were approximately of the same length, and each batch had roughly 25000 source and target tokens. During training, we used label smoothing with value $\epsilon_{ls} = 0.1$, attention dropout and residual dropout with a rate of $p = 0.1$. During decoding, we employed beam search algorithm and set the beam size to 4. Adam optimizer (Kingma and Ba, 2015) with $\beta_1 = 0.9$, $\beta_2 = 0.98$ and $\epsilon = 10^{-9}$ was used to tune model parameters, and the learning rate was varied under a warm-up strategy with $warmup\_steps = 4000$ (Vaswani et al., 2017).

Model	BLEU
Transformer	26.37
Our Model	26.31
Our Model w/o FFN	26.05
Our Model w/o Gate	25.91

Table 2: Case-sensitive tokenized BLEU score on WMT14 English-German translation. BLEU scores are calculated using *multi-bleu.perl*.

The maximum number of training steps was set to 100K. Weights of target-side embedding and output weight matrix were tied for all models. We implemented our model with masking tricks based on the open-sourced *thumt* (Zhang et al., 2017b)[2], and trained and evaluated all models on a single NVIDIA GeForce GTX 1080 GPU. For evaluation, we averaged last five models saved with an interval of 1500 training steps.

5.1.2 Translation Performance

Table 2 reports the translation results. On the same dataset, the Transformer yields a BLEU score of 26.37, while our model achieves 26.31. Both results are almost the same with no significant difference. Clearly, our model is capable of capturing complex translation correspondences so as to generate high-quality translations as effective as the Transformer.

We also show an ablation study in terms of the FFN$(\cdot)$ network in Eq. (1) and the gating layer in Eq. (2). Table 2 shows that without the FFN network, the performance of our model drops 0.26 BLEU points. This degeneration is enlarged to 0.40 BLEU points when the gating layer is not available. In order to reach comparable performance with the original Transformer, integrating both components is desired.

5.1.3 Analysis on Convergency

Different neural architectures might require different number of training steps to converge. In this section, we testify whether our AAN would reveal different characteristics with respect to convergency. We show the loss curve of both the Transformer and our model in Figure 5.

Surprisingly, both model show highly similar tendency, and successfully converge in the end. To train a high-quality translation system, our model consumes almost the same number of training steps as the Transformer. This strongly suggests

[2]https://github.com/thumt/THUMT

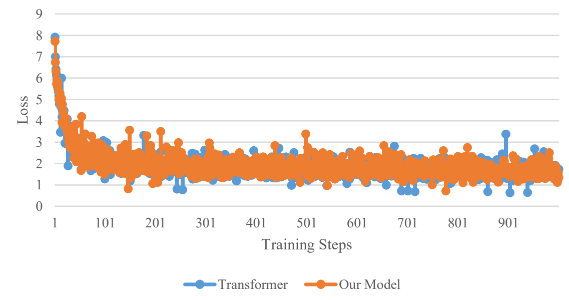

Figure 5: Convergence visualization. The horizontal axis denotes training steps scaled by 10^2, and the vertical axis indicates training loss. Roughly, our model converges similarly to the Transformer.

	Transformer	Our Model	$\triangle_r$
Training	0.2474	0.2464	1.00
Decoding			
beam=4	0.1804	0.0488	3.70
beam=8	0.3576	0.0881	4.06
beam=12	0.5503	0.1291	4.26
beam=16	0.7323	0.1700	4.31
beam=20	0.9172	0.2122	4.32

Table 3: Time required for training and decoding. *Training* denotes the number of global training steps processed per second; *Decoding* indicates the amount of time in seconds required for translating one sentence, which is averaged over the whole newstest2014 dataset. $\triangle_r$ shows the ratio between the Transformer and our model.

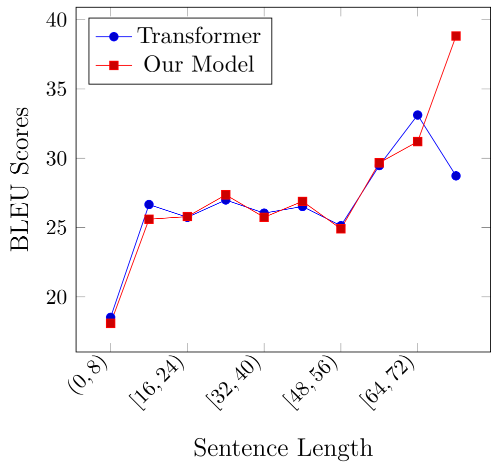
that replacing the self-attention network with our AAN does not have negative impact on the convergency of the entire model.

5.1.4 Analysis on Speed

In Section 3, we demonstrate in theory that our AAN is as efficient as the self-attention during training, but can be substantially accelerated during decoding. In this section, we provide quantitative evidences to examine this point.

We show the training and decoding speed of both the Transformer and our model in Table 3. During training, our model performs approximately 0.2464 training steps per second, while the Transformer processes around 0.2474. This indicates that our model shares similar computational strengths with the Transformer during training, which resonates with the computational analysis in Section 3.

When it comes to decoding procedure, the time of our model required to translate one sentence



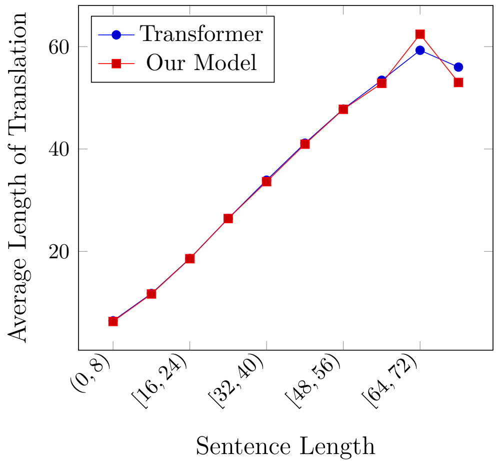


Figure 6: Translation statistics on WMT14 English-German test set (newstest14) with respect to the length of source sentences. The top figure shows tokenized BLEU score, and the bottom one shows the average length of translations, both visa-vis sentence length

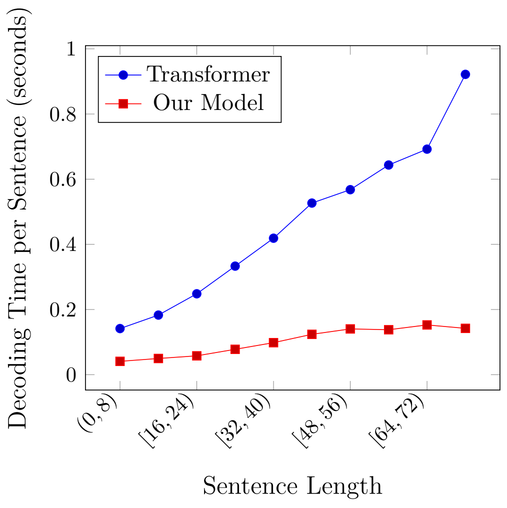

Figure 7: Average time required for translating one source sentence vs. the length of the source sentence. With the increase of sentence length, our model shows more clear and significant advantage over the Transformer in terms of the decoding speed.

is only a quarter of that of the Transformer, with beam size ranging from 4 to 20. Another noticeable feature is that as the beam size increases, the ratio of required decoding time between the Transformer and our model is consistently enlarged. This demonstrates empirically that our model, enhanced with the dynamic decoding acceleration algorithm (Section 3.3), can significantly improve the decoding speed of the Transformer.

5.1.5 Effects on Sentence Length

A serious common challenge for NMT is to translate long source sentences as handling long-distance dependencies and under-translation issues becomes more difficult for longer sentences. Our proposed AAN uses simple cumulative-average operations to deal with long-range dependencies. We want to examine the effectiveness of these operations on long sentence translation. For this, we provide the translation results along sentence length in Figure 6.

We find that both the Transformer and our model generate very similar translations in terms of BLEU score and translation length, and obtain rather promising performance on long source sentences. More specifically, our model yields relatively shorter translation length on the longest source sentences but significantly better translation quality. This suggests that in spite of the simplicity of the cumulative-average operations, our AAN can indeed capture long-range dependences desired for translating long source sentences.

Generally, the decoder takes more time for translating longer sentences. When it comes to the Transformer, this time issue of translating long sentences becomes notably severe as all previous predicted words must be included for estimating both self-attention weights and word prediction. We show the average time required for translating a source sentence with respect to its sentence length in Figure 7. Obviously, the decoding time of the Transformer grows dramatically with the increase of sentence length, while that of our model rises rather slowly. We contribute this great decoding advantage of our model over the Transformer to the average attention architecture which enables

our model to perform next-word prediction by calculating information just from the previous hidden state, rather than considering all previous inputs like the self-attention in the Transformer's decoder.

5.2 WMT17 Translation Tasks

We further demonstrate the effectiveness of our model on six WMT17 translation tasks in both directions (12 translation directions in total). These tasks contain the following language pairs:

- **En-De**: The English-German language pair. This training corpus consists of 5.85M sentence pairs, with 141M English words and 135M German words. We used the concatenation of newstest2014, newstest2015 and newstest2016 as the development set, and the newstest2017 as the test set.

- **En-Fi**: The English-Finnish language pair. This training corpus consists of 2.63M sentence pairs, with 63M English words and 45M Finnish words. We used the concatenation of newstest2015, newsdev2015, newstest2016 and newstestB2016 as the development set, and the newstest2017 as the test set.

- **En-Lv**: The English-Latvian language pair. This training corpus consists of 4.46M sentence pairs, with 63M English words and 52M Latvian words. We used the newsdev2017 as the development set, and the newstest2017 as the test set.

- **En-Ru**: The English-Russian language pair. This training corpus consists of 25M sentence pairs, with 601M English words and 567M Russian words. We used the concatenation of newstest2014, newstest2015 and newstest2016 as the development set, and the newstest2017 as the test set.

- **En-Tr**: The English-Turkish language pair. This training corpus consists of 0.21M sentence pairs, with 5.2M English words and 4.6M Turkish words. We used the concatenation of newsdev2016 and newstest2016 as the development set, and newstest2017 as the test set.

- **En-Cs**: The English-Czech language pair. This training corpus consists of 52M sentence pairs, with 674M English words and 571M Czech words. We used the concatenation of newstest2014, newstest2015 and newstest2016 as the development set, and the newstest2017 as the test set.

Interestingly, these translation tasks involves training corpora with different scales (ranging from 0.21M to 52M sentence pairs). This help us thoroughly examine the ability of our model on different sizes of training data. All these preprocessed datasets are publicly available, and can be downloaded from WMT17 official website.[3]

We used the same modeling settings as in the WMT14 English-German translation task except for the number of training steps for En-Fi and En-Tr, which we set to 60K and 10K respectively. In addition, to compare with official results, we reported both case-sensitive and case-insensitive detokenized BLEU scores.

Table 5: Average seconds required for decoding one source sentence on WMT17 translation tasks.

5.2.1 Translation Results

Table 4 shows the overall results on 12 translation directions. We also provide the results from WMT17 winning systems[4]. Notice that unlike the Transformer and our model, these winner systems typically use model ensemble, system combination and large-scale monolingual corpus.

Although different languages have different linguistic and syntactic structures, our model consistently yields rather competitive results against the Transformer on all language pairs in both directions. Particularly, on the De→En translation task, our model achieves a slight improvement of 0.10/0.07 case-sensitive/case-insensitive BLEU points over the Transformer. The largest performance gap between our model and the Transformer occurs on the En→Tr translation task, where our model is lower than the Transformer by 0.52/0.53 case-sensitive/case-insensitive BLEU points. We conjecture that this difference may be due to the small training corpus of the En-Tr task. In all, these results suggest that our AAN is able to perform comparably to Transformer on different language pairs with different scales of training data.

We also show the decoding speed of both the Transformer and our model in Table 5. On all languages in both directions, our model yields significant and consistent improvements over the Transformer in terms of decoding speed. Our model decodes more than 4 times faster than the Transformer. Surprisingly, our model just consumes 0.02968 seconds to translate one source sentence on the En→Tr language pair, only a seventh of the decoding time of the Transformer. These results show that the benefit of decoding acceleration from the proposed average attention structure is language-invariant, and can be easily adapted to other translation tasks.

[4]http://matrix.statmt.org/matrix

6 Conclusion and Future Work

In this paper, we have described the average attention network that considerably alleviates the decoding bottleneck of the neural Transformer. Our model employs a cumulative average operation to capture important contextual clues from previous target words, and a feed forward gating layer to enrich the expressiveness of learned hidden representations. The model is further enhanced with a masking trick and a dynamic programming method to accelerate the Transformer's decoder. Extensive experiments on one WMT14 and six WMT17 language pairs demonstrate that the proposed average attention network is able to speed up the Transformer's decoder by over 4 times.

In the future, we plan to apply our model on other sequence to sequence learning tasks. We will also attempt to improve our model to enhance its modeling ability so as to consistently outperform the original neural Transformer.

Abstract

With recent advances in network architectures for Neural Machine Translation (NMT) recurrent models have effectively been replaced by either convolutional or self-attentional approaches, such as in the Transformer. While the main innovation of the Transformer architecture is its use of self-attentional layers, there are several other aspects, such as attention with multiple heads and the use of many attention layers, that distinguish the model from previous baselines. In this work we take a fine-grained look at the different architectures for NMT. We introduce an Architecture Definition Language (ADL) allowing for a flexible combination of common building blocks. Making use of this language, we show in experiments that one can bring recurrent and convolutional models very close to the Transformer performance by borrowing concepts from the Transformer architecture, but not using self-attention. Additionally, we find that self-attention is much more important for the encoder side than for the decoder side, where it can be replaced by a RNN or CNN without a loss in performance in most settings. Surprisingly, even a model without any target side self-attention performs well.

1 Introduction

Since the introduction of attention mechanisms (Bahdanau et al., 2014; Luong et al., 2015) Neural Machine Translation (NMT) (Sutskever et al., 2014) has shown some impressive results. Initially, approaches to NMT mainly relied on Recurrent Neural Networks (RNNs) (Kalchbrenner and Blunsom, 2013; Bahdanau et al., 2014; Luong et al., 2015; Wu et al., 2016) such as Long Short-Term Memory (LSTM) networks (Hochreiter and Schmidhuber, 1997) or the Gated Rectified Unit (GRU) (Cho et al., 2014).

Recently, other approaches relying on convolutional networks (Kalchbrenner et al., 2016; Gehring et al., 2017) and self-attention (Vaswani et al., 2017) have been introduced. These approaches remove the dependency between source language time steps, leading to considerable speed-ups in training time and improvements in quality. The Transformer, however, contains other differences besides self-attention, including layer normalization across the entire model, multiple source attention mechanisms, a multi-head dot attention mechanism, and the use of residual feed-forward layers. This raises the question of how much each of these components matters.

To answer this question we first introduce a flexible Architecture Definition Language (ADL) (§2). In this language we standardize existing components in a consistent way making it easier to compare structural differences of architectures. Additionally, it allows us to efficiently perform a granular analysis of architectures, where we can evaluate the impact of individual components, rather than comparing entire architectures as a whole. This ability leads us to the following observations:

- Source attention on lower encoder layers brings no additional benefit (§4.2).
- Multiple source attention layers and residual feed-forward layers are key (§4.3).
- Self-attention is more important for the source than for the target side (§4.4).

2 Flexible Neural Machine Translation Architecture Combination

In order to experiment easily with different architecture variations we define a domain specific NMT Architecture Definition Language (ADL), consisting of combinable and nestable building blocks.

2.1 Neural Machine Translation

NMT is formulated as a sequence to sequence prediction task in which a source sentence $X = x_1, ..., x_n$ is translated auto-regressively into a target sentence $Y = y_1, ..., y_m$ one token at a time as

$$p(y_t|Y_{1:t-1}, X; \boldsymbol{\theta}) = \text{softmax}(\mathbf{W}_o \mathbf{z}^L + \mathbf{b}_o), \tag{1}$$

where $\mathbf{b}_o$ is a bias vector, $\mathbf{W}_o$ projects a model dependent hidden vector $\mathbf{z}^L$ of the Lth decoder layer to the dimension of the target vocabulary $\mathbf{V}_{trg}$ and $\boldsymbol{\theta}$ denotes the model parameters. Typically, during training $Y_{1:t-1}$ consists of the reference sequence tokens, rather then the predictions produced by the model, which is known as teacher-forcing. Training is done by minimizing the cross-entropy loss between the predicted and the reference sequence.

2.2 Architecture Definition Language

In the following we specify the ADL which can be used to define any standard NMT architecture and combinations thereof.

Layers The basic building block of the ADL is a layer l. Layers can be nested, meaning that a layer can consist of several sublayers. Layers optionally take set of named arguments $l(k_1{=}v_1, k_2{=}v_2, ...)$ with names k_1, k_2, ... and values v_1, v_2, ... or positional arguments $l(v_1, v_2, ...)$.

Layer definitions For each layer we have a corresponding layer definition based on the hidden states of the previous layer and any additional arguments. Specifically, each layer takes T hidden states $\mathbf{h}_1^i, ..., \mathbf{h}_T^i$, which in matrix form are $\mathbf{H}^i \in \mathbb{R}^{T \times d_i}$, and produces a new set of hidden states $\mathbf{h}_1^{i+1}, ..., \mathbf{h}_T^{i+1}$ or $\mathbf{H}^{i+1}$. While each layer can have a different number of hidden units d_i, in the following we assume them to stay constant across layers and refer to the model dimensionality as d_{model}. We distinguish the hidden states on the source side $\mathbf{U}^0, ..., \mathbf{U}^{L_s}$ from the hidden states of the target side $\mathbf{Z}^0, ..., \mathbf{Z}^L$. These are produced by the source and target embeddings and L_s source layers and L target layers.

Source attention layers play a special role in that their definition additionally makes use of any of the source hidden states $\mathbf{U}^0, ..., \mathbf{U}^{L_s}$.

Layer chaining Layers can be chained, feeding the output of one layer as the input to the next. We denote this as $l_1 \rightarrow l_2 \rightarrow ... \rightarrow l_L$. This is equivalent to writing $l_L(...\ l_2(l_1(\mathbf{H}^0)))$ if none of the layers is a source attention layer.

In layer chains layers may also contain layers that themselves take arguments. As an example $l_1(k{=}v) \rightarrow l_2 \rightarrow ... \rightarrow l_L$ is equivalent to $l_L(...\ l_2(l_1(\mathbf{H}^0, k{=}v)))$. Note that unlike in the layer definition hidden states are not explicitly stated in the layer chain, but rather implicitly defined through the preceding layers.

Encoder/Decoder structure A NMT model is fully defined through two layer chains, namely one describing the encoder and another describing the decoder. The first layer hidden states on the source $\mathbf{U}^0$ are defined through the source embedding as

$$\mathbf{u}_t^0 = \mathbf{E}_{src} \mathbf{x}_t \tag{2}$$

where $\mathbf{x}_t \in \{0, 1\}^{|\mathbf{V}_{src}|}$ is the one-hot representation of x_t and $\mathbf{E}_S \mathbf{x}_t \in \mathbb{R}^{e \times |\mathbf{V}_{src}|}$ an embedding matrix with embedding dimensionality e. Similarly, $\mathbf{Z}^0$ is defined through the target embedding matrix $\mathbf{E}_{tgt}$.

Given the final decoder hidden state $\mathbf{Z}^L$ the next word predictions are done according to Equation 1.

Layer repetition Networks often consist of substructures that are repeated several times. In order to support this we define a repetition layer as

$$\textit{repeat}(n, l) = l_1 \rightarrow l_2 \rightarrow ... \rightarrow l_n,$$

where l represents a layer chain and each one of $l_1, ..., l_n$ an instantiation of that layer chain with a separate set of weights.

2.3 Layer Definitions

In this section we will introduce the concrete layers and their definitions, which are available for composing NMT architectures. They are based on building blocks common to many current NMT models.

Dropout A dropout (Srivastava et al., 2014) layer, denoted as $\textit{dropout}(\mathbf{h}_t)$, can be applied to hidden states as a form of regularization.

Fixed positional embeddings Fixed positional embeddings (Vaswani et al., 2017) add information about the position in the sequence to the hidden states. With $\mathbf{h}_t \in \mathbb{R}^d$ the positional embedding layer is defined as

$$\begin{aligned} \textit{pos}(\mathbf{h}_t) &= \textit{dropout}(\sqrt{d} \cdot \mathbf{h}_t + \mathbf{p}_t) \\ p_{t,j} &= \sin(t/10000^{2j/d}) \\ p_{t,2j+1} &= \cos(t/10000^{2j/d}). \end{aligned}$$

Linear We define a linear projection layer as

$$\textit{linear}(\mathbf{h}_t, d_o) = \mathbf{W}\mathbf{h}_t + \mathbf{b},$$

where $\mathbf{W} \in \mathbb{R}^{d_o \times d_{in}}$.

Feed-forward Making use of the linear projection layer a feed-forward layer with ReLU activation and dropout is defined as

$$\textit{ff}(\mathbf{h}_t, d_o) = \textit{dropout}(\max(0, \textit{linear}(\mathbf{h}_t, d_o)))$$

and a version which temporarily upscales the number of hidden units, as done by Vaswani et al. (2017), can be defined as

$$\textit{ffl}(\mathbf{h}_t) = \textit{ff}(4d_{in}) \rightarrow \textit{linear}(d_{in})$$

where $\mathbf{h}_t \in \mathbb{R}^{d_{in}}$.

Convolution Convolutions run a small feed-forward network on a sliding window over the input. Formally, on the encoder side this is defined as

$$\textit{cnn}(\mathbf{H}, v, k) = v(\mathbf{W}[\mathbf{h}_{i-\lfloor k/2 \rfloor}; ...; \mathbf{h}_{i+\lfloor k/2 \rfloor}] + \mathbf{b})$$

where k is the kernel size, and v is a non-linearity. The input is padded so that the number of hidden states does not change.

To preserve the auto-regressive property of the decoder we need to make sure to never take future decoder time steps into account, which can be achieved by adding $k-1$ padding vectors $\mathbf{h}_{-k+1} = \mathbf{0}, \ldots, \mathbf{h}_{-1} = \mathbf{0}$ such that the decoder convolution is given as

$$\textit{cnn}(\mathbf{H}, v, k) = v(\mathbf{W}[\mathbf{h}_{t-k+1}; ...; \mathbf{h}_t] + \mathbf{b}).$$

The non-linearity v can either be a ReLU or a Gated Linear Unit (GLU) (Dauphin et al., 2016). With the GLU we set $d_i = 2d$ such that we can split $\mathbf{h} = [\mathbf{h}_A; \mathbf{h}_B] \in \mathbb{R}^{2d}$ and compute the non-linearity as

$$\textit{glu}([\mathbf{h}_A; \mathbf{h}_B]) = \mathbf{h}_A \otimes \sigma(\mathbf{h}_B).$$

Identity We define an identity layer as

$$\textit{id}(\mathbf{h}_t) = \mathbf{h}_t.$$

Concatenation To concatenate the output of p layer chains we define

$$\textit{concat}(\mathbf{h}_t, l_1, ..., l_p) = [l_1(\mathbf{h}_t); ...; l_p(\mathbf{h_t})].$$

Recurrent Neural Network An RNN layer is defined as

$$\begin{aligned} \textit{rnn}(\mathbf{h}_t) &= f_{\textit{rnn\_o}}(\mathbf{h}_t, \mathbf{s}_{t-1}) \\ \mathbf{s}_t &= f_{\textit{rnn\_h}}(\mathbf{h}_t, \mathbf{s}_{t-1}) \end{aligned}$$

where $f_{\textit{rnn\_o}}$ and $f_{\textit{rnn\_h}}$ could be defined through either a GRU (Cho et al., 2014) or a LSTM (Hochreiter and Schmidhuber, 1997) cell. In addition, a bidirectional RNN layer *birnn* is available, which runs one *rnn* in forward and another in reverse direction and concatenates both results.

Attention All attention mechanisms take a set of query vectors $\mathbf{q}_0, ..., \mathbf{q}_M$, key vectors $\mathbf{k}_0, ..., \mathbf{k}_N$ and value vectors $\mathbf{v}_0, ..., \mathbf{v}_N$ in order to produce one context vector per query, which is a linear combination of the value vectors. We define $\mathbf{Q} \in \mathbb{R}^{M \times d}$, $\mathbf{V} \in \mathbb{R}^{N \times d}$ and $\mathbf{K} \in \mathbb{R}^{N \times d}$ as the concatenation of these vectors. What is used as the query, key and value vectors depends on attention type and is defined below.

Dot product attention The scaled dot product attention (Vaswani et al., 2017) is defined as

$$\textit{dot\_att}(\mathbf{Q}, \mathbf{K}, \mathbf{V}, s) = \operatorname{softmax}\left(\frac{\mathbf{Q}\mathbf{K}^\top}{\sqrt{s}}\right)\mathbf{V},$$

where the scaling factor s is implicitly set to d unless noted otherwise. Adding a projection to the queries, keys and values we get the projected dot attention as

$$\begin{gathered} \textit{proj\_dot\_att}(\mathbf{Q}, \mathbf{K}, \mathbf{V}, d_p, s) = \\ \textit{dot\_att}(\mathbf{Q}\mathbf{W}^Q, \mathbf{K}\mathbf{W}^K, \mathbf{V}\mathbf{W}^V, s) \end{gathered}$$

where d_p is dimensionality of the projected vectors such that $\mathbf{W}^Q \in \mathbb{R}^{d_q \times d_p}$, $\mathbf{W}^K \in \mathbb{R}^{d_k \times d_p}$ and $\mathbf{W}^V \in \mathbb{R}^{d_v \times d_p}$.

Vaswani et al. (2017) further introduces a multi-head attention, which applies multiple attentions at a reduced dimensionality. With h heads multi-head attention is computed as

$$\textit{mh\_dot\_att}(\mathbf{Q}, \mathbf{K}, \mathbf{V}, h, s) = [\mathbf{C}_0; ...; \mathbf{C}_h],$$

$$\mathbf{C}_i = \textit{proj\_dot\_att}(\mathbf{Q}, \mathbf{K}, \mathbf{V}, d/h, s).$$

Note that with $h = 1$ we recover the projected dot attention.

MLP attention The MLP attention (Bahdanau et al., 2014) computes the scores with a one-layer neural network as

$$\textit{mlp\_att}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = \text{softmax}(\mathbf{S})\,\mathbf{V},$$
$$S_{ij} = \mathbf{w}_o^T \tanh(\mathbf{W}_q\mathbf{q}_i + \mathbf{W}_k\mathbf{k}_j).$$

Source attention Using the source hidden vectors $\mathbf{U}$, the source attentions are computed as

$$\textit{mh\_dot\_src\_att}(\mathbf{H}, \mathbf{U}, h, s) =$$
$$\textit{mh\_dot\_att}(\mathbf{H}, \mathbf{U}, \mathbf{U}, h, s),$$
$$\textit{mlp\_src\_att}(\mathbf{H}, \mathbf{U}) = \textit{mlp\_att}(\mathbf{H}, \mathbf{U}, \mathbf{U}),$$
$$\textit{dot\_src\_att}(\mathbf{H}, \mathbf{U}, s) = \textit{mh\_dot\_att}(\mathbf{H}, \mathbf{U}, \mathbf{U}, 1, s).$$

Self-attention Self-attention (Vaswani et al., 2017) uses the hidden states as queries, keys and values such that

$$\textit{mh\_dot\_self\_att}(\mathbf{H}, s) = \textit{mh\_dot\_att}(\mathbf{H}, \mathbf{H}, \mathbf{H}, s).$$

Please note that on the target side one needs to make sure to preserve the auto-regressive property by only attending to hidden states at the current or past steps $\mathbf{h} < t$, which is achieved by masking the attention mechanism.

Layer normalization Layer normalization (Ba et al., 2016) uses the mean and standard deviation for normalization. It is computed as

$$\textit{norm}(\mathbf{h}_t) = \frac{\mathbf{g}}{\sigma_t} \otimes (\mathbf{h}_t - \mu_t) + \mathbf{b}$$
$$\mu_t = \frac{1}{d}\sum_{i=1}^{d} \mathbf{h}_{t,j} \quad \sigma_t = \sqrt{\frac{1}{d}\sum_{i=1}^{d}(\mathbf{h}_{t,j} - \mu_j)^2}$$

where $\mathbf{g}$ and $\mathbf{b}$ are learned scale and shift parameters with the same dimensionality as $\mathbf{h}$.

Residual layer A residual layer adds the output of an arbitrary layer chain l to the current hidden states. We define this as

$$\textit{res}(\mathbf{h_t}, l) = \mathbf{h_t} + l(\mathbf{h_t}).$$

For convenience we also define

$$\textit{res\_d}(\mathbf{h}_t, l) = \textit{res}(l(\mathbf{h}_t) \rightarrow \textit{dropout}) \quad \text{and}$$
$$\textit{res\_nd}(\mathbf{h}_t, l) = \textit{res}(\text{norm} \rightarrow l(\mathbf{h}_t) \rightarrow \textit{dropout}).$$

2.4 Standard Architectures

Having defined the common building blocks we now show how standard NMT architectures can be constructed.

RNMT As RNNs have been around the longest in NMT, several smaller architecture variations exist. Similar to Wu et al. (2016) in the following we use a bi-directional RNN followed by a stack of uni-directional RNNs with residual connections on the encoder side. Using the ADL an n layer encoder can be expressed as

$$\mathbf{U}^{L_s} = \textit{dropout} \rightarrow \textit{birnn} \rightarrow \textit{repeat}(n-1, \textit{res\_d}(\textit{rnn})).$$

For the decoder we use the architecture by Luong et al. (2015), which first runs a stacked RNN and then combines the context provided by a single attention mechanism with the hidden state provided by the RNN. This can be expressed by

$$\mathbf{Z}^L = \textit{dropout} \rightarrow \textit{repeat}(n, \textit{res\_d}(\textit{rnn})) \rightarrow$$
$$\textit{concat}(\textit{id}, \textit{mlp\_att}) \rightarrow \textit{ff}.$$

If input feeding (Luong et al., 2015) is used the first layer hidden states are redefined as

$$\mathbf{z}_t^0 = [\mathbf{z}_{t-1}^L; \mathbf{E}_{tgt}\mathbf{y}_t].$$

Note that this inhibits any parallelism across decoder time steps. This is only an issue when using models other than RNNs, as RNNs already do not allow for parallelizing over decoder time steps.

ConvS2S Gehring et al. (2017) introduced a NMT model that fully relies on convolutions, both on the encoder and on the decoder side. The encoder is defined as

$$\mathbf{U}^{L_s} = \textit{pos} \rightarrow \textit{repeat}(n, \textit{res}(\textit{cnn}(\textit{glu}) \rightarrow \textit{dropout}))$$

and the decoder, which uses an unscaled single head dot attention is defined as

$$\mathbf{Z}^L = \textit{pos} \rightarrow \textit{res}(\textit{dropout} \rightarrow \textit{cnn}(\textit{glu}) \rightarrow \textit{dropout}$$
$$\rightarrow \textit{res}(\textit{dot\_src\_att}(s{=}1))).$$

Note that unlike (Gehring et al., 2017) we do not project the query vectors before the attention and do not add the embeddings to the attention values.

Transformer The Transformer (Vaswani et al., 2017) makes use of self-attention, instead of RNNs or Convolutional Neural Networks (CNNs), as the basic computational block. Note that we use a slightly updated residual structure as implemented by *tensor2tensor*[1] than proposed originally. Specifically, layer normalization is applied to the input of the residual block instead of applying it between blocks. The Transformer uses a combination of self-attention and feed-forward layers on the encoder and additionally source attention layers on the decoder side. When defining the Transformer encoder block as

$$t_{\text{enc}} = \mathit{res\_nd}(\mathit{mh\_dot\_self\_att}) \rightarrow \mathit{res\_nd}(\mathit{ffl}),$$

and the decoder block as

$$t_{\text{dec}} = \mathit{res\_nd}(\mathit{mh\_dot\_self\_att}) \rightarrow \mathit{res\_nd}(\mathit{mh\_dot\_src\_att}) \rightarrow \mathit{res\_nd}(\mathit{ffl}).$$

the Transformer encoder is given as

$$\mathbf{U}^{L_s} = \mathit{pos} \rightarrow \mathit{repeat}(n, t_{\text{enc}}) \rightarrow \mathit{norm}$$

and the decoder as

$$\mathbf{Z}^{L} = \mathit{pos} \rightarrow \mathit{repeat}(n, t_{\text{dec}}) \rightarrow \mathit{norm}.$$

3 Related Work

The dot attention mechanism, now heavily used in the Transformer models, was introduced by (Luong et al., 2015) as part of an exploration of different attention mechanisms for RNN based NMT models.

Britz et al. (2017) performed an extensive exploration of hyperparameters of RNN based NMT models. The variations explored include different attention mechanisms, RNN cells types and model depth.

Similar to our work, Schrimpf et al. (2017) define a language for exploring architectures. In this case the architectures are defined for RNN cells and not for the higher level model architecture. Using the language they perform an automatic search of RNN cell architectures.

For the application of image classification there have been several recent successful efforts of automatically searching for successful architectures (Zoph and Le, 2016; Negrinho and Gordon, 2017; Liu et al., 2017).

4 Experiments

What follows is an extensive empirical analysis of current NMT architectures and how certain sublayers as defined through our ADL affect performance.

4.1 Setup

All experiments were run with an adapted version of SOCKEYE (Hieber et al., 2017), which can parse arbitrary model definitions that are expressed in the language described in Section 2.3. The code and configuration are available at https://github.com/awslabs/sockeye/tree/acl18 allowing researchers to easily replicate the experiments and to quickly try new NMT architectures by either making use of existing building blocks in novel ways or adding new ones.

In order to get data points on corpora of different sizes we ran experiments on both WMT and IWSLT data sets. For WMT we ran the majority of our experiments on the most recent WMT'17 data consisting of roughly 5.9 million training sentences for English-German (EN→DE) and 4.5 million sentences for Latvian-English (LV→EN). We used newstest2016 as validation data and report metrics calculated on newstest2017. For the smaller IWSLT'16 English-German corpus, which consists of roughly 200 thousand training sentences, we used TED.tst2013 as validation data and report numbers for TED.tst2014.

For both WMT'17 and IWSLT'16 we preprocessed all data using the Moses[2] tokenizer and apply Byte Pair Encoding (BPE) (Sennrich et al., 2015) with 32,000 merge operations. Unless noted otherwise we run each experiment three times with different random seeds and report the mean and standard deviation of the BLEU and METEOR (Lavie and Denkowski, 2009) scores across runs. Evaluation scores are based on tokenized sequences and calculated with MultEval (Clark et al., 2011).

Model	WMT'14
Vaswani et al. (2017)	27.3
Our Transformer$_{\text{base}}$ impl.	27.5

Table 1: BLEU scores on WMT'14 EN→DE.

In order to compare to previous work, we also ran an additional experiment on WMT'14 using the same data as Vaswani et al. (2017)

[2]https://github.com/moses-smt/mosesdecoder/

as provided in preprocessed form through *tensor2tensor*.[3] This data set consists of WMT'16 training data, which has been tokenized and byte pair encoded with 32,000 merge operations. Evaluation is done on tokenized and compound split newstest2014 data using multi-bleu.perl in order to get scores comparable to Vaswani et al. (2017). As seen in Table 1, our Transformer implementation achieves a score equivalent to the originally reported numbers.

On the smaller IWSLT data we use $d_{model} = 512$ and on WMT $d_{model} = 256$ for all models. Models are trained with 6 encoder and 6 decoder blocks, where in the Transformer model a layer refers to a full encoder or decoder block. All convolutional layers use a kernel of size 3 and a ReLU activation, unless noted otherwise. RNNs use LSTM cells. For training we use the Adam optimizer (Kingma and Ba, 2014) with a learning rate of 0.0002. The learning rate is decayed by a factor of 0.7, whenever the validation perplexity does not improve for 8 consecutive checkpoints, where a checkpoint is created every 4,000 updates on WMT and 1,000 updates on IWSLT. All models use label smoothing (Szegedy et al., 2016) with $\epsilon_{ls} = 0.1$.

4.2 What to attend to?

Source attention is typically based on the top encoder block. With multiple source attention layers one could hypothesize that it could be beneficial to allow attention encoder blocks other than the top encoder block. It might for example be beneficial for lower decoder blocks to use encoder blocks from the same level as they represent the same level of abstraction. Inversely, assuming that the translation is done in a coarse to fine manner it might help to first use the uppermost encoder block and use gradually lower level representations.

Encoder block	IWSLT	WMT'17
upper	25.4 ± 0.2	27.6 ± 0.0
increasing	25.4 ± 0.1	27.3 ± 0.1
decreasing	25.3 ± 0.2	27.1 ± 0.1

Table 2: BLEU scores when varying the encoder block used in the source attention mechanism of a Transformer on the EN→DE IWSLT and WMT'17 datasets.

[3] https://github.com/tensorflow/tensor2tensor/blob/765d33bb/tensor2tensor/data_generators/translate_ende.py

The result of modifying the source attention mechanism to use different encoder blocks is shown in Table 2. The variations include using the result of the encoder Transformer block at the same level as the decoder Transformer block (*increasing*) and using the upper encoder Transformer block in the first decoder block and then gradually using the lower blocks (*decreasing*).

We can see that attention on the upper encoder block performs best and no gains can be observed by attention on different encoder layers in the source attention mechanism.

4.3 Network Structure

The Transformer sets itself apart from both standard RNN models and convolutional model by more than just the multi-head self-attention blocks.

RNN to Transformer The differences to the RNN include the multiple source attention layers, multi-head attention, layer normalization and the residual upscaling feed-forward layers. Additionally, RNN models typically use single head MLP attention instead of the dot attention. This raises the question of what aspect contributes most to the performance of the Transformer.

Table 3 shows the result of taking an RNN and step by step changing the architecture to be similar to the Transformer architecture. We start with a standard RNN architecture with MLP attention similar to Luong et al. (2015) as described in Section 2.4 with and without input feeding denoted as RNMT.

Next, we take a model with a residual connection around the encoder bi-RNN such that the encoder is defined as

$$\mathit{dropout} \rightarrow \mathit{res\_d}(\mathit{birnn}) \rightarrow \mathit{repeat}(5, \mathit{res\_d}(\mathit{rnn})).$$

The decoder uses a residual single head dot attention and no input feeding and is defined as

$$\mathit{dropout} \rightarrow \mathit{repeat}(6, \mathit{res\_d}(\mathit{rnn})) \rightarrow \\ \mathit{res\_d}(\mathit{dot\_src\_att}) \rightarrow \mathit{res\_d}(\mathit{ffl}).$$

We denote this model as RNN in Table 3. This model is then changed to use multi-head attention (mh), positional embeddings (pos), layer normalization on the inputs of the residual blocks (norm), an attention mechanism in a residual block after every RNN layer with multiple (multi-att) and a single head (multi-add-1h), and finally a residual

+ ff	25.1 ± 0.1	26.7 ± 0.1	46.4 ± 0.2	17.8 ± 0.1	50.5 ± 0.1

Table 3: Transforming an RNN into a Transformer style architecture. + shows the incrementally added variation. / denotes an alternative variation to which the subsequent + is relative to.

upscaling feed-forward layer is added after each attention block (ff). The final architecture of the encoder after applying these variations is

$$pos \rightarrow res\_nd(birnn) \rightarrow res\_nd(ffl) \rightarrow \\ repeat(5, res\_nd(rnn) \rightarrow res\_nd(ffl) \rightarrow norm$$

and of the decoder

$$pos \rightarrow repeat(6, res\_nd(rnn) \rightarrow \\ res\_nd(mh\_dot\_src\_att) \rightarrow res\_nd(ffl)) \rightarrow norm.$$

Comparing this to the Transformer as defined in Section 2.4 we note that the model is identical to the Transformer, except that each self-attention has been replaced by an RNN or bi-RNN.

Table 3 shows that not using input feeding has a negative effect on the result, which however can be compensated by the explored model variations. With just a single attention mechanism the model benefits from multiple attention heads. The gains are even larger when an attention mechanism is added to every layer. With multiple source attention mechanisms the benefit of multiple heads decreases. Layer normalization on the inputs of the residual blocks has a small negative effect in all settings and metrics. As RNNs can learn to encode positional information positional embeddings are not strictly necessary. Indeed, we can observe no gains but rather even a small drop in BLEU and METEOR for WMT'17 EN→DE when using them. Adding feed-forward layers leads to large and consistent performance boost. While the final model, which is a Transformer model where each self-attention has been replaced by an RNN, is able to make up for a large amount of the difference between the baseline and the Transformer, it is still outperformed by the Transformer. The largest gains come from multiple attention mechanisms and residual feed-forward layers.

CNN to Transformer While the convolutional models have much more in common with the Transformer than the RNN based models, there are still some notable differences. Like the Transformer, convolutional models have no dependency between decoder time steps during training, use multiple source attention mechanisms and use a slightly different residual structure, as seen in Section 2.4. The Transformer uses a multi-head scaled dot attention while the ConvS2S model uses an unscaled single head dot attention. Other differences include the use of layer normalization as well as residual feed-forward blocks in the Transformer.

The result of making a CNN based architecture more and more similar to the Transformer can be seen in Table 4. As a baseline we use a simple residual CNN structure with a residual single head dot attention. This is denoted as CNN in Table 4. On the encoder side we have

$$pos \rightarrow repeat(6, res\_d(cnn))$$

and for the decoder

$$pos \rightarrow repeat(6, res\_d(cnn) \rightarrow res\_d(dot\_src\_att)).$$

This is similar to, but slightly simpler than, the ConvS2S model described in Section 2.4. In the experiments we explore both the GLU and ReLU as non-linearities for the CNN.

Adding layer normalization (norm), multi-head attention (mh) and upsampling residual feed-forward layers (ff) we arrive at a model that is

Table 4: Transforming a CNN based model into a Transformer style architecture.

identical to a Transformer where the self-attention layers have been replaced by CNNs. This means that we have the following architecture on the encoder

$$pos \rightarrow repeat(6, res\_nd(cnn) \rightarrow res\_nd(ffl)) \rightarrow norm.$$

Whereas for the decoder we have

$$pos \rightarrow repeat(6, res\_nd(cnn) \\ \rightarrow res\_nd(mh\_dot\_src\_att) \rightarrow res\_nd(ffl)) \rightarrow norm.$$

While in the baseline the GLU activation works better than the ReLU activation, when layer normalization, multi-head attention attention and residual feed-forward layers are added, the performance is similar. Except for IWSLT multi-head attention gives consistent gains over single head attention. The largest gains can however be observed by the addition of residual feed-forward layers. The performance of the final model, which is very similar to a Transformer where each self-attention has been replaced by a CNN, matches the performance of the Transformer on IWSLT EN→DE but is still 0.7 BLEU points worse on WMT'17 EN→DE and two BLEU points on WMT'17 LV→EN.

4.4 Self-attention variations

At the core of the Transformer are self-attentional layers, which take the role previously occupied by RNNs and CNNs. Self-attention has the advantage that any two positions are directly connected and that, similar to CNNs, there are no dependencies between consecutive time steps so that the computation can be fully parallelized across time. One disadvantage is that relative positional information is not directly represented and one needs to rely on the different heads to make up for this. In a CNN information is constrained to a local window which grows linearly with depth. Relative positions are therefore taken into account. While an RNN keeps an internal state, which can be used in future time steps, it is unclear how well this works for very long range dependencies (Koehn and Knowles, 2017; Bentivogli et al., 2016). Additionally, having a dependency on the previous hidden state inhibits any parallelization across time.

Given the different advantages and disadvantages we selectively replace self-attention on the encoder and decoder side in order to see where the model benefits most from self-attention.

We take the encoder and decoder block defined in Section 2.4 and try out different layers in place of the self-attention. Concretely, we have

$$t_{\text{enc}} = res\_nd(\mathbf{x}_{\text{enc}}) \rightarrow res\_nd(ffl),$$

on the encoder side and

$$t_{\text{dec}} = res\_nd(\mathbf{x}_{\text{dec}}) \rightarrow \\ res\_nd(mh\_dot\_src\_att) \rightarrow res\_nd(ffl).$$

on the decoder side. Table 5 shows the result of replacing $\mathbf{x}_{\text{enc}}$ and $\mathbf{x}_{\text{dec}}$ with either self-attention, a CNN with ReLU activation or an RNN. Notice that with self-attention used in both $\mathbf{x}_{\text{enc}}$ and $\mathbf{x}_{\text{dec}}$ we recover the Transformer model. Additionally, we remove the residual block on the decoder side entirely (*none*). This results in a decoder block which only has information about the previous target word y_t through the word embedding that is fed as the input to the first layer. The decoder block is reduced to

$$t_{\text{dec}} = res\_nd(mh\_dot\_src\_att) \rightarrow res\_nd(ffl).$$

Table 5: Different variations of the encoder and decoder self-attention layer.

In addition to that, we try a combination where the first and fourth block use self-attention, the second and fifth an RNN, the third and sixth a CNN (*combined*).

Replacing the self-attention on both the encoder and the decoder side with an RNN or CNN results in a degradation of performance. In most settings, such as WMT'17 EN→DE for both variations and WMT'17 LV→EN for the RNN, the performance is comparable when replacing the decoder side self-attention. For the encoder however, except for IWSLT, we see a drop in performance of up to 1.5 BLEU points when not using self-attention. Therefore, self-attention seems to be more important on the encoder side than on the decoder side. Despite the disadvantage of having a limited context window, the CNN performs as well as self-attention on the decoder side on IWLT and WMT'17 EN→DE in terms of BLEU and only slightly worse in terms of METEOR. The combination of the three mechanisms (*combined*) on the decoder side performs almost identical to the full Transformer model, except for IWSLT where it is slightly worse.

It is surprising how well the model works without any self-attention as the decoder essentially looses any information about the history of generated words. Translations are entirely based on the previous word, provided through the target side word embedding, and the current position, provided through the positional embedding.

5 Conclusion

We described an ADL for specifying NMT architectures based on composable building blocks. Instead of committing to a single architecture, the language allows for combining architectures on a granular level. Using this language we explored how specific aspects of the Transformer architecture can successfully be applied to RNNs and CNNs. We performed an extensive evaluation on IWSLT EN→DE, WMT'17 EN→DE and LV→EN, reporting both BLEU and METEOR over multiple runs in each setting.

We found that RNN based models benefit from multiple source attention mechanisms and residual feed-forward blocks. CNN based models on the other hand can be improved through layer normalization and also feed-forward blocks. These variations bring the RNN and CNN based models close to the Transformer. Furthermore, we showed that one can successfully combine architectures. We found that self-attention is much more important on the encoder side than it is on the decoder side, where even a model without self-attention performed surprisingly well. For the data sets we evaluated on, models with self-attention on the encoder side and either an RNN or CNN on the decoder side performed competitively to the Transformer model in most cases.

We make our implementation available so that it can be used for exploring novel architecture variations.

Weakly Supervised Semantic Parsing with Abstract Examples

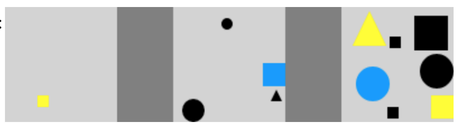
Abstract

Training semantic parsers from weak supervision (denotations) rather than strong supervision (programs) complicates training in two ways. First, a large *search* space of potential programs needs to be explored at training time to find a correct program. Second, *spurious* programs that accidentally lead to a correct denotation add noise to training. In this work we propose that in closed worlds with clear semantic types, one can substantially alleviate these problems by utilizing an abstract representation, where tokens in both the language utterance and program are lifted to an abstract form. We show that these abstractions can be defined with a handful of lexical rules and that they result in sharing between different examples that alleviates the difficulties in training. To test our approach, we develop the first semantic parser for CNLVR, a challenging visual reasoning dataset, where the search space is large and overcoming spuriousness is critical, because denotations are either TRUE or FALSE, and thus random programs are likely to lead to a correct denotation. Our method substantially improves performance, and reaches 82.5% accuracy, a 14.7% absolute accuracy improvement compared to the best reported accuracy so far.

1 Introduction

The goal of semantic parsing is to map language utterances to executable programs. Early work on statistical learning of semantic parsers utilized supervised learning, where training examples included pairs of language utterances and programs (Zelle and Mooney, 1996; Kate et al., 2005; Zettlemoyer and Collins, 2005, 2007). However, collecting such training examples at scale has quickly turned out to be difficult, because expert annotators who are familiar with formal languages are required. This has led to a body of work on weakly-supervised semantic parsing (Clarke et al., 2010; Liang et al., 2011; Krishnamurthy and Mitchell, 2012; Kwiatkowski et al., 2013; Berant et al., 2013; Cai and Yates, 2013; Artzi and Zettlemoyer, 2013). In this setup, training examples correspond to utterance-denotation pairs, where a *denotation* is the result of executing a program against the environment (see Fig. 1). Naturally, collecting denotations is much easier, because it can be performed by non-experts.

I :



k :[[{y_loc: ..., color: 'Black', type: 'square', x_loc: ... size: 20}, ...}]]
x :*There is a small yellow item not touching any wall*
y :`True`
z :`Exist(Filter(ALL_ITEMS,` λx`.And(And(IsYellow(`x`), IsSmall(`x`)), Not(IsTouchingWall(`x`, Side.Any)))))`

Figure 1: Overview of our visual reasoning setup for the CNLVR dataset. Given an image rendered from a KB k and an utterance x, our goal is to parse x to a program z that results in the correct denotation y. Our training data includes (x, k, y) triplets.

Training semantic parsers from denotations rather than programs complicates training in two ways: (a) *Search*: The algorithm must learn to search through the huge space of programs at training time, in order to find the correct program. This is a difficult search problem due to the combinatorial nature of the search space. (b) *Spurious-*

[*] Authors equally contributed to this work.

ness: Incorrect programs can lead to correct denotations, and thus the learner can go astray based on these programs. Of the two mentioned problems, spuriousness has attracted relatively less attention (Pasupat and Liang, 2016; Guu et al., 2017).

Recently, the Cornell Natural Language for Visual Reasoning corpus (CNLVR) was released (Suhr et al., 2017), and has presented an opportunity to better investigate the problem of spuriousness. In this task, an image with boxes that contains objects of various shapes, colors and sizes is shown. Each image is paired with a complex natural language statement, and the goal is to determine whether the statement is true or false (Fig. 1). The task comes in two flavors, where in one the input is the image (pixels), and in the other it is the knowledge-base (KB) from which the image was synthesized. Given the KB, it is easy to view CNLVR as a semantic parsing problem: our goal is to translate language utterances into programs that will be executed against the KB to determine their correctness (Johnson et al., 2017b; Hu et al., 2017). Because there are only two return values, it is easy to generate programs that execute to the right denotation, and thus spuriousness is a major problem compared to previous datasets.

In this paper, we present the first semantic parser for CNLVR. Semantic parsing can be coarsely divided into a *lexical* task (i.e., mapping words and phrases to program constants), and a *structural* task (i.e., mapping language composition to program composition operators). Our core insight is that in closed worlds with clear semantic types, like spatial and visual reasoning, we can manually construct a small lexicon that clusters language tokens and program constants, and create a partially abstract representation for utterances and programs (Table 1) in which the lexical problem is substantially reduced. This scenario is ubiquitous in many semantic parsing applications such as calendar, restaurant reservation systems, housing applications, etc: the formal language has a compact semantic schema and a well-defined typing system, and there are canonical ways to express many program constants.

We show that with abstract representations we can share information across examples and better tackle the search and spuriousness challenges. By pulling together different examples that share the same abstract representation, we can identify programs that obtain high reward across multiple examples, thus reducing the problem of spuriousness. This can also be done at search time, by augmenting the search state with partial programs that have been shown to be useful in earlier iterations. Moreover, we can annotate a small number of abstract utterance-program pairs, and automatically generate training examples, that will be used to warm-start our model to an initialization point in which search is able to find correct programs.

We develop a formal language for visual reasoning, inspired by Johnson et al. (2017b), and train a semantic parser over that language from weak supervision, showing that abstract examples substantially improve parser accuracy. Our parser obtains an accuracy of 82.5%, a 14.7% absolute accuracy improvement compared to state-of-the-art. All our code is publicly available at `https://github.com/udiNaveh/nlvr_tau_nlp_final_proj`.

2 Setup

Problem Statement Given a training set of N examples $\{(x_i, k_i, y_i)\}_{i=1}^N$, where x_i is an utterance, k_i is a KB describing objects in an image and $y_i \in \{\text{TRUE}, \text{FALSE}\}$ denotes whether the utterance is true or false in the KB, our goal is to learn a semantic parser that maps a new utterance x to a program z such that when z is executed against the corresponding KB k, it yields the correct denotation y (see Fig. 1).

Programming language The original KBs in CNLVR describe an image as a set of objects, where each object has a color, shape, size and location in absolute coordinates. We define a programming language over the KB that is more amenable to spatial reasoning, inspired by work on the CLEVR dataset (Johnson et al., 2017b). This programming language provides access to functions that allow us to check the size, shape, and color of an object, to check whether it is touching a wall, to obtain sets of items that are above and below a certain set of items, etc.[1] More formally, a program is a sequence of tokens describing a possibly recursive sequence of function applications in prefix notation. Each token is either a function with fixed arity (all functions have either one or two arguments), a constant, a variable or a λ term used to define Boolean functions. Functions, constants and variables have one of the following

[1]We leave the problem of learning the programming language functions from the original KB for future work.

x:	*"There are exactly 3 yellow squares touching the wall."*

atomic types: `Int`, `Bool`, `Item`, `Size`, `Shape`, `Color`, `Side` (sides of a box in the image); or a composite type `Set(?)`, and `Func(?,?)`. Valid programs have a return type `Bool`. Tables 1 and 2 provide examples for utterances and their correct programs. The supplementary material provides a full description of all program tokens, their arguments and return types.

Unlike CLEVR, CNLVR requires substantial set-theoretic reasoning (utterances refer to various aspects of sets of items in one of the three boxes in the image), which required extending the language described by Johnson et al. (2017b) to include set operators and lambda abstraction. We manually sampled 100 training examples from the training data and estimate that roughly 95% of the utterances in the training data can be expressed with this programming language.

3 Model

We base our model on the semantic parser of Guu et al. (2017). In their work, they used an encoder-decoder architecture (Sutskever et al., 2014) to define a distribution $p_\theta(z \mid x)$. The utterance x is encoded using a bi-directional LSTM (Hochreiter and Schmidhuber, 1997) that creates a contextualized representation h_i for every utterance token x_i, and the decoder is a feed-forward network combined with an attention mechanism over the encoder outputs (Bahdanau et al., 2015). The feed-forward decoder takes as input the last K tokens that were decoded.

More formally the probability of a program is the product of the probability of its tokens given the history: $p_\theta(z \mid x) = \prod_t p_\theta(z_t \mid x, z_{1:t-1})$, and the probability of a decoded token is computed as follows. First, a Bi-LSTM encoder converts the input sequence of utterance embeddings into a sequence of forward and backward states $h_1^{\{F,B\}}, \ldots, h_{|x|}^{\{F,B\}}$. The utterance representation $\hat{x}$ is $\hat{x} = [h_{|x|}^F; h_1^B]$. Then decoding produces the program token-by-token:

$$q_t = \text{ReLU}(W_q[\hat{x}; \hat{v}; z_{t-K-1:t-1}]),$$

$$\alpha_{t,i} \propto \exp(q_t^\top W_\alpha h_i)\ ,\ c_t = \sum_i \alpha_{t,i} h_i,$$

$$p_\theta(z_t \mid x, z_{1:t-1}) \propto \exp(\phi_{z_t}^\top W_s[q_t; c_t]),$$

where ϕ_z is an embedding for program token z, $\hat{v}$ is a bag-of-words vector for the tokens in x, $z_{i:j} = (z_i, \ldots, z_j)$ is a history vector of size K, the matrices W_q, W_α, W_s are learned parameters (along with the LSTM parameters and embedding matrices), and ';' denotes concatenation.

Search: Searching through the large space of programs is a fundamental challenge in semantic parsing. To combat this challenge we apply several techniques. First, we use beam search at decoding time and when training from weak supervision (see Sec. 4), similar to prior work (Liang et al., 2017; Guu et al., 2017). At each decoding step we maintain a beam B of program prefixes of length n, expand them exhaustively to programs of length $n+1$ and keep the top-$|B|$ program prefixes with highest model probability.

Second, we utilize the semantic typing system to only construct programs that are syntactically valid, and substantially prune the program search space (similar to type constraints in Krishnamurthy et al. (2017); Xiao et al. (2016); Liang et al. (2017)). We maintain a stack that keeps track of the expected semantic type at each decoding step. The stack is initialized with the type `Bool`. Then, at each decoding step, only tokens that return the semantic type at the top of the stack are allowed, the stack is popped, and if the decoded token is a function, the semantic types of its arguments are pushed to the stack. This dramatically reduces the search space and guarantees that only syntactically valid programs will be produced. Fig. 2 illustrates the state of the stack when decoding a program for an input utterance.

x : *One tower has a yellow base.*

z :		`EqualInt`	`1`	`Count`	`Filter`	`ALL_ITEMS`	λx	`And`	`IsYellow`	x	`IsBottom`	x
s :		`Int`			`Set`			`Bool`	`Item`			
	`Bool`	`Int`	`Int`	`Set`	`BoolFunc`	`BoolFunc`	`Bool`	`Bool`	`Bool`	`Bool`	`Item`	

Figure 2: An example for the state of the type stack s while decoding a program z for an utterance x.

Given the constrains on valid programs, our model $p'_\theta(z \mid x)$ is defined as:

$$\prod_t \frac{p_\theta(z_t \mid x, z_{1:t-1}) \cdot \mathbb{1}(z_t \mid z_{1:t-1})}{\sum_{z'} p_\theta(z' \mid x, z_{1:t-1}) \cdot \mathbb{1}(z' \mid z_{1:t-1})},$$

where $\mathbb{1}(z_t \mid z_{1:t-1})$ indicates whether a certain program token is valid given the program prefix.

Discriminative re-ranking: The above model is a locally-normalized model that provides a distribution for every decoded token, and thus might suffer from the label bias problem (Andor et al., 2016; Lafferty et al., 2001). Thus, we add a globally-normalized re-ranker $p_\psi(z \mid x)$ that scores all $|B|$ programs in the final beam produced by $p'_\theta(z \mid x)$. Our globally-normalized model is:

$$p^g_\psi(z \mid x) \propto \exp(s_\psi(x, z)),$$

and is normalized over all programs in the beam. The scoring function $s_\psi(x, z)$ is a neural network with identical architecture to the locally-normalized model, except that (a) it feeds the decoder with the candidate program z and does not generate it. (b) the last hidden state is inserted to a feed-forward network whose output is $s_\psi(x, z)$. Our final ranking score is $p'_\theta(z|x)p^g_\psi(z \mid x)$.

4 Training

We now describe our basic method for training from weak supervision, which we extend upon in Sec. 5 using abstract examples. To use weak supervision, we treat the program z as a latent variable that is approximately marginalized. To describe the objective, define $R(z, k, y) \in \{0, 1\}$ to be one if executing program z on KB k results in denotation y, and zero otherwise. The objective is then to maximize $p(y \mid x)$ given by:

$$\begin{aligned}\sum_{z \in \mathcal{Z}} p'_\theta(z \mid x) p(y \mid z, k) &= \sum_{z \in \mathcal{Z}} p'_\theta(z \mid x) R(z, k, y) \\ &\approx \sum_{z \in B} p'_\theta(z \mid x) R(z, k, y)\end{aligned}$$

where $\mathcal{Z}$ is the space of all programs and $B \subset \mathcal{Z}$ are the programs found by beam search.

In most semantic parsers there will be relatively few z that generate the correct denotation y. However, in CNLVR, y is binary, and so spuriousness is a central problem. To alleviate it, we utilize a property of CNLVR: the same utterance appears 4 times with 4 different images.[2] If a program is spurious it is likely that it will yield the wrong denotation in one of those 4 images.

Thus, we can re-define each training example to be $(x, \{(k_j, y_j)\}_{j=1}^4)$, where each utterance x is paired with 4 different KBs and the denotations of the utterance with respect to these KBs. Then, we maximize $p(\{y_j\}_{j=1}^4 \mid x,)$ by maximizing the objective above, except that $R(z, \{k_j, y_j\}_{j=1}^4) = 1$ iff the denotation of z is correct for **all** four KBs. This dramatically reduces the problem of spuriousness, as the chance of randomly obtaining a correct denotation goes down from $\frac{1}{2}$ to $\frac{1}{16}$. This is reminiscent of Pasupat and Liang (2016), where random permutations of Wikipedia tables were shown to crowdsourcing workers to eliminate spurious programs.

We train the discriminative ranker analogously by maximizing the probability of programs with correct denotation $\sum_{z \in B} p^g_\psi(z \mid x) R(z, k, y)$.

This basic training method fails for CNLVR (see Sec. 6), due to the difficulties of search and spuriousness. Thus, we turn to learning from abstract examples, which substantially reduce these problems.

5 Learning from Abstract Examples

The main premise of this work is that in closed, well-typed domains such as visual reasoning, the main challenge is handling language compositionality, since questions may have a complex and nested structure. Conversely, the problem of mapping lexical items to functions and constants in the programming language can be substantially alleviated by taking advantage of the compact KB schema and typing system, and utilizing a

[2] We used the KBs in CNLVR, for which there are 4 KBs per utterance. When working over pixels there are 24 images per utterance, as 6 images were generated from each KB.

Utterance	Program	Cluster	#

"top"	`Side.Top`	`C-Location`	2
"above"	`GetAbove`	`C-SpaceRel`	6
		Total:	**25**

Table 3: Example mappings from utterance tokens to program tokens for the seven clusters used in the abstract representation. The rightmost column counts the number of mapping in each cluster, resulting in a total of 25 mappings.

small lexicon that maps prevalent lexical items into typed program constants. Thus, if we abstract away from the actual utterance into a partially abstract representation, we can combat the search and spuriousness challenges as we can generalize better across examples in small datasets.

Consider the utterances:

1. *"There are exactly 3 yellow squares touching the wall."*
2. *"There are at least 2 blue circles touching the wall."*

While the surface forms of these utterances are different, at an abstract level they are similar and it would be useful to leverage this similarity.

We therefore define an abstract representation for utterances and logical forms that is suitable for spatial reasoning. We define seven abstract clusters (see Table 3) that correspond to the main semantic types in our domain. Then, we associate each cluster with a small lexicon that contains language-program token pairs associated with this cluster. These mappings represent the canonical ways in which program constants are expressed in natural language. Table 3 shows the seven clusters we use, with an example for an utterance-program token pair from the cluster, and the number of mappings in each cluster. In total, 25 mappings are used to define abstract representations.

As we show next, abstract examples can be used to improve the process of training semantic parsers. Specifically, in sections 5.1-5.3, we use abstract examples in several ways, from generating new training data to improving search accuracy. The combined effect of these approaches is quite dramatic, as our evaluation demonstrates.

5.1 High Coverage via Abstract Examples

We begin by demonstrating that abstraction leads to rather effective coverage of the types of questions asked in a dataset. Namely, that many questions in the data correspond to a small set of abstract examples. We created abstract representations for all 3,163 utterances in the training examples by mapping utterance tokens to their cluster label, and then counted how many distinct abstract utterances exist. We found that as few as 200 abstract utterances cover roughly half of the training examples in the original training set.

The above suggests that knowing how to answer a small set of abstract questions may already yield a reasonable baseline. To test this baseline, we constructured a "rule-based" parser as follows. We manually annotated 106 abstract utterances with their corresponding abstract program (including alignment between abstract tokens in the utterance and program). For example, Table 1 shows the abstract utterance and program for the utterance *"There are exactly 3 yellow squares touching the wall"*. Note that the utterance *"There are at least 2 blue circles touching the wall"* will be mapped to the same abstract utterance and program.

Given this set of manual annotations, our rule-based semantic parser operates as follows: Given an utterance x, create its abstract representation $\bar{x}$. If it exactly matches one of the manually annotated utterances, map it to its corresponding abstract program $\bar{z}$. Replace the abstract program tokens with real program tokens based on the alignment with the utterance tokens, and obtain a final program z. If $\bar{x}$ does not match return TRUE, the majority label. The rule-based parser will fail for examples not covered by the manual annotation. However, it already provides a reasonable baseline (see Table 4). As shown next, manual annotations can also be used for generating new training data.

5.2 Data Augmentation

While the rule-based semantic parser has high precision and gauges the amount of structural variance in the data, it cannot generalize beyond observed examples. However, we can automatically generate non-abstract utterance-program pairs from the manually annotated abstract pairs and train a semantic parser with strong supervision that can potentially generalize better. E.g., consider the utterance *"There are exactly 3 yellow squares touching the wall"*, whose abstract representation is given in Table 1. It is clear that we can use this abstract pair to generate a program for a new utterance *"There are exactly 3 blue squares touching the wall"*. This program will be identical

Algorithm 1 Decoding with an Abstract Cache

```

2:      // C is a map where the key is an abstract utterance
        and the value is a pair $(Z, \hat{R})$ of a list of abstract pro-
        grams $Z$ and their average rewards $\hat{R}$. $D$ is an integer.
3:      $\bar{x} \leftarrow$ Abstract utterance of x
4:      $\mathcal{A} \leftarrow D$ programs in $C[\bar{x}]$ with top reward values
5:      $B_1 \leftarrow$ compute beam of programs of length 1
6:      for $t = 2 \dots T$ do // Decode with cache
7:          $B_t \leftarrow$ construct beam from $B_{t-1}$
8:          $\mathcal{A}_t$ = truncate($\mathcal{A}, t$)
9:          $B_t$.add(de-abstract($\mathcal{A}_t$))
10:     for $z \in B_T$ do //Update cache
11:         Update rewards in $C[\bar{x}]$ using $(\bar{z}, R(z, y))$
12:     return $B_T \cup$ de-abstract($\mathcal{A}$).
```

to the program of the first utterance, with `IsBlue` replacing `IsYellow`.

More generally, we can sample any abstract example and instantiate the abstract clusters that appear in it by sampling pairs of utterance-program tokens for each abstract cluster. Formally, this is equivalent to a synchronous context-free grammar (Chiang, 2005) that has a rule for generating each manually-annotated abstract utterance-program pair, and rules for synchronously generating utterance and program tokens from the seven clusters.

We generated 6,158 (x, z) examples using this method and trained a standard sequence to sequence parser by maximizing $\log p'_\theta(z|x)$ in the model above. Although these are generated from a small set of 106 abstract utterances, they can be used to learn a model with higher coverage and accuracy compared to the rule-based parser, as our evaluation demonstrates.[3]

The resulting parser can be used as a standalone semantic parser. However, it can also be used as an initialization point for the weakly-supervised semantic parser. As we observe in Sec. 6, this results in further improvement in accuracy.

5.3 Caching Abstract Examples

We now describe a caching mechanism that uses abstract examples to combat search and spuriousness when training from weak supervision. As shown in Sec. 5.1, many utterances are identical at the abstract level. Thus, a natural idea is to keep track at training time of abstract utterance-program pairs that resulted in a correct denotation, and use this information to direct the search procedure.

[3]Training a parser directly over the 106 abstract examples results in poor performance due to the small number of examples.

Concretely, we construct a cache C that maps abstract utterances to all abstract programs that were decoded by the model, and tracks the average reward obtained for those programs. For every utterance x, after obtaining the final beam of programs, we add to the cache all abstract utterance-program pairs $(\bar{x}, \bar{z})$, and update their average reward (Alg. 1, line 10). To construct an abstract example $(\bar{x}, \bar{z})$ from an utterance-program pair (x, z) in the beam, we perform the following procedure. First, we create $\bar{x}$ by replacing utterance tokens with their cluster label, as in the rule-based semantic parser. Then, we go over every program token in z, and replace it with an abstract cluster if the utterance contains a token that is mapped to this program token according to the mappings from Table 3. This also provides an alignment from abstract program tokens to abstract utterance tokens that is necessary when utilizing the cache.

We propose two variants for taking advantage of the cache C. Both are shown in Algorithm 1.
1. Full program retrieval (Alg. 1, line 12): Given utterance x, construct an abstract utterance $\bar{x}$, retrieve the top D abstract programs $\mathcal{A}$ from the cache, compute the de-abstracted programs Z using alignments from program tokens to utterance tokens, and add the D programs to the *final* beam.
2. Program prefix retrieval (Alg. 1, line 9)**:** Here, we additionally consider prefixes of abstract programs to the beam, to further guide the search process. At each step t, let B_t be the beam of decoded programs at step t. For every abstract program $\bar{z} \in \mathcal{A}$ add the de-abstracted prefix $z_{1:t}$ to B_t and expand B_{t+1} accordingly. This allows the parser to potentially construct new programs that are not in the cache already. This approach combats both spuriousness and the search challenge, because we add promising program prefixes to the beam that might have fallen off of it earlier. Fig. 3 visualizes the caching mechanism.

A high-level overview of our entire approach for utilizing abstract examples at training time for both data augmentation and model training is given in Fig. 4.

last 4 decoded tokens as input as well as encoder states. Token embeddings are of dimension 12, beam size is 40 and $D = 10$ programs are used in Algorithm 1. Word embeddings are initialized from CBOW (Mikolov et al., 2013) trained on the training data, and are then optimized end-to-end. In the weakly-supervised parser we encourage exploration with meritocratic gradient updates with $\beta = 0.5$ (Guu et al., 2017). In the weakly-supervised parser we warm-start the parameters with the supervised parser, as mentioned above. For optimization, Adam is used (Kingma and Ba, 2014)), with learning rate of 0.001, and mini-batch size of 8.

Pre-processing Because the number of utterances is relatively small for training a neural model, we take the following steps to reduce sparsity. We lowercase all utterance tokens, and also use their lemmatized form. We also use spelling correction to replace words that contain typos. After pre-processing we replace every word that occurs less than 5 times with an UNK symbol.

Evaluation We evaluate on the public development and test sets of CNLVR as well as on the hidden test set. The standard evaluation metric is accuracy, i.e., how many examples are correctly classified. In addition, we report *consistency*, which is the proportion of utterances for which the decoded program has the correct denotation for all 4 images/KBs. It captures whether a model consistently produces a correct answer.

Baselines We compare our models to the MAJORITY baseline that picks the majority class (TRUE in our case). We also compare to the state-of-the-art model reported by Suhr et al. (2017)

when taking the KB as input, which is a maximum entropy classifier (MAXENT). For our models, we evaluate the following variants of our approach:

- RULE: The rule-based parser from Sec. 5.1.
- SUP.: The supervised semantic parser trained on augmented data as in Sec. 5.2 ($5,598$ examples for training and 560 for validation).
- WEAKSUP.: Our full weakly-supervised semantic parser that uses abstract examples.
- +DISC: We add a discriminative re-ranker (Sec. 3) for both SUP. and WEAKSUP.

Main results Table 4 describes our main results. Our weakly-supervised semantic parser with re-ranking (W.+DISC) obtains 84.0 accuracy and 65.0 consistency on the public test set and 82.5 accuracy and 63.9 on the hidden one, improving accuracy by 14.7 points compared to state-of-the-art. The accuracy of the rule-based parser (RULE) is less than 2 points below MAXENT, showing that a semantic parsing approach is very suitable for this task. The supervised parser obtains better performance (especially in consistency), and with re-ranking reaches 76.6 accuracy, showing that generalizing from generated examples is better than memorizing manually-defined patterns. Our weakly-supervised parser significantly improves over SUP., reaching an accuracy of 81.7 before re-ranking, and 84.0 after re-ranking (on the public test set). Consistency results show an even crisper trend of improvement across the models.

6.1 Analysis

We analyze our results by running multiple ablations of our best model W.+DISC on the development set.

To examine the overall impact of our procedure, we trained a weakly-supervised parser from scratch without pre-training a supervised parser nor using a cache, which amounts to a re-implementation of the RANDOMER algorithm (Guu et al., 2017). We find that the algorithm is unable to bootstrap in this challenging setup and obtains very low performance. Next, we examined the importance of abstract examples, by pre-training only on examples that were manually annotated (utterances that match the 106 abstract patterns), but with no data augmentation or use of a cache (−ABSTRACTION). This results in performance that is similar to the MAJORITY baseline.

To further examine the importance of abstraction, we decoupled the two contributions, training once with a cache but without data augmentation for pre-training (−DATAAUGMENTATION), and again with pre-training over the augmented data, but without the cache (−BEAMCACHE). We found that the former improves by a few points over the MAXENT baseline, and the latter performs comparably to the supervised parser, that is, we are still unable to improve learning by training from denotations.

Lastly, we use a beam cache without line 9 in Alg. 1 (−EVERYSTEPBEAMCACHE). This already results in good performance, substantially higher than SUP. but is still 3.4 points worse than our best performing model on the development set.

Orthogonally, to analyze the importance of tying the reward of all four examples that share an utterance, we trained a model without this tying, where the reward is 1 iff the denotation is correct (ONEEXAMPLEREWARD). We find that spuriousness becomes a major issue and weakly-supervised learning fails.

Error Analysis We sampled 50 consistent and 50 inconsistent programs from the development set to analyze the weaknesses of our model. By and large, errors correspond to utterances that are more complex syntactically and semantically. In about half of the errors an object was described by two or more modifying clauses: *"there is a box with a yellow circle and three blue items"*; or nesting occurred: *"one of the gray boxes has exactly* *three objects one of which is a circle"*. In these cases the model either ignored one of the conditions, resulting in a program equivalent to *"there is a box with three blue items"* for the first case, or applied composition operators wrongly, outputting an equivalent to *"one of the gray boxes has exactly three circles"* for the second case. However, in some cases the parser succeeds on such examples and we found that 12% of the sampled utterances that were parsed correctly had a similar complex structure. Other, less frequent reasons for failure were problems with cardinality interpretation, i.e. ,*"there are 2"* parsed as *"exactly 2"* instead of *"at least 2"*; applying conditions to items rather than sets, e.g., *"there are 2 boxes with a triangle closely touching a corner"* parsed as *"there are 2 triangles closely touching a corner"*; and utterances with questionable phrasing, e.g., *"there is a tower that has three the same blocks color"*.

Other insights are that the algorithm tended to give higher probability to the top ranked program when it is correct (average probability 0.18), compared to cases when it is incorrect (average probability 0.08), indicating that probabilities are correlated with confidence. In addition, sentence length is not predictive for whether the model will succeed: average sentence length of an utterance is 10.9 when the model is correct, and 11.1 when it errs.

We also note that the model was successful with sentences that deal with spatial relations, but struggled with sentences that refer to the size of shapes. This is due to the data distribution, which includes many examples of the former case and fewer examples of the latter.

7 Related Work

Training semantic parsers from denotations has been one of the most popular training schemes for scaling semantic parsers since the beginning of the decade. Early work focused on traditional log-linear models (Clarke et al., 2010; Liang et al., 2011; Kwiatkowski et al., 2013), but recently denotations have been used to train neural semantic parsers (Liang et al., 2017; Krishnamurthy et al., 2017; Rabinovich et al., 2017; Cheng et al., 2017).

Visual reasoning has attracted considerable attention, with datasets such as VQA (Antol et al., 2015) and CLEVR (Johnson et al., 2017a). The advantage of CNLVR is that language utterances are both natural and compositional. Treating visual reasoning as an end-to-end semantic parsing problem has been previously done on CLEVR (Hu et al., 2017; Johnson et al., 2017b).

Our method for generating training data resembles data re-combination ideas in Jia and Liang (2016), where examples are generated automatically by replacing entities with their categories.

While spuriousness is central to semantic parsing when denotations are not very informative, there has been relatively little work on explicitly tackling it. Pasupat and Liang (2015) used manual rules to prune unlikely programs on the WIKITABLEQUESTIONS dataset, and then later utilized crowdsourcing (Pasupat and Liang, 2016) to eliminate spurious programs. Guu et al. (2017) proposed RANDOMER, a method for increasing exploration and handling spuriousness by adding randomness to beam search and a proposing a "meritocratic" weighting scheme for gradients. In our work we found that random exploration during beam search did not improve results while meritocratic updates slightly improved performance.

8 Discussion

In this work we presented the first semantic parser for the CNLVR dataset, taking structured representations as input. Our main insight is that in closed, well-typed domains we can generate abstract examples that can help combat the difficulties of training a parser from delayed supervision. First, we use abstract examples to semi-automatically generate utterance-program pairs that help warm-start our parameters, thereby reducing the difficult search challenge of finding correct programs with random parameters. Second, we focus on an abstract representation of examples, which allows us to tackle spuriousness and alleviate search, by sharing information about promising programs between different examples. Our approach dramatically improves performance on CNLVR, establishing a new state-of-the-art.

In this paper, we used a manually-built high-precision lexicon to construct abstract examples. This is suitable for well-typed domains, which are ubiquitous in the virtual assistant use case. In future work we plan to extend this work and automatically learn such a lexicon. This can reduce manual effort and scale to larger domains where there is substantial variability on the language side.

Abstract

Counterfactual learning from human bandit feedback describes a scenario where user feedback on the quality of outputs of a historic system is logged and used to improve a target system. We show how to apply this learning framework to neural semantic parsing. From a machine learning perspective, the key challenge lies in a proper reweighting of the estimator so as to avoid known degeneracies in counterfactual learning, while still being applicable to stochastic gradient optimization. To conduct experiments with human users, we devise an easy-to-use interface to collect human feedback on semantic parses. Our work is the first to show that semantic parsers can be improved significantly by counterfactual learning from logged human feedback data.

1 Introduction

In semantic parsing, natural language utterances are mapped to machine readable parses which are complex and often tailored specifically to the underlying task. The cost and difficulty of manually preparing large amounts of such parses thus is a bottleneck for supervised learning in semantic parsing. Recent work (Liang et al. (2017); Mou et al. (2017); Peng et al. (2017); *inter alia*) has applied reinforcement learning to address the annotation bottleneck as follows: Given a question, the existence of a corresponding gold answer is assumed. A semantic parser produces multiple parses per question and corresponding answers are obtained. These answers are then compared against the gold answer and a positive reward is recorded if there is an overlap. The parser is then guided towards correct parses using the REINFORCE algorithm (Williams, 1992) which scales the gradient for the various parses by their obtained reward (see the left half of Figure 1). However, learning from question-answer pairs is only efficient if gold answers are cheap to obtain. For complex open-domain question-answering tasks, correct answers are not unique factoids, but open-ended lists, counts in large ranges, or fuzzily defined objects. For example, geographical queries against databases such as OpenStreetMap (OSM) can involve fuzzy operators such as "near" or "in walking distance" and thus need to allow for fuzziness in the answers as well. A possible solution lies in machine learning from even weaker supervision signals in form of human bandit feedback[1] where the semantic parsing system suggests exactly one parse for which feedback is collected from a human user. In this setup neither gold parse nor gold answer are known and feedback is obtained for only one system output per question.

The goal of our paper is to exploit this scenario of learning from human bandit feedback to train semantic parsers. This learning scenario perfectly fits commercial setups such as virtual personal assistants that embed a semantic parser. Commercial systems can easily log large amounts of interaction data between users and system. Once sufficient data has been collected, the log can then be used to improve the parser. This leads to a counterfactual learning scenario (Bottou et al., 2013) where we have to solve the counterfactual problem of how to improve a target system from logged feedback that was given to the outputs of a different historic system (see the right half of Figure 1).

In order to achieve our goal of counterfactual learning of semantic parsers from human bandit feedback, the following contributions are required:

[1]The term "bandit feedback" is inspired by the scenario of maximizing the reward for a sequence of pulls of arms of "one-armed bandit" slot machines.

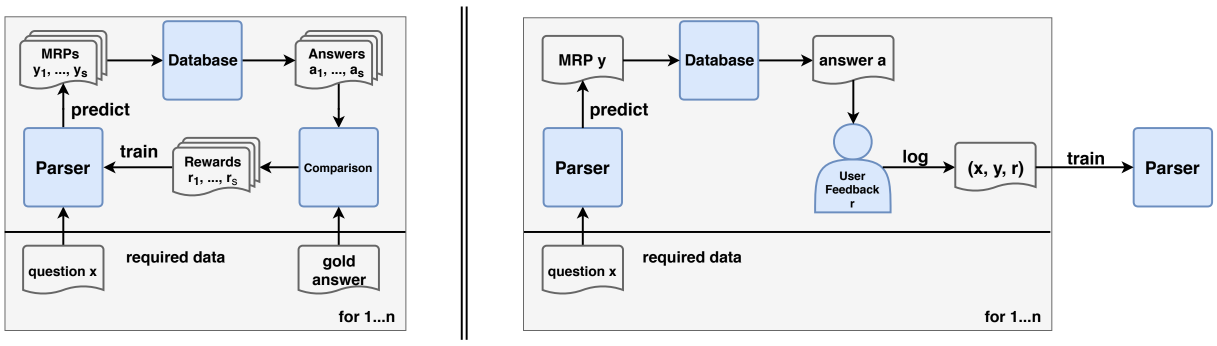

Figure 1: Left: Online reinforcement learning setup for semantic parsing setup where both questions and gold answers are available. The parser attempts to find correct machine readable parses (MRPs) by producing multiple parses, obtaining corresponding answers, and comparing them against the gold answer. Right: In our setup, a question does not have an associated gold answer. The parser outputs a single MRP and the corresponding answer is shown to a user who provides some feedback. Such triplets are collected in a log which can be used for offline training of a semantic parser. This scenario is called counterfactual since the feedback was logged for outputs from a system different from the target system to be optimized.

First, we need to construct an easy-to-use user interface that allows to collect feedback based on the parse rather than the answer. To this aim, we automatically convert the parse to a set of statements that can be judged as correct or incorrect by a human. This approach allows us to assign rewards at the token level, which in turn enables us to perform blame assignment in bandit learning and to learn from partially correct queries where tokens are reinforced individually. We show that users can provide such feedback for one question-parse pair in 16.4 seconds on average. This exemplifies that our approach is more efficient and cheaper than recruiting experts to annotate parses or asking workers to compile large answer sets.

Next, we demonstrate experimentally that counterfactual learning can be applied to neural sequence-to-sequence learning for semantic parsing. A baseline neural semantic parser is trained in fully supervised fashion, human bandit feedback from human users is collected in a log and subsequently used to improve the parser. The resulting parser significantly outperforms the baseline model as well as a simple bandit-to-supervised approach (B2S) where the subset of completely correct parses is treated as a supervised dataset. Finally, we repeat our experiments on a larger but simulated log to show that our gains can scale: the baseline system is improved by 7.45% in answer F1 score without ever seeing a gold standard parse.

Lastly, from a machine learning perspective, we have to solve problems of degenerate behavior in counterfactual learning by lifting the multiplicative control variate technique (Swaminathan and Joachims, 2015b; Lawrence et al., 2017b,a) to stochastic learning for neural models. This is done by reweighting target model probabilities over the logged data under a one-step-late model that decouples the normalization from gradient estimation and is thus applicable in stochastic (minibatch) gradient optimization.

2 Related Work

Semantic parsers have been successfully trained using neural sequence-to-sequence models with a cross-entropy objective and question-parse pairs (Jia and Liang, 2016; Dong and Lapata, 2016)) or question-answer pairs (Neelakantan et al., 2017). Improving semantic parsers using weak feedback has previously been studied (Goldwasser and Roth (2013); Artzi and Zettlemoyer (2013); *inter alia*). More recently, several works have applied policy gradient techniques such as REINFORCE (Williams, 1992) to train neural semantic parsers (Liang et al. (2017); Mou et al. (2017); Peng et al. (2017); *inter alia*). However, they assume the existence of the true target answers that can be used to obtain a reward for any number of output queries suggested by the system. It thus differs from a bandit setup where we assume that a reward is available for only one structure.

Our work most closely resembles the work of

Iyer et al. (2017) who do make the assumption of only being able to judge one output. They improve their parser using simulated and real user feedback. Parses with negative feedback are given to experts to obtain the correct parse. Corrected queries and queries with positive feedback are added to the training corpus and learning continues with a cross-entropy objective. We show that this bandit-to-supervision approach can be outperformed by offline bandit learning from partially correct queries. Yih et al. (2016) proposed a user interface for the Freebase database that enables a fast and easy creation of parses. However, in their setup the worker still requires expert knowledge about the Freebase database, whereas in our approach feedback can be collected freely and from any user interacting with the system.

From a machine learning perspective, related work can be found in the areas of counterfactual bandit learning (Dudik et al., 2011; Swaminathan and Joachims, 2015a), or equivalently, off-policy reinforcement learning (Precup et al., 2000; Jiang and Li, 2016). Our contribution is to modify the self-normalizing estimator (Kong, 1992; Precup et al., 2000; Swaminathan and Joachims, 2015b; Joachims et al., 2018) to be applicable to neural networks. Our work is similar to the counterfactual learning setup for machine translation introduced by Lawrence et al. (2017b). Following their insight, we also assume the logs were created deterministically, i.e. the logging policy always outputs the most likely sequence. Their framework was applied to statistical machine translation using linear models. We show how to generalize their framework to neural models and how to apply it to the task of neural semantic parsing in the OSM domain.

3 Neural Semantic Parsing

Our semantic parsing model is a state-of-the-art sequence-to-sequence neural network using an encoder-decoder setup (Cho et al., 2014; Sutskever et al., 2014) together with an attention mechanism (Bahdanau et al., 2015). We use the settings of Sennrich et al. (2017), where an input sequence $x = x_1, x_2, \dots x_{|x|}$ (a natural language question) is encoded by a Recurrent Neural Network (RNN), each input token has an associated hidden vector $h_i = [\overrightarrow{h}_i; \overleftarrow{h}_i]$ where the former is created by a forward pass over the input, and the latter by a backward pass. $\overrightarrow{h}_i$ is obtained by recursively computing $f(x_i, \overrightarrow{h}_{i-1})$ where f is a Gated Recurrent Unit (GRU) (Chung et al., 2014), and $\overleftarrow{h}_i$ is computed analogously. The input sequence is reduced to a single vector $c = g(\{h_1, \dots, h_{|x|}\})$ which serves as the initialization of the decoder RNN. g calculates the average over all vectors h_i. At each time step t the decoder state is set by $s_t = q(s_{t-1}, y_{t-1}, c_t)$. q is a conditional GRU with an attention mechanism and c_t is the context vector computed by the attention mechanism. Given an output vocabulary $\mathcal{V}_y$ and the decoder state $s_t = \{s_1, \dots, s_{|\mathcal{V}_y|}\}$, a softmax output layer defines a probability distribution over $\mathcal{V}_y$ and the probability for a token y_j is:

$$\pi_w(y_j = t_o | y_{<j}, x) = \frac{\exp(s_{t_o})}{\sum_{v=1}^{|\mathcal{V}_y|} \exp(s_{t_v})}. \quad (1)$$

The model π_w can be seen as parameterized policy over an action space defined by the target language vocabulary. The probability for a full output sequence $y = y_1, y_2, \dots y_{|y|}$ is defined by

$$\pi_w(y|x) = \prod_{j=1}^{|y|} \pi_w(y_j | y_{<j}, x). \quad (2)$$

In our case, output sequences are linearized machine readable parses, called queries in the following. Given supervised data $\mathcal{D}_{sup} = \{(x_t, \bar{y}_t)\}_{t=1}^{n}$ of question-query pairs, where $\bar{y}_t$ is the true target query for x_t, the neural network can be trained using SGD and a cross-entropy (CE) objective:

$$\mathcal{L}_{CE} = -\frac{1}{n} \sum_{t=1}^{n} \sum_{j=1}^{|\bar{y}|} \log \pi_w(\bar{y}_j | \bar{y}_{<j}, x). \quad (3)$$

4 Counterfactual Learning from Deterministic Bandit Logs

Counterfactual Learning Objectives. We assume a policy π_w that, given an input $x \in \mathcal{X}$, defines a conditional probability distribution over possible outputs $y \in \mathcal{Y}(x)$. Furthermore, we assume that the policy is parameterized by w and its gradient can be derived. In this work, π_w is defined by the sequence-to-sequence model described in Section 3. We also assume that the model decomposes over individual output tokens, i.e. that the model produces the output token by token.

$\nabla_w \hat{R}_{\text{DPM}} = \frac{1}{n}\sum_{t=1}^{n} \delta_t \pi_w(y_t\|x_t)\nabla_w \log \pi_w(y_t\|x_t)$.
$\nabla_w \hat{R}_{\text{DPM+R}} = \frac{1}{n}\sum_{t=1}^{n}[\delta_t \bar{\pi}_w(y_t\|x_t)(\nabla_w \log \pi_w(y_t\|x_t) - \frac{1}{n}\sum_{u=1}^{n} \bar{\pi}_w(y_u\|x_u)\nabla \log \pi_w(y_u\|x_u))]$.
$\nabla_w \hat{R}_{\text{DPM+OSL}} = \frac{1}{m}\sum_{t=1}^{m} \delta_t \bar{\pi}_{w,w'}(y_t\|x_t)\nabla_w \log \pi_w(y_t\|x_t)$.
$\nabla_w \hat{R}_{\text{DPM+T}} = \frac{1}{n}\sum_{t=1}^{n} \prod_{j=1}^{\|y\|} \delta_j \pi_w(y_j\|x_t) \sum_{j=1}^{\|y\|} \nabla_w \log \pi_w(y_j\|x_t)$.
$\nabla_w \hat{R}_{\text{DPM+T+OSL}} = \frac{1}{m}\sum_{t=1}^{m} \prod_{j=1}^{\|y\|} \delta_j \bar{\pi}_{w,w'}(y_t\|x_t) \sum_{j=1}^{\|y\|} \nabla_w \log \pi_w(y_j\|x_t)$.

Table 1: Gradients of counterfactual objectives.

The counterfactual learning problem can be described as follows: We are given a data log of triples $\mathcal{D}_{log} = \{(x_t, y_t, \delta_t)\}_{t=1}^{n}$ where outputs y_t for inputs x_t were generated by a logging system under policy π_0, and loss values $\delta_t \in [-1, 0]$[2] were observed for the generated data points. Our goal is to optimize the expected reward (in our case: minimize the expected risk) for a target policy π_w given the data log $\mathcal{D}_{log}$. In case of deterministic logging, outputs are logged with propensity $\pi_0(y_t|x_t) = 1, \ t = 1, \ldots, n$. This results in a *deterministic propensity matching (DPM)* objective (Lawrence et al., 2017b), without the possibility to correct the sampling bias of the logging policy by inverse propensity scoring (Rosenbaum and Rubin, 1983):

$$\hat{R}_{\text{DPM}}(\pi_w) = \frac{1}{n}\sum_{t=1}^{n} \delta_t \pi_w(y_t|x_t). \qquad (4)$$

This objective can show degenerate behavior in that it overfits to the choices of the logging policy (Swaminathan and Joachims, 2015b; Lawrence et al., 2017a). This degenerate behavior can be avoided by reweighting using a multiplicative control variate (Kong, 1992; Precup et al., 2000; Jiang and Li, 2016; Thomas and Brunskill, 2016). The new objective is called the *reweighted deterministic propensity matching (DPM+R)* objective in Lawrence et al. (2017b):

$$\begin{aligned}\hat{R}_{\text{DPM+R}}(\pi_w) &= \frac{1}{n}\sum_{t=1}^{n} \delta_t \bar{\pi}_w(y_t|x_t) \qquad (5)\\ &= \frac{\frac{1}{n}\sum_{t=1}^{n} \delta_t \pi_w(y_t|x_t)}{\frac{1}{n}\sum_{t=1}^{n} \pi_w(y_t|x_t)}.\end{aligned}$$

Algorithms for optimizing the discussed objectives can be derived as gradient descent algorithms where gradients using the score function gradient estimator (Fu, 2006) are shown in Table 1.

[2]We use the terms loss and (negative) rewards interchangeably, depending on context.

Reweighting in Stochastic Learning. As shown in Swaminathan and Joachims (2015b) and Lawrence et al. (2017a), reweighting over the entire data log $\mathcal{D}_{log}$ is crucial since it avoids that high loss outputs in the log take away probability mass from low loss outputs. This multiplicative control variate has the additional effect of reducing the variance of the estimator, at the cost of introducing a bias of order $O(\frac{1}{n})$ that decreases as n increases (Kong, 1992). The desirable properties of this control variate cannot be realized in a stochastic (minibatch) learning setup since minibatch sizes large enough to retain the desirable reweighting properties are infeasible for large neural networks.

We offer a simple solution to this problem that nonetheless retains all desired properties of the reweighting. The idea is inspired by one-step-late algorithms that have been introduced for EM algorithms (Green, 1990). In the EM case, dependencies in objectives are decoupled by evaluating certain terms under parameter settings from previous iterations (thus: one-step-late) in order to achieve closed-form solutions. In our case, we decouple the reweighting from the parameterization of the objective by evaluating the reweighting under parameters w' from some previous iteration. This allows us to perform gradient descent updates and reweighting asynchronously. Updates are performed using minibatches, however, reweighting is based on the entire log, allowing us to retain the desirable properties of the control variate.

The new objective, called *one-step-late reweighted DPM* objective (DPM+OSL), optimizes $\pi_{w,w'}$ with respect to w for a minibatch of size m, with reweighting over the entire log of size n under parameters w':

$$\hat{R}_{\text{DPM+OSL}}(\pi_w) = \frac{1}{m}\sum_{t=1}^{m}\delta_t\bar{\pi}_{w,w'}(y_t|x_t) \quad (6)$$
$$= \frac{\frac{1}{m}\sum_{t=1}^{m}\delta_t\pi_w(y_t|x_t)}{\frac{1}{n}\sum_{t=1}^{n}\pi_{w'}(y_t|x_t)}.$$

If the renormalization is updated periodically, e.g. after every validation step, renormalizations under w or w' are not much different and will not hamper convergence. Despite losing the formal justification from the perspective of control variates, we found empirically that the OSL update schedule for reweighting is sufficient and does not deteriorate performance. The gradient for learning with OSL updates is given in Table 1.

Token-Level Rewards. For our application of counterfactual learning to human bandit feedback, we found another deviation from standard counterfactual learning to be helpful: For humans, it is hard to assign a graded reward to a query at a sequence level because either the query is correct or it is not. In particular, with a sequence level reward of 0 for incorrect queries, we do not know which part of the query is wrong and which parts might be correct. Assigning rewards at token-level will ease the feedback task and allow the semantic parser to learn from partially correct queries. Thus, assuming the underlying policy can decompose over tokens, a token level (DPM+T) reward objective can be defined:

$$\hat{R}_{\text{DPM+T}}(\pi_w) = \frac{1}{n}\sum_{t=1}^{n}\left(\prod_{j=1}^{|y|}\delta_j\pi_w(y_j|x_t)\right). \quad (7)$$

Analogously, we can define an objective that combines the token-level rewards and the minibatched reweighting (DPM+T+OSL):

$$\hat{R}_{\text{DPM+T+OSL}}(\pi_w) = \frac{\frac{1}{m}\sum_{t=1}^{m}\left(\prod_{j=1}^{|y|}\delta_j\pi_w(y_j|x_t)\right)}{\frac{1}{n}\sum_{t=1}^{n}\pi_{w'}(y_t|x_t)}. \quad (8)$$

Gradients for the DPM+T and DPM+T+OSL objectives are given in Table 1.

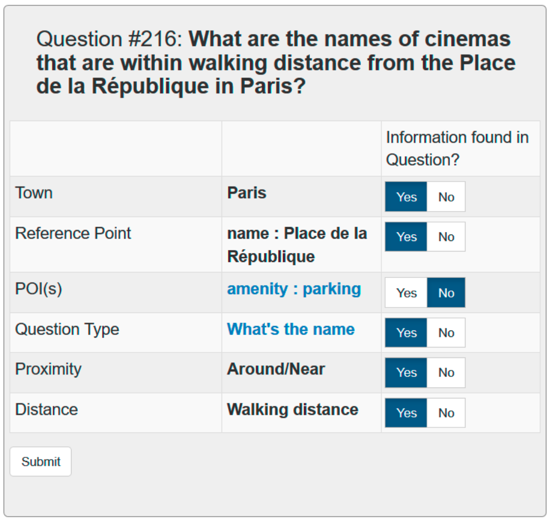
5 Semantic Parsing in the OpenStreetMap Domain

OpenStreetMap (OSM) is a geographical database in which volunteers annotate points of interests in the world. A point of interest consists of one or more associated GPS points. Further relevant information may be added at the discretion of the volunteer in the form of tags. Each tag consists of a key and an associated value, for example "*tourism : hotel*". The NLMAPS corpus was introduced by Haas and Riezler (2016) as a basis to create a natural language interface to the OSM database. It pairs English questions with machine readable parses, i.e. queries that can be executed against OSM.

Human Feedback Collection. The task of creating a natural language interface for OSM demonstrates typical difficulties that make it expensive to collect supervised data. The machine readable language of the queries is based on the OVERPASS query language which was specifically designed for the OSM database. It is thus not easily possible to find experts that could provide correct queries. It is equally difficult to ask workers at crowdsourcing platforms for the correct answer. For many questions, the answer set is too large to expect a worker to count or list them all in a reasonable amount of time and without errors. For example, for the question "*How many hotels are there in Paris?*" there are 951 hotels annotated in the OSM database. Instead we propose to automatically transform the query into a block of statements that can easily be judged as correct or incorrect by a human. The question and the created block of statements are embedded in a user interface with a form that can be filled out by users. Each statement is accompanied by a set of radio buttons where a user can select either "*Yes*" or "*No*". For a screenshot of the interface and an example see Figure 2.

In total there are 8 different types of statements. The presence of certain tokens in a query trigger different statement types. For example, the token "*area*" triggers the statement type "*Town*". The statement is then populated with the corresponding information from the query. In the case of "*area*", the following OSM value is used, e.g. "*Paris*". With this, the meaning of every query can be captured by a set of human-understandable statements. For a full overview of all statement types and their triggers see section B of the supplementary material.

OSM tags and keys are generally understandable. For example, the correct OSM tag for "*hotels*" is "*tourism : hotel*" and when searching for



Question #216: **What are the names of cinemas that are within walking distance from the Place de la République in Paris?**

		Information found in Question?
Town	**Paris**	[✓ Yes] No
Reference Point	**name : Place de la République**	[✓ Yes] No
POI(s)	**amenity : parking**	Yes [✓ No]
Question Type	**What's the name**	[✓ Yes] No
Proximity	**Around/Near**	[✓ Yes] No
Distance	**Walking distance**	[✓ Yes] No

Figure 2: The user interface for collecting feedback from humans with an example question and a correctly filled out form.

websites, the correct question type key would be "*website*". Nevertheless, for each OSM tag or key, we automatically search for the corresponding Wikipedia page on the OpenStreetMap Wiki[3] and extract the description for this tag or key. The description is made available to the user in form of a tool-tip that appears when hovering over the tag or key with the mouse. If a user is unsure if a OSM tag or key is correct, they can read this description to help in their decision making. Once the form is submitted, a script maps each statement back to the corresponding tokens in the original query. These tokens then receive negative or positive feedback based on the feedback the user provided for that statement.

Corpus Extension. Similar to the extension of the NLMAPS corpus by Lawrence and Riezler (2016) who include shortened questions which are more typically used by humans in search tasks, we present an automatic extension that allows a larger coverage of common OSM tags.[4] The basis for the extension is a hand-written, online freely available list[5] that links natural language expressions such as "*cash machine*" to appropriate OSM tags, in this case "*amenity : atm*". Using the list, we generate for each unique expression-tag pair a set of question-query pairs. These latter pairs contain several placeholders which will be filled automatically in a second step.

To fill the area placeholder `$LOC`, we sample from a list of 30 cities from France, Germany and the UK. `$POI` is the placeholder for a point of interest. We sample it from the list of objects which are located in the prior sampled city and which have a *name* key. The corresponding value belonging to the *name* key will be used to fill this spot. The placeholder `$QTYPE` is filled by uniformly sampling from the four primary question types available in the NLMAPS query language. On the natural language side they corresponded to "*How many*", "*Where*", "*Is there*" and `$KEY`. `$KEY` is a further parameter belonging to the primary question operator FINDKEY. It can be filled by any OSM key, such as *name*, *website* or *height*. To ensure that there will be an answer for the generated query, we first ran a query with the current tag ("*amenity : atm*") to find all objects fulfilling this requirement in the area of the already sampled city. From the list of returned objects and the keys that appear in association with them, we uniformly sampled a key. For `$DIST` we chose between the pre-defined options for walking distance and within city distance. The expressions map to corresponding values which define the size of a radius in which objects of interest (with tag "*amenity : atm*") will be located. If the walking distance was selected, we added "*in walking distance*" to the question. Otherwise no extra text was added to the question, assuming the within city distance to be the default. This sampling process was repeated twice.

Table 2 presents the corpus statistics, comparing NLMAPS to our extension. The automatic

	NLMAPS	NLMAPS V2
# question-query pairs	2,380	28,609
tokens	25,906	202,088
types	1,002	8,710
avg. sent. length	10.88	7.06
distinct tags	477	6,582

Table 2: Corpus statistics of the question-answering corpora NLMAPS and our extension NLMAPS V2 which additionally contains the search engine style queries (Lawrence and Riezler, 2016) and the automatic extensions of the most common OSM tags.

[3]https://wiki.openstreetmap.org/

[4]The extended dataset, called NLMAPS V2, will be released upon acceptance of the paper.

[5]http://wiki.openstreetmap.org/wiki/Nominatim/Special_Phrases/EN

extension, obviating the need for expensive manual work, allows a vast increase of question-query pairs by an order of magnitude. Consequently the number of tokens and types increase in a similar vein. However, the average sentence length drops. This comes as no surprise due to the nature of the rather simple hand-written list which contains never more than one tag for an element, resulting in simpler question structures. However, the main idea of utilizing this list is to extend the coverage to previously unknown OSM tags. With 6,582 distinct tags compared to the previous 477, this was clearly successful. Together with the still complex sentences from the original corpus, a semantic parser is now able to learn both complex questions and a large variety of tags. An experiment that empirically validates the usefulness of the automatically created data can be found in the supplementary material, section A.

6 Experiments

General Settings. In our experiments we use the sequence-to-sequence neural network package NEMATUS (Sennrich et al., 2017). Following the method used by Haas and Riezler (2016), we split the queries into individual tokens by taking a pre-order traversal of the original tree-like structure. For example, "*query(west(area(keyval('name','Paris')), nwr(keyval('railway','station'))),qtype(count))*" becomes "*query@2 west@2 area@1 keyval@2 name@0 Paris@s nwr@1 keyval@2 railway@0 station@s qtype@1 count@0*".

The SGD optimizer used is ADADELTA (Zeiler, 2012). The model employs 1,024 hidden units and word embeddings of size 1,000. The maximum sentence length is 200 and gradients are clipped if they exceed a value of 1.0. The stopping point is determined by validation on the development set and selecting the point at which the highest evaluation score is obtained. F1 validation is run after every 100 updates, and each update is made on the basis of a minibatch of size 80.

The evaluation of all models is based on the answers obtained by executing the most likely query obtained after a beam search with a beam of size 12. We report the F1 score which is the harmonic mean of precision and recall. Recall is defined as the percentage of fully correct answers divided by the set size. Precision is the percentage of correct answers out of the set of answers with non-empty strings. Statistical significance between models is measured using an approximate randomization test (Noreen, 1989).

Baseline Parser & Log Creation. Our experiment design assumes a baseline neural semantic parser that is trained in fully supervised fashion, and is to be improved by bandit feedback obtained for system outputs from the baseline system for given questions. For this purpose, we select 2,000 question-query pairs randomly from the full extended NLMAPS V2 corpus. We will call this dataset $\mathcal{D}_{sup}$. Using this dataset, a baseline semantic parser is trained in supervised fashion under a cross-entropy objective. It obtains an F1 score of 57.45% and serves as the logging policy π_0.

Furthermore we randomly split off 1,843 and 2,000 pairs for a development and test set, respectively. This leaves a set of 22,765 question-query pairs. The questions can be used as input and bandit feedback can be collected for the most likely output of the semantic parser. We refer to this dataset as $\mathcal{D}_{log}$.

To collect human feedback, we take the first 1,000 questions from $\mathcal{D}_{log}$ and use π_0 to parse these questions to obtain one output query for each. 5 question-query pairs are discarded because the suggested query is invalid. For the remaining question-query pairs, the queries are each transformed into a block of human-understandable statements and embedded into the user interface described in Section 5. We recruited 9 users to provide feedback for these question-query pairs. The resulting log is referred to as $\mathcal{D}_{human}$. Every question-query pair is purposely evaluated only once to mimic a realistic real-world scenario where user logs are collected as users use the system. In this scenario, it is also not possible to explicitly obtain several evaluations for the same question-query pair. Some examples of the received feedback can be found in the supplementary material, section C.

To verify that the feedback collection is efficient, we measured the time each user took from loading a form to submitting it. To provide feedback for one question-query pair, users took 16.4 seconds on average with a standard deviation of 33.2 seconds. The vast majority (728 instances) are completed in less than 10 seconds.

Learning from Human Bandit Feedback. An analysis of $\mathcal{D}_{human}$ shows that for 531 queries all corresponding statements were marked as correct. We consider a simple baseline that treats completely correct logged data as a supervised data set with which training continues using the cross-entropy objective. We call this baseline bandit-to-supervised conversion (B2S). Furthermore, we present experimental results using the log $\mathcal{D}_{human}$ for stochastic (minibatch) gradient descent optimization of the counterfactual objectives introduced in equations 4, 6, 7 and 8. For the token-level feedback, we map the evaluated statements back to the corresponding tokens in the original query and assign these tokens a feedback of 0 if the corresponding statement was marked as wrong and 1 otherwise. In the case of sequence-level feedback, the query receives a feedback of 1 if all statements are marked correct, 0 otherwise. For the OSL objectives, a separate experiment (see below) showed that updating the reweighting constant after every validation step promises the best trade-off between performance and speed.

Results, averaged over 3 runs, are reported in Table 3. The B2S model can slightly improve upon the baseline but not significantly. DPM improves further, significantly beating the baseline. Using the multiplicative control variate modified for SGD by OSL updates does not seem to help in this setup. By moving to token-level rewards, it is possible to learn from partially correct queries. These partially correct queries provide valuable information that is not present in the subset of correct answers employed by the previous models. Optimizing DPM+T leads to a slight improvement and combined with the multiplicative control variate, DPM+T+OSL yields an improvement of about 1.0 in F1 score upon the baseline. It beats both the baseline and the B2S model by a significant margin.

Learning from Large-Scale Simulated Feedback. We want to investigate whether the results scale if a larger log is used. Thus, we use π_0 to parse all 22,765 questions from $\mathcal{D}_{log}$ and obtain for each an output query. For sequence level rewards, we assign feedback of 1 for a query if it is identical to the true target query, 0 otherwise. We also simulate token-level rewards by iterating over the indices of the output and assigning a feedback of 1 if the same token appears at the current index for the true target query, 0 otherwise.

An analysis of $\mathcal{D}_{log}$ shows that 46.27% of the queries have a sequence level reward of 1 and are thus completely correct. This subset is used to train a bandit-to-supervised (B2S) model using the cross-entropy objective.

Experimental results for the various optimization setups, averaged over 3 runs, are reported in Table 4. We see that the B2S model outperforms the baseline model by a large margin, yielding an increase in F1 score by 6.24 points. Optimizing the DPM objective also yields a significant increase over the baseline, but its performance falls short of the stronger B2S baseline. Optimizing the DPM+OSL objective leads to a substantial improvement in F1 score over optimizing DPM but still falls slightly short of the strong B2S baseline. Token-level rewards are again crucial to beat the B2S baseline significantly. DPM+T is already able to significantly outperform B2S in this setup and DPM+T+OSL can improve upon this further.

Analysis. Comparing the baseline and DPM+T+OSL, we manually examined all queries in the test set where DPM+T+OSL ob-

		F1	Δ F1
1	baseline	57.45	
2	B2S	57.79 ± 0.18	+0.34
3	DPM^{1}	58.04 ± 0.04	+0.59
4	DPM+OSL	58.01 ± 0.23	+0.56
5	DPM+T^{1}	58.11 ± 0.24	+0.66
6	DPM+T+OSL^{1,2}	58.44 ± 0.09	+0.99

Table 3: Human Feedback: Answer F1 scores on the test set for the various setups, averaged over 3 runs. Statistical significance of system differences at $p < 0.05$ are indicated by experiment number in superscript.

		F1	Δ F1
1	baseline	57.45	
2	B2S^{1,3}	63.22 ± 0.27	+5.77
3	DPM^{1}	61.80 ± 0.16	+4.35
4	DPM+OSL^{1,3}	62.91 ± 0.05	+5.46
5	DPM+T^{1,2,3,4}	63.85 ± 0.2	+6.40
6	DPM+T+OSL^{1,2,3,4}	64.41 ± 0.05	+6.96

Table 4: Simulated Feedback: Answer F1 scores on the test set for the various setups, averaged over 3 runs. Statistical significance of system differences at $p < 0.05$ are indicated by experiment number in superscript.

Error Type	Human	Simulated
OSM Tag	90%	86.75%
Question Type	6%	8.43%
Structure	4%	4.82%

Table 5: Analysis of which type of errors DPM+T+OSL corrected on the test set compared to the baseline system for both human and simulated feedback experiments.

tained the correct answer and the baseline system did not (see Table 5). The analysis showed that the vast majority of previously wrong queries were fixed by correcting an OSM tag in the query. For example, for the question "*closest Florist from Manchester in walking distance*" the baseline system chose the tag "*landuse : retail*" in the query, whereas DPM+T+OSL learnt that the correct tag is "*shop : florist*". In some cases, the question type had to be corrected, e.g. the baseline's suggested query returned the location of a point of interest but DPM+T+OSL correctly returns the phone number. Finally, in a few cases DPM+T+OSL corrected the structure for a query, e.g. by searching for a point of interest in the east of an area rather than the south.

OSL Update Variation. Using the DPM+T+OSL objective and the simulated feedback setup, we vary the frequency of updating the reweighting constant. Results are reported in Table 6. Calculating the constant only once at the beginning leads to a near identical result in F1 score as not using OSL. The more frequent update strategies, once or four times per epoch, are more effective. Both strategies reduce variance further and lead to higher F1 scores. Updating four times per epoch compared to once per epoch, leads to a nominally higher performance in F1. It has the additional benefit that the re-calculation is done at the same time as the validation, leading to no additional slow down as executing the queries for the development set against the database takes longer than the re-calculation of the constant. Updating after every minibatch is infeasible as it slows down training too much. Compared to the previous setup, iterating over one epoch takes approximately an additional 5.5 hours.

	OSL Update	F1	Δ F1
1	no OSL (DPM+T)	63.85±0.2	
2	once	63.82±0.1	-0.03
3	every epoch	64.26±0.04	+0.41
4	every validation / 4x per epoch	64.41±0.05	+0.56
5	every minibatch	N/A	N/A

Table 6: Simulated Feedback: Answer F1 scores on the test set for DPM+T and DPM+T+OSL with varying OSL update strategies, averaged over 3 runs. Updating after every minibatch is infeasible as it significantly slows down learning. Statistical significance of system differences at $p < 0.05$ occur for experiment 4 over experiment 2.

7 Conclusion

We introduced a scenario for improving a neural semantic parser from logged bandit feedback. This scenario is important to avoid complex and costly data annotation for supervise learning, and it is realistic in commercial applications where weak feedback can be collected easily in large amounts from users. We presented robust counterfactual learning objectives that allow to perform stochastic gradient optimization which is crucial in working with neural networks. Furthermore, we showed that it is essential to obtain reward signals at the token-level in order to learn from partially correct queries. We presented experimental results using feedback collected from humans and a larger scale setup with simulated feedback. In both cases we show that a strong baseline using a bandit-to-supervised conversion can be significantly outperformed by a combination of a one-step-late reweighting and token-level rewards. Finally, our approach to collecting feedback can also be transferred to other domains. For example, (Yih et al., 2016) designed a user interface to help Freebase experts to efficiently create queries. This interface could be reversed: given a question and a query produced by a parser, the interface is filled out automatically and the user has to verify if the information fits.

Abstract

We present a semantic parser for Abstract Meaning Representations which learns to parse strings into tree representations of the compositional structure of an AMR graph. This allows us to use standard neural techniques for supertagging and dependency tree parsing, constrained by a linguistically principled type system. We present two approximative decoding algorithms, which achieve state-of-the-art accuracy and outperform strong baselines.

1 Introduction

Over the past few years, Abstract Meaning Representations (AMRs, Banarescu et al. (2013)) have become a popular target representation for semantic parsing. AMRs are graphs which describe the predicate-argument structure of a sentence. Because they are graphs and not trees, they can capture reentrant semantic relations, such as those induced by control verbs and coordination. However, it is technically much more challenging to parse a string into a graph than into a tree. For instance, grammar-based approaches (Peng et al., 2015; Artzi et al., 2015) require the induction of a grammar from the training corpus, which is hard because graphs can be decomposed into smaller pieces in far more ways than trees. Neural sequence-to-sequence models, which do very well on string-to-tree parsing (Vinyals et al., 2014), can be applied to AMRs but face the challenge that graphs cannot easily be represented as sequences (van Noord and Bos, 2017a,b).

In this paper, we tackle this challenge by making the compositional structure of the AMR explicit. As in our previous work, Groschwitz et al. (2017), we view an AMR as consisting of atomic graphs representing the meanings of the individual words, which were combined compositionally using linguistically motivated operations for combining a head with its arguments and modifiers. We represent this structure as terms over the *AM algebra* as defined in Groschwitz et al. (2017). This previous work had no parser; here we show that the terms of the AM algebra can be viewed as dependency trees over the string, and we train a dependency parser to map strings into such trees, which we then evaluate into AMRs in a postprocessing step. The dependency parser relies on type information, which encodes the semantic valencies of the atomic graphs, to guide its decisions.

More specifically, we combine a neural supertagger for identifying the elementary graphs for the individual words with a neural dependency model along the lines of Kiperwasser and Goldberg (2016) for identifying the operations of the algebra. One key challenge is that the resulting term of the AM algebra must be semantically well-typed. This makes the decoding problem NP-complete. We present two approximation algorithms: one which takes the unlabeled dependency tree as given, and one which assumes that all dependencies are projective. We evaluate on two data sets, achieving state-of-the-art results on one and near state-of-the-art results on the other (Smatch f-scores of 71.0 and 70.2 respectively). Our approach clearly outperforms strong but non-compositional baselines.

Plan of the paper. After reviewing related work in Section 2, we explain the AM algebra in Section 3 and extend it to a dependency view in Section 4. We explain model training in Section 5 and decoding in Section 6. Section 7 evaluates a number of variants of our system.

2 Related Work

Recently, AMR parsing has generated considerable research activity, due to the availability of large-scale annotated data (Banarescu et al., 2013) and two successful SemEval Challenges (May, 2016; May and Priyadarshi, 2017).

Methods from dependency parsing have been shown to be very successful for AMR parsing. For instance, the JAMR parser (Flanigan et al., 2014, 2016) distinguishes *concept identification* (assigning graph fragments to words) from *relation identification* (adding graph edges which connect these fragments), and solves the former with a supertagging-style method and the latter with a graph-based dependency parser. Foland and Martin (2017) use a variant of this method based on an intricate neural model, yielding state-of-the-art results. We go beyond these approaches by explicitly modeling the compositional structure of the AMR, which allows the dependency parser to combine AMRs for the words using a small set of universal operations, guided by the types of these AMRs.

Other recent methods directly implement a dependency parser for AMRs, e.g. the transition-based model of Damonte et al. (2017), or postprocess the output of a dependency parser by adding missing edges (Du et al., 2014; Wang et al., 2015). In contrast to these, our model makes no strong assumptions on the dependency parsing algorithm that is used; here we choose that of Kiperwasser and Goldberg (2016).

The commitment of our parser to derive AMRs compositionally mirrors that of grammar-based AMR parsers (Artzi et al., 2015; Peng et al., 2015). In particular, there are parallels between the types we use in the AM algebra and CCG categories (see Section 3 for details). As a neural system, our parser struggles less with coverage issues than these, and avoids the complex grammar induction process these models require.

More generally, our use of semantic types to restrict our parser is reminiscent of Kwiatkowski et al. (2010), Krishnamurthy et al. (2017) and Zhang et al. (2017), and the idea of deriving semantic representations from dependency trees is also present in Reddy et al. (2017).

3 The AM algebra

A core idea of this paper is to parse a string into a graph by instead parsing a string into a dependency-style tree representation of the graph's compositional structure, represented as terms of the *Apply-Modify (AM) algebra* (Groschwitz et al., 2017).

The values of the AM algebra are *annotated s-graphs*, or *as-graphs*: directed graphs with node and edge labels in which certain nodes have been designated as *sources* (Courcelle and Engelfriet, 2012) and *annotated* with type information. Some examples of as-graphs are shown in Fig. 1. Each as-graph has exactly one *root*, indicated by the bold outline. The sources are indicated by red labels; for instance, G_{want} has an S-source and an O-source. The annotations, written in square brackets behind the red source names, will be explained below. We use these sources to mark open argument slots; for example, G_{sleep} in Fig. 1 represents an intransitive verb, missing its subject, which will be added at the S-source.

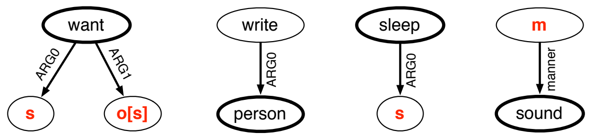

Figure 1: Elementary as-graphs G_{want}, G_{writer}, G_{sleep}, and G_{sound} for the words "want", "writer", "sleep", and "soundly" respectively.

The AM algebra can combine as-graphs with each other using two linguistically motivated operations: *apply* and *modify*. Apply (APP) adds an argument to a predicate. For example, we can add a subject – the graph G_{writer} in Fig. 1 – to the graph G_{VP} in Fig. 2d using APP_{S}, yielding the complete AMR in Fig. 2b. Linguistically, this is like filling the subject (S) slot of the predicate *wants to sleep soundly* with the argument *the writer*. In general, for a source a, $\text{APP}_a(G_P, G_A)$, combines the as-graph G_P representing a predicate, or head, with the as-graph G_A, which represents an argument. It does this by plugging the root node of G_A into the a-source u of G_P – that is, the node u of G_P marked with source a. The root of the resulting as-graph G is the root of G_P, and we remove the a marking on u, since that slot is now filled.

The modify operation (MOD) adds a modifier to a graph. For example, we can combine two elementary graphs from Fig. 1 with MOD_m (G_{sleep}, G_{sound}), yielding the graph in Fig. 2c. The M-source of the modifier G_{soundly} attaches to the root of G_{sleep}. The root of the result is the same as the root of G_{sleep} in the same sense that a verb phrase with an adverb modifier is still a verb phrase. In general, $\text{MOD}_a(G_H, G_M)$, combines a head G_H with a modifier G_M. It plugs the root of G_H into the a-source u of G_M. Although this may add incoming edges to the root of G_H, that node is still the root of the resulting graph G. We remove the a marking from G_M.

In both App and Mod, if there is any other source b which is present in both graphs, the nodes marked with b are unified with each other. For example, when G_{want} is o-applied to t_1 in Fig. 2d, the s-sources of the graphs for "want" and "sleep soundly" are unified into a single node, creating a reentrancy. This falls out of the definition of *merge* for s-graphs which formally underlies both operations (see (Courcelle and Engelfriet, 2012)).

Finally, the AM algebra uses *types* to restrict its operations. Here we define the *type* of an as-graph as the set of its sources with their annotations[1]; thus for example, in Fig. 1, the graph for "writer" has the empty type [ ], G_{sleep} has type $[\text{s}]$, and G_{want} has type $[\text{s}, \text{o}[\text{s}]]$. Each source in an as-graph specifies with its *annotation* the type of the as-graph which is plugged into it via App. In other words, for a source a, we may only a-apply G_P with G_A if the annotation of the a-source in G_P matches the type of G_A. For example, the o-source of G_{wants} (Fig. 1) requires that we plug in an as-graph of type $[\text{s}]$; observe that this means that the reentrancy in Fig. 2b is lexically specified by the control verb "want". All other source nodes in Fig. 1 have no annotation, indicating a type requirement of [ ].

Linguistically, modification is optional; we therefore want the modified graph to be derivationally just like the unmodified graph, in that exactly the same operations can apply to it. In a typed algebra, this means Mod should not change the type of the head. Mod_a therefore requires that the modifier G_M have no sources not already present in the head G_H, except a, which will be deleted anyway.

As in any algebra, we can build *terms* from constants (denoting elementary as-graphs) by recursively combining them with the operations of the AM algebra. By evaluating the operations bottom-up, we obtain an as-graph as the value of such a term; see Fig. 2 for an example. However, as discussed above, an operation in the term may be undefined due to a type mismatch. We call an AM-term *well-typed* if all its operations are defined. Every well-typed AM-term evaluates to an as-graph. Since the applicability of an AM operation depends only on the types, we also write $\tau = f(\tau_1, \tau_2)$ if as-graphs of type τ_1 and τ_2 can be combined with the operation f and the result has type τ.

[1]See (Groschwitz et al., 2017) for a more formally complete definition.

Relationship to CCG. There is close relationship between the types of the AM algebra and the categories of CCG. A type $[\text{s}, \text{o}]$ specifies that the as-graph needs to be applied to two arguments to be semantically complete, similar a CCG category such as $\text{S}\backslash\text{NP}/\text{NP}$, where a string needs to be applied to two NP arguments to be syntactically complete. However, AM types govern the combination of *graphs*, while CCG categories control the combination of strings. This relieves AM types of the need to talk about word order; there are no "forward" or "backward" slashes in AM types, and a smaller set of operations. Also, the AM algebra spells out raising and control phenomena more explicitly in the types.

4 Indexed AM terms

In this paper, we connect AM terms to the input string w for which we want to produce a graph. We do this in an *indexed AM term*, exemplified in Fig. 3a. We assume that every elementary as-graph G at a leaf represents the meaning of an individual word token w_i in w, and write $G[i]$ to annotate the leaf G with the index i of this token. This induces a connection between the nodes of the AMR and the tokens of the string, in that the label of each node was contributed by the elementary as-graph of exactly one token.

We define the *head index* of a subtree t to be the index of the token which contributed the root of the as-graph to which t evaluates. For a leaf with annotation i, the head index is i; for an App or Mod node, the head index is the head index of the left child, i.e. of the head argument. We annotate each App and Mod operation with the head index of the left and right subtree.

4.1 AM dependency trees

We can represent indexed AM terms more compactly as *AM dependency trees*, as shown in Fig. 3b. The nodes of such a dependency tree are the tokens of w. We draw an edge with label f from i to k if there is a node with label $f[i, k]$ in the indexed AM term. For example, the tree in 3b has an edge labeled Mod_m from 5 (G_{sleep}) to 6 (G_{soundly}) because there is a node in the term in 3a labeled $\text{Mod}_m[5, 6]$. The same AM dependency tree may represent multiple indexed AM terms, because the order of apply and modify operations is not specified in the dependency tree. However, it can be shown that all well-typed AM terms that map to

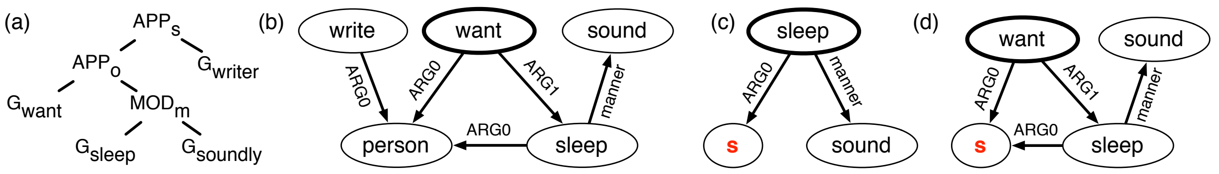

Figure 2: (a) An AM-term with its value (b), along with the values for its subexpressions (c) $t_1 = \text{MOD}_m(G_{\text{sleep}}, G_{\text{sound}})$ and (d) $t_2 = \text{APP}_o(G_{\text{want}}, t_1)$.

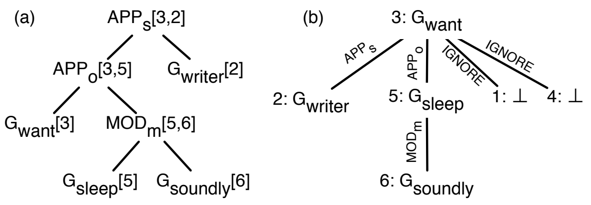

Figure 3: (a) An indexed AM term and (b) an AM dependency tree, linking the term in Fig. 2;a to the sentence “The writer wants to sleep soundly”.

the same AM dependency tree evaluate to the same as-graph. We define a *well-typed* AM dependency tree as one that represents a well-typed AM term.

Because not all words in the sentence contribute to the AMR, we include a mechanism for ignoring words in the input. As a special case, we allow the constant $\perp$, which represents a dummy as-graph (of type $\perp$) which we use as the semantic value of words without a semantic value in the AMR. We furthermore allow the edge label IGNORE in an AM dependency tree, where $\text{IGNORE}(\tau_1, \tau_2) = \tau_1$ if $\tau_2 = \perp$ and is undefined otherwise; in particular, an AM dependency tree with IGNORE edges is only well-typed if all IGNORE edges point into $\perp$ nodes. We keep all other operations $f(\tau_1, \tau_2)$ as is, i.e. they are undefined if either τ_1 or τ_2 is $\perp$, and never yield $\perp$ as a result. When reconstructing an AM term from the AM dependency tree, we skip IGNORE edges, such that the subtree below them will not contribute to the overall AMR.

4.2 Converting AMRs to AM terms

In order to train a model that parses sentences into AM dependency trees, we need to convert an AMR corpus – in which sentences are annotated with AMRs – into a treebank of AM dependency trees. We do this in three steps: first, we break each AMR up into elementary graphs and identify their roots; second, we assign sources and annotations to make elementary as-graphs out of them; and third, combine them into indexed AM terms.

For the first step, an aligner uses hand-written heuristics to identify the string token to which each node in the AMR corresponds (see Section C in the Supplementary Materials for details). We proceed in a similar fashion as the JAMR aligner (Flanigan et al., 2014), i.e. by starting from high-confidence token-node pairs and then extending them until the whole AMR is covered. Unlike the JAMR aligner, our heuristics ensure that exactly one node in each elementary graph is marked as the root, i.e. as the node where other graphs can attach their edges through APP and MOD. When an edge connects nodes of two different elementary graphs, we use the “blob decomposition” algorithm of Groschwitz et al. (2017) to decide to which elementary graph it belongs. For the example AMR in Fig. 2b, we would obtain the graphs in Fig. 1 (without source annotations). Note that ARG edges belong with the nodes at which they start, whereas the “manner” edge in G_{soundly} goes with its target.

In the second step we assign source names and annotations to the unlabeled nodes of each elementary graph. Note that the annotations are crucial to our system’s ability to generate graphs with reentrancies. We mostly follow the algorithm of Groschwitz et al. (2017), which determines necessary annotations based on the structure of the given graph. The algorithm chooses each source name depending on the incoming edge label. For instance, the two leaves of G_{want} can have the source labels S and O because they have incoming edges labeled ARG0 and ARG1. However, the Groschwitz algorithm is not deterministic: It allows object promotion (the sources for an ARG3 edge may be O3, O2, or O), unaccusative subjects (promoting the minimal object to S if the elementary graph contains an ARGi-edge ($i > 0$) but no ARG0-edge (Perlmutter, 1978)), and passive alternation (swapping O and S). To make our as-graphs more consistent, we prefer constants that promote objects as far as possible, use unaccusative subjects, and no passive alternation, but still allow constants that do not satisfy these conditions if necessary. This increased our Smatch score significantly.

Finally, we choose an arbitrary AM dependency tree that combines the chosen elementary as-graphs into the annotated AMR; in practice, the differences between the trees seem to be negligible.[2]

5 Training

We can now model the AMR parsing task as the problem of computing the best well-typed AM dependency tree t for a given sentence w. Because t is well-typed, it can be decoded into an (indexed) AM term and thence evaluated to an as-graph.

We describe t in terms of the elementary as-graphs $G[i]$ it uses for each token i and of its edges $f[i,k]$. We assume a node-factored, edge-factored model for the *score* $\omega(t)$ of t:

$$\omega(t) = \sum_{1 \le i \le n} \omega(G[i]) + \sum_{f[i,k] \in E} \omega(f[i,k]), \quad (1)$$

where the edge weight further decomposes into the sum $\omega(f[i,k]) = \omega(i \to k) + \omega(f \mid i \to k)$ of a score $\omega(i \to k)$ for the presence of an edge from i to k and a score $\omega(f \mid i \to k)$ for this edge having label f. Our aim is to compute the well-typed t with the highest score.

We present three models for ω: one for the graph scores and two for the edge scores. All of these are based on a two-layer bidirectional LSTM, which reads inputs $\mathbf{x} = (x_1, \dots, x_n)$ token by token, concatenating the hidden states of the forward and the backward LSTMs in each layer. On the second layer, we thus obtain vector representations $v_i = \text{BiLSTM}(\mathbf{x}, i)$ for the individual input tokens (see Fig. 4). Our models differ in the inputs $\mathbf{x}$ and the way they predict scores from the v_i.

5.1 Supertagging for elementary as-graphs

We construe the prediction of the as-graphs $G[i]$ for each input position i as a supertagging task (Lewis et al., 2016). The supertagger reads inputs $x_i = (w_i, p_i, c_i)$, where w_i is the word token, p_i its POS tag, and c_i is a character-based LSTM encoding of w_i. We use pretrained GloVe embeddings (Pennington et al., 2014) concatenated with learned embeddings for w_i, and learned embeddings for p_i.

To predict the score for each elementary as-graph out of a set of K options, we add a K-dimensional output layer as follows:

$$\omega(G[i]) = \log \text{softmax}(W \cdot v_i + b)$$

[2]Indeed, we conjecture that for a fixed set of constants and a fixed AMR, there is only one dependency tree.

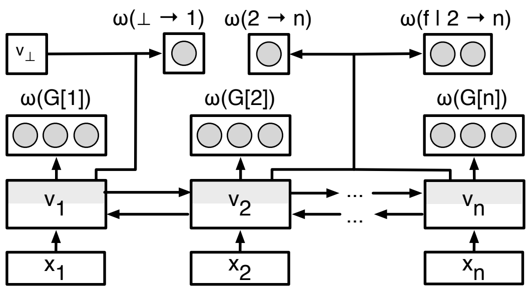

Figure 4: Architecture of the neural taggers.

and train the neural network using a cross-entropy loss function. This maximizes the likelihood of the elementary as-graphs in the training data.

5.2 Kiperwasser & Goldberg edge model

Predicting the edge scores amounts to a dependency parsing problem. We chose the dependency parser of Kiperwasser and Goldberg (2016), henceforth K&G, to learn them, because of its accuracy and its fit with our overall architecture. The K&G parser scores the potential edge from i to k and its label from the concatenations of v_i and v_k:

$$\begin{aligned} \text{MLP}_\theta(v) &= W_2 \cdot \tanh(W_1 \cdot v + b_1) + b_2 \\ \omega(i \to k) &= \text{MLP}_\text{E}(v_i \circ v_k) \\ \omega(f \mid i \to k) &= \text{MLP}_\text{LBL}(v_i \circ v_k) \end{aligned}$$

We use inputs $x_i = (w_i, p_i, \tau_i)$ including the type τ_i of the supertag $G[i]$ at position i, using trained embeddings for all three. At evaluation time, we use the best scoring supertag according to the model of Section 5.1. At training time, we sample from q, where $q(\tau_i) = (1 - \delta) + \delta \cdot p(\tau_i | p_i, p_{i-1})$, $q(\tau) = \delta \cdot p(\tau | p_i, p_{i-1})$ for any $\tau \neq \tau_i$ and δ is a hyperparameter controlling the bias towards the aligned supertag. We train the model using K&G's original DyNet implementation. Their algorithm uses a hinge loss function, which maximizes the score difference between the gold dependency tree and the best predicted dependency tree, and therefore requires parsing each training instance in each iteration. Because the AM dependency trees are highly non-projective, we replaced the projective parser used in the off-the-shelf implementation by the Chu-Liu-Edmonds algorithm implemented in the TurboParser (Martins et al., 2010), improving the LAS on the development set by 30 points.

5.3 Local edge model

We also trained a *local* edge score model, which uses a cross-entropy rather than a hinge loss and therefore avoids the repeated parsing at training time. Instead, we follow the intuition that every node in a dependency tree has at most one incoming edge, and train the model to score the correct incoming edge as high as possible. This model takes inputs $x_i = (w_i, p_i)$.

We define the edge and edge label scores as in Section 5.2, with tanh replaced by ReLU. We further add a learned parameter $v_\perp$ for the "LSTM embedding" of a nonexistent node, obtaining scores $\omega(\perp \rightarrow k)$ for k having no incoming edge.

To train $\omega(i \rightarrow k)$, we collect all scores for edges ending at the same node k into a vector $\omega(\bullet \rightarrow k)$. We then minimize the cross-entropy loss for the gold edge into k under softmax$(\omega(\bullet \rightarrow k))$, maximizing the likelihood of the gold edges. To train the labels $\omega(f \mid i \rightarrow k)$, we simply minimize the cross-entropy loss of the actual edge labels f of the edges which are present in the gold AM dependency trees.

The PyTorch code for this and the supertagger are available at `bitbucket.org/tclup/amr-dependency`.

6 Decoding

Given learned estimates for the graph and edge scores, we now tackle the challenge of computing the best well-typed dependency tree t for the input string w, under the score model (equation (1)). The requirement that t must be well-typed is crucial to ensure that it can be evaluated to an AMR graph, but as we show in the Supplementary Materials (Section A), makes the decoding problem NP-complete. Thus, an exact algorithm is not practical. In this section, we develop two different approximation algorithms for AM dependency parsing: one which assumes the (unlabeled) dependency tree structure as known, and one which assumes that the AM dependency tree is projective.

6.1 Projective decoder

The projective decoder assumes that the AM dependency tree is projective, i.e. has no crossing dependency edges. Because of this assumption, it can recursively combine adjacent substrings using dynamic programming. The algorithm is shown in Fig. 5 as a parsing schema (Shieber et al., 1995), which derives items of the form $([i, k], r, \tau)$ with scores s. An item represents a well-typed derivation of the substring from i to k with head index r, and which evaluates to an as-graph of type τ.

$$\frac{s = \omega(G[i]) \quad G \neq \perp}{([i, i+1], i, \tau(G)) : s} \ \text{Init}$$

$$\frac{([i, k], r, \tau) : s \quad s' = \omega(\perp[k])}{([i, k+1], r, \tau) : s + s'} \ \text{Skip-R}$$

$$\frac{([i, k], r, \tau) : s \quad s' = \omega(\perp[i-1])}{([i-1, k], r, \tau) : s + s'} \ \text{Skip-L}$$

$$\frac{\begin{array}{c}([i, j], r_1, \tau_1) : s_1 \quad ([j, k], r_2, \tau_2) : s_2 \\ \tau = f(\tau_1, \tau_2) \text{ defined} \quad s = \omega(f[r_1, r_2])\end{array}}{([i, k], r_1, \tau) : s_1 + s_2 + s} \ \text{Arc-R } [f]$$

$$\frac{\begin{array}{c}([i, j], r_1, \tau_1) : s_1 \quad ([j, k], r_2, \tau_2) : s_2 \\ \tau = f(\tau_2, \tau_1) \text{ defined} \quad s = \omega(f[r_2, r_1])\end{array}}{([i, k], r_2, \tau) : s_1 + s_2 + s} \ \text{Arc-L } [f]$$

Figure 5: Rules for the projective decoder.

The parsing schema consists of three types of rules. First, the Init rule generates an item for each graph fragment $G[i]$ that the supertagger predicted for the token w_i, along with the score and type of that graph fragment. Second, given items for adjacent substrings $[i, j]$ and $[j, k]$, the Arc rules apply an operation f to combine the indexed AM terms for the two substrings, with Arc-R making the left-hand substring the head and the right-hand substring the argument or modifier, and Arc-L the other way around. We ensure that the result is well-typed by requiring that the types can be combined with f. Finally, the Skip rules allow us to extend a substring such that it covers tokens which do not correspond to a graph fragment (i.e., their AM term is $\perp$), introducing IGNORE edges. After all possible items have been derived, we extract the best well-typed tree from the item of the form $([1, n], r, \tau)$ with the highest score, where $\tau = [\,]$.

Because we keep track of the head indices, the projective decoder is a bilexical parsing algorithm, and shares a parsing complexity of $O(n^5)$ with other bilexical algorithms such as the Collins parser. It could be improved to a complexity of $O(n^4)$ using the algorithm of Eisner and Satta (1999).

6.2 Fixed-tree decoder

The fixed-tree decoder computes the best unlabeled dependency tree t_r for w, using the edge scores $\omega(i \rightarrow k)$, and then computes the best AM dependency tree for w whose unlabeled version is t_r. The Chu-Liu-Edmonds algorithm produces a forest of dependency trees, which we want to combine into t_r. We choose the tree whose root r has the highest score for being the root of the AM dependency tree and make the roots of all others children of r.

At this point, the shape of t_r is fixed. We choose

$$\frac{s = \omega(G[i])}{(i, \emptyset, \tau(G)) : s}\ \text{Init}$$

$$\frac{(i, C_1, \tau_1) : s_1 \quad (k, Ch(k), \tau_2) : s_2 \quad k \in Ch(i) \backslash C_1 \quad \tau = f(\tau_1, \tau_2) \text{ defined} \quad s = \omega(f[i,k])}{(i, C_1 \cup \{k\}, \tau) : s_1 + s_2 + s}\ \text{Edge}[f]$$

Figure 6: Rules for the fixed-tree decoder.

supertags for the nodes and edge labels for the edges by traversing t_r bottom-up, computing types for the subtrees as we go along. Formally, we apply the parsing schema in Fig. 6. It uses items of the form $(i, C, \tau) : s$, where $1 \leq i \leq n$ is a node of t_r, C is the set of children of i for which we have already chosen edge labels, and τ is a type. We write $Ch(i)$ for the set of children of i in t_r.

The Init rule generates an item for each graph that the supertagger can assign to each token i in w, ensuring that every token is also assigned $\perp$ as a possible supertag. The Edge rule labels an edge from a parent node i in t_r to one of its children k, whose children already have edge labels. As above, this rule ensures that a well-typed AM dependency tree is generated by locally checking the types. In particular, if all types τ_2 that can be derived for k are incompatible with τ_1, we fall back to an item for k with $\tau_2 = \perp$ (which always exists), along with an IGNORE edge from i to k.

The complexity of this algorithm is $O(n \cdot 2^d \cdot d)$, where d is the maximal arity of the nodes in t_r.

7 Evaluation

We evaluate our models on the LDC2015E86 and LDC2017T10[3] datasets (henceforth "2015" and "2017"). Technical details and hyperparameters of our implementation can be found in Sections B to D of the Supplementary Materials.

7.1 Training data

The original LDC datasets pair strings with AMRs. We convert each AMR in the training and development set into an AM dependency tree, using the procedure of Section 4.2. About 10% of the training instances cannot be split into elementary as-graphs by our aligner; we removed these from the training data. Of the remaining AM dependency trees, 37% are non-projective.

Furthermore, the AM algebra is designed to handle short-range reentrancies, modeling grammatical phenomena such as control and coordination, as in the derivation in Fig. 2. It cannot easily handle the long-range reentrancies in AMRs which are caused by coreference, a non-compositional phenomenon.[4] We remove such reentrancies from our training data (about 60% of the roughly 20,000 reentrant edges). Despite this, our model performs well on reentrant edges (see Table 2).

7.2 Pre- and postprocessing

We use simple pre- and postprocessing steps to handle rare words and some AMR-specific patterns. In AMRs, named entities follow a pattern shown in Fig. 7. Here the named entity is of type "person", has a name edge to a "name" node whose children spell out the tokens of "Agatha Christie", and a link to a wiki entry. Before training, we replace each "name" node, its children, and the corresponding span in the sentence with a special `NAME` token, and we completely remove wiki edges. In this example, this leaves us with only a "person" and a `NAME` node. Further, we replace numbers and some date patterns with `NUMBER` and `DATE` tokens. On the training data this is straightforward, since names and dates are explicitly annotated in the AMR. At evaluation time, we detect dates and numbers with regular expressions, and names with Stanford CoreNLP (Manning et al., 2014). We also use Stanford CoreNLP for our POS tags.

Each elementary as-graph generated by the procedure of Section 4.2 has a unique node whose label corresponds most closely to the aligned word (e.g. the "want" node in G_{want} and the "write" node in G_{writer}). We replace these node labels with `LEX` in preprocessing, reducing the number of different elementary as-graphs from 28730 to 2370. We factor the supertagger model of Section 5.1 such that the unlexicalized version of $G[i]$ and the label for `LEX` are predicted separately.

At evaluation, we re-lexicalize all `LEX` nodes in the predicted AMR. For words that were frequent in the training data (at least 10 times), we take the supertagger's prediction for the label. For rarer words, we use simple heuristics, explained in the Supplementary Materials (Section D). For names, we just look up name nodes with their children and wiki entries observed for the name string in the training data, and for unseen names use the literal tokens as the name, and no wiki entry. Similarly,

[3]https://catalog.ldc.upenn.edu/LDC2017T10, identical to LDC2016E25.

[4]As Damonte et al. (2017) comment: "A valid criticism of AMR is that these two reentrancies are of a completely different type, and should not be collapsed together."

we collect the type for each encountered name (e.g. "person" for "Agatha Christie"), and correct it in the output if the tagger made a different prediction. We recover dates and numbers straightforwardly.

7.3 Supertagger accuracy

All of our models rely on the supertagger to predict elementary as-graphs; they differ only in the edge scores. We evaluated the accuracy of the supertagger on the converted development set (in which each token has a supertag) of the 2015 data set, and achieved an accuracy of 73%. The correct supertag is within the supertagger's 4 best predictions for 90% of the tokens, and within the 10 best for 95%.

Interestingly, supertags that introduce grammatical reentrancies are predicted quite reliably, although they are relatively rare in the training data. The elementary as-graph for subject control verbs (see G_{want} in Fig. 1) accounts for only 0.8% of supertags in the training data, yet 58% of its occurrences in the development data are predicted correctly (84% in 4-best). The supertag for VP coordination (with type $[\text{OP}1[\text{S}], \text{OP}2[\text{S}]]$) makes up for 0.4% of the training data, but 74% of its occurrences are recognized correctly (92% in 4-best). Thus the prediction of informative types for individual words is feasible.

7.4 Comparison to Baselines

Type-unaware fixed-tree baseline. The fixed-tree decoder is built to ensure well-typedness of the predicted AM dependency trees. To investigate to what extent this is required, we consider a baseline which just adds the individually highest-scoring supertags and edge labels to the unlabeled dependency tree t_u, ignoring types. This leads to AM dependency trees which are not well-typed for 75% of the sentences (we fall back to the largest well-typed subtree in these cases). Thus, an off-the-shelf dependency parser can reliably predict the tree structure of the AM dependency tree, but correct supertag and edge label assignment requires a decoder which takes the types into account.

JAMR-style baseline. Our elementary as-graphs differ from the elementary graphs used in JAMR-style algorithms in that they contain explicit source nodes, which restrict the way in which they can be combined with other as-graphs. We investigate the impact of this choice by implementing a strong JAMR-style baseline. We adapt the AMR-to-dependency conversion of Section 4.2 by removing all unlabeled nodes with source names from the

elementary graphs. For instance, the graph G_{want} in Fig. 1 now only consists of a single "want" node. We then aim to directly predict AMR edges between these graphs, using a variant of the local edge scoring model of Section 5.3 which learns scores for each edge in isolation. (The assumption for the original local model, that each node has only one incoming edge, does not apply here.)

When parsing a string, we choose the highest-scoring supertag for each word; there are only 628 different supertags in this setting, and 1-best supertagging accuracy is high at 88%. We then follow the JAMR parsing algorithm by predicting all edges whose score is over a threshold (we found -0.02 to be optimal) and then adding edges until the graph is connected. Because we do not predict which node is the root of the AMR, we evaluated this model as if it always predicted the root correctly, overestimating its score slightly.

7.5 Results

Table 1 shows the Smatch scores (Cai and Knight, 2013) of our models, compared to a selection of previously published results. Our results are averages over 4 runs with 95% confidence intervals (JAMR-style baselines are single runs). On the 2015 dataset, our best models (local + projective, K&G + fixed-tree) outperform all previous work, with the exception of the Foland and Martin (2017) model; on the 2017 set we match state of the art results (though note that van Noord and Bos (2017b) use 100k additional sentences of silver data). The fixed-tree decoder seems to work well with either edge model, but performance of the projective decoder drops with the K&G edge scores. It may be that, while the hinge loss used in the K&G edge scoring model is useful to finding the correct un-

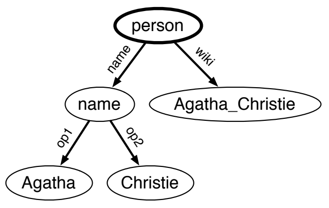

Figure 7: A named entity

labeled dependency tree in the fixed-tree decoder, scores for bad edges – which are never used when computing the hinge loss – are not trained accurately. Thus such edges may be erroneously used by the projective decoder.

As expected, the type-unaware baseline has low recall, due to its inability to produce well-typed trees. The fact that our models outperform the JAMR-style baseline so clearly is an indication that they indeed gain some of their accuracy from the type information in the elementary as-graphs, confirming our hypothesis that an explicit model of the compositional structure of the AMR can help the parser learn an accurate model.

Table 2 analyzes the performance of our two best systems (PD = projective, FTD = fixed-tree) in more detail, using the categories of Damonte et al. (2017), and compares them to Wang's, Flanigan's, and Damonte's AMR parsers on the 2015 set and , and van Noord and Bos (2017b) for the 2017 dataset. (Foland and Martin (2017) did not publish such results.) The good scores we achieve on reentrancy identification, despite removing a large amount of reentrant edges from the training data, indicates that our elementary as-graphs successfully encode phenomena such as control and coordination.

The projective decoder is given 4, and the fixed-tree decoder 6, supertags for each token. We trained the supertagging and edge scoring models of Section 5 separately; joint training did not help. Not sampling the supertag types τ_i during training of the K&G model, removing them from the input, and removing the character-based LSTM encodings c_i from the input of the supertagger, all reduced our models' accuracy.

7.6 Differences between the parsers

Although the Smatch scores for our two best models are close, they sometimes struggle with different sentences. The fixed-tree parser is at the mercy of the fixed tree; the projective parser cannot produce non-projective AM dependency trees. It is remarkable that the projective parser does so well, given the prevalence of non-projective trees in the training data. Looking at its analyses, we find that it frequently manages to find a projective tree which yields an (almost) correct AMR, by choosing supertags with unusual types, and by using modify rather than apply (or vice versa).

8 Conclusion

We presented an AMR parser which applies methods from supertagging and dependency parsing to map a string into a well-typed AM term, which it then evaluates into an AMR. The AM term represents the compositional semantic structure of the AMR explicitly, allowing us to use standard tree-based parsing techniques.

The projective parser currently computes the complete parse chart. In future work, we will speed it up through the use of pruning techniques. We will also look into more principled methods for splitting the AMRs into elementary as-graphs to replace our hand-crafted heuristics. In particular, advanced methods for alignments, as in Lyu and Titov (2018), seem promising. Overcoming the need for heuristics also seems to be a crucial ingredient for applying our method to other semantic representations.

Acknowledgements We would like to thank the anonymous reviewers for their comments. We thank Stefan Grünewald for his contribution to our PyTorch implementation, and want to acknowledge the inspiration obtained from Nguyen et al. (2017). We also extend our thanks to the organizers and participants of the Oslo CAS Meaning Construction workshop on Universal Dependencies. Abstract

In this paper, we present a sequence-to-sequence based approach for mapping natural language sentences to AMR semantic graphs. We transform the sequence to graph mapping problem to a word sequence to transition action sequence problem using a special transition system called a cache transition system. To address the sparsity issue of neural AMR parsing, we feed feature embeddings from the transition state to provide relevant local information for each decoder state. We present a monotonic hard attention model for the transition framework to handle the strictly left-to-right alignment between each transition state and the current buffer input focus. We evaluate our neural transition model on the AMR parsing task, and our parser outperforms other sequence-to-sequence approaches and achieves competitive results in comparison with the best-performing models.[1]

1 Introduction

Abstract Meaning Representation (AMR) (Banarescu et al., 2013) is a semantic formalism where the meaning of a sentence is encoded as a rooted, directed graph. Figure 1 shows an example of an AMR in which the nodes represent the AMR concepts and the edges represent the relations between the concepts. AMR has been used in various applications such as text summarization (Liu et al., 2015), sentence compression (Takase et al., 2016), and event extraction (Huang et al., 2016).

[1]The implementation of our parser is available at https://github.com/xiaochang13/CacheTransition-Seq2seq

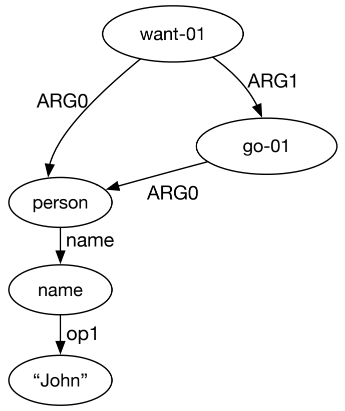

Figure 1: An example of AMR graph representing the meaning of: "John wants to go"

The task of AMR graph parsing is to map natural language strings to AMR semantic graphs. Different parsers have been developed to tackle this problem (Flanigan et al., 2014; Wang et al., 2015b,a; Peng et al., 2015; Artzi et al., 2015; Pust et al., 2015; van Noord and Bos, 2017). On the other hand, due to the limited amount of labeled data and the large output vocabulary, the sequence-to-sequence model has not been very successful on AMR parsing. Peng et al. (2017) propose a linearization approach that encodes labeled graphs as sequences. To address the data sparsity issue, low-frequency entities and tokens are mapped to special categories to reduce the vocabulary size for the neural models. Konstas et al. (2017) use self-training on a huge amount of unlabeled text to lower the out-of-vocabulary rate. However, the final performance still falls behind the best-performing models.

The best performing AMR parsers model graph structures directly. One approach to modeling graph structures is to use a transition system to build graphs step by step, as shown by the system of Wang and Xue (2017), which is currently the top performing system. This raises the question of whether the advantages of neural and transition-based system can be combined, as for example with the syntactic parser of Dyer et al. (2015), who use stack LSTMs to capture action history information in the transition state of the transition system. Ballesteros and Al-Onaizan (2017) apply stack-LSTM to transition-based AMR parsing and achieve competitive results, which shows that local transition state information is important for predicting transition actions.

Instead of linearizing the target AMR graph to a sequence structure, Buys and Blunsom (2017) propose a *sequence-to-action-sequence* approach where the reference AMR graph is replaced with an action derivation sequence by running a deterministic *oracle* algorithm on the training sentence, AMR graph pairs. They use a separate alignment probability to explicitly model the hard alignment from graph nodes to sentence tokens in the buffer.

Gildea et al. (2018) propose a special transition framework called a cache transition system to generate the set of semantic graphs. They adapt the stack-based parsing system by adding a working set, which they refer to as a cache, to the traditional stack and buffer. Peng et al. (2018) apply the cache transition system to AMR parsing and design refined action phases, each modeled with a separate feedforward neural network, to deal with some practical implementation issues.

In this paper, we propose a sequence-to-action-sequence approach for AMR parsing with cache transition systems. We want to take advantage of the sequence-to-sequence model to encode whole-sentence context information and the history action sequence, while using the transition system to constrain the possible output. The transition system can also provide better local context information than the linearized graph representation, which is important for neural AMR parsing given the limited amount of data.

More specifically, we use bi-LSTM to encode two levels of input information for AMR parsing: word level and concept level, each refined with more general category information such as lemmatization, POS tags, and concept categories.

We also want to make better use of the complex transition system to address the data sparsity issue for neural AMR parsing. We extend the hard attention model of Aharoni and Goldberg (2017), which deals with the nearly-monotonic alignment in the morphological inflection task, to the more general scenario of transition systems where the input buffer is processed from left-to-right. When we process the buffer in this ordered manner, the sequence of target transition actions are also strictly aligned left-to-right according to the input order. On the decoder side, we augment the prediction of output action with embedding features from the current transition state. Our experiments show that encoding information from the transition state significantly improves sequence-to-sequence models for AMR parsing.

2 Cache Transition Parser

We adopt the transition system of Gildea et al. (2018), which has been shown to have good coverage of the graphs found in AMR.

A **cache transition parser** consists of a stack, a cache, and an input buffer. The stack is a sequence σ of (integer, concept) pairs, as explained below, with the topmost element always at the rightmost position. The buffer is a sequence of ordered concepts β containing a suffix of the input concept sequence, with the first element to be read as a newly introduced concept/vertex of the graph. (We use the terms concept and vertex interchangeably in this paper.) Finally, the cache is a sequence of concepts $\eta = [v_1, \dots, v_m]$. The element at the leftmost position is called the first element of the cache, and the element at the rightmost position is called the last element.

Operationally, the functioning of the parser can be described in terms of configurations and transitions. A **configuration** of our parser has the form:

$$C = (\sigma, \eta, \beta, G_p)$$

where σ, η and β are as described above, and G_p is the partial graph that has been built so far. The initial configuration of the parser is $([], [\$, \dots, \$], [c_1, \dots, c_n], \emptyset)$, meaning that the stack and the partial graph are initially empty, and the cache is filled with m occurrences of the special symbol $\$$. The buffer is initialized with all the graph vertices constrained by the order of the input sentence. The final configuration is $([], [\$, \dots, \$], [], G)$, where the stack and the cache are as in the initial configuration and the buffer is empty. The constructed graph is the target AMR graph.

stack	cache	buffer	edges	actions taken
[]	[\$, \$, \$]	[Per, want-01, go-01]	$\emptyset$	—
[1, \$]	[\$, \$, Per]	[want-01, go-01]	$\emptyset$	*Shift*; *PushIndex*(1)
[1, \$]	[\$, \$, Per]	[want-01, go-01]	$\emptyset$	*Arc(1, -, NULL)*; *Arc(2, -, NULL)*
[1, \$, 1, \$]	[\$, Per, want-01]	[go-01]	$\emptyset$	*Shift*; *PushIndex*(1)
[1, \$, 1, \$]	[\$, Per, want-01]	[go-01]	E_1	*Arc(1, -, NULL)*; *Arc(2, L, ARG0)*
[1, \$, 1, \$, 1, \$]	[Per, want-01, go-01]	[]	E_1	*Shift*; *PushIndex*(1)
[1, \$, 1, \$, 1, \$]	[Per, want-01, go-01]	[]	E_2	*Arc(1, L, ARG0)*; *Arc(2, R, ARG1)*
[1, \$, 1, \$]	[\$, Per, want-01]	[]	E_2	*Pop*
[1, \$]	[\$, \$, Per]	[]	E_2	*Pop*
[]	[\$, \$, \$]	[]	E_2	*Pop*

Figure 2: Example run of the cache transition system constructing the graph for the sentence "John wants to go" with cache size of 3. The left four columns show the parser configurations after taking the actions shown in the last column. $E_1 = \{(Per, want\text{-}01, L\text{-}ARG0)\}$, $E_2 = \{(Per, want\text{-}01, L\text{-}ARG0), (Per, go\text{-}01, L\text{-}ARG0), (want\text{-}01, go\text{-}01, R\text{-}ARG1)\}$.

In the first step, which is called concept identification, we map the input sentence $w_{1:n'} = w_1, \ldots, w_{n'}$ to a sequence of concepts $c_{1:n} = c_1, \ldots, c_n$. We decouple the problem of concept identification from the transition system and initialize the buffer with a recognized concept sequence from another classifier, which we will introduce later. As the sequence-to-sequence model uses all possible output actions as the target vocabulary, this can significantly reduce the target vocabulary size. The **transitions** of the parser are specified as follows.

1. *Pop* pops a pair (i, v) from the stack, where the integer i records the position in the cache that it originally came from. We place concept v in position i in the cache, shifting the remainder of the cache one position to the right, and discarding the last element in the cache.
2. *Shift* signals that we will start processing the next input concept, which will become a new vertex in the output graph.
3. *PushIndex*(i) shifts the next input concept out of the buffer and moves it into the last position of the cache. We also take out the concept v_i appearing at position i in the cache and push it onto the stack σ, along with the integer i recording its original position in the cache.[2]
4. *Arc(i, d, l)* builds an arc with direction d and label l between the rightmost concept and the i-th concept in the cache. The label l is *NULL* if no arc is made and we use the action *NOARC* in this case. Otherwise we decompose the arc decision into two actions *ARC* and *d-l*. We consider all arc decisions between the rightmost cache concept and each of the other concepts in the cache. We can consider this phase as first making a binary decision whether there is an arc, and then predicting the label in case there is one, between each concept pair.

[2]Our transition design is different from Peng et al. (2018) in two ways: the PushIndex phase is initiated before making all the arc decisions; the newly introduced concept is placed at the last cache position instead of the leftmost buffer position, which essentially increases the cache size by 1.

Given the sentence "John wants to go" and the recognized concept sequence "Per want-01 go-01" (person name category *Per* for "John"), our cache transition parser can construct the AMR graph shown in Figure 1 using the run shown in Figure 2 with cache size of 3.

2.1 Oracle Extraction Algorithm

We use the following **oracle** algorithm (Nivre, 2008) to derive the sequence of actions that leads to the gold AMR graph for a cache transition parser with cache size m. The correctness of the oracle is shown by Gildea et al. (2018).

Let E_G be the set of edges of the gold graph G. We maintain the set of vertices that is not yet shifted into the cache as S, which is initialized with all vertices in G. The vertices are ordered according to their aligned position in the word sequence and the unaligned vertices are listed according to their order in the depth-first traversal of the graph. The oracle algorithm can look into

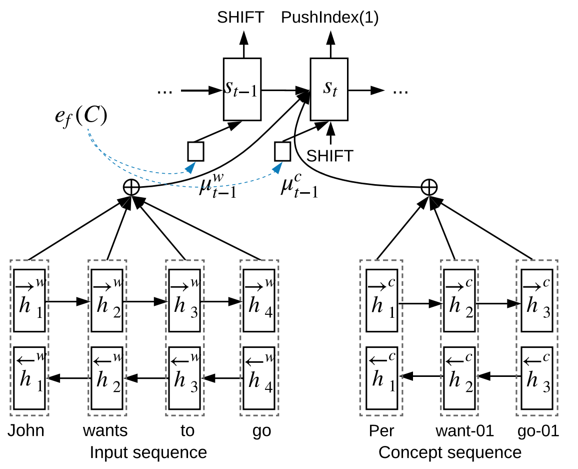

Figure 3: Sequence-to-sequence model with soft attention, encoding a word sequence and concept sequence separately by two BiLSTM encoders.

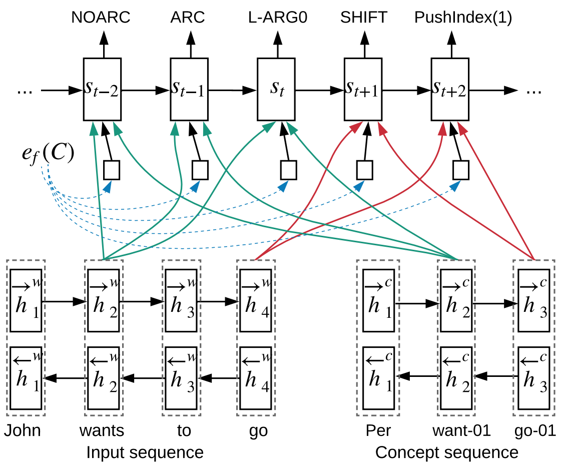

Figure 4: Sequence-to-sequence model with monotonic hard attention. Different colors show the changes of hard attention focus.

E_G to decide which transition to take next, or else to decide that it should fail. This decision is based on the mutually exclusive rules listed below.

1. ShiftOrPop phase: the oracle chooses transition *Pop*, in case there is no edge (v_m, v) in E_G such that vertex v is in S, or chooses transition *Shift* and proceeds to the next phase.
2. PushIndex phase: in this phase, the oracle first chooses a position i (as explained below) in the cache to place the candidate concept and removes the vertex at this position and places its index, vertex pair onto the stack. The oracle chooses transition *PushIndex(i)* and proceeds to the next phase.
3. ArcBinary, ArcLabel phases: between the rightmost cache concept and each concept in the cache, we make a binary decision about whether there is an arc between them. If there is an arc, the oracle chooses its direction and label. After arc decisions to $m-1$ cache concepts are made, we jump to the next step.
4. If the stack and buffer are both empty, and the cache is in the initial state, the oracle finishes with success, otherwise we proceed to the first step.

We use the equation below to choose the cache concept to take out in the step *PushIndex(i)*. For $j \in [|\beta|]$, we write β_j to denote the j-th vertex in β. We choose a vertex v_{i^*} in η such that:

$$i^* = \underset{i \in [m]}{\operatorname{argmax}} \min \{j \mid (v_i, \beta_j) \in E_G\}$$

In words, v_{i^*} is the concept from the cache whose closest neighbor in the buffer β is furthest forward in β. We move out of the cache vertex v_{i^*} and push it onto the stack, for later processing.

For each training example $(x_{1:n}, g)$, the transition system generates the output AMR graph g from the input sequence $x_{1:n}$ through an oracle sequence $a_{1:q} \in \Sigma_a^*$, where Σ_a is the union of all possible actions. We model the probability of the output with the action sequence:

$$P(a_{1:q}|x_{1:n}) = \prod_{t=1}^{q} P(a_t|a_1, \ldots, a_{t-1}, x_{1:n}; \theta)$$

which we estimate using a sequence-to-sequence model, as we will describe in the next section.

3 Soft vs Hard Attention for Sequence-to-action-sequence

Shown in Figure 3, our sequence-to-sequence model takes a word sequence $w_{1:n'}$ and its mapped concept sequence $c_{1:n}$ as the input, and the action sequence $a_{1:q}$ as the output. It uses two BiLSTM encoders, each encoding an input sequence. As the two encoders have the same structure, we only introduce the encoder for the word sequence in detail below.

3.1 BiLSTM Encoder

Given an input word sequence $w_{1:n'}$, we use a bidirectional LSTM to encode it. At each step j, the current hidden states $\overleftarrow{h}^w_j$ and $\overrightarrow{h}^w_j$ are generated from the previous hidden states $\overleftarrow{h}^w_{j+1}$ and $\overrightarrow{h}^w_{j-1}$, and the representation vector x_j of the current input word w_j:

$$\overleftarrow{h}^{w}_{j} = \text{LSTM}(\overleftarrow{h}^{w}_{j+1}, x_j)$$
$$\overrightarrow{h}^{w}_{j} = \text{LSTM}(\overrightarrow{h}^{w}_{j-1}, x_j)$$

The representation vector x_j is the concatenation of the embeddings of its word, lemma, and POS tag, respectively. Then the hidden states of both directions are concatenated as the final hidden state for word w_j:

$$h^w_j = [\overleftarrow{h}^{w}_{j}; \overrightarrow{h}^{w}_{j}]$$

Similarly, for the concept sequence, the final hidden state for concept c_j is:

$$h^c_j = [\overleftarrow{h}^{c}_{j}; \overrightarrow{h}^{c}_{j}]$$

3.2 LSTM Decoder with Soft Attention

We use an attention-based LSTM decoder (Bahdanau et al., 2014) with two attention memories H_w and H_c, where H_w is the concatenation of the state vectors of all input words, and H_c for input concepts correspondingly:

$$H_w = [h^w_1; h^w_2; \ldots; h^w_{n'}] \quad (1)$$
$$H_c = [h^c_1; h^c_2; \ldots; h^c_n] \quad (2)$$

The decoder yields an action sequence $a_1, a_2, \ldots, a_q$ as the output by calculating a sequence of hidden states $s_1, s_2 \ldots, s_q$ recurrently. While generating the t-th output action, the decoder considers three factors: (1) the previous hidden state of the LSTM model s_{t-1}; (2) the embedding of the previous generated action e_{t-1}; and (3) the previous context vectors for words μ^w_{t-1} and concepts μ^c_{t-1}, which are calculated using H_w and H_c, respectively. When $t = 1$, we initialize μ_0 as a zero vector, and set e_0 to the embedding of the start token "$\langle s \rangle$". The hidden state s_0 is initialized as:

$$s_0 = W_d[\overleftarrow{h}^{w}_{1}; \overrightarrow{h}^{w}_{n}; \overleftarrow{h}^{c}_{1}; \overrightarrow{h}^{c}_{n}] + b_d,$$

where W_d and b_d are model parameters.

For each time-step t, the decoder feeds the concatenation of the embedding of previous action e_{t-1} and the previous context vectors for words μ^w_{t-1} and concepts μ^c_{t-1} into the LSTM model to update its hidden state.

$$s_t = \text{LSTM}(s_{t-1}, [e_{t-1}; \mu^w_{t-1}; \mu^c_{t-1}]) \quad (3)$$

Then the attention probabilities for the word sequence and the concept sequence are calculated similarly. Take the word sequence as an example, $\alpha^w_{t,i}$ on $h^w_i \in H_w$ for time-step t is calculated as:

$$\epsilon_{t,i} = v_c^T \tanh(W_h h^w_i + W_s s_t + b_c)$$
$$\alpha^w_{t,i} = \frac{\exp(\epsilon_{t,i})}{\sum_{j=1}^{N} \exp(\epsilon_{t,j})}$$

W_h, W_s, v_c and b_c are model parameters. The new context vector $\mu^w_t = \sum_{i=1}^{n} \alpha^w_{t,i} h^w_i$. The calculation of μ^c_t follows the same procedure, but with a different set of model parameters.

The output probability distribution over all actions at the current state is calculated by:

$$P_{\Sigma_a} = \text{softmax}(V_a[s_t; \mu^w_t; \mu^c_t] + b_a), \quad (4)$$

where V_a and b_a are learnable parameters, and the number of rows in V_a represents the number of all actions. The symbol Σ_a is the set of all actions.

3.3 Monotonic Hard Attention for Transition Systems

When we process each buffer input, the next few transition actions are closely related to this input position. The buffer maintains the order information of the input sequence and is processed strictly left-to-right, which essentially encodes a monotone alignment between the transition action sequence and the input sequence.

As we have generated a concept sequence from the input word sequence, we maintain two hard attention pointers, l_w and l_c, to model monotonic attention to word and concept sequences respectively. The update to the decoder state now relies on a single position of each input sequence in contrast to Equation 3:

$$s_t = \text{LSTM}(s_{t-1}, [e_{t-1}; h^w_{l_w}; h^c_{l_c}]) \quad (5)$$

Control Mechanism. Both pointers are initialized as 0 and advanced to the next position deterministically. We move the concept attention focus l_c to the next position after arc decisions to all the other $m - 1$ cache concepts are made. We move the word attention focus l_w to its aligned position in case the new concept is aligned, otherwise we don't move the word focus. As shown in Figure 4, after we have made arc decisions from concept *want-01* to the other cache concepts, we move the concept focus to the next concept *go-01*. As this concept is aligned, we move the word focus to its aligned position *go* in the word sequence and skip the unaligned word *to*.

3.4 Transition State Features for Decoder

Another difference of our model with Buys and Blunsom (2017) is that we extract features from the current transition state configuration C_t:

$$e_f(C_t) = [e_{f_1}(C_t); e_{f_2}(C_t); \cdots ; e_{f_l}(C_t)]$$

where l is the number of features extracted from C_t and $e_{f_k}(C_t)$ $(k = 1, \ldots, l)$ represents the embedding for the k-th feature, which is learned during training. These feature embeddings are concatenated as $e_f(C_t)$, and fed as additional input to the decoder. For the soft attention decoder:

$$s_t = \text{LSTM}(s_{t-1}, [e_{t-1}; \mu^w_{t-1}; \mu^c_{t-1}; e_f(C_t)])$$

and for the hard attention decoder:

$$s_t = \text{LSTM}(s_{t-1}, [e_{t-1}; h^w_{l_w}; h^c_{l_c}; e_f(C_t)])$$

We use the following features in our experiments:

1. Phase type: indicator features showing which phase the next transition is.
2. ShiftOrPop features: *token features*[3] for the rightmost cache concept and the leftmost buffer concept. Number of dependencies to words on the right, and the top three dependency labels for them.
3. ArcBinary or ArcLabel features: token features for the rightmost concept and the current cache concept it makes arc decisions to. Word, concept and dependency distance between the two concepts. The labels for the two most recent outgoing arcs for these two concepts and their first incoming arc and the number of incoming arcs. Dependency label between the two positions if there is a dependency arc between them.
4. PushIndex features: token features for the leftmost buffer concept and all the concepts in the cache.

The phase type features are deterministic from the last action output. For example, if the last action output is *Shift*, the current phase type would be *PushIndex*. We only extract corresponding features for this phase and fill all the other feature types with *-NULL-* as placeholders. The features for other phases are similar.

[3]Concept, concept category at the specified position in concept sequence. And the word, lemma, POS tag at the aligned input position.

4 AMR Parsing

4.1 Training and Decoding

We train our models using the cross-entropy loss, over each oracle action sequence $a^*_1, \ldots, a^*_q$:

$$L = -\sum_{t=1}^{q} \log P(a^*_t | a^*_1, \ldots, a^*_{t-1}, X; \theta), \quad (6)$$

where X represents the input word and concept sequences, and θ is the model parameters. Adam (Kingma and Ba, 2014) with a learning rate of 0.001 is used as the optimizer, and the model that yields the best performance on the dev set is selected to evaluate on the test set. Dropout with rate 0.3 is used during training. Beam search with a beam size of 10 is used for decoding. Both training and decoding use a Tesla K20X GPU.

Hidden state sizes for both encoder and decoder are set to 100. The word embeddings are initialized from Glove pretrained word embeddings (Pennington et al., 2014) on Common Crawl, and are not updated during training. The embeddings for POS tags and features are randomly initialized, with the sizes of 20 and 50, respectively.

4.2 Preprocessing and Postprocessing

As the AMR data is very sparse, we collapse some subgraphs or spans into categories based on the alignment. We define some special categories such as named entities (*NE*), dates (*DATE*), single rooted subgraphs involving multiple concepts (*MULT*)[4], numbers (*NUMBER*) and phrases (*PHRASE*). The phrases are extracted based on the multiple-to-one alignment in the training data. One example phrase is *more than* which aligns to a single concept *more-than*. We first collapse spans and subgraphs into these categories based on the alignment from the JAMR aligner (Flanigan et al., 2014), which greedily aligns a span of words to AMR subgraphs using a set of heuristics. This categorization procedure enables the parser to capture mappings from continuous spans on the sentence side to connected subgraphs on the AMR side.

We use the semi-Markov model from Flanigan et al. (2016) as the concept identifier, which jointly segments the sentence into a sequence of spans and maps each span to a subgraph. During decoding, our output has categories, and we need to map

[4]For example, verbalization of "teacher" as "(person :ARG0-of teach-01)", or "minister" as "(person :ARG0-of (have-org-role-91 :ARG2 minister))".

	ShiftOrPop	PushIndex	ArcBinary	ArcLabel
Peng et al. (2018)	0.87	**0.87**	0.83	**0.81**
Soft+feats	0.93	0.84	0.91	0.75
Hard+feats	**0.94**	0.85	**0.93**	0.77

Table 1: Performance breakdown of each transition phase.

each category to the corresponding AMR concept or subgraph. We save a table Q which shows the original subgraph each category is collapsed from, and map each category to its original subgraph representation. We also use heuristic rules to generate the target-side AMR subgraph representation for *NE*, *DATE*, and *NUMBER* based on the source side tokens.

5 Experiments

We evaluate our system on the released dataset (LDC2015E86) for SemEval 2016 task 8 on meaning representation parsing (May, 2016). The dataset contains 16,833 training, 1,368 development, and 1,371 test sentences which mainly cover domains like newswire, discussion forum, etc. All parsing results are measured by Smatch (version 2.0.2) (Cai and Knight, 2013).

5.1 Experiment Settings

We categorize the training data using the automatic alignment and dump a template for date entities and frequent phrases from the multiple to one alignment. We also generate an alignment table from tokens or phrases to their candidate target-side subgraphs. For the dev and test data, we first extract the named entities using the Illinois Named Entity Tagger (Ratinov and Roth, 2009) and extract date entities by matching spans with the date template. We further categorize the dataset with the categories we have defined. After categorization, we use Stanford CoreNLP (Manning et al., 2014) to get the POS tags and dependencies of the categorized dataset. We run the oracle algorithm separately for training and dev data (with alignment) to get the statistics of individual phases. We use a cache size of 5 in our experiments.

5.2 Results

Individual Phase Accuracy We first evaluate the prediction accuracy of individual phases on the dev oracle data assuming gold prediction history. The four transition phases *ShiftOrPop*, *PushIndex*, *ArcBinary*, and *ArcLabel* account for 25%, 12.5%, 50.1%, and 12.4% of the total transition actions respectively. Table 1 shows the phase-wise accuracy of our sequence-to-sequence model. Peng et al. (2018) use a separate feedforward network to predict each phase independently. We use the same alignment from the SemEval dataset as in Peng et al. (2018) to avoid differences resulting from the aligner. *Soft+feats* shows the performance of our sequence-to-sequence model with soft attention and transition state features, while *Hard+feats* is using hard attention. We can see that the hard attention model outperforms the soft attention model in all phases, which shows that the single-pointer attention finds more relevant information than the soft attention on the relatively small dataset. The sequence-to-sequence models perform better than the feedforward model of Peng et al. (2018) on *ShiftOrPop* and *ArcBinary*, which shows that the whole-sentence context information is important for the prediction of these two phases. On the other hand, the sequence-to-sequence models perform worse than the feedforward models on *PushIndex* and *ArcLabel*. One possible reason is that the model tries to optimize the overall accuracy, while these two phases account for fewer than 25% of the total transition actions and might be less attended to during the update.

Impact of Different Components Table 2 shows the impact of different components for the sequence-to-sequence model. We can see that the transition state features play a very important role for predicting the correct transition action. This is because different transition phases have very different prediction behaviors and need different types of local information for the prediction. Relying on the sequence-to-sequence model alone does not perform well in disambiguating these choices, while the transition state can enforce direct constraints. We can also see that while the hard attention only attends to one position of the input, it performs slightly better than the soft attention model, while the time complexity is lower.

Impact of Different Cache Sizes The cache size of the transition system can be optimized as a trade-off between coverage of AMR graphs and the prediction accuracy. While larger cache size increases the coverage of AMR graphs, it complicates the prediction procedure with more cache decisions to make. From Table 3 we can see that

System	P	R	F
Soft	0.55	0.51	0.53
Soft+feats	0.69	0.63	0.66
Hard+feats	0.70	0.64	0.67

Table 2: Impact of various components for the sequence-to-sequence model (dev).

Cache Size	P	R	F
4	0.69	0.63	0.66
5	0.70	0.64	0.67
6	0.69	0.64	0.66

Table 3: Impact of cache size for the sequence-to-sequence model, hard attention (dev).

the hard attention model performs best with cache size 5. The soft attention model also achieves best performance with the same cache size.

Comparison with other Parsers Table 4 shows the comparison with other AMR parsers. The first three systems are some competitive neural models. We can see that our parser significantly outperforms the sequence-to-action-sequence model of Buys and Blunsom (2017). Konstas et al. (2017) use a linearization approach that linearizes the AMR graph to a sequence structure and use self-training on 20M unlabeled Gigaword sentences. Our model achieves better results without using additional unlabeled data, which shows that relevant information from the transition system is very useful for the prediction. Our model also outperforms the stack-LSTM model by Ballesteros and Al-Onaizan (2017), while their model is evaluated on the previous release of LDC2014T12.

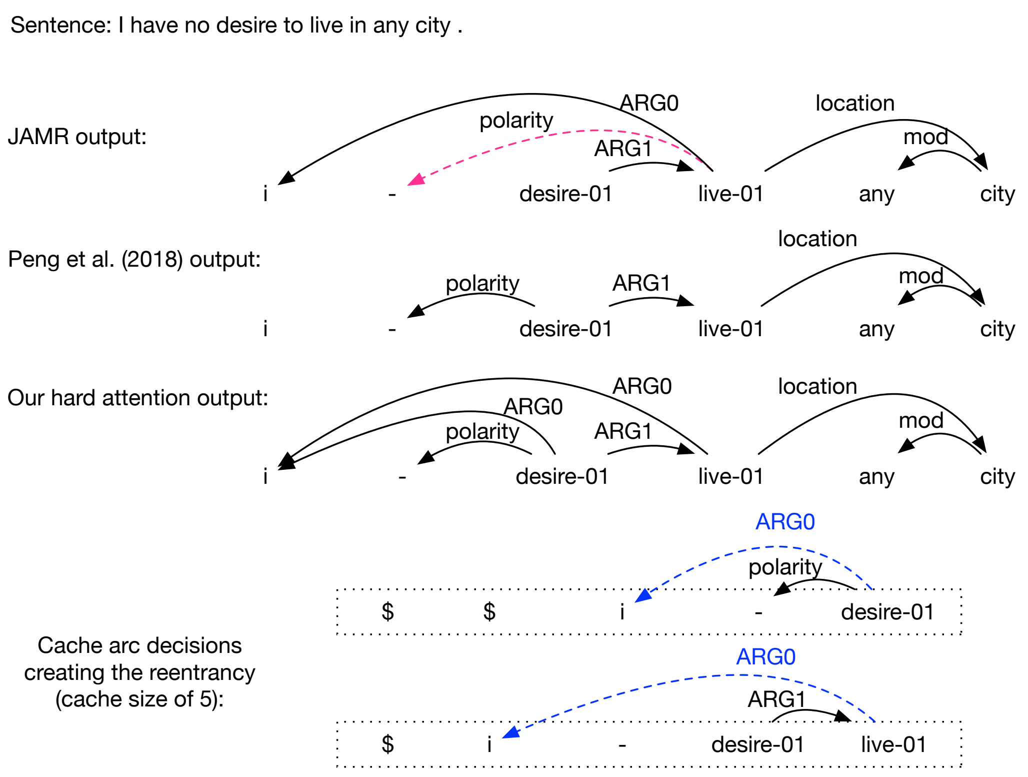
Table 5: Reentrancy statistics.

We also show the performance of some of the best-performing models. While our hard attention achieves slightly lower performance in comparison with Wang et al. (2015a) and Wang and Xue (2017), it is worth noting that their approaches of using WordNet, semantic role labels and word cluster features are complimentary to ours. The alignment from the aligner and the concept identification identifier also play an important role for improving the performance. Wang and Xue (2017) propose to improve AMR parsing by improving the alignment and concept identification, which can also be combined with our system to improve the performance of a sequence-to-sequence model.

Dealing with Reentrancy Reentrancy is an important characteristic of AMR, and we evaluate the Smatch score only on the reentrant edges following Damonte et al. (2017). From Table 5 we can see that our hard attention model significantly outperforms the feedforward model of Peng et al. (2018) in predicting reentrancies. This is because predicting reentrancy is directly related to the *ArcBinary* phase of the cache transition system since it decides to make multiple arc decisions to the same vertex, and we can see from Table 1 that the hard attention model has significantly better prediction accuracy in this phase. We also compare the reentrancy results of our transition system with two other systems, Damonte et al. (2017) and JAMR, where these statistics are available. From Table 5, we can see that our cache transition system slightly outperforms these two systems in predicting reentrancies.

Figure 5 shows a reentrancy example where JAMR and the feedforward network of Peng et al. (2018) do not predict well, while our system predicts the correct output. JAMR fails to predict the reentrancy arc from *desire-01* to *i*, and connects the wrong arc from "live-01" to "-" instead of from "desire-01". The feedforward model of Peng et al. (2018) fails to predict the two arcs from *desire-01*



Sentence: I have no desire to live in any city .

any
city
$

Figure 5: An example showing how our system predicts the correct reentrancy.

and *live-01* to *i*. This error is because their feed-forward ArcBinary classifier does not model long-term dependency and usually prefers making arcs between words that are close and not if they are distant. Our classifier, which encodes both word and concept sequence information, can accurately predict the reentrancy through the two arc decisions shown in Figure 5. When *desire-01* and *live-01* are shifted into the cache respectively, the transition system makes a left-going arc from each of them to the same concept *i*, thus creating the reentrancy as desired.

6 Conclusion

In this paper, we have presented a sequence-to-action-sequence approach for cache transition systems and applied it to AMR parsing. To address the data sparsity issue for neural AMR parsing, we show that the transition state features are very helpful in constraining the possible output and improving the performance of sequence-to-sequence models. We also show that the monotonic hard attention model can be generalized to the transition-based framework and outperforms the soft attention model when limited data is available. While we are focused on AMR parsing in this paper, in future work our cache transition system and the presented sequence-to-sequence models can be potentially applied to other semantic graph parsing tasks (Oepen et al., 2015; Du et al., 2015; Zhang et al., 2016; Cao et al., 2017).

Batch IS NOT Heavy: Learning Word Representations From All Samples

Abstract

Stochastic Gradient Descent (SGD) with negative sampling is the most prevalent approach to learn word representations. However, it is known that sampling methods are biased especially when the sampling distribution deviates from the true data distribution. Besides, SGD suffers from dramatic fluctuation due to the one-sample learning scheme. In this work, we propose AllVec that uses batch gradient learning to generate word representations from *all* training samples. Remarkably, the time complexity of AllVec remains at the same level as SGD, being determined by the number of positive samples rather than all samples. We evaluate AllVec on several benchmark tasks. Experiments show that AllVec outperforms sampling-based SGD methods with comparable efficiency, especially for small training corpora.

1 Introduction

Representing words using dense and real-valued vectors, aka word embeddings, has become the cornerstone for many natural language processing (NLP) tasks, such as document classification (Sebastiani, 2002), parsing (Huang et al., 2012), discourse relation recognition (Lei et al., 2017) and named entity recognition (Turian et al., 2010). Word embeddings can be learned by optimizing that words occurring in similar contexts have similar embeddings, i.e. the well-known distributional hypothesis (Harris, 1954). A representative method is skip-gram (SG) (Mikolov et al., 2013a,b), which realizes the hypothesis using a shallow neural network model. The other family of methods is count-based, such as GloVe (Pennington et al., 2014) and LexVec (Salle et al., 2016a,b), which exploit low-rank models such as matrix factorization (MF) to learn embeddings by reconstructing the word co-occurrence statistics.

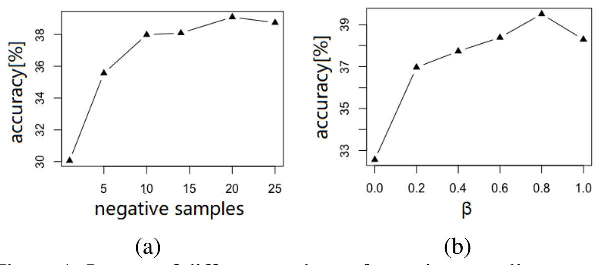

Figure 1: Impact of different settings of negative sampling on skip-gram for the word analogy task on Text8. Clearly, the accuracy depends largely on (a) the sampling size of negative words, and (b) the sampling distribution ($\beta = 0$ means the uniform distribution and $\beta = 1$ means the word frequency distribution).

By far, most state-of-the-art embedding methods rely on SGD and negative sampling for optimization. However, the performance of SGD is highly sensitive to the sampling distribution and the number of negative samples (Chen et al., 2018; Yuan et al., 2016), as shown in Figure 1. Essentially, sampling is biased, making it difficult to converge to the same loss with all examples, regardless of how many update steps have been taken. Moreover, SGD exhibits dramatic fluctuation and suffers from overshooting on local minimums (Ruder, 2016). These drawbacks of SGD can be attributed to its one-sample learning scheme, which updates parameters based on one training sample in each step.

To address the above-mentioned limitations of SGD, a natural solution is to perform exact (full) batch learning. In contrast to SGD, batch learning does not involve any sampling procedure and computes the gradient over all training samples. As such, it can easily converge to a better optimum in a more stable way. Nevertheless, a well-known

*The first two authors contributed equally to this paper and share the first-authorship.

difficulty in applying full batch learning lies in the expensive computational cost for large-scale data. Taking the word embedding learning as an example, if the vocabulary size is $|V|$, then evaluating the loss function and computing the full gradient takes $O(|V|^2 k)$ time, where k is the embedding size. This high complexity is unaffordable in practice, since $|V|^2$ can easily reach billion level or even higher.

In this paper, we introduce AllVec, an exact and efficient word embedding method based on full batch learning. To address the efficiency challenge in learning from all training samples, we devise a regression-based loss function for word embedding, which allows fast optimization with memorization strategies. Specifically, the acceleration is achieved by reformulating the expensive loss over all negative samples using a *partition* and a *decouple* operation. By decoupling and caching the bottleneck terms, we succeed to use all samples for each parameter update in a manageable time complexity which is mainly determined by the positive samples. The main contributions of this work are summarized as follows:

- We present a fine-grained weighted least square loss for learning word embeddings. Unlike GloVe, it explicitly accounts for all negative samples and reweights them with a frequency-aware strategy.
- We propose an efficient and exact optimization algorithm based on full batch gradient optimization. It has a comparable time complexity with SGD, but being more effective and stable due to the consideration of all samples in each parameter update.
- We perform extensive experiments on several benchmark datasets and tasks to demonstrate the effectiveness, efficiency, and convergence property of our AllVec method.

2 Related Work

2.1 Skip-gram with Negative Sampling

Mikolov et al. (2013a,b) proposed the skip-gram model to learn word embeddings. SG formulates the problem as a predictive task, aiming at predicting the proper context c for a target word w within a local window. To speed up the training process, it applies the negative sampling (Mikolov et al., 2013b) to approximate the full softmax. That is, each positive (w, c) pair is trained with n randomly sampled negative pairs (w, w_i). The sampled loss function of SG is defined as

$$L_{wc}^{SG} = \log \sigma(U_w \tilde{U}_c^T) + \sum_{i=1}^{n} \mathbf{E}_{w_i \sim P_n(w)} \log \sigma(-U_w \tilde{U}_{w_i}^T)$$

where U_w and $\tilde{U}_c$ denote the k-dimensional embedding vectors for word w and context c. $P_n(w)$ is the distribution from which negative context w_i is sampled.

Plenty of research has been done based on SG, such as the use of prior knowledge from another source (Kumar and Araki, 2016; Liu et al., 2015a; Bollegala et al., 2016), incorporating word type information (Cao and Lu, 2017; Niu et al., 2017), character level n-gram models (Bojanowski et al., 2016; Joulin et al., 2016) and jointly learning with topic models like LDA (Shi et al., 2017; Liu et al., 2015b).

2.2 Importance of the Sampling Distribution

Mikolov et al. (2013b) showed that the unigram distribution raised to the 3/4th power as $P_n(w)$ significantly outperformed both the unigram and the uniform distribution. This suggests that the sampling distribution (of negative words) has a great impact on the embedding quality. Furthermore, Chen et al. (2018) and Guo et al. (2018) recently found that replacing the original sampler with adaptive samplers could result in better performance. The adaptive samplers are used to find more informative negative examples during the training process. Compared with the original word-frequency based sampler, adaptive samplers adapt to both the target word and the current state of the model. They also showed that the fine-grained samplers not only speeded up the convergence but also significantly improved the embedding quality. Similar observations were also found in other fields like collaborative filtering (Yuan et al., 2016). While being effective, it is proven that negative sampling is a biased approximation and does not converges to the same loss as the full softmax — regardless of how many update steps have been taken (Bengio and Senécal, 2008; Blanc and Rendle, 2017).

2.3 Count-based Embedding Methods

Another line of research is the count-based embedding, such as GloVe (Pennington et al., 2014). GloVe performs a biased MF on the word-context co-occurrence statistics, which is a common approach in the field of collaborative filtering (Koren, 2008). However, GloVe only formulates the loss on positive entries of the co-occurrence matrix, meaning that negative signals about word-context co-occurrence are discarded. A remedy solution is LexVec (Salle et al., 2016a,b) which integrates negative sampling into MF. Some other methods (Li et al., 2015; Stratos et al., 2015; Ailem et al., 2017) also use MF to approximate the word-context co-occurrence statistics. Although predictive models and count-based models seem different at first glance, Levy and Goldberg (2014) proved that SG with negative sampling is implicitly factorizing a shifted pointwise mutual information (PMI) matrix, which means that the two families of embedding models resemble each other to a certain degree.

Our proposed method departs from all above methods by using the full batch gradient optimizer to learn from all (positive and negative) samples. We propose a fast learning algorithm to show that such batch learning is not "heavy" even with tens of billions of training examples.

3 AllVec Loss

In this work, we adopt the regression loss that is commonly used in count-based models (Pennington et al., 2014; Stratos et al., 2015; Ailem et al., 2017) to perform matrix factorization on word co-occurrence statistics. As highlighted, to retain the modeling fidelity, AllVec eschews using any sampling but optimizes the loss on all positive and negative word-context pairs.

Given a word w and a symmetric window of win contexts, the set of positive contexts can be obtained by sliding through the corpus. Let c denote a specific context, M_{wc} be the number of co-occurred (w,c) pairs in the corpus within the window. $M_{wc}=0$ means that the pair (w,c) has never been observed, i.e. the negative signal. r_{wc} is the association coefficient between w and c, which is calculated from M_{wc}. Specifically, we use r^{+}_{wc} to denote the ground truth value for positive (w,c) pairs and a constant value r^{-}(e.g., 0 or -1) for negative ones since there is no interaction between w and c in negative pairs. Finally, with all positive and negative pairs considered, a regular loss function can be given as Eq.(1), where V is the vocabulary and S is the set of positive pairs. α^{+}_{wc} and α^{-}_{wc} represent the weight for positive and negative (w,c) pairs, respectively.

$$L = \underbrace{\sum_{(w,c)\in S} \alpha^{+}_{wc}(r^{+}_{wc} - U_w\tilde{U}_c^T)^2}_{L_P} + \underbrace{\sum_{(w,c)\in(V\times V)\setminus S} \alpha^{-}_{wc}(r^{-} - U_w\tilde{U}_c^T)^2}_{L_N} \tag{1}$$

When it comes to r^{+}_{wc}, there are several choices. For example, GloVe applies the log of M_{wc} with bias terms for w and c. However, research from Levy and Goldberg (2014) showed that the SG model with negative sampling implicitly factorizes a shifted PMI matrix. The PMI value for a (w,c) pair can be defined as

$$PMI_{wc} = log\frac{P(w,c)}{P(w)P(c)} = log\frac{M_{wc}M_{**}}{M_{w*}M_{*c}} \tag{2}$$

where '*' denotes the summation of all corresponding indexes (e.g., $M_{w*}=\sum_{c\in V} M_{wc}$). Inspired by this connection, we set r^{+}_{wc} as the positive point-wise mutual information (PPMI) which has been commonly used in the NLP literature (Stratos et al., 2015; Levy and Goldberg, 2014). Sepcifically, PPMI is the positive version of PMI by setting the negative values to zero. Finally, r^{+}_{wc} is defined as

$$r^{+}_{wc} = PPMI_{wc} = \max(PMI_{wc}, 0) \tag{3}$$

3.1 Weighting Strategies

Regarding α^{+}_{wc}, we follow the design in GloVe, where it is defined as

$$\alpha^{+}_{wc} = \begin{cases} (M_{wc}/xmax)^{\rho} & M_{wc} < xmax \\ 1 & M_{wc} \geq xmax \end{cases} \tag{4}$$

As for the weight for negative instances α^{-}_{wc}, considering that there is no interaction between w and negative c, we set α^{-}_{wc} as α^{-}_{c} (or α^{-}_{w}), which means that the weight is determined by the word itself rather than the word-context interaction. Note that either $\alpha^{-}_{wc} = \alpha^{-}_{c}$ or $\alpha^{-}_{wc} = \alpha^{-}_{w}$ does not influence the complexity of AllVec learning algorithm described in the next section. The design of α^{-}_{c} is inspired by the frequency-based oversampling scheme in skip-gram and missing data reweighting in recommendation (He et al., 2016). The intuition is that a word with high frequency is more likely to be a true negative context word if there is no observed word-context interactions. Hence, to effectively differentiate the positive and negative examples, we assign a higher weight for the negative examples that have a higher word frequency, and a smaller weight for infrequent words. Formally, α^-_{wc} is defined as

$$\alpha^-_{wc} = \alpha^-_c = \alpha_0 \frac{M^\delta_{*c}}{\sum_{c\in V} M^\delta_{*c}} \tag{5}$$

where α_0 can be seen as a global weight to control the overall importance of negative samples. $\alpha_0 = 0$ means that no negative information is utilized in the training. The exponent δ is used for smoothing the weights. Specially, $\delta = 0$ means a uniform weight for all negative examples and $\delta = 1$ means that no smoothing is applied.

4 Fast Batch Gradient Optimization

Once specifying the loss function, the main challenge is how to perform an efficient optimization for Eq.(1). In the following, we develop a fast batch gradient optimization algorithm that is based on a *partition* reformulation for the loss and a *decouple* operation for the inner product.

4.1 Loss Partition

As can be seen, the major computational cost in Eq.(1) lies in the term L_N, because the size of $(V\times V)\setminus S$ is very huge, which typically contains over billions of negative examples. To this end, we show our first key design that separates the loss of negative samples into the difference between the loss on all samples and that on positive samples[1]. The loss partition serves as the prerequisite for the efficient computation of full batch gradients.

$$L_N=\sum_{w\in V}\sum_{c\in V}\alpha^-_c(r^- - U_w\tilde{U}^T_c)^2 - \sum_{(w,c)\in S}\alpha^-_c(r^- - U_w\tilde{U}^T_c)^2 \tag{6}$$

By replacing L_N in Eq.(1) with Eq.(6), we can obtain a new loss function with a more clear structure. We further simplify the loss function by merging the terms on positive examples. Finally, we achieve a reformulated loss

$$L = \underbrace{\sum_{w\in V}\sum_{c\in V}\alpha^-_c(r^- - U_w\tilde{U}^T_c)^2}_{L_A} + \underbrace{\sum_{(w,c)\in S}(\alpha^+_{wc} - \alpha^-_c)(\Delta - U_w\tilde{U}^T_c)^2}_{L_{P'}} + C \tag{7}$$

where $\Delta = (\alpha^+_{wc}r^+_{wc} - \alpha^-_c r^-)/(\alpha^+_{wc} - \alpha^-_c)$. It can be seen that the new loss function consists of two components: the loss L_A on the whole $V \times V$ training examples and $L_{P'}$ on positive examples. The major computation now lies in L_A which has a time complexity of $O(k|V|^2)$. In the following, we show how to reduce the huge volume of computation by a simple mathematical decouple.

[1]The idea here is similar to that used in (He et al., 2016; Li et al., 2016) for a different problem.

4.2 Decouple

To clearly show the *decouple* operation, we rewrite L_A as $\widetilde{L}_A$ by omitting the constant term $\alpha^-_c(r^-)^2$. Note that u_{wd} and $\tilde{u}_{cd}$ denote the d-th element in U_w and $\tilde{U}_c$, respectively.

$$\begin{aligned}\widetilde{L}_A = &\sum_{w\in V}\sum_{c\in V}\alpha^-_c\sum_{d=0}^{k}u_{wd}\tilde{u}_{cd}\sum_{d'=0}^{k}u_{wd'}\tilde{u}_{cd'}\\ &- 2r^-\sum_{w\in V}\sum_{c\in V}\alpha^-_c\sum_{d=0}^{k}u_{wd}\tilde{u}_{cd}\end{aligned} \tag{8}$$

Now we show our second key design that is based on a *decouple* manipulation for the inner product operation. Interestingly, we observe that the summation operator and elements in U_w and $\tilde{U}_c$ can be rearranged by the commutative property (Dai et al., 2007), as shown below.

$$\begin{aligned}\widetilde{L}_A = &\sum_{d=0}^{k}\sum_{d'=0}^{k}\sum_{w\in V}u_{wd}u_{wd'}\sum_{c\in V}\alpha^-_c\tilde{u}_{cd}\tilde{u}_{cd'}\\ &- 2r^-\sum_{d=0}^{k}\sum_{w\in V}u_{wd}\sum_{c\in V}\alpha^-_c\tilde{u}_{cd}\end{aligned} \tag{9}$$

An important feature in Eq.(9) is that the original inner product terms are disappeared, while in the new equation $\sum_{c\in V}\alpha^-_c\tilde{u}_{cd}\tilde{u}_{cd'}$ and $\sum_{c\in V}\alpha^-_c\tilde{u}_{cd}$ are "constant" values relative to $u_{wd}u_{wd'}$ and u_{wd} respectively. This means that they can be pre-calculated before training in each iteration. Specifically, we define $p^w_{dd'}$, $p^c_{dd'}$, q^w_d and q^c_d as the pre-calculated terms

$$\begin{aligned}p^w_{dd'} &= \sum_{w\in V}u_{wd}u_{wd'} & q^w_d &= \sum_{w\in V}u_{wd}\\ p^c_{dd'} &= \sum_{c\in V}\alpha^-_c\tilde{u}_{cd}\tilde{u}_{cd'} & q^c_d &= \sum_{c\in V}\alpha^-_c\tilde{u}_{cd}\end{aligned} \tag{10}$$

Then the computation of $\tilde{L}_A$ can be simplified to $\sum_{d=0}^{k}\sum_{d'=0}^{k}p^w_{dd'}p^c_{dd'} - 2r^- q^w_d q^c_d$.

It can be seen that the time complexity to compute all $p^w_{dd'}$ is $O(|V|k^2)$, and similarly, $O(|V|k^2)$ for $p^c_{dd'}$ and $O(|V|k)$ for q^w_d and q^c_d. With all terms pre-calculated before each iteration, the time complexity of computing $\tilde{L}_A$ is just $O(k^2)$. As a result, the total time complexity of computing L_A is decreased to $O(2|V|k^2+2|V|k+k^2) \approx O(2|V|k^2)$, which is much smaller than the original $O(k|V|^2)$. Moreover, it's worth noting that our efficient computation for $\widetilde{L}_A$ is strictly equal to its original value, which means AllVec does not introduce any approximation in evaluating the loss function.

Finally, we can derive the batch gradients for

u_{wd} and $\tilde{u}_{cd}$ as

$$\frac{\partial L}{\partial u_{wd}} = \sum_{d'=0}^{k} u_{wd'} p^{c}_{dd'} - \sum_{c \in I_w^+} \Lambda \cdot \tilde{u}_{cd} - r^- q^c_d$$

$$\frac{\partial L}{\partial \tilde{u}_{cd}} = \sum_{d'=0}^{k} \tilde{u}_{cd'} p^{w}_{dd'} \alpha_c^- - \sum_{w \in I_c^+} \Lambda \cdot u_{wd} - r^- \alpha_c^- q^w_d \tag{11}$$

where I_w^+ denotes the set of positive contexts for w, I_c^+ denotes the set of positive words for c and $\Lambda = (\alpha^+_{wc} - \alpha^-_c)(\Delta - U_w \tilde{U}_c^T)$. Algorithm 1 shows the training procedure of AllVec.

Algorithm 1 AllVec learning

```
Input: corpus $\mathbf{\Gamma}$, $win$, $\alpha_0$, $\delta$, $iter$, learning rate $\eta$
Output: embedding matrices $U$ and $\tilde{U}$
 1: Build vocabulary V from $\mathbf{\Gamma}$
 2: Obtain all positive $(w, c)$ and $M_{wc}$ from $\mathbf{\Gamma}$
 3: Compute all $r^+_{wc}$, $\alpha^+_{wc}$ and $\alpha^-_c$
 4: Initialize $U$ and $\tilde{U}$
 5: for $i = 1, ..., iter$ do
 6:     for $d \in \{0, .., k\}$ do
 7:         Compute and store $q^c_d$                 $\triangleright O(|V|k)$
 8:         for $d' \in \{0, .., k\}$ do
 9:             Compute and store $p^c_{dd'}$         $\triangleright O(|V|k^2)$
10:         end for
11:     end for
12:     for $w \in V$ do
13:         Compute $\Lambda$                         $\triangleright O(|S|k)$
14:         for $d \in \{0, .., k\}$ do
15:             Update $u_{wd}$                       $\triangleright O(|S|k + |V|k^2)$
16:         end for
17:     end for
18:     Repeat 6-17 for $\tilde{u}_{cd}$              $\triangleright O(2|S|k+2|V|k^2)$
19: end for
```

4.3 Time Complexity Analysis

In the following, we show that AllVec can achieve the same time complexity with negative sampling based SGD methods.

Given the sample size n, the total time complexity for SG is $O((n + 1)|S|k)$, where $n + 1$ denotes n negative samples and 1 positive example. Regarding the complexity of AllVec, we can see that the overall complexity of Algorithm 1 is $O(4|S|k + 4|V|k^2)$.

For the ease of discussion, we denote $\bar{c}$ as the average number of positive contexts for a word in the training corpus, i.e. $|S| = \bar{c}|V|$ ($\bar{c} \geq 1000$ in most cases). We then obtain the ratio

$$\frac{4|S|k + 4|V|k^2}{(n + 1)|S|k} = \frac{4}{n+1}(1 + \frac{k}{\bar{c}}) \tag{12}$$

where k is typically set from 100 to 300 (Mikolov et al., 2013a; Pennington et al., 2014), resulting in $k \leq \bar{c}$. Hence, we can give the lower and upper bound for the ratio:

$$\frac{4}{n+1} < \frac{4|S|k+4|V|k^2}{(n+1)|S|k} = \frac{4}{n+1}(1+\frac{k}{\bar{c}}) \leq \frac{8}{n+1} \tag{13}$$

The above analysis suggests that the complexity of AllVec is same as that of SGD with negative sample size between 3 and 7. In fact, considering that $\bar{c}$ is much larger than k in most datasets, the major cost of AllVec comes from the part $4|S|k$ (see Section 5.4 for details), which is linear with respect to the number of positive samples.

5 Experiments

We conduct experiments on three popular evaluation tasks, namely word analogy (Mikolov et al., 2013a), word similarity (Faruqui and Dyer, 2014) and QVEC (Tsvetkov et al., 2015).

Word analogy task. The task aims to answer questions like, "a is to b as c is to _?". We adopt the Google testbed[2] which contains 19,544 such questions in two categories: semantic and syntactic. The semantic questions are usually analogies about people or locations, like "king is to man as queen is to _?", while the syntactic questions focus on forms or tenses, e.g., "swimming is to swim as running to _?".

Word similarity tasks. We perform evaluation on six datasets, including MEN (Bruni et al., 2012), MC (Miller and Charles, 1991), RW (Luong et al., 2013), RG (Rubenstein and Goodenough, 1965), WS-353 Similarity (WSim) and Relatedness (WRel) (Finkelstein et al., 2001). We compute the spearman rank correlation between the similarity scores calculated based on the trained embeddings and human labeled scores.

QVEC. QVEC is an intrinsic evaluation metric of word embeddings based on the alignment to features extracted from manually crafted lexical resources. QVEC has shown strong correlation with the performance of embeddings in several semantic tasks (Tsvetkov et al., 2015).

We compare AllVec with the following word embedding methods.

- SG: This is the original skip-gram model with SGD and negative sampling (Mikolov et al., 2013a,b).
- SGA: This is the skip-gram model with an adaptive sampler (Chen et al., 2018).

[2]https://code.google.com/archive/p/word2vec/

Table 1: Corpora statistics.

Corpus	Tokens	Vocab	Size
Text8	17M	71K	100M
NewsIR	78M	83K	500M
Wiki-sub	0.8B	190K	4.0G
Wiki-all	2.3B	200K	13.4G

- GloVe: This method applies biased MF on the positive samples of word co-occurrence matrix (Pennington et al., 2014).
- LexVec: This method applies MF on the PPMI matrix. The optimization is done with negative sampling and mini-batch gradient descent (Salle et al., 2016b).

For all baselines, we use the original implementation released by the authors.

5.1 Datasets and Experimental Setup

We evaluate the performance of AllVec on four real-world corpora, namely Text8[3], NewsIR[4], Wiki-sub and Wiki-all. Wiki-sub is a subset of 2017 Wikipedia dump[5]. All corpora have been pre-processed by a standard pipeline (i.e. removing non-textual elements, lowercasing and tokenization). Table 1 summarizes the statistics of these corpora.

To obtain M_{wc} for positive (w, c) pairs, we follow GloVe where word pairs that are x words apart contribute $1/x$ to M_{wc}. The window size is set as $win = 8$. Regarding α_{wc}^{+}, we set $xmax = 100$ and $\rho = 0.75$. For a fair comparison, the embedding size k is set as 200 for all models and corpora. AllVec can be easily trained by AdaGrad (Zeiler, 2012) like GloVe or Newton-like (Bayer et al., 2017; Bradley et al., 2011) second order methods. For models based on negative sampling (i.e. SG, SGA and LexVec), the sample size is set as $n = 25$ for Text8, $n = 10$ for NewsIR and $n = 5$ for Wiki-sub and Wiki-all. The setting is also suggested by Mikolov et al. (2013b). Other detailed hyper-parameters are reported in Table 2.

5.2 Accuracy Comparison

We present results on the word analogy task in Table 2. As shown, AllVec achieves the highest total accuracy (Tot.) in all corpora, particularly in smaller corpora (Text8 and NewsIR). The reason is that in smaller corpora the number of positive (w, c) pairs is very limited, thus making use of negative examples will bring more benefits. Similar reason also explains the poor accuracy of GloVe in Text8, because GloVe does not consider negative samples. Even in the very large corpus (Wiki-all), ignoring negative samples still results in sub-optimal performance.

Our results also show that SGA achieves better performance than SG, which demonstrates the importance of a good sampling strategy. However, regardless what sampler (except the full softmax sampling) is utilized and how many updates are taken, sampling is still a biased approach. AllVec achieves the best performance because it is trained on the whole batch data for each parameter update rather than a fraction of sampled data.

Another interesting observation is AllVec performs better in semantic tasks in general. The reason is that our model utilizes global co-occurrence statistics, which capture more semantic signals than syntactic signals. While both AllVec and GloVe use global contexts, AllVec performs much better than GloVe in syntactic tasks. We argue that the main reason is because AllVec can distill useful signals from negative examples, while GloVe simply ignores all negative information. By contrast, local-window based methods, such as SG and SGA, are more effective to capture local sentence features, resulting in good performance on syntactic analogies. However, Rekabsaz et al. (2017) argues that these local-window based methods may suffer from the topic shifting issue.

Table 3 and Table 4 provide results in the word similarity and QVEC tasks. We can see that AllVec achieves the best performance in most tasks, which admits the advantage of batch learning with all samples. Interestingly, although GloVe performs well in semantic analogy tasks, it shows extremely worse results in word similarity and QVEC. The reason shall be the same as that it performs poorly in syntactic tasks.

5.3 Impact of α_c^-

In this subsection, we investigate the impact of the proposed weighting scheme for negative (context) words. We show the performance change of word analogy tasks on NewsIR in Figure 2 by tuning α_0 and δ. Results in other corpora show similar trends thus are omitted due to space limitation.

SG	1e-5	10	5	72.05	55.88	63.24	1e-5	10	5	73.91	61.91	67.37
SGA	6e-3	-	-	73.93	56.10	63.81	6e-3	-	-	75.11	61.94	67.92
GloVe	100	8	1	77.22	53.16	64.13	100	8	1	77.38	58.94	67.33
LexVec	1e-5	5	-	75.95	52.78	63.33	1e-5	5	-	76.31	56.83	65.48
AllVec	100	0.75	-	76.66	54.72	**64.75**	50	0.75	-	77.64	60.96	**68.52**

The parameter columns (para.) for each model are given from left to right as follows. SG: subsampling of frequent words, window size and the number of negative samples; SGA: λ (Chen et al., 2018) that controls the distribution of the rank, the other parameters are the same with SG; GloVe: $xmax$, window size and symmetric window; LexVec: subsampling of frequent words and the number of negative samples; AllVec: the negative weight α_0 and δ. Boldface denotes the highest total accuracy.

Figure 2(a) shows the impact of the overall weight α_0 by setting δ as 0.75 (inspired by the setting of skip-gram). Clearly, we observe that all results (including semantic, syntactic and total accuracy) have been greatly improved when α_0 increases from 0 to a larger value. As mentioned before, $\alpha_0 = 0$ means that no negative information is considered. This observation verifies that negative samples are very important for learning good embeddings. It also helps to explain why GloVe performs poorly on syntactic tasks. In addition, we find that in all corpora the optimal results are usually obtained when α_0 falls in the range of 50 to 400. For example, in the NewIR corpus as shown, AllVec achieves the best performance when $\alpha_0 = 100$. Figure 2(b) shows the impact of δ with $\alpha_0 = 100$. As mentioned before, $\delta = 0$ denotes a uniform value for all negative words and $\delta = 1$ denotes that no smoothing is applied to word frequency. We can see that the total accuracy is only around 55% when $\delta = 0$. By increasing its value, the performance is gradually improved, achieving the highest score when δ is around 0.8. Further increase of δ will degrade the total accuracy. This analysis demonstrates the effectiveness of the proposed negative weighting scheme.

5.4 Convergence Rate and Runtime

Figure 3(a) compares the convergence between AllVec and GloVe on NewsIR. Clearly, AllVec ex-

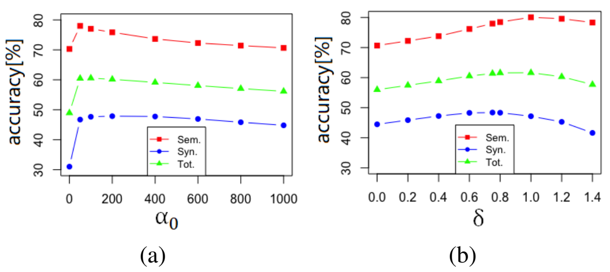

Figure 2: Effect of α_0 and δ on NewsIR.

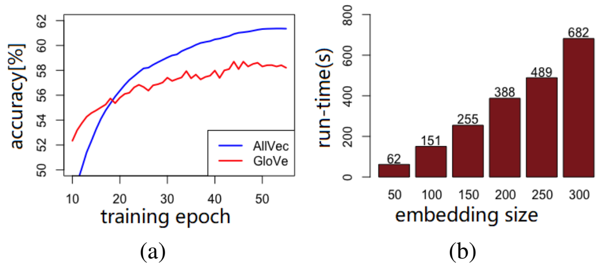

Figure 3: Convergence and runtime.

hibits a more stable convergence due to its full batch learning. In contrast, GloVe has a more dramatic fluctuation because of the one-sample learning scheme. Figure 3(b) shows the relationship between the embedding size k and runtime on NewsIR. Although the analysis in Section 4.3 demonstrates that the time complexity of AllVec is $O(4|S|k + 4|V|k^2)$, the actual runtime shows a near linear relationship with k. This is because $4|V|k^2/4|S|k = k/\bar{c}$, where $\bar{c}$ generally ranges from $1000 \sim 6000$ and k is set from 200 to 300 in practice. The above ratio explains the fact that $4|S|k$ dominates the complexity, which is linear

AllVec	388s	50	322m

SG-n represents n negative samples for skip-gram, SI represents the runtime for a single iteration, and Tot. denotes the total runtime. All models are of embedding size 200 and trained with 8 threads.

with k and $|S|$.

We also compare the overall runtime of AllVec and SG on NewsIR and show the results in Table 5. As can be seen, the runtime of AllVec falls in the range of SG-3 and SG-7 in a single iteration, which confirms the theoretical analysis in Section 4.3. In contrast with SG, AllVec needs more iterations to converge. The reason is that each parameter in SG is updated many times during each iteration, although only one training example is used in each update. Despite this, the total run time of AllVec is still in a feasible range. Assuming the convergence is measured by the number of parameter updates, our AllVec yields a much faster convergence rate than the one-sample SG method.

In practice, the runtime of our model in each iteration can be further reduced by increasing the number of parallel workers. Although baseline methods like SG and GloVe can also be parallelized, the stochastic gradient steps in these methods unnecessarily influence each other as there is no exact way to separate these updates for different workers. In other words, the parallelization of SGD is not well suited to a large number of workers. In contrast, the parameter updates in AllVec are completely independent of each other, therefore AllVec does not have the update collision issue. This means we can achieve the embarrassing parallelization by simply separating the updates by words; that is, letting different workers update the model parameters for disjoint sets of words. As such, AllVec can provide a near linear scaling without any approximation since there is no potential conflicts between updates.

6 Conclusion

In this paper, we presented AllVec, an efficient batch learning based word embedding model that is capable to leverage all positive and negative training examples without any sampling and approximation. In contrast with models based on SGD and negative sampling, AllVec shows more stable convergence and better embedding quality by the all-sample optimization. Besides, both theoretical analysis and experiments demonstrate that AllVec achieves the same time complexity with the classic SGD models. In future, we will extend our proposed all-sample learning scheme to deep learning methods, which are more expressive than the shallow embedding model. Moreover, we will integrate prior knowledge, such as the words that are synonyms and antonyms, into the word embedding process. Lastly, we are interested in exploring the recent adversarial learning techniques to enhance the robustness of word embeddings.

Backpropagating through Structured Argmax using a SPIGOT

Abstract

We introduce the **structured projection of intermediate gradients** optimization technique (SPIGOT), a new method for backpropagating through neural networks that include hard-decision structured predictions (e.g., parsing) in intermediate layers. SPIGOT requires no marginal inference, unlike structured attention networks (Kim et al., 2017) and some reinforcement learning-inspired solutions (Yogatama et al., 2017). Like so-called straight-through estimators (Hinton, 2012), SPIGOT defines gradient-like quantities associated with intermediate nondifferentiable operations, allowing backpropagation before and after them; SPIGOT's proxy aims to ensure that, after a parameter update, the intermediate structure will remain well-formed.

We experiment on two structured NLP pipelines: syntactic-then-semantic dependency parsing, and semantic parsing followed by sentiment classification. We show that training with SPIGOT leads to a larger improvement on the downstream task than a modularly-trained pipeline, the straight-through estimator, and structured attention, reaching a new state of the art on semantic dependency parsing.

1 Introduction

Learning methods for natural language processing are increasingly dominated by end-to-end differentiable functions that can be trained using gradient-based optimization. Yet traditional NLP often assumed modular stages of processing that formed a pipeline; e.g., text was tokenized, then tagged with parts of speech, then parsed into a phrase-structure or dependency tree, then semantically analyzed. Pipelines, which make "hard" (i.e., discrete) decisions at each stage, appear to be incompatible with neural learning, leading many researchers to abandon earlier-stage processing.

Inspired by findings that continue to see benefit from various kinds of linguistic or domain-specific preprocessing (He et al., 2017; Oepen et al., 2017; Ji and Smith, 2017), we argue that pipelines can be treated as layers in neural architectures for NLP tasks. Several solutions are readily available:

- Reinforcement learning (most notably the REINFORCE algorithm; Williams, 1992), and **structured attention** (SA; Kim et al., 2017). These methods replace argmax with a sampling or marginalization operation. We note two potential downsides of these approaches: (i) not all argmax-able operations have corresponding sampling or marginalization methods that are efficient, and (ii) inspection of intermediate outputs, which could benefit error analysis and system improvement, is more straightforward for hard decisions than for posteriors.
- The **straight-through estimator** (STE; Hinton, 2012) treats discrete decisions as if they were differentiable and simply passes through gradients. While fast and surprisingly effective, it ignores *constraints* on the argmax problem, such as the requirement that every word has exactly one syntactic parent. We will find, experimentally, that the quality of intermediate representations degrades substantially under STE.

This paper introduces a new method, the **structured projection of intermediate gradients** optimization technique (SPIGOT; §2), which defines a proxy for the gradient of a loss function with respect to the input to argmax. Unlike STE's gradient proxy, SPIGOT aims to respect the constraints in the argmax problem. SPIGOT can be applied with any intermediate layer that is expressible as a constrained maximization problem, and whose feasible set can be projected onto. We show empirically that SPIGOT works even when the maximization and the projection are done approximately.

We offer two concrete architectures that employ structured argmax as an intermediate layer: semantic parsing with syntactic parsing in the middle, and sentiment analysis with semantic parsing in the middle (§3). These architectures are trained using a joint objective, with one part using data for the intermediate task, and the other using data for the end task. The datasets are not assumed to overlap at all, but the parameters for the intermediate task are affected by both parts of the training data.

Our experiments (§4) show that our architecture improves over a state-of-the-art semantic dependency parser, and that SPIGOT offers stronger performance than a pipeline, SA, and STE. On sentiment classification, we show that semantic parsing offers improvement over a BiLSTM, more so with SPIGOT than with alternatives. Our analysis considers how the behavior of the intermediate parser is affected by the end task (§5). Our code is open-source and available at `https://github.com/Noahs-ARK/SPIGOT`.

2 Method

Our aim is to allow a (structured) argmax layer in a neural network to be treated almost like any other differentiable function. This would allow us to place, for example, a syntactic parser in the middle of a neural network, so that the forward calculation simply calls the parser and passes the parse tree to the next layer, which might derive syntactic features for the next stage of processing.

The challenge is in the *backward* computation, which is key to learning with standard gradient-based methods. When its output is discrete as we assume here, argmax is a piecewise constant function. At every point, its gradient is either zero or undefined. So instead of using the true gradient, we will introduce a *proxy* for the gradient of the loss function with respect to the inputs to argmax, allowing backpropagation to proceed through the argmax layer. Our proxy is designed as an improvement to earlier methods (discussed below) that completely ignore constraints on the argmax operation. It accomplishes this through a projection of the gradients.

We first lay out notation, and then briefly review max-decoding and its relaxation (§2.1). We define SPIGOT in §2.2, and show how to use it to backpropagate through NLP pipelines in §2.3.

Notation. Our discussion centers around two tasks: a structured *intermediate* task followed by an *end* task, where the latter considers the outputs of the former (e.g., syntactic-then-semantic parsing). Inputs are denoted as $\mathbf{x}$, and end task outputs as $\mathbf{y}$. We use $\mathbf{z}$ to denote intermediate structures derived from $\mathbf{x}$. We will often refer to the intermediate task as "decoding", in the structured prediction sense. It seeks an output $\hat{\mathbf{z}} = \operatorname{argmax}_{\mathbf{z}\in\mathcal{Z}} S$ from the feasible set $\mathcal{Z}$, maximizing a (learned, parameterized) scoring function S for the structured intermediate task. L denotes the loss of the end task, which may or may not also involve structured predictions. We use $\Delta^{k-1} = \{\mathbf{p} \in \mathbb{R}^k \mid \mathbf{1}^\top\mathbf{p} = 1, \mathbf{p} \geq \mathbf{0}\}$ to denote the $(k-1)$-dimensional simplex. We denote the domain of binary variables as $\mathbb{B} = \{0, 1\}$, and the unit interval as $\mathbb{U} = [0, 1]$. By projection of a vector $\mathbf{v}$ onto a set $\mathcal{A}$, we mean the closest point in $\mathcal{A}$ to $\mathbf{v}$, measured by Euclidean distance: $\operatorname{proj}_{\mathcal{A}}(\mathbf{v}) = \operatorname{argmin}_{\mathbf{v}'\in\mathcal{A}} \|\mathbf{v}' - \mathbf{v}\|_2$.

2.1 Relaxed Decoding

Decoding problems are typically decomposed into a collection of "parts", such as arcs in a dependency tree or graph. In such a setup, each element of $\mathbf{z}$, z_i, corresponds to one possible part, and z_i takes a boolean value to indicate whether the part is included in the output structure. The scoring function S is assumed to decompose into a vector $\mathbf{s}(\mathbf{x})$ of part-local, input-specific scores:

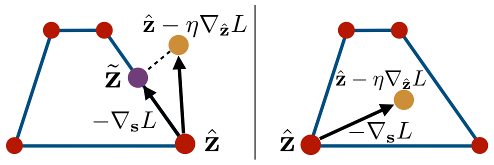
$$\hat{\mathbf{z}} = \operatorname*{argmax}_{\mathbf{z}\in\mathcal{Z}} S(\mathbf{x}, \mathbf{z}) = \operatorname*{argmax}_{\mathbf{z}\in\mathcal{Z}} \mathbf{z}^\top \mathbf{s}(\mathbf{x}) \tag{1}$$

In the following, we drop $\mathbf{s}$'s dependence on $\mathbf{x}$ for clarity.

In many NLP problems, the output space $\mathcal{Z}$ can be specified by linear constraints (Roth and Yih, 2004):

$$\mathbf{A}\begin{bmatrix}\mathbf{z}\\ \boldsymbol{\psi}\end{bmatrix} \leq \mathbf{b}, \tag{2}$$

where $\boldsymbol{\psi}$ are auxiliary variables (also scoped by argmax), together with integer constraints (typically, each $z_i \in \mathbb{B}$).



$\hat{\mathbf{z}} - \eta\nabla_{\hat{\mathbf{z}}}L$
$\tilde{\mathbf{z}}$
$-\nabla_{\mathbf{s}}L$
$\hat{\mathbf{z}}$
$\hat{\mathbf{z}} - \eta\nabla_{\hat{\mathbf{z}}}L$
$-\nabla_{\mathbf{s}}L$
$\hat{\mathbf{z}}$

Figure 1: The original feasible set $\mathcal{Z}$ (red vertices), is relaxed into a convex polytope $\mathcal{P}$ (the area encompassed by blue edges). Left: making a gradient update to $\hat{\mathbf{z}}$ makes it step outside the polytope, and it is projected back to $\mathcal{P}$, resulting in the projected point $\tilde{\mathbf{z}}$. $\nabla_{\mathbf{s}}L$ is then along the edge. Right: updating $\hat{\mathbf{z}}$ keeps it within $\mathcal{P}$, and thus $\nabla_{\mathbf{s}}L = \eta\nabla_{\hat{\mathbf{z}}}L$.

The problem in Equation 1 can be NP-complete in general, so the $\{0,1\}$ constraints are often relaxed to $[0,1]$ to make decoding tractable (Martins et al., 2009). Then the discrete combinatorial problem over $\mathcal{Z}$ is transformed into the optimization of a linear objective over a convex polytope $\mathcal{P}=\{\mathbf{p} \in \mathbb{R}^d | \mathbf{A}\mathbf{p} \leq \mathbf{b}\}$, which is solvable in polynomial time (Bertsimas and Tsitsiklis, 1997). This is not necessary in some cases, where the argmax can be solved exactly with dynamic programming.

2.2 From STE to SPIGOT

We now view structured argmax as an activation function that takes a vector of input-specific part-scores $\mathbf{s}$ and outputs a solution $\hat{\mathbf{z}}$. For backpropagation, to calculate gradients for parameters of $\mathbf{s}$, the chain rule defines:

$$\nabla_{\mathbf{s}}L = \mathbf{J}\ \nabla_{\hat{\mathbf{z}}}L, \tag{3}$$

where the Jacobian matrix $\mathbf{J} = \frac{\partial \hat{\mathbf{z}}}{\partial \mathbf{s}}$ contains the derivative of each element of $\hat{\mathbf{z}}$ with respect to each element of $\mathbf{s}$. Unfortunately, argmax is a piecewise constant function, so its Jacobian is either zero (almost everywhere) or undefined (in the case of ties).

One solution, taken in *structured attention*, is to replace the argmax with marginal inference and a softmax function, so that $\hat{\mathbf{z}}$ encodes probability distributions over parts (Kim et al., 2017; Liu and Lapata, 2018). As discussed in §1, there are two reasons to avoid this modification. Softmax can only be used when marginal inference is feasible, by sum-product algorithms for example (Eisner, 2016; Friesen and Domingos, 2016); in general marginal inference can be #P-complete. Further, a soft intermediate layer will be less amenable to inspection by anyone wishing to understand and improve the model.

In another line of work, argmax is augmented with a strongly-convex penalty on the solutions (Martins and Astudillo, 2016; Amos and Kolter, 2017; Niculae and Blondel, 2017; Niculae et al., 2018; Mensch and Blondel, 2018). However, their approaches require solving a relaxation even when exact decoding is tractable. Also, the penalty will bias the solutions found by the decoder, which may be an undesirable conflation of computational and modeling concerns.

A simpler solution is the STE method (Hinton, 2012), which replaces the Jacobian matrix in Equation 3 by the identity matrix. This method has been demonstrated to work well when used to "backpropagate" through hard threshold functions (Bengio et al., 2013; Friesen and Domingos, 2018) and categorical random variables (Jang et al., 2016; Choi et al., 2017).

Consider for a moment what we would do if $\hat{\mathbf{z}}$ were a vector of parameters, rather than intermediate predictions. In this case, we are seeking points in $\mathcal{Z}$ that minimize L; denote that set of minimizers by $\mathcal{Z}^*$. Given $\nabla_{\hat{\mathbf{z}}}L$ and step size η, we would update $\hat{\mathbf{z}}$ to be $\hat{\mathbf{z}} - \eta\nabla_{\hat{\mathbf{z}}}L$. This update, however, might not return a value in the feasible set $\mathcal{Z}$, or even (if we are using a linear relaxation) the relaxed set $\mathcal{P}$.

SPIGOT therefore introduces a *projection* step that aims to keep the "updated" $\hat{\mathbf{z}}$ in the feasible set. Of course, we do not directly update $\hat{\mathbf{z}}$; we continue backpropagation through $\mathbf{s}$ and onward to the parameters. But the projection step nonetheless alters the parameter updates in the way that our proxy for "$\nabla_{\mathbf{s}}L$" is defined.

The procedure is defined as follows:

$$\hat{\mathbf{p}} = \hat{\mathbf{z}} - \eta\nabla_{\hat{\mathbf{z}}}L, \tag{4a}$$
$$\tilde{\mathbf{z}} = \mathrm{proj}_{\mathcal{P}}(\hat{\mathbf{p}}), \tag{4b}$$
$$\nabla_{\mathbf{s}}L \triangleq \hat{\mathbf{z}} - \tilde{\mathbf{z}}. \tag{4c}$$

First, the method makes an "update" to $\hat{\mathbf{z}}$ as if it contained parameters (Equation 4a), letting $\hat{\mathbf{p}}$ denote the new value. Next, $\hat{\mathbf{p}}$ is projected back onto the (relaxed) feasible set (Equation 4b), yielding a feasible new value $\tilde{\mathbf{z}}$. Finally, the gradients with respect to $\mathbf{s}$ are computed by Equation 4c.

Due to the convexity of $\mathcal{P}$, the projected point $\tilde{\mathbf{z}}$ will always be unique, and is guaranteed to be no farther than $\hat{\mathbf{p}}$ from any point in $\mathcal{Z}^*$ (Luenberger and Ye, 2015).[1] Compared to STE, SPIGOT in-

[1]Note that this property follows from $\mathcal{P}$'s convexity, and we do not assume the convexity of L.

volves a projection and limits $\nabla_{\mathbf{s}} L$ to a smaller space to satisfy constraints. See Figure 1 for an illustration.

When efficient exact solutions (such as dynamic programming) are available, they can be used. Yet, we note that SPIGOT does not assume the argmax operation is solved exactly.

2.3 Backpropagation through Pipelines

Using SPIGOT, we now devise an algorithm to "backpropagate" through NLP pipelines. In these pipelines, an intermediate task's output is fed into an end task for use as features. The parameters of the complete model are divided into two parts: denote the parameters of the intermediate task model by $\boldsymbol{\phi}$ (used to calculate $\mathbf{s}$), and those in the end task model as $\boldsymbol{\theta}$.[2] As introduced earlier, the end-task loss function to be minimized is L, which depends on both $\boldsymbol{\phi}$ and $\boldsymbol{\theta}$.

Algorithm 1 describes the forward and backward computations. It takes an end task training pair $\langle \mathbf{x}, \mathbf{y} \rangle$, along with the intermediate task's feasible set $\mathcal{Z}$, which is determined by $\mathbf{x}$. It first runs the intermediate model and decodes to get intermediate structure $\hat{\mathbf{z}}$, just as in a standard pipeline. Then forward propagation is continued into the end-task model to compute loss L, using $\hat{\mathbf{z}}$ to define input features. Backpropagation in the end-task model computes $\nabla_{\boldsymbol{\theta}} L$ and $\nabla_{\hat{\mathbf{z}}} L$, and $\nabla_{\mathbf{s}} L$ is then constructed using Equations 4. Backpropagation then continues into the intermediate model, computing $\nabla_{\boldsymbol{\phi}} L$.

Due to its flexibility, SPIGOT is applicable to many training scenarios. When there is no $\langle \mathbf{x}, \mathbf{z} \rangle$ training data for the intermediate task, SPIGOT can be used to induce latent structures for the end-task (Yogatama et al., 2017; Kim et al., 2017; Choi et al., 2017, *inter alia*). When intermediate-task training data *is* available, one can use SPIGOT to adopt joint learning by minimizing an interpolation of L (on end-task data $\langle \mathbf{x}, \mathbf{y} \rangle$) and an intermediate-task loss function $\widetilde{L}$ (on intermediate task data $\langle \mathbf{x}, \mathbf{z} \rangle$). This is the setting in our experiments; note that we do not assume any overlap in the training examples for the two tasks.

 7:     Backprop and compute $\nabla_{\boldsymbol{\theta}} L$ and $\nabla_{\hat{\mathbf{z}}} L$
 8:     $\tilde{\mathbf{z}} \leftarrow \text{proj}_{\mathcal{P}}(\hat{\mathbf{z}} - \eta \nabla_{\hat{\mathbf{z}}} L)$        ▷ Projection
 9:     $\nabla_{\mathbf{s}} L \leftarrow \hat{\mathbf{z}} - \tilde{\mathbf{z}}$
10:     Backprop and compute $\nabla_{\boldsymbol{\phi}} L$
11: end procedure
```

3 Solving the Projections

In this section we discuss how to compute approximate projections for the two intermediate tasks considered in this work, arc-factored unlabeled dependency parsing and first-order semantic dependency parsing.

In early experiments we observe that for both tasks, projecting with respect to *all* constraints of their original formulations using a generic quadratic program solver was prohibitively slow. Therefore, we construct relaxed polytopes by considering only a subset of the constraints.[3] The projection then decomposes into a series of singly constrained quadratic programs (QP), each of which can be efficiently solved in linear time.

The two approximate projections discussed here are used in backpropagation only. In the forward pass, we solve the decoding problem using the models' original decoding algorithms.

Arc-factored unlabeled dependency parsing. For unlabeled dependency trees, we impose $[0, 1]$ constraints and single-headedness constraints.[4]

Formally, given a length-n input sentence, excluding self-loops, an arc-factored parser considers $d = n(n-1)$ candidate arcs. Let $i \rightarrow j$ denote an arc from the ith token to the jth, and $\sigma(i \rightarrow j)$ denote its index. We construct the relaxed feasible set by:

$$\mathcal{P}_{\text{DEP}} = \left\{ \mathbf{p} \in \mathbb{U}^d \;\middle|\; \sum_{i \neq j} p_{\sigma(i \rightarrow j)} = 1, \forall j \right\}, \quad (5)$$

i.e., we consider each token j individually, and force single-headedness by constraining the number of arcs incoming to j to sum to 1. Algorithm 2 summarizes the procedure to project onto $\mathcal{P}_{\text{DEP}}$.

[2]Nothing prohibits tying across pre-argmax parameters and post-argmax parameters; this separation is notationally convenient but not at all necessary.

[3]A parallel work introduces an active-set algorithm to solve the same class of quadratic programs (Niculae et al., 2018). It might be an efficient approach to solve the projections in Equation 4b, which we leave to future work.

[4] It requires $O(n^2)$ auxiliary variables and $O(n^3)$ additional constraints to ensure well-formed tree structures (Martins et al., 2013).

Line 3 forms a singly constrained QP, and can be solved in $O(n)$ time (Brucker, 1984).

Algorithm 2 Projection onto the relaxed polytope $\mathcal{P}_{\text{DEP}}$ for dependency tree structures. Let bold $\boldsymbol{\sigma}(\cdot \to j)$ denote the index set of arcs incoming to j. For a vector $\mathbf{v}$, we use $\mathbf{v}_{\boldsymbol{\sigma}(\cdot\to j)}$ to denote vector $[v_k]_{k\in\boldsymbol{\sigma}(\cdot\to j)}$.

```
1: procedure DEPPROJ($\hat{\mathbf{p}}$)
2:     for $j = 1, 2, \dots, n$ do
3:         $\tilde{\mathbf{z}}_{\boldsymbol{\sigma}(\cdot\to j)} \leftarrow \text{proj}_{\triangle^{n-2}}\left(\hat{\mathbf{p}}_{\boldsymbol{\sigma}(\cdot\to j)}\right)$
4:     end for
5:     return $\tilde{\mathbf{z}}$
6: end procedure
```

First-order semantic dependency parsing. Semantic dependency parsing uses labeled bilexical dependencies to represent sentence-level semantics (Oepen et al., 2014, 2015, 2016). Each dependency is represented by a labeled directed arc from a head token to a modifier token, where the arc label encodes broadly applicable semantic relations. Figure 2 diagrams a semantic graph from the DELPH-IN MRS-derived dependencies (DM), together with a syntactic tree.

We use a state-of-the-art semantic dependency parser (Peng et al., 2017) that considers three types of parts: heads, unlabeled arcs, and labeled arcs. Let $\sigma(i \xrightarrow{\ell} j)$ denote the index of the arc from i to j with semantic role ℓ. In addition to $[0,1]$ constraints, we constrain that the predictions for labeled arcs sum to the prediction of their associated unlabeled arc:

$$\mathcal{P}_{\text{SDP}} \left\{ \mathbf{p} \in \mathbb{U}^d \,\middle|\, \sum_{\ell} p_{\sigma(i \xrightarrow{\ell} j)} = p_{\sigma(i\to j)}, \forall i \neq j \right\}. \tag{6}$$

This ensures that exactly one label is predicted if and only if its arc is present. The projection onto $\mathcal{P}_{\text{SDP}}$ can be solved similarly to Algorithm 2. We drop the determinism constraint imposed by Peng et al. (2017) in the backward computation.

4 Experiments

We empirically evaluate our method with two sets of experiments: using syntactic tree structures in semantic dependency parsing, and using semantic dependency graphs in sentiment classification.

4.1 Syntactic-then-Semantic Parsing

In this experiment we consider an intermediate syntactic parsing task, followed by semantic dependency parsing as the end task. We first briefly review the neural network architectures for the two models (§4.1.1), and then introduce the datasets (§4.1.2) and baselines (§4.1.3).

Figure 2: A development instance annotated with both gold DM semantic dependency graph (red arcs on the top), and gold syntactic dependency tree (blue arcs at the bottom). A pretrained syntactic parser predicts the same tree as the gold; the semantic parser backpropagates into the intermediate syntactic parser, and changes the dashed blue arcs into dashed red arcs (§5).

4.1.1 Architectures

Syntactic dependency parser. For intermediate syntactic dependencies, we use the unlabeled arc-factored parser of Kiperwasser and Goldberg (2016). It uses bidirectional LSTMs (BiLSTM) to encode the input, followed by a multilayer-perceptron (MLP) to score each potential dependency. One notable modification is that we replace their use of Chu-Liu/Edmonds' algorithm (Chu and Liu, 1965; Edmonds, 1967) with the Eisner algorithm (Eisner, 1996, 2000), since our dataset is in English and mostly projective.

Semantic dependency parser. We use the basic model of Peng et al. (2017) (denoted as NEURBOPARSER) as the end model. It is a first-order parser, and uses local factors for heads, unlabeled arcs, and labeled arcs. NEURBOPARSER does not use syntax. It first encodes an input sentence with a two-layer BiLSTM, and then computes part scores with two-layer tanh-MLPs. Inference is conducted with AD^3 (Martins et al., 2015). To add syntactic features to NEURBOPARSER, we concatenate a token's contextualized representation to that of its syntactic head, predicted by the intermediate parser. Formally, given length-n input sentence, we first run a BiLSTM. We use the concatenation of the two hidden representations $\mathbf{h}_j = [\overrightarrow{\mathbf{h}}_j; \overleftarrow{\mathbf{h}}_j]$ at each position j as the contextualized token representations. We then concatenate

$\mathbf{h}_j$ with the representation of its head $\mathbf{h}_{\text{HEAD}(j)}$ by

$$\widetilde{\mathbf{h}}_j = [\mathbf{h}_j; \mathbf{h}_{\text{HEAD}(j)}] = \left[\mathbf{h}_j; \sum_{i \neq j} \hat{z}_{\sigma(i \to j)}\ \mathbf{h}_i\right], \tag{7}$$

where $\hat{\mathbf{z}} \in \mathbb{B}^{n(n-1)}$ is a binary encoding of the tree structure predicted by by the intermediate parser. We then use $\widetilde{\mathbf{h}}_j$ anywhere $\mathbf{h}_j$ would have been used in NEURBOPARSER. In backpropagation, we compute $\nabla_{\hat{\mathbf{z}}} L$ with an automatic differentiation toolkit (DyNet; Neubig et al., 2017).

We note that this approach can be generalized to convolutional neural networks over graphs (Mou et al., 2015; Duvenaud et al., 2015; Kipf and Welling, 2017, *inter alia*), recurrent neural networks along paths (Xu et al., 2015; Roth and Lapata, 2016, *inter alia*) or dependency trees (Tai et al., 2015). We choose to use concatenations to control the model's complexity, and thus to better understand which parts of the model work.

We refer the readers to Kiperwasser and Goldberg (2016) and Peng et al. (2017) for further details of the parsing models.

Training procedure. Following previous work, we minimize structured hinge loss (Tsochantaridis et al., 2004) for both models. We jointly train both models from scratch, by randomly sampling an instance from the union of their training data at each step. In order to isolate the effect of backpropagation, we do not share any parameters between the two models.[5] Implementation details are summarized in the supplementary materials.

4.1.2 Datasets

- For semantic dependencies, we use the English dataset from SemEval 2015 Task 18 (Oepen et al., 2015). Among the three formalisms provided by the shared task, we consider DELPH-IN MRS-derived dependencies (DM) and Prague Semantic Dependencies (PSD).[6] It includes §00–19 of the WSJ corpus as training data, §20 and §21 for development and in-domain test data, resulting in a 33,961/1,692/1,410 train/dev./test split, and 1,849 out-of-domain test instances from the Brown corpus.[7]
- For syntactic dependencies, we use the Stanford Dependency (de Marneffe and Manning, 2008) conversion of the the Penn Treebank WSJ portion (Marcus et al., 1993). To avoid data leak, we depart from standard split and use §20 and §21 as development and test data, and the remaining sections as training data. The number of training/dev./test instances is 40,265/2,012/1,671.

Table 1: Semantic dependency parsing performance in both unlabeled (UF) and labeled (LF) F_1 scores. Bold font indicates the best performance. Peng et al. (2017) does not report UF.

4.1.3 Baselines

We compare to the following baselines:

- A pipelined system (PIPELINE). The pretrained parser achieves 92.9 test unlabeled attachment score (UAS).[8]

[5] Parameter sharing has proved successful in many related tasks (Collobert and Weston, 2008; Søgaard and Goldberg, 2016; Ammar et al., 2016; Swayamdipta et al., 2016, 2017, *inter alia*), and could be easily combined with our approach.

[6] We drop the third (PAS) because its structure is highly predictable from parts-of-speech, making it less interesting.

[7] The organizers remove, e.g., instances with cyclic graphs, and thus only a subset of the WSJ corpus is included. See Oepen et al. (2015) for details.

[8] Note that this number is not comparable to the parsing literature due to the different split. As a sanity check, we found in preliminary experiments that the same parser archi-

- Structured attention networks (SA; Kim et al., 2017). We use the inside-outside algorithm (Baker, 1979) to populate $\mathbf{z}$ with arcs' marginal probabilities, use log-loss as the objective in training the intermediate parser.
- The straight-through estimator (STE; Hinton, 2012), introduced in §2.2.

4.1.4 Empirical Results

Table 1 compares the semantic dependency parsing performance of SPIGOT to all five baselines. FREDA3 (Peng et al., 2017) is a state-of-the-art variant of NEURBOPARSER that is trained using multitask learning to jointly predict three different semantic dependency graph formalisms. Like the basic NEURBOPARSER model that we build from, FREDA3 does not use any syntax. Strong DM performance is achieved in a more recent work by using joint learning and an ensemble (Peng et al., 2018), which is beyond fair comparisons to the models discussed here.

We found that using syntactic information improves semantic parsing performance: using pipelined syntactic head features brings 0.5–1.4% absolute labeled F_1 improvement to NEURBOPARSER. Such improvements are smaller compared to previous works, where dependency path and syntactic relation features are included (Almeida and Martins, 2015; Ribeyre et al., 2015; Zhang et al., 2016), indicating the potential to get better performance by using more syntactic information, which we leave to future work.

Both STE and SPIGOT use hard syntactic features. By allowing backpropation into the intermediate syntactic parser, they both consistently outperform PIPELINE. On the other hand, when marginal syntactic tree structures are used, SA outperforms PIPELINE only on the out-of-domain PSD test set, and improvements under other cases are not observed.

Compared to STE, SPIGOT outperforms STE on DM by more than 0.3% absolute labeled F_1, both in-domain and out-of-domain. For PSD, SPIGOT achieves similar performance to STE on in-domain test set, but has a 0.5% absolute labeled F_1 improvement on out-of-domain data, where syntactic parsing is less accurate.

tecture achieves 93.5 UAS when trained and evaluated with the standard split, close to the results reported by Kiperwasser and Goldberg (2016).

4.2 Semantic Dependencies for Sentiment Classification

Our second experiment uses semantic dependency graphs to improve sentiment classification performance. We are not aware of any efficient algorithm that solves marginal inference for semantic dependency graphs under determinism constraints, so we do not include a comparison to SA.

4.2.1 Architectures

Here we use NEURBOPARSER as the intermediate model, as described in §4.1.1, but with no syntactic enhancements.

Sentiment classifier. We first introduce a baseline that does not use any structural information. It learns a one-layer BiLSTM to encode the input sentence, and then feeds the sum of all hidden states into a two-layer ReLU-MLP.

To use semantic dependency features, we concatenate a word's BiLSTM-encoded representation to the averaged representation of its heads, together with the corresponding semantic roles, similarly to that in Equation 7.[9] Then the concatenation is fed into an affine transformation followed by a ReLU activation. The rest of the model is kept the same as the BiLSTM baseline.

Training procedure. We use structured hinge loss to train the semantic dependency parser, and log-loss for the sentiment classifier. Due to the discrepancy in the training data size of the two tasks (33K vs. 7K), we pre-train a semantic dependency parser, and then adopt joint training together with the classifier. In the joint training stage, we randomly sample 20% of the semantic dependency training instances each epoch. Implementations are detailed in the supplementary materials.

4.2.2 Datasets

For semantic dependencies, we use the DM dataset introduced in §4.1.2.

We consider a binary classification task using the Stanford Sentiment Treebank (Socher et al., 2013). It consists of roughly 10K movie review sentences from Rotten Tomatoes. The full dataset includes a rating on a scale from 1 to 5 for each constituent (including the full sentences), resulting in more than 200K instances. Following previous work (Iyyer et al., 2015), we only use full-sentence

[9]In a well-formed semantic dependency graph, a token may have multiple heads. Therefore we use average instead of the sum in Equation 7.

Model	Accuracy (%)
BiLSTM	84.8
PIPELINE	85.7
STE	85.4
SPIGOT	**86.3**

Table 2: Test accuracy of sentiment classification on Stanford Sentiment Treebank. Bold font indicates the best performance.

instances, with neutral instances excluded (3s) and the remaining four rating levels converted to binary "positive" or "negative" labels. This results in a 6,920/872/1,821 train/dev./test split.

4.2.3 Empirical Results

Table 2 compares our SPIGOT method to three baselines. Pipelined semantic dependency predictions brings 0.9% absolute improvement in classification accuracy, and SPIGOT outperforms all baselines. In this task STE achieves slightly worse performance than a fixed pre-trained PIPELINE.

5 Analysis

We examine here how the intermediate model is affected by the end-task training signal. Is the end-task signal able to "overrule" intermediate predictions?

We use the syntactic-then-semantic parsing model (§4.1) as a case study. Table 3 compares a pipelined system to one jointly trained using SPIGOT. We consider the development set instances where both syntactic and semantic annotations are available, and partition them based on whether the two systems' syntactic predictions agree (SAME), or not (DIFF). The second group includes sentences with much lower syntactic parsing accuracy (91.3 vs. 97.4 UAS), and SPIGOT further reduces this to 89.6. Even though these changes hurt syntactic parsing accuracy, they lead to a 1.1% absolute gain in labeled F_1 for semantic parsing. Furthermore, SPIGOT has an overall less detrimental effect on the intermediate parser than STE: using SPIGOT, intermediate dev. parsing UAS drops to 92.5 from the 92.9 pipelined performance, while STE reduces it to 91.8.

We then take a detailed look and categorize the changes in intermediate trees by their correlations with the semantic graphs. Specifically, when a modifier m's head is changed from h to h' in the

Split	# Sent.	Model	UAS	DM
SAME	1011	PIPELINE	97.4	94.0
		SPIGOT	97.4	94.3
DIFF	681	PIPELINE	91.3	88.1
		SPIGOT	89.6	89.2

Table 3: Syntactic parsing performance (in unlabeled attachment score, UAS) and DM semantic parsing performance (in labeled F_1) on different groups of the development data. Both systems predict the same syntactic parses for instances from SAME, and they disagree on instances from DIFF (§5).

tree, we consider three cases: (a) h' is a head of m in the semantic graph; (b) h' is a modifier of m in the semantic graph; (c) h is the modifier of m in the semantic graph. The first two reflect modifications to the syntactic parse that rearrange semantically linked words to be neighbors. Under (c), the semantic parser removes a syntactic dependency that reverses the direction of a semantic dependency. These cases account for 17.6%, 10.9%, and 12.8%, respectively (41.2% combined) of the total changes. Making these changes, of course, is complicated, since they often require *other* modifications to maintain well-formedness of the tree. Figure 2 gives an example.

6 Related Work

Joint learning in NLP pipelines. To avoid cascading errors, much effort has been devoted to joint decoding in NLP pipelines (Habash and Rambow, 2005; Cohen and Smith, 2007; Goldberg and Tsarfaty, 2008; Lewis et al., 2015; Zhang et al., 2015, *inter alia*). However, joint inference can sometimes be prohibitively expensive. Recent advances in representation learning facilitate exploration in the joint learning of multiple tasks by sharing parameters (Collobert and Weston, 2008; Blitzer et al., 2006; Finkel and Manning, 2010; Zhang and Weiss, 2016; Hashimoto et al., 2017, *inter alia*).

Differentiable optimization. Gould et al. (2016) review the generic approaches to differentiation in bi-level optimization (Bard, 2010; Kunisch and Pock, 2013). Amos and Kolter (2017) extend their efforts to a class of subdifferentiable quadratic programs. However, they both require that the intermediate objective has an invertible Hessian, limiting their application in NLP. In another line of work, the steps of a gradient-based optimization procedure are unrolled into a single computation graph (Stoyanov et al., 2011; Domke, 2012; Goodfellow et al., 2013; Brakel et al., 2013). This comes at a high computational cost due to the second-order derivative computation during backpropagation. Moreover, constrained optimization problems (like many NLP problems) often require projection steps within the procedure, which can be difficult to differentiate through (Belanger and McCallum, 2016; Belanger et al., 2017).

7 Conclusion

We presented SPIGOT, a novel approach to backpropagating through neural network architectures that include discrete structured decisions in intermediate layers. SPIGOT devises a proxy for the gradients with respect to argmax's inputs, employing a projection that aims to respect the constraints in the intermediate task. We empirically evaluate our method with two architectures: a semantic parser with an intermediate syntactic parser, and a sentiment classifier with an intermediate semantic parser. Experiments show that SPIGOT achieves stronger performance than baselines under both settings, and outperforms state-of-the-art systems on semantic dependency parsing. Our implementation is available at `https://github.com/Noahs-ARK/SPIGOT`.

Learning How to Actively Learn: A Deep Imitation Learning Approach

Abstract

Heuristic-based active learning (AL) methods are limited when the data distribution of the underlying learning problems vary. We introduce a method that learns an AL *policy* using *imitation learning* (IL). Our IL-based approach makes use of an efficient and effective *algorithmic expert*, which provides the policy learner with good actions in the encountered AL situations. The AL strategy is then learned with a feedforward network, mapping situations to most informative query datapoints. We evaluate our method on two different tasks: text classification and named entity recognition. Experimental results show that our IL-based AL strategy is more effective than strong previous methods using heuristics and reinforcement learning.

1 Introduction

For many real-world NLP tasks, labeled data is rare while unlabelled data is abundant. Active learning (AL) seeks to learn an accurate model with minimum amount of annotation cost. It is inspired by the observation that a model can get better performance if it is allowed to choose the data points on which it is trained. For example, the learner can identify the areas of the space where it does not have enough knowledge, and query those data points which bridge its knowledge gap.

Traditionally, AL is performed using engineered heuristics in order to estimate the usefulness of unlabeled data points as queries to an annotator. Recent work (Fang et al., 2017; Bachman et al., 2017; Woodward and Finn, 2017) have focused on learning the AL querying strategy, as engineered heuristics are not flexible to exploit characteristics inherent to a given problem. The basic idea is to cast AL as a decision process, where the most informative unlabeled data point needs to be selected based on the history of previous queries. However, previous works train for the AL policy by a reinforcement learning (RL) formulation, where the rewards are provided at the end of sequences of queries. This makes learning the AL policy difficult, as the policy learner needs to deal with the credit assignment problem. Intuitively, the learner needs to observe many pairs of query sequences and the resulting end-rewards to be able to associate single queries with their utility scores.

In this work, we formulate learning AL strategies as an imitation learning problem. In particular, we consider the popular pool-based AL scenario, where an AL agent is presented with a pool of unlabelled data. Inspired by the Dataset Aggregation (DAGGER) algorithm (Ross et al., 2011), we develop an effective AL policy learning method by designing an efficient and effective algorithmic expert, which provides the AL agent with good decisions in the encountered states. We then use a deep feedforward network to learn the AL policy to associate states to actions. Unlike the RL approach, our method can get observations and actions directly from the expert's trajectory. Therefore, our trained policy can make better rankings of unlabelled datapoints in the pool, leading to more effective AL strategies.

We evaluate our method on text classification and named entity recognition. The results show our method performs better than strong AL methods using heuristics and reinforcement learning, in that it boosts the performance of the underlying model with fewer labelling queries. An open source implementation of our model is available at: `https://github.com/Grayming/ALIL`.

2 Pool-based AL as a Decision Process

We consider the popular pool-based AL setting where we are given a small set of initial labeled data and a large pool of unlabelled data, and a budget for getting the annotation of some unlabelled data by querying an oracle, e.g. a human annotator. The goal is to intelligently pick those unlabelled data for which if the annotations were available, the performance of the underlying re-trained model would be improved the most.

The main challenge in AL is how to identify and select the most beneficial unlabelled data points. Various *heuristics* have been proposed to guide the unlabelled data selection (Settles, 2010). However, there is no one AL heuristic which performs best for all problems. The goal of this paper is to provide an approach to *learn* an AL strategy which is best suited for the problem at hand, instead of resorting to ad-hoc heuristics.

The AL strategy can be learned by attempting to actively learn on tasks sampled from a distribution over the tasks (Bachman et al., 2017). The idea is to *simulate* the AL scenario on *instances* of the problem created using available labeled data, where the label of some part of the data is kept hidden. This allows to have an *automatic* oracle to reveal the labels of the queried data, resulting in an efficient way to quickly evaluate a hypothesised AL strategy. Once the AL strategy is learned on simulations, it is then applied to real AL scenarios. The more related are the tasks in the real scenario to those used to train the AL strategy, the more effective the AL strategy would be.

We are interested to train a model $m_{\boldsymbol{\phi}}$ which maps an input $\boldsymbol{x} \in \mathcal{X}$ to its label $\boldsymbol{y} \in \mathcal{Y}_{\boldsymbol{x}}$, where $\mathcal{Y}_{\boldsymbol{x}}$ is the set of labels for the input $\boldsymbol{x}$ and $\boldsymbol{\phi}$ is the parameter vector of the underling model. For example, in the named entity recognition (NER) task, the input is a sentence and the output is its label sequence, e.g. in the IBO format. Let $D = \{(\boldsymbol{x}, \boldsymbol{y})\}$ be a support set of labeled data, which is randomly partitioned into labeled D^{lab}, unlabelled D^{unl}, and evaluation D^{evl} datasets. Repeated random partitioning creates multiple instances of the AL problem. At each time step t of an AL problem, the algorithm interacts with the oracle and queries the label of a datapoint $\boldsymbol{x}_t \in D^{unl}_t$. As the result of this *action*, the followings happen:

- The automatic oracle reveals the label $\boldsymbol{y}_t$;
- The labeled and unlabelled datasets are updated to include and exclude the recently queried data point, respectively;
- The underlying model is re-trained based on the enlarged labeled data to update $\boldsymbol{\phi}$; and
- The AL algorithm receives a reward $-loss(m_{\boldsymbol{\phi}}, D^{evl})$, which is the negative loss of the current trained model on the evaluation set, defined as

$$loss(m_{\boldsymbol{\phi}}, D^{evl}) := \sum_{(\boldsymbol{x},\boldsymbol{y}) \in D^{evl}} loss(m_{\boldsymbol{\phi}}(\boldsymbol{x}), \boldsymbol{y})$$

  where $loss(\boldsymbol{y}', \boldsymbol{y})$ is the loss incurred due to predicting $\boldsymbol{y}'$ instead of the ground truth $\boldsymbol{y}$.

More formally, a pool-based AL problem is a Markov decision process (MDP), denoted by $(S, A, Pr(\boldsymbol{s}_{t+1}|\boldsymbol{s}_t, a_t), R)$ where S is the state space, A is the set of actions, $Pr(\boldsymbol{s}_{t+1}|\boldsymbol{s}_t, a_t)$ is the transition function, and R is the reward function. The state $\boldsymbol{s}_t \in S$ at time t consists of the labeled D^{lab}_t and unlabelled D^{unl}_t datasets paired with the parameters of the currently trained model ϕ_t. An action $a_t \in A$ corresponds to the selection of a query datapoint, and the reward function $R(\boldsymbol{s}_t, a_t, \boldsymbol{s}_{t+1}) := -loss(m_{\boldsymbol{\phi}_t}, D^{evl})$.

We aim to find the optimal AL *policy* prescribing which datapoint needs to be queried in a given state to get the most benefit. The optimal policy is found by maximising the following objective over the parameterised policies:

$$\mathbb{E}_{(D^{lab}, D^{unl}, D^{evl}) \sim \mathcal{D}} \left[\mathbb{E}_{\pi_{\boldsymbol{\theta}}} \left[\sum_{t=1}^{\mathcal{B}} R(\boldsymbol{s}_t, a_t, \boldsymbol{s}_{t+1}) \right] \right] \quad (1)$$

where $\pi_{\boldsymbol{\theta}}$ is the *policy network* parameterised by $\boldsymbol{\theta}$, $\mathcal{D}$ is a distribution over possible AL problem instances, and $\mathcal{B}$ is the maximum number of queries made in an AL run, a.k.a. an *episode*. Following (Bachman et al., 2017), we maximise the sum of the rewards after each time step to encourage the *anytime* behaviour, i.e. the model should perform well after each label query.

3 Deep Imitation Learning to Train the AL Policy

The question remains as how can we train the policy network to maximise the training objective in eqn 1. Typical learning approaches resort to deep reinforcement learning (RL) and provide training signal at the end of each episode to learn the optimal policy (Fang et al., 2017; Bachman et al., 2017) e.g., using policy gradient methods. These approaches, however, need a large number of training episodes to learn a reasonable policy as they need to deal with the credit assignment problem, i.e. discovery of the utility of individual actions in the sequence based on the achieved reward at the end of the episode. This exacerbates the difficulty of finding a good AL policy.

We formulate learning for the AL policy as an imitation learning problem. At each state, we provide the AL agent with *a correct* action which is computed by an *algorithmic expert*. The AL agent uses the sequence of states observed in an episode paired with the expert's sequence of actions to update its policy. This directly addresses the credit assignment problem, and reduces the complexity of the problem compared to the RL approaches. In what follows, we describe the ingredients of our deep imitation learning (IL) approach, which is summarised in Algorithm 1.

Algorithmic Expert. At a given AL state $\boldsymbol{s}_t$, our algorithmic expert computes an action by evaluating the current pool of unlabeled data. More concretely, for each $\boldsymbol{x}' \in D^{pool}_{rnd}$ and its correct label $\boldsymbol{y}'$, the underlying model $m_{\boldsymbol{\phi}_t}$ is re-trained to get $m^{\boldsymbol{x}'}_{\boldsymbol{\phi}_t}$, where $D^{pool}_{rnd} \subset D^{unl}_t$ is a small subset of the current large pool of unlabeled data. The expert action is then computed as:

$$\arg\min_{\boldsymbol{x}' \in D^{pool}_{rnd}} loss(m^{\boldsymbol{x}'}_{\boldsymbol{\phi}_t}(\boldsymbol{x}), D^{evl}). \qquad (2)$$

In other words, our algorithmic expert tries a subset of actions to *roll-out* one step from the current state, in order to *efficiently* compute a reasonable action. Searching for the *optimal* action would be $\mathcal{O}(|D^{unl}|^{\mathcal{B}})$, which is computationally challenging due to (i) the large action set, and (ii) the exponential dependence on the length of the roll out. We will see in the experiments that our method efficiently learns effective AL policies.

Policy Network. Our policy network is a feed-forward network with two fully-connected hidden layers. It receives the current AL state, and provides a *preference* score for a given unlabeled data point, allowing to select the most beneficial one corresponding to the highest score. The input to our policy network consists of three parts: (i) a fixed dimensional representation of the content and the predicted label of the unlabeled data point under consideration, (ii) a fixed-dimensional representation of the content and the labels of the labeled dataset, and (iii) a fixed-dimensional representation of the content of the unlabeled dataset.

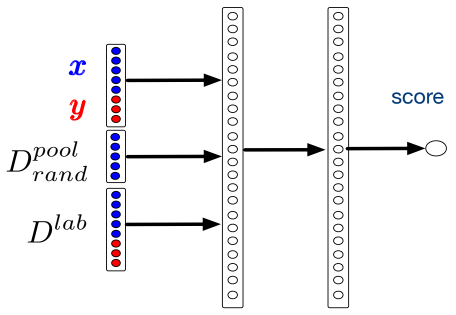

Figure 1: The policy network and its inputs.

Imitation Learning Algorithm. A typical approach to imitation learning (IL) is to train the policy network so that it mimics the expert's behaviour given training data of the encountered states (input) and actions (output) performed by the expert. The policy network's prediction affects future inputs during the execution of the policy. This violates the crucial independent and identically distributed (iid) assumption, inherent to most statistical supervised learning approaches for learning a mapping from states to actions.

We make use of Dataset Aggregation (DAGGER) (Ross et al., 2011), an iterative algorithm for IL which addresses the *non*-iid nature of the encountered states during the AL process (see Algorithm 1). In round τ of DAGGER, the learned policy network $\hat{\pi}_\tau$ is applied to the AL problem to collect a sequence of states which are paired with the expert actions. The collected pair of states and actions are aggregated to the dataset of such pairs M, collected from the previous iterations of the algorithm. The policy network is then re-trained on the aggregated set, resulting in $\hat{\pi}_{\tau+1}$ for the next iteration of the algorithm. The intuition is to build up the set of states that the algorithm is likely to encounter during its execution, in order to increase the generalization of the policy network. To better leverage the training signal from the algorithmic expert, we allow the algorithm to collect state-action pairs according to a modified policy which is a mixture of $\hat{\pi}_\tau$ and the expert policy $\tilde{\pi}^*_\tau$, i.e.

$$\pi_\tau = \beta_\tau \tilde{\pi}^* + (1 - \beta_\tau)\hat{\pi}_\tau$$

where $\beta_\tau \in [0, 1]$ is a mixing coefficient. This amounts to tossing a coin with parameter β_τ in each iteration of the algorithm to decide one of these two policies for data collection.

Re-training the Policy Network. To train our policy network, we turn the preference scores to probabilities, and optimise the parameters such that the probability of the action prescribed by the expert is maximized. More specifically, let $\mathcal{M} := \{(\boldsymbol{s}_i, \boldsymbol{a}_i)\}_{i=1}^{I}$ be the collected states paired with their expert's prescribed actions. Let D_i^{pool} be the set of unlabelled datapoints in the pool within the state, and $\boldsymbol{a}_i$ denote the datapoint selected by the expert in the set. Our training objective is $\sum_{i=1}^{I} \log Pr(\boldsymbol{a}_i|D_i^{pool})$ where

$$Pr(\boldsymbol{a}_i|D_i^{pool}) := \frac{\exp \hat{\pi}(\boldsymbol{a}_i; \boldsymbol{s}_i)}{\sum_{\boldsymbol{x} \in D_i^{pool}} \exp \hat{\pi}(\boldsymbol{x}; \boldsymbol{s}_i)}.$$

The above can be interpreted as the probability of $\boldsymbol{a}_i$ being the best action among all possible actions in the state. Following (Mnih et al., 2015), we randomly sample multiple[1] mini-batches from the *replay memory* $\mathcal{M}$, in addition to the current round's stat-action pair, in order to retrain the policy network. For each mini-batch, we make one SGD step to update the policy, where the gradients of the network parameters are calculated using the backpropagation algorithm.

Transferring the Policy. We now apply the policy learned on the source task to AL in the target task. We expect the learned policy to be effective for target tasks which are related to the source task in terms of the data distribution and characteristics. Algorithm 2 illustrates the policy transfer. The pool-based AL scenario in Algorithm 2 is cold-start; however, extending to incorporate initially available labeled data is straightforward.

4 Experiments

We conduct experiments on text classification and named entity recognition (NER). The AL scenarios include cross-domain sentiment classification, cross-lingual authorship profiling, and cross-lingual named entity recognition (NER), whereby an AL policy trained on a source domain/language is transferred to the target domain/language.

We compare our proposed AL method using imitation learning (ALIL) with the followings:

- *Random sampling*: The query datapoint is chosen randomly.

[1]In our experiments, we use 10 mini-bathes, each of which of size 100.

Algorithm 1 Learn active learning policy via imitation learning

```
Input: large labeled data $D$, max episodes $T$, budget $\mathcal{B}$,
    sample size $K$, the coin parameter $\beta$
Output: The learned policy
 1: $M \leftarrow \emptyset$                          ▷ the aggregated dataset
 2: initialise $\hat{\pi}_1$ with a random policy
 3: for $\tau$=1, ..., T do
 4:     $D^{lab}, D^{unl}, D^{evl} \leftarrow$ dataPartition($D$)
 5:     $\boldsymbol{\phi}_1 \leftarrow$ trainModel($D^{lab}$)
 6:     $c \leftarrow$ coinToss($\beta$)
 7:     for $t \in 1, \dots, \mathcal{B}$ do
 8:         $D^{pool}_{rnd} \leftarrow$ sampleUniform($D^{unl}, K$)
 9:         $\boldsymbol{s}_t \leftarrow (D^{lab}, D^{pool}_{rnd}, \boldsymbol{\phi}_t)$
10:         $\boldsymbol{a}_t \leftarrow \arg\min_{\boldsymbol{x}' \in D^{pool}_{rnd}} loss(m^{\boldsymbol{x}'}_{\boldsymbol{\phi}_t}, D^{evl})$
11:         if $c$ is head then                      ▷ the expert
12:             $\boldsymbol{x}_t \leftarrow \boldsymbol{a}_t$
13:         else                                     ▷ the policy
14:             $\boldsymbol{x}_t \leftarrow \arg\max_{\boldsymbol{x}' \in D^{pool}_{rnd}} \hat{\pi}_\tau(\boldsymbol{x}'; \boldsymbol{s}_t)$
15:         end if
16:         $D^{lab} \leftarrow D^{lab} + \{(\boldsymbol{x}_t, \boldsymbol{y}_t)\}$
17:         $D^{unl} \leftarrow D^{unl} - \{\boldsymbol{x}_t\}$
18:         $M \leftarrow M + \{(\boldsymbol{s}_t, \boldsymbol{a}_t)\}$
19:         $\boldsymbol{\phi}_{t+1} \leftarrow$ retrainModel($\boldsymbol{\phi}_t, D^{lab}$)
20:     end for
21:     $\hat{\pi}_{\tau+1} \leftarrow$ retrainPolicy($\hat{\pi}_\tau, M$)
22: end for
23: return $\hat{\pi}_{T+1}$
```

Algorithm 2 Active learning by policy transfer

```
Input: unlabeled pool $D^{unl}$, budget $\mathcal{B}$, policy $\hat{\pi}$
Output: labeled dataset and trained model
 1: $D^{lab} \leftarrow \emptyset$
 2: initialise $\boldsymbol{\phi}$ randomly
 3: for $t \in 1, \dots, \mathcal{B}$ do
 4:     $\boldsymbol{s}_t \leftarrow (D^{lab}, D^{unl}, \boldsymbol{\phi})$
 5:     $\boldsymbol{x}_t \leftarrow \arg\max_{\boldsymbol{x}' \in D^{unl}} \hat{\pi}(\boldsymbol{x}'; \boldsymbol{s}_t)$
 6:     $\boldsymbol{y}_t \leftarrow$ askAnnotation($\boldsymbol{x}_t$)
 7:     $D^{lab} \leftarrow D^{lab} + \{(\boldsymbol{x}_t, \boldsymbol{y}_t)\}$
 8:     $D^{unl} \leftarrow D^{unl} - \{\boldsymbol{x}_t\}$
 9:     $\phi \leftarrow$ retrainModel($\boldsymbol{\phi}, D^{lab}$)
10: end for
11: return $D^{lab}$ and $\boldsymbol{\phi}$
```

- *Diversity sampling*: The query datapoint is $\arg\min_{\boldsymbol{x}} \sum_{\boldsymbol{x}' \in D^{lab}}$ Jaccard$(\boldsymbol{x}, \boldsymbol{x}')$, where the Jaccard coefficient between the unigram features of the two given texts is used as the similarity measure.

- *Uncertainty-based sampling*: For text classification, we use the datapoint with the highest predictive entropy, $\arg\max_{\boldsymbol{x}} -\sum_y p(y|\boldsymbol{x}, D^{lab}) \log p(y|\boldsymbol{x}, D^{lab})$ where $p(\boldsymbol{y}|\boldsymbol{x}, D^{lab})$ comes from the underlying model. We further use a state-of-the-art extension of this method, called *uncertainty with rationals* (Sharma et al., 2015), which not only considers uncertainty but also looks whether

the unlabelled document contains sentiment words or phrases that were returned as rationales for any of the existing labeled documents. For NER, we use the Total Token Entropy (TTE) as the uncertainty sampling method, $\arg\max_{\boldsymbol{x}} -\sum_{i=1}^{|\boldsymbol{x}|}\sum_{y_i} p(y_i|\boldsymbol{x}, D^{lab}) \log p(y_i|\boldsymbol{x}, D^{lab})$ which has been shown to be the best heuristic for this task among 17 different heuristics (Settles and Craven, 2008).

- *PAL*: A reinforcement learning based approach (Fang et al., 2017), which makes use a deep Q-network to make the selection decision for stream-based active learning.

4.1 Text Classification

Datasets and Setup. The first task is sentiment classification, in which product reviews express either positive or negative sentiment. The data comes from the Amazon product reviews (McAuley and Yang, 2016); see Table 1 for data statistics.

The second task is Authorship Profiling, in which we aim to predict the gender of the text author. The data comes from the gender profiling task in PAN 2017 (Rangel et al., 2017), which consists of a large Twitter corpus in multiple languages: English (en), Spanish (es) and Portuguese (pt). For each language, all tweets collected from a user constitute one document; Table 1 shows data statistics. The multilingual embeddings for this task come from off-the-shelf CCA-trained embeddings (Ammar et al., 2016) for twelve languages, including English, Spanish and Portuguese. We fix these word embeddings during training of both the policy and the underlying classification model.

For training, 10% of the source data is used as the evaluation set for computing the best action in imitation learning. We run $T = 100$ episodes with the budget $\mathcal{B} = 100$ documents in each episode, set the sample size $K = 5$, and fix the mixing coefficient $\beta_\tau = 0.5$. For testing, we take 90% of the target data as the unlabeled pool, and the remaining 10% as the test set. We show the test accuracy w.r.t. the number of labelled documents selected in the AL process.

As the underlying model $m_{\boldsymbol{\phi}}$, we use a fast and efficient text classifier based on convolutional neural networks. More specifically, we apply 50 convolutional filters with ReLU activation on the embedding of all words in a document $\boldsymbol{x}$, where the width of the filters is 3. The filter outputs are averaged to produce a 50-dimensional document representation $\boldsymbol{h}(\boldsymbol{x})$, which is then fed into a softmax to predict the class.

Representing state-action. The input to the policy network, i.e. the feature vector representing a state-action pair, includes: the candidate document represented by the convolutional net $\boldsymbol{h}(\boldsymbol{x})$, the distribution over the document's class labels $m_{\boldsymbol{\phi}}(\boldsymbol{x})$, the sum of all document vector representations in the labeled set $\sum_{\boldsymbol{x}'\in D^{lab}} \boldsymbol{h}(\boldsymbol{x}')$, the sum of all document vectors in the random pool of unlabelled data $\sum_{\boldsymbol{x}'\in D^{pool}_{rnd}} \boldsymbol{h}(\boldsymbol{x}')$, and the empirical distribution of class labels in the labeled dataset.

Results. Fig 2 shows the results on product sentiment prediction and authorship profiling, in cross-domain and cross-lingual AL scenarios[2]. Our ALIL method consistently outperforms both heuristic-based and RL-based (PAL) (Fang et al., 2017) approaches across all tasks. ALIL tends to convergence faster than other methods, which indicates its policy can quickly select the most informative datapoints. Interestingly, the uncertainty and diversity sampling heuristics perform worse than random sampling on sentiment classification. We speculate this may be due to these two heuristics not being able to capture the polarity information during the data selection process. PAL performs on-par with uncertainty with rationals on musical device, both of which outperform the traditional diversity and uncertainty sampling heuristics. Interestingly, PAL is outperformed by random sampling on movie reviews, and by the traditional uncertainty sampling heuristic on authorship profiling tasks. We attribute this to ineffectiveness of the RL-based approach for learning a reasonable AL query strategy.

We further investigate combining the transfer of the policy network with the transfer of the underlying classifier. That is, we first train a classi-

[2]Uncertainty with rationale cannot be done for authorship profiling as the rationales come from a sentiment dictionary.

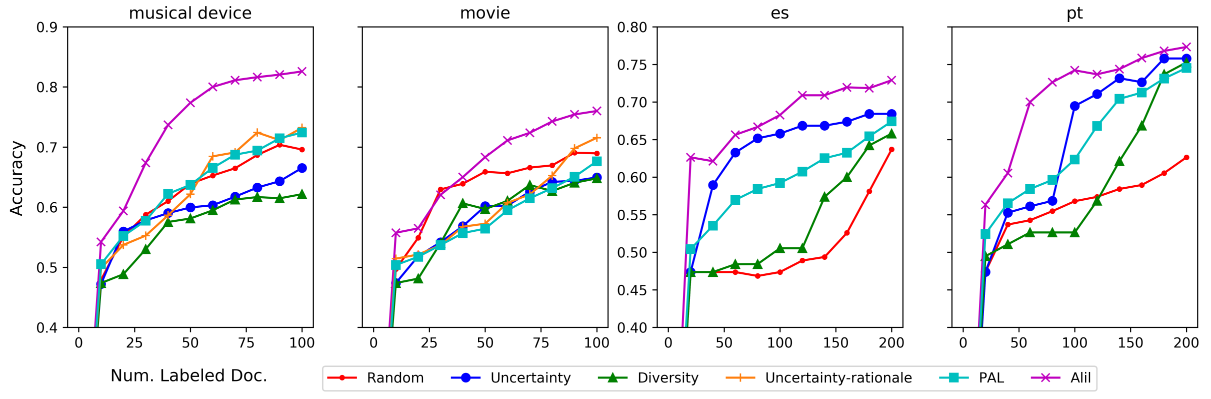

Figure 2: The performance of different active learning methods for cross domain sentiment classification (left two plots) and cross lingual authorship profiling (right two plots).

fier on all of the annotated data from the source domain/language. Then, this classifier is ported to the target domain/language; for cross-language transfer, we make use of multilingual word embeddings. We start the AL process starting from the transferred classifier, referred to as the warm-start AL. We compare the performance of the *directly transferred* classifier with those obtained after the AL process in the warm-start and cold-start scenarios. The results are shown in Table 2. We have run the cold-start and warm-start AL for 25 times, and reported the average accuracy in Table 2. As seen from the results, both the cold and warm start AL settings outperform the direct transfer significantly, and the warm start consistently gets higher accuracy than the cold start. The difference between the results are statistically significant, with a p-value of .001, according to McNemar test[3] (Dietterich, 1998).

	musical	movie	es	pt
direct transfer	0.715	0.640	0.675	0.740
cold-start AL	0.800	0.760	0.728	0.773
warm-start AL	**0.825**	**0.765**	**0.730**	**0.780**

Table 2: Classifiers performance under three different transfer settings.

4.2 Named Entity Recognition

Data and setup We use NER corpora from the CONLL2002/2003 shared tasks, which include annotated text in English (en), German (de), Spanish (es), and Dutch (nl). The original annotation is based on IOB1, which we convert to the IO labelling scheme. Following Fang et al. (2017), we consider two experimental conditions: (i) the bilingual scenario where English is the source (used for policy training) and other languages are the target, and (ii) the multilingual scenario where one of the languages (except English) is the target and the remaining ones are the source used in joint training of the AL policy. The underlying model $m_{\boldsymbol{\phi}}$ is a conditional random field (CRF) treating NER as a sequence labelling task. The prediction is made using the Viterbi algorithm.

In the existing corpus partitions from CoNLL, each language has three subsets: **train**, **testa** and **testb**. During policy training with the source language(s), we combine these three subsets, shuffle, and re-split them into simulated training, unlabelled pool, and evaluation sets in every episode. We run $N = 100$ episodes with the budget $\mathcal{B} = 200$, and set the sample size $k = 5$. When we transfer the policy to the target language, we do one episode and select $\mathcal{B}$ datapoints from **train** (treated as the pool of unlabeled data) and report F1 scores on **testa**.

Representing state-action. The input to the policy network includes the representation of the candidate sentence using the sum of its words' embeddings $\boldsymbol{h}(\boldsymbol{x})$, the representation of the labelling marginals using the label-level convolutional network $\text{cnn}_{\text{lab}}(\mathbb{E}_{m_{\boldsymbol{\phi}}(\boldsymbol{y}|\boldsymbol{x})}[\boldsymbol{y}])$ (Fang et al., 2017), the representation of sentences in the labeled data $\sum_{(\boldsymbol{x}',\boldsymbol{y}')\in D^{lab}} \boldsymbol{h}(\boldsymbol{x}')$, the representation of sentences in the random pool of unlabelled data $\sum_{\boldsymbol{x}'\in D^{pool}_{rnd}} \boldsymbol{h}(\boldsymbol{x}')$, the representation of ground-truth labels in the labeled data $\sum_{(\boldsymbol{x}',\boldsymbol{y}')\in D^{lab}} \text{cnn}_{\text{lab}}(\boldsymbol{y}')$ using the empirical distributions, and the confidence of the sequential pre-

[3]As the contingency table needed for the McNemar test, we have used the average counts across the 25 runs.

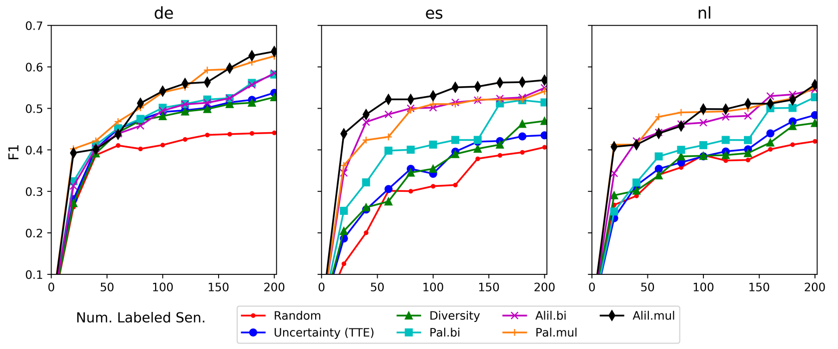

Figure 3: The performance of active learning methods on the bilingual and multilingual settings for three target languages: German (de), Spanish (es) and Dutch (nl).

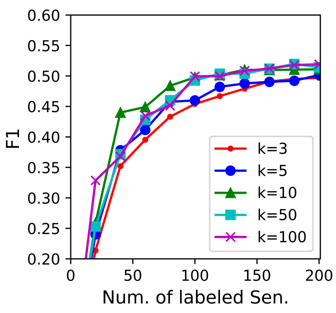

Figure 4: The learning curves of agents with different K on Spanish (es) NER.

diction $\sqrt[|\boldsymbol{x}|]{\max_{\boldsymbol{y}} m_{\boldsymbol{\phi}}(\boldsymbol{y}|\boldsymbol{x})}$, where $|\boldsymbol{x}|$ denotes the length of the sentence $\boldsymbol{x}$. For the word embeddings, we use off-the-shelf CCA trained multilingual embeddings (Ammar et al., 2016) with 40 dimensions; we fix these during policy training.

Results. Fig. 3 shows the results for three target languages. In addition to the strong heuristic-based methods, we compare our imitation learning approach (ALIL) with the reinforcement learning approach (PAL) (Fang et al., 2017), in both bilingual (bi) and multilingual (mul) transfer settings. Across all three languages, ALIL.bi and ALIL.mul outperform the heuristic methods, including Uncertainty Sampling based on TTE. This is expected as the uncertainty sampling largely relies on a high quality underlying model, and diversity sampling ignores the labelling information. In the bilingual case, ALIL.bi outperforms PAL.bi on Spanish (es) and Dutch (nl), and performs similarly on German (de). In the multilingual case, ALIL.mul achieves the best performance on Spanish, and performs competitively with PAL.mul on German and Dutch.

4.3 Analysis

Insight on the selected data. We compare the data selected by ALIL to other methods. This will confirm that ALIL learns policies which are suitable for the problem at hand, without resorting to a fixed engineered heuristics. For this analysis, we report the mean reciprocal rank (MRR) of the data points selected by the ALIL policy under rankings of the unlabelled pool generated by the uncertainty and diversity sampling. Furthermore, we measure the fraction of times the decisions made by the ALIL policy agrees with those which would

	movie sentiment	gender pt	NER es
acc Unc.	0.06	0.58	0.51
MRR Unc.	0.083	0.674	0.551
acc Div.	0.05	0.52	0.45
MRR Div.	0.057	0.593	0.530
acc PAL	0.15	0.56	0.52

Table 3: The first four rows show MRR and accuracy of instances returned by ALIL under the rankings of uncertainty and diversity sampling, the last row give average accuracy of instances under PAL.

have been made by the heuristic methods, which is measured by the accuracy (acc). Table 3 report these measures. As we can see, for sentiment classification since uncertainty and diversity sampling perform badly, ALIL has a big disagreement with them on the selected data points. While for gender classification on Portuguese and NER on Spanish, ALIL shows much more agreement with other three heuristics.

Lastly, we compare chosen queries by ALIL to those by PAL, to investigate the extent of the agreement between these two methods. This is simply measure by the fraction of identical query data points among the total number of queries (i.e. accuracy). Since PAL is stream-based and sensitive to the order in which it receives the data points, we report the *average* accuracy taken over multiple runs with random input streams. The expected accuracy numbers are reported in Table 3. As seen, ALIL has higher overlap with PAL than the heuristic-based methods, in terms of the selected queries.

Sensitivity to K. As seen in Algorithm 1, we resort to an approximate algorithmic expert, which selects the best action in a random subset of the

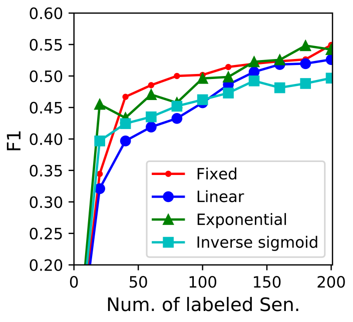

Figure 5: The learning curves of agents with different schedules for β before the trajectory on Spanish (es) NER.

pool of unlabelled data with size K, in order to make the policy training efficient. Note that, in policy training, setting K to one and the size of the unlabelled data pool correspond to stream-based and pool-based AL scenarios, respectively. By changing K to values between these two extremes, we can analyse the effect of the quality of the algorithmic expert on the trained policy; Figure 4 shows the results. A larger candidate set may correspond to a better learned policy, needed to be traded off with the training time growing linearly with K. Interestingly, even small candidate sets lead to strong AL policies as increasing K beyond 10 does not change the performance significantly.

Dynamically changing β. In our algorithm, β plays an important role as it trades off exploration versus exploitation. In the above experiments, we fix it to 0.5; however, we can change its value throughout trajectory collection as a function of τ (see Algorithm 1). We investigate schedules which tend to put more emphasis on exploration and exploitation towards the beginning and end of data collection, respectively. We investigate the following schedules: (i) linear $\beta_\tau = \max(0.5, 1 - 0.01\tau)$, (ii) exponential $\beta_\tau = 0.9^\tau$, and (iii) and inverse sigmoid $\beta_\tau = \frac{5}{5+exp(\tau/5)}$, as a function of iterations. Fig. 5 shows the comparisons of these schedules. The learned policy seems to perform competitively with either a fixed or an exponential schedule. We have also investigated tossing the coin in each step *within* the trajectory roll out, but found that it is more effective to have it *before* the full trajectory roll out (as currently done in Algorithm 1).

5 Related Work

Traditional active learning algorithms rely on various heuristics (Settles, 2010), such as uncertainty sampling (Settles and Craven, 2008; Houlsby et al., 2011), query-by-committee (Gilad-Bachrach et al., 2006), and diversity sampling (Brinker, 2003; Joshi et al., 2009; Yang et al., 2015). Apart from these, different heuristics can be combined, thus creating integrated strategy which consider one or more heuristics at the same time. Combined with transfer learning, pre-existing labeled data from related tasks can help improve the performance of an active learner (Xiao and Guo, 2013; Kale and Liu, 2013; Huang and Chen, 2016; Konyushkova et al., 2017). More recently, deep reinforcement learning is used as the framework for *learning* active learning algorithms, where the active learning cycle is considered as a decision process. (Woodward and Finn, 2017) extended one shot learning to active learning and combined reinforcement learning with a deep recurrent model to make labeling decisions. (Bachman et al., 2017) introduced a policy gradient based method which jointly learns data representation, selection heuristic as well as the model prediction function. (Fang et al., 2017) designed an active learning algorithm based on a deep Q-network, in which the action corresponds to binary annotation decisions applied to a stream of data. The learned policy can then be transferred between languages or domains.

Imitation learning (IL) refers to an agent's acquisition of skills or behaviours by observing an expert's trajectory in a given task. It helps reduce sequential prediction tasks into supervised learning by employing a (near) optimal oracle at training time. Several IL algorithms has been proposed in sequential prediction tasks, including SEARA (Daumé et al., 2009), AggreVaTe (Ross and Bagnell, 2014), DaD (Venkatraman et al., 2015), LOLS(Chang et al., 2015), DeeplyAggreVaTe (Sun et al., 2017). Our work is closely related to Dagger (Ross et al., 2011), which can guarantee to find a good policy by addressing the dependency nature of encountered states in a trajectory.

6 Conclusion

In this paper, we have proposed a new method for learning active learning algorithms using deep imitation learning. We formalize pool-based active learning as a Markov decision process, in which active learning corresponds to the selection decision of the most informative data points from the pool. Our efficient algorithmic expert provides state-action pairs from which effective active learning policies can be learned. We show that the algorithmic expert allows direct policy learning, while at the same time, the learned policies transfer successfully between domains and languages, demonstrating improvement over previous heuristic and reinforcement learning approaches.

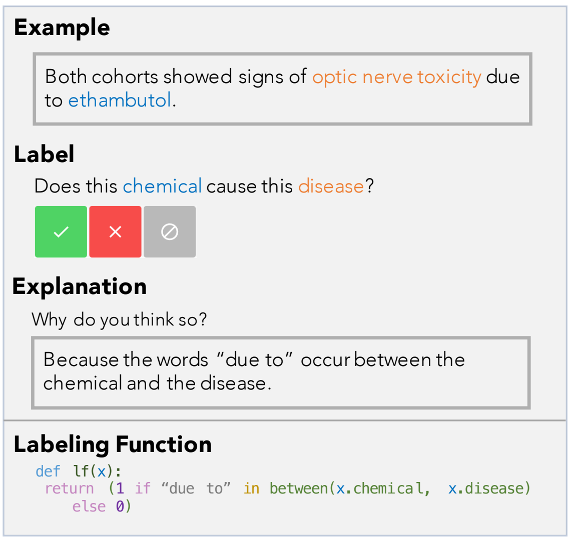
Abstract

Training accurate classifiers requires many labels, but each label provides only limited information (one bit for binary classification). In this work, we propose `BabbleLabble`, a framework for training classifiers in which an annotator provides a natural language explanation for each labeling decision. A semantic parser converts these explanations into programmatic labeling functions that generate noisy labels for an arbitrary amount of unlabeled data, which is used to train a classifier. On three relation extraction tasks, we find that users are able to train classifiers with comparable F1 scores from 5–100 faster by providing explanations instead of just labels. Furthermore, given the inherent imperfection of labeling functions, we find that a simple rule-based semantic parser suffices.

1 Introduction

The standard protocol for obtaining a labeled dataset is to have a human annotator view each example, assess its relevance, and provide a label (e.g., positive or negative for binary classification). However, this only provides one bit of information per example. This invites the question: how can we get more information per example, given that the annotator has already spent the effort reading and understanding an example?

Previous works have relied on identifying relevant parts of the input such as labeling features (Druck et al., 2009; Raghavan et al., 2005; Liang et al., 2009), highlighting rationale phrases in text (Zaidan and Eisner, 2008; Arora and Nyberg, 2009), or marking relevant regions in images (Ahn et al., 2006). But there are certain types of information which cannot be easily reduced to annotating a portion of the input, such as the absence of a certain word, or the presence of at least two words. In this work, we tap into the power of natural language and allow annotators to provide supervision to a classifier via *natural language explanations*.



Example

Both cohorts showed signs of optic nerve toxicity due to ethambutol.

Label

Does this chemical cause this disease?

Explanation

Why do you think so?

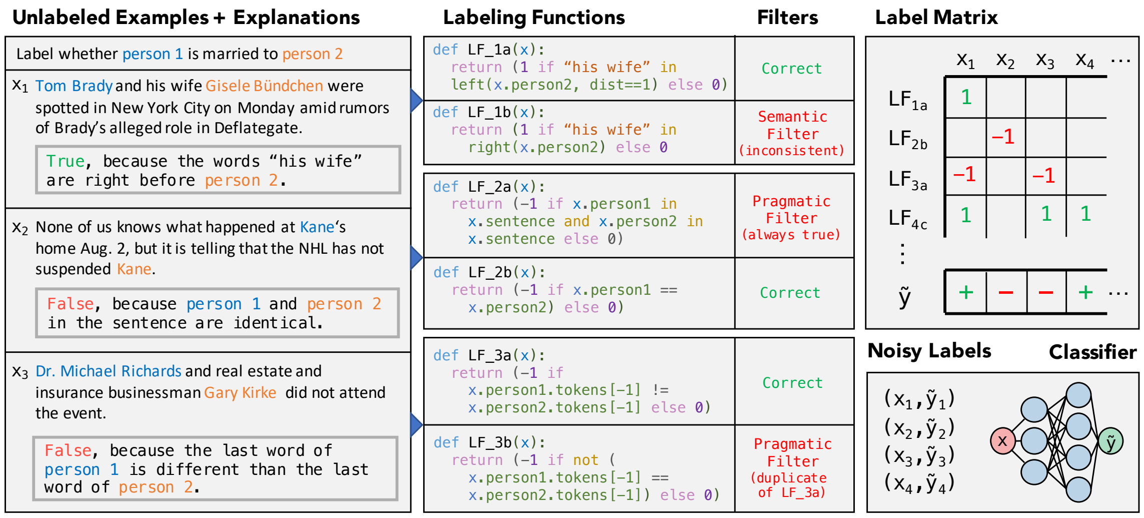
Because the words "due to" occur between the chemical and the disease.

Labeling Function

```
def lf(x):
  return (1 if "due to" in between(x.chemical, x.disease)
      else 0)
```

Figure 1: In `BabbleLabble`, the user provides a natural language explanation for each labeling decision. These explanations are parsed into labeling functions that convert unlabeled data into a large labeled dataset for training a classifier.

Specifically, we propose a framework in which annotators provide a natural language explanation for each label they assign to an example (see Figure 1). These explanations are parsed into logical forms representing labeling functions (LFs), functions that heuristically map examples to labels (Ratner et al., 2016). The labeling functions are



Unlabeled Examples + Explanations
Label whether person 1 is married to person 2
x_1 Tom Brady and his wife Gisele Bündchen were spotted in New York City on Monday amid rumors of Brady's alleged role in Deflategate.
True, because the words "his wife" are right before person 2.
x_2 None of us knows what happened at Kane's home Aug. 2, but it is telling that the NHL has not suspended Kane.
False, because person 1 and person 2 in the sentence are identical.
x_3 Dr. Michael Richards and real estate and insurance businessman Gary Kirke did not attend the event.
False, because the last word of person 1 is different than the last word of person 2.

Figure 2: Natural language explanations are parsed into candidate labeling functions (LFs). Many incorrect LFs are filtered out automatically by the filter bank. The remaining functions provide heuristic labels over the unlabeled dataset, which are aggregated into one noisy label per example, yielding a large, noisily-labeled training set for a classifier.

then executed on many unlabeled examples, resulting in a large, weakly-supervised training set that is then used to train a classifier.

Semantic parsing of natural language into logical forms is recognized as a challenging problem and has been studied extensively (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Liang et al., 2011; Liang, 2016). One of our major findings is that in our setting, even a simple rule-based semantic parser suffices for three reasons: First, we find that the majority of incorrect LFs can be automatically filtered out either semantically (e.g., is it consistent with the associated example?) or pragmatically (e.g., does it avoid assigning the same label to the entire training set?). Second, LFs near the gold LF in the space of logical forms are often just as accurate (and sometimes even more accurate). Third, techniques for combining weak supervision sources are built to tolerate some noise (Alfonseca et al., 2012; Takamatsu et al., 2012; Ratner et al., 2018). The significance of this is that we can deploy the same semantic parser across tasks without task-specific training. We show how we can tackle a real-world biomedical application with the same semantic parser used to extract instances of spouses.

Our work is most similar to that of Srivastava et al. (2017), who also use natural language explanations to train a classifier, but with two important differences. First, they jointly train a task-specific semantic parser and classifier, whereas we use a simple rule-based parser. In Section 4, we find that in our weak supervision framework, the rule-based semantic parser and the perfect parser yield nearly identical downstream performance. Second, while they use the logical forms of explanations to produce *features* that are fed directly to a classifier, we use them as *functions* for labeling a much larger training set. In Section 4, we show that using functions yields a 9.5 F1 improvement (26% relative improvement) over features, and that the F1 score scales with the amount of available unlabeled data.

We validate our approach on two existing datasets from the literature (extracting spouses from news articles and disease-causing chemicals from biomedical abstracts) and one real-world use case with our biomedical collaborators at OccamzRazor to extract protein-kinase interactions related to Parkinson's disease from text. We find empirically that users are able to train classifiers with comparable F1 scores up to two orders of magnitude faster when they provide natural language explanations instead of individual labels. Our code and data can be found at `https://github.com/HazyResearch/babble`.

2 The `BabbleLabble` Framework

The `BabbleLabble` framework converts natural language explanations and unlabeled data into a noisily-labeled training set (see Figure 2). There are three key components: a semantic parser, a filter bank, and a label aggregator. The semantic

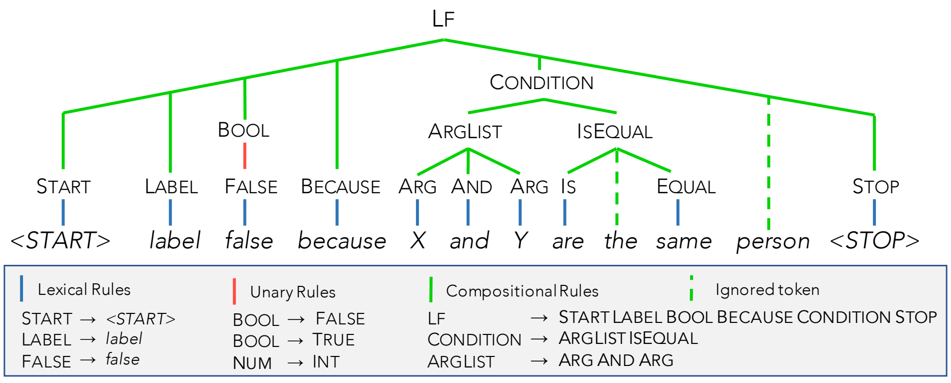

Figure 3: Valid parses are found by iterating over increasingly large subspans of the input looking for matches among the right hand sides of the rules in the grammar. Rules are either lexical (converting tokens into symbols), unary (converting one symbol into another symbol), or compositional (combining many symbols into a single higher-order symbol). A rule may optionally ignore unrecognized tokens in a span (denoted here with a dashed line).

parser converts natural language explanations into a set of logical forms representing labeling functions (LFs). The filter bank removes as many incorrect LFs as possible without requiring ground truth labels. The remaining LFs are applied to unlabeled examples to produce a matrix of labels. This label matrix is passed into the label aggregator, which combines these potentially conflicting and overlapping labels into one label for each example. The resulting labeled examples are then used to train an arbitrary discriminative model.

2.1 Explanations

To create the input explanations, the user views a subset S of an unlabeled dataset D (where $|S| \ll |D|$) and provides for each input $x_i \in S$ a label y_i and a natural language explanation e_i, a sentence explaining why the example should receive that label. The explanation e_i generally refers to specific aspects of the example (e.g., in Figure 2, the location of a specific string "his wife").

2.2 Semantic Parser

The semantic parser takes a natural language explanation e_i and returns a set of LFs (logical forms or labeling functions) $\{f_1, \ldots, f_k\}$ of the form $f_i : \mathcal{X} \to \{-1, 0, 1\}$ in a binary classification setting, with 0 representing abstention. We emphasize that the goal of this semantic parser is *not* to generate the single correct parse, but rather to have coverage over many potentially useful LFs.[1]

[1]Indeed, we find empirically that an incorrect LF nearby the correct one in the space of logical forms actually has higher end-task accuracy 57% of the time (see Section 4.2).

We choose a simple rule-based semantic parser that can be used without any training. Formally, the parser uses a set of rules of the form $\alpha \to \beta$, where α can be replaced by the token(s) in β (see Figure 3 for example rules). To identify candidate LFs, we recursively construct a set of valid parses for each span of the explanation, based on the substitutions defined by the grammar rules. At the end, the parser returns all valid parses (LFs in our case) corresponding to the entire explanation.

We also allow an arbitrary number of tokens in a given span to be ignored when looking for a matching rule. This improves the ability of the parser to handle unexpected input, such as unknown words or typos, since the portions of the input that *are* parseable can still result in a valid parse. For example, in Figure 3, the word "person" is ignored.

All predicates included in our grammar (summarized in Table 1) are provided to annotators, with minimal examples of each in use (Appendix A). Importantly, all rules are domain independent (e.g., all three relation extraction tasks that we tested used the same grammar), making the semantic parser easily transferrable to new domains. Additionally, while this paper focuses on the task of relation extraction, in principle the `BabbleLabble` framework can be applied to other tasks or settings by extending the grammar with the necessary primitives (e.g., adding primitives for rows and columns to enable explanations about the alignments of words in tables). To guide the construction of the grammar, we collected 500 explanations for the `Spouse` domain from workers

Predicate	Description
`bool, string, int, float, tuple, list, set`	Standard primitive data types
`and, or, not, any, all, none`	Standard logic operators
$=, \neq, <, \leq, >, \geq$	Standard comparison operators
`lower, upper, capital, all_caps`	Return True for strings of the corresponding case
`starts_with, ends_with, substring`	Return True if the first string starts/ends with or contains the second
`person, location, date, number, organization`	Return True if a string has the corresponding NER tag
`alias`	A frequently used list of words may be predefined and referred to with an alias
`count, contains, intersection`	Operators for checking size, membership, or common elements of a `list/set`
`map, filter`	Apply a functional primitive to each member of `list/set` to transform or filter the elements
`word_distance, character_distance`	Return the distance between two strings by words or characters
`left, right, between, within`	Return as a string the text that is left/right/within some distance of a string or between two designated strings

Table 1: Predicates in the grammar supported by `BabbleLabble`'s rule-based semantic parser.

on Amazon Mechanical Turk and added support for the most commonly used predicates. These were added before the experiments described in Section 4. Altogether the grammar contains 200 rule templates.

2.3 Filter Bank

The input to the filter bank is a set of candidate LFs produced by the semantic parser. The purpose of the filter bank is to discard as many incorrect LFs as possible without requiring additional labels. It consists of two classes of filters: semantic and pragmatic.

Recall that each explanation e_i is collected in the context of a specific labeled example (x_i, y_i). The *semantic filter* checks for LFs that are inconsistent with their corresponding example; formally, any LF f for which $f(x_i) \neq y_i$ is discarded. For example, in the first explanation in Figure 2, the word "right" can be interpreted as either "immediately" (as in "right before") or simply "to the right." The latter interpretation results in a function that is inconsistent with the associated example (since "his wife" is actually to the left of person 2), so it can be safely removed.

The *pragmatic filters* removes LFs that are constant, redundant, or correlated. For example, in Figure 2, `LF_2a` is constant, as it labels every example positively (since all examples contain two people from the same sentence). `LF_3b` is redundant, since even though it has a different syntax tree from `LF_3a`, it labels the training set identically and therefore provides no new signal.

Finally, out of all LFs from the same explanation that pass all the other filters, we keep only the most specific (lowest coverage) LF. This prevents multiple correlated LFs from a single example from dominating.

As we show in Section 4, over three tasks, the filter bank removes 86% of incorrect parses, and the incorrect ones that remain have average end-task accuracy within 2.5% of the corresponding correct parses.

2.4 Label Aggregator

The label aggregator combines multiple (potentially conflicting) suggested labels from the LFs and combines them into a single probabilistic label per example. Concretely, if m LFs pass the filter bank and are applied to n examples, the label aggregator implements a function $f : \{-1, 0, 1\}^{m \times n} \to [0, 1]^n$.

A naive solution would be to use a simple majority vote, but this fails to account for the fact that LFs can vary widely in accuracy and coverage. Instead, we use data programming (Ratner et al., 2016), which models the relationship between the true labels and the output of the labeling functions as a factor graph. More specifically, given the true labels $Y \in \{-1, 1\}^n$ (latent) and label matrix $\Lambda \in \{-1, 0, 1\}^{m \times n}$ (observed) where $\Lambda_{i,j} = \text{LF}_i(x_j)$, we define two types of factors representing labeling propensity and accuracy:

$$\phi_{i,j}^{\text{Lab}}(\Lambda, Y) = \mathbb{1}\{\Lambda_{i,j} \neq 0\} \tag{1}$$
$$\phi_{i,j}^{\text{Acc}}(\Lambda, Y) = \mathbb{1}\{\Lambda_{i,j} = y_j\}. \tag{2}$$

Denoting the vector of factors pertaining to a given data point x_j as $\phi_j(\Lambda, Y) \in \mathbb{R}^m$, define the model:

$$p_w(\Lambda, Y) = Z_w^{-1} \exp\Big(\sum_{j=1}^{n} w \cdot \phi_j(\Lambda, Y)\Big), \tag{3}$$

Spouse (person 1, person 2)	Example	They include Joan Ridsdale, a 62-year-old payroll administrator from County Durham who was hit with a €16,000 tax bill when her husband Gordon died.
	Explanation	True, because the phrase "her husband" is within three words of person 2.
Disease (chemical, disease)	Example	Young women on replacement estrogens for ovarian failure after cancer therapy may also have increased risk of endometrial carcinoma and should be examined periodically.
	Explanation	True, because "risk of" comes before the disease.
Protein (protein, kinase)	Example	Here we show that c-Jun N-terminal kinases JNK1, JNK2 and JNK3 phosphorylate tau at many serine/threonine-prolines, as assessed by the generation of the epitopes of phosphorylation-dependent anti-tau antibodies.
	Explanation	True, because at least one of the words 'phosphorylation', 'phosphorylate', 'phosphorylated', 'phosphorylates' is found in the sentence and the number of words between the protein and kinase is smaller than 8."

Figure 4: An example and explanation for each of the three datasets.

where $w \in \mathbb{R}^{2m}$ is the weight vector and Z_w is the normalization constant. To learn this model without knowing the true labels Y, we minimize the negative log marginal likelihood given the observed labels Λ:

$$\hat{w} = \arg\min_{w} -\log \sum_{Y} p_w(\Lambda, Y) \tag{4}$$

using SGD and Gibbs sampling for inference, and then use the marginals $p_{\hat{w}}(Y \mid \Lambda)$ as probabilistic training labels.

Intuitively, we infer accuracies of the LFs based on the way they overlap and conflict with one another. Since noisier LFs are more likely to have high conflict rates with others, their corresponding accuracy weights in w will be smaller, reducing their influence on the aggregated labels.

2.5 Discriminative Model

The noisily-labeled training set that the label aggregator outputs is used to train an arbitrary discriminative model. One advantage of training a discriminative model on the task instead of using the label aggregator as a classifier directly is that the label aggregator only takes into account those signals included in the LFs. A discriminative model, on the other hand, can incorporate features that were not identified by the user but are nevertheless informative.[2] Consequently, even examples for which all LFs abstained can still be classified correctly. On the three tasks we evaluate, using the discriminative model averages 4.3 F1 points higher than using the label aggregator directly.

For the results reported in this paper, our discriminative model is a simple logistic regression classifier with generic features defined over dependency paths.[3] These features include unigrams, bigrams, and trigrams of lemmas, dependency labels, and part of speech tags found in the siblings, parents, and nodes between the entities in the dependency parse of the sentence. We found this to perform better on average than a biLSTM, particularly for the traditional supervision baselines with small training set sizes; it also provided easily interpretable features for analysis.

[2]We give an example of two such features in Section 4.3.

[3]https://github.com/HazyResearch/treedlib

Task	Train	Dev	Test	% Pos.
Spouse	22195	2796	2697	8%
Disease	6667	773	4101	20%
Protein	5546	1011	1058	22%

Table 2: The total number of unlabeled training examples (a pair of annotated entities in a sentence), labeled development examples (for hyperparameter tuning), labeled test examples (for assessment), and the fraction of positive labels in the test split.

3 Experimental Setup

We evaluate the accuracy of BabbleLabble on three relation extraction tasks, which we refer to as Spouse, Disease, and Protein. The goal of each task is to train a classifier for predicting whether the two entities in an example are participating in the relationship of interest, as described below.

3.1 Datasets

Statistics for each dataset are reported in Table 2, with one example and one explanation for each given in Figure 4 and additional explanations shown in Appendix B.

In the Spouse task, annotators were shown a sentence with two highlighted names and asked to label whether the sentence suggests that the two people are spouses. Sentences were pulled from the Signal Media dataset of news articles (Corney

	BL				TS			
# Inputs	30	30	60	150	300	1,000	3,000	10,000
`Spouse`	50.1	15.5	15.9	16.4	17.2	22.8	41.8	55.0
`Disease`	42.3	32.1	32.6	34.4	37.5	41.9	44.5	-
`Protein`	47.3	39.3	42.1	46.8	51.0	57.6	-	-
Average	46.6	28.9	30.2	32.5	35.2	40.8	43.2	55.0

Table 3: F1 scores obtained by a classifier trained with `BabbleLabble` (BL) using 30 explanations or with traditional supervision (TS) using the specified number of individually labeled examples. `BabbleLabble` achieves the same F1 score as traditional supervision while using fewer user inputs by a factor of over 5 (`Protein`) to over 100 (`Spouse`).

et al., 2016). Ground truth data was collected from Amazon Mechanical Turk workers, accepting the majority label over three annotations. The 30 explanations we report on were sampled randomly from a pool of 200 that were generated by 10 graduate students unfamiliar with `BabbleLabble`.

In the `Disease` task, annotators were shown a sentence with highlighted names of a chemical and a disease and asked to label whether the sentence suggests that the chemical causes the disease. Sentences and ground truth labels came from a portion of the 2015 BioCreative chemical-disease relation dataset (Wei et al., 2015), which contains abstracts from PubMed. Because this task requires specialized domain expertise, we obtained explanations by having someone unfamiliar with `BabbleLabble` translate from Python to natural language labeling functions from an existing publication that explored applying weak supervision to this task (Ratner et al., 2018).

The `Protein` task was completed in conjunction with OccamzRazor, a neuroscience company targeting biological pathways of Parkinson's disease. For this task, annotators were shown a sentence from the relevant biomedical literature with highlighted names of a protein and a kinase and asked to label whether or not the kinase influences the protein in terms of a physical interaction or phosphorylation. The annotators had domain expertise but minimal programming experience, making `BabbleLabble` a natural fit for their use case.

3.2 Experimental Settings

Text documents are tokenized with spaCy.[4] The semantic parser is built on top of the Python-based implementation SippyCup.[5] On a single core, parsing 360 explanations takes approximately two seconds. We use existing implementations of the label aggregator, feature library, and discriminative classifier described in Sections 2.4–2.5 provided by the open-source project Snorkel (Ratner et al., 2018).

Hyperparameters for all methods we report were selected via random search over thirty configurations on the same held-out development set. We searched over learning rate, batch size, L_2 regularization, and the subsampling rate (for improving balance between classes).[6] All reported F1 scores are the average value of 40 runs with random seeds and otherwise identical settings.

4 Experimental Results

We evaluate the performance of `BabbleLabble` with respect to its rate of improvement by number of user inputs, its dependence on correctly parsed logical forms, and the mechanism by which it utilizes logical forms.

4.1 High Bandwidth Supervision

In Table 3 we report the average F1 score of a classifier trained with `BabbleLabble` using 30 explanations or traditional supervision with the indicated number of labels. On average, it took the same amount of time to collect 30 explanations as 60 labels.[7] We observe that in all three tasks, `BabbleLabble` achieves a given F1 score with far fewer user inputs than traditional supervision, by

[4]https://github.com/explosion/spaCy

[5]https://github.com/wcmac/sippycup

[6]Hyperparameter ranges: learning rate (1e-2 to 1e-4), batch size (32 to 128), L_2 regularization (0 to 100), subsampling rate (0 to 0.5)

[7]Zaidan and Eisner (2008) also found that collecting annotator rationales in the form of highlighted substrings from the sentence only doubled annotation time.

	Pre-filters		Discarded		Post-filters	
	LFs	Correct	Sem.	Prag.	LFs	Correct
Spouse	153	10%	19	115	19	84%
Disease	104	23%	41	36	27	89%
Protein	122	14%	44	58	20	85%

Table 4: The number of LFs generated from 30 explanations (pre-filters), discarded by the filter bank, and remaining (post-filters), along with the percentage of LFs that were correctly parsed from their corresponding explanations.

	BL-FB	BL	BL+PP
Spouse	15.7	50.1	49.8
Disease	39.8	42.3	43.2
Protein	38.2	47.3	47.4
Average	31.2	46.6	46.8

Table 5: F1 scores obtained using BabbleLabble with no filter bank (BL-FB), as normal (BL), and with a perfect parser (BL+PP) simulated by hand.

as much as 100 times in the case of the Spouse task. Because explanations are applied to many unlabeled examples, each individual input from the user can implicitly contribute many (noisy) labels to the learning algorithm.

We also observe, however, that once the number of labeled examples is sufficiently large, traditional supervision once again dominates, since ground truth labels are preferable to noisy ones generated by labeling functions. However, in domains where there is much more unlabeled data available than labeled data (which in our experience is most domains), we can gain in supervision efficiency from using BabbleLabble.

Of those explanations that did not produce a correct LF, 4% were caused by the explanation referring to unsupported concepts (e.g., one explanation referred to "the subject of the sentence," which our simple parser doesn't support). Another 2% were caused by human errors (the correct LF for the explanation was inconsistent with the example). The remainder were due to unrecognized paraphrases (e.g., the explanation said "the order of appearance is X, Y" instead of a supported phrasing like "X comes before Y").

4.2 Utility of Incorrect Parses

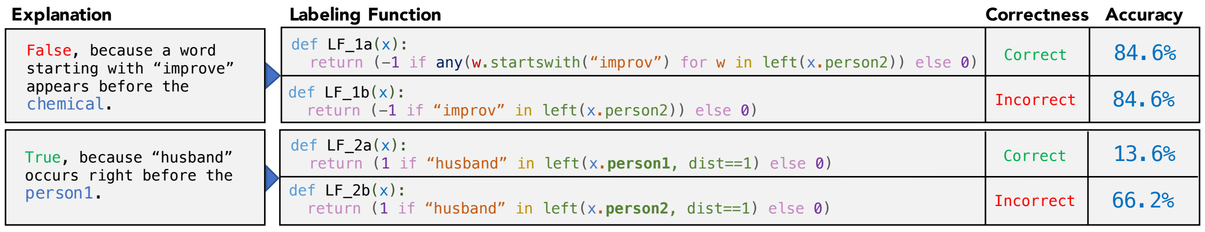
In Table 4, we report LF summary statistics before and after filtering. LF correctness is based on exact match with a manually generated parse for each explanation. Surprisingly, the simple heuristic-based filter bank successfully removes over 95% of incorrect LFs in all three tasks, resulting in final LF sets that are 86% correct on average. Furthermore, among those LFs that pass through the filter bank, we found that the average difference in end-task accuracy between correct and incorrect parses is less than 2.5%. Intuitively, the filters are effective because it is quite difficult for an LF to be parsed from the explanation, label its own example correctly (passing the semantic filter), and not label all examples in the training set with the same label or identically to another LF (passing the pragmatic filter).

We went one step further: using the LFs that would be produced by a perfect semantic parser as starting points, we searched for "nearby" LFs (LFs differing by only one predicate) with higher end-task accuracy on the test set and succeeded 57% of the time (see Figure 5 for an example). In other words, when users provide explanations, the signals they describe provide good starting points, but they are actually unlikely to be optimal. This observation is further supported by Table 5, which shows that the filter bank is necessary to remove clearly irrelevant LFs, but with that in place, the simple rule-based semantic parser and a perfect parser have nearly identical average F1 scores.

4.3 Using LFs as Functions or Features

Once we have relevant logical forms from user-provided explanations, we have multiple options for how to use them. Srivastava et al. (2017) propose using these logical forms as features in a linear classifier. We choose instead to use them as functions for weakly supervising the creation of a larger training set via data programming (Ratner et al., 2016). In Table 6, we compare the two approaches directly, finding that the the data programming approach outperforms a feature-based one by 9.5 F1 points with the rule-based parser, and by 4.5 points with a perfect parser.

We attribute this difference primarily to the ability of data programming to utilize unlabeled data. In Figure 6, we show how the data programming approach improves with the number of unlabeled examples, even as the number of LFs remains constant. We also observe qualitatively that data programming exposes the classifier to additional patterns that are correlated with our explanations but not mentioned directly. For example, in the Disease task, two of the features weighted most



Explanation	Labeling Function	Correctness	Accuracy
False, because a word starting with "improve" appears before the chemical.	`def LF_1a(x): return (-1 if any(w.startswith("improv") for w in left(x.person2)) else 0)`	Correct	84.6%
	`def LF_1b(x): return (-1 if "improv" in left(x.person2)) else 0)`	Incorrect	84.6%
True, because "husband" occurs right before the person1.	`def LF_2a(x): return (1 if "husband" in left(x.person1, dist==1) else 0)`	Correct	13.6%
	`def LF_2b(x): return (1 if "husband" in left(x.person2, dist==1) else 0)`	Incorrect	66.2%

Figure 5: Incorrect LFs often still provide useful signal. On top is an incorrect LF produced for the `Disease` task that had the same accuracy as the correct LF. On bottom is a correct LF from the `Spouse` task and a more accurate incorrect LF discovered by randomly perturbing one predicate at a time as described in Section 4.2. (Person 2 is always the second person in the sentence).

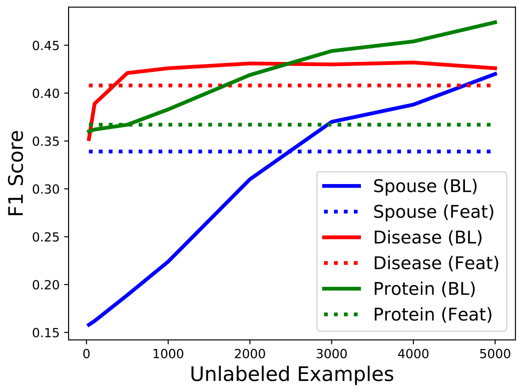


Figure 6: When logical forms of natural language explanations are used as functions for data programming (as they are in `BabbleLabble`), performance can improve with the addition of *unlabeled* data, whereas using them as features does not benefit from unlabeled data.

	BL-DM	BL	BL+PP	Feat	Feat+PP
`Spouse`	46.5	50.1	49.8	33.9	39.2
`Disease`	39.7	42.3	43.2	40.8	43.8
`Protein`	40.6	47.3	47.4	36.7	44.0
Average	42.3	46.6	46.8	37.1	42.3

Table 6: F1 scores obtained using explanations as functions for data programming (BL) or features (Feat), optionally with no discriminative model (-DM) or using a perfect parser (+PP).

highly by the discriminative model were the presence of the trigrams "could produce a" or "support diagnosis of" between the chemical and disease, despite none of these words occurring in the explanations for that task. In Table 6 we see a 4.3 F1 point improvement (10%) when we use the discriminative model that can take advantage of these features rather than applying the LFs directly to the test set and making predictions based on the output of the label aggregator.

5 Related Work and Discussion

Our work has two themes: modeling natural language explanations/instructions and learning from weak supervision. The closest body of work is on "learning from natural language." As mentioned earlier, Srivastava et al. (2017) convert natural language explanations into classifier features (whereas we convert them into labeling functions). Goldwasser and Roth (2011) convert natural language into concepts (e.g., the rules of a card game). Ling and Fidler (2017) use natural language explanations to assist in supervising an image captioning model. Weston (2016); Li et al. (2016) learn from natural language feedback in a dialogue. Wang et al. (2017) convert natural language definitions to rules in a semantic parser to build up progressively higher-level concepts.

We lean on the formalism of semantic parsing (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Liang, 2016). One notable trend is to learn semantic parsers from weak supervision (Clarke et al., 2010; Liang et al., 2011), whereas our goal is to obtain weak supervision signal from semantic parsers.

The broader topic of weak supervision has received much attention; we mention some works most related to relation extraction. In distant supervision (Craven et al., 1999; Mintz et al., 2009) and multi-instance learning (Riedel et al., 2010; Hoffmann et al., 2011), an existing knowledge base is used to (probabilistically) impute a training set. Various extensions have focused on aggregating a variety of supervision sources by learning generative models from noisy labels (Alfonseca et al., 2012; Takamatsu et al., 2012; Roth and Klakow, 2013; Ratner et al., 2016; Varma et al., 2017).

Finally, while we have used natural language explanations as *input* to train models, they can also be *output* to interpret models (Krening et al., 2017; Lei et al., 2016). More generally, from a machine learning perspective, labels are the primary asset, but they are a low bandwidth signal between annotators and the learning algorithm. Natural language opens up a much higher-bandwidth communication channel. We have shown promising results in relation extraction (where one explanation can be "worth" 100 labels), and it would be interesting to extend our framework to other tasks and more interactive settings.

Reproducibility

The code, data, and experiments for this paper are available on the CodaLab platform at https://worksheets.codalab.org/worksheets/0x900e7e41deaa4ec5b2fe41dc50594548/.

A Predicate Examples

Below are the predicates in the rule-based semantic parser grammar, each of which may have many supported paraphrases, only one of which is listed here in a minimal example.

Logic
```
and:  X is true and Y is true
or:  X is true or Y is true
not:  X is not true
any:  Any of X or Y or Z is true
all:  All of X and Y and Z are true
none:  None of X or Y or Z is true
```

Comparison
```
=:  X is equal to Y
≠:  X is not Y
<:  X is smaller than Y
≤:  X is no more than Y
>:  X is larger than Y
≥:  X is at least Y
```

Syntax
```
lower:  X is lowercase
upper:  X is upper case
capital:  X is capitalized
all_caps:  X is in all caps
starts_with:  X starts with "cardio"
ends_with:  X ends with "itis"
substring:  X contains "-induced"
```

Named-entity Tags
```
person:  A person is between X and Y
location:  A place is within two words of X
date:  A date is between X and Y
number:  There are three numbers in the sentence
organization:  An organization is right after X
```

Lists
```
list:  (X, Y) is in Z
set:  X, Y, and Z are true
count:  There is one word between X and Y
contains:  X is in Y
intersection:  At least two of X are in Y
map:  X is at the start of a word in Y
filter:  There are three capitalized words to the left of X
alias:  A spouse word is in the sentence (“spouse” is a predefined list from the user)
```

Position
```
word_distance:  X is two words before Y
char_distance:  X is twenty characters after Y
left:  X is before Y
right:  X is after Y
between:  X is between Y and Z
within:  X is within five words of Y
```

B Sample Explanations

The following are a sample of the explanations provided by users for each task.

`Spouse`
Users referred to the first person in the sentence as "X" and the second as "Y".

```
Label true because "and" occurs between X and Y and "marriage" occurs
one word after person1.

Label true because person Y is preceded by ‘beau’.

Label false because the words "married", "spouse", "husband", and
"wife" do not occur in the sentence.

Label false because there are more than 2 people in the sentence and
"actor" or "actress" is left of person1 or person2.
```

`Disease`

```
Label true because the disease is immediately after the chemical and
'induc' or 'assoc' is in the chemical name.

Label true because a word containing 'develop' appears somewhere
before the chemical, and the word 'following' is between the disease
and the chemical.

Label true because "induced by", "caused by", or "due to" appears
between the chemical and the disease."

Label false because "none", "not", or "no" is within 30 characters to
the left of the disease.
```

`Protein`

```
Label true because "Ser" or "Tyr" are within 10 characters of the
protein.

Label true because the words "by" or "with" are between the protein
and kinase and the words "no", "not" or "none" are not in between
the protein and kinase and the total number of words between them is
smaller than 10.

Label false because the sentence contains "mRNA", "DNA", or "RNA".

Label false because there are two "," between the protein and the
kinase with less than 30 characters between them.
```

Did the Model Understand the Question?

Abstract

We analyze state-of-the-art deep learning models for three tasks: question answering on (1) images, (2) tables, and (3) passages of text. Using the notion of *attribution* (word importance), we find that these deep networks often ignore important question terms. Leveraging such behavior, we perturb questions to craft a variety of adversarial examples. Our strongest attacks drop the accuracy of a visual question answering model from 61.1% to 19%, and that of a tabular question answering model from 33.5% to 3.3%. Additionally, we show how attributions can strengthen attacks proposed by Jia and Liang (2017) on paragraph comprehension models. Our results demonstrate that attributions can augment standard measures of accuracy and empower investigation of model performance. When a model is accurate but for the wrong reasons, attributions can surface erroneous logic in the model that indicates inadequacies in the test data.

1 Introduction

Recently, deep learning has been applied to a variety of question answering tasks. For instance, to answer questions about images (e.g. (Kazemi and Elqursh, 2017)), tabular data (e.g. (Neelakantan et al., 2017)), and passages of text (e.g. (Yu et al., 2018)). Developers, end-users, and reviewers (in academia) would all like to understand the capabilities of these models.

The standard way of measuring the goodness of a system is to evaluate its error on a test set. High accuracy is indicative of a good model only if the test set is representative of the underlying real-world task. Most tasks have large test and training sets, and it is hard to manually check that they are representative of the real world.

In this paper, we propose techniques to analyze the sensitivity of a deep learning model to question words. We do this by applying *attribution* (as discussed in section 3), and generating adversarial questions. Here is an illustrative example: recall Visual Question Answering (Agrawal et al., 2015) where the task is to answer questions about images. Consider the question "*how symmetrical are the white bricks on either side of the building?*" (corresponding image in Figure 1). The system that we study gets the answer right ("*very*"). But, we find (using an attribution approach) that the system relies on only a few of the words like "how" and "bricks". Indeed, we can construct adversarial questions about the same image that the system gets wrong. For instance, "*how spherical are the white bricks on either side of the building?*" returns the same answer ("*very*"). A key premise of our work is that most humans have expertise in question answering. Even if they cannot manually check that a dataset is representative of the real world, they can identify important question words, and anticipate their function in question answering.

1.1 Our Contributions

We follow an analysis workflow to understand three question answering models. There are two steps. First, we apply Integrated Gradients (henceforth, IG) (Sundararajan et al., 2017) to attribute the systems' predictions to words in the questions. We propose visualizations of attributions to make analysis easy. Second, we identify weaknesses (e.g., relying on unimportant words) in the networks' logic as exposed by the attributions, and leverage them to craft adversarial questions.

A key contribution of this work is an *overstability* test for question answering networks. Jia and Liang (2017) showed that reading comprehension networks are overly stable to semantics-altering edits to the passage. In this work, we find that such overstability also applies to questions. Furthermore, this behavior can be seen in visual and tabular question answering networks as well. We use attributions to a define a general-purpose test for measuring the extent of the overstability (sections 4.3 and 5.3). It involves measuring how a network's accuracy changes as words are systematically dropped from questions.

We emphasize that, in contrast to model-independent adversarial techniques such as that of Jia and Liang (2017), our method exploits the strengths and weaknesses of the model(s) at hand. This allows our attacks to have a high success rate. Additionally, using insights derived from attributions we were able to improve the attack success rate of Jia and Liang (2017) (section 6.2). Such extensive use of attributions in crafting adversarial examples is novel to the best of our knowledge.

Next, we provide an overview of our results. In each case, we evaluate a pre-trained model on new inputs. We keep the networks' parameters intact.

Visual QA (section 4): The task is to answer questions about images. We analyze the deep network in Kazemi and Elqursh (2017). We find that the network ignores many question words, relying largely on the image to produce answers. For instance, we show that the model retains more than 50% of its original accuracy even when every word that is not "color" is deleted from all questions in the validation set. We also show that the model under-relies on important question words (e.g. nouns) and attaching content-free prefixes (e.g., "in not many words, ...") to questions drops the accuracy from 61.1% to 19%.

QA on tables (section 5): We analyze a system called Neural Programmer (henceforth, NP) (Neelakantan et al., 2017) that answers questions on tabular data. NP determines the answer to a question by selecting a sequence of operations to apply on the accompanying table (akin to an SQL query; details in section 5). We find that these operation selections are more influenced by content-free words (e.g., "in", "at", "the", etc.) in questions than important words such as nouns or adjectives. Dropping all content-free words reduces the validation accuracy of the network from 33.5%[1] to 28.5%. Similar to Visual QA, we show that attaching content-free phrases (e.g., "in not a lot of words") to the question drops the network's accuracy from 33.5% to 3.3%. We also find that NP often gets the answer right for the wrong reasons. For instance, for the question "*which nation earned the most gold medals?*", one of the operations selected by NP is "first" (pick the first row of the table). Its answer is right only because the table happens to be arranged in order of rank. We quantify this weakness by evaluating NP on the set of perturbed tables generated by Pasupat and Liang (2016) and find that its accuracy drops from 33.5% to 23%. Finally, we show an extreme form of overstability where the table itself induces a large bias in the network regardless of the question. For instance, we found that in tables about Olympic medal counts, NP was predisposed to selecting the "prev" operator.

Reading comprehension (Section 6): The task is to answer questions about paragraphs of text. We analyze the network by Yu et al. (2018). Again, we find that the network often ignores words that should be important. Jia and Liang (2017) proposed attacks wherein sentences are added to paragraphs that ought not to change the network's answers, but sometimes do. Our main finding is that these attacks are more likely to succeed when an added sentence includes all the question words that the model found important (for the original paragraph). For instance, we find that attacks are 50% more likely to be successful when the added sentence includes top-attributed nouns in the question. This insight should allow the construction of more successful attacks and better training data sets.

In summary, we find that all networks ignore important parts of questions. One can fix this by either improving training data, or introducing an inductive bias. Our analysis workflow is helpful in both cases. It would also make sense to expose end-users to attribution visualizations. Knowing which words were ignored, or which operations the words were mapped to, can help the user decide whether to trust a system's response.

2 Related Work

We are motivated by Jia and Liang (2017). As they discuss, "*the extent to which [reading comprehension systems] truly understand language remains unclear*". The contrast between Jia and Liang

[1]This is the single-model accuracy that we obtained on training the Neural Programmer network. The accuracy reported in the paper is 34.1%.

(2017) and our work is instructive. Their main contribution is to fix the evaluation of reading comprehension systems by augmenting the test set with adversarially constructed examples. (As they point out in Section 4.6 of their paper, this does not necessarily fix the model; the model may simply learn to circumvent the specific attack underlying the adversarial examples.) Their method is independent of the specification of the model at hand. They use crowdsourcing to craft passage perturbations intended to fool the network, and then query the network to test their effectiveness.

In contrast, we propose improving the analysis of question answering systems. Our method peeks into the logic of a network to identify high-attribution question terms. Often there are several important question terms (e.g., nouns, adjectives) that receive tiny attribution. We leverage this weakness and perturb questions to craft targeted attacks. While Jia and Liang (2017) focus exclusively on systems for the reading comprehension task, we analyze one system each for three different tasks. Our method also helps improve the efficacy Jia and Liang (2017)'s attacks; see table 4 for examples. Our analysis technique is specific to deep-learning-based systems, whereas theirs is not.

We could use many other methods instead of Integrated Gradients (IG) to attribute a deep network's prediction to its input features (Baehrens et al., 2010; Simonyan et al., 2013; Shrikumar et al., 2016; Binder et al., 2016; Springenberg et al., 2014). One could also use model agnostic techniques like Ribeiro et al. (2016b). We choose IG for its ease and efficiency of implementation (requires just a few gradient-calls) and its axiomatic justification (see Sundararajan et al. (2017) for a detailed comparison with other attribution methods).

Recently, there have been a number of techniques for crafting and defending against adversarial attacks on image-based deep learning models (cf. Goodfellow et al. (2015)). They are based on oversensitivity of models, i.e., tiny, imperceptible perturbations of the image to change a model's response. In contrast, our attacks are based on models' over-reliance on few question words even when other words should matter.

We discuss task-specific related work in corresponding sections (sections 4 to 6).

3 Integrated Gradients (IG)

We employ an attribution technique called Integrated Gradients (IG) (Sundararajan et al., 2017) to isolate question words that a deep learning system uses to produce an answer.

Formally, suppose a function $F : \mathbb{R}^n \rightarrow [0, 1]$ represents a deep network, and an input $x = (x_1, \ldots, x_n) \in \mathbb{R}^n$. An attribution of the prediction at input x relative to a baseline input x' is a vector $A_F(x, x') = (a_1, \ldots, a_n) \in \mathbb{R}^n$ where a_i is the *contribution* of x_i to the prediction $F(x)$. One can think of F as the probability of a specific response. $x_1, \ldots, x_n$ are the question words; to be precise, they are going to be vector representations of these terms. The attributions $a_1, \ldots, a_n$ are the influences/blame-assignments to the variables $x_1, \ldots, x_n$ on the probability F.

Notice that attributions are defined relative to a special, uninformative input called the *baseline*. In this paper, we use an empty question as the baseline, that is, a sequence of word embeddings corresponding to padding value. Note that the context (image, table, or passage) of the baseline x' is set to be that of x; only the question is set to empty. We now describe how IG produces attributions.

Intuitively, as we interpolate between the baseline and the input, the prediction moves along a trajectory, from uncertainty to certainty (the final probability). At each point on this trajectory, one can use the gradient of the function F with respect to the input to attribute the change in probability back to the input variables. IG simply aggregates the gradients of the probability with respect to the input along this trajectory using a path integral.

Definition 1 (Integrated Gradients) *Given an input x and baseline x', the integrated gradient along the i^{th} dimension is defined as follows.*

$$\mathsf{IG}_i(x, x') ::= (x_i - x'_i) \times \int_{\alpha=0}^{1} \frac{\partial F(x' + \alpha \times (x - x'))}{\partial x_i} \, d\alpha$$

(here $\frac{\partial F(x)}{\partial x_i}$ is the gradient of F along the i^{th} dimension at x).

Sundararajan et al. (2017) discuss several properties of IG. Here, we informally mention a few desirable ones, deferring the reader to Sundararajan et al. (2017) for formal definitions.

IG satisfies the condition that the attributions sum to the difference between the probabilities at the input and the baseline. We call a variable uninfluential if all else fixed, varying it does not change the output probability. IG satisfies the property that uninfluential variables do not get any attribution. Conversely, influential variables always get some attribution. Attributions for a linear combination of two functions F_1 and F_2 are a linear combination of the attributions for F_1 and F_2. Finally, IG satisfies the condition that symmetric variables get equal attributions.

In this work, we validate the use of IG empirically via question perturbations. We observe that perturbing high-attribution terms changes the networks' response (sections 4.4 and 5.5). Conversely, perturbing terms that receive a low attribution does not change the network's response (sections 4.3 and 5.3). We use these observations to craft attacks against the network by perturbing instances where generic words (e.g., "a", "the") receive high attribution or contentful words receive low attribution.

4 Visual Question Answering

4.1 Task, model, and data

The Visual Question Answering Task (Agrawal et al., 2015; Teney et al., 2017; Kazemi and Elqursh, 2017; Ben-younes et al., 2017; Zhu et al., 2016) requires a system to answer questions about images (fig. 1). We analyze the deep network from Kazemi and Elqursh (2017). It achieves 61.1% accuracy on the validation set (the state of the art (Fukui et al., 2016) achieves 66.7%). We chose this model for its easy reproducibility.

The VQA 1.0 dataset (Agrawal et al., 2015) consists of 614,163 questions posed over 204,721 images (3 questions per image). The images were taken from COCO (Lin et al., 2014), and the questions and answers were crowdsourced.

The network in Kazemi and Elqursh (2017) treats question answering as a classification task wherein the classes are 3000 most frequent answers in the training data. The input question is tokenized, embedded and fed to a multi-layer LSTM. The states of the LSTM attend to a featurized version of the image, and ultimately produce a probability distribution over the answer classes.

4.2 Observations

We applied IG and attributed the top selected answer class to input question words. The baseline for a given input instance is the image and an empty question[2]. We omit instances where the top answer class predicted by the network remains the same even when the question is emptied (i.e., the baseline input). This is because IG attributions are not informative when the input and the baseline have the same prediction.

Question: how symmetrical are the white bricks on either side of the building
Prediction: very
Ground truth: very

Figure 1: Visual QA (Kazemi and Elqursh, 2017): Visualization of attributions (word importances) for a question that the network gets right. Red indicates high attribution, blue negative attribution, and gray near-zero attribution. The colors are determined by attributions normalized w.r.t the maximum magnitude of attributions among the question's words.

A visualization of the attributions is shown in fig. 1. Notice that very few words have high attribution. We verified that altering the low attribution words in the question does not change the network's answer. For instance, the following questions still return "*very*" as the answer: "*how spherical are the white bricks on either side of the building*", "*how soon are the bricks fading on either side of the building*", "*how fast are the bricks speaking on either side of the building*".

On analyzing attributions across examples, we find that most of the highly attributed words are words such as "*there*", "*what*", "*how*", "*doing*"– they are usually the less important words in questions. In section 4.3 we describe a test to measure the extent to which the network depends on such words. We also find that informative words in the question (e.g., nouns) often receive very low attribution, indicating a weakness on part of the network. In Section 4.4, we describe various attacks that exploit this weakness.

4.3 Overstability test

To determine the set of question words that the network finds most important, we isolate words that most frequently occur as top attributed words in questions. We then drop all words except these and compute the accuracy.

Figure 2 shows how the accuracy changes as the size of this isolated set is varied from 0 to 5305.

[2]We do not black out the image in our baseline as our objective is to study the influence of just the question words for a given image

We find that just one word is enough for the model to achieve more than 50% of its final accuracy. That word is “color”.

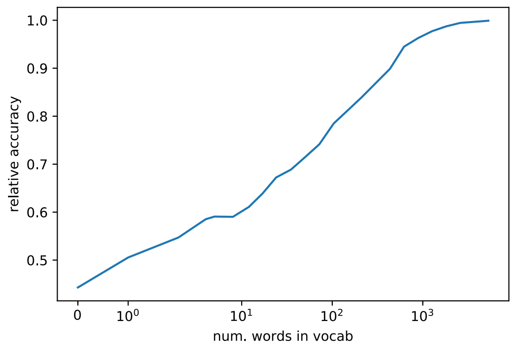

Figure 2: VQA network (Kazemi and Elqursh, 2017): Accuracy as a function of vocabulary size, relative to its original accuracy. Words are chosen in the descending order of how frequently they appear as top attributions. The X-axis is on logscale, except near zero where it is linear.

Note that even when empty questions are passed as input to the network, its accuracy remains at about 44.3% of its original accuracy. This shows that the model is largely reliant on the image for producing the answer.

The accuracy increases (almost) monotonically with the size of the isolated set. The top 6 words in the isolated set are “color”, “many”, “what”, “is”, “there”, and “how”. We suspect that generic words like these are used to determine the type of the answer. The network then uses the type to choose between a few answers it can give for the image.

4.4 Attacks

Attributions reveal that the network relies largely on generic words in answering questions (section 4.3). This is a weakness in the network’s logic. We now describe a few attacks against the network that exploit this weakness.

Subject ablation attack

In this attack, we replace the subject of a question with a specific noun that consistently receives low attribution across questions. We then determine, among the questions that the network originally answered correctly, what percentage result in the same answer after the ablation. We repeat this process for different nouns; specifically, “fits”, “childhood”, “copyrights”, “mornings”, “disorder”, “importance”, “topless”, “critter”, “jumper”, “tweet”, and average the result.

Prefix	Accuracy
in not a lot of words	35.5%
in not many words	32.5%
what is the answer to	31.7%
Union of all three	**19%**
Baseline prefix	
tell me	51.3%
answer this	55.7%
answer this for me	49.8%
Union of baseline prefixes	**46.9%**

Table 1: VQA network (Kazemi and Elqursh, 2017): Accuracy for prefix attacks; original accuracy is 61.1%.

We find that, among the set of questions that the network originally answered correctly, 75.6% of the questions return the same answer despite the subject replacement.

Prefix attack

In this attack, we attach content-free phrases to questions. The phrases are manually crafted using generic words that the network finds important (section 4.3). Table 1 (top half) shows the resulting accuracy for three prefixes —“*in not a lot of words*”, “*what is the answer to*”, and “*in not many words*”. All of these phrases nearly halve the model’s accuracy. The union of the three attacks drops the model’s accuracy from 61.1% to 19%.

We note that the attributions computed for the network were crucial in crafting the prefixes. For instance, we find that other prefixes like “*tell me*”, “*answer this*” and “*answer this for me*” do not drop the accuracy by much; see table 1 (bottom half). The union of these three ineffective prefixes drops the accuracy from 61.1% to only 46.9%. Per attributions, words present in these prefixes are not deemed important by the network.

4.5 Related work

Agrawal et al. (2016) analyze several VQA models. Among other attacks, they test the models on question fragments of telescopically increasing length. They observe that VQA models often arrive at the same answer by looking at a small fragment of the question. Our stability analysis in section 4.3 explains, and intuitively subsumes this; indeed, several of the top attributed words appear in the prefix, while important words like “color” often occur in the middle of the question. Our analysis enables additional attacks, for instance, replacing question subject with low attribution nouns. Ribeiro et al. (2016a) use a model explanation technique to illustrate overstability for two examples. They do not quantify their analysis at scale. Kafle and Kanan (2017); Zhang et al. (2016) examine the VQA data, identify deficiencies, and propose data augmentation to reduce over-representation of certain question/answer types. Goyal et al. (2016) propose the VQA 2.0 dataset, which has pairs of similar images that have different answers on the same question. We note that our method can be used to improve these datasets by identifying inputs where models ignore several words. Huang et al. (2017) evaluate robustness of VQA models by appending *questions* with semantically similar questions. Our prefix attacks in section 4.4 are in a similar vein and perhaps a more natural and targeted approach. Finally, Fong and Vedaldi (2017) use saliency methods to produce image perturbations as adversarial examples; our attacks are on the question.

5 Question Answering over Tables

5.1 Task, model, and data

We now analyze question answering over tables based on the WikiTableQuestions benchmark dataset (Pasupat and Liang, 2015). The dataset has 22033 questions posed over 2108 tables scraped from Wikipedia. Answers are either contents of table cells or some table aggregations. Models performing QA on tables translate the question into a structured program (akin to an SQL query) which is then executed on the table to produce the answer. We analyze a model called Neural Programmer (NP) (Neelakantan et al., 2017). NP is the state of the art among models that are weakly supervised, i.e., supervised using the final answer instead of the correct structured program. It achieves 33.5% accuracy on the validation set.

NP translates the input into a structured program consisting of four operator and table column selections. An example of such a program is "reset (score), reset (score), min (score), print (name)", where the output is the name of the person who has the lowest score.

5.2 Observations

We applied IG to attribute operator and column selection to question words. NP preprocesses inputs and whenever applicable, appends symbols tm_token, cm_token to questions that signify matches between a question and the accompanying table. These symbols are treated the same as question words. NP also computes priors for column selection using question-table matches. These vectors, tm and cm, are passed as additional inputs to the neural network. In the baseline for IG, we use an empty question, and zero vectors for column selection priors[3].

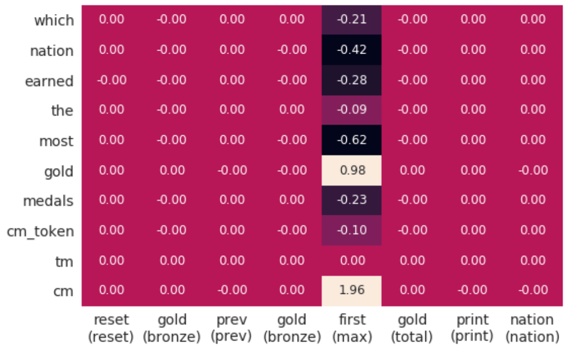

Figure 3: Visualization of attributions. Question words, preprocessing tokens and column selection priors on the Y-axis. Along the X-axis are operator and column selections with their baseline counterparts in parentheses. Operators and columns not affecting the final answer, and those which are same as their baseline counterparts, are given zero attribution.

We visualize the attributions using an alignment matrix; they are commonly used in the analysis of translation models (fig. 3). Observe that the operator "first" is used when the question is asking for a superlative. Further, we see that the word "gold" is a trigger for this operator. We investigate implications of this behavior in the following sections.

5.3 Overstability test

Similar to the test we did for Visual QA (section 4.3), we check for overstability in NP by looking at accuracy as a function of the vocabulary size. We treat table match annotations tm_token, cm_token and the out-of-vocab token (unk) as part of the vocabulary. The results are in fig. 4. We see that the curve is similar to that of Visual QA (fig. 2). Just 5 words (along with the column selection priors) are sufficient for the model to reach more than 50% of its final accuracy on the validation set. These five words are: "many", "number", "tm_token", "after", and "total".

5.4 Table-specific default programs

We saw in the previous section that the model relies on only a few words in producing correct answers. An extreme case of overstability is when

[3]Note that the table is left intact in the baseline

Operator sequence	#	Triggers	Insights
reset, reset, max, print	109	[*unk*, date, position, points, name, competition, notes, no, year, venue]	sports
reset, prev, max, print	68	[*unk*, rank, total, bronze, gold, silver, nation, name, date, no]	medal tallies
reset, reset, first, print	29	[name, *unk*, notes, year, nationality, rank, location, date, comments, hometown]	player rankings
reset, mfe, first, print	25	[notes, date, title, *unk*, role, genre, year, score, opponent, event]	awards
reset, reset, min, print	17	[year, height, *unk*, name, position, floors, notes, jan, jun, may]	building info.
reset, mfe, max, print	14	[opponent, date, result, location, rank, site, attendance, notes, city, listing]	politics
reset, next, first, print	10	[*unk*, name, year, edition, birth, death, men, time, women, type]	census

Table 2: Attributions to column names for table-specific default programs (programs returned by NP on empty input questions). See supplementary material, table 6 for the full list. These results are indication that the network is predisposed towards picking certain operators solely based on the table.

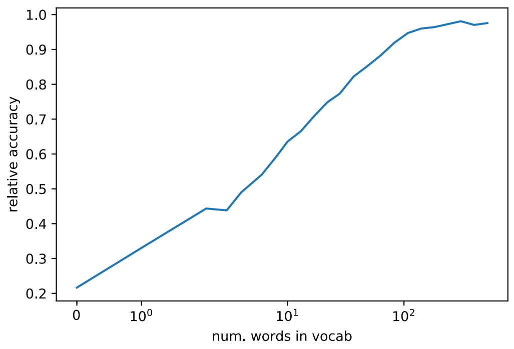

Figure 4: Accuracy as a function of vocabulary size. The words are chosen in the descending order of their frequency appearance as top attributions to question terms. The X-axis is on logscale, except near zero where it is linear. Note that just 5 words are necessary for the network to reach more than 50% of its final accuracy.

Attack phrase	Prefix	Suffix
in not a lot of words	20.6%	10.0%
if its all the same	21.8%	18.7%
in not many words	15.6%	11.2%
one way or another	23.5%	20.0%
Union of above attacks	**3.3%**	
Baseline		
please answer	32.3%	30.7%
do you know	31.2%	29.5%
Union of baseline prefixes	**27.1%**	

Table 3: Neural Programmer (Neelakantan et al., 2017): Left: Validation accuracy when attack phrases are concatenated to the question. (Original: 33.5%)

the operator sequences produced by the model are independent of the question. We find that if we supply an empty question as an input, i.e., the output is a function only of the table, then the distribution over programs is quite skewed. We call these programs table-specific default programs. On average, about 36.9% of the selected operators match their table-default counterparts, indicating that the model relies significantly on the table for producing an answer.

For each default program, we used IG to attribute operator and column selections to column names and show ten most frequently occurring ones across tables in the validation set (table 2).

Here is an insight from this analysis: NP uses the combination "reset, prev" to exclude the last row of the table from answer computation. The default program corresponding to "reset, prev, max, print" has attributions to column names such as *"rank"*, *"gold"*, *"silver"*, *"bronze"*, *"nation"*, *"year"*. These column names indicate medal tallies and usually have a *"total"* row. If the table happens not to have a *"total"* row, the model may produce an incorrect answer.

We now describe attacks that add or drop content-free words from the question, and cause NP to produce the wrong answer. These attacks leverage the attribution analysis.

5.5 Attacks

Question concatenation attacks

In these attacks, we either suffix or prefix content-free phrases to questions. The phrases are crafted using irrelevant trigger words for operator selections (supplementary material, table 5). We manually ensure that the phrases are content-free.

Table 3 describes our results. The first 4 phrases use irrelevant trigger words and result in a large drop in accuracy. For instance, the first phrase uses "not" which is a trigger for "next", "last", and "min", and the second uses "same" which is a trigger for "next" and "mfe". The four phrases combined results in the model's accuracy going down from 33.5% to 3.3%. The first two phrases alone drop the accuracy to 5.6%.

The next set of phrases use words that receive low attribution across questions, and are hence non-triggers for any operator. The resulting drop in accuracy on using these phrases is relatively low. Combined, they result in the model's accuracy dropping from 33.5% to 27.1%.

Stop word deletion attacks

We find that sometimes an operator is selected based on *stop words* like: "a", "at", "the", etc. For instance, in the question, "what ethnicity is at the top?", the operator "next" is triggered on the word "at". Dropping the word "at" from the question changes the operator selection and causes NP to return the wrong answer.

We drop stop words from questions in the validation dataset that were originally answered correctly and test NP on them. The stop words to be dropped were manually selected[4] and are shown in Figure 5 in the supplementary material.

By dropping stop words, the accuracy drops from 33.5% to 28.5%. Selecting operators based on stop words is not robust. In real world search queries, users often phrase questions without stop words, trading grammatical correctness for conciseness. For instance, the user may simply say "top ethnicity". It may be possible to defend against such examples by generating synthetic training data, and re-training the network on it.

Row reordering attacks

We found that NP often got the question right by leveraging artifacts of the table. For instance, the operators for the question "which nation earned the most gold medals" are "reset", "prev", "first" and "print". The "prev" operator essentially excludes the last row from the answer computation. It gets the answer right for two reasons: (1) the answer is not in the last row, and (2) rows are sorted by the values in the column "gold".

In general, a question answering system should not rely on row ordering in tables. To quantify the extent of such biases, we used a perturbed version of WikiTableQuestions validation dataset as described in Pasupat and Liang (2016)[5] and evaluated the existing NP model on it (there was no re-training involved here). We found that NP has only 23% accuracy on it, in constrast to an accuracy of 33.5% on the original validation dataset.

One approach to making the network robust to row-reordering attacks is to train against perturbed tables. This may also help the model generalize better. Indeed, Mudrakarta et al. (2018) note that the state-of-the-art strongly supervised[6] model on WikiTableQuestions (Krishnamurthy et al., 2017) enjoys a 7% gain in its final accuracy by leveraging perturbed tables during training.

[4]We avoided standard stop word lists (e.g. NLTK) as they contain contentful words (e.g "after") which may be important in some questions (e.g. "who ranked right after turkey?")

[5]based on data at https://nlp.stanford.edu/software/sempre/wikitable/dpd/

6 Reading Comprehension

6.1 Task, model, and data

The reading comprehension task involves identifying a span from a context paragraph as an answer to a question. The SQuAD dataset (Rajpurkar et al., 2016) for machine reading comprehension contains 107.7K query-answer pairs, with 87.5K for training, 10.1K for validation, and another 10.1K for testing. Deep learning methods are quite successful on this problem, with the state-of-the-art F1 score at 84.6 achieved by Yu et al. (2018); we analyze their model.

6.2 Analyzing adversarial examples

Recall the adversarial attacks proposed by Jia and Liang (2017) for reading comprehension systems. Their attack ADDSENT appends sentences to the paragraph that resemble an answer to the question without changing the ground truth. See the second column of table 4 for a few examples.

We investigate the effectiveness of their attacks using attributions. We analyze 100 examples generated by the ADDSENT method in Jia and Liang (2017), and find that an adversarial sentence is successful in fooling the model in two cases:

First, a contentful word in the question gets low/zero attribution and the adversarially added sentence modifies that word. E.g. in the question, "Who did Kubiak take the place of after Super Bowl XXIV?", the word "Super" gets low attribution. Adding "After *Champ* Bowl XXV, Crowton took the place of Jeff Dean" changes the prediction for the model. Second, a contentful word in the question that is not present in the context. For e.g. in the question "Where hotel did the Panthers stay at?", "hotel", is not present in the context. Adding "The Vikings stayed at Chicago hotel." changes the prediction for the model.

On the flip side, an adversarial sentence is unsuccessful when a contentful word in the question having high attribution is not present in the added sentence. E.g. for "Where according to gross state product does Victoria rank in Australia?", "Australia" receives high attribution. Adding "Accord-

[6]supervised on the structured program

Question	AddSent attack that does not work	Attack that works
Who was Count of Melfi	Jeff Dean was the mayor of Bracco.	Jeff Dean was the mayor of Melfi.
What country was Abhisit Vejjajiva prime minister of , despite having been born in Newcastle ?	Samak Samak was prime minister of the country of Chicago, despite having been born in Leeds.	Abhisit Vejjajiva was chief minister of the country of Chicago, despite having been born in Leeds.
Where according to gross state product does Victoria rank in Australia ?	According to net state product, Adelaide ranks 7 in New Zealand	According to net state product, Adelaide ranked 7 in Australia. (as a prefix)
When did the Methodist Protestant Church split from the Methodist Episcopal Church ?	The Presbyterian Catholics split from the Presbyterian Anglican in 1805.	The Methodist Protestant Church split from the Presbyterian Anglican in 1805. (as a prefix)
What period was 2.5 million years ago ?	The period of Plasticean era was 2.5 billion years ago.	The period of Plasticean era was 1.5 billion years ago. (as a prefix)

Table 4: AddSent attacks that failed to fool the model. With modifications to preserve nouns with high attributions, these are successful in fooling the model. Question words that receive high attribution are colored red (intensity indicates magnitude).

ing to net state product, Adelaide ranks 7 in New Zealand." does not fool the model. However, retaining "Australia" in the adversarial sentence does change the model's prediction.

6.3 Predicting the effectiveness of attacks

Next we correlate attributions with efficacy of the AddSent attacks. We analyzed 1000 (question, attack phrase) instances[7] where Yu et al. (2018) model has the correct baseline prediction. Of the 1000 cases, 508 are able to fool the model, while 492 are not. We split the examples into two groups. The first group has examples where a noun or adjective in the question has high attribution, but is missing from the adversarial sentence and the rest are in the second group. Our attribution analysis suggests that we should find more failed examples in the first group. That is indeed the case. The first group has 63% failed examples, while the second has only 40%.

Recall that the attack sentences were constructed by (a) generating a sentence that answers the question, (b) replacing all the adjectives and nouns with antonyms, and named entities by the nearest word in GloVe word vector space (Pennington et al., 2014) and (c) crowdsourcing to check that the new sentence is grammatically correct. This suggests a use of attributions to improve the effectiveness of the attacks, namely ensuring that question words that the model thinks are important are left untouched in step (b) (we note that other changes in should be carried out). In table 4, we show a few examples where an original attack did not fool the model, but preserving a noun with high attribution did.

7 Conclusion

We analyzed three question answering models using an attribution technique. Attributions helped us identify weaknesses of these models more effectively than conventional methods (based on validation sets). We believe that a workflow that uses attributions can aid the developer in iterating on model quality more effectively.

While the attacks in this paper may seem unrealistic, they do expose real weaknesses that affect the usage of a QA product. Under-reliance on important question terms is not safe. We also believe that other QA models may share these weaknesses. Our attribution-based methods can be directly used to gauge the extent of such problems. Additionally, our perturbation attacks (sections 4.4 and 5.5) serve as empirical validation of attributions.

Reproducibility

Code to generate attributions and reproduce our results is freely available at https://github.com/pramodkaushik/acl18_results.

Acknowledgments

We thank the anonymous reviewers and Kevin Gimpel for feedback on our work, and David Dohan for helping with the reading comprehension network. We are grateful to Jiří Šimša for helpful comments on drafts of this paper.

Abstract

We study the task of generating from Wikipedia articles question-answer pairs that cover content beyond a single sentence. We propose a neural network approach that incorporates coreference knowledge via a novel gating mechanism. Compared to models that only take into account sentence-level information (Heilman and Smith, 2010; Du et al., 2017; Zhou et al., 2017), we find that the linguistic knowledge introduced by the coreference representation aids question generation significantly, producing models that outperform the current state-of-the-art. We apply our system (composed of an answer span extraction system and the passage-level QG system) to the 10,000 top-ranking Wikipedia articles and create a corpus of over one million question-answer pairs. We also provide a qualitative analysis for this large-scale generated corpus from Wikipedia.

Paragraph:
[(1)] *Tesla* was renowned for *his* achievements and showmanship, eventually earning *him* a reputation in popular culture as an archetypal "mad scientist". [(2)] *His* patents earned *him* a considerable amount of money, much of which was used to finance *his* own projects with varying degrees of success. [(3)] *He* lived most of his life in a series of New York hotels, through *his* retirement. [(4)] *Tesla* died on 7 January 1943. ...

Questions:
– What was Tesla's reputation in popular culture?
mad scientist

– How did Tesla finance his work?
patents

– Where did Tesla live for much of his life?
New York hotels

Figure 1: Example input from the fourth paragraph of a Wikipedia article on *Nikola Tesla*, along with the natural questions and their answers from the SQuAD (Rajpurkar et al., 2016) dataset. We show in italics the set of mentions that refer to Nikola Tesla — *Tesla*, *him*, *his*, *he*, etc.

1 Introduction

Recently, there has been a resurgence of work in NLP on reading comprehension (Hermann et al., 2015; Rajpurkar et al., 2016; Joshi et al., 2017) with the goal of developing systems that can answer questions about the content of a given passage or document. Large-scale QA datasets are indispensable for training expressive statistical models for this task and play a critical role in advancing the field. And there have been a number of efforts in this direction. Miller et al. (2016), for example, develop a dataset for open-domain question answering; Rajpurkar et al. (2016) and Joshi et al. (2017) do so for reading comprehension (RC); and Hill et al. (2015) and Hermann et al. (2015), for the related task of answering cloze questions (Winograd, 1972; Levesque et al., 2011). To create these datasets, either crowdsourcing or *(semi-)synthetic* approaches are used. The (semi-)synthetic datasets (e.g., Hermann et al. (2015)) are large in size and cheap to obtain; however, they do not share the same characteristics as explicit QA/RC questions (Rajpurkar et al., 2016). In comparison, high-quality *crowdsourced* datasets are much smaller in size, and the annotation process is quite expensive because the labeled examples require expertise and careful design (Chen et al., 2016).

Thus, there is a need for methods that can automatically generate high-quality question-answer pairs. Serban et al. (2016) propose the use of recurrent neural networks to generate QA pairs from structured knowledge resources such as Freebase. Their work relies on the existence of automatically acquired KBs, which are known to have errors and suffer from incompleteness. They are also nontrivial to obtain. In addition, the questions in the resulting dataset are limited to queries regarding a single fact (i.e., tuple) in the KB.

Motivated by the need for large scale QA pairs and the limitations of recent work, we investigate methods that can automatically "harvest" (generate) question-answer pairs from raw text/unstructured documents, such as Wikipedia-type articles.

Recent work along these lines (Du et al., 2017; Zhou et al., 2017) (see Section 2) has proposed the use of attention-based recurrent neural models trained on the crowdsourced SQuAD dataset (Rajpurkar et al., 2016) for question generation. While successful, the resulting QA pairs are based on information from a single sentence. As described in Du et al. (2017), however, nearly 30% of the questions in the human-generated questions of SQuAD rely on information beyond a single sentence. For example, in Figure 1, the second and third questions require coreference information (i.e., recognizing that "His" in sentence 2 and "He" in sentence 3 both corefer with "Tesla" in sentence 1) to answer them.

Thus, our research studies methods for incorporating coreference information into the training of a question generation system. In particular, we propose gated **Coref**erence knowledge for **N**eural **Q**uestion **G**eneration (**CorefNQG**), a neural sequence model with a novel gating mechanism that leverages continuous representations of *coreference clusters* — the set of mentions used to refer to each entity — to better encode linguistic knowledge introduced by coreference, for paragraph-level question generation.

In an evaluation using the SQuAD dataset, we find that CorefNQG enables better question generation. It outperforms significantly the baseline neural sequence models that encode information from a single sentence, and a model that encodes *all* preceding context and the input sentence itself. When evaluated on only the portion of SQuAD that requires coreference resolution, the gap between our system and the baseline systems is even larger.

By applying our approach to the 10,000 top-ranking Wikipedia articles, we obtain a question answering/reading comprehension dataset with over one million QA pairs; we provide a qualitative analysis in Section 6. The dataset and the source code for the system are available at `https://github.com/xinyadu/HarvestingQA`.

2 Related Work

2.1 Question Generation

Since the work by Rus et al. (2010), question generation (QG) has attracted interest from both the NLP and NLG communities. Most early work in QG employed rule-based approaches to transform input text into questions, usually requiring the application of a sequence of well-designed general rules or templates (Mitkov and Ha, 2003; Labutov et al., 2015). Heilman and Smith (2010) introduced an overgenerate-and-rank approach: their system generates a set of questions and then ranks them to select the top candidates. Apart from generating questions from raw text, there has also been research on question generation from symbolic representations (Yao et al., 2012; Olney et al., 2012).

With the recent development of deep representation learning and large QA datasets, there has been research on recurrent neural network based approaches for question generation. Serban et al. (2016) used the encoder-decoder framework to generate QA pairs from knowledge base triples; Reddy et al. (2017) generated questions from a knowledge graph; Du et al. (2017) studied how to generate questions from sentences using an attention-based sequence-to-sequence model and investigated the effect of exploiting sentence- vs. paragraph-level information. Du and Cardie (2017) proposed a hierarchical neural sentence-level sequence tagging model for identifying question-worthy sentences in a text passage. Finally, Duan et al. (2017) investigated how to use question generation to help improve question answering systems on the sentence selection subtask.

In comparison to the related methods from above that generate questions from raw text, our method is different in its ability to take into account contextual information beyond the sentence-level by introducing coreference knowledge.

2.2 Question Answering Datasets and Creation

Recently there has been an increasing interest in question answering with the creation of many datasets. Most are built using crowdsourcing; they are generally comprised of fewer than 100,000 QA pairs and are time-consuming to create. WebQuestions (Berant et al., 2013), for example, contains 5,810 questions crawled via the Google Suggest API and is designed for knowledge base QA with answers restricted to Freebase entities. To tackle the size issues associated with WebQuestions, Bordes et al. (2015) introduce SimpleQuestions, a dataset of 108,442 questions authored by English speakers. SQuAD (Rajpurkar et al., 2016) is a dataset for machine comprehension; it is created by showing a Wikipedia paragraph to human annotators and asking them to write questions based on the paragraph. TriviaQA (Joshi et al., 2017) includes 95k question-answer authored by trivia enthusiasts and corresponding evidence documents.

(Semi-)synthetic generated datasets are easier to build to large-scale (Hill et al., 2015; Hermann et al., 2015). They usually come in the form of cloze-style questions. For example, Hermann et al. (2015) created over a million examples by pairing CNN and Daily Mail news articles with their summarized bullet points. Chen et al. (2016) showed that this dataset is quite noisy due to the method of data creation and concluded that performance of QA systems on the dataset is almost saturated.

Closest to our work is that of Serban et al. (2016). They train a neural triple-to-sequence model on SimpleQuestions, and apply their system to Freebase to produce a large collection of human-like question-answer pairs.

3 Task Definition

Our goal is to harvest high quality question-answer pairs from the paragraphs of an article of interest. In our task formulation, this consists of two steps: **candidate answer extraction** and **answer-specific question generation**. Given an input paragraph, we first identify a set of *question-worthy* candidate answers $ans = (ans_1, ans_2, ..., ans_l)$, each a span of text as denoted in color in Figure 1. For each candidate answer ans_i, we then aim to generate a question Q — a sequence of tokens $y_1, ..., y_N$ — based on the sentence S that contains candidate ans_i such that:

- Q asks about an aspect of ans_i that is of potential interest to a human;
- Q might rely on information from sentences that precede S in the paragraph.

Mathematically then,

$$Q = \arg\max_{Q} P\left(Q|S, C\right) \tag{1}$$

where $P(Q|S,C) = \prod_{n=1}^{N} P\left(y_n|y_{<n}, S, C\right)$ where C is the set of sentences that precede S in the paragraph.

4 Methodology

In this section, we introduce our framework for harvesting the question-answer pairs. As described above, it consists of the question generator CorefNQG (Figure 2) and a candidate answer extraction module. During test/generation time, we (1) run the answer extraction module on the input text to obtain answers, and then (2) run the question generation module to obtain the corresponding questions.

4.1 Question Generation

As shown in Figure 2, our generator prepares the feature-rich input embedding — a concatenation of (a) a refined coreference position feature embedding, (b) an answer feature embedding, and (c) a word embedding, each of which is described below. It then encodes the textual input using an LSTM unit (Hochreiter and Schmidhuber, 1997). Finally, an attention-copy equipped decoder is used to decode the question.

More specifically, given the input sentence S (containing an answer span) and the preceding context C, we first run a coreference resolution system to get the coref-clusters for S and C and use them to create a *coreference transformed* input sentence: for each pronoun, we append its most representative non-pronominal coreferent mention. Specifically, we apply the simple feed-forward network based mention-ranking model of Clark and Manning (2016) to the concatenation of C and S to get the coref-clusters for all entities in C and S. The C&M model produces a score/representation s for each mention pair (m_1, m_2),

$$s(m_1, m_2) = \mathbf{W}_m h_m(m_1, m_2) + b_m \tag{2}$$

ans. feature	O	O	O	O	B_ANS	I_ANS	I_ANS	O	O	O	...
coref. feature	B_PRO	B_ANT	I_ANT	O	O	O	O	O	O	O	...

Table 1: Example input sentence with coreference and answer position features. The corresponding gold question is "What team did the Panthers defeat in the NFC championship game ?"

where $\mathbf{W}_m$ is a $1 \times d$ weight matrix and b is the bias. $h_m(m_1, m_2)$ is representation of the last hidden layer of the three layer feedforward neural network.

For each pronoun in S, we then heuristically identify the most "representative" antecedent from its coref-cluster. (Proper nouns are preferred.) We append the new mention after the pronoun. For example, in Table 1, "the panthers" is the most representative mention in the coref-cluster for "they". The new sentence with the appended coreferent mention is our *coreference transformed* input sentence $S^{'}$ (see Figure 2).

Coreference Position Feature Embedding For each token in $S^{'}$, we also maintain one position feature $\mathbf{f^c} = (c_1, ..., c_n)$, to denote pronouns (e.g., "they") and antecedents (e.g., "the panthers"). We use the BIO tagging scheme to label the associated spans in $S^{'}$. "B_ANT" denotes the start of an antecedent span, tag "I_ANT" continues the antecedent span and tag "O" marks tokens that do not form part of a mention span. Similarly, tags "B_PRO" and "I_PRO" denote the pronoun span. (See Table 1, "coref. feature".)

Refined Coref. Position Feature Embedding Inspired by the success of gating mechanisms for controlling information flow in neural networks (Hochreiter and Schmidhuber, 1997; Dauphin et al., 2017), we propose to use a gating network here to obtain a refined representation of the coreference position feature vectors $\mathbf{f^c} = (c_1, ..., c_n)$. The main idea is to utilize the mention-pair score (see Equation 2) to help the neural network learn the importance of the coreferent phrases. We compute the refined (gated) coreference position feature vector $\mathbf{f^d} = (d_1, ..., d_n)$ as follows,

$$\begin{aligned} g_i &= \text{ReLU}(\mathbf{W}_a c_i + \mathbf{W}_b score_i + b) \\ d_i &= g_i \odot c_i \end{aligned} \tag{3}$$

where $\odot$ denotes an element-wise product between two vectors and ReLU is the rectified linear activation function. $score_i$ denotes the mention-pair score for each antecedent token (e.g., "the" and "panthers") with the pronoun (e.g., "they"); $score_i$ is obtained from the trained model (Equation 2) of the C&M. If token i is not added later as an antecedent token, $score_i$ is set to zero. $\mathbf{W}_a$, $\mathbf{W}_b$ are weight matrices and b is the bias vector.

Answer Feature Embedding We also include an answer position feature embedding to generate answer-specific questions; we denote the answer span with the usual BIO tagging scheme (see, e.g., "the arizona cardinals" in Table 1). During training and testing, the answer span feature (i.e., "`B_ANS`", "`I_ANS`" or "`O`") is mapped to its feature embedding space: $\mathbf{f^a} = (a_1, ..., a_n)$.

Word Embedding To obtain the word embedding for the tokens themselves, we just map the tokens to the word embedding space: $\mathbf{x} = (x_1, ..., x_n)$.

Final Encoder Input As noted above, the final input to the LSTM-based encoder is a concatenation of (1) the refined coreference position feature embedding (light blue units in Figure 2), (2) the answer position feature embedding (red units), and (3) the word embedding for the token (green units),

$$e_i = \text{concat}(d_i, a_i, x_i) \tag{4}$$

Encoder As for the encoder itself, we use bidirectional LSTMs to read the input $\mathbf{e} = (e_1, ..., e_n)$ in both the forward and backward directions. After encoding, we obtain two sequences of hidden vectors, namely, $\overrightarrow{\mathbf{h}} = (\overrightarrow{h_1}, ..., \overrightarrow{h_n})$ and $\overleftarrow{\mathbf{h}} = (\overleftarrow{h_1}, ..., \overleftarrow{h_n})$. The final output state of the encoder is the concatenation of $\overrightarrow{\mathbf{h}}$ and $\overleftarrow{\mathbf{h}}$ where

$$h_i = \text{concat}(\overrightarrow{h_i}, \overleftarrow{h_i}) \tag{5}$$

Question Decoder with Attention & Copy On top of the feature-rich encoder, we use LSTMs with attention (Bahdanau et al., 2015) as the decoder for generating the question $y_1, ..., y_m$ one token at a time. To deal with rare/unknown words, the decoder also allows directly copying words from the source sentence via pointing (Vinyals et al., 2015).

At each time step t, the decoder LSTM reads the previous word embedding w_{t-1} and previous hidden state s_{t-1} to compute the new hidden state,

$$s_t = \text{LSTM}(w_{t-1}, s_{t-1}) \tag{6}$$

Then we calculate the *attention distribution* α_t as in Bahdanau et al. (2015),

$$\begin{aligned} e_{t,i} &= h_i^T \mathbf{W}_c s_{t-1} \\ \alpha_t &= \text{softmax}(e_t) \end{aligned} \tag{7}$$

where $\mathbf{W}_c$ is a weight matrix and attention distribution α_t is a probability distribution over the source sentence words. With α_t, we can obtain the context vector h_t^*,

$$h_t^* = \sum_{i=1}^{n} \alpha_t^i h_i \tag{8}$$

Then, using the context vector h_t^* and hidden state s_t, the probability distribution over the target (question) side vocabulary is calculated as,

$$P_{vocab} = \text{softmax}(\mathbf{W}_d \text{concat}(h_t^*, s_t)) \tag{9}$$

Instead of directly using P_{vocab} for training/generating with the fixed target side vocabulary, we also consider *copying* from the source sentence. The copy probability is based on the context vector h_t^* and hidden state s_t,

$$\lambda_t^{copy} = \sigma\left(\mathbf{W}_e h_t^* + \mathbf{W}_f s_t\right) \tag{10}$$

and the probability distribution over the source sentence words is the sum of the attention scores of the corresponding words,
