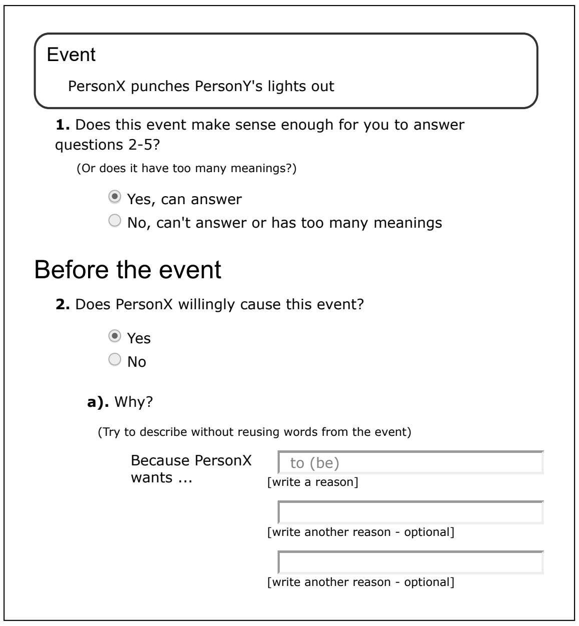
We extract phrasal events from three different corpora for broad coverage: the ROC Story training set (Mostafazadeh et al., 2016), the Google Syntactic N-grams (Goldberg and Orwant, 2013), and the Spinn3r corpus (Gordon and Swanson, 2008). We derive events from the set of verb phrases in our corpora, based on syntactic parses (Klein and Manning, 2003). We then replace the predicate subject and other entities with the typed variables (e.g., `PersonX`, `PersonY`), and selectively substitute verb arguments with blanks (___). We use frequency thresholds to select events to annotate (for details, see Appendix A.1). Additionally, we supplement the list of events with all 2,000 verb idioms found in Wiktionary, in order to cover events that are less compositional.[2] Our final annotation corpus contains nearly 25,000 event phrases, spanning over 1,300 unique verb predicates (Table 2).

2.2 Crowdsourcing

We design an Amazon Mechanical Turk task to annotate the mental pre- and post-conditions of event phrases. A snippet of our MTurk HIT design is shown in Figure 2. For each phrase, we ask three annotators whether the agent of the event, PersonX, intentionally causes the event, and if so, to provide up to three possible textual descriptions of their intents. We then ask annotators to provide up to three possible reactions that PersonX might experience as a result. We also ask annotators to provide up to three possible reactions of *other people*, when applicable. These other people can be either explicitly mentioned (e.g., "PersonY" in `PersonX punches PersonY's lights out`), or only implied

[2]We compiled the list of idiomatic verb phrases by cross-referencing between Wiktionary's English idioms category and the Wiktionary English verbs categories.



Event

PersonX punches PersonY's lights out

1. Does this event make sense enough for you to answer questions 2-5?

(Or does it have too many meanings?)

[✓ Yes, can answer]
No, can't answer or has too many meanings

Before the event

2. Does PersonX willingly cause this event?

[✓ Yes]
No

a). Why?

(Try to describe without reusing words from the event)

Because PersonX wants ... to (be)
[write a reason]
[write another reason - optional]
[write another reason - optional]

Figure 2: *Intent* portion of our annotation task. We allow annotators to label events as invalid if the phrase is unintelligible. The full annotation setup is shown in Figure 8 in the appendix.

(e.g., given the event description `PersonX yells at the classroom`, we can infer that other people such as "students" in the classroom may be affected by the act of PersonX). For quality control, we periodically removed workers with high disagreement rates, at our discretion.

Coreference among `Person` variables With the typed `Person` variable setup, events involving multiple people can have multiple meanings depending on coreference interpretation (e.g., `PersonX eats PersonY's lunch` has very different mental state implications from `PersonX eats PersonX's lunch`). To prune the set of events that will be annotated for intent and reaction, we ran a preliminary annotation to filter out candidate events that have implausible coreferences. In this preliminary task, annotators were shown a combinatorial list of coreferences for an event (e.g., `PersonX punches PersonX's lights out`, `PersonX punches PersonY's lights out`) and were asked to select only the plausible ones (e.g., `PersonX punches PersonY's lights out`). Each set of coreferences was annotated by 3 workers, yielding an overall agreement of κ =0.4. This annotation excluded 8,406 events with implausible coreference from our set (out of 17,806 events).

2.3 Mental State Descriptions

Our dataset contains nearly 25,000 event phrases, with annotators rating 91% of our extracted events as "valid" (i.e., the event makes sense). Of those events, annotations for the multiple choice portions of the task (whether or not there exists intent/reaction) agree moderately, with an average Cohen's $\kappa = 0.45$ (Table 2). The individual κ scores generally indicate that turkers disagree half as often as if they were randomly selecting answers.

Importantly, this level of agreement is acceptable in our task formulation for two reasons. First, unlike linguistic annotations on syntax or semantics where experts in the corresponding theory would generally agree on a single correct label, pragmatic interpretations may better be defined as distributions over multiple correct labels (e.g., after `PersonX takes a test`, PersonX might feel relieved and/or stressed; de Marneffe et al., 2012). Second, because we formulate our task as a conditional language modeling problem, where a distribution over the textual descriptions of intents and reactions is conditioned on the event description, this variation in the labels is only as expected.

A majority of our events are annotated as willingly caused by the agent (86%, Cohen's $\kappa = 0.48$), and 26% involve other people ($\kappa = 0.41$). Most event patterns in our data are fully instantiated, with only 22% containing blanks (___). In our corpus, the intent annotations are slightly longer (3.4 words on average) than the reaction annotations (1.5 words).

3 Models

Given an event phrase, our models aim to generate three entity-specific pragmatic inferences: PersonX's intent, PersonX's reaction, and others' reactions. The general outline of our model architecture is illustrated in Figure 3.

The input to our model is an event pattern described through free-form text with typed variables such as `PersonX gives PersonY ___ as a gift`. For notation purposes, we describe each event pattern E as a sequence of word embeddings $\langle e_1, e_2, \ldots, e_n \rangle \in \mathbb{R}^{n \times D}$. This input is encoded as a vector $h_E \in \mathbb{R}^H$ that will be used for predicting output. The output of the model is its hypotheses about PersonX's intent, PersonX's reaction, and others' reactions (v_i,v_x, and v_o, respectively). We experiment with representing the

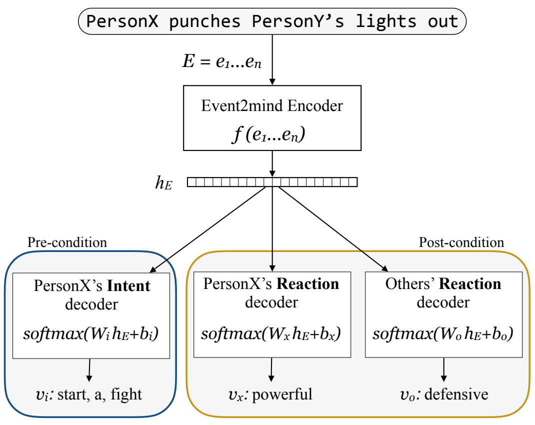


Figure 3: Overview of the model architecture. From an encoded event, our model predicts intents and reactions in a multitask setting.

output in two decoding set-ups: three vectors interpretable as discrete distributions over words and phrases (n-gram reranking) or three sequences of words (sequence decoding).

Encoding events The input event phrase E is compressed into an H-dimensional embedding h_E via an encoding function $f : \mathbb{R}^{n \times D} \rightarrow \mathbb{R}^H$:

$$h_E = f(e_1, \dots, e_n)$$

We experiment with several ways for defining f, inspired by standard techniques in sentence and phrase classification (Kim, 2014). First, we experiment with max-pooling and mean-pooling over the word vectors $\{e_i\}_{i=1}^n$. We also consider a convolutional neural network (ConvNet; LeCun et al., 1998) taking the last layer of the network as the encoded version of the event. Lastly, we encode the event phrase with a bi-directional RNN (specifically, a GRU; Cho et al., 2014), concatenating the final hidden states of the forward and backward cells as the encoding: $h_E = [\overrightarrow{h_n}; \overleftarrow{h_1}]$. For hyperparameters and other details, we refer the reader to Appendix B.

Though the event sequences are typically rather short (4.6 tokens on average), our model still benefits from the ConvNet and BiRNN's ability to compose words.

Pragmatic inference decoding We use three decoding modules that take the event phrase embedding h_E and output distributions of possible PersonX's intent (v_i), PersonX's reactions (v_x), and others' reactions (v_o). We experiment with two different decoder set-ups.

First, we experiment with *n-gram re-ranking*, considering the $|V|$ most frequent $\{1, 2, 3\}$-grams in our annotations. Each decoder projects the event phrase embedding h_E into a $|V|$-dimensional vector, which is then passed through a softmax function. For instance, the distribution over descriptions of PersonX's intent is given by:

$$v_i = \text{softmax}(W_i h_E + b_i)$$

Second, we experiment with *sequence generation*, using RNN decoders to generate the textual description. The event phrase embedding h_E is set as the initial state h_{dec} of three decoder RNNs (using GRU cells), which then output the intent/reactions one word at a time (using beam-search at test time). For example, an event's intent sequence ($v_i = v_i^{(0)} v_i^{(1)} \dots$) is computed as follows:

$$v_i^{(t+1)} = \text{softmax}(W_i \, \text{RNN}(v_i^{(t)}, h_{i,dec}^{(t)}) + b_i)$$

Training objective We minimize the cross-entropy between the predicted distribution over words and phrases, against the one actually observed in our dataset. Further, we employ multitask learning, simultaneously minimizing the loss for all three decoders at each iteration.

Training details We fix our input embeddings, using 300-dimensional skip-gram word embeddings trained on Google News (Mikolov et al., 2013). For decoding, we consider a vocabulary of size $|V|$ = 14,034 in the n-gram re-ranking setup. For the sequence decoding setup, we only consider the unigrams in V, yielding an output space of 7,110 at each time step.

We randomly divided our set of 24,716 unique events (57,094 annotations) into a training/dev./test set using an 80/10/10% split. Some annotations have multiple responses (i.e., a crowdworker gave multiple possible intents and reactions), in which case we take each of the combinations of their responses as a separate training example.

4 Empirical Results

Table 3 summarizes the performance of different encoding models on the dev and test set in terms of cross-entropy and recall at 10 predicted intents and reactions. As expected, we see a moderate improvement in recall and cross-entropy when using the more compositional encoder models (ConvNet and BiRNN; both n-gram and sequence de-

Encoding Function	Decoder	Development Average Cross-Ent	Development Recall @10 (%) Intent	XReact	OReact	Test Average Cross-Ent	Test Recall @10 (%) Intent	XReact	OReact
max-pool	n-gram	5.75	31	35	68	5.14	31	37	67
mean-pool	n-gram	4.82	35	39	69	4.94	34	40	68
ConvNet	n-gram	4.85	36	42	69	4.81	37	44	69
BiRNN 300d	n-gram	4.78	36	42	68	4.74	36	43	69
BiRNN 100d	n-gram	4.76	36	41	68	4.73	37	43	68
mean-pool	sequence	4.59	39	36	67	4.54	40	38	66
ConvNet	sequence	4.44	42	39	68	4.40	43	40	67
BiRNN 100d	sequence	4.25	39	38	67	4.22	40	40	67

Table 3: Average cross-entropy (lower is better) and recall @10 (percentage of times the gold falls within the top 10 decoded; higher is better) on development and test sets for different modeling variations. We show recall values for PersonX's intent, PersonX's reaction and others' reaction (denoted as "Intent", "XReact", and "OReact"). Note that because of two different decoding setups, cross-entropy between n-gram and sequence decoding are not directly comparable.

coding setups). Additionally, BiRNN models outperform ConvNets on cross-entropy in both decoding setups. Looking at the recall split across intent vs. reaction labels ("Intent", "XReact" and "OReact" columns), we see that much of the improvement in using these two models is within the prediction of PersonX's intents. Note that recall for "OReact" is much higher, since a majority of events do not involve other people.

Human evaluation To further assess the quality of our models, we randomly select 100 events from our test set and ask crowd-workers to rate generated intents and reactions. We present 5 workers with an event's top 10 most likely intents and reactions according to our model and ask them to select all those that make sense to them. We evaluate each model's precision @10 by computing the average number of generated responses that make sense to annotators.

Figure 4 summarizes the results of this evaluation. In most cases, the performance is higher for the sequential decoder than the corresponding n-gram decoder. The biggest gain from using sequence decoders is in intent prediction, possibly because intent explanations are more likely to be longer. The BiRNN and ConvNet encoders consistently have higher precision than the mean-pooling with the BiRNN-seq setup slightly outperforming other models. Unless otherwise specified, this is the model we employ in further sections.

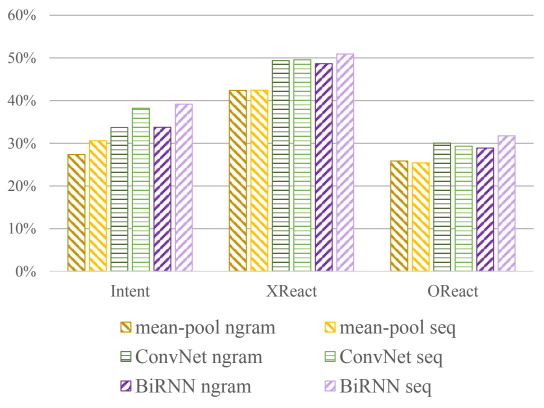

Figure 4: Average precision @10 of each model's top ten responses in the human evaluation. We show results for various encoder functions (mean-pool, ConvNet, BiRNN-100d) combined with two decoding setups (n-gram re-ranking, sequence generation).

Error analyses We test whether certain types of events are easier for predicting commonsense inference. In Figure 6, we show the difference in cross-entropy of the BiRNN 100d model on predicting different portions of the development set including: `Blank` events (events containing non-instantiated arguments), `2+ People` events (events containing multiple different Person variables), and `Idiom` events (events coming from the Wiktionary idiom list). Our results show that, while intent prediction performance remains sim-

	Event1						Event2
Intent	PersonX goes to school	learn, graduate, learn a new skill, learn more	learn, graduate, learn a new skill, get a job	learn, get a job, learn a new skill, get better	relax, get somewhere, go home, get some exercise	relax, go home, get somewhere, get home	PersonX comes home after school
PersonX's Reaction	PersonX washes PersonX's legs	clean, refreshed, satisfied, accomplished, wet	refreshed, clean, accomplished, good	satisfied, refreshed, accomplished, exhausted	satisfied, healthy, sad, exhausted, relieved	tired, sad, scared, pain, hurt	PersonX cuts PersonX's legs
Others' Reaction	PersonX punches PersonY's face	hurt, angry, sad, upset, dead, scared	hurt, angry, sad, upset, annoyed, scared	angry, upset, sad, annoyed, hurt	grateful, annoyed, angry, upset	grateful, thankful, relieved, happy, satisfied	PersonX takes PersonY to the emergency room

Figure 5: Sample predictions from homotopic embeddings (gradual interpolation between Event1 and Event2), selected from the top 10 beam elements decoded in the sequence generation setup. Examples highlight differences captured when ideas are similar (*going to* and *coming from* school), when only a single word differs (*washes* versus *cuts*), and when two events are unrelated.

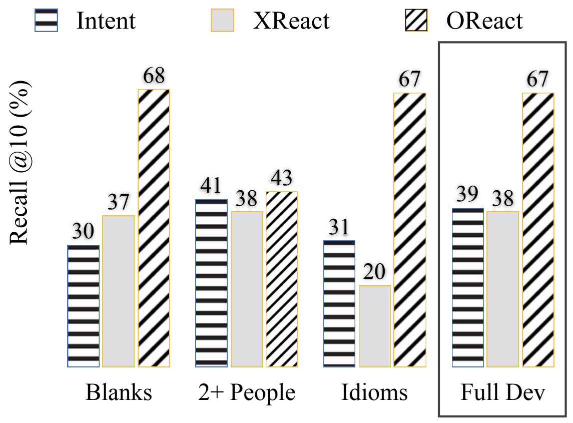

Figure 6: Recall @ 10 (%) on different subsets of the development set for intents, PersonX's reactions, and other people's reactions, using the BiRNN 100d model. "Full dev" represents the recall on the entire development dataset.

ilar for all three sets of events, it is 10% behind intent prediction on the full development set. Additionally, predicting other people's reactions is more difficult for the model when other people are explicitly mentioned. Unsurprisingly, idioms are particularly difficult for commonsense inference, perhaps due to the difficulty in composing meaning over nonliteral or noncompositional event descriptions.

To further evaluate the geometry of the embedding space, we analyze interpolations between pairs of event phrases (from outside the train set), similar to the homotopic analysis of Bowman et al. (2016). For a handful of event pairs, we decode intents, reactions for PersonX, and reactions for other people from points sampled at equal intervals on the interpolated line between two event phrases. We show examples in Figure 5. The embedding space distinguishes changes from generally positive to generally negative words and is also able to capture small differences between event phrases (such as "washes" versus "cuts").

5 Analyzing Bias via Event2Mind Inference

Through Event2Mind inference, we can attempt to bring to the surface what is implied about people's behavior and mental states. We employ this inference to analyze implicit bias in modern films. As shown in Figure 7, our model is able to analyze character portrayal beyond what is explicit in text, by performing pragmatic inference on character actions to explain aspects of a character's mental state. In this section, we use our model's inference to shed light on gender differences in intents behind and reactions to characters' actions.

5.1 Processing of Movie Scripts

For our portrayal analyses, we use scene descriptions from 772 movie scripts released by Gorinski and Lapata (2015), assigned to over 21,000 characters as done by Sap et al. (2017). We extract events from the scene descriptions, and generate their 10 most probable intent and reaction sequences using our BiRNN sequence model (as in Figure 7).

We then categorize generated intents and reactions into groups based on LIWC category scores of the generated output (Tausczik and Pennebaker, 2016).[3] The intent and reaction categories are then

[3]We only consider content word categories: 'Core Drives

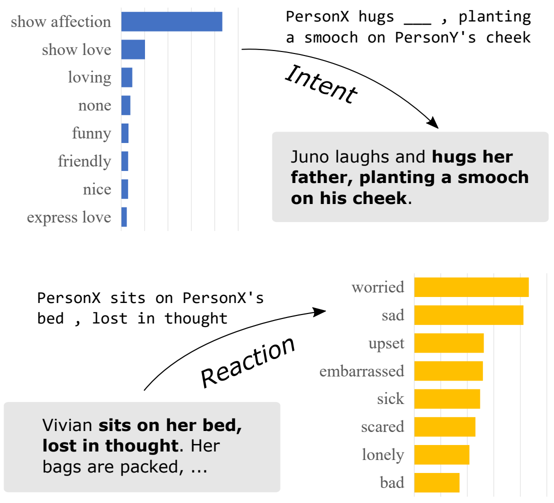

Figure 7: Two scene description snippets from *Juno* (2007, top) and *Pretty Woman* (1990, bottom), augmented with Event2mind inferences on the characters' intents and reactions. E.g., our model infers that the event `PersonX sits on PersonX's bed, lost in thought` implies that the agent, Vivian, is sad or worried.

aggregated for each character, and standardized (zero-mean and unit variance).

We compute correlations with gender for each category of intent or reaction using a logistic regression model, testing significance while using Holm's correction for multiple comparisons (Holm, 1979).[4] To account for the gender skew in scene presence (29.4% of scenes have women), we statistically control for the total number of words in a character's scene descriptions. Note that the original event phrases are all gender agnostic, as their participants have been replaced by variables (e.g., `PersonX`). We also find that the types of gender biases uncovered remain similar when we run these analyses on the human annotations or the generated words and phrases from the BiRNN with n-gram re-ranking decoding setup.

5.2 Revealing Implicit Bias via Explicit Intents and Reactions

Female: intents
AFFILIATION, FRIEND, FAMILY
BODY, SEXUAL, INGEST
SEE, INSIGHT, DISCREP
Male: intents
DEATH, HEALTH, ANGER, NEGEMO
RISK, POWER, ACHIEVE, REWARD, WORK
CAUSE, TENTATIVE‡
Female: reactions
POSEMO, AFFILIATION, FRIEND, REWARD
INGEST, SEXUAL‡, BODY‡
Male: reactions
WORK, ACHIEVE, POWER, HEALTH†
Female: others' reactions
POSEMO, AFFILIATION, FRIEND
INGEST, SEE, INSIGHT
Male: others' reactions
ACHIEVE, RISK†
SAD, NEGEMO‡, ANGER†

Table 4: Select LIWC categories correlated with gender. All results are significant when corrected for multiple comparisons at $p < 0.001$, except $^\dagger p < 0.05$ and $^\ddagger p < 0.01$.

Our Event2Mind inferences automate portrayal analyses that previously required manual annotations (Behm-Morawitz and Mastro, 2008; Prentice and Carranza, 2002; England et al., 2011). Shown in Table 4, our results indicate a gender bias in the behavior ascribed to characters, consistent with psychology and gender studies literature (Collins, 2011). Specifically, events with female semantic agents are intended to be helpful to other people (intents involving FRIEND, FAMILY, and AFFILIATION), particularly relating to eating and making food for themselves and others (INGEST, BODY). Events with male agents on the other hand are motivated by and resulting in achievements (ACHIEVE, MONEY, REWARDS, POWER).

Women's looks and sexuality are also emphasized, as their actions' intents and reactions are sexual, seen, or felt (SEXUAL, SEE, PERCEPT). Men's actions, on the other hand, are motivated by violence or fighting (DEATH, ANGER, RISK), with strong negative reactions (SAD, ANGER, NEGATIVE EMOTION).

Our approach decodes nuanced implications

and Needs', 'Personal Concerns', 'Biological Processes', 'Cognitive Processes', 'Social Words', 'Affect Words', 'Perceptual Processes'. We refer the reader to Tausczik and Pennebaker (2016) or http://liwc.wpengine.com/compare-dictionaries/ for a complete list of category descriptions.

[4] Given the data limitation, we represent gender as a binary, but acknowledge that gender is a more complex social construct.

into more explicit statements, helping to identify and explain gender bias that is prevalent in modern literature and media. Specifically, our results indicate that modern movies have the bias to portray female characters as having pro-social attitudes, whereas male characters are portrayed as being competitive or pro-achievement. This is consistent with gender stereotypes that have been studied in movies in both NLP and psychology literature (Agarwal et al., 2015; Madaan et al., 2017; Prentice and Carranza, 2002; England et al., 2011).

6 Related Work

Prior work has sought formal frameworks for inferring roles and other attributes in relation to events (Baker et al., 1998; Das et al., 2014; Schuler et al., 2009; Hartshorne et al., 2013, *inter alia*), implicitly connoted by events (Reisinger et al., 2015; White et al., 2016; Greene, 2007; Rashkin et al., 2016), or sentiment polarities of events (Ding and Riloff, 2016; Choi and Wiebe, 2014; Russo et al., 2015; Ding and Riloff, 2018). In addition, recent work has studied the patterns which evoke certain polarities (Reed et al., 2017), the desires which make events affective (Ding et al., 2017), the emotions caused by events (Vu et al., 2014), or, conversely, identifying events or reasoning behind particular emotions (Gui et al., 2017). Compared to this prior literature, our work uniquely learns to model intents and reactions over a diverse set of events, includes inference over event participants not explicitly mentioned in text, and formulates the task as predicting the textual descriptions of the implied commonsense instead of classifying various event attributes.

Previous work in natural language inference has focused on linguistic entailment (Bowman et al., 2015; Bos and Markert, 2005) while ours focuses on commonsense-based inference. There also has been inference or entailment work that is more generation focused: generating, e.g., entailed statements (Zhang et al., 2017; Blouw and Eliasmith, 2018), explanations of causality (Kang et al., 2017), or paraphrases (Dong et al., 2017). Our work also aims at generating inferences from sentences; however, our models infer implicit information about mental states and causality, which has not been studied by most previous systems.

Also related are commonsense knowledge bases (Espinosa and Lieberman, 2005; Speer and Havasi, 2012). Our work complements these existing resources by providing commonsense relations that are relatively less populated in previous work. For instance, ConceptNet contains only 25% of our events, and only 12% have relations that resemble intent and reaction. We present a more detailed comparison with ConceptNet in Appendix C.

7 Conclusion

We introduced a new corpus, task, and model for performing commonsense inference on textually-described everyday events, focusing on stereotypical intents and reactions of people involved in the events. Our corpus supports learning representations over a diverse range of events and reasoning about the likely intents and reactions of previously unseen events. We also demonstrate that such inference can help reveal implicit gender bias in movie scripts.

Acknowledgments

We thank the anonymous reviewers for their insightful comments. We also thank xlab members at the University of Washington, Martha Palmer, Tim O'Gorman, Susan Windisch Brown, Ghazaleh Kazeminejad as well as other members at the University of Colorado at Boulder for many helpful comments for our development of the annotation pipeline. This work was supported in part by National Science Foundation Graduate Research Fellowship Program under grant DGE-1256082, NSF grant IIS-1714566, and the DARPA CwC program through ARO (W911NF-15-1-0543).

Abstract

Japanese predicate-argument structure (PAS) analysis involves zero anaphora resolution, which is notoriously difficult. To improve the performance of Japanese PAS analysis, it is straightforward to increase the size of corpora annotated with PAS. However, since it is prohibitively expensive, it is promising to take advantage of a large amount of raw corpora. In this paper, we propose a novel Japanese PAS analysis model based on semi-supervised adversarial training with a raw corpus. In our experiments, our model outperforms existing state-of-the-art models for Japanese PAS analysis.

1 Introduction

In pro-drop languages, such as Japanese and Chinese, pronouns are frequently omitted when they are inferable from their contexts and background knowledge. The natural language processing (NLP) task for detecting such omitted pronouns and searching for their antecedents is called zero anaphora resolution. This task is essential for downstream NLP tasks, such as information extraction and summarization.

For Japanese, zero anaphora resolution is usually conducted within predicate-argument structure (PAS) analysis as a task of finding an omitted argument for a predicate. PAS analysis is a task to find an argument for each case of a predicate. For Japanese PAS analysis, the *ga* (nominative, NOM), *wo* (accusative, ACC) and *ni* (dative, DAT) cases are generally handled. To develop models for Japanese PAS analysis, supervised learning methods using annotated corpora have been applied on the basis of morpho-syntactic clues. However, omitted pronouns have few clues and thus these models try to learn relations between a predicate and its (omitted) argument from the annotated corpora. The annotated corpora consist of several tens of thousands sentences, and it is difficult to learn predicate-argument relations or selectional preferences from such small-scale corpora. The state-of-the-art models for Japanese PAS analysis achieve an accuracy of around 50% for zero pronouns (Ouchi et al., 2015; Shibata et al., 2016; Iida et al., 2016; Ouchi et al., 2017; Matsubayashi and Inui, 2017).

A promising way to solve this data scarcity problem is enhancing models with a large amount of raw corpora. There are two major approaches to using raw corpora: extracting knowledge from raw corpora beforehand (Sasano and Kurohashi, 2011; Shibata et al., 2016) and using raw corpora for data augmentation (Liu et al., 2017b).

In traditional studies on Japanese PAS analysis, selectional preferences are extracted from raw corpora beforehand and are used in PAS analysis models. For example, Sasano and Kurohashi (2011) propose a supervised model for Japanese PAS analysis based on case frames, which are automatically acquired from a raw corpus by clustering predicate-argument structures. However, case frames are not based on distributed representations of words and have a data sparseness problem even if a large raw corpus is employed. Some recent approaches to Japanese PAS analysis combines neural network models with knowledge extraction from raw corpora. Shibata et al. (2016) extract selectional preferences by an unsupervised method that is similar to negative sampling (Mikolov et al., 2013). They then use the pre-extracted selectional preferences as one of the features to their PAS analysis model. The PAS analysis model is trained by a supervised method and the selectional preference representations are fixed during training. Us-

	Predicate	NOM	ACC	DAT
(1) タクシーが$_{\mathrm{NOM}}$ 客を$_{\mathrm{ACC}}$ 駅に$_{\mathrm{DAT}}$ 送った 。 takushi-ga kyaku-wo eki-ni okutta . A taxi carried passengers to the station.	送った okutta sent/carried	タクシー takushi taxi	客 kyaku passenger	駅 eki station
(2) その 列車は 荷物を$_{\mathrm{ACC}}$ 運んだ 。 sono ressha-wa nimotsu-wo hakonda. The train also carried baggages.	運んだ hakonda carried	[列車 ressha train]	荷物 nimotsu baggage	`NULL`
(3) タクシーが$_{\mathrm{NOM}}$ 客を$_{\mathrm{ACC}}$ 乗せた とき 事故に$_{\mathrm{DAT}}$ 巻き込まれた 。 takushi-ga kyaku-wo noseta toki jiko-ni makikomareta. When the taxi picked up passengers, it was involved in the accident.	乗せた noseta picked up	タクシー takushi taxi	客 kyaku passenger	`NULL`
	巻き込まれた makikomareta was involved	[タクシー takushi taxi]	`NULL`	事故 jiko accident
(4) この 列車に は 乗れません 。 kono ressha-ni-wa noremasen. You can not take this train.	乗れません noremasen can not take	[あなた anata you]	`NULL`	列車 ressha train

Table 1: Examples of Japanese sentences and their PAS analysis. In sentence (1), case markers (が(ga), を(wo), and に(ni)) correspond to NOM, ACC, and DAT. In example (2), the correct case marker is hidden by the topic marker は (wa). In sentence (3), the NOM argument of the second predicate 巻き込まれた (was involved), is dropped. `NULL` indicates that the predicate does not have the corresponding case argument or that the case argument is not written in the sentence.

ing pre-trained external knowledge in the form of word embeddings has also been ubiquitous. However, such external knowledge is overwritten in the task-specific training.

The other approach to using raw corpora for PAS analysis is data augmentation. Liu et al. (2017b) generate pseudo training data from a raw corpus and use them for their zero pronoun resolution model. They generate the pseudo training data by dropping certain words or pronouns in a raw corpus and assuming them as correct antecedents. After generating the pseudo training data, they rely on ordinary supervised training based on neural networks.

In this paper, we propose a neural semi-supervised model for Japanese PAS analysis. We adopt neural adversarial training to directly exploit the advantage of using a raw corpus. Our model consists of two neural network models: a generator model of Japanese PAS analysis and a so-called "validator" model of the generator prediction. The generator neural network is a model that predicts probabilities of candidate arguments of each predicate using RNN-based features and a head-selection model (Zhang et al., 2017). The validator neural network gets inputs from the generator and scores them. This validator can score the generator prediction even when PAS gold labels are not available. We apply supervised learning to the generator and unsupervised learning to the entire network using a raw corpus.

Our contributions are summarized as follows: (1) a novel adversarial training model for PAS analysis; (2) learning from a raw corpus as a source of external knowledge; and (3) as a result, we achieve state-of-the-art performance on Japanese PAS analysis.

2 Task Description

Japanese PAS analysis determines essential case roles of words for each predicate: *who* did *what* to *whom*. In many languages, such as English, case roles are mainly determined by word order. However, in Japanese, word order is highly flexible. In Japanese, major case roles are the nominative case (NOM), the accusative case (ACC) and the dative case (DAT), which roughly correspond to Japanese surface case markers: が(ga), を(wo), and に(ni). These case markers are often hidden by topic markers, and case arguments are also often omitted.

We explain two detailed tasks of PAS analysis: case analysis and zero anaphora resolution. In Table 1, we show four example Japanese sentences and their PAS labels. PAS labels are attached to nominative, accusative and dative cases of each predicate. Sentence (1) has surface case markers that correspond to argument cases.

Sentence (2) is an example sentence for case analysis. Case analysis is a task to find hidden case markers of arguments that have direct depen-

Figure 1: The overall model of adversarial training with a raw corpus. The PAS generator $G(x)$ and validator $V(x)$. The validator takes inputs from the generator as a form of the attention mechanism. The validator itself is a simple feed-forward network with inputs of j-th predicate and its argument representations: $\{h'_{\mathrm{pred}_j}, h'^{\mathrm{case}_k}_{\mathrm{pred}_j}\}$. The validator returns scores for three cases and they are used for both the supervised training of the validator and the unsupervised training of the generator. The supervised training of the generator is not included in this figure.

dencies to their predicates. Sentence (2) does not have the nominative case marker が(ga). It is hidden by the topic case marker は(wa). Therefore, a case analysis model has to find the correct NOM case argument 列車(train).

Sentence (3) is an example sentence for zero anaphora resolution. Zero anaphora resolution is a task to find arguments that do not have direct dependencies to their predicates. At the second predicate "巻き込まれた"(was involved), the correct nominative argument is "タクシー"(taxi), while this does not have direct dependencies to the second predicate. A zero anaphora resolution model has to find "タクシー"(taxi) from the sentence, and assign it to the NOM case of the second predicate.

In the zero anaphora resolution task, some correct arguments are not specified in the article. This is called as *exophora*. We consider "author" and "reader" arguments as exophora (Hangyo et al., 2013). They are frequently dropped from Japanese natural sentences. Sentence (4) is an example of dropped nominative arguments. In this sentence, the nominative argument is "あなた" (you), but "あなた" (you) does not appear in the sentence. This is also included in zero anaphora resolution. Except these special arguments of exophora, we focus on intra-sentential anaphora resolution in the same way as (Shibata et al., 2016; Iida et al., 2016; Ouchi et al., 2017; Matsubayashi and Inui, 2017). We also attach `NULL` labels to cases that predicates do not have.

3 Model

3.1 Generative Adversarial Networks

Generative adversarial networks are originally proposed in image generation tasks (Goodfellow et al., 2014; Salimans et al., 2016; Springenberg, 2015). In the original model in Goodfellow et al. (2014), they propose a generator G and a discriminator D. The discriminator D is trained to devide the real data distribution $p_{data}(\mathbf{x})$ and images generated from the noise samples $\mathbf{z}^{(i)} \in \mathcal{D}_\mathbf{z}$ from noise prior $p(\mathbf{z})$. The discriminator loss is

$$\mathcal{L}_D = -\big(\mathbb{E}_{\mathbf{x}\sim p_{data}(\mathbf{x})}[\log D(\mathbf{x})] \\ +\mathbb{E}_{\mathbf{z}\sim p_z(\mathbf{z})}[\log(1 - D(G(\mathbf{z})))]\big) \ , \quad (1)$$

and they train the discriminator by minimizing this loss while fixing the generator G. Similarly, the generator G is trained through minimizing

$$\mathcal{L}_G = \frac{1}{|\mathcal{D}_\mathbf{z}|}\sum_i \Big[\log\Big(1 - D(G(\mathbf{z}^{(i)}))\Big)\Big] \ , \quad (2)$$

while fixing the discriminator D. By doing this, the discriminator tries to descriminate the generated images from real images, while the generator tries to generate images that can deceive the adversarial discriminator. This training scheme is applied for many generative tasks including sentence generation (Subramanian et al., 2017), machine translation (Britz et al., 2017), dialog generation (Li et al., 2017), and text classification (Liu et al., 2017a).

3.2 Proposed Adversarial Training Using Raw Corpus

Japanese PAS analysis and many other syntactic analyses in NLP are not purely generative, and we can make use of a raw corpus instead of the numerical noise distribution $p(\mathbf{z})$. In this work, we use an adversarial training method using a raw corpus, combined with ordinary supervised learning using an annotated corpus. Let $\mathbf{x}_l \in \mathcal{D}_l$ indicate labeled data and $p(\mathbf{x}_l)$ indicate their label distribution. We also use unlabeled data $\mathbf{x}_{ul} \in \mathcal{D}_{ul}$ later. Our generator G can be trained by the cross entropy loss with labeled data:

$$\mathcal{L}_{G/SL} = -\mathbb{E}_{\mathbf{x}_l, y \sim p(\mathbf{x}_l)} \left[\log G(\mathbf{x}_l) \right] \quad . \qquad (3)$$

Supervised training of the generator works by minimizing this loss. Note that we follow the notations of Subramanian et al. (2017) in this subsection.

In addition, we train a so-called *validator* against the generator errors. We use the term "validator" instead of "discriminator" for our adversarial training. Unlike the discriminator that is used for dividing generated images and real images, our validator is used to score the generator results. Assume that $\mathbf{y}_l$ is the true labels and $G(\mathbf{x}_l)$ is the predicted label distribution of data $\mathbf{x}_l$ from the generator. We define the labels of the generator errors as:

$$q(G(\mathbf{x}_l), \mathbf{y}_l) = \delta_{\arg\max[G(\mathbf{x}_l)],\, \mathbf{y}_l} \quad , \qquad (4)$$

where $\delta_{i,j} = 1$ only if $i = j$, otherwise $\delta_{i,j} = 0$. This means that q is equal to 1 if the argument that the generator predicts is correct, otherwise 0. We use this generator error for training labels of the following validator. The inputs of the validator are both the generator outputs $G(\mathbf{x})$ and data $\mathbf{x} \in \mathcal{D}$. The validator can be written as $V(G(\mathbf{x}))$. The validator V is trained with labeled data $\mathbf{x}_l$ by

$$\mathcal{L}_{V/SL} = -\mathbb{E}_{\mathbf{x}_l, y \sim q(G(\mathbf{x}_l), \mathbf{y}_l)} \left[\log V(G(\mathbf{x}_l)) \right] \quad , \qquad (5)$$

while fixing the generator G. This equation means that the validator is trained with labels of the generator error $q(G(\mathbf{x}_l), \mathbf{y}_l)$.

Once the validator is trained, we train the generator with an unsupervised method. The generator G is trained with unlabeled data $\mathbf{x}_{ul} \in \mathcal{D}_{ul}$ by minimizing the loss

$$\mathcal{L}_{G/UL} = -\frac{1}{|\mathcal{D}_{ul}|} \sum_i \left[\log V(G(\mathbf{x}_{ul}^{(i)})) \right] \quad , \qquad (6)$$

while fixing the validator V. This generator training loss using the validator can be explained as follows. The generator tries to increase the validator scores to 1, while the validator is fixed. If the validator is well-trained, it returns scores close to 1 for correct PAS labels that the generator outputs, and 0 for wrong labels. Therefore, in Equation (6), the generator tries to predict correct labels in order to increase the scores of fixed validator. Note that the validator has a sigmoid function for the output of scores. Therefore output scores of the validator are in $[0, 1]$.

We first conduct the supervised training of generator network with Equation (3). After this, following Goodfellow et al. (2014), we use k-steps of the validator training and one-step of the generator training. We also alternately conduct l-steps of supervised training of the generator. The entire loss function of this adversarial training is

$$\mathcal{L} = \mathcal{L}_{G/SL} + \mathcal{L}_{V/SL} + \mathcal{L}_{G/UL} \quad . \qquad (7)$$

Our contribution is that we propose the validator and train it against the generator errors, instead of discriminating generated data from real data. Salimans et al. (2016) explore the semi-supervised learning using adversarial training for K-classes image classification tasks. They add a new class of images that are generated by the generator and classify them.

Miyato et al. (2016) propose virtual adversarial training for semi-supervised learning. They exploit unlabeled data for continuous smoothing of data distributions based on the adversarial perturbation of Goodfellow et al. (2015). These studies, however, do not use the counterpart neural networks for learning structures of unlabeled data.

In our Japanese PAS analysis model, the generator corresponds to the head-selection-based neural network for Japanese anaphora resolution. Figure 1 shows the entire model. The labeled data correspond to the annotated corpora and the labels correspond to the PAS argument labels. The unlabeled data correspond to raw corpora. We explain the details of the generator and the validator neural networks in Sec.3.3 and Sec.3.4 in turn.

3.3 Generator of PAS Analysis

The generator predicts the probabilities of arguments for each of the NOM, ACC and DAT cases of a predicate. As shown in Figure 2, the generator consists of a sentence encoder and an argument selection model. In the sentence encoder, we

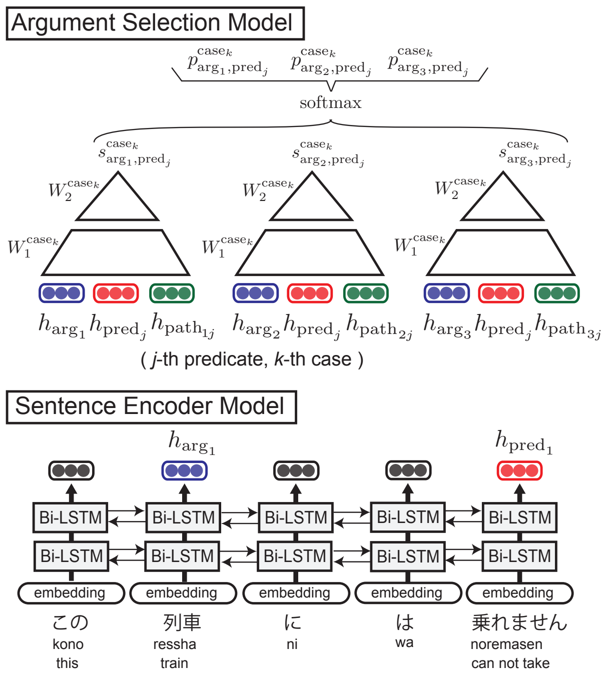

Figure 2: The generator of PAS. The sentence encoder is a three-layer bi-LSTM to compute the distributed representations of a predicate and its arguments: h_{pred_i} and h_{arg_i}. The argument selection model is two-layer feedforward neural networks to compute the scores, $s^{\text{case}_k}_{\text{arg}_i,\text{pred}_j}$, of candidate arguments for each case of a predicate.

use a three-layer bidirectional-LSTM (bi-LSTM) to read the whole sentence and extract both global and local features as distributed representations. The argument selection model consists of a two-layer feedforward neural network (FNN) and a softmax function.

For the sentence encoder, inputs are given as a sequence of embeddings $v(x)$, each of which consist of word x, its inflection from, POS and detailed POS. They are concatenated and fed into the bi-LSTM layers. The bi-LSTM layers read these embeddings in forward and backward order and outputs the distributed representations of a predicate and a candidate argument: h_{pred_j} and h_{arg_i}. Note that we also use the exophora entities, i.e., an author and a reader, as argument candidates. Therefore, we use specific embeddings for them. These embeddings are not generated by the bi-LSTM layers but are directly used in the argument selection model.

We also use path embeddings to capture a dependency relation between a predicate and its candidate argument as used in Roth and Lapata (2016). Although Roth and Lapata (2016) use a one-way LSTM layer to represent the dependency path from a predicate to its potential argument, we use a bi-LSTM layer for this purpose. We feed the embeddings of words and POS tags to the bi-LSTM layer. In this way, the resulting path embedding represents both predicate-to-argument and argument-to-predicate paths. We concatenate the bidirectional path embeddings to generate $h_{\text{path}_{ij}}$, which represents the dependency relation between the predicate j and its candidate argument i.

For the argument selection model, we apply the argument selection model (Zhang et al., 2017) to evaluate the relation between a predicate and its potential argument for each argument case. In the argument selection model, a single FNN is repeatedly used to calculate scores for a child word and its head candidate word, and then a softmax function calculates normalized probabilities of candidate heads. We use three different FNNs that correspond to the NOM, ACC and DAT cases. These three FNNs have the same inputs of the distributed representations of j-th predicate h_{pred_j}, i-th candidate argument h_{arg_i} and path embedding $h_{\text{path}_{ij}}$ between the predicate j and candidate argument i. The FNNs for NOM, ACC and DAT compute the argument scores $s^{\text{case}_k}_{\text{arg}_i,\text{pred}_j}$, where $\text{case}_k \in \{\text{NOM}, \text{ACC}, \text{DAT}\}$. Finally, the softmax function computes the probability $p(\text{arg}_i|\text{pred}_j, \text{case}_k)$ of candidate argument i for case k of j-th predicate as:

$$p(\text{arg}_i|\text{pred}_j,\text{case}_k) = \frac{\exp\left(s^{\text{case}_k}_{\text{arg}_i,\text{pred}_j}\right)}{\sum_{\text{arg}_i} \exp\left(s^{\text{case}_k}_{\text{arg}_i,\text{pred}_j}\right)}. \quad (8)$$

Our argument selection model is similar to the neural network structure of Matsubayashi and Inui (2017). However, Matsubayashi and Inui (2017) does not use RNNs to read the whole sentence. Their model is also designed to choose a case label for a pair of a predicate and its argument candidate. In other words, their model can assign the same case label to multiple arguments by itself, while our model does not. Since case arguments are almost unique for each case of a predicate in Japanese, Matsubayashi and Inui (2017) select the argument that has the highest probability for each case, even though probabilities of case arguments are not normalized over argument candidates. The model of Ouchi et al. (2017) has the same problem.

3.4 Validator

We exploit a validator to train the generator using a raw corpus. It consists of a two-layer FNN to which embeddings of a predicate and its arguments are fed. For predicate j, the input of the FNN is the representations of the predicate h'_{pred_j} and three arguments $\left\{h'^{\text{NOM}}_{\text{pred}_j}, h'^{\text{ACC}}_{\text{pred}_j}, h'^{\text{DAT}}_{\text{pred}_j}\right\}$ that are inferred by the generator. The two-layer FNN outputs three values, and then three sigmoid functions compute the scores of scalar values in a range of $[0, 1]$ for the NOM, ACC and DAT cases: $\left\{s'^{\text{NOM}}_{\text{pred}_j}, s'^{\text{ACC}}_{\text{pred}_j}, s'^{\text{DAT}}_{\text{pred}_j}\right\}$. These scores are the outputs of the validator $D(x)$. We use dropout of 0.5 at the FNN input and hidden layer.

The generator and validator networks are coupled by the attention mechanism, or the weighted sum of the validator embeddings. As shown in Equation (8), we compute a probability distribution of candidate arguments. We use the weighted sum of embeddings $v'(x)$ of candidate arguments to compute the input representations of the validator:

$$\begin{aligned} h'^{\text{case}_k}_{\text{pred}_j} &= E_{\mathbf{x}\sim p(\text{arg}_i)}[v'(\mathbf{x})] \\ &= \sum_{\text{arg}_i} p(\text{arg}_i|\text{pred}_j,\text{case}_k)v'(\text{arg}_i). \end{aligned}$$

This summation is taken over candidate arguments in the sentence and the exophora entities. Note that we use embeddings $v'(x)$ for the validator that are different from the embeddings $v(x)$ for the generator, in order to separate the computation graphs of the generator and the validator neural networks except the joint part. We use this weighted sum by the softmax outputs instead of the argmax function. This allows the backpropagation through this joint. We also feed the embedding of a predicate to the validator:

$$h'_{\text{pred}_j} = v'(\text{pred}_j). \tag{9}$$

Note that the validator is a simple neural network compared with the generator. The validator has limited inputs of predicates and arguments and no inputs of other words in sentences. This allows the generator to overwhelm the validator during the adversarial training.

Type	Value

3.5 Implementation Details

The neural networks are trained using backpropagation. The backpropagation has been done to the word and POS tags. We use Adam (Kingma and Ba, 2015) at the initial training of the generator network for the gradient learning rule. In adversarial learning, Adagrad (Duchi et al., 2010) is suitable because of the stability of learning. We use pre-trained word embeddings from 100M sentences from Japanese web corpus by word2vec (Mikolov et al., 2013). Other embeddings and hidden weights of neural networks are randomly initialized.

For adversarial training, we first train the generator for two epochs by the supervised method, and train the validator while fixing the generator for another epoch. This is because the validator training preceding the generator training makes the validator result worse. After this, we alternately do the unsupervised training of the generator ($L_{G/UL}$), k-times of supervised training of the validator ($L_{V/SL}$) and l-times of supervised training of the generator ($L_{G/SL}$).

We use the $N(L_{G/UL})/N(L_{G/SL}) = 1/4$ and $N(L_{V/SL})/N(L_{G/SL}) = 1/4$, where $N(\cdot)$ indicates the number of sentences used for training. Also we use minibatch of 16 sentences for both supervised and unsupervised training of the generator, while we do not use minibatch for validator training. Therefore, we use $k = 16$ and $l = 4$. Other parameters are summarized in Table 2.

4 Experiments

4.1 Experimental Settings

Following Shibata et al. (2016), we use the KWDLC (Kyoto University Web Document Leads Corpus) corpus (Hangyo et al., 2012) for our experiments.[1] This corpus contains various Web documents, such as news articles, personal blogs, and commerce sites. In KWDLC, lead three sentences of each document are annotated with PAS structures including zero pronouns. For a raw corpus, we use a Japanese web corpus created by Hangyo et al. (2012), which has no duplicated sentences with KWDLC. This raw corpus is automatically parsed by the Japanese dependency parser KNP.

We focus on intra-sentential anaphora resolution, and so we apply a preprocess to KWDLC. We regard the anaphors whose antecedents are in the preceding sentences as `NULL` in the same way as Ouchi et al. (2015); Shibata et al. (2016). Tables 3 and 4 list the statistics of KWDLC.

We use the exophora entities, i.e., an author and a reader, following the annotations in KWDLC. We also assign author/reader labels to the following expressions in the same way as Hangyo et al. (2013); Shibata et al. (2016):

author "私" (I), "僕" (I), "我々" (we), "弊社" (our company)

reader "あなた" (you), "君" (you), "客" (customer), "皆様" (you all)

Following Ouchi et al. (2015) and Shibata et al. (2016), we conduct two kinds of analysis: (1) case analysis and (2) zero anaphora resolution. Case analysis is the task to determine the correct case labels when predicates and their arguments have direct dependencies but their case markers are hidden by surface markers, such as topic markers. Zero anaphora resolution is a task to find certain case arguments that do not have direct dependencies to their predicates in the sentence.

Following Shibata et al. (2016), we exclude predicates that the same arguments are filled in multiple cases of a predicate. This is relatively uncommon and 1.5 % of the whole corpus are excluded. Predicates are marked in the gold dependency parses. Candidate arguments are just other tokens than predicates. This setting is also the same as Shibata et al. (2016).

All performances are evaluated with micro-averaged F-measure (Shibata et al., 2016).

4.2 Experimental Results

We compare two models: the supervised generator model (Gen) and the proposed semi-supervised model with adversarial training (Gen+Adv). We also compare our models with two previous models: Ouchi et al. (2015) and Shibata et al. (2016), whose performance on the KWDLC corpus is reported.

Table 5 lists the experimental results. Our models (Gen and Gen+Adv) outperformed the previous models. Furthermore, the proposed model with adversarial training (Gen+Adv) was significantly better than the supervised model (Gen).

4.3 Comparison with Data Augmentation Model

We also compare our GAN-based approach with data augmentation techniques. A data augmentation approach is used in Liu et al. (2017b). They automatically process raw corpora and make drops of words with some rules. However, it is difficult to directly apply their approach to Japanese PAS analysis because Japanese zero-pronoun depends on dependency trees. If we make some drops of arguments of predicates in sentences, this can cause lacks of nodes in dependency trees. If we prune some branches of dependency trees of the sentence, this cause the data bias problem.

[1] The KWDLC corpus is available at http://nlp.ist.i.kyoto-u.ac.jp/EN/index.php?KWDLC

	Case analysis			Zero anaphora resolution		
Model	NOM	ACC	DAT	NOM	ACC	DAT
Ouchi+ 2015	87.4	40.2	27.6	48.8	0.0	10.7
Shibata+ 2016	94.1	75.6	30.0	57.7	17.3	37.8
Gen	**95.3**	83.6	39.7	60.7	30.4	41.2
Gen+Adv	**95.3**	**85.4**	**51.5**	**62.3**	**31.1**	**44.6**

Table 6: The detailed results of case analysis and zero anaphora resolution for the NOM, ACC and DAT cases. Our models outperform the existing models in all cases. All values are evaluated with F-measure.

	Case	Zero
Gen	91.5	56.2
Gen+Aug	91.2	57.0
Gen+Adv	**92.0**‡	**58.4**‡

Table 7: The comparisons of Gen+Adv with Gen and the data augmentation model (Gen+Aug). ‡ denotes that the improvement is statistically significant at $p < 0.05$, compared with Gen+Aug.

Therefore we use existing training corpora and word embeddings for the data augmentation. First we randomly choose an argument word w in the training corpus and then swap it with another word w' with the probability of $p(w, w')$. We choose top-20 nearest words to the original word w in the pre-trained word embedding as candidates of swapped words. The probability is defined as $p(w, w') \propto [v(w)^\top v(w')]^r$, where $r = 10$. This probability is normalized by top-20 nearest words. We then merge this pseudo data and the original training corpus and train the model in the same way with the Gen model. We conducted several experiments and found that the model trained with the same amount of the pseudo data as the training corpus achieved the best result.

Table 7 shows the results of the data augmentation model and the GAN-based model. Our Gen+Adv model performs better than the data augmented model. Note that our data augmentation model does not use raw corpora directly.

4.4 Discussion

4.4.1 Result Analysis

We report the detailed performance for each case in Table 6. Among the three cases, zero anaphora resolution of the ACC and DAT cases is notoriously difficult. This is attributed to the fact that these ACC and DAT cases are fewer than the NOM case in the corpus as shown in Table 4. However, we can see that our proposed model, Gen+Adv, performs much better than the previous models especially for the ACC and DAT cases. Although the number of training instances of ACC and DAT is much smaller than that of NOM, our semi-supervised model can learn PAS for all three cases using a raw corpus. This indicates that our model can work well in resource-poor cases.

We analyzed the results of Gen+Adv by comparing with Gen and the model of Shibata et al. (2016). Here, we focus on the ACC and DAT cases because their improvements are notable.

- “パックは 洗って、 分別して リサイクルに 出さなきゃいけないので 手間がかかる。“
  It is bothersome to wash, classify and recycle spent packs.

In this sentence, the predicates “洗って” (wash), “分別して” (classify), “(リサイクルに) 出す” (recycle) takes the same ACC argument, “パック” (pack). This is not so easy for Japanese PAS analysis because the actual ACC case marker “を” (wo) of “パック” (pack) is hidden by the topic marker “は” (wa). The Gen+Adv model can detect the correct argument while the model of Shibata et al. (2016) fails. In the Gen+Adv model, each predicate gives a high probability to “パック” (pack) as an ACC argument and finally chooses this. We found many examples similar to this and speculate that our model captures a kind of selectional preferences.

The next example is an error of the DAT case by the Gen+Adv model.

- “各専門分野も お任せ下さい。”
  please leave every professional field (to ϕ)

The gold label of this DAT case (to ϕ) is NULL because this argument is not written in the sentence.

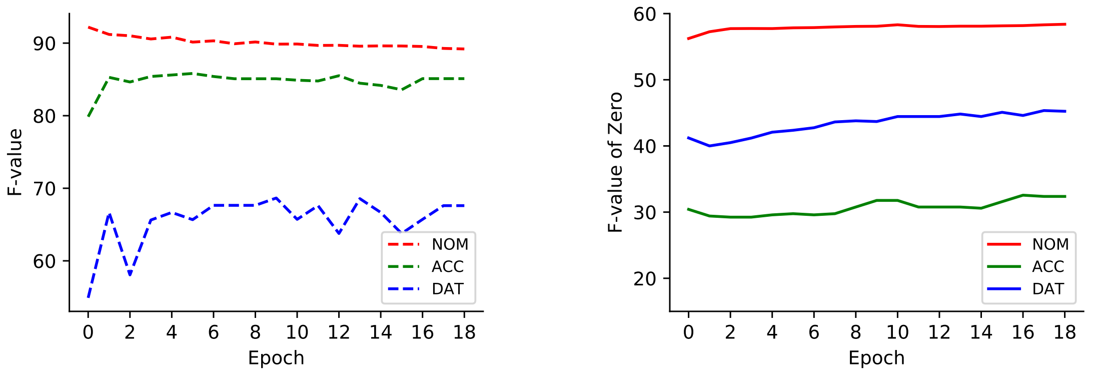

Figure 3: Left: validator scores with the development set during adversarial training epochs. Right: generator scores for Zero with the development set during adversarial training epochs.

However, the Gen+Adv model judged the DAT argument as "author". Although we cannot specify ϕ as "author" only from this sentence, "author" is a possible argument depending on the context.

4.4.2 Validator Analysis

We also evaluate the performance of the validator during the adversarial training with raw corpora. Figure 3 shows the validator performance and the generator performance of Zero on the development set. The validator score is evaluated with the outputs of generator.

We notice that the NOM case and the other two cases have different curves in both graphs. This can be explained by the speciality of the NOM case. The NOM case has much more author/reader expressions than the other cases. The prediction of author/reader expressions depends not only on selectional preferences of predicates and arguments but on the whole of sentences. Therefore the validator that relies only on predicate and argument representations cannot predict author/reader expressions well.

In the ACC and DAT cases, the scores of the generator and validator increase in the first epochs. This suggests that the validator learns the weakness of the generator and vice versa. However, in later epochs, the scores of the generator increase with fluctuation, while the scores of the validator saturates. This suggests that the generator gradually becomes stronger than the validator.

5 Related Work

Shibata et al. (2016) proposed a neural network-based PAS analysis model using local and global features. This model is based on the non-neural model of Ouchi et al. (2015). They achieved state-of-the-art results on case analysis and zero anaphora resolution using the KWDLC corpus. They use an external resource to extract selectional preferences. Since our model uses an external resource, we compare our model with the models of Shibata et al. (2016) and Ouchi et al. (2015).

Ouchi et al. (2017) proposed a semantic role labeling-based PAS analysis model using Grid-RNNs. Matsubayashi and Inui (2017) proposed a case label selection model with feature-based neural networks. They conducted their experiments on NAIST Text Corpus (NTC) (Iida et al., 2007, 2016). NTC consists of newspaper articles, and does not include the annotations of author/reader expressions that are common in Japanese natural sentences.

6 Conclusion

We proposed a novel Japanese PAS analysis model that exploits a semi-supervised adversarial training. The generator neural network learns Japanese PAS and selectional preferences, while the validator is trained against the generator errors. This validator enables the generator to be trained from raw corpora and enhance it with external knowledge. In the future, we will apply this semi-supervised training method to other NLP tasks.

Improving Event Coreference Resolution by Modeling Correlations between Event Coreference Chains and Document Topic Structures

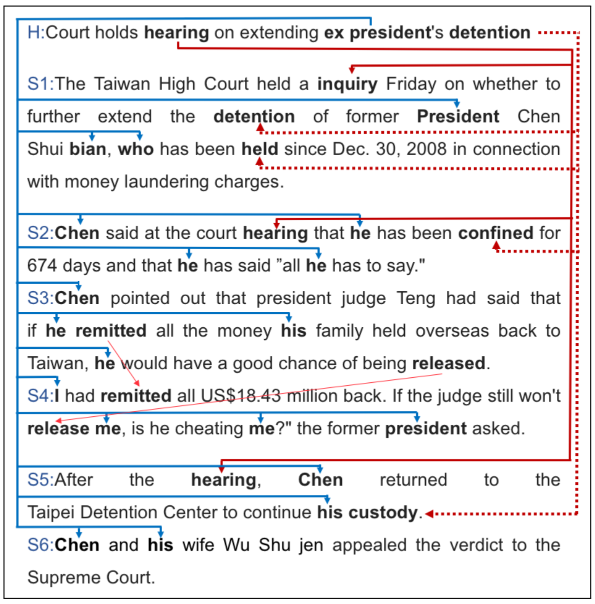
Abstract

This paper proposes a novel approach for event coreference resolution that models correlations between event coreference chains and document topical structures through an Integer Linear Programming formulation. We explicitly model correlations between the main event chains of a document with topic transition sentences, inter-coreference chain correlations, event mention distributional characteristics and sub-event structure, and use them with scores obtained from a local coreference relation classifier for jointly resolving multiple event chains in a document. Our experiments across KBP 2016 and 2017 datasets suggest that each of the structures contribute to improving event coreference resolution performance.



H:Court holds **hearing** on extending **ex president**'s **detention**

S1:The Taiwan High Court held a **inquiry** Friday on whether to further extend the **detention** of former **President** Chen Shui **bian**, **who** has been **held** since Dec. 30, 2008 in connection with money laundering charges.

S2:**Chen** said at the court **hearing** that **he** has been **confined** for 674 days and that **he** has said "all **he** has to say."

S3:**Chen** pointed out that president judge Teng had said that if **he remitted** all the money **his** family held overseas back to Taiwan, **he** would have a good chance of being **released**.

S4:**I** had **remitted** all US$18.43 million back. If the judge still won't **release me**, is he cheating **me**?" the former **president** asked.

S5:After the **hearing**, **Chen** returned to the Taipei Detention Center to continue **his custody**.

S6:**Chen** and **his** wife Wu Shu jen appealed the verdict to the Supreme Court.

Figure 1: An example document to illustrate the characteristics of event (red) and entity (blue) coreference chains.

1 Introduction

Event coreference resolution aims to identify and link event mentions in a document that refer to the same real-world event, which is vital for identifying the skeleton of a story and text understanding and is beneficial to numerous other NLP applications such as question answering and summarization. In spite of its importance, compared to considerable research for resolving coreferential entity mentions, far less attention has been devoted to event coreference resolution. Event coreference resolution thus remained a challenging task and the best performance remained low.

Event coreference resolution presents unique challenges. Compared to entities, coreferential event mentions are fewer in a document and much more sparsely scattered across sentences. Figure 1 shows a typical news article. Here, the main entity, "President Chen", appears frequently in every sentence, while the main event "hearing" and its accompanying event "detention" are mentioned much less frequently. If we look more closely, referring back to the same entity serves a different purpose than referring to the same event. The protagonist entity of a story is involved in many events and relations; thus, the entity is referred back each time such an event or relation is described. In this example, the entity was mentioned when describing various events he participated or was involved in, including "detention", "said", "pointed out", "remitted", "have a chance", "release", "cheating", "asked" and "returned", as well as when describing several relations involving him, including "former president", "his family" and "his wife". In contrast, most events only appear once in a text, and there is less motivation to repeat them: a story is mainly formed by a se-

Table 1: Percentages of adjacent (event vs. entity) mention pairs based on the number of sentences between two mentions.

ries of related but different events. Essentially, (1) the same event is referred back only when a new aspect or further information of the event has to be described, and (2) repetitions of the same events are mainly used for content organization purposes and, consequently, correlate well with topic structures.

Table 1 further shows the comparisons of positional patterns between event coreference and entity coreference chains, based on two benchmark datasets, ERE (Song et al., 2015) and ACE05 (Walker et al., 2006), where we paired each event (entity) mention with its nearest antecedent event (entity) mention and calculated the percentage of (event vs. entity) coreferent mention pairs based on the number of sentences between two mentions. Indeed, for entity coreference resolution, centering and nearness are striking properties (Grosz et al., 1995), and the nearest antecedent of an entity mention is mostly in the same sentence or in the immediately preceding sentence (70%). This is especially true for nominals and pronouns, two common types of entity mentions, where the nearest preceding mention that is also compatible in basic properties (e.g., gender, person and number) is likely to co-refer with the current mention. In contrast, coreferential event mentions are rarely from the same sentence (10%) and are often sentences apart. The sparse distribution of coreferent event mentions also applies to the three KBP corpora used in this work.

To address severe sparsity of event coreference relations in a document, we propose a holistic approach to identify coreference relations between event mentions by considering their correlations with document topic structures. Our key observation is that event mentions make the backbone of a document and coreferent mentions of the same event play a key role in achieving a coherent content structure. For example, in figure 1, the events "hearing" and "detention" were mentioned in the headline (H), in the first sentence (S1) as a story overview, in the second sentence (S2) for transitioning to the body section of the story describing what happened during the hearing, and then in the fifth sentence (S5) for transitioning to the ending section of the story describing what happened after the hearing. By attaching individual event mentions to a coherent story and its topic structures, our approach recognizes event coreference relations that are otherwise not easily seen due to a mismatch of two event mentions' local contexts or long distances between event mentions.

We model several aspects of correlations between event coreference chains and document level topic structures, in an Integer Linear Programming (ILP) joint inference framework. Experimental results on the benchmark event coreference resolution dataset KBP-2016 (Ellis et al., 2016) and KBP 2017 (Getman et al., 2017) show that the ILP system greatly improves event coreference resolution performance by modeling different aspects of correlations between event coreferences and document topic structures, which outperforms the previous best system on the same dataset consistently across several event coreference evaluation metrics.

2 Correlations between Event Coreference Chains and Document Topic Structures

We model four aspects of correlations.

Correlations between Main Event Chains and Topic Transition Sentences: the main events of a document, e.g., "hearing" and "detention" in this example 1, usually have multiple coreferent event mentions that span over a large portion of the document and align well with the document topic layout structure (Choubey et al., 2018). While fine-grained topic segmentation is a difficult task in its own right, we find that topic transition sentences often overlap in content (for reminding purposes) and can be identified by calculating sentence similarities. For example, sentences S1, S2 and S5 in Figure 1 all mentioned the two main events and the main entity "President Chen". We, therefore, encourage coreference links between event mentions that appear in topic transition sentences by designing constraints in ILP and modifying the objective function. In addition, to avoid fragmented partial event chains and recover complete chains for the main events, we also encourage associating more coreferent event mentions to a chain that has a large stretch (the number of sentences between the first and the last event mention based on their textual positions).

Correlations across Semantically Associated Event Chains: semantically associated events often co-occur in the same sentence. For example, mentions of the two main events "hearing" and "detention" co-occur across the document in sentences H, S1, S2 and S5. The correlation across event chains is not specific to global main events, for example, the local events "remitted" and "release" have their mentions co-occur in sentences S3 and S4 as well. In ILP, we leverage this observation and encourage creating coreference links between event mentions in sentences that contain other already known coreferent event mentions.

Genre-specific Distributional Patterns: we model document level distributional patterns of coreferent event mentions that may be specific to a genre in ILP. Specifically, news article often begins with a summary of the overall story and then introduces the main events and their closely associated events. In subsequent paragraphs, detailed information of events may be introduced to provide supportive evidence to the main story. Thereby, a majority of event coreference chains tend to be initiated in the early sections of the document. Event mentions in the later paragraphs may exist as coreferent mentions of an established coreference chain or as singleton event mentions which, however, are less likely to initiate a new coreference chain. Inspired by this observation, we simply modify the objective function of ILP to encourage more event coreference links in early sections of a document.

Subevents: subevents exist mainly to provide details and evidence for the parent event, therefore, the relation between subevents and their parent event presents another aspect of correlations between event relations and hierarchical document topic structures. Subevents may share the same lexical form as the parent event and cause spurious event coreference links (Araki et al., 2014). We observe that subevents referring to specific actions were seldomly referred back in a document and are often singleton events. Following the approach proposed by (Badgett and Huang, 2016), we identify such specific action events and improve event coreference resolution by specifying constraints in ILP to discourage coreference links between a specific action event and other event mentions.

3 Related Work

Compared to entity coreference resolution (Lee et al., 2017; Clark and Manning, 2016a,b; Martschat and Strube, 2015; Lee et al., 2013), far less research was conducted for event coreference resolution. Most existing methods (Ahn, 2006; Chen et al., 2009; Cybulska and Vossen, 2015a,b) heavily rely on surface features, mainly event arguments (i.e., entities such as event participants, time, location, etc.) that were extracted from local contexts of two events, and determine that two events are coreferential if their arguments match. Often, a clustering algorithm, hierarchical Bayesian (Bejan and Harabagiu, 2010, 2014; Yang et al., 2015) or spectral clustering algorithms (Chen and Ji, 2009), is applied on top of a pairwise surface feature based classifier for inducing event clusters. However, identifying potential arguments, linking arguments to a proper event mention, and recognizing compatibilities between arguments are all error-prone (Lu et al., 2016). Joint event and entity coreference resolution (Lee et al., 2012), joint inferences of event detection and event coreference resolution (Lu and Ng, 2017), and iterative information propagation (Liu et al., 2014; Choubey and Huang, 2017a) have been proposed to mitigate argument mismatch issues.

However, such methods are incapable of handling more complex and subtle cases, such as partial event coreference with incompatible arguments (Choubey and Huang, 2017a) and cases lacking informative local contexts. Consequently, many event coreference links were missing and the resulted event chains are fragmented. The low performance of event coreference resolution limited its uses in downstream applications. (**?**) shows that instead of human annotated event coreference relations, using system predicted relations resulted in a significant performance reduction in identifying the central event of a document. Moreover, the recent research by Moosavi and Strube (2017) found that the extensive use of lexical and surface features biases entity coreference resolvers towards seen mentions and do not generalize to unseen domains, and the finding can perfectly apply to event coreference resolution. Therefore, we propose to improve event coreference resolution by modeling correlations between event coreferences and the overall topic structures of a document, which is more likely to yield robust and generalizable event coreference resolvers.

4 Modeling Event Coreference Chain - Topic Structure Correlations Using Integer Linear Programming

We model discourse level event-topic correlation structures by formulating the event coreference resolution task as an Integer Linear Programming (ILP) problem. Our baseline ILP system is defined over pairwise scores between event mentions obtained from a pairwise neural network-based coreference resolution classifier.

4.1 The Local Pairwise Coreference Resolution Classifier

Our local pairwise coreference classifier uses a neural network model based on features defined for an event mention pair. It includes a common layer with 347 neurons shared between two event mentions to generate embeddings corresponding to word lemmas (300) and parts-of-speech (POS) tags (47). The common layer aims to enrich event word embeddings with the POS tags using the shared weight parameters. It also includes a second layer with 380 neurons to embed suffix[1] and prefix [2] of event words, distances (euclidean, absolute and cosine) between word embeddings of two event lemmas and common arguments between two event mentions. The output from the second layer is concatenated and fed into the third neural layer with 10 neurons. The output embedding from the third layer is finally fed into an output layer with 1 neuron that generates a score indicating the confidence of assigning the given event pair to the same coreference cluster. All three layers and the output layer use the sigmoid activation function.

4.2 The Basic ILP for Event Coreference Resolution

Let λ represents the set of all event mentions in a document, Λ denotes the set of all event mention pairs i.e. $\Lambda = \{< i,j > \mid < i,j > \in \lambda \times \lambda \; and \; i < j\}$ and $p_{ij} = p_{cls}(coref|i,j)$ represents the cost of assigning event mentions i and j to the same coreferent cluster, we can formulate the baseline objective function that minimizes equation 1. Further we add constraints (equation 2) over each triplets of mentions to enforce transitivity (Denis et al., 2007; Finkel and Manning, 2008). This guarantees legal clustering by ensuring that $x_{ij} = x_{jk} = 1$ implies x_{ik} = 1.

$$\Theta_B = \sum_{i,j \in \Lambda} -log(p_{ij})x_{ij} - log(1-p_{ij})(\neg x_{ij}) \quad s.t. \; x_{ij} \in \{0,1\} \tag{1}$$

$$\neg x_{ij} + \neg x_{jk} \geq \neg x_{ik} \tag{2}$$

We then add constituent objective functions and constraints to the baseline ILP formulation to induce correlations between coreference chains and topical structures (Θ_T), discourage fragmented chains (Θ_G), encourage semantic associations among chains (Θ_C), model genre-specific distributional patterns (Θ_D) and discourage subevents from having coreferent mentions (Θ_S). They are described in the following subsections.

4.2.1 Modeling the Correlation between Main Event Chains and Topic Transition Sentences

As shown in the example Figure 1, main events are likely to have mentions appear in topic transition sentences. Therefore, We add the following objective function (equation 3) to the basic objective function and add the new constraint 4 in order to encourage coreferent event mentions to occur in topic transition sentences.

$$\Theta_T = \sum_{m,n \in \Omega} -log(s_{mn})w_{mn} - log(1-s_{mn})(\neg w_{mn}) \quad s.t. \; w_{mn} \in \{0,1\}, \; (n-m) \geq |S|/\theta_s \tag{3}$$

$$\sum_{i' \in \xi_m, j' \in \xi_n} x_{i'j'} \geq w_{mn} \tag{4}$$

Specifically, let ω represents the set of sentences in a document and Ω denotes the set of sentence pairs i.e. $\Omega = \{< m,n > \mid < m,n > \in \omega \times \omega$ and $m < n\}$. Then, let $s_{ij} = p_{sim}(simscore|m,n)$, which represents the similarity score between sentences m and n and |S| equals to the number of sentences in a given document. Here, the indicator variable w_{mn} indicates if the two sentences m and n are topic transition sentences. Essentially, when two sentences have a high similarity score (> 0.5) and are not near (with $|S|/\theta_s$or more sentences

[1] te, tor, or, ing, cy, id, ed, en, er, ee, pt, de, on, ion, tion, ation, ction, de, ve, ive, ce, se, ty, al, ar, ge, nd, ize, ze, it, lt

[2] re, in, at, tr, op

apart, in our experiments we set θ_s to 5), this objective function Θ_T tries to set the corresponding indicator variable w_{mn} to 1. Then, we add constraint 4 to encourage coreferent event mentions to occur in topic transition sentences. Note that ξ_m refers to all the event mentions in sentence m, and x_{ij} is the indicator variable which is set to 1 if event mentions defined by index i and j are coreferent. Thus, the above constraint ensures that two topic transition sentences contain at least one coreferent event pair.

Identifying Topic Transition Sentences Using Sentence Similarities: First, we use the unsupervised method based on weighted word embedding average proposed by Arora et al. (2016) to obtain sentence embeddings. We first compute the weighted average of words' embeddings in a sentence, where the weight of a word w is given by $a/(a+p(w))$. Here, p(w) represents the estimated word frequency obtained from English Wikipedia and a is a small constant (1e-5). We then compute the first principal component of averaged word embeddings corresponding to sentences in a document and remove the projection on the first principal component from each averaged word embedding for each sentence.

Then using the resulted averaged word embedding as the sentence embedding, we compute the similarity between two sentences as cosine similarity between their embeddings. We particularly choose this simple unsupervised model to reduce the reliance on any additional corpus for training a new model for calculating sentence similarities. This model was found to perform comparably to supervised RNN-LSTM based models for the semantic textual similarity task.

Constraints for Avoiding Fragmented Partial Event Chains: The above equations (3-4) consider a pair of sentences and encourage two coreferent event mentions to appear in a pair of topic transition sentences. But the local nature of these constraints can lead to fragmented main event chains. Therefore, we further model the distributional characteristics of global event chains and encourage the main event chains to have a large number of coreferential mentions and a long stretch (the number of sentences that are present in between the first and last event mention of a chain), to avoid creating partial chains. Specifically, we add the following objective function (equation 5) and the new constraints (equation 6 and 7):

$$\Theta_G = -\sum_{i,j\in\mu} \gamma_{ij} \tag{5}$$

$$\begin{gathered}\sigma_{ij} = \sum_{k<i} \neg x_{ki} \wedge \sum_{j<l} \neg x_{jl} \wedge x_{ij} \\ \sigma_{ij} \in \{0,1\}\end{gathered} \tag{6}$$

$$\begin{gathered}\Gamma_i = \sum_{k,i\in\Lambda} x_{ki} + \sum_{i,j\in\Lambda} x_{ij} \\ M(1-y_{ij}) \geq (\varphi[j]-\varphi[i]).\sigma_{ij} - \lceil 0.75\,(|S|)\rceil \\ \gamma_{ij} - \Gamma_i - \Gamma_j \geq M.y_{ij} \\ \Gamma_i, \Gamma_j, \gamma_{ij} \in Z;\ \Gamma_i, \Gamma_j, \gamma_{ij} \geq 0;\ y_{ij} \in \{0,1\}\end{gathered} \tag{7}$$

First, we define an indicator variable σ_{ij} by equation 6 [3], corresponding to each event mention pair, that takes value 1 if (1) the event mentions at index i and j are coreferent; (2) the event mention at index i doesn't corefer to any of the mentions preceding it; and (3) mention at index j doesn't corefer to any event mention following it. Essentially, setting σ_{ij} to 1 defines an event chain that starts from the event mention i and ends at the event mention j.

Then with equation 7, variable σ_{ij} is used to identify main event chains as those chains which are extended to at least 75% of the document. When a chain is identified as a global chain, we encourage it to have more coreferential mentions. Here, Γ_i (Γ_j) equals the sum of indicator variables x corresponding to event pairs that include the event mention at index i (j) i.e. the number of mentions that are coreferent to i (j), $\varphi[i]$ ($\varphi[j]$) represents the sentence number of event mention i (j), M is a large positive number and y_{ij} represents a slack variable that takes the value 0 if the event chain represented by σ_{ij} is a global chain. Given $\sigma_{i,j}$ is identified as a global chain, variable γ_{ij} equals the sum of variables Γ_i and Γ_j and is used in the objective function Θ_G (equation 5) to encourage more coreferential mentions.

[3] Equation 6 can be implemented as

$$n_p + n_s \leq \sum_{k<i} x_{ki} + \sum_{j<l} x_{jl} - x_{ij} + (n_p + n_s + 1).\sigma_{ij}$$
$$\sum_{k<i} x_{ki} + \sum_{j<l} x_{jl} - x_{ij} + (n_p + n_s + 1).\sigma_{ij} \geq 0$$

where n_p, n_s represent the number of event mentions preceding event mention i and the number of event mentions following event mention j respectively.

4.2.2 Cross-chain Inferences

As illustrated through Figure 1, semantically related events tend to have their mentions co-occur within the same sentence. So, we define the objective function (equation 8) and constraints (9) to favor a sentence with a mention from one event chain to also contain a mention from another event chain, if the two event chains are known to have event mentions co-occur in several other sentences.

$$\Theta_C = -\sum_{m,n\in\Omega} \Phi_{mn} \tag{8}$$

$$\Phi_{mn} = \sum_{i\in\xi_m, j\in\xi_n} x_{ij}$$
$$|\xi_m| > 1;\ |\xi_n| > 1;\ \Phi_{mn} \in Z;\ \Phi_{mn} \geq 0 \tag{9}$$

To do so, we first define a variable ϕ_{mn} that equals the number of coreferent event pairs in a sentence pair, with each sentence having more than one event mention. We then define Θ_C to minimize the negative sum of ϕ_{mn}. Following the previous notations, ξ_m in the above equation represents the event mentions in sentence m.

4.2.3 Modeling Segment-wise Distributional Patterns

The position of an event mention in a document has a direct influence on event coreference chains. Event mentions that occur in the first few paragraphs are more likely to initiate an event chain. On the other hand, event mentions in later parts of a document may be coreferential with a previously seen event mention but are extremely unlikely to begin a new coreference chain. This distributional association is even stronger in the journalistic style of writing. We model this through a simple objective function and constraints (equation 10).

$$\begin{aligned}\Theta_D = -\sum_{i\in\xi_m, j\in\xi_n} x_{ij} + \sum_{k\in\xi_p, l\in\xi_q} x_{kl}\\ s.t.\ m,n < \lfloor\alpha|S|\rfloor;\ p,q > \lceil\beta|S|\rceil\\ \alpha\in[0,1];\ \beta\in[0,1]\end{aligned} \tag{10}$$

Specifically, for the event pairs that belong to the first α (or the last β) sentences in a document, we add the negative (positive) sum of their indicator variables (x) in objective function Θ_D.

The equation 10 is meant to inhibit coreference links between event mentions that exist within the latter half of document. They do not influence the links within event chains that start early and extend till the later segments of the document. It is also important to understand that position-based features used in entity coreference resolution (Haghighi and Klein, 2007) are usually defined for an entity pair. However, we model the distributional patterns of an event chain in a document.

4.2.4 Restraining Subevents from Being Included in Coreference Chains

Subevents are known to be a major source of false coreference links due to their high surface similarity with their parent events. Therefore, we discourage subevents from being included in coreference chains in our model and modify the global optimization goal by adding a new objective function (equation 11).

$$\Theta_S = \sum_{s\in\mathbb{S}} \Gamma_s \tag{11}$$

where $\mathbb{S}$ represents the set of subevents in a document. We define the objective function Θ_S as the sum of Γ_s, where Γ_s equals the number of mentions that are coreferent to s. Then our goal is to minimize Θ_S and restrict the subevents from being included in coreference chains.

We identify probable subevents by using surface syntactic cues corresponding to identifying a sequence of events in a sentence (Badgett and Huang, 2016). In particular, a sequence of two or more verb event mentions in a conjunction structure are extracted as subevents.

4.3 The full ILP Model and the Parameters

The equations 3-11 model correlations between non-local structures within or across event chains and document topical structures. We perform ILP inference for coreference resolution by optimizing a global objective function(Θ), defined in equation 12, that incorporates prior knowledge by means of hard or soft constraints.

$$\Theta = \kappa_B\Theta_B + \kappa_T\Theta_T + \kappa_G\Theta_G + \kappa_C\Theta_C + \kappa_D\Theta_D + \kappa_S\Theta_S \tag{12}$$

Here, all the κ parameters are floating point constants. For the sake of simplicity, we set κ_B and κ_T to 1.0 and $\kappa_G = \kappa_C$. Then we estimate the parameters $\kappa_G(\kappa_C)$ and κ_D through 2-d grid search in range [0, 5.0] at the interval of 0.5 on a held out training data. We found that the best performance was obtained for $\kappa_C = \kappa_G = 0.5$ and $\kappa_D = 2.5$. Since, Θ_S aims to inhibit subevents from being included in coreference chains, we set a high value for κ_S and found that, indeed, the performance remained same for all the values of κ_S in range [5.0,15.0]. In our final model, we keep κ_S = 10.0. Also, we found that the performance is roughly invariant to the parameters κ_G and κ_C if they are set to values between 0.5 and 2.5.

In our experiments, we process each document to define a distinct ILP problem which is solved using the PuLP library (Mitchell et al., 2011).

5 Evaluation

5.1 Experimental Setup

We trained our ILP system on the KBP 2015 (Ellis et al., 2015) English dataset and evaluated the system on KBP 2016 and KBP 2017 English datasets[4]. All the KBP corpora include documents from both discussion forum[5] and news articles. But as the goal of this study is to leverage discourse level topic structure in a document for improving event coreference resolution performance, we only evaluate the ILP system using regular documents (news articles) in the KBP corpora. Specifically, we train our event extraction system and local coreference resolution classifier on 310 documents from the KBP 2015 corpus that consists of both discussion forum documents and news articles, tune the hyper-parameters corresponding to ILP using 50 news articles[6] from the KBP 2015 corpus and evaluate our system on news articles from the official KBP 2016 and 2017 evaluation corpora[7] respectively. For direct comparisons, the results reported for the baselines, including the previous state-of-the-art model, were based on news articles in the test datasets as well.

We report the event coreference resolution results based on the version 1.8 of the official KBP 2017 scorer. The scorer employs four coreference scoring measures, namely B^3 (Bagga and Baldwin, 1998), $CEAF_e$ (Luo, 2005), MUC (Vilain et al., 1995) and BLANC (Recasens and Hovy, 2011) and the unweighted average of their F1 scores (AVG_{F1}).

5.2 Event Mention Identification

	Lu and Ng (2017)		Ours	
Corpus	Untyped	Typed	Untyped	Typed
KBP 2016	60.13	49.00	60.03	45.45
KBP 2017	-	-	62.89	49.34

Table 2: F1 scores for event mention extraction on the KBP 2016 and 2017 corpus

We use an ensemble of multi-layer feed forward neural network classifiers to identify event mentions (Choubey and Huang, 2017b). All basic classifiers are trained on features derived from the local context of words. The features include the embedding of word lemma, absolute difference between embeddings of word and its lemma, prefix and suffix of word and pos-tag and dependency relation of its context words, modifiers and governor.

We trained 10 classifiers on same feature sets with slightly different neural network architectures and different training parameters including dropout rate, optimizer, learning rate, epochs and network initialization. All the classifiers use relu, tanh and softmax activations in the input, hidden and output layers respectively. We use GloVe vectors (Pennington et al., 2014) for word embeddings and one-hot vectors for pos-tag and dependency relations in each individual model. Pos-tagging, dependency parsing, named entity recognition and entity coreference resolution are performed using Stanford CoreNLP (Manning et al., 2014)

Table 2 shows the event mention identification results. We report the F1 score for event mention identification based on the KBP scorer, which considers a mention correct if its span, type and sub-

[4]The ECB+ (Cybulska and Vossen, 2014) corpus is another commonly used dataset for evaluating event coreference resolution performance. But we determined that this corpus is not appropriate for evaluating our ILP model that explicitly focuses on using discourse level topic structures for event coreference resolution. Particularly, the ECB+ corpus was created to facilitate both cross-document and in-document event coreference resolution research. Thus, the documents in the corpus were grouped based on several common topics and in each document, event mentions and coreference relations were only annotated selectively in sentences that are on a common topic. When the annotated sentences in each document are stitched together, they do not well reveal the original document structure, which makes the ECB+ corpus a bad choice for evaluating our approach. In addition, due to the selective annotation issue, in-document event coreference resolution with the ECB+ corpus is somewhat easier than with the KBP corpus, which partly explained the significant differences of published in-document event coreference resolution results on the two corpora.

[5]Each discussion forum document consists of a series of posts in an online discussion thread, which lacks coherent discourse structures as a regular document. Therefore, only news articles in the KBP corpora are appropriate for evaluating our approach.

[6]KBP 2015 dataset consists of 181 and 179 documents from discussion forum and news articles respectively. We randomly picked 50 documents from news articles for tuning ILP hyper-parameters and remaining 310 documents for training classifiers.

[7]There are 85 and 83 news articles in KBP 2016 and 2017 corpora respectively.

type are the same as the gold mention and assigns a partial score if span partially overlaps with the gold mention. We also report the event mention identification F1 score that only considers mention spans and ignores mention types. We can see that compared to the recent system by (Lu and Ng, 2017) which conducts joint inferences of both event mention detection and event coreference resolution, detecting types for event mentions is a major bottleneck to our event extraction system.

Note that the official KBP 2017 event coreference resolution scorer considers a mention pair coreferent if they strictly match on the event type and subtype, which has been discussed recently to be too conservative (Mitamura et al., 2017). But since improving event mention type detection is not our main goal, we therefore relax the constraints and do not consider event mention type match while evaluating event coreference resolution systems. This allows us to directly interpret the influences of document structures in the event coreference resolution task by overlooking any bias from upstream tasks.

5.3 Baseline Systems

We compare our document-structure guided event coreference resolution model with three baselines. Local classifier performs greedy merging of event mentions using scores predicted by the local pairwise coreference resolution classifier. An event mention is merged to its best matching antecedent event mention if the predicted score between the two event mentions is highest and greater than 0.5. Clustering performs spectral graph clustering (Pedregosa et al., 2011), which represents commonly used clustering algorithms for event coreference resolution. We used the relation between the size of event mentions and the number of coreference clusters in training data for pre-specifying the number of clusters. Its low performance is partially accounted to the difficulty of determining the number of coreference clusters.

Joint learning uses a structured conditional random field model that operates at the document level to jointly model event mention extraction, event coreference resolution and an auxiliary task of event anaphoricity determination. This model has achieved the best event coreference resolution performance to date on the KBP 2016 corpus (Lu and Ng, 2017).

5.4 Our Systems

We gradually augment the ILP baseline with additional objective functions and constraints described in sub-sections 4.2.1, 4.2.2, 4.2.3 and 4.2.4. In all the systems below, we combine objective functions with their corresponding coefficients (as described in sub-section 4.3).

The Basic ILP System formulates event coreference resolution as an ILP optimization task. It uses scores produced by the local pairwise classifier as weights on variables that represent ILP assignments for event coreference relations. (Equations 1, 2).

+Topic structure incorporates the topical structure and the characteristics of main event chains in baseline ILP system (Equations 1-5).

+Cross-chain adds constraints and objective function defined for cross-chain inference to the Topical structure system (Equations 1-8).

+Distribution further adds distributional patterns to the Cross-chain system (Equations 1-10).

+Subevent (Full) optimizes the objective function defined in equation 12 by considering all the constraints defined in 1-11, including constraints for modeling subevent structures.

5.5 Results and Analysis

Table 3 shows performance comparisons of our ILP systems with other event coreference resolution approaches including the recent joint learning approach (Lu and Ng, 2017) which is the best performing model on the KBP 2016 corpus. For both datasets, the full discourse structure augmented model achieved superior performance compared to the local classifier based system. The improvement is observed across all metrics with average F1 gain of 3.1 for KBP 2016 and 2.17 for KBP 2017. Most interestingly, we see over 28% improvement in MUC F1 score which directly evaluates the pairwise coreference link predictions. This implies that the document level structures, indeed, helps in linking more coreferent event mentions, which otherwise are difficult with the local classifier trained on lexical and surface features. Our ILP based system also outperforms the previous best model on the KBP 2016 corpus (Lu and Ng, 2017) consistently using all the evaluation metrics, with an overall improvement of 1.21 based on the average F1 scores.

In Table 3, we also report the F1 scores when we increasingly add each type of structure in the ILP baseline. Among different scoring metrics, all structures positively contributed to the MUC and BLANC scores for KBP 2016 corpus. However, subevent based constraints slightly reduced the F1 scores on KBP 2017 corpus. Based on our preliminary analysis, this can be accounted to the simple method applied for subevent extraction. We only extracted 31 subevents in KBP 2017 corpus compared to 211 in KBP 2016 corpus.

5.6 Discussions on Generalizability

The correlations between event coreference chains and document topic structures are not specific to news articles and widely exist. Several main distributional characteristics of coreferent event mentions, including 1) main event coreference chains often have extended presence and have mentions scattered across segments, and 2) semantically correlated events often have their respective event mentions co-occur in a sentence, directly apply to other sources of texts such as clinical notes. But certain distributional characteristics are genre specific. For instance, while it is common to observe more coreferent event mentions early on in a news article, coreference chains in a clinical note often align well with pre-defined segments like the history of present illness, description of a visit and treatment plan. Thus, the objective functions and constraints defined in equations 1-8 can be directly applied for other domains as well, while other structures like segment-wise distributional patterns may require alteration based on domain-specific knowledge.

6 Conclusions and the Future Work

We have presented an ILP based joint inference system for event coreference resolution that utilizes scores predicted by a pairwise event coreference resolution classifier, and models several aspects of correlations between event coreference chains and document level topic structures, including the correlation between the main event chains and topic transition sentences, interdependencies among event coreference chains, genre-specific coreferent mention distributions and subevents. We have shown that these structures are generalizable by conducting experiments on both the KBP 2016 and KBP 2017 datasets. Our model outperformed the previous state-of-the-art model across all coreference scoring metrics. In the future, we will explore the use of additional discourse structures that correlate highly with event coreference chains. Moreover, we will extend this work to other domains such as biomedical domains.

Abstract

Distant supervision can effectively label data for relation extraction, but suffers from the noise labeling problem. Recent works mainly perform soft bag-level noise reduction strategies to find the relatively better samples in a sentence bag, which is suboptimal compared with making a hard decision of false positive samples in sentence level. In this paper, we introduce an adversarial learning framework, which we named DSGAN, to learn a sentence-level true-positive generator. Inspired by Generative Adversarial Networks, we regard the positive samples generated by the generator as the negative samples to train the discriminator. The optimal generator is obtained until the discrimination ability of the discriminator has the greatest decline. We adopt the generator to filter distant supervision training dataset and redistribute the false positive instances into the negative set, in which way to provide a cleaned dataset for relation classification. The experimental results show that the proposed strategy significantly improves the performance of distant supervision relation extraction comparing to state-of-the-art systems.

1 Introduction

Relation extraction is a crucial task in the field of natural language processing (NLP). It has a wide range of applications including information retrieval, question answering, and knowledge base completion. The goal of relation extraction system is to predict relation between entity pair in a sentence (Zelenko et al., 2003; Bunescu and Mooney, 2005; GuoDong et al., 2005). For example, given a sentence "The $[owl]_{e1}$ held the mouse in its $[claw]_{e2}$.", a relation classifier should figure out the relation **Component-Whole** between entity owl and $claw$.

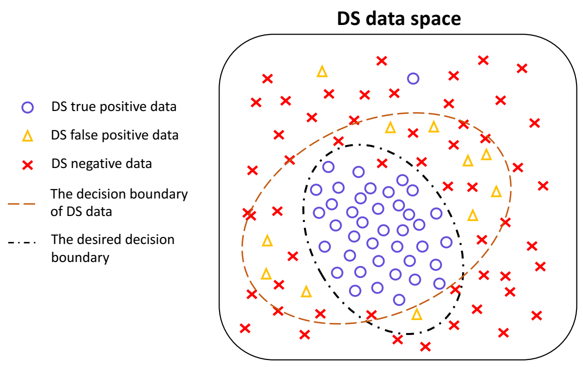

Figure 1: Illustration of the distant supervision training data distribution for one relation type.

With the infinite amount of facts in real world, it is extremely expensive, and almost impossible for human annotators to annotate training dataset to meet the needs of all walks of life. This problem has received increasingly attention. Few-shot learning and Zero-shot Learning (Xian et al., 2017) try to predict the unseen classes with few labeled data or even without labeled data. Differently, distant supervision (Mintz et al., 2009; Hoffmann et al., 2011; Surdeanu et al., 2012) is to efficiently generate relational data from plain text for unseen relations with distant supervision (DS). However, it naturally brings with some defects: the resulted distantly-supervised training samples are often very noisy (shown in Figure 1), which is the main problem of impeding the performance (Roth et al., 2013). Most of the current state-of-the-art methods (Zeng et al., 2015; Lin et al., 2016) make the denoising operation in the sentence bag of entity pair, and integrate this process into the distant supervision relation extraction. Indeed, these methods can filter a substantial number of noise samples; However, they overlook the case that all sentences of an entity pair are false positive, which is also the common phenomenon in distant supervision datasets. Under this consideration, an independent and accurate **sentence-level** noise reduction strategy is the better choice.

In this paper, we design an adversarial learning process (Goodfellow et al., 2014; Radford et al., 2015) to obtain a sentence-level generator that can recognize the true positive samples from the noisy distant supervision dataset without any supervised information. In Figure 1, the existence of false positive samples makes the DS decision boundary suboptimal, therefore hinders the performance of relation extraction. However, in terms of quantity, the true positive samples still occupy most of the proportion; this is the prerequisite of our method. Given the discriminator that possesses the decision boundary of DS dataset (the brown decision boundary in Figure 1), the generator tries to generate true positive samples from DS positive dataset; Then, we assign the generated samples with negative label and the rest samples with positive label to challenge the discriminator. Under this adversarial setting, if the generated sample set includes more true positive samples and more false positive samples are left in the rest set, the classification ability of the discriminator will drop faster. Empirically, we show that our method has brought consistent performance gains in various deep-neural-network-based models, achieving strong performances on the widely used New York Times dataset (Riedel et al., 2010). Our contributions are three-fold:

- We are the first to consider adversarial learning to denoise the distant supervision relation extraction dataset.
- Our method is sentence-level and model-agnostic, so it can be used as a plug-and-play technique for any relation extractors.
- We show that our method can generate a cleaned dataset without any supervised information, in which way to boost the performance of recently proposed neural relation extractors.

In Section 2, we outline some related works on distant supervision relation extraction. Next, we describe our adversarial learning strategy in Section 3. In Section 4, we show the stability analyses of DSGAN and the empirical evaluation results. And finally, we conclude in Section 5.

2 Related Work

To address the above-mentioned data sparsity issue, Mintz et al. (2009) first align unlabeled text corpus with Freebase by distant supervision. However, distant supervision inevitably suffers from the wrong labeling problem. Instead of explicitly removing noisy instances, the early works intend to suppress the noise. Riedel et al. (2010) adopt multi-instance single-label learning in relation extraction; Hoffmann et al. (2011) and Surdeanu et al. (2012) model distant supervision relation extraction as a multi-instance multi-label problem.

Recently, some deep-learning-based models (Zeng et al., 2014; Shen and Huang, 2016) have been proposed to solve relation extraction. Naturally, some works try to alleviate the wrong labeling problem with deep learning technique, and their denoising process is integrated into relation extraction. Zeng et al. (2015) select one most plausible sentence to represent the relation between entity pairs, which inevitably misses some valuable information. Lin et al. (2016) calculate a series of soft attention weights for all sentences of one entity pair and the incorrect sentences can be down-weighted; Base on the same idea, Ji et al. (2017) bring the useful entity information into the calculation of the attention weights. However, compared to these soft attention weight assignment strategies, recognizing the true positive samples from distant supervision dataset before relation extraction is a better choice. Takamatsu et al. (2012) build a noise-filtering strategy based on the linguistic features extracted from many NLP tools, including NER and dependency tree, which inevitably suffers the error propagation problem; while we just utilize word embedding as the input information. In this work, we learn a true-positive identifier (the generator) which is independent of the relation prediction of entity pairs, so it can be directly applied on top of any existing relation extraction classifiers. Then, we redistribute the false positive samples into the negative set, in which way to make full use of the distantly labeled resources.

3 Adversarial Learning for Distant Supervision

In this section, we introduce an adversarial learning pipeline to obtain a robust generator which can automatically discover the true positive samples from the noisy distantly-supervised dataset without any supervised information. The overview of our adversarial learning process is shown in Figure 2. Given a set of distantly-labeled sentences, the generator tries to generate true positive samples from it; But, these generated samples are regarded as negative samples to train the discriminator. Thus, when finishing scanning the DS positive dataset one time, the more true positive samples that the generator discovers, the sharper drop of performance the discriminator obtains. After adversarial training, we hope to obtain a robust generator that is capable of forcing discriminator into maximumly losing its classification ability.

In the following section, we describe the adversarial training pipeline between the generator and the discriminator, including the pre-training strategy, objective functions and gradient calculation. Because the generator involves a discrete sampling step, we introduce a policy gradient method to calculate gradients for the generator.

3.1 Pre-Training Strategy

Both the generator and the discriminator require the pre-training process, which is the common setting for GANs (Cai and Wang, 2017; Wang et al., 2017). With the better initial parameters, the adversarial learning is prone to convergence. As presented in Figure 2, the discriminator is pre-trained with DS positive dataset P (label 1) and DS negative set N^D (label 0). After our adversarial learning process, we desire a strong generator that can, to the maximum extent, collapse the discriminator. Therefore, the more robust generator can be obtained via competing with the more robust discriminator. So we pre-train the discriminator until the accuracy reaches 90% or more. The pre-training of generator is similar to the discriminator; however, for the negative dataset, we use another completely different dataset N^G, which makes sure the robustness of the experiment. Specially, we let the generator overfits the DS positive dataset P. The reason of this setting is that we hope the generator wrongly give high probabilities to all of the noisy DS positive samples at the beginning of the training process. Then, along with our adversarial learning, the generator learns to gradually decrease the probabilities of the false positive samples.

3.2 Generative Adversarial Training for Distant Supervision Relation Extraction

The generator and the discriminator of DSGAN are both modeled by simple CNN, because CNN performs well in understanding sentence (Zeng et al., 2014), and it has less parameters than RNN-based networks. For relation extraction, the input information consists of the sentences and entity pairs; thus, as the common setting (Zeng et al., 2014; Nguyen and Grishman, 2015), we use both word embedding and position embedding to convert input instances into continuous real-valued vectors.

What we desire the generator to do is to accurately recognize true positive samples. Unlike the generator applied in computer vision field (Im et al., 2016) that generates new image from the input noise, our generator just needs to discover true positive samples from the noisy DS positive dataset. Thus, it is to realize the "sampling from a probability distribution" process of the discrete GANs (Figure 2). For a input sentence s_j, we define the probability of being true positive sample by generator as $p_G(s_j)$. Similarly, for discriminator, the probability of being true positive sample is represented as $p_D(s_j)$. We define that one epoch means that one time scanning of the entire DS positive dataset. In order to obtain more feedbacks and make the training process more efficient, we split the DS positive dataset $P = \{s_1, s_2, ..., s_j, ...\}$ into N bags $B = \{B^1, B^2, ...B^N\}$, and the network parameters θ_G, θ_D are updated when finishing processing one bag B_i[1]. Based on the notion of adversarial learning, we define the objectives of the generator and the discriminator as follow, and they are alternatively trained towards their respective objectives.

Generator Suppose that the generator produces a set of probability distribution $\{p_G(s_j)\}_{j=1...|B_i|}$ for a sentence bag B_i. Based on these probabilities, a set of sentence are sampled and we denote this set as T.

$$T = \{s_j\}, s_j \sim p_G(s_j), j = 1, 2, ..., |B_i| \quad (1)$$

[1]The *bag* here has the different definition from the sentence *bag* of an entity pair mentioned in the Section 1.

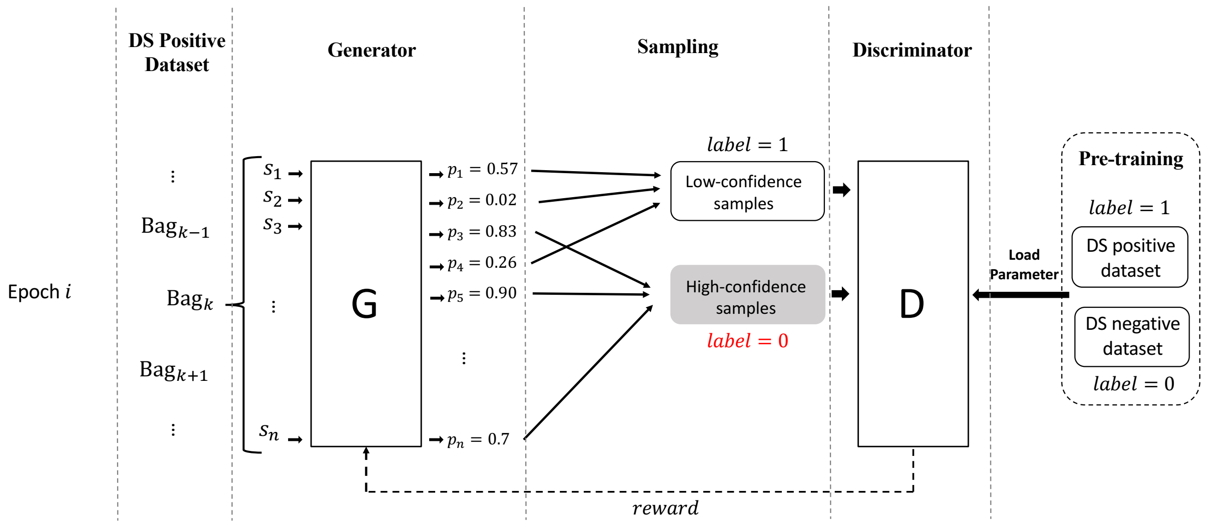

Figure 2: An overview of the DSGAN training pipeline. The generator (denoted by **G**) calculates the probability distribution over a bag of DS positive samples, and then samples according to this probability distribution. The high-confidence samples generated by G are regarded as true positive samples. The discriminator (denoted by **D**) receives these high-confidence samples but regards them as negative samples; conversely, the low-confidence samples are still treated as positive samples. For the generated samples, **G maximizes** the probability of being true positive; on the contrary, **D minimizes** this probability.

This generated dataset T consists of the high-confidence sentences, and is regard as true positive samples by the current generator; however, it will be treated as the negative samples to train the discriminator. In order to challenge the discriminator, the objective of the generator can be formulated as **maximizing** the following probabilities of the generated dataset T:

$$L_G = \sum_{s_j \in T} \log p_D(s_j) \tag{2}$$

Because L_G involves a discrete sampling step, so it cannot be directly optimized by gradient-based algorithm. We adopt a common approach: the policy-gradient-based reinforcement learning. The following section will give the detailed introduction of the setting of reinforcement learning. The parameters of the generator are continually updated until reaching the convergence condition.

Discriminator After the generator has generated the sample subset T , the discriminator treats them as the negative samples; conversely, the rest part $F = B_i - T$ is treated as positive samples. So, the objective of the discriminator can be formulated as **minimizing** the following cross-entropy loss function:

$$\begin{aligned} L_D = -(&\sum_{s_j \in (B_i - T)} \log p_D(s_j) \\ &+ \sum_{s_j \in T} \log(1 - p_D(s_j))) \end{aligned} \tag{3}$$

The update of discriminator is identical to the common binary classification problem. Naturally, it can be simply optimized by any gradient-based algorithm.

What needs to be explained is that, unlike the common setting of discriminator in previous works, our discriminator *loads the same pre-trained parameter set at the beginning of each epoch* as shown in Figure 2. There are two reasons. First, at the end of our adversarial training, what we need is a robust generator rather than a discriminator. Second, our generator is to sample data rather than generate new data from scratch; Therefore, the discriminator is relatively easy to be collapsed. So we design this new adversarial strategy: the robustest generator is yielded when the discriminator has the largest drop of performance in one epoch. In order to create the equal condition, the bag set B for each epoch is identical, including the sequence and the sentences in each

Algorithm 1 The DSGAN algorithm.

```

bag B_i.

Optimizing Generator The objective of the generator is similar to the objective of the one-step reinforcement learning problem: Maximizing the expectation of a given function of samples from a parametrized probability distribution. Therefore, we use a policy gradient strategy to update the generator. Corresponding to the terminology of reinforcement learning, s_j is the *state* and $P_G(s_j)$ is the *policy*. In order to better reflect the quality of the generator, we define the reward r from two angles:

- As the common setting in adversarial learning, for the generated sample set, we hope the confidence of being positive samples by the discriminator becomes higher. Therefore, the first component of our reward is formulated as below:

$$r_1 = \frac{1}{|T|} \sum_{s_j \in T} p_D(s_j) - b_1 \tag{4}$$

  the function of b_1 is to reduce variance during reinforcement learning.

- The second component is from the average prediction probability of N^D,

$$\tilde{p} = \frac{1}{|N^D|} \sum_{s_j \in N^D} p_D(s_j) \tag{5}$$

  N^D participates the pre-training process of the discriminator, but not the adversarial training process. When the classification capacity of discriminator declines, the accuracy of being predicted as negative sample on N^D gradually drops; thus, $\tilde{p}$ increases. In other words, the generator becomes better. Therefore, for epoch k, after processing the bag B_i, reward r_2 is calculated as below,

$$\begin{gathered} r_2 = \eta(\tilde{p}_i^k - b_2) \\ where\ b_2 = \max\{\tilde{p}_i^m\}, m = 1..., k-1 \end{gathered} \tag{6}$$

  b_2 has the same function as b_1.

The gradient of L_G can be formulated as below:

$$\begin{aligned} \nabla_{\theta_D} L_G &= \sum_{s_j \in B_i} \mathbb{E}_{s_j \sim p_G(s_j)} r \nabla_{\theta_G} \log p_G(s_j) \\ &= \frac{1}{|T|} \sum_{s_j \in T} r \nabla_{\theta_G} \log p_G(s_j) \end{aligned} \tag{7}$$

3.3 Cleaning Noisy Dataset with Generator

After our adversarial learning process, we obtain one generator for one relation type; These generators possess the capability of generating true positive samples for the corresponding relation type. Thus, we can adopt the generator to filter the noise samples from distant supervision dataset. Simply and clearly, we utilize the generator as a binary classifier. In order to reach the maximum utilization of data, we develop a strategy: for an entity pair with a set of annotated sentences, if all of these sentences are determined as false negative by our generator, this entity pair will be redistributed into the negative set. Under this strategy, the scale of distant supervision training set keeps unchanged.

4 Experiments

This paper proposes an adversarial learning strategy to detect true positive samples from the noisy distant supervision dataset. Due to the absence of supervised information, we define a generator to heuristically learn to recognize true positive samples through competing with a discriminator. Therefore, our experiments are intended to demonstrate that our DSGAN method possess this capability. To this end, we first briefly introduce the dataset and the evaluation metrics. Empirically, the adversarial learning process, to some extent, has instability; Therefore, we next illustrate the convergence of our adversarial training process. Finally, we demonstrate the efficiency of our generator from two angles: the quality of the generated samples and the performance on the widely-used distant supervision relation extraction task.

4.1 Evaluation and Implementation Details

The Reidel dataset[2] (Riedel et al., 2010) is a commonly-used distant supervision relation extraction dataset. Freebase is a huge knowledge base including billions of triples: the entity pair and the specific relationship between them. Given these triples, the sentences of each entity pair are selected from the New York Times corpus(NYT). Entity mentions of NYT corpus are recognized by the Stanford named entity recognizer (Finkel et al., 2005). There are 52 actual relationships and a special relation NA which indicates there is no relation between head and tail entities. Entity pairs of NA are defined as the entity pairs that appear in the same sentence but are not related according to Freebase.

Due to the absence of the corresponding labeled dataset, there is not a ground-truth test dataset to evaluate the performance of distant supervision relation extraction system. Under this circumstance, the previous work adopt the held-out evaluation to evaluate their systems, which can provide an approximate measure of precision without requiring costly human evaluation. It builds a test set where entity pairs are also extracted from Freebase. Similarly, relation facts that discovered from test articles are automatically compared with those in Freebase. CNN is widely used in relation classification (Santos et al., 2015; Qin et al., 2017), thus the generator and the discriminator are both modeled as a simple CNN with the window size c_w and the kernel size c_k. Word embedding is directly from the released word embedding matrix by Lin et al. (2016)[3]. Position embedding has the same setting with the previous works: the maximum distance of -30 and 30. Some detailed hyperparameter settings are displayed in Table 1.

Hyperparameter	**Value**
CNN Window c_w, kernel size c_k	3, 100
Word embedding d_e, $\|V\|$	50, 114042
Position embedding d_p	5
Learning rate of G, D	1e-5, 1e-4

Table 1: Hyperparameter settings of the generator and the discriminator.

4.2 Training Process of DSGAN

Because adversarial learning is widely regarded as an effective but unstable technique, here we illustrate some property changes during the training process, in which way to indicate the learning trend of our proposed approach. We use 3 relation types as the examples: */business/person/company*, */people/person/place_lived* and */location/neighborhood/neighborhood_of*. Because they are from three major classes (*bussiness*, *people*, *location*) of Reidel dataset and they all have enough distant-supervised instances. The first row in Figure 3 shows the classification ability change of the discriminator during training. The accuracy is calculated from the negative set N^D. At the beginning of adversarial learning, the

[2]http://iesl.cs.umass.edu/riedel/ecml/

[3]https://github.com/thunlp/NRE

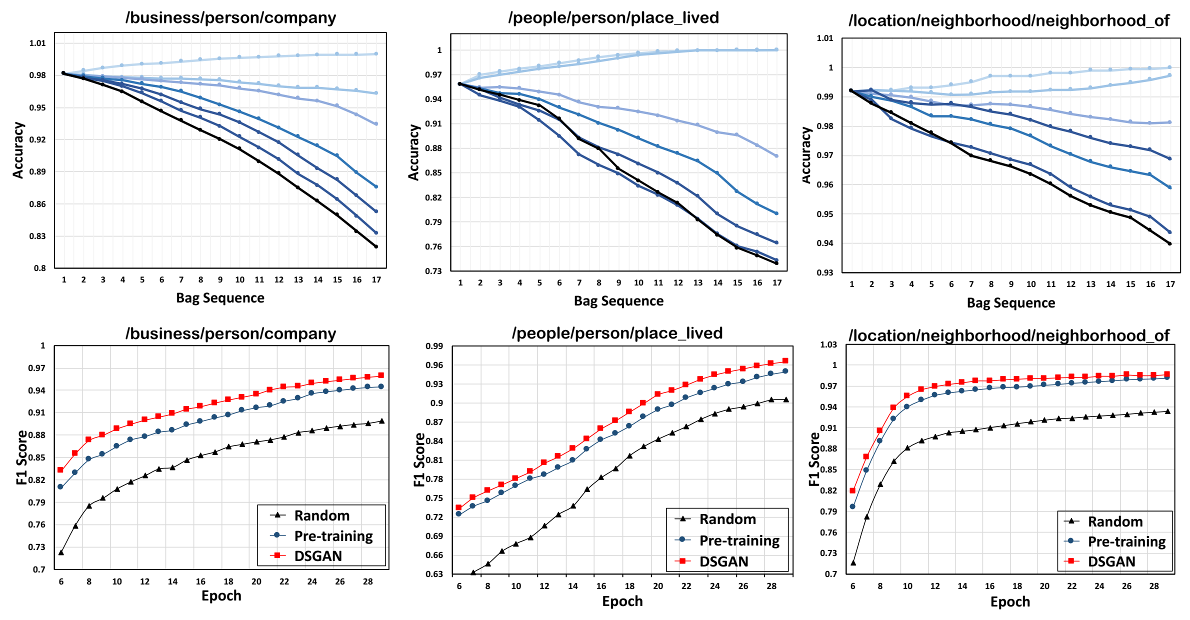

Figure 3: The convergence of the DSGAN training process for 3 relation types and the performance of their corresponding generators. The figures in the first row present the performance change on N^D in some specific epochs during processing the $B = \{B^1, B^2, ...B^N\}$. Each curve stands for one epoch; The color of curves become darker as long as the epoch goes on. Because the discriminator reloads the pre-trained parameters at the beginning of each epoch, all curves start from the same point for each relation type; Along with the adversarial training, the generator gradually collapses the discriminator. The figures in the second row reflect the performance of generators from the view of the difficulty level of training with the positive datasets that are generated by different strategies. Based on the noisy DS positive dataset P, *DSGAN* represents that the cleaned positive dataset is generated by our DSGAN generator; *Random* means that the positive set is randomly selected from P; *Pre-training* denotes that the dataset is selected according to the prediction probability of the pre-trained generator. These three new positive datasets are in the same size.

discriminator performs well on N^D; moreover, N^D is not used during adversarial training. Therefore, the accuracy on N^D is the criterion to reflect the performance of the discriminator. In the early epochs, the generated samples from the generator increases the accuracy, because it has not possessed the ability of challenging the discriminator; however, as the training epoch increases, this accuracy gradually decreases, which means the discriminator becomes weaker. It is because the generator gradually learn to generate more accurate true positive samples in each bag. After the proposed adversarial learning process, the generator is strong enough to collapse the discriminator. Figure 4 gives more intuitive display of the trend of accuracy. Note that there is a critical point of the decline of accuracy for each presented relation types. It is because that the chance we give the generator to challenge the discriminator is just one time scanning of the noisy dataset; this critical point is yielded when the generator has already been robust enough. Thus, we stop the training process when the model reaches this critical point. To sum up, the capability of our generator can steadily increases, which indicates that DSGAN is a robust adversarial learning strategy.

4.3 Quality of Generator

Due to the absence of supervised information, we validate the quality of the generator from another angle. Combining with Figure 1, for one relation type, the true positive samples must have evidently higher relevance (the cluster of purple circles). Therefore, a positive set with more true positive samples is easier to be trained; In other words, the convergence speed is faster and the fitting degree on training set is higher. Based on this , we present the comparison tests in the second row of Figure 3. We build three positive

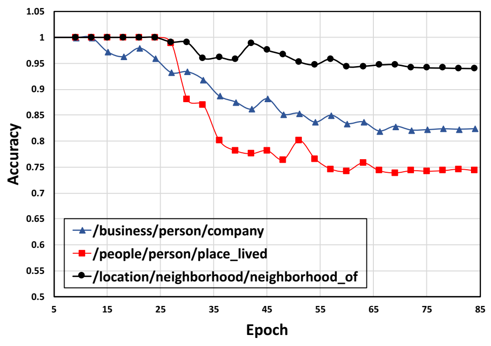

Figure 4: The performance change of the discriminator on N^D during the training process. Each point in the curves records the prediction accuracy on N^D when finishing each epoch. We stop the training process when this accuracy no longer decreases.

datasets from the noisy distant supervision dataset P: the randomly-selected positive set, the positive set base on the pre-trained generator and the positive set base on the DSGAN generator. For the pre-trained generator, the positive set is selected according to the probability of being positive from high to low. These three sets have the same size and are accompanied by the same negative set. Obviously, the positive set from the DSGAN generator yields the best performance, which indicates that our adversarial learning process is able to produce a robust true-positive generator. In addition, the pre-trained generator also has a good performance; however, compared with the DSGAN generator, it cannot provide the boundary between the false positives and the true positives.

4.4 Performance on Distant Supervision Relation Extraction

Based on the proposed adversarial learning process, we obtain a generator that can recognize the true positive samples from the noisy distant supervision dataset. Naturally, the improvement of distant supervision relation extraction can provide a intuitive evaluation of our generator. We adopt the strategy mentioned in Section 3.3 to relocate the dataset. After obtaining this redistributed dataset, we apply it to train the recent state-of-the-art models and observe whether it brings further improvement for these systems. Zeng et al. (2015) and Lin et al. (2016) are both the robust models to solve wrong labeling problem of distant supervision relation extraction. According to the comparison displayed in Figure 5 and Figure 6, all four models (*CNN+ONE*, *CNN+ATT*, *PCNN+ONE* and *PCNN+ATT*) achieve further improvement.

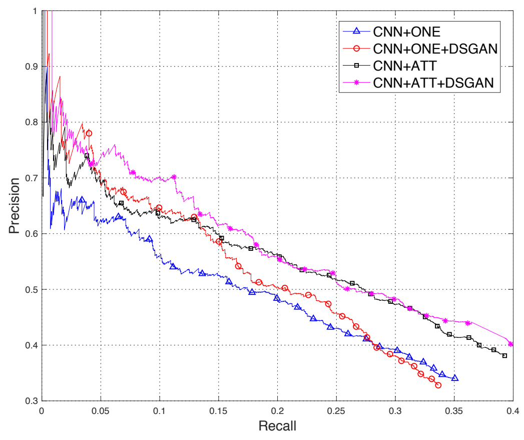

Figure 5: Aggregate PR curves of CNN˙based model.

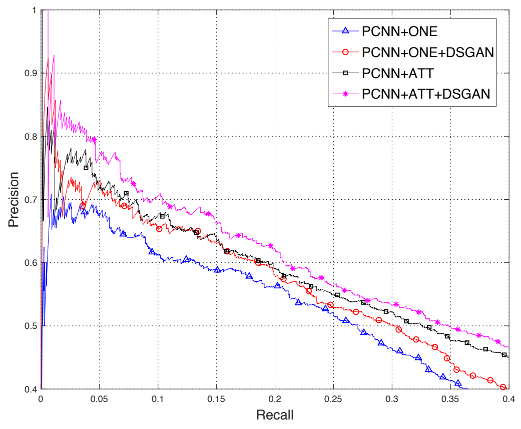

Figure 6: Aggregate PR curves of PCNN˙based model.

Even though Zeng et al. (2015) and Lin et al. (2016) are designed to alleviate the influence of false positive samples, both of them merely focus on the noise filtering in the sentence bag of entity pairs. Zeng et al. (2015) combine at-least-one multi-instance learning with deep neural network to extract only one active sentence to represent the target entity pair; Lin et al. (2016) assign soft attention weights to the representations of all sentences of one entity pair, then employ the weighted sum of these representations to predict the relation between the target entity pair. However, from our manual inspection of Riedel dataset (Riedel et al., 2010), we found another false positive case that all the sentences of a specific entity pair are wrong; but the aforementioned methods overlook

Model	-	+DSGAN	p-value
CNN+ONE	0.177	**0.189**	4.37e-04
CNN+ATT	0.219	**0.226**	8.36e-03
PCNN+ONE	0.206	**0.221**	2.89e-06
PCNN+ATT	0.253	**0.264**	2.34e-03

Table 2: Comparison of AUC values between previous studies and our DSGAN method. The *p-value* stands for the result of t-test evaluation.

this case, while the proposed method can solve this problem. Our DSGAN pipeline is independent of the relation prediction of entity pairs, so we can adopt our generator as the true-positive indicator to filter the noisy distant supervision dataset before relation extraction, which explains the origin of these further improvements in Figure 5 and Figure 6. In order to give more intuitive comparison, in Table 2, we present the AUC value of each PR curve, which reflects the area size under these curves. The larger value of AUC reflects the better performance. Also, as can be seen from the result of t-test evaluation, all the p-values are less than 5e-02, so the improvements are obvious.

5 Conclusion

Distant supervision has become a standard method in relation extraction. However, while it brings the convenience, it also introduces noise in distantly labeled sentences. In this work, we propose the first generative adversarial training method for robust distant supervision relation extraction. More specifically, our framework has two components: a generator that generates true positives, and a discriminator that tries to classify positive and negative data samples. With adversarial training, our goal is to gradually decrease the performance of the discriminator, while the generator improves the performance for predicting true positives when reaching equilibrium. Our approach is model-agnostic, and thus can be applied to any distant supervision model. Empirically, we show that our method can significantly improve the performances of many competitive baselines on the widely used New York Time dataset.

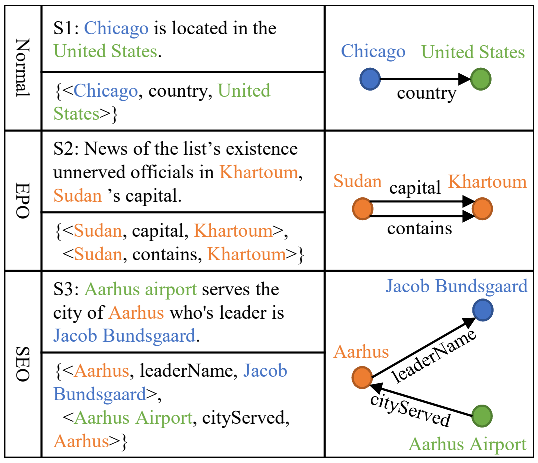
Abstract

The relational facts in sentences are often complicated. Different relational triplets may have overlaps in a sentence. We divided the sentences into three types according to triplet overlap degree, including *Normal*, *EntityPairOverlap* and *SingleEntiyOverlap*. Existing methods mainly focus on *Normal* class and fail to extract relational triplets precisely. In this paper, we propose an end-to-end model based on sequence-to-sequence learning with copy mechanism, which can jointly extract relational facts from sentences of any of these classes. We adopt two different strategies in decoding process: employing only one united decoder or applying multiple separated decoders. We test our models in two public datasets and our model outperform the baseline method significantly.

1 Introduction

Recently, to build large structural knowledge bases (KB), great efforts have been made on extracting relational facts from natural language texts. A relational fact is often represented as a triplet which consists of two entities (an entity pair) and a semantic relation between them, such as $< Chicago, country, UnitedStates >$.

So far, most previous methods mainly focused on the task of relation extraction or classification which identifies the semantic relations between two pre-assigned entities. Although great progresses have been made (Hendrickx et al., 2010; Zeng et al., 2014; Xu et al., 2015a,b), they all assume that the entities are identified beforehand and neglect the extraction of entities. To extract both of entities and relations, early works(Zelenko et al., 2003; Chan and Roth, 2011) adopted a pipeline



Normal	S1: Chicago is located in the United States.	
	{<Chicago, country, United States>}	
EPO	S2: News of the list's existence unnerved officials in Khartoum, Sudan 's capital.	
	{<Sudan, capital, Khartoum>, <Sudan, contains, Khartoum>}	
SEO	S3: Aarhus airport serves the city of Aarhus who's leader is Jacob Bundsgaard.	
	{<Aarhus, leaderName, Jacob Bundsgaard>, <Aarhus Airport, cityServed, Aarhus>}	

Figure 1: Examples of *Normal*, *EntityPairOverlap* (*EPO*) and *SingleEntityOverlap* (*SEO*) classes. The overlapped entities are marked in yellow. S1 belongs to *Normal* class because none of its triplets have overlapped entities; S2 belongs to *EntityPairOverlap* class since the entity pair $< Sudan, Khartoum >$ of it's two triplets are overlapped; And S3 belongs to *SingleEntityOverlap* class because the entity *Aarhus* of it's two triplets are overlapped and these two triplets have no overlapped entity pair.

manner, where they first conduct entity recognition and then predict relations between extracted entities. However, the pipeline framework ignores the relevance of entity identification and relation prediction (Li and Ji, 2014). Recent works attempted to extract entities and relations jointly. Yu and Lam (2010); Li and Ji (2014); Miwa and Sasaki (2014) designed several elaborate features to construct the bridge between these two subtasks. Similar to other natural language processing (NLP) tasks, they need complicated feature engineering and heavily rely on pre-existing NLP tools for feature extraction.

Recently, with the success of deep learning on many NLP tasks, it is also applied on relational facts extraction. Zeng et al. (2014); Xu et al. (2015a,b) employed CNN or RNN on relation classification. Miwa and Bansal (2016); Gupta et al. (2016); Zhang et al. (2017) treated relation extraction task as an end-to-end (end2end) table-filling problem. Zheng et al. (2017) proposed a novel tagging schema and employed a Recurrent Neural Networks (RNN) based sequence labeling model to jointly extract entities and relations.

Nevertheless, the relational facts in sentences are often complicated. Different relational triplets may have overlaps in a sentence. Such phenomenon makes aforementioned methods, whatever deep learning based models and traditional feature engineering based joint models, always fail to extract relational triplets precisely. Generally, according to our observation, we divide the sentences into three types according to triplet overlap degree, including *Normal*, *EntityPairOverlap* (*EPO*) and *SingleEntityOverlap* (*SEO*). As shown in Figure 1, a sentence belongs to *Normal* class if none of its triplets have overlapped entities. A sentence belongs to *EntityPairOverlap* class if some of its triplets have overlapped entity pair. And a sentence belongs to *SingleEntityOverlap* class if some of its triplets have an overlapped entity and these triplets don't have overlapped entity pair. In our knowledge, most previous methods focused on *Normal* type and seldom consider other types. Even the joint models based on neural network (Zheng et al., 2017), it only assigns a single tag to a word, which means one word can only participate in at most one triplet. As a result, the triplet overlap issue is not actually addressed.

To address the aforementioned challenge, we aim to design a model that could extract triplets, including entities and relations, from sentences of *Normal*, *EntityPairOverlap* and *SingleEntityOverlap* classes. To handle the problem of triplet overlap, one entity must be allowed to freely participate in multiple triplets. Different from previous neural methods, we propose an end2end model based on sequence-to-sequence (Seq2Seq) learning with copy mechanism, which can jointly extract relational facts from sentences of any of these classes. Specially, the main component of this model includes two parts: encoder and decoder. The encoder converts a natural language sentence (the source sentence) into a fixed length semantic vector. Then, the decoder reads in this vector and generates triplets directly. To generate a triplet, firstly, the decoder generates the relation. Secondly, by adopting the copy mechanism, the decoder copies the first entity (head entity) from the source sentence. Lastly, the decoder copies the second entity (tail entity) from the source sentence. In this way, multiple triplets can be extracted (In detail, we adopt two different strategies in decoding process: employing only one unified decoder (OneDecoder) to generate all triplets or applying multiple separated decoders (MultiDecoder) and each of them generating one triplet). In our model, one entity is allowed to be copied several times when it needs to participate in different triplets. Therefore, our model could handle the triplet overlap issue and deal with both of *EntityPairOverlap* and *SingleEntityOverlap* sentence types. Moreover, since extracting entities and relations in a single end2end neural network, our model could extract entities and relations jointly.

The main contributions of our work are as follows:

- We propose an end2end neural model based on sequence-to-sequence learning with copy mechanism to extract relational facts from sentences, where the entities and relations could be jointly extracted.
- Our model could consider the relational triplet overlap problem through copy mechanism. In our knowledge, the relational triplet overlap problem has never been addressed before.
- We conduct experiments on two public datasets. Experimental results show that we outperforms the state-of-the-arts with 39.8% and 31.1% improvements respectively.

2 Related Work

By giving a sentence with annotated entities, Hendrickx et al. (2010); Zeng et al. (2014); Xu et al. (2015a,b) treat identifying relations in sentences as a multi-class classification problem. Zeng et al. (2014) among the first to introduce CNN into relation classification. Xu et al. (2015a) and Xu et al. (2015b) learned relation representations from shortest dependency paths through a CNN or RNN. Despite their success, these models ignore the extraction of the entities from sentences and could not truly extract relational facts.

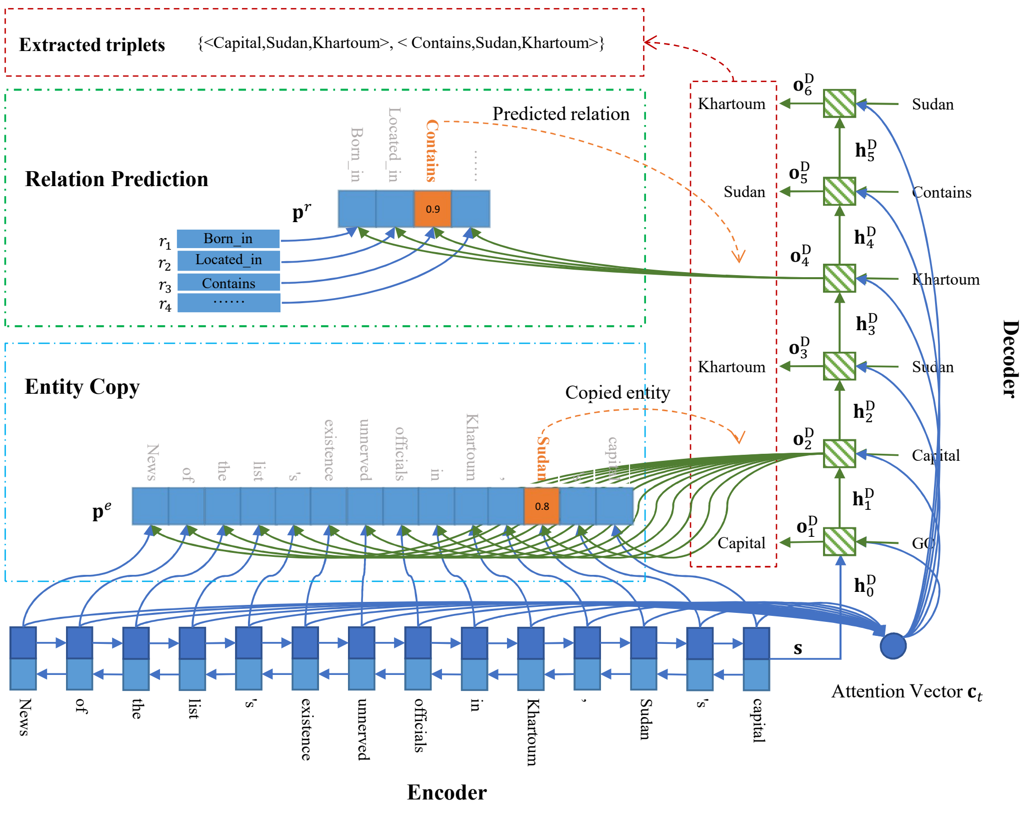


Figure 2: The overall structure of OneDecoder model. A bi-directional RNN is used to encode the source sentence and then a decoder is used to generate triples directly. The relation is predicted and the entity is copied from source sentence.

By giving a sentence without any annotated entities, researchers proposed several methods to extract both entities and relations. Pipeline based methods, like Zelenko et al. (2003) and Chan and Roth (2011), neglected the relevance of entity extraction and relation prediction. To resolve this problem, several joint models have been proposed. Early works (Yu and Lam, 2010; Li and Ji, 2014; Miwa and Sasaki, 2014) need complicated process of feature engineering and heavily depends on NLP tools for feature extraction. Recent models, like Miwa and Bansal (2016); Gupta et al. (2016); Zhang et al. (2017); Zheng et al. (2017), jointly extract the entities and relations based on neural networks. These models are based on tagging framework, which assigns a relational tag to a word or a word pair. Despite their success, none of these models can fully handle the triplet overlap problem mentioned in the first section. The reason is in their hypothesis, that is, a word (or a word pair) can only be assigned with just one relational tag.

This work is based on sequence-to-sequence learning with copy mechanism, which have been adopted for some NLP tasks. Dong and Lapata (2016) presented a method based on an attention-enhanced and encoder-decoder model, which encodes input utterances and generates their logical forms. Gu et al. (2016); He et al. (2017) applied copy mechanism to sentence generation. They copy a segment from the source sequence to the target sequence.

3 Our Model

In this section, we introduce a differentiable neural model based on Seq2Seq learning with copy mechanism, which is able to extract multiple relational facts in an end2end fashion.

Our neural model encodes a variable-length sentence into a fixed-length vector representation first and then decodes this vector into the corresponding relational facts (triplets). When decoding, we can either decode all triplets with one unified decoder or decode every triplet with a separated decoder. We denote them as **OneDecoder** model and **MultiDecoder** model separately.

3.1 OneDecoder Model

The overall structure of OneDecoder model is shown in Figure 2.

3.1.1 Encoder

To encode a sentence $s = [w_1, .., w_n]$, where w_t represent the t-th word and n is the source sentence length, we first turn it into a matrix $X = [x_1, \cdots, x_n]$, where x_t is the embedding of t-th word.

The canonical RNN encoder reads this matrix X sequentially and generates output $\mathbf{o}_t^E$ and hidden state $\mathbf{h}_t^E$ in time step $t (1 \leq t \leq n)$ by

$$\mathbf{o}_t^E, \mathbf{h}_t^E = f(x_t, \mathbf{h}_{t-1}^E) \quad (1)$$

where $f(\cdot)$ represents the encoder function.

Following (Gu et al., 2016), our encoder uses a bi-directional RNN (Chung et al., 2014) to encode the input sentence. The forward and backward RNN obtain output sequence $\{\overrightarrow{\mathbf{o}_1^E}, \cdots, \overrightarrow{\mathbf{o}_n^E}\}$ and $\{\overleftarrow{\mathbf{o}_n^E}, \cdots, \overleftarrow{\mathbf{o}_1^E}\}$, respectively. We then concatenate $\overrightarrow{\mathbf{o}_t^E}$ and $\overleftarrow{\mathbf{o}_{n-t+1}^E}$ to represent the t-th word. We use $\mathbf{O}^E = [\mathbf{o}_1^E, ..., \mathbf{o}_n^E]$, where $\mathbf{o}_t^E = [\overrightarrow{\mathbf{o}_t^E}; \overleftarrow{\mathbf{o}_{n-t+1}^E}]$, to represent the concatenate result. Similarly, the concatenation of forward and backward RNN hidden states are used as the representation of sentence, that is $\mathbf{s} = [\overrightarrow{\mathbf{h}_n^E}; \overleftarrow{\mathbf{h}_n^E}]$

3.1.2 Decoder

The decoder is used to generate triplets directly. Firstly, the decoder generates a relation for the triplet. Secondly, the decoder copies an entity from the source sentence as the first entity of the triplet. Lastly, the decoder copies the second entity from the source sentence. Repeat this process, the decoder could generate multiple triplets. Once all valid triplets are generated, the decoder will generate NA triplets, which means "stopping" and is similar to the "*eos*" symbol in neural sentence generation. Note that, a NA triplet is composed of an NA-relation and an NA-entity pair.

As shown in Figure 3 (a), in time step t $(1 \leq t)$, we calculate the decoder output $\mathbf{o}_t^D$ and hidden state $\mathbf{h}_t^D$ as follows:

$$\mathbf{o}_t^D, \mathbf{h}_t^D = g(\mathbf{u}_t, \mathbf{h}_{t-1}^D) \quad (2)$$

where $g(\cdot)$ is the decoder function and $\mathbf{h}_{t-1}^D$ is the hidden state of time step $t-1$. We initialize $\mathbf{h}_0^D$ with the representation of source sentence $\mathbf{s}$. $\mathbf{u}_t$ is the decoder input in time step t and we calculate it as:

$$\mathbf{u}_t = [\mathbf{v}_t; \mathbf{c}_t] \cdot \mathbf{W}^u \quad (3)$$

where $\mathbf{c}_t$ is the attention vector and $\mathbf{v}_t$ is the embedding of copied entity or predicted relation in time step $t-1$. $\mathbf{W}^u$ is a weight matrix.

Attention Vector. The attention vector $\mathbf{c}_t$ is calculated as follows:

$$\mathbf{c}_t = \sum_{i=1}^{n} \alpha_i \times \mathbf{o}_i^E \quad (4)$$

$$\boldsymbol{\alpha} = softmax(\boldsymbol{\beta}) \quad (5)$$

$$\beta_i = selu([\mathbf{h}_{t-1}^D; \mathbf{o}_i^E] \cdot \mathbf{w}^c) \quad (6)$$

where $\mathbf{o}_i^E$ is the output of encoder in time step i, $\boldsymbol{\alpha} = [\alpha_1, ..., \alpha_n]$ and $\boldsymbol{\beta} = [\beta_1, ..., \beta_n]$ are vectors, $\mathbf{w}^c$ is a weight vector. $selu(\cdot)$ is activation function (Klambauer et al., 2017).

After we get decoder output $\mathbf{o}_t^D$ in time step t $(1 \leq t)$, if $t\%3 = 1$ (that is $t = 1, 4, 7, ...$), we use $\mathbf{o}_t^D$ to predict a relation, which means we are decoding a new triplet. Otherwise, if $t\%3 = 2$ (that is $t = 2, 5, 8, ...$), we use $\mathbf{o}_t^D$ to copy the first entity from the source sentence, and if $t\%3 = 0$ (that is $t = 3, 6, 9, ...$), we copy the second entity.

Predict Relation. Suppose there are m valid relations in total. We use a fully connected layer to calculate the confidence vector $\mathbf{q}^r = [q_1^r, ..., q_m^r]$ of all valid relations:

$$\mathbf{q}^r = selu(\mathbf{o}_t^D \cdot \mathbf{W}^r + \mathbf{b}^r) \quad (7)$$

where $\mathbf{W}^r$ is the weight matrix and $\mathbf{b}^r$ is the bias. When predict the relation, it is possible to predict the NA-relation when the model try to generate NA-triplet. To take this into consideration, we calculate the confidence value of NA-relation as:

$$\mathbf{q}^{NA} = selu(\mathbf{o}_t^D \cdot \mathbf{W}^{NA} + \mathbf{b}^{NA}) \quad (8)$$

where $\mathbf{W}^{NA}$ is the weight matrix and $\mathbf{b}^{NA}$ is the bias. We then concatenate $\mathbf{q}^r$ and $\mathbf{q}^{NA}$ to form the confidence vector of all relations (including the NA-relation) and apply softmax to obtain the probability distribution $\mathbf{p}^r = [p_1^r, ..., p_{m+1}^r]$ as:

$$\mathbf{p}^r = softmax([\mathbf{q}^r; \mathbf{q}^{NA}]) \quad (9)$$

We select the relation with the highest probability as the predict relation and use it's embedding as the next time step input $\mathbf{v}_{t+1}$.

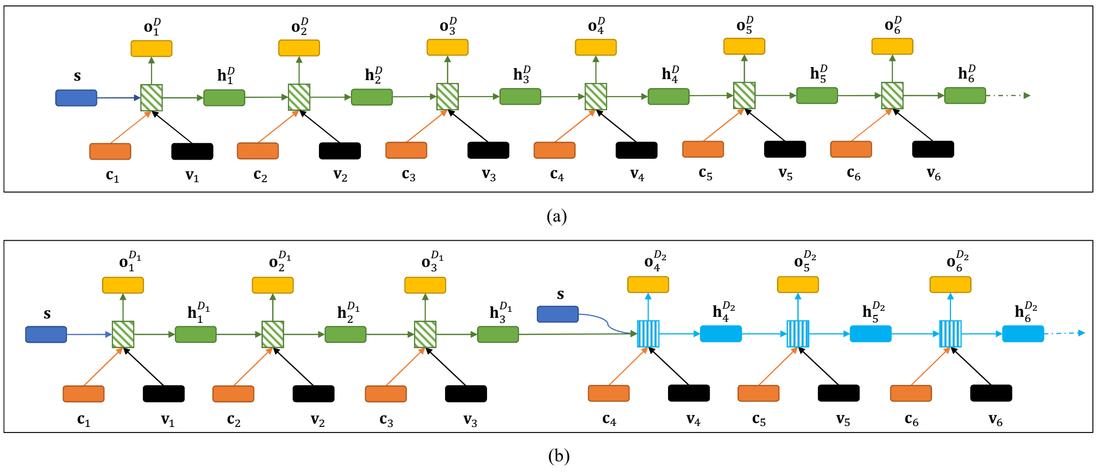

Figure 3: The inputs and outputs of the decoder(s) of OneDecoder model and MultiDecoder model. (a) is the decoder of OneDecoder model. As we can see, only one decoder (the green rectangle with shadows) is used and this encoder is initialized with the sentence representation **s**. (b) is the decoders of MultiDecoder model. There are two decoders (the green rectangle and blue rectangle with shadows). The first decoder is initialized with **s**; Other decoder(s) are initialized with **s** and previous decoder's state.

Copy the First Entity. To copy the first entity, we calculate the confidence vector $\mathbf{q}^e = [q_1^e, ..., q_n^e]$ of all words in source sentence as:

$$q_i^e = selu([\mathbf{o}_t^D; \mathbf{o}_i^E] \cdot \mathbf{w}^e) \tag{10}$$

where $\mathbf{w}^e$ is the weight vector. Similar with the relation prediction, we concatenate $\mathbf{q}^e$ and $\mathbf{q}^{NA}$ to form the confidence vector and apply softmax to obtain the probability distribution $\mathbf{p}^e = [p_1^e, ..., p_{n+1}^e]$:

$$\mathbf{p}^e = softmax([\mathbf{q}^e; \mathbf{q}^{NA}]) \tag{11}$$

Similarly, We select the word with the highest probability as the predict the word and use it's embedding as the next time step input $\mathbf{v}_{t+1}$.

Copy the Second Entity. Copy the second entity is almost the same as copy the first entity. The only difference is when copying the second entity, we cannot copy the first entity again. This is because in a valid triplet, two entities must be different. Suppose the first copied entity is the k-th word in the source sentence, we introduce a mask vector M with n (n is the length of source sentence) elements, where:

$$M_i = \begin{cases} 1, & i \neq k \\ 0, & i = k \end{cases} \tag{12}$$

then we calculate the probability distribution $\mathbf{p}^e$ as:

$$\mathbf{p}^e = softmax([M \otimes \mathbf{q}^e; \mathbf{q}^{NA}]) \tag{13}$$

where $\otimes$ is element-wise multiplication. Just like copy the first entity, We select the word with the highest probability as the predict word and use it's embedding as the next time step input $\mathbf{v}_{t+1}$.

3.2 MultiDecoder Model

MultiDecoder model is an extension of the proposed OneDecoder model. The main difference is when decoding triplets, MultiDecoder model decode triplets with several separated decoders. Figure 3 (b) shows the inputs and outputs of decoders of MultiDecoder model. There are two decoders (the green and blue rectangle with shadows). Decoders work in a sequential order: the first decoder generate the first triplet and then the second decoder generate the second triplet.

Similar with Eq 2, we calculate the hidden state $\mathbf{h}_t^{D_i}$ and output $\mathbf{o}_t^{D_i}$ of i-th ($1 \leq i$) decoder in time step t as follows:

$$\mathbf{o}_t^{D_i}, \mathbf{h}_t^{D_i} = \begin{cases} g^{D_i}(\mathbf{u}_t, \mathbf{h}_{t-1}^{D_i}), & t\%3 = 2, 0 \\ g^{D_i}(\mathbf{u}_t, \hat{\mathbf{h}}_{t-1}^{D_i}), & t\%3 = 1 \end{cases} \tag{14}$$

$g^{D_i}(\cdot)$ is the decoder function of decoder i. $\mathbf{u}_t$ is the decoder input in time step t and we calculated it as Eq 3. $\mathbf{h}_{t-1}^{D_i}$ is the hidden state of i-th decoder in time step $t-1$. $\hat{\mathbf{h}}_{t-1}^{D_i}$ is the initial hidden state of i-th decoder, which is calculated as follows:

$$\hat{\mathbf{h}}_{t-1}^{D_i} = \begin{cases} \mathbf{s}, & i = 1 \\ \frac{1}{2}(\mathbf{s} + \mathbf{h}_{t-1}^{D_{i-1}}), & i > 1 \end{cases} \tag{15}$$

Class	NYT		WebNLG	
	Train	Test	Train	Test
Normal	37013	3266	1596	246
EPO	9782	978	227	26
SEO	14735	1297	3406	457
ALL	56195	5000	5019	703

Table 1: The number of sentences of *Normal*, *EntityPairOverlap* (*EPO*) and *SingleEntityOverlap* (*SEO*) classes. It's worthy noting that a sentence can belongs to both *EPO* class and *SEO* class.

3.3 Training

Both OneDecoder and MultiDecoder models are trained with the negative log-likelihood loss function. Given a batch of data with B sentences $S = \{s_1, ..., s_B\}$ with the target results $Y = \{\mathbf{y}_1, ..., \mathbf{y}_B\}$, where $\mathbf{y}_i = [y_i^1, ..., y_i^T]$ is the target result of s_i, the loss function is defined as follows:

$$\mathbf{L} = \frac{1}{B \times T} \sum_{i=1}^{B} \sum_{t=1}^{T} -log(p(y_i^t | y_i^{<t}, s_i, \theta)) \quad (16)$$

T is the maximum time step of decoder. $p(x|y)$ is the conditional probability of x given y. θ denotes parameters of the entire model.

4 Experiments

4.1 Dataset

To evaluate the performance of our methods, we conduct experiments on two widely used datasets.

The first is New York Times (NYT) dataset, which is produced by distant supervision method (Riedel et al., 2010). This dataset consists of 1.18M sentences sampled from 294k 1987-2007 New York Times news articles. There are 24 valid relations in total. In this paper, we treat this dataset as supervised data as the same as Zheng et al. (2017). We filter the sentences with more than 100 words and the sentences containing no positive triplets, and 66195 sentences are left. We randomly select 5000 sentences from it as the test set, 5000 sentences as the validation set and the rest 56195 sentences are used as train set.

The second is WebNLG dataset (Gardent et al., 2017). It is originally created for Natural Language Generation (NLG) task. This dataset contains 246 valid relations. In this dataset, a instance including a group of triplets and several standard sentences (written by human). Every standard sentence contains all triplets of this instance. We only use the first standard sentence in our experiments and we filter out the instances if all entities of triplets are not found in this standard sentence. The origin WebNLG dataset contains train set and development set. In our experiments, we treat the origin development set as test set and randomly split the origin train set into validation set and train set. After filtering and splitting, the train set contains 5019 instances, the test set contains 703 instances and the validation set contains 500 instances.

The number of sentences of every class in NYT and WebNLG dataset are shown in Table 1. It's worthy noting that a sentence can belongs to both *EntityPairOverlap* class and *SingleEntityOverlap* class.

4.2 Settings

In our experiments, for both dataset, we use LSTM (Hochreiter and Schmidhuber, 1997) as the model cell; The cell unit number is set to 1000; The embedding dimension is set to 100; The batch size is 100 and the learning rate is 0.001; The maximum time steps T is 15, which means we predict at most 5 triplets for each sentence (therefore, there are 5 decoders in MultiDecoder model). These hyperparameters are tuned on the validation set. We use Adam (Kingma and Ba, 2015) to optimize parameters and we stop the training when we find the best result in the validation set.

4.3 Baseline and Evaluation Metrics

We compare our models with NovelTagging model (Zheng et al., 2017), which conduct the best performance on relational facts extraction. We directly run the code released by Zheng et al. (2017) to acquire the results.

Following Zheng et al. (2017), we use the standard micro Precision, Recall and F1 score to evaluate the results. Triplets are regarded as correct when it's relation and entities are both correct. When copying the entity, we only copy the last word of it. A triplet is regarded as NA-triplet when and only when it's relation is NA-relation and it has an NA-entity pair. The predicted NA-triplets will be excluded.

4.4 Results

Table 2 shows the Precision, Recall and F1 value of NovelTagging model (Zheng et al., 2017) and our OneDecoder and MultiDecoder models.

Model	NYT			WebNLG		
	Precision	Recall	F1	Precision	Recall	F1
NovelTagging	**0.624**	0.317	0.420	**0.525**	0.193	0.283
OneDecoder	0.594	0.531	0.560	0.322	0.289	0.305
MultiDecoder	0.610	**0.566**	**0.587**	0.377	**0.364**	**0.371**

Table 2: Results of different models in NYT dataset and WebNLG dataset.

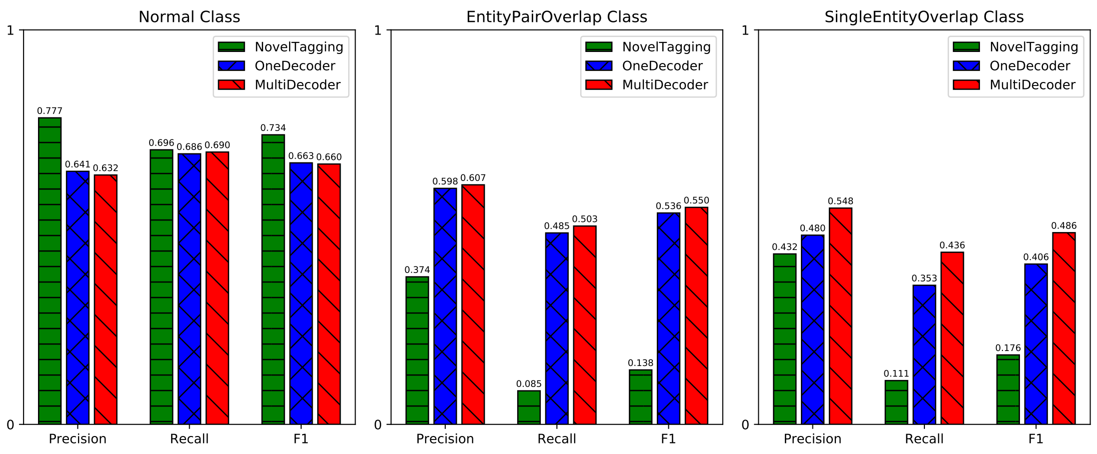

Figure 4: Results of NovelTagging, OneDecoder, and MultiDecoder model in *Normal*, *EntityPairOverlap* and *SingleEntityOverlap* classes in NYT dataset.

As we can see, in NYT dataset, our MultiDecoder model achieves the best F1 score, which is 0.587. There is 39.8% improvement compared with the NovelTagging model, which is 0.420. Besides, our OneDecoder model also outperforms the NovelTagging model. In the WebNLG dataset, MultiDecoder model achieves the highest F1 score (0.371). MultiDecoder and OneDecoder models outperform the NovelTagging model with 31.1% and 7.8% improvements, respectively. These observations verify the effectiveness of our models.

We can also observe that, in both NYT and WebNLG dataset, the NovelTagging model achieves the highest precision value and lowest recall value. By contrast, our models are much more balanced. We think that the reason is in the structure of the proposed models. The NovelTagging method finds triplets through tagging the words. However, they assume that only one tag could be assigned to just one word. As a result, one word can participate at most one triplet. Therefore, the NovelTagging model can only recall a small number of triplets, which harms the recall performance. Different from the NovelTagging model, our models apply copy mechanism to find entities for a triplet, and a word can be copied many times when this word needs to participate in multiple different triplets. Not surprisingly, our models recall more triplets and achieve higher recall value. Further experiments verified this.

4.5 Detailed Results on Different Sentence Types

To verify the ability of our models in handling the overlapping problem, we conduct further experiments on NYT dataset.

Figure 4 shows the results of NovelTagging, OneDecoder and MultiDecoder model in *Normal*, *EntityPairOverlap* and *SingleEntityOverlap* classes. As we can see, our proposed models perform much better than NovelTagging model in *EntityPairOverlap* class and *SingleEntityOverlap* classes. Specifically, our models achieve much higher performance on all metrics. Another observation is that NovelTagging model achieves the best performance in *Normal* class. This is because the NovelTagging model is designed more suitable for *Normal* class. However, our proposed models are more suitable for the triplet overlap issues. Furthermore, it is still difficult for our models to judge how many triplets are needed for the input sentence. As a result, there is a loss in our models for *Normal* class. Nevertheless, the overall perfor-

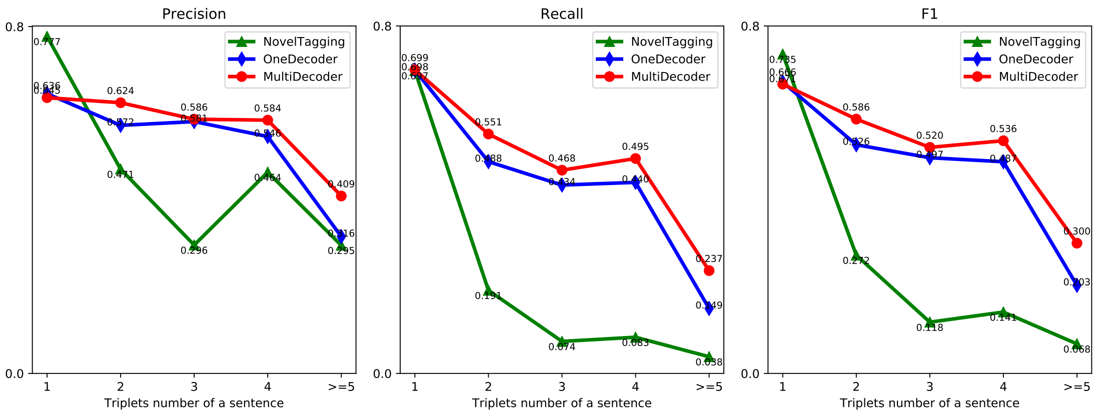

Figure 5: Relation Extraction from sentences that contains different number of triplets. We divide the sentences of NYT test set into 5 subclasses. Each class contains sentences that have 1,2,3,4 or $>=5$ triplets.

Model	NYT	WebNLG
OneDecoder	0.858	0.745
MultiDecoder	0.862	0.821

Table 3: F1 values of entity generation.

Model	NYT	WebNLG
OneDecoder	0.874	0.759
MultiDecoder	0.870	0.751

Table 4: F1 values of relation generation.

mance of the proposed models still outperforms NoverTagging. Moreover, we notice that the whole extracted performance of *EntityPairOverlap* and *SingleEntityOverlap* class is lower than that in *Normal* class. It proves that extracting relational facts from *EntityPairOverlap* and *SingleEntity-Overlap* classes are much more challenging than from *Normal* class.

We also compare the model's ability of extracting relations from sentences that contains different number of triplets. We divide the sentences in NYT test set into 5 subclasses. Each class contains sentences that has 1,2,3,4 or $>=5$ triplets. The results are shown in Figure 5. When extracting relation from sentences that contains 1 triplets, NovelTagging model achieve the best performance. However, when the number of triplets increases, the performance of NovelTagging model decreases significantly. We can also observe the huge decrease of recall value of NovelTagging model. These experimental results demonstrate the ability of our model in handling multiple relation extraction.

4.6 OneDecoder vs. MultiDecoder

As shown in the previous experiments (Table 2, Figure 4 and Figure 5), our MultiDecoder model performs better then OneDecoder model and NovelTagging model. To find out why MultiDecoder model performs better than OneDecoder model, we analyzed their ability of entity generation and relation generation. The experiment results are shown in Table 3 and Table 4. We can observe that on both NYT and WebNLG datasets, these two models have comparable abilities on relation generation. However, MultiDecoder performs better than OneDecoder model when generating entities. We think that it is because MultiDecoder model utilizes different decoder to generate different triplets so that the entity generation results could be more diverse.

Conclusions and Future Work

In this paper, we proposed an end2end neural model based on Seq2Seq learning framework with copy mechanism for relational facts extraction. Our model can jointly extract relation and entity from sentences, especially when triplets in the sentences are overlapped. Moreover, we analyze the different overlap types and adopt two strategies for this issue, including one unified decoder and multiple separated decoders. We conduct experiments on two public datasets to evaluate the effectiveness of our models. The experiment results show that our models outperform the baseline method significantly and our models can extract relational facts from all three classes.

This challenging task is far from being solved. Our future work will concentrate on how to improve the performance further. Another future work is test our model in other NLP tasks like event extraction.

Self-regulation: Employing a Generative Adversarial Network to Improve Event Detection

Abstract

Due to the ability of encoding and mapping semantic information into a high-dimensional latent feature space, neural networks have been successfully used for detecting events to a certain extent. However, such a feature space can be easily contaminated by spurious features inherent in event detection. In this paper, we propose a self-regulated learning approach by utilizing a generative adversarial network to generate spurious features. On the basis, we employ a recurrent network to eliminate the fakes. Detailed experiments on the ACE 2005 and TAC-KBP 2015 corpora show that our proposed method is highly effective and adaptable.

1 Introduction

Event detection aims to locate the event triggers of specified types in text. Normally, triggers are words or nuggets that evoke the events of interest.

Detecting events in an automatic way is challenging, not only because an event can be expressed in different words, but also because a word may express a variety of events in different contexts. In particular, the frequent utilization of common words, ambiguous words and pronouns in event mentions makes them harder to detect:

1) **Generality** – *<u>taken</u> home* <`Transport`>
Ambiguity 1 – *<u>campaign</u> in Iraq* <`Attack`>
Ambiguity 2 – *political <u>campaign</u>* <`Elect`>
Coreference – *Either <u>its</u> bad or good* <`Marry`>

A promising solution to this challenge is through semantic understanding. Recently, neural networks have been widely used in this direction (Nguyen and Grishman, 2016; Ghaeini et al., 2016; Feng et al., 2016; Liu et al., 2017b; Chen et al., 2017), which allows semantics of event mentions (trigger plus context) to be encoded in a high-dimensional latent feature space. This facilitates the learning of deep-level semantics. Besides, the use of neural networks not only strengthens current supervised classification of events but alleviates the complexity of feature engineering.

However, compared to the earlier study (Liao and Grishman, 2010; Hong et al., 2011; Li et al., 2013), in which the features are carefully designed by experts, the neural network based methods suffer more from spurious features. Here, spurious feature is specified as the latent information which looks like the semantically related information to an event, but actually not (Liu et al., 2017a). For example, in the following sample, the semantic information of the word "*prison*" most probably enables spurious features to come into being, because the word often co-occurs with the trigger "*taken*" to evoke an `Arrest-jail` event instead of the ground-truth event `Transport`:

2) *<u>Prison</u> authorities have given the nod for Anwar to be <u>taken</u> home later in the afternoon.*
Trigger: *taken*. **Event Type**: `Transport`

It is certain that spurious features often result from the semantically pseudo-related context, and during training, a neural network may mistakenly and unconsciously preserve the memory to produce the fakes. However, it is difficult to determine which words are pseudo-related in a specific case, and when they will "jump out" to mislead the generation of latent features during testing.

To address the challenge, we suggest to regulate the learning process with a two-channel self-regulated learning strategy. In the self-regulation process, on one hand, a generative adversarial network is trained to produce the most spurious features, while on the other hand, a neural network

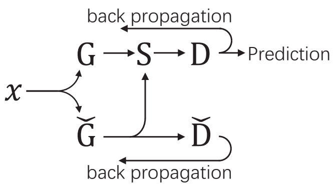

Figure 1: Self-regulated learning scheme

is equipped with a memory suppressor to eliminate the fakes. Detailed experiments on event detection show that our proposed method achieves a substantial performance gain, and is capable of robust domain adaptation.

2 Task Definition

The task of event detection is to determine whether there is one or more event triggers in a sentence. Trigger is defined as a token or nugget that best signals the occurrence of an event. If successfully identified, a trigger is required to be assigned a tag to indicate the event type:

Input: *Either its bad or good*

Output: *its* <trigger>; Marry <type>

We formalize the event detection problem as a multi-class classification problem. Given a sentence, we classify every token of the sentence into one of the predefined event classes (Doddington et al., 2004) or non-trigger class.

3 Self-Regulated Learning (SELF)

SELF is a double-channel model (Figure 1), consisted of a cooperative network (Islam et al., 2003) and a generative adversarial net (GAN) (Goodfellow et al., 2014). A memory suppressor *S* is used to regulate communication between the channels.

3.1 Cooperative Network

In channel 1, the generator G is specified as a multilayer perceptron. It plays a role of a "diligent student". By a differentiable function $G(x, \theta_g)$ with parameters θ_g, the generator learns to produce a vector of latent features o_g that may best characterize the token x, i.e., $o_g = G(x, \theta_g)$.

The discriminator D (called "a lucky professor") is a single-layer perceptron, implemented as a differentiable function $D(o_g, \theta_d)$ with parameters θ_d. Relying on the feature vector o_g, it attempts to accurately predict the probability of the token x triggering an event for all event classes, i.e., $\hat{y} = D(o_g, \theta_d)$, and assigns x to the most probable class c (*iff* $\hat{y}_c > \forall \hat{y}_{\bar{c}}, \bar{c} \neq c$).

Therefore, G and D cooperate with each other during training, developing the parameters θ_g and θ_d with the same goal – to minimize the performance loss $\mathcal{L}(\hat{y}, y)$ in the detection task:

$$\begin{bmatrix}\theta_g \\ \theta_d\end{bmatrix} = argmin\ \mathcal{L}(\hat{y}, y) \qquad (1)$$

where, y denotes the ground-truth probability distribution over event classes, and $\mathcal{L}$ indicates the deviation of the prediction from the ground truth.

3.2 Generative Adversarial Network

In channel 2, the generator $\check{G}$ and discriminator $\check{D}$ have the same perceptual structures as G and D. They also perform learning by differentiable functions, respectively $\check{G}(x, \theta_{\check{g}})$ and $\check{D}(o_{\check{g}}, \theta_{\check{d}})$. A major difference, however, is that they are caught into a cycle of highly adversarial competition.

The generator $\check{G}$ is a "trouble maker". It learns to produce spurious features, and utilizes them to contaminate the feature vector $o_{\check{g}}$ of the token x. Thus $\check{G}$ changes a real sample x into a fake z – sometimes successfully, sometimes less so. Using the fakes, $\check{G}$ repeatedly instigates the discriminator $\check{D}$ to make mistakes. On the other side, $\check{D}$ ("a hapless professor") has to avoid being deceived, and struggles to correctly detect events no matter whether it encounters x or z.

In order to outsmart the adversary, $\check{G}$ develops the parameters $\theta_{\check{g}}$ during training to maximize the performance loss, but on the contrary, $\check{D}$ develops the parameters $\theta_{\check{d}}$ to minimize the loss:

$$\theta_{\check{g}} = argmax\ \mathcal{L}(\hat{y}, y) \qquad (2)$$

$$\theta_{\check{d}} = argmin\ \mathcal{L}(\hat{y}, y) \qquad (3)$$

Numerous studies have confirmed that the two-player minmax game enables both $\check{G}$ and $\check{D}$ to improve their methods (Goodfellow et al., 2014; Liu and Tuzel, 2016; Huang et al., 2017).

3.3 Regulation with Memory Suppressor

Using a memory suppressor, we try to optimize the diligent student G. The goal is to enable G to be as dissimilar as possible to the troublemaker $\check{G}$.

The suppressor uses the output $o_{\check{g}}$ of $\check{G}$ as a reference resource which should be full of spurious features. On the basis, it looks over the output o_g of G, so as to verify whether the features in o_g are different to those in $o_{\check{g}}$. If very different, the suppressor allows G to preserve the memory (viz., θ_g in $G(x, \theta_g)$), otherwise update. In other word, for G, the suppressor forcibly erases the memory which may result in the generation of spurious features. We call this the self-regulation.

Self-regulation is performed for the whole sentence which is fed into G and $\check{G}$. Assume that O_g is a matrix, constituted with a series of feature vectors, i.e., the vectors generated by G for all the tokens in an input sentence ($o_g \in O_g$), while $O_{\check{g}}$ is another feature matrix, generated by $\check{G}$ for the tokens ($o_{\check{g}} \in O_{\check{g}}$). Thus, we utilize the matrix approximation between O_g and $O_{\check{g}}$ for measuring the loss of self-regulation learning $\mathcal{L}_{diff}$. The higher the similarity, the greater the loss. During training, the generator G is required to develop the parameters θ_g to minimize the loss:

$$\theta_g = argmin\ \mathcal{L}_{diff}(o_g, o_{\check{g}}) \tag{4}$$

We present in detail the matrix approximate calculation in section 4.4, where the squared Frobenius norm (Bousmalis et al., 2016) is used.

3.4 Learning to Predict

We incorporate the cooperative network with the GAN, and enhance their learning by joint training.

In the 4-member incorporation, i.e., $\{G, \check{G}, D$ and $\check{D}\}$, the primary beneficiary is the lucky professor D. It can benefit from both the cooperation in channel 1 and the competition in channel 2. The latent features it uses are well-produced by G, and decontaminated by eliminating possible fakes like those made by $\check{G}$. Therefore, in experiments, we choose to output the prediction results of D.

In this paper, we use two recurrent neural networks (RNN) (Sutskever et al., 2014; Chung et al., 2014) of the same structure as the generators. And both the discriminators are implemented as a fully-connected layer followed by a softmax layer.

4 Recurrent Models for SELF

RNN with long short-term memory (abbr., LSTM) is adopted due to the superior performance in a variety of NLP tasks (Liu et al., 2016a; Lin et al., 2017; Liu et al., 2017a). Furthermore, the bidirectional LSTM (Bi-LSTM) architecture (Schuster and Paliwal, 1997; Ghaeini et al., 2016; Feng et al., 2016) is strictly followed. This architecture enables modeling of the semantics of a token with both the preceding and following contexts.

4.1 LSTM based Generator

Given a sentence, we follow Chen et al (2015) to take all the tokens of the whole sentence as the input. Before feeding the tokens into the network, we transform each of them into a real-valued vector $x \in \mathbb{R}^e$. The vector is formed by concatenating a word embedding with an entity type embedding.

- **Word Embedding**: It is a fixed-dimensional real-valued vector which represents the hidden semantic properties of a token (Collobert and Weston, 2008; Turian et al., 2010).

- **Entity Type Embedding**: It is specially used to characterize the entity type associated with a token. The BIO2 tagging scheme (Wang and Manning, 2013; Huang et al., 2015) is employed for assigning a type label to each token in the sentence.

For the input token x_t at the current time step t, the LSTM generates the latent feature vector $o_t \in \mathbb{R}^d$ by the previous memory. Meanwhile, the token is used to update the current memory.

The LSTM possesses a long-term memory unit $c_t \in \mathbb{R}^d$ and short-term $\widetilde{c}_t \in \mathbb{R}^d$. In addition, it is equipped with the input gate i_t, forgetting gate f_t and a hidden state h_t, which are assembled together to promote the use of memory, as well as dynamic memory updating. Similarly, they are defined as a d-dimensional vector in $\mathbb{R}^d$. Thus LSTM works in the following way:

$$\begin{bmatrix} o_t \\ \widetilde{c}_t \\ i_t \\ f_t \end{bmatrix} = \begin{bmatrix} \sigma \\ tanh \\ \sigma \\ \sigma \end{bmatrix} \left(\mathrm{W} \begin{bmatrix} x_t \\ h_{t-1} \end{bmatrix} + \mathrm{b} \right) \tag{5}$$

$$h_t = o_t \odot tanh(c_t) \tag{6}$$

$$c_t = \widetilde{c}_t \odot i_t + c_{t-1} \odot \mathrm{f}_t \tag{7}$$

where $\mathrm{W} \in \mathbb{R}^{4d \times (d+e)}$ and $\mathrm{b} \in \mathbb{R}^{4d}$ are parameters of affine transformation; σ refers to the logistic sigmoid function and $\odot$ denotes element-wise multiplication.

The output functions of both the generators in SELF, i.e., G and $\check{G}$, can be boiled down to the output gate $o_t \in \mathbb{R}^d$ of the LSTM cell:

$$o_t = LSTM(x_t; \theta) \tag{8}$$

where, the function LSTM (·;·) is a shorthand for Eq. (5-7) and θ represents all the parameters of LSTM. For both G and $\check{G}$, θ are initialized with the same values in experiments. But due to the distinct training goals of G and $\check{G}$ (diligence or making-trouble), the values of the parameters in the two cases will change to be very different after training. Therefore, we have $o_{g,t} = LSTM(x_t, \theta_{g,t})$ and $o_{\breve{g},t} = LSTM(x_t, \theta_{\breve{g},t})$.

4.2 Fully-connected Layer for Discrimination

Depending on the feature vectors $o_{g,t}$ and $o_{\breve{g},t}$, the two discriminators D and $\breve{D}$ predict the probability of the token x_t triggering an event for all event classes. As usual, they compute the probability distribution over classes using a fully connected layer followed by a softmax layer:

$$\hat{y} = softmax(\hat{W} \cdot o_t + \hat{b}) \tag{9}$$

where $\breve{y}$ is a C-dimensional vector, in which each dimension indicates the prediction for a class; C is the class number; $\hat{W} \in \mathbb{R}^d$ is the weight which needs to be learned; $\hat{b}$ is a bias term.

It is noteworthy that the discriminator D and $\breve{D}$ don't share the weight and the bias. It means that, for the same token x_t, they may make markedly different predictions: $\hat{y}_{g,t} = softmax(\hat{W}_g \cdot o_{g,t} + \hat{b}_g)$ and $\hat{y}_{\breve{g},t} = softmax(\hat{W}_{\breve{g}} \cdot o_{\breve{g},t} + \hat{b}_{\breve{g}})$.

4.3 Classification Loss

We specify the loss as the cross-entropy between the predicted and ground-truth probability distributions over classes. Given a batch of training data that includes N samples (x_i, y_i), we calculate the losses the discriminators cause as below:

$$\mathcal{L}(\hat{y}_g, y) = -\sum_{i=1}^{N}\sum_{j=1}^{C} y_i^j log(\hat{y}_{g,i}^j) \tag{10}$$

$$\mathcal{L}(\hat{y}_{\breve{g}}, y) = -\sum_{i=1}^{N}\sum_{j=1}^{C} y_i^j log(\hat{y}_{\breve{g},i}^j) \tag{11}$$

where y_i is a C-dimensional one-hot vector. The value of its j-th dimension is set to be 1 only if the token x_i triggers an event of the j-th class, otherwise 0. Both $\hat{y}_{g,i}$ and $\hat{y}_{\breve{g},i}$ are the predicted probability distributions over the C classes for x_i.

4.4 Loss of Self-regulated Learning

Assume that O_g is a matrix, consisted of the feature vectors output by G for all the tokens in a sentence, i.e., $o_{g,t} \in O_g$, and $O_{\breve{g}}$ is that provided by $\breve{G}$, i.e., $o_{\breve{g},t} \in O_{\breve{g}}$, thus we compute the similarity between O_g and $O_{\breve{g}}$ and use it as the measure of self-regulation loss $\mathcal{L}_{diff}(O_g, O_{\breve{g}})$:

$$\mathcal{L}_{diff}(O_g, O_{\breve{g}}) = \|O_g O_{\breve{g}}^{\top}\|_F^2 \tag{12}$$

where, $\|\cdot\|_F^2$ denotes the squared Frobenius norm (Bousmalis et al., 2016), which is used to calculate the similarity between matrices.

It is noteworthy that the feature vectors a generator outputs are required to serve as the rows in the matrix, deployed in a top-down manner and arranged in the order in which they are generated. For example, the feature vector $o_{g,t}$ the generator G outputs at the time t needs to be placed in the t-th row of the matrix O_g.

At the very beginning of the measurement, the similarity between every feature vector in O_g and that in $O_{\breve{G}}$ is first calculated by the matrix-matrix multiplication $O_g O_{\breve{g}}^{\top}$:

$$\begin{pmatrix} o_{g,1}o_{\breve{g},1}^{\top} & \dots & o_{g,1}o_{\breve{g},t}^{\top} & \dots & o_{g,1}o_{\breve{g},l}^{\top} \\ \dots & \dots & \dots & \dots & \dots \\ o_{g,1}o_{\breve{g},t}^{\top} & \dots & o_{g,t}o_{\breve{g},t}^{\top} & \dots & o_{g,t}o_{\breve{g},l}^{\top} \\ \dots & \dots & \dots & \dots & \dots \\ o_{g,1}o_{\breve{g},l}^{\top} & \dots & o_{g,l}o_{\breve{g},t}^{\top} & \dots & o_{g,l}o_{\breve{g},l}^{\top} \end{pmatrix}$$

where, the symbol $\top$ denotes the transpose operation; l is the sentence length which is defined to be uniform for all sentences (l=80), and if it is larger than the real ones, padding is used; $o_{g,i}o_{\breve{g},j}$ denotes the scalar product between the feature vectors $o_{g,i}$ and $o_{\breve{g},j}$.

Let $A_{m\times n}$ be a matrix, the squared Frobenius norm of $A_{m\times n}$ (i.e., $\|A_{m\times n}\|_F^2$) is defined as:

$$\|A_{m\times n}\|_F^2 = \left(\sum_{i=1}^{m}\sum_{j=1}^{n} |a_{ij}|^2\right)^{\frac{1}{2}} \tag{13}$$

where, a_{ij} denotes the j-th element in the i-th row of $A_{m\times n}$. Thus, if we let $A_{m\times n}$ be the matrix produced by the matrix-matrix multiplication $O_g O_{\breve{g}}^{\top}$, the self-regulation loss $\mathcal{L}_{diff}(O_g, O_{\breve{g}})$ can be eventually obtained by:

$$\mathcal{L}_{diff}(O_g, O_{\breve{g}}) = \left(\sum_{i=1}^{l}\sum_{j=1}^{l} |o_{g,i}o_{\breve{g},j}|^2\right)^{\frac{1}{2}} \tag{14}$$

For a batch of training data that includes N' sentences, the global self-regulation loss is specified as the sum of the losses for all the sentences: $\mathcal{L}_{SELF} = \sum_{i=1}^{N'} \mathcal{L}_{diff}(O_g, O_{\breve{g}})$.

4.5 Training

We train the cooperative network in SELF to minimize the classification loss $\mathcal{L}(\hat{y}_g, y)$ and the loss of self-regulated learning $\mathcal{L}_{SELF}$:

$$\theta_g = argmin\ (\mathcal{L}\hat{y}_g, y) \quad (15)$$

$$\theta_d = argmin\ (\mathcal{L}(\hat{y}_g, y) + \lambda \cdot \mathcal{L}_{SELF}) \quad (16)$$

where λ is a hyper-parameter, which is used to harmonize the two losses.

The min-max game is utilized for training the adversarial net in SELF: $\theta_{\breve{g}} = argmax\ \mathcal{L}(\hat{y}_{\breve{g}}, y)$; $\theta_{\breve{d}} = argmin\ \mathcal{L}(\hat{y}_{\breve{g}}, y)$.

All the networks in SELF are trained jointly using the same batches of samples. They are trained via stochastic gradient descent (Nguyen and Grishman, 2015) with shuffled mini-batches and the AdaDelta update rule (Zeiler, 2012). The gradients are computed using back propagation. And regularization is implemented by a dropout (Hinton et al., 2012).

5 Experimentation

5.1 Resource and Experimental Datasets

We test the presented model on the ACE 2005 corpus. The corpus is annotated with single-token event triggers and has 33 predefined event types (Doddington et al., 2004; Ahn, 2006), along with one class "*None*" for the non-trigger tokens, constitutes a 34-class classification problem.

For comparison purpose, we use the corpus in the traditional way, randomly selecting 30 articles in English from different genres as the development set, and utilizing a separate set of 40 English newswire articles as the test set. The remaining 529 English articles are used as the training set.

5.2 Hyperparameter Settings

The word embeddings are initialized with the 300-dimensional real-valued vectors. We follow Chen et al (2015) and Feng et al (2016) to pre-train the embeddings over NYT corpus using Mikolov et al (2013)'s skip-gram tool. The entity type embeddings, as usual (Nguyen et al., 2016; Feng et al., 2016; Liu et al., 2017b), are specified as the 50-dimensional real-valued vectors. They are initialized with the 32-bit floating-point values, which are all randomly sampled from the uniformly distributed values in [-1, 1][1]. We initialize other adjustable parameters of the back-propagation algorithm by randomly sampling in [-0.1, 0.1].

We follow Feng et al (2016) to set the dropout rate as 0.2 and the mini-batch size as 10. We tune the initialized parameters mentioned above, harmonic coefficient λ, learning rate and the L2 norm on the development set. Grid search (Liu et al., 2017a) is used to seek for the optimal parameters. Eventually, we take the coefficient λ of 0.1^{+3}, learning rate of 0.3 and L2 norm of 0.

The source code of SELF[2] to reproduce the experiments has been made publicly available.

5.3 Compared Systems

The state-of-the-art models proposed in the past decade are compared with ours. By taking learning framework as the criterion, we divide the models into three classes:

Minimally supervised approach: is Peng et al (2016)'s **MSEP-EMD**.

Feature based approaches: primarily including Liao and Grishman (2010)'s **Cross-Event** inference model, which is based on the max-entropy classification and embeds the document-level confident information in the feature space; Hong et al (2011)'s **Cross-Entity** inference model, in which existential backgrounds of name entities are employed as the additional discriminant features; and Li et al (2013)'s **Joint** model, a sophisticated predictor frequently ranked among the top 3 in recent TAC-KBP evaluations for nugget and coreference detection (Hong et al., 2014, 2015; Yu et al., 2016). It is based on structured perceptron and combines the local and global features.

Neural network based approaches: including the convolutional neural network (**CNN**) (Nguyen and Grishman, 2015), the non-consecutive *N*-grams based CNN (**NC-CNN**) (Nguyen and Grishman, 2016) and the CNN that is assembled with a dynamic multi-pooling layer (**DM-CNN**) (Chen et al., 2015). Others include Ghaeini et al (2016)'s forward-backward recurrent neural network (**FB-RNN**) which is developed using gated recurrent units (GRU), Nguyen et al (2016)'s bidirectional RNN (**Bi-RNN**) and Feng et al (2016)'s **Hybrid** networks that consist of a Bi-LSTM and a CNN.

Besides, we compare our model with Liu et al (2016b)'s artificial neural networks (**ANNs**), Liu et al (2017b)'s attention-based ANN (**ANN-S2**) and Chen et al (2017)'s **DM-CNN***. The models recently have become popular because, although simple in structure, they are very analytic by learning from richer event examples, such as those in

Method	P (%)	R (%)	F (%)
Joint (Local+Global)	76.9	65.0	70.4
MSEP-EMD	75.6	69.8	72.6
DM-CNN	80.4	67.7	73.5
DM-CNN*	79.7	69.6	74.3
Bi-RNN	68.5	75.7	71.9
Hybrid: Bi-LSTM+CNN	80.8	71.5	75.9
SELF: Bi-LSTM+GAN	**75.3**	**78.8**	**77.0**

Table 1: Trigger identification performance

FrameNet (**FN**) and Wikipeida (**Wiki**).

5.4 Experimental Results

We evaluate our model using Precision (P), Recall (R) and F-score (F). To facilitate the comparison, we review the best performance of the competitors, which has been evaluated using the same metrics, and publicly reported earlier.

Trigger identification

Table 1 shows the trigger identification performance. It can be observed that SELF outperforms other models, with a performance gain of no less than 1.1% F-score.

Frankly, the performance mainly benefits from the higher recall (78.8%). But in fact the relatively comparable precision (75.3%) to the recall reinforces the advantages. By contrast, although most of the compared models achieve much higher precision over SELF, they suffer greatly from the substantial gaps between precision and recall. The advantage is offset by the greater loss of recall.

GAN plays an important role in optimizing Bi-RNN. This is proven by the fact that SELF (Bi-LSTM+GAN) outperforms Nguyen et al (2016)'s Bi-RNN. To be honest, the models use two different kinds of recurrent units. Bi-RNN uses GRUs, but SELF uses the units that possess LSTM. Nevertheless, GRU has been experimentally proven to be comparable in performance to LSTM (Chung et al., 2014; Jozefowicz et al., 2015). This allows a fair comparison between Bi-RNN and SELF.

Event classification

Table 2 shows the performance of multi-class classification. SELF achieves nearly the same F-score as Feng et al (2016)'s Hybrid, and outperforms the others. More importantly, SELF is the only one which obtains a performance higher than 70% for both precision and recall.

Besides, by analyzing the experimental results, we have identified the following regularities:

Methods	P (%)	R (%)	F (%)
MSEP-EMD	70.4	65.0	67.6
Cross-Event	68.8	68.9	68.8
Cross-Entity	72.9	64.3	68.3
Joint (Local+Global)	73.7	62.3	67.5
CNN	71.8	66.4	69.0
DM-CNN	75.6	63.6	69.1
NC-CNN	-	-	71.3
FB-RNN (GRU)	66.8	68.0	67.4
Bi-RNN (GRU)	66.0	73.0	69.3
ANNs (ACE+FN)	77.6	65.2	70.7
DM-CNN*(ACE+Wiki)	75.7	66.0	70.5
ANN-S2 (ACE+FN)	76.8	67.5	71.9
Hybrid: Bi-LSTM+**CNN**	**84.6**	64.9	**73.4**
SELF: Bi-LSTM+**GAN**	71.3	**74.7**	**73.0**

Table 2: Detection performance (trigger identification plus multi-class classification)

- Similar to the pattern classifiers that are based on hand-designed features, the CNN models enable higher precision to be obtained. However the recall is lower.
- The RNN models contribute to achieving a higher recall. However the precision is lower.
- Expansion of the training data set helps to increase the precision.

Let us turn to the structurally more complicated models, SELF and Hybrid.

SELF inherits the merits of the RNN models, classifying the events with higher recall. Besides, by the utilization of GAN, SELF has evolved from the traditional learning strategies, being capable of learning from GAN and getting rid of the mistakenly generated spurious features. So that it outperforms other RNNs, with improvements of no less than 4.5% precision and 1.7% recall.

Hybrid is elaborately established by assembling a RNN with a CNN. It models an event from two perspectives: language generation and pragmatics. The former is deeply learned by using the continuous states hidden in the recurrent units, while the later the convolutional features. Multi-angled cognition enables Hybrid to be more precise. However it is built using a single-channel architecture, concatenating the RNN and the CNN. This results in twofold accumulation of feature information, causing a serious overfitting problem. Therefore, Hybrid is localized to much higher precision but substantially lower recall.

Overfitting results in enlargement of the gap between precision and recall when the task changes to be more difficult. For Hybrid, as illustrated in

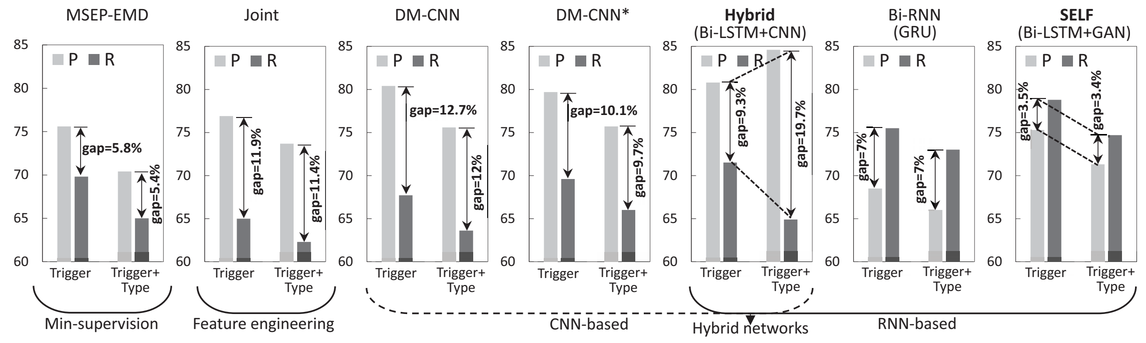

Figure 2: Gaps between precision and recall in the tasks of trigger identification and event classification

Methods	Embedding Types	Training Data
ANNs	word	ACE+FN
ANN-S2	word, NE-type	ACE+FN
DM-CNN*	word, PSN	ACE+Wiki
CNN	word, NE-type, PSN	ACE
NC-CNN	word, NE-type, PSN	ACE
Bi-RNN	word, NE-type, DEP	ACE
Hybrid	word, NE-type, PSN	ACE
DM-CNN	word, PSN	ACE
FB-RNN	word, branch	ACE
SELF	**word, NE-type**	**ACE**

Table 3: Embedding types and training data (DEP: Dependency grammar; PSN: Position)

Figure 2, the gap becomes much wider (from 9% to 19.7%) when the binary classification task (trigger identification) is shifted to multi-class classification (event detection). By contrast, other work shows a nearly constant gap. In particular, SELF yields a minimum gap in each task, which changes negligibly from 3.5% to 3.4%.

It may be added that, similar to DM-CNN and FB-RNN, SELF is cost-effective. Compared to other models (Table 3), it either uses less training data, or is only required to learn two kinds of embeddings, such as that of words and entity types.

5.5 Discussion: Adaptation, Robustness and Effectiveness

Domain adaptation is a key criteria for evaluating the utility of a model in practical application. A model can be thought of being adaptable only if it works well for the unlabeled data in the target domain when trained on the source domain (Blitzer et al., 2006; Plank and Moschitti, 2013).

We perform two groups of domain adaptation experiments, respectively, using the ACE 2005 corpus and the corpus for TAC-KBP 2015 event nugget track (Ellis et al., 2015).

The ACE corpus consists of 6 domains: broadcast conversation (`bc`), broadcast news (`bn`), telephone conversation (`cts`), newswire (`nw`), usenet (`un`) and web blogs (`wl`). Following the common practice of adaptation research on this data (Nguyen and Grishman, 2014, 2015; Plank and Moschitti, 2013), we take the union of `bn` and `nw` as the source domain and `bc`, `cts` and `wl` as three different target domains. We randomly select half of the instances from `bc` to constitute the development set. The TAC-KBP corpus consists of 2 domains: newswire (`NW`) and discussion forum (`DF`). We follow Peng et al (2016) to use one of `NW` and `DF` in alternation as the source domain, while the other the target domain. We randomly select a proportion (20%) of the instances from the target domain to constitute the development set.

We compare with **Joint**, **CNN**, **MSEP-EMD**, **SSED** (Sammons et al., 2015) and **Hybrid**. All the models except Hybrid have been reported for the performance assessment of domain adaptation. In this section, we only cite the best performance they obtained. We reproduce Hybrid by using the source code given by authors. To ensure a fair comparison, we perform 3 runs, in each of which, both Hybrid and SELF were redeveloped on a new development set. What we report herein is the average performance they obtained over the 3 runs.

Adaptation Performance

We show the adaptation performance on the ACE corpus in Tables 4 and that on TAC-KBP in Table 5. It can be observed that SELF outperforms other models in the out-of-domain scenarios.

Besides, when testing is performed on the out-of-domain ACE corpus, the performance degradation of SELF is not much larger than that of CNN and Hybrid. When the out-of-domain TAC-KBP corpus is used, the performance of SELF is impaired much less severely than SSED and Hybrid.

Methods	In-domain (`bn+nw`)			Out-of-domain (`bc`)				Out-of-domain (`cts`)				Out-of-domain (`wl`)			
	P(%)	R(%)	F(%)	P(%)	R(%)	F(%)	Loss	P(%)	R(%)	F(%)	Loss	P(%)	R(%)	F(%)	Loss
Joint	72.9	63.2	67.7	68.8	57.5	62.6	↓5.1	64.5	52.3	57.7	↓10.0	56.4	38.5	45.7	↓22.0
CNN	69.2	67.0	68.0	70.2	65.2	67.6	↓0.4	68.3	58.2	62.8	↓5.2	54.8	42.0	47.5	↓20.5
Hybrid	68.8	54.8	61.0	64.7	58.8	61.6	↑0.6	59.9	50.6	54.9	↓6.1	54.0	37.9	44.5	↓16.5
SELF	**73.8**	**65.7**	**69.5**	**70.0**	**67.2**	**68.9**	**↓0.6**	**68.3**	**60.2**	**63.3**	**↓6.2**	**58.0**	**44.0**	**50.0**	**↓19.5**

Table 4: Experimental results of domain adaptation on the ACE 2005 corpus

Methods	In-domain (`NW`)			Out-of-domain (`DF`)				In-domain (`DF`)			Out-of-domain (`NW`)			
	P(%)	R(%)	F(%)	P(%)	R(%)	F(%)	Loss	P(%)	R(%)	F(%)	P(%)	R(%)	F(%)	Loss
MSEP-EMD	NA	NA	58.5	NA	NA	52.8	↓5.7	NA	NA	57.9	NA	NA	55.1	↓2.8
SSED	NA	NA	63.7	NA	NA	52.3	↓11.4	NA	NA	62.6	NA	NA	54.8	↓7.8
Hybrid	72.6	55.4	62.9	62.3	39.2	48.1	↓14.8	66.0	42.6	51.8	59.1	48.4	53.3	↑1.5
SELF	**67.6**	**60.6**	**63.9**	**69.0**	**58.7**	**56.7**	**↓7.2**	**70.5**	**48.3**	**57.3**	**69.3**	**51.7**	**59.2**	**↑1.9**

Table 5: Experimental results of domain adaptation on the TAC-KBP 2015 corpus (NA: not released)

More importantly, the adaptability of SELF is relatively close to that of MSEP-EMD. Considering that MSEP-EMD is stable due to using minimal supervision (Peng et al., 2016), we suggest the fully trained networks in SELF may not appear to be extremely inflexible, but on the contrary, they should be transferable for use (Ge et al., 2016).

Robustness in Resource-Poor Settings

There are two resource-poor conditions discussed in this section, including lack of in-domain training data and that of out-domain. Hybrid and SELF are brought into the discussion.

For the former (**in-domain**) case, we went over the numbers of samples used for training in the adaptation experiments, which are shown in Table 6. It can be observed that there is a minimum number of training samples (triggers plus tokens) contained in the domain of `NW`. By contrast, the domain of `bn+nw` contains the smallest number of positive samples (triggers) though an overwhelming number of negative samples (general tokens).

Under such conditions, Hybrid performs better in the domain of `NW` compared to `bn+nw` and `DF` in the three in-domain adaptation experiments (see the column labelled as "In-domain `bn+nw`" in Table 4 as well as "In-domain `NW`" and "In-domain `DF`" in Table 5). It illustrates that Hybrid unnecessarily relies on a tremendous number of training samples to ensure the robustness. But SELF does. It needs far more negative samples than Hybrid because of the following reasons:

- It relies on the use of spurious features to implement self-regulation during training.

Domain	**Training**		**Testing**	
	trigger	token	trigger	token
`bn+nw`	1,721	74,179	343	16,336
`NW`	2,098	31,014	2,813	55,459
`DF`	4,106	10,9275	1,773	43,877

Table 6: Data distribution in the source domains

- For a positive sample, the concerned spurious features (if have) most probably hide in some negative samples.
- It's impossible to be aware of such negative samples. Therefore, taking into consideration as many negative samples as possible may help to increase the probability that the spurious features will be discovered.

This is demonstrated by the fact that SELF obtains better performance in the domain of `bn+nw` but not `NW` (see the column labeled as "Training" in Table 6 and "In-domain" in Table 4 and 5). It may be added that SELF performs worse in `DF` although there are more negative samples used for training (see Table 6). Taking a glance at the number of positive samples, one may find that it is approximately 2.4 times more than that in `bn+nw`. But the number of negative samples in `DF` is only 1.5 times more than that in `bn+nw`. It implies that, if there are more positive samples used for training, SELF needs to consume proportionally more negative samples for self-regulation. Otherwise, the performance will degrade.

For the **out-domain** case, ideally, both Hybrid and SELF encounter the problem that there is lack of target domain data available for training. In this case, SELF displays less performance degradation

Event mentions	Type
*And **<u>it</u>** still does*	Die
*We had no part in **<u>it</u>***	Arrest-Jail
*Nobody questions if **<u>this</u>** is right or ...*	Attack
*And **<u>that</u>** is what ha- what is happening*	End-Position
*Oh, yeah, **<u>it</u>** wasn't perfect*	Marry

Table 7: Examples of pronouns that act as a trigger

(7.2%) than Hybrid (14.8%) when `NW` is used for training. Considering that `NW` contains the minimum number of samples, we would like to believe that SELF is more robust than Hybrid for cross-domain event detection in a resource-poor setting.

Recall and Missing

SELF is able to accurately recall the events whose occurrence is triggered by ambiguous words, such as "*fine*", "*charge*", "*campaign*", etc. These ambiguous words easily causes confusion. For example, "*campaign*" may trigger an `Elect` event or `Attack` in the ACE corpus.

More importantly, SELF fishes out the common words which serve as a trigger, although they are not closely related to any kind of events, such as "*take*", "*try*", "*acquire*", "*become*", "*create*", etc. In general, it is very difficult to accurately recall such triggers because their meanings are not concrete enough, and the contexts may be full of kinds of noises (see example 2 in pg. 1). We observe that Bi-RNN and Hybrid seldom pick them up.

However, SELF fails to recall the pronouns that act as a trigger. This is because they occur in spoken language much more frequently than they occur in written language. The lack of narrative content makes it difficult to learn the relationship between the pronouns and the events. Some real examples collected from ACE are shown in Table 7.

6 Related Work

Event detection is an important subtask of event extraction (Doddington et al., 2004; Ahn, 2006).

The research can be traced back to the pattern based approach (Grishman et al., 2005). Encouraged by the high accuracy and the benefit of easy-to-use, researchers have made great efforts to extract discriminative patterns. Cao et al (2015a; 2015b) use dependency regularization and active leaning to generalize and expand the patterns.

In the earlier study, another trend is to explore the features that best characterize each event class, so as to facilitate supervised classification. A variety of strategies have emerged for converting classification clues into feature vectors (Ahn, 2006; Patwardhan and Riloff, 2009; Liao and Grishman, 2010; Hong et al., 2011; Li et al., 2013, 2014; Wei et al., 2017). Benefiting from the general modeling framework, the methods enable the fusion of multiple features, and more importantly, they are flexible to use by feature selection. But considerable expertise is required for feature engineering.

Recently, the use of neural networks for event detection has become a promising line of research. The closely related work has been presented in section 5.3. The primary advantages of neural networks have been demonstrated in the work, such as performance enhancement, self-learning capability and robustness.

The generative adversarial network (Goodfellow et al., 2014) has emerged as an increasingly popular approach for text processing (Zhang et al., 2016; Lamb et al., 2016; Yu et al., 2017). Liu et al (2017a) use the adversarial multi-task learning for text classification. We follow the work to create spurious features, but use them to regulate the self-learning process in a single-task situation.

7 Conclusion

We use a self-regulated learning approach to improve event detection. In the learning process, the adversarial and cooperative models are utilized in decontaminating the latent feature space.

In this study, the performance of the discriminator in the adversarial network is left to be evaluated. Most probably, the discriminator also performs well because it is gradually enhanced by fierce competition. Considering this possibility, we suggest to drive the two discriminators in our self-regulation framework to cooperate with each other. Besides, the global features extracted in Li et al (2013)'s work are potentially useful for detecting the event instances referred by pronouns, although involve noises. Therefore, in the future, we will encode the global information by neural networks and use the self-regulation strategy to reduce the negative influence of noises.

Acknowledgments

We thank Xiaocheng Feng and his colleagues who shared the source code of Hybrid with us.

Abstract

We propose a context-aware neural network model for temporal information extraction, with a uniform architecture for event-event, event-timex and timex-timex pairs. A Global Context Layer (GCL), inspired by the Neural Turing Machine (NTM), stores processed temporal relations in the narrative order, and retrieves them for use when the relevant entities are encountered. Relations are then classified in this larger context. The GCL model uses long-term memory and attention mechanisms to resolve long-distance dependencies that regular RNNs cannot recognize. GCL does not use postprocessing to resolve timegraph conflicts, outperforming previous approaches that do so. To our knowledge, GCL is also the first model to use an NTM-like architecture to incorporate the information about global context into discourse-scale processing of natural text.

1 Introduction

Extracting information about the order and timing of events from text is crucial to any system that attempts an in-depth natural language understanding, whether related to question answering, temporal inference, or other related tasks. Earlier temporal information extraction (TemporalIE) systems tended to rely on traditional statistical learning with feature-engineered task-specific models, typically used in succession (Yoshikawa et al., 2009; Ling and Weld, 2010; Sun et al., 2013; Chambers et al., 2014; Mirza and Minard, 2015).

Recently, there have been some attempts to extract temporal relations with neural network models, particularly with recurrent neural networks (RNN) models (Meng et al., 2017; Cheng and Miyao, 2017; Tourille et al., 2017) and convolutional neural networks (CNN) (Lin et al., 2017). These models predominantly use token embeddings as input, avoiding handcrafted features for each task. Typically, neural network models outperform traditional statistical models. Some studies also try to combine neural network models with rule-based information retrieval methods (Fries, 2016). These systems require different models for different pair types, so several models must be combined to fully process text.

A common disadvantage of all these models is that they build relations from *isolated* pairs of entities (events or temporal expressions). This context-blind, pairwise classification often generates conflicts in the resulting timegraph. Common ways of ameliorating the conflicts is to apply some *ad hoc* constraints to account for basic properties of relations (e.g. transitivity), often without considering the content of the text *per se*. For example, Ling and Weld (2010) designed transitivity formulae, used with local features. Sun (2014) proposed a strategy that "prefers the edges that can be inferred by other edges in the graph and remove the ones that are least so". Another approach is to use the results from separate classifiers to rank results according to their general confidence (Mani et al., 2007; Chambers et al., 2014). High-ranking results overwrite low-ranking ones. Meng et al. (2017) used a greedy pruning algorithm to remove weak edges from the timegraph until it is coherent.

When humans read text, we certainly do not follow the procedure of interpreting interpret relations only locally first, and later come up with a compromise solution that involves all the entities. Instead, if local information is insufficient, we consider the relevant information from the wider context, and resolve the ambiguity as soon as possible. The resolved relations are stored in our memory as "context" for further processing. If the later evidence suggests our early interpretation was wrong, we can correct it.

This paper proposes a model to simulate such mechanisms. Our model introduces a Global Context Layer (GCL), inspired by the Neural Turing Machine (NTM) architecture (Graves et al., 2014), to store processed relations in narrative order, and retrieve them for use when related entities are encountered. The stored information can also be updated if necessary, allowing for self-correction.

This paper's contributions are as follows. To our knowledge, this is the first attempt to use neural network models with updateable external memory to incorporate global context information for discourse-level processing of natural text in general and for temporal relation extraction in particular. It gives a uniform treatment of *all* pairs of temporally relevant entities. We obtain state-of-the-art results on TimeBank-Dense, which is a standard benchmark for TemporalIE.

2 Dataset

We train and evaluate our model on TimeBank-Dense[1] (Chambers et al., 2014). There are 6 classes of relations: SIMULTANEOUS, BEFORE, AFTER, IS_INCLUDED, INCLUDES, and VAGUE TimeBank-Dense annotation aims to approximate a complete temporal relation graph by including all intra-sentential relations, all relations between adjacent sentences, and all relations with document creation time. TimeBank-Dense is one of the standard benchmarks for intrinsic evalution of TemporalIE systems. We follow the experimental setup in Chambers et al. (2014), which splits the corpus into training/validation/test sets of 22, 5, and 9 documents, respectively. Previous publications often use the micro-averaged F1 score, which is equivalent to accuracy in this case. We also rely on the micro-averaged F1 score for model selection and evaluation.

Following Meng et al. (2017), we augment the data by flipping all pairs, except for relations involving document creation time (DCT). In other words, if a pair (e_i, e_j) exists, we add (e_j, e_i) to the dataset with the opposite label (e.g. BEFORE becomes AFTER). The augmentation applies to the validation and test sets also. In the final evaluation, a double-checking technique picks one result from the two-way classification, based on output scores. The dataset is heavily imbalanced. The training set has as much as 44.1% VAGUE labels, whereas only 1.8% labels are SIMULTANEOUS. We did not do any up-sampling or down-sampling.

3 System

Our system has two main components. The first one is a pairwise relation classifier, and the other is the Global Context Layer (GCL). The pairwise relation classifier follows the architecture designed by Meng et al. (2017), which used the dependency paths to the least common ancestor (LCA) from each entity as input. We train the first component first, and then assemble them in a combined neural network to continue training. Fig. 1 gives an overview of the system.

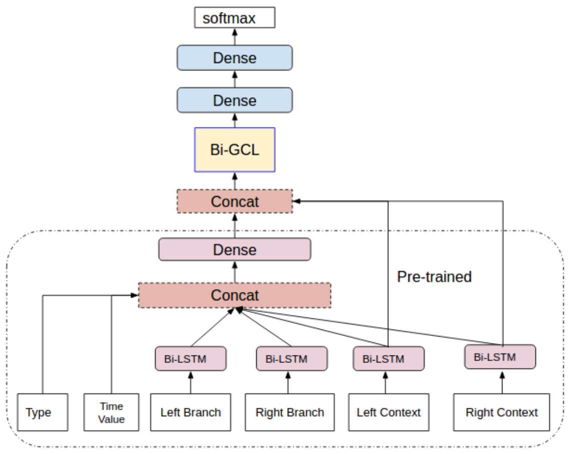

Figure 1: System overview. Originally, the pre-trained system has one more dense layer and an output layer, but they are truncated before combination. The max pooling layers on top of each Bi-LSTM layers are omitted here.

3.1 Global Context Layer

The Global Context Layer (GCL) we propose is inspired by the Neural Turing Machine (NTM) architecture, which is an extension of a recurrent neural network with external memory and an attention mechanism for reading and writing to that memory. NTM has been shown to perform basic tasks such as copying, sorting, and associative recall (Graves et al., 2014). The external memory not only enables a large (theoretically infinite) capacity for information storage, but also allows flexible access based on attention mechanisms.

Essentially, GCL is a specialized form of NTM, which eliminates some parameters to facilitate training, and specializes some functions to impose restrictions. While not as powerful as the canonical NTM, it is more suitable for the task of retaining and updating global context information.

3.1.1 Motivation

Vanilla RNNs struggle with capturing long-distance dependencies. Gated RNNs such as LSTM have trainable gates to address the "vanishing and exploding gradient" problem (Hochreiter and Schmidhuber, 1997). At each time step, it chooses what to memorize and forget, so patterns over arbitrary time intervals can be recognized. However, the memory in LSTM is still *short-term*. No matter how long the cell states keep certain information, once it is forgotten, it gets lost forever. Such a mechanism suffices for modeling contiguous sequences. For example, sentences are naturally fit units for such models, since a sentence starts only after the preceding sentence is finished, and LSTM may be an adequate tool to process sentences. However, when the sequences are not contiguous, as in temporal and other discourse-scale relations, LSTM models do not have the capability to look for input pieces across sequences.

When humans read text, discourse-level information is often distributed across the full scope of the text. To fully understand an article, we must be able to organize the processed information across sentences and paragraphs. In particular, to interpret temporal relations between entities in a sentence, sometimes we also look at relations with other entities elsewhere in the text. Such entities or relations form no regular sequences, and only a system with long-term memory as well as attention mechanisms can process them. An NTM-like architecture has an external memory with attention mechanisms, so it is an ideal candidate for such tasks. Furthermore, unlike the models that use attention over inputs (Vinyals et al., 2015; Kumar et al., 2016), NTM-like models are capable of updating previously stored representations. We describe below the GCL architecture that we use to store and update the global context information.

3.1.2 Reading

The input to the GCL layer is a concatenation of three layers from the pairwise neural network. Two of these are the entity context representation layers, encoded by the two LSTM branches. The other is the penultimate hidden layer before the output layer, which encodes the relation. We can write them as $[\mathbf{e_1}, \mathbf{e_2}, \mathbf{x}]$. The context representations are used as "keys" to uniquely identify the

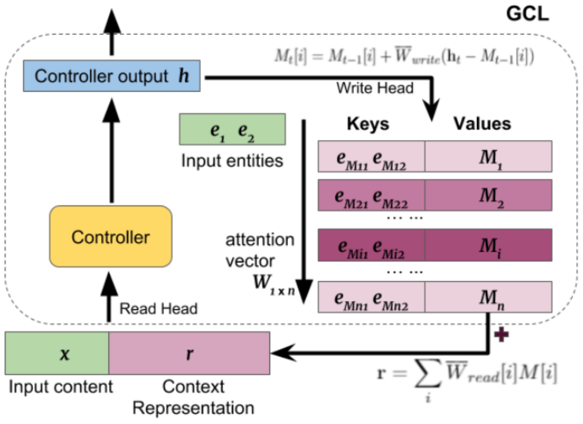

Figure 2: GCL computing attention weights. Input entity representations are compared to the Key section of GCL memory. Slots with the same or similar entities get more attention.

entities. Note that we use flat context embeddings, rather than dependency path embeddings, because dependency paths tend to be short and will also vary for the same entity, depending on the other entity in the pair. As such, they do not provide a unique way to represent an entity.

The original design of NTM has a complex addressing mechanism for reading, which also makes it difficult to train. An important difference in GCL is that we separate the "key" component from the "content" component of memory. Each memory slot $S[i]$ consists of $[K[i]; M[i]]$, where S is the whole memory with n slots, $i \leq n$ is the index, K is the key and M is the content. Addressing is only performed on the key component. The key component stores the representation of two entities, provided by the layers encoding the flat entity context.

$$K[i] = \mathbf{e_{M1}}[i] \oplus \mathbf{e_{M2}}[i] \tag{1}$$

Here $\oplus$ is the concatenation operator. In the GCL model, the read head computes a reading weight $W_{n\times 1}$ from the input entity representations $\mathbf{e_1}$, $\mathbf{e_2}$ and the entity representations $\mathbf{e_{M1}}$, $\mathbf{e_{M2}}$ in memory (i.e., the keys in each memory slot). The first step is to compute the distance between current input and the memory columns, as shown in Eq. 2. $D[i]$ is the Euclidean distance between the input key and the memory key of slot $M[i]$. $D'[i]$ is computed after flipping the two entities. We do so because the order of entities in a pair should not affect their relevance.

$$\begin{aligned} D[i] &= \frac{1}{Z}||\mathbf{e_1} \oplus \mathbf{e_2} - \mathbf{e_{M1}}[i] \oplus \mathbf{e_{M2}}[i]||_2^2 \\ D'[i] &= \frac{1}{Z'}||\mathbf{e_2} \oplus \mathbf{e_1} - \mathbf{e_{M1}}[i] \oplus \mathbf{e_{M2}}[i]||_2^2 \end{aligned} \tag{2}$$

where $Z = \sum_i D[i]$ is the normalization factor, and so is Z' for the flipped case. The reading weight is then calculated as in Eq. 3, where $\mathbf{1}_{n\times 1}$ is a vector of all 1's.

$$W[i] = \max(\mathrm{softmax}(\mathbf{1} - \mathbf{D})[i], \\ \mathrm{softmax}(\mathbf{1} - \mathbf{D}')[i]) \tag{3}$$

Every element of W represents the relevance of the corresponding memory slot (see Fig. 2). Often it is still too blurred and needs to be further sharpened as in Eq. 4. Here β is a positive number. W^β is a point-wise exponential function by power of β. A large β allows "winner takes all", so only the most relevant memory slots are read.

$$\overline{W}_{read} = \mathrm{softmax}(W^\beta) \tag{4}$$

Parameter β could be a constant, or could be trainable. Our model computes it from the current input $\mathbf{x}_t$ and the previous output h_{t-1}, and thus it varies in each time step. W_{sharp} and b_{sharp} are trainable weights and bias, c_β is a constant, and $ReLU$ is the rectified linear function.

$$\beta_t = ReLU(W_{sharp}[\mathbf{x}_t, \mathbf{h}_{t-1}] + b_{sharp}) + c_\beta \tag{5}$$

With the sharpened reading weight vector, we are able to obtain the read vector $\mathbf{r}_{1\times m}$ from M as a weighted sum, as in Eq. 6.

$$\mathbf{r} = \sum_i \overline{W}_{read}[i]M[i] \tag{6}$$

Generally speaking, the depth of memory M should be large enough to allow sparse encoding, so that crucial information is not lost after the summation. The read vector then contains contextual information relevant to current input. Both the read vector and the current input are fed to the controller, yielding GCL output. Unlike the canonical NTM, the CGL model does not have a trainable gate interpolating the $\overline{W}_t$ computed at time t, with $\overline{W}_{t-1}$ computed at previous time $t-1$. The weight vector is not passed to next time step, so the attention has no "inertia".

We tried two variants of the controller: (a) *state-tracking*, with an LSTM layer, and (b) *stateless*, with a dense layer. An LSTM controller has an internal state, and also has gates to select input and output. If the input data and/or the read vector from M have regular patterns with respect to time steps, an LSTM controller would be a better choice. For the specific task of temporal relation extraction, we saw no difference in performance.

3.1.3 Writing

The controller produces an output h_t, which is sent to the next layer and also used to update M. Similar to reading, the first step of writing procedure is to compute an attention weight vector over the slots of M. As described above, the reading procedure computes a weighted sum over slots of M. The writing procedure writes a weighted h_t to each slot. The attention mechanism here is *de facto* a soft addressing mechanism. The slots with a higher attention value will be the addresses which will get more of an update.

The same weight vector W computed as shown in Eq. 3 is used for writing. However, an additional operation is introduced for writing. Recall that the weights are computed from entity representations. If the input entities are $\mathbf{e_1}$ and $\mathbf{e_2}$, the weight vector should have high values in the slots corresponding to $\mathbf{e_1}$ and/or $\mathbf{e_2}$. But we may not always want relevant memory slots to be overwritten. Instead, additional information can be written to a different slot. Additionally, when M is relatively empty, as at the beginning, the addressing mechanism may treat all slots equally, and uniformly update all slots in the same way. In this case we want the weight vector to shift each time, so M can diversify fast.

Therefore we use a shift function similar to the canonical NTM. The idea is to compute a shifted weight vector $\widetilde{W}$ by convolving W with a shift kernel $\mathbf{s}$ which maps a shift distance to a probability value. For example, $\mathbf{s}(-1) = 0.2$, $\mathbf{s}(0) = 0.5$, $\mathbf{s}(1) = 0.3$ means the probabilities of shifting left, no shifting, and shifting right are 0.2, 0.5, 0.3, respectively. Generally speaking, we want $\mathbf{s}$ to give zeros for most shift distances, so the shifting operation is limited to a small range.

$$\widetilde{W}[i] = \sum_{j=0}^{n-1} W[j]\mathbf{s}[i-j] \tag{7}$$

At each time step, the shift kernel depends on current input and output. If the allowed shift range is [-s/2, +s/2], we train a weight W_s and bias b_s to calculate the shift weights $C_{s\times 1}$,

$$C_t = \mathrm{softmax}(W_s[\mathbf{x}_t, \mathbf{h}_t] + b_s) \tag{8}$$

Then the weights are mapped to a circulant kernel to perform the convolution in Eq. 7, the final output is $\widetilde{W}$.

Finally, the sharpening still needs to be applied. For the writing procedure, both addressing and shifting are "soft" in nature, and thus could yield a blurred outcome. Again, we train the weights to obtain a sharpening parameter γ each time, and perform softmax over $\widetilde{W}$.

$$\gamma_t = ReLU(W_{sharp}[\mathbf{x}_t, \mathbf{h}_t] + b_{sharp}) + c_\gamma \quad (9)$$

$$\overline{W}_{write} = \text{softmax}(\widetilde{W}^\gamma) \quad (10)$$

$\widetilde{W}^\gamma$ is the point-wise exponential function, over the shifted weight vector. c_γ is a positive constant.

The original NTM model has gates for interpolating $\widetilde{W}^\gamma$ at the current time with the one computed at the previous time step, but we omit this operation. We also omit the *erase vector* and the *add vector*, so $\overline{W}_{write}$ fully controls what to overwrite in M and what to retain. As a result, the writing operation can be expressed as:

$$M_t[i] = M_{t-1}[i] + \overline{W}_{write}[i](\mathbf{h}_t - M_{t-1}[i]) \quad (11)$$

The first term in Eq. 11 is the memory in the previous time step, and the second term is the update. We update the keys in the same way. As we can see, the keys come from entity representations, but are not exactly the same, due to $\overline{W}_{write}$.

$$K_t[i] = K_{t-1}[i] + \overline{W}_{write}[i](\mathbf{e_1} \oplus \mathbf{e_2} - K_{t-1}[i]) \quad (12)$$

3.1.4 GCL vs. Canonical NTM

We highlight below some major differences between the canonical NTM and the GCL model. Typically, NTM computes the keys from input and output for accessing different memory addresses. In GCL, the keys are simply the entity representations $[\mathbf{e_1}, \mathbf{e_2}]$ from input, in either order. The key function effectively involves slicing and flipping the input. Further discussion of the differences between the GCL addressing mechanism and some of the other NTM variations is provided in Sec. 5.

Another major difference is that we do not use any gates to interpolate the attention vector at the current time step with the one from the previous time step. Instead, the previous attention vector is totally ignored. Since we do not compute the erase vector or the add vector, this allows the attention vector to fully control memory updates.

In addition, we unified the trainable weights for calculating β and γ at each time step. We found these parameters not to be crucial, and setting them to be constant does not affect the results. We also do not shift attention for reading. A possible advantage of shifting attention is that neighboring slots of the focus can also be accessed, providing a way to simulate associative recall. This is based on the fact that the writing procedure tends to write similar memories close to each other. However, in this study we want the reading procedure to be restricted. Associative recall can be realized from attention vector itself, without shifting.

3.2 Pairwise Classification Model

The pairwise model classifies individual entity pairs, where entities are events and time expressions (timexes). In other words, for each pair, we only use the local context, and the relation of one pair does not affect the classification results for other pairs. We follow the architecture proposed in Meng et al. (2017), but with the following changes: (1) all three types of pairs are handled by the same neural network, rather than by three separately trained models; (2) the neighboring words (a flat context) of entity mentions are used to generate input, in addition to words on syntactic dependency paths; (3) all timex-timex pairs are included as well, not only event-timex and event-event pairs; (4) every pair is assigned a 3-dimensional "time value", to approximate the rule-based approach when possible.

3.2.1 Event Pairs and Event-Timex Pairs

TimeBank-Dense dataset labels three types of pairs: intra-sentence, cross-sentence and document creation time (DCT). For intra-sentence pairs and cross-sentence pairs, we follow Meng et al. (2017). The shortest dependency path between the two entities is identified, and the word embeddings from the path to the least common ancestor for each entity are processed by two LSTM branches, with a separate max pooling layer for each branch. Path to the root is used for cross-sentence relations. For relations with the DCT, we use a single word now as a placeholder for the DCT branch. Unlike Meng et al. (2017), we allow the model to accept all three pair types, with a "pair type" feature as a component of input, defined as an integer with the value 1, -1 or 0, respectively.

In addition to the shortest dependency path, our model also uses a flat local context window, that is, the words around each entity mention, regardless of syntactic structures. For an entity starting with word w_i, the local context window is 5 words to the left and 10 words to its right i.e. $w_{i-5}w_{i-4}...w_iw_{i+1}...w_{i+10}$. The windows are cut short at the edge of a sentence, or when the second entity in encountered. By using this context window, the words between two entities are often used twice by the system, and thus given more consideration. To inform the system of other entity mentions, we also add special input tokens at the locations where events and timexes are tagged. The embeddings of the special tokens are uniformly initialized, and automatically tuned during the training process.

3.2.2 Timex Pairs

The method described in Meng et al. (2017) classifies timex pairs by handcrafted rules and then adds them to the final results prior to postprocessing. Since timexes have concrete time values, a rule-based method would seem appropriate. However, since our model uses global context to help classify relations and timex-timex pairs enrich the global context representation, we design a way for a common classifier model to handle such pairs.

When DCT is not involved, timex pairs are created the same way as cross-sentence pairs, that is, path to the root is used for each entity. DCT is represented by the placeholder word *now*. In addition to the word-based representations, another input vector is used to simulate the rule-based approach, to be explained next.

3.2.3 Time Value Vectors

Every timex tag has a time value, following the ISO-8601 standard. Every value can be mapped to a 2D vector of real values $(start, end)$. For a pair we use the subtraction of the vectors to represent the difference. Suppose we have timexes in below:

```
THE HAGUE, Netherlands (AP)_ The World Court
<TIMEX3 tid="t21" type="DATE" value="1998-02-27"
temporalFunction="true" functionInDocument="NONE"
anchorTimeID="t0">Friday</TIMEX3> rejected U.S.
and British objections to a Libyan World Court
case that has  the trial of two Libyans suspected
of blowing up a Pan Am jumbo jet over Scotland in
<TIMEX3 tid="t22" type="DATE" value="1988"
temporalFunction="false"
functionInDocument="NONE">1988</TIMEX3>.
```

The first timex can be represented as (1998 + 1/12 + 26/365, 1998 + 1/12 + 26/365) = (1998.155, 1998.155), and the second one (1988, 1988 + 364/365) = (1988, 1988.997). The difference of the values are put in the sign function, to obtain the representation: (sign(1988 - 1998.155), sign(1988.997 - 1998.155)) = (-1, -1). Vector (-1, -1) clearly indicates the AFTER relation between $t21$ and $t22$. We set the minimum interval to be a day, which is generally sufficient for our data. The DURATION timexes are not considered, and word-based input vectors are used to represent them.

In order to make all the input data have the same shape, we assign the time value vector to all pairs, even if a timex is not involved. For non-timex pairs, a vector (-1, 0, 0) is used. The first element -1 to indicate a "pseudo" time value. Real timex pairs have the first value of 1, so the example we just discussed would be assigned a vector (1, -1, -1). The time value vectors allow the model to take advantage of rule-based information.

3.3 Combining Two Components

We tried training the two components in a combined system, but found it slow to converge. In our experiments, we trained the pairwise model first, froze it, and then combined it with the GCL layer to train the GCL. This method also helps us observe whether the GCL component alone improves results, given the same input.

We tried combining the systems in two ways. One is to connect the output layer of the pre-trained model to GCL, and the other is to slice the pre-trained model and connect its hidden layer to GCL. All the GCL layers are bi-directional, averaging forward and backward passes. By connecting the output layer, which has a softmax activation, we hand the final decisions made by the pairwise model to GCL. On the other hand, the hidden layer provides higher layers with cruder but richer information. We found that the latter performs better. It is also possible to train the two components together from scratch. In this case, the learning rate has to be set much lower to assure convergence, and the training requires more epochs.

4 Experiments

For all the experiments, hyperparameters including the number of epochs are tuned with the validation set only. Training data is segmented into chunks. Each chunk contains relation pairs in the narrative order. The size of chunks is randomly chosen from [40, 60, 80, 120, 160] at the beginning of each epoch of training. The GCL maintains a memory for each chunk, and clears it at the end of a chunk. The idea here is to train the model on short paragraphs to avoid overfitting.

To introduce further randomness, the chunks are rotated for each epoch. For a specific training file, if chunk i starts with pair n_i in epoch 1, in epoch

2, chunk i will start with pair $n_i + chunksize + 11$. 11 is a prime number we chose to assure each epoch observes different compositions of chunks. By doing the rotation, some pairs in the final chunk of epoch 1 will show up in the first chunk in epoch 2 as well. However, within each chunk, we do not randomize pairs, so narrative order is preserved at this level. We also do not shuffle the chunks, but only rotate them.

Evaluation on the test set uses only one chunk for each file (chunk size is the number of pairs). Each relation pair is only processed once, without "multiple rounds of reading". Thus, we essentially train the model to read shorter paragraphs (varied in length), but test it on long articles.

4.1 Pairwise Model

As described in Section 3.2, the pairwise classifier has the following input vectors: left and right shortest path branches, two flat context vectors, a pair type flag, and a time value vector. Word embeddings are initialized with glove.840B.300d word vectors[2], and set to be trainable. The Bi-LSTM layers are followed by max-pooling. The two hidden layers have size 512 and 128, respectively. We train this model for 40 epochs, using the RMSProp optimizer (Tieleman and Hinton, 2012). The learning rate is scheduled as $lr = 2 \times 10^{-3} \times 2^{-\frac{n}{5}}$, where n is the number of epochs.

The middle block of Table 1 shows the performance of the pairwise model after applying double-checking. Since all pairs are flipped, double-checking combines results from (e_i, e_j) and (e_j, e_i), picking the label with the higher probability score, which typically boosts performance. The results without double-checking show similar trends.

4.2 GCL model

After training the pairwise model, we combine it with GCL. Unless otherwise indicated, the results reported in this section use the model configuration that connects the hidden layer (rather than the output layer) of the pairwise model with a bidirectional GCL layer. The bidirectional GCL is realized as the average of a forward GCL and a backward GCL, each producing a sequence. Then two more hidden layers are put on top of it, followed by an output layer. All the layers in the pre-trained pairwise model are set to be untrainable. The two trainable hidden layers have sizes 512 and 128, respectively, with ReLU activtion and 0.3 dropout after each one. The GCLs have 128 memory slots. Learning rate is scheduled as $lr = 2 \times 10^{-4} \times 2^{-\frac{n}{2}}$. In the experiments, we found the models converge quite fast with respect to the number of epochs. It is not surprising because the lower layers are already well trained, and frozen (no updating). After the 5th epoch, the training accuracy typically reaches 0.95. We stop training after 10 epochs.

Model	Micro-F1	Macro-F1
CAEVO (not NN model)	.507	
CATENA (not NN model)	.511	
Cheng et al. 2017	.520[3]	
Meng et al. 2017		.519
pairwise	.535	.528
Two more hidden layers	.539	.532
GCL w/ state-tracking controller	.545	**.538**
GCL w/ stateless controller	**.546**	**.538**
GCL w/ pre-trained output layer	.541	.536

Table 1: Results on the test set. The GCL models use the same hyperparameters, if possible. The two models on the top do not use neural networks. The results in the two lower blocks all use double-check. "Two more hidden layers" means adding two dense layers on top of the pre-trained model without using GCL. The last row corresponds to connecting the output layer of a pre-trained model to GCL layers with stateless controller.

The bottom block of Table 1 presents the results, showing that all models from the present paper outperform existing models from the literature. One may argue the combined system adds more hidden layers over a pre-trained model, which contributes to the improvement in performance. We show a comparison to a baseline model which adds two dense layers on top of the pairwise model, without the GCL. The configuration of the two layers is the same as we used for the GCL models. The result shows that the performance is slightly higher than what we get from the pairwise model, but the difference is smaller than what we get from GCL models – suggesting that the performance improvement with GCL models is not just due to more parameters. We also tried adding an LSTM layer on top of the pre-trained model, and found the system cannot converge. It again confirms that GCL is more powerful than LSTM in handling irregular time series.

We found no difference in performance between the stateless controller and state-tracking controller. Connecting the output layer of the pre-

[2]https://nlp.stanford.edu/projects/glove/

[3]This result does not include timex-timex pairs, which is 3% of total test instances.

trained model to GCL seems to generate weaker results than connecting the hidden layer, although it also outperforms the pairwise model, and all previous models in literature.

We performed significance testing to compare the pairwise model and the GCL-enabled model. A paired one-tailed t-test shows the results from the GCL model are significantly higher than results from pairwise model (p-value 0.0015). While significant, the improvement is relatively small, we believe due in part to the small size of Timebank-Dense dataset.

4.3 Case Study

To illustrate the difference in performance of the pairwise model and the GCL model, we created a sample paragraph in which long-distance dependencies and references to DCT are needed to resolve some of the temporal relations:

> John *met* Mary in Massachusetts when they *attended* the same university. They are *getting married* in 2019, 2 years after their *graduation*. But this year, they have *relocated* to New Hampshire.

We created the gold standard annotation for this text with 5 events, 2 timexes, and 24 TLINKS (see appendix)[4]. We set the DCT to an arbitrary date "2018-04-01". There are no VAGUE or SIMULTANEOUS relations.

For this paragraph, the pairwise model yields an accuracy (i.e. micro-averaged F1) of 0.292, while the GCL-enabled model yields 0.417. Overall, the GCL-enabled model assigns 6 VAGUE labels while the pairwise assigns 11. It reflects the fact that GCL tries to infer relations from otherwise vague evidence. For example, it is difficult to infer the relation between *met* and *2019* from the local context (without DCT, particularly), so the pairwise model labels it as VAGUE, while the GCL-enabled model correctly assigns BEFORE.

Recall that the GCL is placed on top of a pretrained pairwise model, so the mistakes made by the pairwise model propagate to GCL. For example, the pairwise model incorrectly classifies *2019* as BEFORE *graduation* – perhaps, due to a somewhat unusual syntax. But the GCL-enabled system assigns it a VAGUE label, probably as a way to compromise. In the TimeBank-Dense test data, VAGUE cases dominate, which may have made it more difficult for GCL to assign proper labels. In the future, we believe it may be better to omit writing (and reading) the VAGUE relations to/from GCL.

[4]Note that in TimeBank-Dense, no TLINKS are associated DURATION timexes, so 2 years is not annotated

4.4 Error Analysis

Table 2 shows the overall performance for each relation using the GCL system with the stateless controller. Since we flip pairs and use double-checking to pick one result for each pair, BEFORE/AFTER and IS_INCLUDED/INCLUDES are actually treated in the same way, respectively. Here we map the results to original pairs, in order to compare to other systems.

	Predicted labels						
	SIMUL	**BEF**	**AFT**	**IS_INCL**	**INCL**	**VAG**	Total
SIMUL	10	0	9	2	1	17	39
BEF	0	327	27	15	5	215	589
AFT	1	26	208	4	5	184	428
IS_INCL	1	27	3	59	2	67	159
INCL	0	16	9	2	19	70	116
VAG	1	171	87	28	17	596	900

Table 2: Overall results per relation.

As the table shows, the VAGUE relation causes the most trouble. It is not only because VAGUE is the largest class, but also because it is often semantically ambiguous, so even human experts have low inter-annotator agreement. If we allow a relatively sparse labeling of data, and use other evaluation methods (e.g. question answering), the VAGUE class is not likely to have similar effects.

We also break down the results according to the types of pairs. Compared to other systems, our approach has a big advantage for event-event (E-E) pairs, which is by far the most common (64%) relation pairs for all data, and also requires more complex natural language understanding. Compared to CAEVO, our performance on event-DCT (E-D) and event-timex (E-T) pairs is not that great. CAEVO uses engineered features such as entity attributes, temporal signals, and semantic information from WordNet, which seems to work well in these two cases. We took a closer look at our E-D

Systems	**E-D**	**E-E**	**E-T**	**Overall**
Frequency	14%	64%	19%	97%
CAEVO	**.553**	.494	**.494**	.502
CATENA	.534	.519	.468	.512
Cheng et al. 2017	.546	.529	.471	.520
GCL	.489	**.570**	.487	**.542**

Table 3: Results on the E-D, E-D and E-T pairs. GCL stands for the GCL-enabled system with a stateless controller. Frequencies are percentages in the test set. T-T pairs are not shown here. CAEVO is from Chambers et al. (2014). CATENA is from Mirza and Tonelli (2016)

results, and found that the relatively low performance is mainly caused by misclassifying VAGUE as AFTER. As Table 4 shows, among the 72

	Predicted labels					
	SIMUL	BEF	AFT	IS_INCL	INCL	VAG
SIMUL	0	0	0	0	0	0
BEF	0	57	11	15	6	37
AFT	0	3	36	0	0	10
IS_INCL	0	11	1	31	1	12
INCL	0	0	2	1	3	2
VAG	0	4	20	9	14	25

Table 4: Test results from event and document creation time (E-D) pairs. The rows are true labels and the columns are predicted labels.

VAGUE relations in E-D pairs, 20 are labeled AFTER by our system. In a news article, most events occur before the DCT i.e. the time when the article was written. If the temporal relation is vague, our system tends to guess that the event occurs after the DCT. It is interesting because AFTER only accounts for 16% of all E-D pairs in test data (and about the same in training data), behind BEFORE (41%), VAGUE (21%), and IS_INCLUDED (18%). However, E-D is a relatively small category with only 311 instances in the test set, so it is difficult to draw any a substantive conclusion in this case.

Recall that our model has a uniform architecture for all input types and is trained on event-event, event-timex and event-DCT pairs simultaneously. As a result, its performance is not optimal for some lower-frequency pair types. Tuning the model for each pair type separately, as well as resampling to deal with class imbalance would, perhaps, improve performance. However, the point of these experiments was not to get the largest improvement, but to show that the GCL mechanism can replace heuristic-based timegraph conflict resolution, improving the performance of an otherwise very similar model.

5 Related Work

While the GCL model is inspired by NTM, other NTM variants have also been proposed recently. Zhang et al. (2015) proposed structured memory architectures for NTMs, and argue they could alleviate overfitting and increase predictive accuracy. Graves et al. (2016) proposed a memory access mechanism on top of NTM, which they call Differentiable Neural Computer (DNC). DNC can store the transitions between memory locations it accesses, and thus can model some structured data.

Gülçehre et al. (2016) proposed a Dynamic Neural Turing Machine (D-NTM) model, which allows discrete access to memory. Gülçehre et al. (2017) further simplified the addressing algorithm, so a single trainable matrix is used to get locations for read and write. Both models separate the address section from the content section of memory, as do we. We came up with the idea independently, noting that the content-based addressing in the canonical NTM model is difficult to train. A crucial difference between GCL and these models is that they use input "content" to compute keys. In GCL, the addressing mechanism fully depends on the entity representations, which are provided by the context encoding layers and not computed by the GCL controller. Addressing then involves matching the input entities and the entities in memory.

Other than NTM-based approaches, there are models that use an attention mechanism over either input or external memory. For instance, the Pointer Networks (Vinyals et al., 2015) uses attention over input timesteps. However, it has no power to rewrite information for later use, since they have no "memory" except for the RNN states. The Dynamic Memory Networks (Kumar et al., 2016) has an "episodic memory" module which can be updated at each timestep. However, the memory there is a vector ("episode") without internal structure, and the attention mechanism works on inputs, just as in Pointer Networks. Our GCL model and other NTM-based models have a memory with multiple slots, and the addressing function (attention) dictates writing and reading to/from certain slots in the memory.

6 Conclusion

We have proposed the first context-aware neural model for temporal information extraction using an external memory to represent global context. Our model introduces a Global Context Layer which is able to save and retrieve processed temporal relations, and then use this global context to infer new relations from new input. The memory can be updated, allowing self-correction. Experimental results show that the proposed model beats previous results without resorting to ad-hoc resolution of timegraph conflicts in postprocessing.

Temporal Event Knowledge Acquisition via Identifying Narratives

Wenlin Yao and Ruihong Huang
Department of Computer Science and Engineering
Texas A&M University
{wenlinyao, huangrh}@tamu.edu

Abstract

Inspired by the double temporality characteristic of narrative texts, we propose a novel approach for acquiring rich temporal "before/after" event knowledge across sentences in narrative stories. The double temporality states that a narrative story often describes a sequence of events following the chronological order and therefore, the temporal order of events matches with their textual order. We explored narratology principles and built a weakly supervised approach that identifies 287k narrative paragraphs from three large text corpora. We then extracted rich temporal event knowledge from these narrative paragraphs. Such event knowledge is shown useful to improve temporal relation classification and outperform several recent neural network models on the narrative cloze task.

Michael Kennedy graduated with a bachelor's degree from Harvard University in 1980. He married his wife, Victoria, in 1981 and attended law school at the University of Virginia. After receiving his law degree, he briefly worked for a private law firm before joining Citizens Energy Corp. He took over management of the corporation, a non-profit firm that delivered heating fuel to the poor, from his brother Joseph in 1988. Kennedy expanded the organization goals and increased fund raising.

Beth paid the taxi driver. She jumped out of the taxi and headed towards the door of her small cottage. She reached into her purse for keys. Beth entered her cottage and got undressed. Beth quickly showered deciding a bath would take too long. She changed into a pair of jeans, a tee shirt, and a sweater. Then, she grabbed her bag and left the cottage.

Figure 1: Two narrative examples

1 Introduction

Occurrences of events, referring to changes and actions, show regularities. Specifically, certain events often co-occur and in a particular temporal order. For example, people often go to *work* after *graduation* with a degree. Such "before/after" temporal event knowledge can be used to recognize temporal relations between events in a document even when their local contexts do not indicate any temporal relations. Temporal event knowledge is also useful to predict an event given several other events in the context. Improving event temporal relation identification and event prediction capabilities can benefit various NLP applications, including event timeline generation, text summarization and question answering.

While being in high demand, temporal event knowledge is lacking and difficult to obtain. Existing knowledge bases, such as Freebase (Bollacker et al., 2008) or Probase (Wu et al., 2012), often contain rich knowledge about entities, e.g., the birthplace of a person, but contain little event knowledge. Several approaches have been proposed to acquire temporal event knowledge from a text corpus, by either utilizing textual patterns (Chklovski and Pantel, 2004) or building a temporal relation identifier (Yao et al., 2017). However, most of these approaches are limited to identifying temporal relations within one sentence.

Inspired by the double temporality characteristic of narrative texts, we propose a novel approach for acquiring rich temporal "before/after" event knowledge across sentences via identifying narrative stories. The double temporality states that a narrative story often describes a sequence of events following the chronological order and therefore, the temporal order of events matches with their textual order (Walsh, 2001; Riedl and Young, 2010; Grabes, 2013). Therefore, we can easily distill temporal event knowledge if we have identified a large collection of narrative texts. Consider the two narrative examples in figure 1, where the top one is from a news article of New York Times and the bottom one is from a novel book. From the top one, we can easily extract one chronologically ordered event sequence {graduated, marry, attend, receive, work, take over, expand, increase}, with all events related to the main character Michael Kennedy. While some parts of the event sequence are specific to this story, the event sequence contains regular event temporal relations, e.g., people often {graduate} first and then get {married}, or {take over} a role first and then {expand} a goal. Similarly, from the bottom one, we can easily extract another event sequence {pay, jump out, head, reach into, enter, undress, shower, change, grab, leave} that contains routine actions when people take a shower and change clothes.

There has been recent research on narrative identification from blogs by building a text classifier in a supervised manner (Gordon and Swanson, 2009; Ceran et al., 2012). However, narrative texts are common in other genres as well, including news articles and novel books, where little annotated data is readily available. Therefore, in order to identify narrative texts from rich sources, we develop a weakly supervised method that can quickly adapt and identify narrative texts from different genres, by heavily exploring the principles that are used to characterize narrative structures in narratology studies. It is generally agreed in narratology (Forster, 1962; Mani, 2012; Pentland, 1999; Bal, 2009) that a narrative is a discourse presenting a sequence of events arranged in their time order (the plot) and involving specific characters (the characters). First, we derive specific grammatical and entity co-reference rules to identify narrative paragraphs that each contains a sequence of sentences sharing the same actantial syntax structure (i.e., *NP VP* describing *a character did something*) (Greimas, 1971) and mentioning the same character. Then, we train a classifier using the initially identified seed narrative texts and a collection of grammatical, co-reference and linguistic features that capture the two key principles and other textual devices of narratives. Next, the classifier is applied back to identify new narratives from raw texts. The newly identified narratives will be used to augment seed narratives and the bootstrapping learning process iterates until no enough new narratives can be found.

Then by leveraging the double temporality characteristic of narrative paragraphs, we distill general temporal event knowledge. Specifically, we extract event pairs as well as longer event sequences consisting of strongly associated events that often appear in a particular textual order in narrative paragraphs, by calculating Causal Potential (Beamer and Girju, 2009; Hu et al., 2013) between events.

Specifically, we obtained 19k event pairs and 25k event sequences with three to five events from the 287k narrative paragraphs we identified across three genres, news articles, novel books and blogs. Our evaluation shows that both the automatically identified narrative paragraphs and the extracted event knowledge are of high quality. Furthermore, the learned temporal event knowledge is shown to yield additional performance gains when used for temporal relation identification and the Narrative Cloze task. The acquired event temporal knowledge and the knowledge acquisition system are publicly available[1].

2 Related Work

Several previous works have focused on acquiring temporal event knowledge from texts. VerbOcean (Chklovski and Pantel, 2004) used predefined lexico-syntactic patterns (e.g., "X and then Y") to acquire event pairs with the temporal *happens_before* relation from the Web. Yao et al. (2017) simultaneously trained a temporal "before/after" relation classifier and acquired event pairs that are regularly in a temporal relation by exploring the observation that some event pairs tend to show the same temporal relation regardless of contexts. Note that these prior works are limited to identifying temporal relations within individual sentences. In contrast, our approach is designed to acquire temporal relations across sentences in a narrative paragraph. Interestingly, only 195 (1%) out of 19k event pairs acquired by our approach can be found in VerbOcean or regular event pairs learned by the previous two approaches.

Our design of the overall event knowledge acquisition also benefits from recent progress on narrative identification. Gordon and Swanson (2009) annotated a small set of paragraphs presenting stories in the ICWSM Spinn3r Blog corpus (Burton et al., 2009) and trained a classifier using bag-of-words features to identify more stories. (Ceran

[1]`http://nlp.cs.tamu.edu/resources.html`

et al., 2012) trained a narrative classifier using semantic triplet features on the CSC Islamic Extremist corpus. Our weakly supervised narrative identification method is closely related to Eisenberg and Finlayson (2017), which also explored the two key elements of narratives, the plot and the characters, in designing features with the goal of obtaining a generalizable story detector. But different from this work, our narrative identification method does not require any human annotations and can quickly adapt to new text sources.

Temporal event knowledge acquisition is related to script learning (Chambers and Jurafsky, 2008), where a script consists of a sequence of events that are often temporally ordered and represent a typical scenario. However, most of the existing approaches on script learning (Chambers and Jurafsky, 2009; Pichotta and Mooney, 2016; Granroth-Wilding and Clark, 2016) were designed to identify clusters of closely related events, not to learn the temporal order between events though. For example, Chambers and Jurafsky (2008, 2009) learned event scripts by first identifying closely related events that share an argument and then recognizing their partial temporal orders by a separate temporal relation classifier trained on the small labeled dataset TimeBank (Pustejovsky et al., 2003). Using the same method to get training data, Jans et al. (2012); Granroth-Wilding and Clark (2016); Pichotta and Mooney (2016); Wang et al. (2017) applied neural networks to learn event embeddings and predict the following event in a context. Distinguished from the previous script learning works, we focus on acquiring event pairs or longer script-like event sequences with events arranged in a complete temporal order. In addition, recent works (Regneri et al., 2010; Modi et al., 2016) collected script knowledge by directly asking Amazon Mechanical Turk (AMT) to write down typical temporally ordered event sequences in a given scenario (e.g., shopping or cooking). Interestingly, our evaluation shows that our approach can yield temporal event knowledge that covers 48% of human-provided script knowledge.

3 Key Elements of Narratives

It is generally agreed in narratology (Forster, 1962; Mani, 2012; Pentland, 1999; Bal, 2009) that a narrative presents a sequence of events arranged in their time order (the plot) and involving specific characters (the characters).

Plot. The plot consists of a sequence of closely related events. According to (Bal, 2009), an event in a narrative often describes a “transition from one state to another state, caused or experienced by actors”. Moreover, as Mani (2012) illustrates, a narrative is often “an account of past events in someone’s life or in the development of something”. These prior studies suggest that sentences containing a plot event are likely to have the actantial syntax “NP VP”[2] (Greimas, 1971) with the main verb in the past tense.

Character. A narrative usually describes events caused or experienced by actors. Therefore, a narrative story often has one or two main characters, called protagonists, who are involved in multiple events and tie events together. The main character can be a person or an organization.

Other Textual Devices. A narrative may contain peripheral contents other than events and characters, including time, place, the emotional and psychological states of characters etc., which do not advance the plot but provide essential information to the interpretation of the events (Pentland, 1999). We use rich Linguistic Inquiry and Word Count (LIWC) (Pennebaker et al., 2015) features to capture a variety of textual devices used to describe such contents.

4 Phase One: Weakly Supervised Narrative Identification

In order to acquire rich temporal event knowledge, we first develop a weakly supervised approach that can quickly adapt to identify narrative paragraphs from various text sources.

4.1 System Overview

The weakly supervised method is designed to capture key elements of narratives in each of two stages. As shown in figure 2, in the first stage, we identify the initial batch of narrative paragraphs that satisfy strict rules and the key principles of narratives. Then in the second stage, we train a statistical classifier using the initially identified seed narrative texts and a collection of soft features for capturing the same key principles and other textual devices of narratives. Next, the classifier is applied to identify new narratives from raw texts again. The newly identified narratives will be used to augment seed narratives and the bootstrapping

[2]NP is Noun Phrase and VP is Verb Phrase.

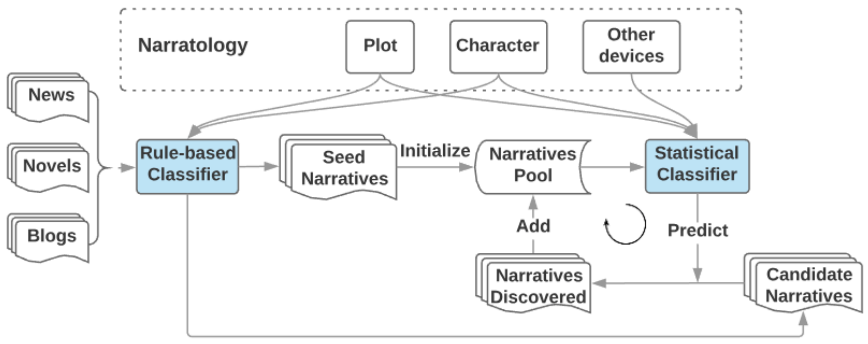

Figure 2: Overview of the Narrative Learning System

learning process iterates until no enough (specifically, less than 2,000) new narratives can be found. Here, in order to specialize the statistical classifier to each genre, we conduct the learning process on news, novels and blogs separately.

4.2 Rules for Identifying Seed Narratives

Grammar Rules for Identifying Plot Events. Guided by the prior narratology studies (Greimas, 1971; Mani, 2012) and our observations, we use context-free grammar production rules to identify sentences that describe an event in an actantial syntax structure. Specifically, we use three sets of grammar rules to specify the overall syntactic structure of a sentence. First, we require a sentence to have the basic active voiced structure "S → NP VP" or one of the more complex sentence structures that are derived from the basic structure considering Coordinating Conjunctions (CC), Adverbial Phrase (ADVP) or Prepositional Phrase (PP) attachments[3]. For example, in the narrative of Figure 1, the sentence *"Michael Kennedy earned a bachelor's degree from Harvard University in 1980."* has the basic sentence structure "S → NP VP", where the "NP" governs the character mention of 'Michael Kennedy' and the "VP" governs the rest of the sentence and describes a plot event.

In addition, considering that a narrative is usually "an account of past events in someone's life or in the development of something" (Mani, 2012; Dictionary, 2007), we require the headword of the VP to be in the past tense. Furthermore, the subject of the sentence is meant to represent a character. Therefore, we specify 12 grammar rules[4] to require the sentence subject noun phrase to have a simple structure and have a proper noun or pronoun as its head word.

For seed narratives, we consider paragraphs containing at least four sentences and we require 60% or more sentences to satisfy the sentence structure specified above. We also require a narrative paragraph to contain no more than 20% of sentences that are interrogative, exclamatory or dialogue, which normally do not contain any plot events. The specific parameter settings are mainly determined based on our observations and analysis of narrative samples. The threshold of 60% for "sentences with actantial structure" was set to reflect the observation that sentences in a narrative paragraph usually (over half) have an actantial structure. A small portion (20%) of interrogative, exclamatory or dialogue sentences is allowed to reflect the observation that many paragraphs are overall narratives even though they may contain 1 or 2 such sentences, so that we achieve a good coverage in narrative identification.

The Character Rule. A narrative usually has a protagonist character that appears in multiple sentences and ties a sequence of events, therefore, we also specify a rule requiring a narrative paragraph to have a protagonist character. Concretely, inspired by Eisenberg and Finlayson (2017), we applied the named entity recognizer (Finkel et al., 2005) and entity coreference resolver (Lee et al., 2013) from the CoreNLP toolkit (Manning et al., 2014) to identify the longest entity chain in a paragraph that has at least one mention recognized as a *Person* or *Organization*, or a gendered pronoun. Then we calculate the normalized length of this entity chain by dividing the number of entity mentions by the number of sentences in the paragraph. We require the normalized length of this longest

[3]We manually identified 14 top-level sentence production rules, for example, "S → NP ADVP VP", "S → PP , NP VP" and "S → S CC S". Appendix shows all the rules.

[4]The example NP rules include "NP → NNP", "NP → NP CC NP" and "NP → DT NNP".

entity chain to be ≥ 0.4, meaning that 40% or more sentences in a narrative mention a character [5].

4.3 The Statistical Classifier for Identifying New Narratives

Using the seed narrative paragraphs identified in the first stage as positive instances, we train a statistical classifier to continue to identify more narrative paragraphs that may not satisfy the specific rules. We also prepare negative instances to compete with positive narrative paragraphs in training. Negative instances are paragraphs that are not likely to be narratives and do not present a plot or protagonist character, but are similar to seed narratives in others aspects. Specifically, similar to seed narratives, we require a non-narrative paragraph to contain at least four sentences with no more than 20% of sentences being interrogative, exclamatory or dialogue; but in contrast to seed narratives, a non-narrative paragraph should contain 30% of or fewer sentences that have the actantial sentence structure, where the longest character entity chain should not span over 20% of sentences. We randomly sample such non-narrative paragraphs that are five times of narrative paragraphs [6].

In addition, since it is infeasible to apply the trained classifier to all the paragraphs in a large text corpus, such as the Gigaword corpus (Graff and Cieri, 2003), we identify candidate narrative paragraphs and only apply the statistical classifier to these candidate paragraphs. Specifically, we require a candidate paragraph to satisfy all the constraints used for identifying seed narrative paragraphs but contain only 30%[7] or more sentences with an actantial structure and have the longest character entity chain spanning over 20%[8] of or more sentences.

We choose Maximum Entropy (Berger et al., 1996) as the classifier. Specifically, we use the MaxEnt model implementation in the LIBLINEAR library[9] (Fan et al., 2008) with default parameter settings. Next, we describe the features used to capture the key elements of narratives.

Features for Identifying Plot Events: Realizing that grammar production rules are effective in identifying sentences that contain a plot event, we encode all the production rules as features in the statistical classifier. Specifically, for each narrative paragraph, we use the frequency of all syntactic production rules as features. Note that the bottom level syntactic production rules have the form of POS tag $\rightarrow$ WORD and contain a lexical word, which made these rules dependent on specific contexts of a paragraph. Therefore, we exclude these bottom level production rules from the feature set in order to model generalizable narrative elements rather than specific contents of a paragraph.

In addition, to capture potential event sequence overlaps between new narratives and the already learned narratives, we build a verb bigram language model using verb sequences extracted from the learned narrative paragraphs and calculate the perplexity score (as a feature) of the verb sequence in a candidate narrative paragraph. Specifically, we calculate the perplexity score of an event sequence that is normalized by the number of events, $PP(e_1, ..., e_N) = \sqrt[N]{\prod_{i=1}^{N} \frac{1}{P(e_i|e_{i-1})}}$, where N is the total number of events in a sequence and e_i is a event word. We approximate $P(e_i|e_{i-1}) = \frac{C(e_{i-1}, e_i)}{C(e_{i-1})}$, where $C(e_{i-1})$ is the number of occurrences of e_{i-1} and $C(e_{i-1}, e_i)$ is the number of co-occurrences of e_{i-1} and e_i. $C(e_{i-1}, e_i)$ and $C(e_{i-1})$ are calculated based on all event sequences from known narrative paragraphs.

Features for the Protagonist Characters: We consider the longest three coreferent entity chains in a paragraph that have at least one mention recognized as a *Person* or *Organization*, or a gendered pronoun. Similar to the seed narrative identification stage, we obtain the normalized length of each entity chain by dividing the number of entity mentions with the number of sentences in the paragraph. In addition, we also observe that a protagonist character appears frequently in the surrounding paragraphs as well, therefore, we calculate the normalized length of each entity chain based on its presences in the target paragraph as well as one preceding paragraph and one follow-

[5]40% was chosen to reflect that a narrative paragraph often contains a main character that is commonly mentioned across sentences (half or a bit less than half of all the sentences).

[6]We used the skewed pos:neg ratio of 1:5 in all bootstrapping iterations to reflect the observation that there are generally many more non-narrative paragraphs than narrative paragraphs in a document.

[7]This value is half of the corresponding thresshold used for identifying seed narrative paragraphs.

[8]This value is half of the corresponding thresshold used for identifying seed narrative paragraphs.

Table 1: Number of new narratives generated after each bootstrapping iteration

ing paragraph. We use 6 normalized lengths (3 from the target paragraph [10] and 3 from surrounding paragraphs) as features.

Other Writing Style Features: We create a feature for each semantic category in the Linguistic Inquiry and Word Count (LIWC) dictionary (Pennebaker et al., 2015), and the feature value is the total number of occurrences of all words in that category. These LIWC features capture presences of certain types of words, such as words denoting relativity (e.g., motion, time, space) and words referring to psychological processes (e.g., emotion and cognitive). In addition, we encode Parts-of-Speech (POS) tag frequencies as features as well which have been shown effective in identifying text genres and writing styles.

4.4 Identifying Narrative Paragraphs from Three Text Corpora

Our weakly supervised system is based on the principles shared across all narratives, so it can be applied to different text sources for identifying narratives. We considered three types of texts: (1) **News Articles**. News articles contain narrative paragraphs to describe the background of an important figure or to provide details for a significant event. We use English Gigaword 5th edition (Graff and Cieri, 2003; Napoles et al., 2012), which contains 10 million news articles. (2) **Novel Books**. Novels contain rich narratives to describe actions by characters. BookCorpus (Zhu et al., 2015) is a large collection of free novel books written by unpublished authors, which contains 11,038 books of 16 different sub-genres (e.g., Romance, Historical, Adventure, etc.). (3) **Blogs**. Vast publicly accessible blogs also contain narratives because "personal life and experiences" is a primary topic of blog posts (Lenhart, 2006). We use the Blog Authorship Corpus (Schler et al., 2006) collected from the blogger.com website, which consists of 680k posts written by thousands of authors. We applied the Stanford CoreNLP tools (Manning et al., 2014) to the three text corpora to obtain POS tags, parse trees, named entities, coreference chains, etc.

In order to combat semantic drifts (McIntosh and Curran, 2009) in bootstrapping learning, we set the initial selection confidence score produced by the statistical classifier at 0.5 and increase it by 0.05 after each iteration. The bootstrapping system runs for four iterations and learns 287k narrative paragraphs in total. Table 1 shows the number of narratives that were obtained in the seeding stage and in each bootstrapping iteration from each text corpus.

5 Phase Two: Extract Event Temporal Knowledge from Narratives

Narratives we obtained from the first phase may describe specific stories and contain uncommon events or event transitions. Therefore, we apply Pointwise Mutual Information (PMI) based statistical metrics to measure strengths of event temporal relations in order to identify general knowledge that is not specific to any particular story. Our goal is to learn event pairs and longer event chains with events completely ordered in the temporal "before/after" relation.

First, by leveraging the double temporality characteristic of narratives, we only consider event pairs and longer event chains with 3-5 events that have occurred as a segment in at least one event sequence extracted from a narrative paragraph. Specifically, we extract the event sequence (the plot) from a narrative paragraph by finding the main event in each sentence and chaining the main events[11] according to their textual order.

Then we rank candidate event pairs based on two factors, how strongly associated two events are and how common they appear in a particular temporal order. We adopt the existing metric, Causal Potential (CP), which has been applied to acquire causally related events (Beamer and Girju, 2009) and exactly measures the two aspects. Specifically, the CP score of an event pair is calculated using the following equation:

$$cp(e_i, e_j) = pmi(e_i, e_j) + log\frac{P(e_i \to e_j)}{P(e_j \to e_i)} \quad (1)$$

where, the first part refers to the Pointwise Mutual Information (PMI) between two events and the

[10]Specifically, the lengths of the longest, second longest and third longest entity chains.

[11]We only consider main events that are in base verb forms or in the past tense, by requiring their POS tags to be VB, VBP, VBZ or VBD.

second part measures the relative ordering or two events. $P(e_i \to e_j)$ refers to the probability that e_i occurs before e_j in a text, which is proportional to the raw frequency of the pair. PMI measures the association strength of two events, formally, $pmi(e_i, e_j) = log\frac{P(e_i,e_j)}{P(e_i)P(e_j)}$, $P(e_i) = \frac{C(e_i)}{\sum_x C(e_x)}$ and $P(e_i, e_j) = \frac{C(e_i,e_j)}{\sum_x \sum_y C(e_x,e_y)}$, where, x and y refer to all the events in a corpus, $C(e_i)$ is the number of occurrences of e_i, $C(e_i, e_j)$ is the number of co-occurrences of e_i and e_j.

While each candidate pair of events should have appeared consecutively as a segment in at least one narrative paragraph, when calculating the CP score, we consider event co-occurrences even when two events are not consecutive in a narrative paragraph but have one or two other events in between. Specifically, the same as in (Hu and Walker, 2017), we calculate separate CP scores based on event co-occurrences with zero (consecutive), one or two events in between, and use the weighted average CP score for ranking an event pair, formally, $CP(e_i, e_j) = \sum_{d=1}^{3} \frac{cp_d(e_i,e_j)}{d}$.

Then we rank longer event sequences based on CP scores for individual event pairs that are included in an event sequence. However, an event sequence of length n is more than $n-1$ event pairs with any two consecutive events as a pair. We prefer event sequences that are coherent overall, where the events that are one or two events away are highly related as well. Therefore, we define the following metric to measure the quality of an event sequence:

$$CP(e_1, e_2, \cdots, e_n) = \frac{\sum_{d=1}^{3} \sum_{j=1}^{n-d} \frac{CP(e_j,e_{j+d})}{d}}{n-1}. \quad (2)$$

6 Evaluation

6.1 Precision of Narrative Paragraphs

From all the learned narrative paragraphs, we randomly selected 150 texts, with 25 texts selected from narratives learned in each of the two stages (i.e., seed narratives and bootstrapped narratives) using each of the three text corpora (i.e., news, novels, and blogs). Following the same definition "A story is a narrative of events arranged in their time sequence" (Forster, 1962; Gordon and Swanson, 2009), two human adjudicators were asked to judge whether each text is a narrative or a non-narrative. In order to obtain high inter-agreements, before the official annotations, we trained the two annotators for several iterations. Note that the texts we used in training annotators are different from the final texts we used for evaluation purposes. The overall kappa inter-agreement between the two annotators is 0.77.

Narratives	Seed	Bootstrapped
News	0.84	0.72
Novel	0.88	0.92
Blogs	0.92	0.88
AVG	0.88	0.84

Table 2: Precision of narratives based on human annotation

pairs	graduate $\to$ teach (5.7), meet $\to$ marry (5.3) pick up $\to$ carry (6.3), park $\to$ get out (7.3) turn around $\to$ face (6.5), dial $\to$ ring (6.3)
chains	drive $\to$ park $\to$ get out (7.8) toss $\to$ fly $\to$ land (5.9) grow up $\to$ attend $\to$ graduate $\to$ marry (6.9) contact $\to$ call $\to$ invite $\to$ accept (4.2) knock $\to$ open $\to$ reach $\to$ pull out $\to$ hold (6.0)

Table 3: Examples of event pairs and chains (with CP scores). $\to$ represents *before* relation.

Table 2 shows the precision of narratives learned in the two stages using the three corpora. We determined that a text is a correct narrative if both annotators labeled it as a narrative. We can see that on average, the rule-based classifier achieves the precision of 88% on initializing seed narratives and the statistical classifier achieves the precision of 84% on bootstrapping new ones. Using narratology based features enables the statistical classifier to extensively learn new narrative, and meanwhile maintain a high precision.

6.2 Precision of Event Pairs and Chains

To evaluate the quality of the extracted event pairs and chains, we randomly sampled 20 pairs (2%) from every 1,000 event pairs up to the top 18,929 pairs with CP score $\geq$ 2.0 (380 pairs selected in total), and 10 chains (1%) from every 1,000 up to the top 25,000 event chains[12] (250 chains selected in total). The average CP scores for all event pairs and all event chains we considered are 2.9 and 5.1 respectively. Two human adjudicators were asked to judge whether or not events are likely to occur in the temporal order shown. For event chains, we have one additional criterion requiring that events form a coherent sequence overall. An

[12]It turns out that many event chains have a high CP score close to 5.0, so we decided not to use a cut-off CP score of event chains but simply chose to evaluate the top 25,000 event chains.

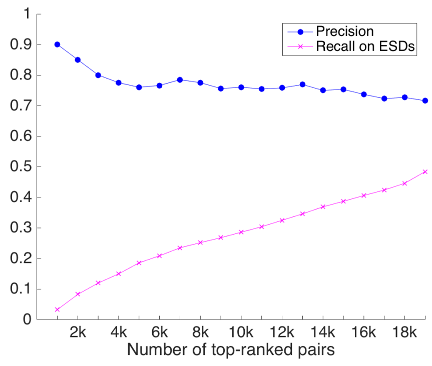

Figure 3: Top-ranked event pairs evaluation

# of top chains	5k	10k	15k	20k	25k
Precision	0.76	0.8	0.75	0.73	0.69

Table 4: Precision of top-ranked event chains

event pair/chain is deemed correct if both annotators labeled it as correct. The two annotators achieved kappa inter-agreement scores of 0.71 and 0.66, on annotating event pairs and event chains respectively.

As we know, coverage on acquired knowledge is often hard to evaluate because we do not have a complete knowledge base to compare to. Thus, we propose a pseudo recall metric to evaluate the coverage of event knowledge we acquired. Regneri et al. (2010) collected Event Sequence Descriptions (ESDs) of several types of human activities (e.g., baking a cake, going to the theater, etc.) using crowdsourcing. Our first pseudo recall score is calculated based on how many consecutive event pairs in human-written scripts can be found in our top-ranked event pairs. Figure 3 illustrates the precision of top-ranked pairs based on human annotation and the pseudo recall score based on ESDs. We can see that about 75% of the top 19k event pairs are correct, which captures 48% of human-written script knowledge in ESDs. In addition, table 4 shows the precision of top-ranked event chains with 3 to 5 events. Among the top 25k event chains, about 70% are correctly ordered with the temporal "after" relation. Table 3 shows several examples of event pairs and chains.

6.3 Improving Temporal Relation Classification by Incorporating Event Knowledge

To find out whether the learned temporal event knowledge can help with improving temporal re-

Models	Acc.(%)

(Wang et al., 2017)	46.67
Our Results	**48.83**

Table 6: Results on MCNC task

lation classification performance, we conducted experiments on a benchmark dataset - TimeBank corpus v1.2, which contains 2308 event pairs that are annotated with 14 temporal relations [13].

To facilitate direct comparisons, we used the same state-of-the-art temporal relation classification system as described in our previous work Choubey and Huang (2017) and considered all the 14 relations in classification. Choubey and Huang (2017) forms three sequences (i.e., word forms, POS tags, and dependency relations) of context words that align with the dependency path between two event mentions and uses three bi-directional LSTMs to get the embedding of each sequence. The final fully connected layer maps the concatenated embeddings of all sequences to 14 fine-grained temporal relations. We applied the same model here, but if an event pair appears in our learned list of event pairs, we concatenated the CP score of the event pair as additional evidence in the final layer. To be consistent with Choubey and Huang (2017), we used the same train/test splitting, the same parameters for the neural network and only considered intra-sentence event pairs. Table 5 shows that by incorporating our learned event knowledge, the overall prediction accuracy was improved by 1.1%. Not surprisingly, out of the 14 temporal relations, the performance on the relation *before* was improved the most by 4.9%.

6.4 Narrative Cloze

Multiple Choice version of the Narrative Cloze task (MCNC) proposed by Granroth-Wilding and Clark (2016); Wang et al. (2017), aims to eval-

[13]Specifically, the 14 relations are *simultaneous, before, after, ibefore, iafter, begins, begun by, ends, ended by, includes, is included, during, during inv, identity*

uate understanding of a script by predicting the next event given several context events. Presenting a chain of contextual events $e_1, e_2, ..., e_{n-1}$, the task is to select the next event from five event candidates, one of which is correct and the others are randomly sampled elsewhere in the corpus. Following the same settings of Wang et al. (2017) and Granroth-Wilding and Clark (2016), we adapted the dataset (test set) of Chambers and Jurafsky (2008) to the multiple choice setting. The dataset contains 69 documents and 349 multiple choice questions.

We calculated a PMI score between a candidate event and each context event $e_1, e_2, ..., e_{n-1}$ based on event sequences extracted from our learned 287k narratives and we chose the event that have the highest sum score of all individual PMI scores. Since the prediction accuracy on 349 multiple choice questions depends on the random initialization of four negative candidate events, we ran the experiment 10 times and took the average accuracy as the final performance.

Table 6 shows the comparisons of our results with the performance of several previous models, which were all trained with 1,500k event chains extracted from the NYT portion of the Gigaword corpus (Graff and Cieri, 2003). Each event chain consists of a sequence of verbs sharing an actor within a news article. Except Chambers and Jurafsky (2008), other recent models utilized more and more sophisticated neural language models. Granroth-Wilding and Clark (2016) proposed a two layer neural network model that learns embeddings of event predicates and their arguments for predicting the next event. Pichotta and Mooney (2016) introduced a LSTM-based language model for event prediction. Wang et al. (2017) used dynamic memory as attention in LSTM for prediction. It is encouraging that by using event knowledge extracted from automatically identified narratives, we achieved the best event prediction performance, which is 2.2% higher than the best neural network model.

7 Conclusions

This paper presents a novel approach for leveraging the double temporality characteristic of narrative texts and acquiring temporal event knowledge across sentences in narrative paragraphs. We developed a weakly supervised system that explores narratology principles and identifies narrative texts from three text corpora of distinct genres. The temporal event knowledge distilled from narrative texts were shown useful to improve temporal relation classification and outperform several neural language models on the narrative cloze task. For the future work, we plan to expand event temporal knowledge acquisition by dealing with event sense disambiguation and event synonym identification (e.g., drag, pull and haul).

Abstract

In this paper, we propose a new strategy, called Text Deconvolution Saliency (TDS), to visualize linguistic information detected by a CNN for text classification. We extend Deconvolution Networks to text in order to present a new perspective on text analysis to the linguistic community. We empirically demonstrated the efficiency of our Text Deconvolution Saliency on corpora from three different languages: English, French, and Latin. For every tested dataset, our Text Deconvolution Saliency automatically encodes complex linguistic patterns based on co-occurrences and possibly on grammatical and syntax analysis.

1 Introduction

As in many other fields of data analysis, Natural Language Processing (NLP) has been strongly impacted by the recent advances in Machine Learning, more particularly with the emergence of Deep Learning techniques. These techniques outperform all other state-of-the-art approaches on a wide range of NLP tasks and so they have been quickly and intensively used in industrial systems. Such systems rely on end-to-end training on large amounts of data, making no prior assumptions about linguistic structure and focusing on stastically frequent patterns. Thus, they somehow step away from computational linguistics as they learn implicit linguistic information automatically without aiming at explaining or even exhibiting classic linguistic structures underlying the decision.

This is the question we raise in this article and that we intend to address by exhibiting classic linguistic patterns which are indeed exploited implictly in deep architectures to lead to higher performances. Do neural networks make use of co-occurrences and other standard features, considered in traditional Textual Data Analysis (TDA) (Textual Mining)? Do they also rely on complementary linguistic structure which is invisible to traditional techniques? If so, projecting neural networks features back onto the input space would highlight new linguistic structures and would lead to improving the analysis of a corpus and a better understanding on where the power of the Deep Learning techniques comes from.

Our hypothesis is that Deep Learning is sensitive to the linguistic units on which the computation of the key statistical sentences is based as well as to phenomena other than frequency and complex linguistic observables. The TDA has more difficulty taking such elements into account – such as linguistic linguistic patterns. Our contribution confronts Textual Data Analysis and Convolutional Neural Networks for text analysis. We take advantage of deconvolution networks for image analysis in order to present a new perspective on text analysis to the linguistic community that we call Text Deconvolution Saliency (TDS). Our deconvolution saliency corresponds to the sum over the word embedding of the deconvolution projection of a given feature map. Such a score provides a heat-map of words in a sentence that highlights the pattern relevant for the classification decision. We examine z-test (see section 4.2) and TDS for three languages: English, French and Latin. For all our datasets, TDS highlights new linguistic observables, invisible with z-test alone.

2 Related work

Convolutional Neural Networks (CNNs) are widely used in the computer vision community for

* L. Vanni and M. Ducoffe contributed equally to this work and should be considered as co-first authors.

a wide panel of tasks: ranging from image classification, object detection to semantic segmentation. It is a bottom-up approach where we applied an input image, stacked layers of convolutions, nonlinearities and sub-sampling.

Encouraged by the success for vision tasks, researchers applied CNNs to text-related problems Kalchbrenner et al. (2014); Kim (2014). The use of CNNs for sentence modeling traces back to Collobert and Weston (2008). Collobert adapted CNNs for various NLP problems including Part-of-Speech tagging, chunking, Named Entity Recognition and semantic labeling. CNNs for NLP work as an analogy between an image and a text representation. Indeed each word is embedded in a vector representation, then several words build a matrix (concatenation of the vectors).

We first discuss our choice of architectures. If Recurrent Neural Networks (*mostly GRU and LSTM*) are known to perform well on a broad range of tasks for text, recent comparisons have confirmed the advantage of CNNs over RNNs when the task at hand is essentially a keyphrase recognition task Yin et al. (2017).

In Textual Mining, we aim at highlighting linguistics patterns in order to analyze their constrast: specificities and similarities in a corpus Feldman, R., and J. Sanger (2007); L. Lebart, A. Salem and L. Berry (1998). It mostly relies on frequential based methods such as z-test. However, such existing methods have so far encountered difficulties in underlining more challenging linguistic knowledge, which up to now have not been empirically observed as for instance syntactical motifs Mellet and Longrée (2009).

In that context, supervised classification, especially CNNs, may be exploited for corpus analysis. Indeed, CNN learns automatically parameters to cluster similar instances and drive away instances from different categories. Eventually, their prediction relies on features which inferred specificities and similarities in a corpus. Projecting such features in the word embedding will reveal relevant spots and may automatize the discovery of new linguistic structures as in the previously cited syntactical motifs. Moreover, CNNs hold other advantages for linguistic analysis. They are static architectures that, according to specific settings are more robust to the vanishing gradient problem, and thus can also model long-term dependency in a sentence Dauphin et al. (2017); Wen et al. (2017); Adel and Schütze (2017). Such a property may help to detect structures relying on different parts of a sentence.

All previous works converged to a shared assessment: both CNNs and RNNs provide relevant, but different kinds of information for text classification. However, though several works have studied linguistic structures inherent in RNNs, to our knowledge, none of them have focused on CNNs. A first line of research has extensively studied the interpretability of word embeddings and their semantic representations Ji and Eisenstein (2014). When it comes to deep architectures, Karpathy et al. Karpathy et al. (2015) used LSTMs on character level language as a testbed. They demonstrate the existence of long-range dependencies on real word data. Their analysis is based on gate activation statistics and is thus global. On another side, Li et al. Li et al. (2015) provided new visualization tools for recurrent models. They use decoders, t-SNE and first derivative saliency, in order to shed light on how neural models work. Our perspective differs from their line of research, as we do not intend to explain how CNNs work on textual data, but rather use their features to provide complementary information for linguistic analysis.

Although the usage of RNNs is more common, there are various visualization tools for CNNs analysis, inspired by the computer vision field. Such works may help us to highlight the linguistic features learned by a CNN. Consequently, our method takes inspiration from those works. Visualization models in computer vision mainly consist in inverting hidden layers in order to spot active regions or features that are relevant to the classification decision. One can either train a decoder network or use backpropagation on the input instance to highlight its most relevant features. While those methods may hold accurate information in their input recovery, they have two main drawbacks: (i) they are computationally expensive: the first method requires training a model for each latent representation, and the second relies on backpropagation for each submitted sentence; (ii) they are highly hyperparameter dependent and may require some finetuning depending on the task at hand. On the other hand, Deconvolution Networks, proposed by Zeiler et al Zeiler and Fergus (2014), provide an off-the-shelf method to project a feature map in the input space. It consists in inverting each convolutional layer iteratively, back to the input space. The inverse of a discrete convolution is computationally challenging. In response, a coarse approximation may be employed which consists of inverting channels and filter weights in a convolutional layer and then transposing their kernel matrix. More details of the deconvolution heuristic are provided in section 3. Deconvolution has several advantages. First, it induces minimal computational requirements compared to previous visualization methods. Also, it has been used with success for semantic segmentation on images: in Noh et al. (2015); Noh et al demonstrate the efficiency of deconvolution networks to predict segmentation masks to identify pixel-wise class labels. Thus deconvolution is able to localize meaningful structure in the input space.

3 Model

3.1 CNN for Text Classification

We propose a deep neural model to capture linguistics patterns in text. This model is based on Convolutional Neural Networks with an embedding layer for word representations, one convolutional with pooling layer and non-linearities. Finally we have two fully-connected layers. The final output size corresponds to the number of classes. The model is trained by cross-entropy with an Adam optimizer. Figure 1 shows the global structure of our architecture. The input is a sequence of words $w_1, w_2...w_n$ and the output contains class probabilities (for text classification).

The embedding is built on top of a Word2Vec architecture, here we consider a Skip-gram model. This embedding is also finetuned by the model to to increase the accuracy. Notice that we do not use lemmatisation, as in Collobert and Weston (2008), thus the linguistic material which is automatically detected does not rely on any prior assumptions about the part of speech. In computer vision, we consider images as 2-dimensional isotropic signals. A text representation may also be considered as a matrix: each word is embedded in a feature vector and their concatenation builds a matrix. However, we cannot assume both dimensions the sequence of words and their embedding representation are isotropic. Thus the filters of CNNs for text typically differ from their counterparts designed for images. Consequently in text, the width of the filter is usually equal to the dimension of the embedding, as illustrated with the red, yellow, blue and green filters in figure 1

Using CNNs has another advantage in our context: due to the convolution operators involved, they can be easily parallelized and may also be easily used by the CPU, which is a practical solution for avoiding the use of GPUs at test time.

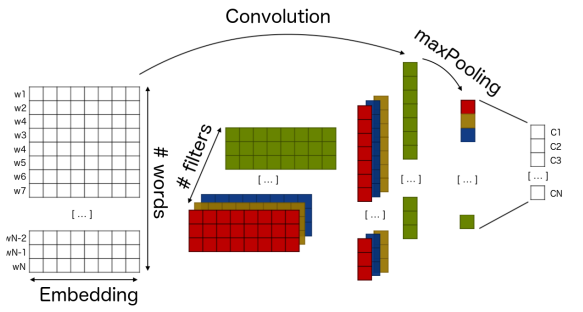

Figure 1: CNN for Text Classification

3.2 Deconvolution

Extending Deconvolution Networks for text is not straightforward. Usually, in computer vision, the deconvolution is represented by a convolution whose weights depends on the filters of the CNN: we invert the weights of the channels and the filters and then transpose each kernel matrix. When considering deconvolution for text, transposing the kernel matrices is not realistic since we are dealing with nonisotropic dimensions - the word sequences and the filter dimension. Eventually, the kernel matrix is not transposed.

Another drawback concerns the dimension of the feature map. Here feature map means the output of the convolution before applying max pooling. Its shape is actually the tuple *(# words, # filters)*. Because the filters' width (red, yellow, blue and green in fig 1) matches the embedding dimension, the feature maps cannot contain this information. To project the feature map in the embedding space, we need to convolve our feature map with the kernel matrices. To this aim, we upsample the feature map to obtain a 3-dimensional sample of size *(# words, embedding dimension, # filters)*.

To analyze the relevance of a word in a sentence, we only keep one value per word which corresponds to the sum along the embedding axis of the output of the deconvolution. We call this sum Text Deconvolution Saliency (TDS).

For the sake of consistency, we sum up our method in figure 2

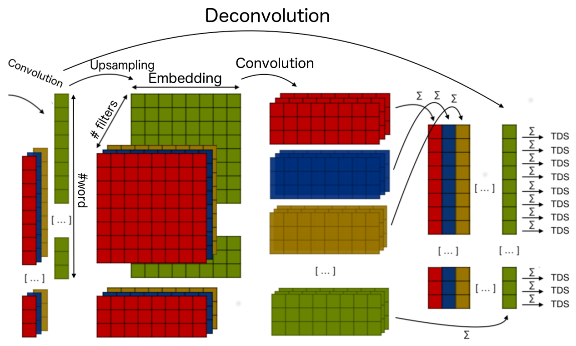

Figure 2: Textual Deconvolution Saliency (TDS)

Eventually, every word in a sentence has a unique TDS score whose value is related to the others. In the next section, we analyze the relevance of TDS. We thoroughly demonstrate empirically, that the TDS encodes complex linguistic patterns based on co-occurrences and possibly also on grammatical and syntaxic analysis.

4 Experiments

4.1 Datasets

In order to understand what the linguistic markers found by the convolutional neural network approach are, we conducted several tests on different languages and our model seems to get the same behavior in all of them. In order to perform all the linguistic statistical tests, we used our own simple linguistic toolbox Hyperbase, which allows the creation of databases from textual corpus, the analysis and the calculations such as z-test, co-occurrences, PCA, K-Means distance,... We use it to evaluate TDS against z-test scoring. We compel our analysis by only presenting cases on which z-test fail while TDS does not. Indeed TDS captures z-test, as we did not find any sentence on which z-test succeeds while TDS fails. Red words in the studied examples are the highest TDS.

The first dataset we used for our experiments is the well known IMDB movie review corpus for sentiment classification. It consists of 25,000 reviews labeled by positive or negative sentiment with around 230,000 words.

The second dataset targets French political discourses. It is a corpus of 2.5 millions of words of French Presidents from 1958 (with De Gaulle, the first President of the Fifth Republic) to 2018 with the first speeches by Macron. In this corpus we have removed Macron's speech from the 31st of December 2017, to use it as a test data set. The training task is to recognize each french president.

The last dataset we used is based on Latin. We assembled a contrastive corpus of 2 million words with 22 principle authors writting in classical Latin. As with the French dataset, the learning task here is to be able to predict each author according to new sequences of words. The next example is an excerpt of chapter 26 of the 23th book of Livy:

> *[...] tutus tenebat se quoad multum ac diu obtestanti quattuor milia peditum et quingenti equites in supplementum missi ex Africa sunt . tum refecta tandem spe* ***castra propius hostem*** *mouit classem que et ipse instrui parari que iubet ad insulas maritimam que oram tutandam . in* ***ipso impetu*** *mouendarum de [...]*

4.2 Z-test Versus Text Deconvolution Saliency

Z-test is one of the standard metrics used in linguistic statistics, in particular to measure the occurrences of word collocations Manning and Schütze (1999). Indeed, the z-test provides a statistical score of the co-occurrence of a sequence of words to appear more frequently than any other sequence of words of the same length. This score results from the comparison between the frequency of the observerd word sequence with the frequency expected in the case of a "Normal" distribution. In the context of constrative corpus analysis, this same calculation applied to single words can readily provide, for example, the most specific vocabulary of a given author. The highest z-test are the most specific words of this given author in this case. This is a simple but strong method for analyzing features of text. It can also be used to classify word sentences according to the global z-test (sum of the scores) of all the words in the given sentence. We can thus use this global z-test as a very simple metric for authorship classification. The resulting authorship of a given sentence is for instance given by the author corresponding to the highest global z-test on that sentence compared to all other global z-test obtained by summing up the z-test of each word of the same sentence but with the vocabulary specificity of another author. The mean accuracy of assigning the right author to the right sentence, in our data set, is around 87%, which confirms that z-test is indeed meaningful for

	z-test	Deep Learning
Latin	84%	93%
French	89%	91%
English	90%	97%

Table 1: Test accuray with z-test and Deep Learning

contrast pattern analysis. On the other hand, most of the time CNN reaches an accuracy greater than 90% for text classification (as shown in Table 1).

This means that the CNN approaches can learn also on their own some of the linguistic specificities useful in discriminating text categories. Previous works on image classification have highlighted the key role of convolutional layers which learn different level of abstractions of the data to make classification easier.

The question is: what is the nature of the abstraction on text?

We show in this article that CNN approach detects automatically words with high z-test but obviously this is not the only linguistic structure detected.

To make the two values comparable, we normalize them. The values can be either positive or negative. And we distinguish between two thresholds[1] for the z-test: over 2 a word is considered as specific and over 5 it is strongly specific (and the oposite with negative values). For the TDS it is just a matter of activation strength.

The Figure 3 shows us a comparison between z-test and TDS on a sentence extracted from our Latin corpora (Livy Book XXIII Chap. 26). This sentence is an example of specific words used by Livy[2]. As we can see, when the z-test is the highest, the TDS is also the highest and the TDS values are high also for the neighbor words (for example around the word *castra*). However, this is not always the case: for example small words as *que* or *et* are also high in z-test but they do not impact the network at the same level. We can see also on Figure 3 that words like *tenebat*, *multum* or *propius* are totally uncorrelated. The Pearson correlation coefficient[3] tells us that in this sentence there is no linear correlation between z-test and TDS (with a Pearson of 0.38). This example is one of the most correlated examples of our dataset, thus CNN seems to learn more than a simple z-test.

[1]The z-test can be approximated by a normal distribution. The score we obtain by the z-test is the standard deviation. A low standard deviation indicates that the data points tend to be close to the mean (the expected value). Over 2 this score means there is less than 2% of chance to have this distribution. Over 5 it's less than 0.1%.

[2]Titus Livius Patavinus – (64 or 59 BC - AD 12 or 17) – was a Roman historian.

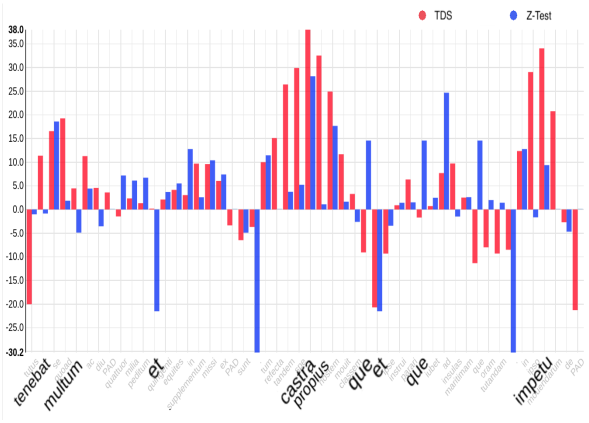

Figure 3: z-test versus Text Deconvolution Saliency (TDS) - Example on Livy Book XXIII Chap. 26

4.3 Dataset: English

For English, we used the IMDB movie review corpus for sentiment classification. With the default methods, we can easily show the specific vocabulary of each class (positive/negative), according to the z-test. There are for example the words *too*, *bad*, *no* or *boring* as most indicitive of negative sentiment, and the words *and*, *performance*, *powerful* or *best* for positive. Is it enough to detect automatically if a new review is positive or not? Let's see an example excerpted from a review from December 2017 (not in the training set) on the last American blockbuster:

> *[...]* ***i enjoyed three moments*** *in the film in total ,* ***and if i am being honest and*** *the person* ***next to me fell asleep*** *in the middle and started snoring during the slow space chasescenes .* ***the story failed to*** *draw me in and entertain* ***me the way*** *[...]*

In general the z-test is sufficient to predict the class of this kind of comment. But in this case, the CNN seems to do better, but why?

[3]Pearson correlation coefficient measures the linear relationship between two datasets. It has a value between $+1$ and -1, where 1 is total positive linear correlation, 0 is no linear correlation, and -1 is total negative

If we sum all the z-test (for negative and positive), the positive class obtains a greater score than the negative. The words *film*, *and*, *honest* and *entertain* – with scores 5.38, 12.23, 4 and 2.4 – make this example positive. CNN has activated different parts of this sentence (as we show in bold/red in the example). If we take the sub-sequence *and if i am being honest and*, there are two occurences of *and* but the first one is followed by *if* and our toolbox gives us 0.84 for *and if* as a negative class. This is far from the 12.23 in the positive. And if we go further, we can do a co-occurrence analysis on *and if* on the training set. As we see with our co-occurrence analysis[4] (Figure 4), *honest* is among the most specific adjectivals[5] associated with *and if*. Exactly what we found in our example.

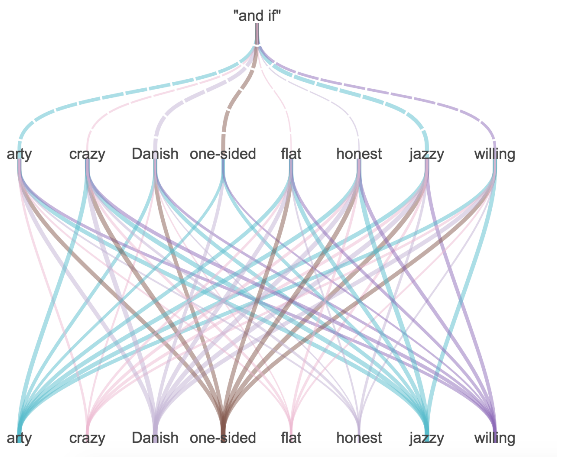

Figure 4: co-occurrences analysis of *and if* (Hyperbase)

In addition, we have the same behavior with the verb *fall*. There is the word *asleep* next to it. *Asleep* alone is not really specific of negative review (z-test of 1.13). But the association of both words become highly specific of negative sentences (see the co-occurrences analysis - Figure 5).

[4]Those figures shows the major co-occurrences for a given word (or lemma or PartOfSpeech). There two layers of co-occurrences, the first one (on top) show the direct co-occurrence and the second (on bottom) show a second level of co-occurrence. This level is given by the context of two words (taken together). The colors and the dotted lines are only used to make it more readable (dotted lines are used for the first level). The width of each line is related to the z-test score (more the z-test is big, more the line is wide).

[5]With our toolbox, we can focus on different part of speech.

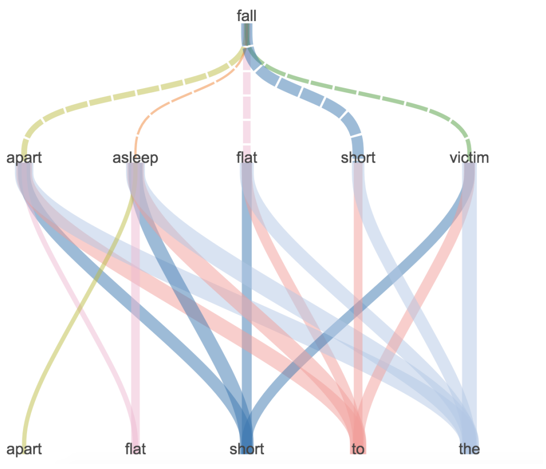

Figure 5: co-occurrences analysis of *fall* (Hyperbase)

The Text Deconvolution Saliency here confirms that the CNN seems to focus not only on high z-test but on more complex patterns and maybe detects the lemma or the part of speech linked to each word. We will see now that these observations are still valid for other languages and can even be generalized between different TDS.

4.4 Dataset: French

In this corpus we have removed Macron's speech from the 31st of December 2017, to use it as a test data set. In this speech, the CNN primarily recognizes Macron (the training task was to be able to predict the correct President). To achieve this task the CNN seems to succeed in finding really complex patterns specific to Macron. For example in this sequence:

> *[...] notre pays* ***advienne à*** *l'école pour nos enfants, au travail pour l' ensemble de* ***nos concitoyens*** *pour le climat pour le quotidien de chacune et chacun d' entre vous .* ***Ces transformations profondes*** *ont commencé et se* ***poursuivront*** *avec la même force le même rythme la même intensité [...]*

The z-test gives a result statistically closer to De Gaulle than to Macron. The error in the statistical attribution can be explained by a Gaullist phraseology and the multiplication of linguistic markers strongly indexed with De Gaulle: De Gaulle had the specificity of making long and literary sentences articulated around co-ordination conjunctions as in *et* (z-test = 28 for de Gaulle, two oc-

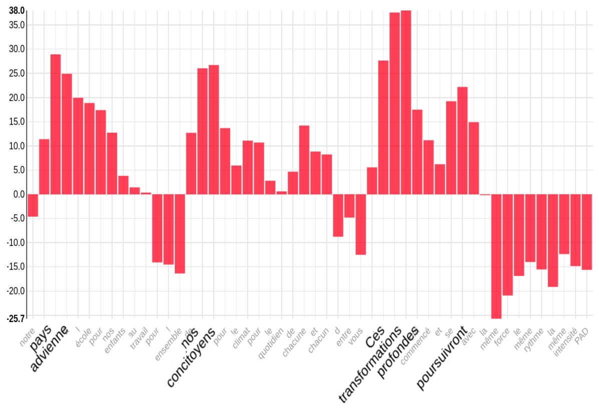

Figure 6: Deconvolution on Macron speech.

currences in the excerpt). His speech was also more conceptual than average, and this resulted in an over-use of the articles defined *le*, *la*, *l´*, *les*) very numerous in the excerpt (7 occurrences); especially in the feminine singular (*la république*, *la liberté*, *la nation*, *la guerre*, etc., here we have *la même force*, *la même intensité*.

The best results given by the CNN may be surprising for a linguist but match perfectly with what is known about the sociolinguistics of Macron's dynamic kind of speeches.

The part of the excerpt, which impacts most the CNN classification, is related to the nominal syntagm *transformations profondes*. Taken separately, neither of the phrase's two words are very Macronian from a statistical point of view (*transformations* = 1.9 *profondes* = 2.9). Better, the syntagm itself does not appear in the President's learning corpus (0 occurrence). However, it can be seen that the co-occurrence of *transformation* and *profondes* amounts to 4.81 at Macron: so it is not the occurrence of one word alone, or the other, which is Macronian but the simultaneous appearance of both in the same window. The second and complementary most impacting part of the excerpt thus is related to the two verbs *advienne* and *poursuivront*. From a semantic point of view, the two verbs perfectly contribute, after the phrase *transformations profondes*, to give the necessary dynamic to a discourse that advocates change. However it is the verb tenses (carried by the morphology of the verbs) that appear to be the determining factor in the analysis. The calculation of the grammatical codes co-occurring with the word *transformations* thus indicates that the verbs in the subjunctive and the verbs in the future (and also the nouns) are the privileged codes for Macron (Figure 7).

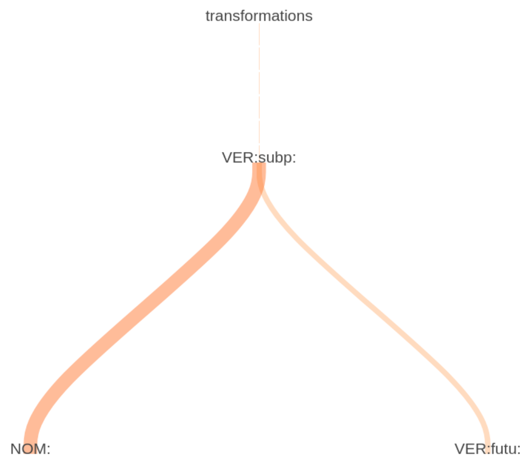

Figure 7: Main part-of-speech co-occurrences for *transformations* (Hyperbase)

More precisely the algorithm indicates that, for Macron, when *transformation* is associated with a verb in the subjunctive (here *advienne*), then there is usually a verb in the future co-present (here *poursuivront*). *transformations profondes*, *advienne* to the subjunctive, *poursuivront* to the future: all these elements together form a speech promising action, from the mouth of a young and dynamic President. Finally, the graph indicates that *transformations* is especially associated with nouns in the President's speeches: in an extraordinary concentration, the excerpt lists 11 (*pays*, *école*, *enfants*, *travail*, *concitoyens*, *climat*, *quotidien*, *transformations*, *force*, *rythme*, *intensité*).

4.5 Dataset: Latin

As with the French dataset, the learning task here is to be able to predict the identity of each author from a contrastive corpus of 2 million words with 22 principle authors writting in classical Latin.

The statistics here identify this sentence as Caesar[6] but Livy is not far off. As historians, Caesar and Livy share a number of specific words: for example tool words like *se* (reflexive pronoun) or *que* (a coordinator) and prepositions like *in*, *ad*, *ex*, *of*. There are also nouns like *equites* (cavalry) or *castra* (fortified camp).

The attribution of the sentence to Caesar cannot only rely only on z-test: *que* or *in* or *castra*, with

[6]Gaius Julius Caesar, 100 BC - 44 BC, usually called Julius Caesar, was a Roman politician and general and a notable author of Latin prose.

differences thereof equivalent or inferior to Livy. On the other hand, the differences of *se*, *ex*, are greater, as is that of *equites*. Two very Caesarian terms undoubtedly make the difference *iubet* (he orders) and *milia* (thousands).

The greater score of *quattuor* (four), *castra*, *hostem* (the enemy), *impetu* (the assault) in Livy are not enough to switch the attribution to this author.

On the other hand, CNN activates several zones appearing at the beginning of sentences and corresponding to coherent syntactic structures (for Livy) – *Tandem reflexes spe castra propius hostem mouit* (then, hope having finally returned, he moved the camp closer to the camp of the enemy) – despite the fact that *castra* in *hostem mouit* is attested only by Tacitus[7].

There are also *in ipso metu* (in fear itself), while *in* followed by *metu* is counted one time with Caesar and one time also with Quinte-Curce[8].

More complex structures are possibly also detected by the CNN: the structure *tum* + participates Ablative Absolute (*tum refecta*) is more characteristic of Livy (z-test 3.3 with 8 occurrences) than of Caesar (z-test 1.7 with 3 occurrences), even if it is even more specific of Tacitus (z-test 4.2 with 10 occurrences).

Finally and more likely, the co-occurrence between *castra*, *hostem* and *impetu* may have played a major role: Figure 8

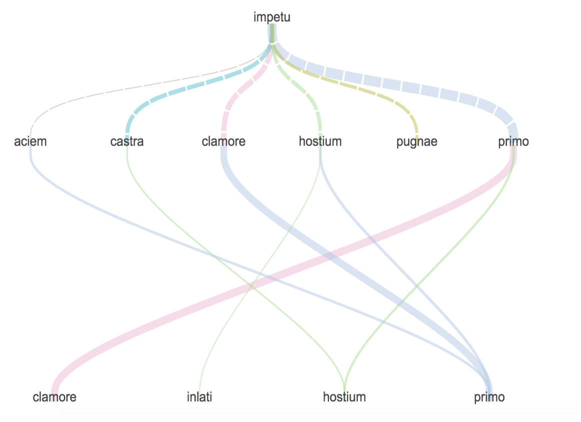

Figure 8: Specific co-occurrences between *impetu* and *castra* (Hyperbase)

With Livy, *impetu* appears as a co-occurrent with the lemmas *hostis* (z-test 9.42) and *castra* (z-test 6.75), while *hostis* only has a gap of 3.41 in Caesar and that *castra* does not appear in the list of co-occurrents.

For *castra*, the first co-occurent for Livy is *hostis* (z-test 22.72), before *castra* (z-test 10.18), *ad* (z-test 10.85), *in* (z-test 8.21), *impetus* (z-test 7.35), *que* (z-test 5.86) while in Caesar, *impetus* does not appear and the scores of all other lemmas are lower except *castra* (z-test 15.15), *hostis* (8), *ad* (10,35), *in* (5,17), *que* (4.79).

Thus, our results suggest that CNNs manage to account for specificity, phrase structure, and co-occurence networks...

4.6 Preprocessings and hyperparameters

In order to make our experiments reproductible, we detail here all the hyperparameters used in our architecture. The neural network is written in python with the library Keras (an tensorflow as backend).

The embedding uses a Word2Vec implementation given by the gensim Library. Here we use the SkipGram model with a window size of 10 words and output vectors of 128 values (embedding dimension).

The textual datas are tokenized by a home-made tokensizer (which work on English, Latin and French). The corpus is splited into 50 length sequence of words (punctuation is keeped) and each word is converted inta an unique vector of 128 value.

The first layer of our model takes the text sequence (as word vectors) and applies a weight corresponding to our WordToVec values. Those weights are still trainable during model training.

The second layer is the convolution, a Conv2D in Keras with 512 filters of size $3 * 128$ (filtering three words at time), with a Relu activation method. Then, there is the Maxpooling (MaxPooling2D)

(The deconvolution model is identical until here. We replace the rest of the classification model (Dense) by a transposed convolution (Conv2DTranspose).)

The last layers of the model are Dense layers. One hidden layer of 100 neurons with a Relu activation and one final layer of size equal to the number of classes with a softmax activation.

All experiments in this paper share the same architecture and the same hyperparameters, and

[7]Publius (or Gaius) Cornelius Tacitus, 56 BC - 120 BC, was a senator and a historian of the Roman Empire.

[8]Quintus Curtius Rufus was a Roman historian, probably of the 1st century, his only known and only surviving work being "Histories of Alexander the Great"

are trained with a cross-entropy method (with an Adam optimizer) with 90% of the dataset for the training data and 10% for the validation. All the tests in this paper are done with new data not included in the original dataset.

5 Conclusion

In a nutshell, Text Deconvolution Saliency is efficient on a wide range of corpora. By crossing statistical approaches with neural networks, we propose a new strategy for automatically detecting complex linguistic observables, which up to now hardly detectable by frequency-based methods. Recall that the linguistic matter and the topology recovered by our TDS cannot return to chance: the zones of activation make it possible to obtain recognition rates of more than 91% on the French political speech and 93% on the Latin corpus; both rates equivalent to or higher than the rates obtained by the statistical calculation of the key passages. Improving the model and understanding all the mathematical and linguistic outcomes remains an import goal. In future work, we intend to thoroughly study the impact of TDS given morphosyntactic information.

Abstract

We propose a novel coherence model for written asynchronous conversations (e.g., forums, emails), and show its applications in coherence assessment and thread reconstruction tasks. We conduct our research in two steps. First, we propose improvements to the recently proposed neural entity grid model by lexicalizing its entity transitions. Then, we extend the model to asynchronous conversations by incorporating the underlying conversational structure in the entity grid representation and feature computation. Our model achieves state of the art results on standard coherence assessment tasks in monologue and conversations outperforming existing models. We also demonstrate its effectiveness in reconstructing thread structures.

1 Introduction

Sentences in a text or a conversation do not occur independently, rather they are connected to form a coherent discourse that is easy to comprehend. **Coherence models** are computational models that can distinguish a coherent discourse from incoherent ones. It has ranges of applications in text generation, summarization, and coherence scoring.

Inspired by formal theories of discourse, a number of coherence models have been proposed (Barzilay and Lapata, 2008; Lin et al., 2011; Li and Jurafsky, 2017). The **entity grid** model (Barzilay and Lapata, 2008) is one of the most popular coherence models that has received much attention over the years. As exemplified in Table 1, the model represents a text by a grid that captures how grammatical roles of different discourse entities (*e.g.,* nouns) change from one sentence to another in the text. The grid is then converted into a feature vector containing probabilities of local entity transitions, enabling machine learning models to measure the degree of coherence. Earlier extensions of this basic model incorporate entity-specific features (Elsner and Charniak, 2011b), multiple ranks (Feng and Hirst, 2012), and coherence relations (Feng et al., 2014).

Recently, Nguyen and Joty (2017) proposed a neural version of the grid models. Their model first transforms the grammatical roles in a grid into their distributed representations, and employs a convolution operation over it to model entity transitions in the distributed space. The spatially max-pooled features from the convoluted features are used for coherence scoring. This model achieves state-of-the-art results in standard evaluation tasks on the Wall Street Journal (WSJ) corpus.

Although the neural grid model effectively captures long entity transitions, it is still limited in that it does not consider any lexical information regarding the entities, thereby, fails to distinguish

between entity types. Although the extended neural grid considers entity features like named entity and proper mention, it requires an explicit feature extraction step, which can prevent us to transfer the model to a resource-poor language or domain.

Apart from these limitations, previous research on coherence models has mainly focused on monologic discourse (*e.g.,* news article). The only exception is the work of Elsner and Charniak (2011a), who applied coherence models to the task of conversation disentanglement in **synchronous** conversations like phone and chat conversations.

With the emergence of Internet technologies, **asynchronous** communication media like emails, blogs, and forums have become a commonplace for discussing events and issues, seeking answers, and sharing personal experiences. Participants in these media interact with each other asynchronously, by writing at different times. We believe coherence models for asynchronous conversations can help many downstream applications in these domains. For example, we will demonstrate later that coherence models can be used to predict the underlying thread structure of a conversation, which provides crucial information for building effective conversation summarization systems (Carenini et al., 2008) and community question answering systems (Barron-Cedeno et al., 2015).

To the best of our knowledge, none has studied the problem of coherence modeling in asynchronous conversation before. Because of its asynchronous nature, information flow in these conversations is often not sequential as in monologue or synchronous conversation. This poses a novel set of challenges for discourse analysis models (Joty et al., 2013; Louis and Cohen, 2015). For example, consider the forum conversation in Figure 2(a). It is not obvious how a coherence model like the entity grid can represent the conversation, and use it in downstream tasks effectively.

In this paper we aim to remedy the above limitations of existing models in two steps. First, we propose improvements to the existing neural grid model by *lexicalizing* its entity transitions. We propose methods based on word embeddings to achieve better generalization with the lexicalized model. Second, we adapt the model to asynchronous conversations by incorporating the underlying *conversational structure* in the grid representation and subsequently in feature computation. For this, we propose a novel grid representation for asynchronous conversations, and adapt the convolution layer of the neural model accordingly.

We evaluate our approach on two discrimination tasks. The first task is the standard one, where we assess the models based on their performance in discriminating an original document from its random permutation. In our second task, we ask the models to distinguish an original document from its inverse order of the sentences. For our adapted model to asynchronous conversation, we also evaluate it on *thread reconstruction*, a task specific to asynchronous conversation. We performed a series of experiments, and our main findings are:

(a) Our experiments on the WSJ corpus validate the utility of our proposed extension to the existing neural grid model, yielding absolute F_1 improvements of up to 4.2% in the standard task and up to 5.2% in the inverse-order discrimination task, setting a new state-of-the-art.

(b) Our experiments on a forum dataset show that our adapted model that considers the conversational structure outperforms the temporal baseline by more than 4% F_1 in the standard task and by about 10% F_1 in the inverse order discrimination task.

(c) When applied to the thread reconstruction task, our model achieves promising results outperforming several strong baselines.

We have released our source code and datasets at `https://ntunlpsg.github.io/project/coherence/n-coh-acl18/`

2 Background

In this section we give an overview of existing coherence models. In the interest of coherence, we defer description of the neural grid model (Nguyen and Joty, 2017) until next section, where we present our extension to this model.

2.1 Traditional Entity Grid Models

Introduced by Barzilay and Lapata (2008), the **entity grid** model represents a text by a two-dimensional matrix. As shown in Table 1, the rows correspond to sentences, and the columns correspond to entities (noun phrases). Each entry $E_{i,j}$ represents the syntactic role that entity e_j plays in sentence s_i, which can be one of: subject (S), object (O), other (X), or absent (–). In cases where an entity appears more than once with different grammatical roles in the same sentence, the role with the highest rank (S $\succ$ O $\succ$ X) is considered.

Motivated by the Centering Theory (Grosz et al., 1995), the model considers **local entity transitions** as the deciding patterns for assessing coherence. A local entity transition of length k is a sequence of $\{\text{S,O,X,–}\}^k$, representing grammatical roles played by an entity in k consecutive sentences. Each grid is represented by a vector of 4^k transition probabilities computed from the grid. To distinguish between transitions of important entities from unimportant ones, the model considers the *salience* of the entities, which is measured by their occurrence frequency in the document. With the feature vector representation, coherence assessment task is formulated as a ranking problem in a SVM preference ranking framework (Joachims, 2002). Barzilay and Lapata (2008) showed significant improvements in two out of three evaluation tasks when a coreference resolver is used to identify coreferent entities in a text.

Elsner and Charniak (2011b) show improvements to the grid model by including non-head nouns as entities. Instead of employing a coreference resolver, they match the nouns to detect coreferent entities. They demonstrate further improvements by extending the grid to distinguish between entities of different types. They do so by incorporating entity-specific features like named entity, noun class and modifiers. Lin et al. (2011) model transitions of discourse roles for entities as opposed to their grammatical roles. They instantiate discourse roles by discourse relations in Penn Discourse Treebank (Prasad et al., 2008). In a follow up work, Feng et al. (2014) trained the same model but using relations derived from deep discourse structures annotated with Rhetorical Structure Theory (Mann and Thompson, 1988).

2.2 Other Existing Models

Guinaudeau and Strube (2013) proposed a **graph-based** unsupervised method. They convert an entity grid into a bipartite graph consisting of two sets of nodes, representing sentences and entities, respectively. The edges are assigned weights based on the grammatical role of the entities in the respective sentences. They perform one-mode projections to transform the bipartite graph to a directed graph containing only sentence nodes. The coherence score of the document is then computed as the average *out-degree* of sentence nodes.

Louis and Nenkova (2012) introduced a coherence model based on **syntactic patterns** by assuming that sentences in a coherent text exhibit certain syntactic regularities. They propose a local coherence model that captures the co-occurrence of structural features in adjacent sentences, and a global model based on a hidden Markov model, which learns the global syntactic patterns from clusters of sentences with similar syntax.

Li and Hovy (2014) proposed a **neural** framework to compute the coherence score of a document by estimating coherence probability for every window of three sentences. They encode each sentence in the window using either a recurrent or a recursive neural network. To get a document-level coherence score, they sum up the window-level log probabilities. Li and Jurafsky (2017) proposed two encoder-decoder models augmented with latent variables for both coherence evaluation and discourse generation. Their first model incorporates global discourse information (topics) by feeding the output of a sentence-level HMM-LDA model (Gruber et al., 2007) into the encoder-decoder model. Their second model is trained end-to-end with variational inference.

In our work, we take an entity-based approach, and extend the neural grid model proposed recently by Nguyen and Joty (2017).

3 Extending Neural Entity Grid

In this section we first briefly describe the neural entity grid model proposed by Nguyen and Joty (2017). Then, we propose our extension to this model that leads to improved performance. We present our coherence model for asynchronous conversation in the next section.

3.1 Neural Entity Grid

Figure 1 depicts the neural grid model of Nguyen and Joty (2017). Given an entity grid E, they first transform each entry $E_{i,j}$ (a grammatical role) into a distributed representation of d dimensions by looking up a shared embedding matrix $M \in \mathbb{R}^{|G|\times d}$, where G is the vocabulary of possible grammatical roles, *i.e.,* $G = \{S, O, X, -\}$. Formally, the look-up operation can be expressed as:

$$L = \Big[M(E_{1,1}) \cdots M(E_{i,j}) \cdots M(E_{I,J})\Big] \quad (1)$$

where $M(E_{i,j})$ refers to the row in M that corresponds to grammatical role $E_{i,j}$, and I and J are

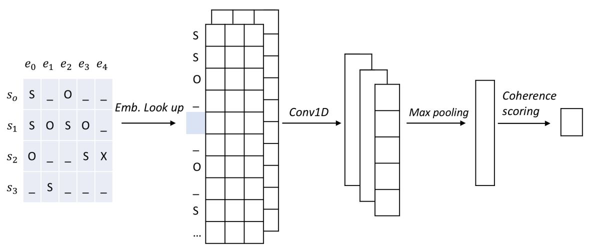

Figure 1: Neural entity grid model proposed by Nguyen and Joty (2017). The model is trained using a pairwise ranking approach with shared parameters for positive and negative documents.

the number of rows (sentences) and columns (entities) in the entity grid, respectively. The result of the look-up operation is a tensor $L \in \mathbb{R}^{I \times J \times d}$, which is fed to a convolution layer to model local entity transitions in the distributed space.

The convolution layer of the neural network composes patches of entity transitions into high-level abstract features by treating entities independently (*i.e.,* 1D convolution). Formally, it applies a *filter* $\mathbf{w} \in \mathbb{R}^{m.d}$ to each local entity transition of length m to generate a new abstract feature z_i:

$$z_i = h(\mathbf{w}^T L_{i:i+m,j} + b_i) \qquad (2)$$

where $L_{i:i+m,j}$ denotes concatenation of m vectors in L for entity e_j, b_i is a bias term, and h is a nonlinear activation function. Repeated application of this filter to each possible m-length transitions of different entities in the grid generates a *feature map*, $\mathbf{z}^i = [z_1, \cdots, z_{I.J+m-1}]$. This process is repeated N times with N different filters to get N different feature maps, $[\mathbf{z}^1, \cdots, \mathbf{z}^N]$. A *max-pooling* operation is then applied to extract the most salient features from each feature map:

$$\mathbf{p} = [\mu_l(\mathbf{z}^1), \cdots, \mu_l(\mathbf{z}^N)] \qquad (3)$$

where $\mu_l(\mathbf{z}^i)$ refers to the $\max$ operation applied to each non-overlapping window of l features in the feature map $\mathbf{z}^i$. Finally, the pooled features are used in a linear layer to produce a *coherence score*:

$$y = \mathbf{u}^T \mathbf{p} + b \qquad (4)$$

where $\mathbf{u}$ is the weight vector and b is a bias term. The model is trained with a *pairwise ranking* loss based on ordered training pairs (E_i, E_j):

$$\mathcal{L}(\theta) = \max\{0, 1 - \phi(E_i|\theta) + \phi(E_j|\theta)\} \qquad (5)$$

where entity grid E_i exhibits a higher degree of coherence than grid E_j, and $y = \phi(E_k|\theta)$ denotes the transformation of input grid E_k to a coherence score y done by the model with parameters θ. We will see later that such ordering of documents (grids) can be obtained automatically by permuting the original document. Notice that the network shares its parameters (θ) between the positive (E_i) and the negative (E_j) instances in a pair.

Since entity transitions in the convolution step are modeled in a continuous space, it can effectively capture longer transitions compared to traditional grid models. Unlike traditional grid models that compute transition probabilities from a *single* grid, convolution filters and role embeddings in the neural model are learned from all training instances, which helps the model to generalize well.

Since the abstract features in the feature maps are generated by convolving over role transitions of different entities in a document, the model implicitly considers relations between entities in a document, whereas transition probabilities in traditional entity grid models are computed without considering any such relation between entities. Convolution over the entire grid also incorporates *global* information (*e.g.,* topic) of a discourse.

3.2 Lexicalized Neural Entity Grid

Despite its effectiveness, the neural grid model presented above has a limitation. It does not consider any lexical information regarding the entities, thus, cannot distinguish between transitions of different entities. Although the extended neural grid model proposed in (Nguyen and Joty, 2017) does incorporate entity features like named entity type and proper mention, it requires an explicit feature extraction step using tools like named entity recognizer. This can prevent us in transferring the model to resource-poor languages or domains.

To address this limitation, we propose to lexicalize entity transitions. This can be achieved by attaching the entity with the grammatical roles. For example, if an entity e_j appears as a subject (S) in sentence s_i, the grid entry $E_{i,j}$ will be encoded as e_j-S. This way, an entity OBAMA as subject (OBAMA-S) and as object (OBAMA-O) will have separate entries in the embedding matrix M. We can initialize the word-role embeddings randomly, or with pre-trained embeddings for the word (OBAMA). In another variation, we kept word and role embeddings separate and con-

catenated them after the look-up, thus enforcing OBAMA-S and OBAMA-O to share a part of their representations. However, in our experiments, we found the former approach to be more effective.

4 Coherence Models for Asynchronous Conversations

The main difference between monologue and asynchronous conversation is that information flow in asynchronous conversation is not sequential as in monologue, rather it is often interleaved. For example, consider the forum conversation in Figure 2(a). There are three possible subconversations, each corresponding to a path from the root node to a leaf node in the conversation graph in Figure 2(b). In response to seeking suggestions about how to clean *system registry*, the first path ($p_1 \leftarrow p_2$) suggests to use *regedit*, the second path ($p_1 \leftarrow p_3$) suggests *ccleaner*, and the third one ($p_1 \leftarrow p_4$) suggests using *regseeker*. These discussions are interleaved in the chronological order of the posts ($p_1 \leftarrow p_2 \leftarrow p_3 \leftarrow p_4 \leftarrow p_5$). Therefore, monologue-based coherence models may not be effective if applied directly to the conversation.

We hypothesize that coherence models for asynchronous conversation should incorporate the conversational structure like the tree structure in Figure 2(b), where the nodes represent posts and the edges represent ‘reply-to’ links between them. Since the grid models operate at the sentence level, we construct conversational structure at the sentence level. We do this by linking the boundary sentences across posts and by linking sentences in the same post chronologically. Specifically, we connect the first sentence of post p_j to the last sentence of post p_i if p_j replies to p_i, and sentence s_{t+1} is linked to s_t if both s_t and s_{t+1} are in the same post.[1] Now the question is, how can we represent a conversation tree with an entity grid, and then model entity transitions in the tree? In the following, we describe our approach to this problem.

4.1 Conversational Entity Grid

The conversation tree captures how topics flow in an asynchronous conversation. Our key hypothesis is that in a coherent conversation entities exhibit certain local patterns in the conversation tree in terms of their distribution and syntactic realization. Figure 2(c) shows how the grammatical roles of entity *‘registry’* in our example conversation change over the tree. For coherence assessment, we wish to model entity transitions along each of the conversation paths (top-to-bottom), and also their spatial relations across the paths (left-to-right). The existing grid representation is insufficient to model the *two-dimensional (2D) spatial* entity transitions in a conversation tree.

We propose a three-dimensional (3D) grid for representing entity transitions in an asynchronous conversation. The first dimension in our grid rep-

[1]The links between sentences are not explicitly shown in Figure 2(b) to avoid visual clutter.

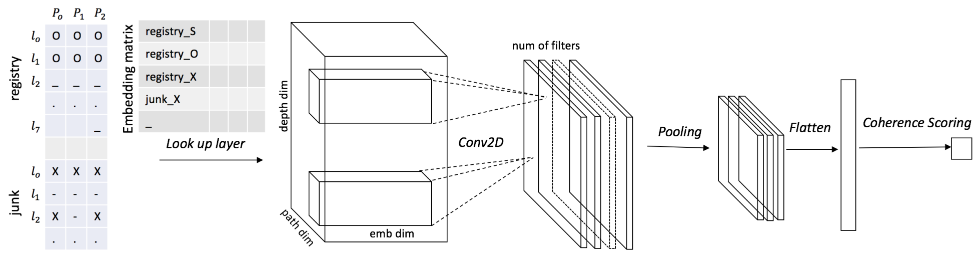

Figure 3: **Conversational Neural Grid** model for assessing coherence in asynchronous conversations.

resents *entities*, while the second and third dimensions represent *depth* and *path* of the tree, respectively. Figure 2(d) shows an example representation for an entity '*registry*'. Each column in the matrix represents transitions of the entity along a path, whereas each row represents transitions of the entity at a level of the conversation tree.

Although illustrated with a tree structure, our method is applicable to general graph-structured conversations, where a post can reply to multiple previous posts. Our model relies on paths from the root to the leaf nodes, which can be extracted for any graph as long as we avoid loops.

4.2 Modeling Entity Transitions

As shown in Figure 3, given a 3D entity grid as input, the look-up layer (Eq. 1) of our neural grid model produces a 4D tensor $L \in \mathbb{R}^{I \times J \times P \times d}$, where I is the total number of entities in the conversation, J is the depth of the tree, P is the number of paths in the tree, and d is the embedding dimension. The convolution layer then uses a 2D filter $\mathbf{w} \in \mathbb{R}^{m.n.d}$ to convolve local patches of entity transitions

$$z_i = h(\mathbf{w}^T L_{i,j:j+m,p:p+n} + b_i) \tag{6}$$

where m and n are the height and width of the filter, and $L_{i,j:j+m,p:p+n} \in \mathbb{R}^{m.n.d}$ denotes a concatenated vector containing $(m \times n)$ embeddings representing a 2D window of entity transitions. As we repeatedly apply the filter to each possible window with stride size 1, we get a 2D feature map Z^i of dimensions $(I.J+m-1) \times (I.P+n-1)$. Employing N different filters, we get N such 2D feature maps, $[Z^1, \cdots, Z^N]$, based on which the max pooling layer extracts the most salient features:

$$\mathbf{p} = [\mu_{l \times w}(Z^1), \cdots, \mu_{l \times w}(Z^N)] \tag{7}$$

where $\mu_{l \times w}$ refers to the $\max$ operation applied to each non-overlapping 2D window of $l \times w$ features in a feature map. The pooled features are then linearized and used for coherence scoring in the final layer of the network as described by Equation 4.

5 Experiments on Monologue

To validate our proposed extension to the neural grid model, we first evaluate our lexicalized neural grid model in the standard evaluation setting.

Evaluation Tasks and Dataset: We evaluate our models on the standard **discrimination** task (Barzilay and Lapata, 2008), where a coherence model is asked to distinguish an original document from its incoherent renderings generated by random permutations of its sentences. The model is considered correct if it ranks the original document higher than the permuted one.

We use the same train-test split of the WSJ dataset as used in (Nguyen and Joty, 2017) and other studies (Elsner and Charniak, 2011b; Feng et al., 2014). Following previous studies, we use 20 random permutations of each article for both training and testing, and exclude permutations that match the original article. Table 2 gives some statistics about the dataset along with the number of pairs used for training and testing. Nguyen and Joty (2017) randomly selected 10% of the training pairs for development purposes, which we also use for tuning hyperparameters in our models.

In addition to the standard setting, we also evaluate our models on an *inverse-order* setting, where we ask the models to distinguish an original document from the inverse order of its sentences (*i.e.,* from last to first). The transitions of roles in a negative grid are in the reverse order of the original grid. We do not train our models explicitly on this task, rather use the trained model from the standard setting. The number of test pairs in this setting is same as the number of test documents.

Model Settings and Training: We train the neural models with the pairwise ranking loss in Equation 5. For a fair comparison, we use

similar model settings as in (Nguyen and Joty, 2017)[2] – ReLU as activation functions (h), RMSprop (Tieleman and Hinton, 2012) as the learning algorithm, Glorot-uniform (Glorot and Bengio, 2010) for initializing weight matrices, and uniform $\mathcal{U}(-0.01, 0.01)$ for initializing embeddings randomly. We applied batch normalization (Ioffe and Szegedy, 2015), which gave better results than using dropout. Minibatch size, embedding size and filter number were fixed to 32, 300 and 150, respectively. We tuned for optimal filter and pooling lengths in $\{2, \cdots, 12\}$. We train up to 25 epochs, and select the model that performs best on the development set; see **supplementary** documents for best hyperparameter settings for different models. We run each experiment five times, each time with a different random seed, and we report the average of the runs to avoid any randomness in results. Statistical significance tests are done using an *approximate randomization* test with SIGF V.2 (Padó, 2006).

Results and Discussions: We present our results on the standard discrimination task and the inverse-order task in Table 3; see Std (F_1) and Inv (F_1) columns, respectively. For space limitations, we only show F_1 scores here, and report both accuracy and F_1 in the supplementary document. We compare our lexicalized models (group III) with the unlexicalized models (group II) of Nguyen and Joty (2017).[3] We also report the results of non-neural entity grid models (Elsner and Charniak, 2011b) in group I. The extended versions use entity-specific features.

We experimented with both *random* and *pre-trained* initialization for word embeddings in our lexicalized models. As can be noticed in Table 3, both versions give significant improvements over the unlexicalized models on both the standard and the inverse-order discrimination tasks (2.7 - 4.3% absolute). Our best model with Google pre-trained embeddings (Mikolov et al., 2013) yields state-of-the-art results. We also experimented

[2]https://ntunlpsg.github.io/project/coherence/n-coh-acl17

[3]Our reproduced results for the neural grid model are slightly lower than their reported results ($\sim 1\%$). We suspect this is due to the randomness in the experimental setup.

	Model	Emb.	**Std** (F_1)	**Inv** (F_1)
I	Grid (E&C)	-	81.60	75.78
	Ext. Grid (E&C)	-	84.95	80.34
II	Neural Grid (N&J)	Random	84.36	83.94
	Ext. Neural Grid (N&J)	Random	85.93	83.00
III	Lex. Neural Grid	Random	$87.03^{\dagger}$	$86.88^{\dagger}$
	Lex. Neural Grid	Google	$\mathbf{88.56}^{\dagger}$	$\mathbf{88.23}^{\dagger}$

Table 3: Discrimination results on the **WSJ** dataset. Superscript † indicates a lexicalized model is significantly superior to the unlexicalized Neural Grid (N&J) model with p-value < 0.01.

with Glove (Pennington et al., 2014), which has more vocabulary coverage than word2vec – Glove covers 89.77% of our vocabulary items, whereas word2vec covers 85.66%. However, Glove did not perform well giving F_1 score of 86% in the standard discrimination task. Schnabel et al. (2015) also report similar results where word2vec was found to be superior to Glove in most evaluation tasks. Our model also outperforms the extended neural grid model that relies on an additional feature extraction step for entity features. These results demonstrate the efficacy of lexicalization in capturing fine-grained entity information without loosing generalizability, thanks to distributed representation and pre-trained embeddings.

6 Experiments on Conversation

We evaluate our coherence models for asynchronous conversations on two tasks: discrimination and thread reconstruction.

6.1 Evaluation on Discrimination

The discrimination tasks are applicable to conversations also. We first present the dataset we use, then we describe how we create coherent and incoherent examples to train and test our models.

Dataset: Our conversational corpus contains discussion threads regarding *computer troubleshooting* from the technology related news site CNET.[4] This corpus was originally collected by Louis and Cohen (2015), and it contains 13,352 threads. For our experiments, we selected 3,825 threads assuring that each contains at least 3 and at most 15 posts. We use 2,400 threads for training, 750 for testing and 675 for development purposes. Table 4 shows some basic statistics about the resulting dataset. The threads roughly contain 29 sentences and 6 comments on average.

[4]https://www.cnet.com/

	#Thread	Avg Com	Avg Sen	#Pairs (tree)	#Pairs (path)
Train	2,400	6.01	28.76	47,948	106,122
Test	750	5.75	27.79	14,986	33,852
Dev	675	6.27	30.70	13,485	28,897
Total	3,825	5.98	28.77	76,419	168,871

Table 4: Statistics on the **CNET** dataset.

Model Settings and Training: To validate the efficacy of our conversational grid model, we compare it with the following baseline settings:

• **Temporal:** In the temporal setting, we construct an entity grid from the chronological order of the sentences in a conversation, and use it with our monologue-based coherence models. Models in this setting thus disregard the structure of the conversation and treat it as a monologue.

• **Path-level:** This is a special case of our model, where we consider each path (a column in our conversational grid) in the conversation tree separately. We construct an entity grid for a path and provide as input to our monologue-based models.

To train the models with pairwise ranking, we create 20 incoherent conversations for each original conversation by shuffling the sentences in their temporal order. For models involving conversation trees (path-level and our model), the tree structure remains unchanged for original and permuted conversations, only the position of the sentences vary based on the permutation. Since the shuffling is done globally at the conversation level, this scheme allows us to compare the three representations (temporal, path-level and tree-level) fairly with the same set of permutations.

An incoherent conversation may have paths in the tree that match the original paths. We remove those matched paths when training the path-level model. See Table 4 for number of pairs used for training and testing our models. We evaluate path-level models by aggregating correct/wrong decisions for the paths – if the model makes more correct decisions for the original conversation than the incoherent one, it is counted as a correct decision overall. Aggregating path-level *coherence scores* (*e.g.,* by averaging or summing) would allow a coherence model to get awarded for assigning higher score to an original path (hence, correct) while making wrong decisions for the rest; see supplementary document for an example. Similar to the setting in Monologue, we did not train explicitly on the inverse-order task, rather use the trained model from the standard setting.

Conv. Rep	Model	Emb.	**Std** (F_1)	**Inv** (F_1)
Temporal	Neural Grid (N&J)	random	82.28	70.53
	Lex. Neural Grid	random	86.63	80.40
	Lex. Neural Grid	Google	87.17	80.76
Path-level	Neural Grid (N&J)	random	82.39	75.68†
	Lex. Neural Grid	random	88.13	88.38†
	Lex. Neural Grid	Google	88.44	89.31†
Tree-level	Neural Grid (N&J)	random	83.98†	77.33†
	Lex. Neural Grid	random	89.87†	89.23†
	Lex. Neural Grid	Google	**91.29**†	**90.40**†

Table 5: Discrimination results on **CNET**. Superscript † indicates a model is significantly superior to its temporal counterpart with p-value < 0.01.

Results and Discussions: Table 5 compares the results of our models on the two discrimination tasks. We observe more gains in conversation than in monologue for the lexicalized models – 4.9% to 7.3% on the standard task, and 10% to 13.6% on the inverse-order task. Notice especially the huge gains on the inverse-order task. This indicates lexicalization helps to better adapt to new domains.

A comparison of the results on the standard task across the representations shows that path-level models perform on par with the temporal models, whereas the tree-level models outperform others by a significant margin. The improvements are 2.7% for randomly initialized word vectors and 4% for Google embeddings. Although, the path-level model considers some conversational structures, it observes only a portion of the conversation in its input. The common topics (expressed by entities) of a conversation get distributed across multiple conversational paths. This limits the path-level model to learn complex relationships between entities in a conversation. By encoding an entire conversation into a single grid and by modeling the spatial relations between the entities, our conversational grid model captures both local and global information (topic) of a conversation.

Interestingly, the improvements are higher on the inverse-order task for both path- and tree-level models. The inverse order yields more dissimilarity at the paths with respect to the original order, thus making them easier to distinguish.

If we notice the hyperparameter settings for the best models on this task (see supplementary document), we see they use a filter width of 1. This indicates that to find the right order of the sentences in conversations, it is sufficient to consider entity transitions along the conversational paths in a tree.

6.2 Evaluation on Thread Reconstruction

One crucial advantage of our tree-level model over other models is that we can use it to build predictive models to uncover the thread structure of a conversation from its posts. Consider again the thread in Figure 2. Our goal is to train a coherence model that can recover the tree structure in Figure 2(b) from the sequence of posts $(p_1, p_2, \ldots, p_5)$.

This task has been addressed previously (Wang et al., 2008, 2011). Most methods learn an edge-level classifier to decide for a possible link between two posts using features like distance in position/time, cosine similarity, etc. To our knowledge, we are the first to use coherence models for this problem. However, our goal in this paper is not to build a state-of-the-art system for thread reconstruction, rather to evaluate coherence models by showing its effectiveness in scoring candidate tree hypotheses. In contrast to previous methods, our approach therefore considers the whole thread structure at once, and computes coherence scores for all possible candidate trees of a conversation. The tree that receives the highest score is predicted as the thread structure of the conversation.

Training: We train our coherence model for thread reconstruction using pairwise ranking loss as before. For a given sequence of comments in a thread, we construct a set of valid candidate trees; a valid tree is one that respects the chronological order of the comments, *i.e.,* a comment can only reply to a comment that precedes it. The training set contains ordered pairs (T_i, T_j), where T_i is a true (gold) tree and T_j is a valid but false tree.

Experiments: The number of valid trees grows exponentially with the number of posts in a thread, which makes the inference difficult. As a proof of concept that coherence models are useful for finding the right tree, we built a simpler dataset by selecting forum threads from the CNET corpus ensuring that a thread contains at most 5 posts. The final dataset contains 1200 threads with an average of 3.8 posts and 27.64 sentences per thread.

We assess the performance of the models at two levels: (*i*) **thread-level**, where we evaluate if the model could identify the entire conversation thread correctly, and (*ii*) **edge-level**, where we evaluate if the model could identify individual replies correctly. For comparison, we use a number of simple but well performing baselines:

- **All-previous** creates thread structure by linking a comment to its previous (in time) comment.
- **All-first** creates thread structure by linking all the comments to the initial comment.
- **COS-sim** creates thread structure by linking a comment to one of the previous comments with which it has the highest cosine similarity. We use TF.IDF representation for the comments.

	Thread-level	**Edge-level**	
	Acc	F_1	Acc
All-previous	27.00	52.00	61.83
All-first	25.67	48.23	58.19
COS-sim	27.66	50.56	60.30
Conv. Entity Grid	**30.33**†	**53.59**†	**62.81**†

Table 6: Thread reconstruction results; † indicates significant difference from COS-sim (p< .01).

Table 6 compares our best conversational grid model (tree-level with Google vectors) with the baselines. The low thread-level accuracy across all the systems prove that reconstructing an entire tree is a difficult task. Models are reasonably accurate at the edge level. Our coherence model shows promising results, yielding substantial improvements over the baselines. It delivers 2.7% improvements in thread-level and 2.5% in edge-level accuracy over the best baseline (COS-sim).

Interestingly, our best model for this task uses a filter width of 2 (maximum can be 4 for 5 posts). This indicates that spatial (left-to-right) relations between entity transitions are important to find the right thread structure of a conversation.

7 Conclusion

We presented a coherence model for asynchronous conversations. We first extended the existing neural grid model by lexicalizing its entity transitions. We then adapt the model to conversational discourse by incorporating the thread structure in its grid representation and feature computation. We designed a 3D grid representation for capturing spatio-temporal entity transitions in a conversation tree, and employed a 2D convolution to compose high-level features from this representation.

Our lexicalized grid model yields state of the art results on standard coherence assessment tasks in monologue and conversations. We also show a novel application of our model in forum thread reconstruction. Our future goal is to use the coherence model to generate new conversations.

Abstract

Deep neural network models for Chinese zero pronoun resolution learn semantic information for zero pronoun and candidate antecedents, but tend to be short-sighted—they often make local decisions. They typically predict coreference chains between the zero pronoun and one single candidate antecedent one link at a time, while overlooking their long-term influence on future decisions. Ideally, modeling useful information of preceding potential antecedents is critical when later predicting zero pronoun-candidate antecedent pairs. In this study, we show how to integrate local and global decision-making by exploiting deep reinforcement learning models. With the help of the reinforcement learning agent, our model learns the policy of selecting antecedents in a sequential manner, where useful information provided by earlier predicted antecedents could be utilized for making later coreference decisions. Experimental results on OntoNotes 5.0 dataset show that our technique surpasses the state-of-the-art models.

1 Introduction

Zero pronoun, as a special linguistic phenomenon in pro-dropped languages, is pervasive in Chinese documents (Zhao and Ng, 2007). A zero pronoun is a gap in the sentence, which refers to the component that is omitted because of the coherence of language. Following shows an example of zero pronoun in Chinese document, where zero pronouns are represented as "ϕ".

[当事人 李亚鼎] 除了 表示 ϕ_1 欣然 接受 但 ϕ_2 也 希望 国家 要 有 人 负责。

([Litigant Li Yading] not only shows ϕ_1 willing of acception, but also ϕ_2 hopes that there should be someone in charge of it.)

A zero pronoun can be an anaphoric zero pronoun if it coreferes to one or more mentions in the associated text, or unanaphoric, if there are no such mentions. In this example, the second zero pronoun "ϕ_2" is anaphoric and corefers to the mention "当事人李亚鼎/Litigant Li Yading" while the zero pronoun "ϕ_1" is unanaphoric. These mentions that contain the important information for interpreting the zero pronoun are called the antecedents.

In recent years, deep learning models for Chinese zero pronoun resolution have been widely investigated (Chen and Ng, 2016; Yin et al., 2017a,b). These solutions concentrate on anaphoric zero pronoun resolution, applying numerous neural network models to zero pronoun-candidate antecedent prediction. Neural network models have demonstrated their capabilities to learn vector-space semantics of zero pronouns and their antecedents (Yin et al., 2017a,b), and substantially surpass classic models (Zhao and Ng, 2007; Chen and Ng, 2013, 2015), obtaining state-of-the-art results on the benchmark dataset.

However, these models are heavily making local coreference decisions. They simply consider the coreference chain between the zero pronoun and one single candidate antecedent one link at a time while overlooking their impacts on future decisions. Intuitively, antecedents provide key linguistic cues for explaining the zero pronoun, it is therefore reasonable to leverage useful information provided by previously predicted antecedents as cues for predicting the later zero pronoun-candidate antecedent pairs. For instance, given a sentence "I have confidence that ϕ can do it." with its candidate mentions "he", "the boy" and "I", it is challenging to infer whether mention "I" is pos-

[*]Corresponding author.

sible to be the antecedent if it is considered separately. In that case, the resolver may incorrectly predict "I" to be the antecedent since "I" is the nearest mention. Nevertheless, if we know that "he" and "the boy" have already been predicted to be the antecedents, it is uncomplicated to infer the ϕ-"I" pair as "non-coreference" because "I" corefers to the disparate entity that is refered by "he". Hence, a desirable resolver should be able to 1) take advantage of cues of previously predicted antecedents, which could be incorporated to help classify later candidate antecedents and 2) model the long-term influence of the single coreference decision in a sequential manner.

To achieve these goals, we propose a deep reinforcement learning model for anaphoric zero pronoun resolution. On top of the neural network models (Yin et al., 2017a,b), two main innovations are introduced that are capable of efficaciously leveraging effective information provided by potential antecedents, and making long-term decisions from a global perspective. First, when dealing with a specific zero pronoun-candidate antecedent pair, our system encodes all its preceding candidate antecedents that are predicted to be the antecedents in the vector space. Consequently, this representative vector is regarded as the antecedent information, which can be utilized to measure the coreference probability of the zero pronoun-candidate antecedent pair. In addition, the policy-based deep reinforcement learning algorithm is applied to learn the policy of making coreference decisions for zero pronoun-candidate antecedent pairs. The innovative idea behind our reinforcement learning model is to model the antecedent determination as a sequential decision process, where our model learns to link the zero pronoun to its potential antecedents incrementally. By encoding the antecedents predicted in previous states, our model is capable of exploring the long-term influence of independent decisions, producing more accurate results than models that simply consider the limited information in one single state.

Our strategy is favorable in the following aspects. First, the proposed model learns to make decisions by linguistic cues of previously predicted antecedents. Instead of simply making local decisions, our technique allows the model to learn which action (predict to be an antecedent) available from the current state can eventually lead to a high-scoring overall performance. Second, instead of requiring supervised signals at each time step, deep reinforcement learning model optimizes its policy based on an overall reward signal. In other words, it learns to directly optimize the overall evaluation metrics, which is more effective than models that learn with loss functions that heuristically define the goodness of a particular single decision. Our experiments are conducted on the OntoNotes dataset. Comparing to baseline systems, our model obtains significant improvements, achieving the state-of-the-art performance for zero pronoun resolution. The major contributions of this paper are three-fold.

- We are the first to consider reinforcement learning models for zero pronoun resolution in Chinese documents;
- The proposed deep reinforcement learning model leverages linguistic cues provided by the antecedents predicted in earlier states when classifying later candidate antecedents;
- We evaluate our reinforcement learning model on a benchmark dataset, where a considerable improvement is gained over the state-of-the-art systems.

The rest of this paper is organized as follows. The next section describes our deep reinforcement learning model for anaphoric zero pronoun resolution. Section 3 presents our experiments, including the dataset description, evaluation metrics, experiment results, and analysis. We outline related work in Section 4. The Section 5 is about the conclusion and future work.

2 modelology

In this section, we introduce the technical details of the proposed reinforcement learning framework. The specific task of anaphoric zero pronoun resolution is to select antecedents from candidate antecedents for the zero pronoun. Here we formulate it as a sequential decision process in a reinforcement learning setting. We first describe the environment of the Markov decision making process and our reinforcement learning agent. Then, we introduce the modules. The last subsection is about the supervised pre-training technique of our model.

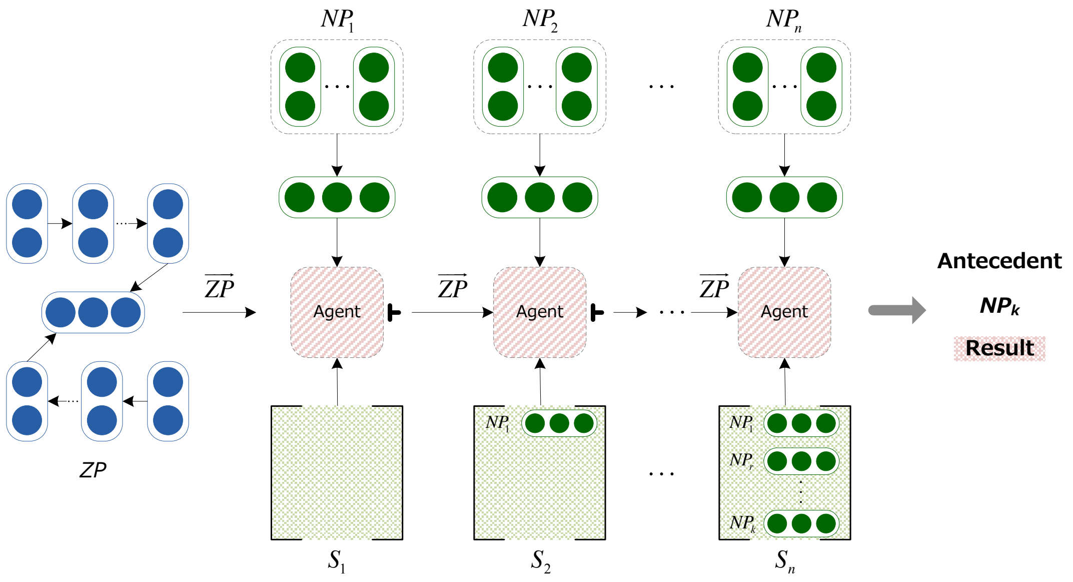

Figure 1: Illustration of our reinforcement learning framework. Given a zero pronoun with n candidate antecedents (presented as "NP"), for each time, the agent scores pairs of zero pronoun-candidate antecedent for their likelihood of coreference by 1) zero pronoun; 2) candidate antecedent and 3) antecedent information. Antecedent information at time t is generated by all the antecedents predicted in previous states.

2.1 Reinforcement Learning for Zero Pronoun Resolution

Given an anaphoric zero pronoun zp, a set of candidate antecedents are required to be selected from its associated text. In particular, we adopt the heuristic model utilized in recent Chinese anaphoric zero pronoun resolution work (Chen and Ng, 2016; Yin et al., 2017a,b) for this purpose. For those noun phrases that are two sentences away at most from the zero pronoun, we select those who are maximal noun phrases or modifier ones to compose the candidate set. These noun phrases ($\{np_1, np_2, ..., np_n\}$) and the zero pronoun ($zp$) are then encoded into representation vectors: $\{v_{np_1}, v_{np_2}, ..., v_{np_n}\}$ and v_{zp}.

Previous neural network models (Chen and Ng, 2016; Yin et al., 2017a,b) generally consider some pairwise models to select antecedents. In these work, candidate antecedents and the zero pronoun are first merged into pairs $\{(zp, np_1), (zp, np_2), ..., (zp, np_n)\}$, and then different neural networks are applied to deal with each pair independently. We argue that these models only make local decisions while overlooking their impacts on future decisions. In contrast, we formulate the antecedent determination process in as Markov decision process problem. An innovative reinforcement learning algorithm is designed that learns to classify candidate antecedents incrementally. When predicting one single zero pronoun-candidate antecedent pair, our model leverages antecedent information generated by previously predicted antecedents, making coreference decisions based on global signals.

The architecture of our reinforcement learning framework is shown in Figure 1. For each time step, our reinforcement learning agent predicts the zero pronoun-candidate antecedent pair by using 1) the zero pronoun; 2) information of current candidate antecedent and 3) antecedent information generated by antecedents predicted in previous states. In particular, our reinforcement learning agent is designed as a policy network $\pi_\theta(s, a) = p(a|s; \theta)$, where s represents the *state*; a indicates the *action* and θ represents the parameters of the model. The parameters θ are trained using stochastic gradient descent. Compared with Deep Q-Network (Mnih et al., 2013) that commonly learns a greedy policy, policy network is able to learn a stochastic policy that prevents the agent from getting stuck at an intermediate state (Xiong et al., 2017). Additionally, the learned policy is more explainable, comparing to learned value functions in Deep Q-Network. We here introduce the definitions of components of our reinforcement learning model, namely, *state*, *action* and *reward*.

2.1.1 State

Given a zero pronoun zp with its representation v_{zp} and all of its candidate antecedents representations $\{v_{np_1}, v_{np_2}, ..., v_{np_n}\}$, our model generate coreference decisions for zero pronoun-candidate antecedent pairs in sequence. More specifically, for each time, the *state* is generated by using both the vectors of the current zero pronoun-candidate antecedent pair and candidates that have been predicted to be the antecedents in the previous states. For time t, the state vector s_t is generated as follows:

$$s_t = (v_{zp}, v_{np_t}, v_{ante}(t), v_{feature_t}) \qquad (1)$$

where v_{zp} and v_{np_t} are the vectors of zp and np_t at time t. As shown in Chen and Ng (2016), human-designed handcrafted features are essential for the resolver since they reveal the syntactical, positional and other relations between a zero pronoun and its counterpart antecedents. Hence, to evaluate the coreference possibility of each candidate antecedent in a comprehensive manner, we integrate a group of features that are utilized in previous work (Zhao and Ng, 2007; Chen and Ng, 2013, 2016) into our model. For these multi-value features, we decompose them into a corresponding set of binary-value ones. $v_{feature_t}$ represents the feature vector. $v_{ante}(t)$ represents the antecedent information generated by candidates that have been predicted to be antecedents in previous states. After that, these vectors are concatenated to be the representation of *state* and fed into the deep reinforcement learning agent to generate the *action*.

2.1.2 Action

The action for each state is defined to be: *corefer* that indicates the zero pronoun and candidate antecedent are coreference; or otherwise, *non-corefer*. If an action *corefer* is made, we retain the vector of the counterpart antecedent together with those of the antecedents predicted in previous states to generate the vector v_{ante}, which is utilized to produce the antecedent information in the next state.

2.1.3 Reward

Normally, once the agent executes a series of actions, it observes a reward $R(a_{1:T})$ that could be any function. To encourage the agent to find accurate antecedents, we regard the F-score for the selected antecedents as the *reward* for each action in a path.

2.2 Reinforcement Learning Agent

Basically, our reinforcement learning agent is comprised of three parts, namely, the zero pronoun encoder that learns to encode a zero pronoun into vectors by using its context words; the candidate mention encoder that represents the candidate antecedents by content words; and the agent that maps the state vector s to a probability distribution over all possible actions.

In this work, the ZP-centered neural network model proposed by Yin et al. (2017a) is employed to be the zero pronoun encoder. The encoder learns to encode the zero pronoun by its associated text into its vector-space semantics. In particular, two standard recurrent neural networks are employed to encode the preceding text and the following text of a zero pronoun, separately. Such a model learns to encode the associated text around the zero pronoun, exploiting sentence-level information for the zero pronoun. For the candidate mentions encoder, we adopt the recurrent neural network-based model that encodes these phrases by using its content words. More specifically, we utilize a standard recurrent neural network to model the content of a phrase from left to right. This model learns to produce the vector of a phrase by considering its content, providing our model an ability to reveal its vector-space semantics. In this way, we generate the vector for zp, the v_{zp}, and representation vectors of all its candidate antecedents, which are denoted as $\{v_{np_1}, v_{np_2}, ..., v_{np_n}\}$.

Moreover, we employ pooling operations to encode antecedent information by using the antecedents that are predicted in previous states. In particular, we generate two vectors by applying the max-pooling and average-pooling, respectively. These two vectors are then concatenated together. Let the representative vector of the tth candidate antecedent to be $v_{np_t} \in \mathbb{R}^d$, and the predicted antecedents at time t be writen as $S(t) = [v_{np_i}, v_{np_j}, ..., v_{np_r}]$, the vector at time t, $v_{ante}(t)_k$ is generated by:

$$v_{ante}(t)_k = \begin{cases} max\{S(t)_{k,\cdot}\} & \text{for } 0 \leq \text{k} < \text{d} \\ ave\{S(t)_{k-d,\cdot}\} & \text{for d} \leq \text{k} < \text{2d} \end{cases}$$

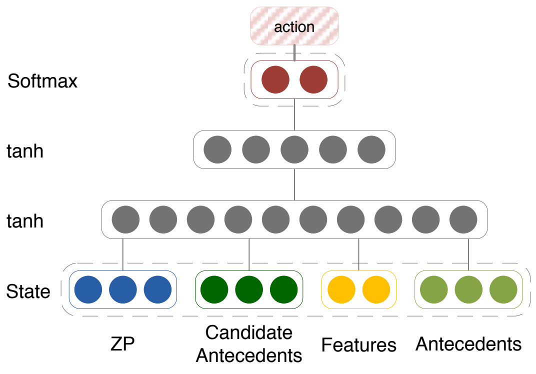

Figure 2: Illustration of the feedforward neural network model employed as the agent. Its input vector includes these parts: (1) Zero pronoun; (2) Candidate Antecedents; (3) Pair Features and (4) Antecedents. By going through all the full-connected hidden layers and one $softmax$ layer, the agent maps the state vector into the probability distribution over actions that indicates the coreference likelihood of the input zero pronoun-candidate antecedent pair.

The concatenation of these vectors is regarded as input and is fed into our reinforcement learning agent. More specifically, a feed-forward neural network is utilized to constitute the agent that maps the state vector to a probability distribution over all possible actions. Figure 2 shows the architecture of the agent. Two hidden layers are employed in our model, each of which utilizes the $tanh$ as the activation function. For each layer, we generate the output by:

$$h_i(s_t) = tanh(W_i h_{i-1}(s_t) + b_i) \tag{2}$$

where W_i and b_i are the parameters of the ith hidden layer; s_i represents the state vector. After going through all the layers, we can get the representative vector for the zero pronoun-candidate antecedent pair (zp, np_t). We then feed it into a scoring-layer to get their coreference score. The scoring-layer is a fully-connected layer of dimension 2:

$$score(zp, np_t) = W_s h_2(s_t) + b_s \tag{3}$$

where h_2 represents the output of the second hidden layer; $W_s \in \mathbb{R}^{2\times r}$ is the parameter of the layer and r is the dimension of h_2. Consequently, we generate the probability distribution over actions using the output generated by the scoring-layer of the neural network, where a $softmax$ layer is employed to gain the probability of each action:

$$p_\theta(a) \propto e^{score(zp,np_t)} \tag{4}$$

In this work, the policy-based reinforcement learning model is employed to train the parameter of the agent. More specifically, we explore using the REINFORCE policy gradient algorithm (Williams, 1992), which learns to maximize the expected reward:

$$\begin{aligned} J(\theta) &= \mathbb{E}_{a_{1:T}\sim p(a|zp,np_t;\theta)} R(a_{1:T}) \\ &= \sum_t \sum_a p(a|zp, np_t; \theta) R(a_t) \end{aligned} \tag{5}$$

where $p(a|zp, np_t; \theta)$ indicates the probability of selecting action a.

Intuitively, the estimation of the gradient might have very high variance. One commonly used remedy to reduce the variance is to subtract a *baseline* value b from the reward. Hence, we utilize the gradient estimate as follows:

$$\nabla_\theta J(\theta) = \nabla_\theta \sum_t \log p(a|zp, np_t; \theta)(R(a_t) - b_t) \tag{6}$$

Following Clark and Manning (2016), we interduce the baseline b and get the value of b_t at time t by $\mathbb{E}_{a_{t'}\sim p} R(a_1, ..., a_{t'}, ..., a_T)$.

2.3 Pretraining

Pretraining is crucial in reinforcement learning techniques (Clark and Manning, 2016; Xiong et al., 2017). In this work, we pretrain the model by using the loss function from Yin et al. (2017a):

$$loss = -\sum_{i=1}^{N} \sum_{np\in\mathcal{A}(zp_i)} \delta(zp_i, np) log(P(np|zp_i)) \tag{7}$$

where $P(np|zp_i)$ is the coreference score generated by the agent (the probability of choosing *corefer* action); $\mathcal{A}(zp_i)$ represents the candidate antecedents of zp_i; $\delta(zp, np)$ is 1 or 0, representing zp and np are coreference or not.

3 Experiments

3.1 Dataset and Settings

3.1.1 Dataset

Same to recent work on Chinese zero pronoun (Chen and Ng, 2016; Yin et al., 2017a,b), the proposed model is evaluated on the Chinese portion of the OntoNotes 5.0 dataset[1] that was used in the Conll-2012 Shared Task. Documents in this dataset are from six different sources, namely, Broadcast News (BN), Newswires (NW), Broadcast Conversations (BC), Telephone Conversations (TC), Web Blogs (WB) and Magazines (MZ). Since zero pronoun coreference annotations exist in only the training and development set (Chen and Ng, 2016), we utilize the training dataset for training purposes and test our model on the development set. The statistics of our dataset are reported in Table 1. To make equal comparison, we adopt the strategy as utilized in the existing work (Chen and Ng, 2016; Yin et al., 2017a), where 20% of the training dataset are randomly selected and reserved as a development dataset for tuning the model.

	#Documents	#Sentences	#AZPs
Training	1,391	36,487	12,111
Test	172	6,083	1,713

Table 1: Statistics on the training and test dataset.

3.1.2 Evaluation Measures

Following previous work on zero pronoun resolution (Zhao and Ng, 2007; Chen and Ng, 2016; Yin et al., 2017a,b), metrics employed to evaluate our model are: recall, precision, and F-score (F). We report the performance for each source in addition to the overall result.

3.1.3 Baselines and Experiment Settings

Five recent zero pronoun resolution systems are employed as our baselines, namely, Zhao and Ng (2007), Chen and Ng (2015), Chen and Ng (2016), Yin et al. (2017a) and Yin et al. (2017b). The first of them is machine learning-based, the second is the unsupervised and the other ones are all deep learning models. Since we concentrate on the anaphoric zero pronoun resolution process, we run experiments by employing the experiment setting with ground truth parse results and ground truth anaphoric zero pronoun, all of which are from the original dataset. Moreover, to illustrate the effectiveness of our reinforcement learning model, we run a set of ablation experiments by using different pretraining iterations and report the performance of our model with different iterations. Besides, to explore the randomness of the reinforcement learning technique, we report the performance variation of our model with different random seeds.

3.1.4 Implementation Details

We randomly initialize the parameters and minimize the objective function using Adagrad (Duchi et al., 2011). The embedding dimension is 100, and hidden layers are 256 and 512 dimensions, respectively. Moreover, the dropout (Hinton et al., 2012) regularization is added to the output of each layer. Table 2 shows the hyperparameters we utilized for both the pre-training and reinforcement learning process. Hyperparameters here are selected based on preliminary experiments and there remains considerable space for improvement, for instance, applying the annealing.

	Pre	RL
hidden dimentions	256 & 512	256 & 512
training epochs	70	50
batch	256	256
dropout rate	0.5	0.7
learning rate	0.003	0.00009

Table 2: Hyperparameters for the pre-training (Pre) and reinforcement learning (RL).

3.2 Experiment Results

In Table 3, we compare the results of our model with baselines in the test dataset. Our reinforcement learning model surpasses all previous baselines. More specifically, for the "Overall" results, our model obtains a considerable improvement by 2.3% in F-score over the best baseline (Yin et al., 2017a). Moreover, we run experiments in different sources of documents and report the results for each source. The number following a source's name indicates the amount of anaphoric zero pronoun in that source. Our model beats the best baseline in four of six sources, demonstrating the efficiency of our reinforcement learning model. The improvement gained over the best baseline in source "BC" is 4.3% in F-score, which is encouraging since it contains the most anaphoric zero pronoun. In all words, all these suggest that our model surpasses existed baselines, which demonstrates the efficiency of the proposed technique.

Ideally, our model learns useful information

	NW (84)	MZ (162)	WB (284)	BN (390)	BC (510)	TC (283)	**Overall**
Zhao and Ng (2007)	40.5	28.4	40.1	43.1	44.7	42.8	41.5
Chen and Ng (2015)	46.4	39.0	51.8	53.8	49.4	52.7	50.2
Chen and Ng (2016)	48.8	41.5	56.3	55.4	50.8	53.1	52.2
Yin et al. (2017b)	50.0	45.0	55.9	53.3	55.3	54.4	53.6
Yin et al. (2017a)	48.8	46.3	59.8	**58.4**	53.2	**54.8**	54.9
Our model	**63.1**	**50.2**	**63.1**	56.7	**57.5**	54.0	**57.2**

Table 3: Experiment results on the test data. The first six columns show the results on different source of documents and the last column is the overall results.

gathered from candidates that have been predicted to be the antecedents in previous states, which brings a global-view instead of simply making partial decisions. By applying the reinforcement learning, our model learns to directly optimize the overall performance in expectation, guiding benefit in making decisions in a sequential manner. Consequently, they bring benefit to predict accurate antecedents, leading to the better performance.

Moreover, on purpose of better illustrating the effectiveness of the proposed reinforcement learning model, we run a set of experiments with different settings. In particular, we compare the model with and without the proposed reinforcement learning process using different pre-training iterations. For each time, we report the performance of our model on both the test and development set. For all these experiments, we retain the rest of the model unchanged.

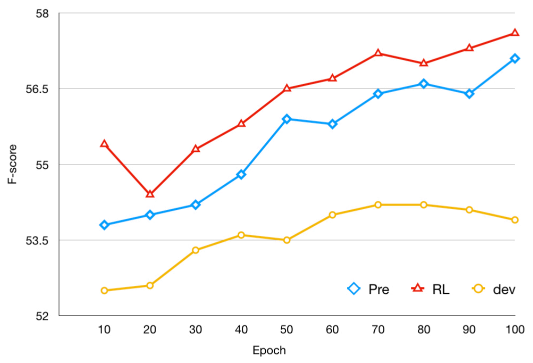

Figure 3: Experiment results of different models, where "RL" represents the reinforcement learning algorithm and "Pre" presents the model without reinforcement learning. "dev" shows the performance of our reinforcement learning model on the development dataset.

Figure 3 shows the performance of our model with and without reinforcement learning. We can see from the table that our model with reinforcement learning achieves better performance than the model without this all across the board. With the help of reinforcement learning, our model learns to choose effective actions in sequential decisions. It empowers the model to directly optimize the overall evaluation metrics, which brings a more effective and natural way of dealing with the task. Moreover, by seeing that the performance on development dataset stops increasing with iterations bigger than 70, we therefore set the pre-training iterations to 70.

Following Reimers and Gurevych (2017), to illustrate the impact of randomness in our reinforcement learning model, we run our model with different random seed values. Table 4 shows the performance of our model with different random seeds on the test dataset. We report the minimum, the maximum, the median F-scores results and the standard deviation σ of F-scores. We run

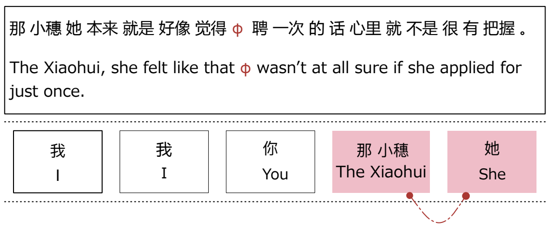
Min F	Median F	Max F	σ
56.5	57.1	57.5	0.00253

Table 4: Performance of our model with different random seeds.

the model with 38 different random seeds. The maximum F-score is 57.5% and the minimum one is 56.5%. Based on this observation, we can draw the conclusion that our proposed reinforcement learning model generally beats the baselines and achieves the state-of-the-art performance.

3.3 Case Study

Lastly, we show a case to illustrate the effectiveness of our proposed model, as is shown in Figure 4. In this case, we can see that our model correctly predict mentions "那小穗/The Xiaohui"



那 小穗 她 本来 就是 好像 觉得 ϕ 聘 一次 的 话 心里 就 不是 很 有 把握 。
The Xiaohui, she felt like that ϕ wasn't at all sure if she applied for just once.
我 I
我 I
你 You
那 小穗 The Xiaohui
她 She

Figure 4: Example of case study. Noun phrases with pink background color are the ones selected to be the antecedents by our model.

and "她/She" as the antecedents of the zero pronoun "ϕ". This case demonstrates the efficiency of our model. Instead of making only local decisions, our model learns to predict potential antecedents incrementally, selecting global-optimal antecedents in a sequential manner. In the end, our model successfully predicts "她/She" as the result.

4 Related Work

4.1 Zero Pronoun Resolution

A wide variety of techniques for machine learning models for Chinese zero pronoun resolution have been proposed. Zhao and Ng (2007) utilized the decision tree to learn the anaphoric zero pronoun resolver by using syntactical and positional features. It is the first time that machine learning techniques are applied for this task. To better explore syntactics, Kong and Zhou (2010) employed the tree kernel technique in their model. Chen and Ng (2013) extended Zhao and Ng (2007)'s model further by integrating innovative features and coreference chains between zero pronoun as bridges to find antecedents. In contrast, unsupervised techniques have been proposed and shown their efficiency. Chen and Ng (2014) proposed an unsupervised model, where a model trained on manually resolved pronoun was employed for the resolution of zero pronoun. Chen and Ng (2015) proposed an unsupervised anaphoric zero pronoun resolver, using the salience model to deal with the issue. Besides, there has been extensive work on zero anaphora for other languages. Efforts for zero pronoun resolution fall into two major categories, namely, (1) heuristic techniques (Han, 2006); and (2) learning-based models (Iida and Poesio, 2011; Isozaki and Hirao, 2003; Iida et al., 2006, 2007; Sasano and Kurohashi, 2011; Iida and Poesio, 2011; Iida et al., 2015, 2016).

In recent years, deep learning techniques have been extensively studied for zero pronoun resolution. Chen and Ng (2016) introduced a deep neural network resolver for this task. In their work, zero pronoun and candidates are encoded by a feed-forward neural network. Liu et al. (2017) explored to produce pseudo dataset for anaphoric zero pronoun resolution. They trained their deep learning model by adopting a two-step learning method that overcomes the discrepancy between the generated pseudo dataset and the real one. To better utilize vector-space semantics, Yin et al. (2017b) employed recurrent neural network to encode zero pronoun and antecedents. In particular, a two-layer antecedent encoder was employed to generate the hierarchical representation of antecedents. Yin et al. (2017a) developed an innovative deep memory network resolver, where zero pronouns are encoded by its potential antecedent mentions and associated text.

The major difference between our model and existed techniques lies in the applying of deep reinforcement learning. In this work, we formulate the anaphoric zero pronoun resolution as a sequential decision process in a reinforcement learning setting. With the help of reinforcement learning, our resolver learns to classify mentions in a sequential manner, making global-optimal decisions. Consequently, our model learns to take advantage of earlier predicted antecedents when making later coreference decisions.

4.2 Deep Reinforcement Learning

Recent advances in deep reinforcement learning have shown promise results in a variety of natural language processing tasks (Branavan et al., 2012; Narasimhan et al., 2015; Li et al., 2016). In recent time, Clark and Manning (2016) proposed a deep reinforcement learning model for coreference resolution, where an agent is utilized for linking mentions to their potential antecedents. They utilized the policy gradient algorithm to train the model and achieves better results compared with the counterpart neural network model. Narasimhan et al. (2016) introduced a deep Q-learning based slot-filling technique, where the agent's action is to retrieve or reconcile content from a new document. Xiong et al. (2017) proposed an innovative reinforcement learning framework for learning multi-hop relational paths. Deep reinforcement learning is a natural choice for tasks that require making incremental decisions. By combining non-linear function approximations with reinforcement learning, the deep reinforcement learning paradigm can integrate vector-space semantic into a robust joint learning and reasoning process. Moreover, by optimizing the policy-based on the reward signal, deep reinforcement learning model relies less on heuristic loss functions that require careful tuning.

5 Conclusion

We introduce a deep reinforcement learning framework for Chinese zero pronoun resolution. Our model learns the policy on selecting antecedents in a sequential manner, leveraging effective information provided by the earlier predicted antecedents. This strategy contributes to the predicting for later antecedents, bringing a natural view for the task. Experiments on the benchmark dataset show that our reinforcement learning model achieves an F-score of 67.2% on the test dataset, surpassing all the existed models by a considerable margin.

In the future, we plan to explore neural network models for efficaciously resolving anaphoric zero pronoun documents and research on some specific components which might influence the performance of the model, such as the embedding. Meanwhile, we plan to research on the possibility of applying adversarial learning (Goodfellow et al., 2014) to generate better rewards than the human-defined reward functions. Besides, to deal with the problematic scenario when ground truth parse tree and anaphoric zero pronoun are unavailable, we are interested in exploring the neural network model that integrates the anaphoric zero pronoun determination and anaphoric zero pronoun resolution jointly in a hierarchical architecture without using parser or anaphoric zero pronoun detector.

Our code is available at `https://github.com/qyyin/Reinforce4ZP.git`.

Abstract

Predicate argument structure analysis is a task of identifying structured events. To improve this field, we need to identify a salient entity, which cannot be identified without performing coreference resolution and predicate argument structure analysis simultaneously. This paper presents an entity-centric joint model for Japanese coreference resolution and predicate argument structure analysis. Each entity is assigned an embedding, and when the result of both analyses refers to an entity, the entity embedding is updated. The analyses take the entity embedding into consideration to access the global information of entities. Our experimental results demonstrate the proposed method can improve the performance of the inter-sentential zero anaphora resolution drastically, which is a notoriously difficult task in predicate argument structure analysis.

1 Introduction

Natural language often conveys a sequence of events like "who did what to whom", and extracting structured events from the raw text is a kind of touchstone for machine reading. This is realized by a combination of coreference resolution (called *CR*, hereafter) and predicate argument structure analysis (called *PA*, hereafter).

The characteristics and difficulties in the analyses vary among languages. In English, there are few omissions of arguments, and thus PA is relatively easy, around 83% accuracy (He et al., 2017), while CR is relatively difficult, around 70% accuracy (Lee et al., 2017).

On the other hand, in Japanese and Chinese, where arguments are often omitted, PA is a difficult task, and even state-of-the-art systems only achieve around 50% accuracy. Zero anaphora resolution (ZAR) is a difficult subtask of PA, detecting a zero pronoun and identifying a referent of the zero pronoun. As the following example shows, CR in English (identifying the antecedent of *it*) and ZAR in Japanese (identifying the omitted nominative argument) are similar problems.

(1) a. John bought a car last month.
It was made by Toyota.

b. ジョンは 先月 車を 買った。
John-TOP last month a car-ACC bought.
(ϕ が) トヨタ製だった。
(ϕ-NOM) Toyota made-COPULA.

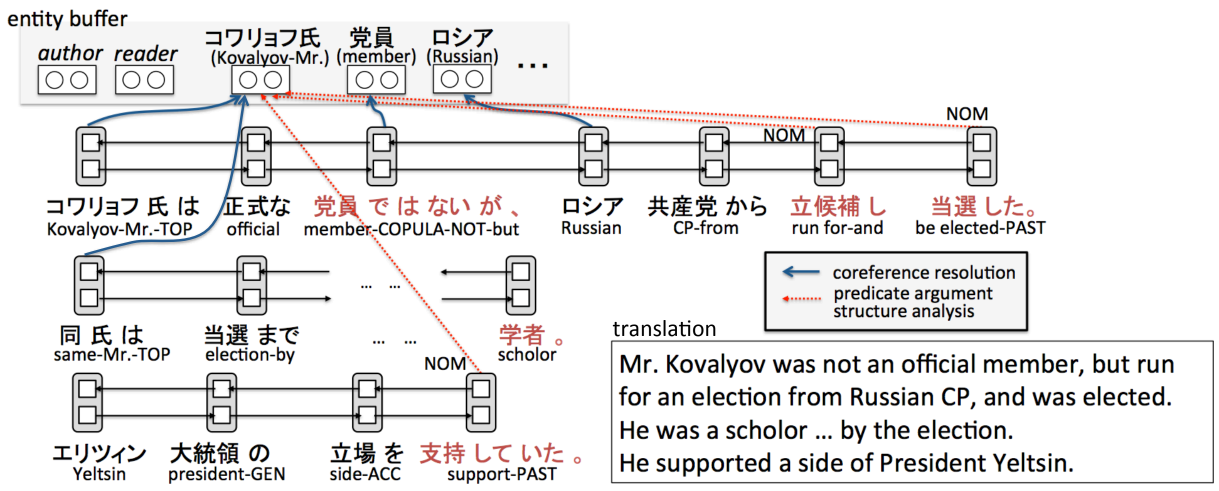
Note that CR such as the relation between "the company" and "Toyota" is also difficult in Japanese.

According to the argument position relative to the predicate, ZAR is classified into the following three types:

- *intra-sentential* (*intra* in short): an argument is located in the same sentence with the predicate
- *inter-sentential* (*inter* in short): an argument is located in the preceding sentences, such as "車" for "トヨタ製だった" (Toyota made-COPULA) in sentence (1b)
- *exophora*: an argument does not appear in a document, such as *author* and *reader*

Among these three types, the analysis of *inter* is extremely difficult because there are many candidates in preceding sentences, and clues such as a dependency path between a predicate and an argument cannot be used.

This paper presents a joint model of CR and PA in Japanese. It is necessary to perform them together because PA (especially inter-sentential



Mr. Kovalyov was not an official member, but run for an election from Russian CP, and was elected. He was a scholor ... by the election. He supported a side of President Yeltsin.

Figure 1: An overview of our proposed method. The phrases with red represent a predicate.

ZAR) needs to identify salient entities, which cannot be identified without performing CR and PA simultaneously. Our results support this claim, and suggest that the status quo of PA-exclusive research in Japanese is an insufficient approach.

Our work is inspired by (Wiseman et al., 2016), which described an English CR system, where entities are represented by embeddings, and they are updated by CR results dynamically. We perform Japanese CR and PA by extending this idea. Our experimental results demonstrate the proposed method can improve the performance of the inter-sentential zero anaphora resolution drastically.

2 Related Work

Predicate Argument Structure Analysis. Early studies have handled both *intra-* and *inter-*sentential anaphora (Taira et al., 2008; Sasano and Kurohashi, 2011), and Hangyo et al. (2013) present a method for handling *exophora*. Recent studies, however, focus on only *intra*-sentential anaphora (Ouchi et al., 2015; Shibata et al., 2016; Iida et al., 2016; Ouchi et al., 2017; Matsubayashi and Inui, 2017), because the analysis of *inter*-sentential anaphora is extremely difficult. Neural network-based approaches (Shibata et al., 2016; Iida et al., 2016; Ouchi et al., 2017; Matsubayashi and Inui, 2017) have improved its performance.

Although most of studies did not consider the notion *entity*, Sasano and Kurohashi (2011) consider an entity, and its salience score is calculated based on simple rules. However, they used gold coreference links to form the entities, and reported the salience score did not improve the performance. In contrast, we perform CR automatically, and capture the entity salience by using RNNs.

For Chinese, where zero anaphors are often used, neural network-based approaches (Chen and Ng, 2016; Yin et al., 2017) outperformed conventional machine learning approaches (Zhao and Ng, 2007).

Coreference Resolution. CR has been actively studied in English and Chinese. Neural network-based approaches (Wiseman et al., 2016; Clark and Manning, 2016b,a; Lee et al., 2017) outperformed conventional machine learning approaches (Clark and Manning, 2015). Wiseman et al. (2016) and Clark and Manning (2016b) learn an entity representation and integrate this into a mention-based model. Our work is inspired by Wiseman et al. (2016), which learn the entity representation by using Recurrent Neural Networks (RNNs). Clark and Manning (2016b) adopt a clustering approach for the entity representation. The reason why we do not use this is that if we take a clustering approach in our setting, zero pronouns need to be first identified before clustering, and thus, it is hard to perform CR and PA jointly. Lee et al. (2017) take an end-to-end approach, aiming at not relying on hand-engineering mention detector (consider all spans as potential mentions). In used Japanese evaluation corpora, since the basic unit for the annotations and our analyses (CR and PA) is fixed, we do not need consider all spans.

In Japanese, CR has not been actively studied other than Iida et al. (2003); Sasano et al. (2007)

since the use of zero pronouns is more common and problematic.

Semantic Role Labeling. Japanese PA is similar to Semantic Role Labeling (SRL) in English. Neural network-based approaches have improved the performance (Zhou and Xu, 2015; He et al., 2017). In these approaches, an appropriate argument for a predicate is searched among mentions in a text. The notion *entity* is not considered.

Other Entity-Centric Study. There are several studies that consider the notion *entity* in other areas: text comprehension (Kobayashi et al., 2016; Henaff et al., 2016) and language modeling (Ji et al., 2017).

3 Japanese Preliminaries

Before presenting our proposed method, we describe the basics of Japanese predicate argument structure and its analysis.

Since the word order is relatively free among arguments in Japanese, an argument is followed by a case marking postposition. The postpositions が (*ga*), を (*wo*), and に (*ni*) indicate nominative (NOM), accusative (ACC) and dative (DAT), respectively. In the double nominative construction such as "私が英語が上手だ" (My English is good), "英語" (English) is regarded as NOM, and "私" (I), the outer nominative is regarded as NOM2. This paper targets these four cases.

PA is tightly related to a dependency structure of a sentence. Considering the relation between a predicate and its argument, and a necessary analysis can be classified into the following three categories (see example sentence (2) below).

(2) ジョン は 買った パン を 食べた
John-TOP bought bread–ACC ate.

Overt case: When an argument with a case marking postposition has a dependency relation with a predicate, PA is not necessary. In example (2), since "パン を" (bread-ACC) has a dependency relation with "食べた" (ate), it is obvious that "食べた" takes "パン" as its ACC argument.

Case analysis: When a topic marker は (*wa*) is attached to an argument, the case marking postposition disappears, and the analysis of identifying the case role becomes necessary. The analysis is called *case analysis*. In the example, although "ジョン は" (John-TOP) has a dependency relation with "食べた" (ate), the analysis of identifying NOM is necessary. The same phenomenon happens when a relative clause is used. When an argument is modified by a relative clause, we do not know its case role to the predicate in the relative clause. In the example, although "パン" has a dependency relation with "買った" (bought), the analysis of identifying ACC is necessary.

Zero anaphora resolution (ZAR): Some arguments are not included in the phrases with which a predicate has a dependency relation. While pronouns are mostly used in English, they are rarely used in Japanese. This phenomenon is called *zero anaphora*, and the analysis of identifying an argument (referent of the zero pronoun) is called *zero anaphora resolution* (ZAR). In the example, although "買った" takes "ジョン" as its NOM argument, they do not have a dependency relation, and thus zero anaphora resolution is necessary.

When dependency relations are identified by parsing, what Japanese PA has to do is case analysis and zero anaphora resolution.

Each predicate has a set of required cases, but not all the four cases. For example, "買う" (buy) takes NOM and ACC, but neither DAT nor NOM2. PA for "買う" in sentence (2) has to find John as NOM, but also has to judge that it does not take DAT and NOM2 arguments.

Another difficulty lies in that a predicate takes a case, but in a sentence it does not take a specific argument. For example, in the sentence "it is difficult to bake a bread", NOM of "bake" is not a specific person, but means "anyone" or "in general". In such cases, PA has to regard arguments as *unspecified*.

4 Overview of Our Proposed Method

An overview of our proposed model is described with a motivated example (Figure 1). Our model equips an *entity buffer* for entity management. At first, it contains only special entities, *author* and *reader*.

In Japanese CR and PA, a basic phrase, which consists of one content word and zero or more function words, is adopted as a basic unit. When an input text is given, the contextual representations of basic phrases are obtained by using Convolutional Neural Network (CNN) and Bidirectional LSTM. Then, from the beginning of the text, CR is performed if a target phrase is a noun phrase, and PA is performed if a target phrase is a predicate phrase. Both of these analyses take into consideration not only the mentions in the text but also the entities in the entity buffer.

In CR, when a mention refers to an existing entity, the entity embedding in the entity buffer is updated. In Figure 1, "同氏" (said person) is analyzed to refer to "コワリョフ氏" (Mr.Kovalyov), and the entity embedding of "コワリョフ氏" is updated. When a mention is analyzed to have no antecedent, it is registered to the entity buffer as a new entity.

In PA, when a predicate has no argument for any case, its argument is searched among any mentions in the text, *author* and *reader*. In the same way as CR, PA takes into consideration not only the mentions but also entities in the entity buffer, and updates the entity embedding.

In Figure 1, the predicate "立候補し" (run for) has no NOM argument. Our method finds "コワリョフ氏" as its NOM argument, and then updates its entity embedding. As mentioned before, the entity embedding of "コワリョフ氏" is updated by the coreference relation with "同氏" in the second sentence. In the third sentence, the predicate "支持していた" (support) has also no NOM argument, and "コワリョフ氏" is identified as its NOM argument, because the frequent reference implies its salience.

5 Base Model

5.1 Input Encoding

Conventional machine learning techniques have extracted features from a basic phrase, which require much effort on feature engineering. Our method obtains an embedding of each basic phrase using CNN and bi-LSTM as shown in Figure 2.

Suppose the i-th basic phrase bp_i consists of $|bp_i|$ words. First, the embedding of each word is represented as a concatenation of word (lemma), part of speech (POS), sub-POS and conjugation embeddings. We append start-of-phrase and end-of-phrase special words to each phrase in order to better represent prefixes and suffixes. Let $W^i \in \mathbb{R}^{d\times(|bp_i|+2)}$ be an embedding matrix for bp_i where d denotes the dimension of word representation.

The embedding of the basic phrase is obtained by applying CNN to the sequence of words. A feature map $\boldsymbol{f}^i$ is obtained by applying a convolution between W^i and a filter H of width n. The m-th element of $\boldsymbol{f}^i$ is obtained as follows:

$$\boldsymbol{f}^i[m] = \tanh(\langle W^i[*, m : m+n-1], H\rangle), \quad (1)$$

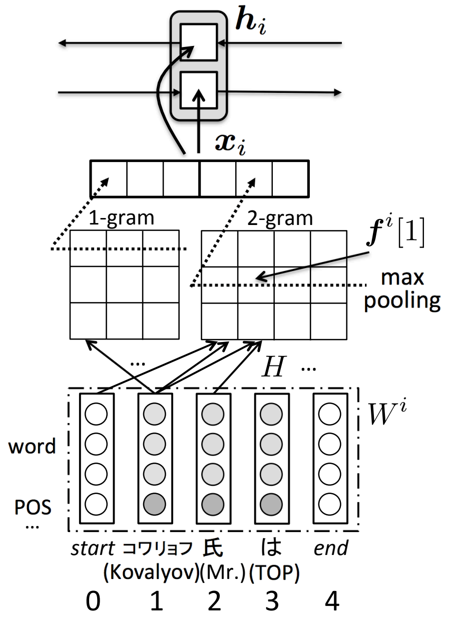


Figure 2: Basic phrase embedding obtained with CNN and Bi-LSTM.

where $W^i[*, m : m+n-1]$ denotes the m-to-($m+n-1$)-th column of W^i, and $\langle A, B\rangle = \mathrm{Tr}(AB^{\mathrm{T}})$ is the Frobenius inner product. Then, to capture the most important feature for a given filter in bp_i, the max pooling is applied as follows:

$$x^i = \max_m \boldsymbol{f}^i[m]. \quad (2)$$

The process described so far is for one filter. The multiple filters of varying widths are applied to obtain the representation of bp_i. When we set h filters, $\boldsymbol{x}_i$, the embedding of the i-th basic phrase, is represented as $[x^i_1, \cdots, x^i_h]$.

The embeddings of basic phrases are read by bi-LSTM to capture their context as follows:

$$\begin{aligned} \overrightarrow{\boldsymbol{h}}_i &= \overrightarrow{LSTM}(\boldsymbol{x}_i, \overrightarrow{\boldsymbol{h}}_{i-1}), \\ \overleftarrow{\boldsymbol{h}}_i &= \overleftarrow{LSTM}(\boldsymbol{x}_i, \overleftarrow{\boldsymbol{h}}_{i+1}), \end{aligned} \quad (3)$$

and the contextualized embedding of the i-th basic phrase is represented as a concatenation of the hidden layers of forward and backward LSTM.

$$\boldsymbol{h}_i = [\overrightarrow{\boldsymbol{h}}_i; \overleftarrow{\boldsymbol{h}}_i] \quad (4)$$

This process is performed for each sentence. Since CR and PA are performed for a whole document D, the indices of basic phrases are reassigned from the beginning to the end of D in a consecutive order: $D = \{\boldsymbol{h}_1, \boldsymbol{h}_2, \cdots, \boldsymbol{h}_i, \cdots\}$.

To handle exophora, *author* and *reader* are assigned a unique trainable embedding, respectively.

5.2 Coreference Resolution

We adopt a mention-ranking model that assigns each mention its highest scoring candidate antecedent. This model assigns a score $s^m_{CR}(ant, m_i)$ to a target mention m_i and its candidate antecedent ant[1]. The candidate antecedents include i) mentions preceding m_i, ii) *author* and *reader*, and iii) $\texttt{NA}_{\texttt{CR}}$ (no antecedent). $s^m_{CR}(ant, m_i)$ is calculated as follows:

$$s^m_{CR}(ant, m_i) = W_2^{CR} ReLU(W_1^{CR} \boldsymbol{v}^{CR}_{input}), \quad (5)$$

where W_1^{CR} and W_2^{CR} are weight matrices, and $\boldsymbol{v}^{CR}_{input}$ is an input vector, a concatenation of the following vectors:

- embeddings of m_i and ant
- exact match or partial match between strings of m_i and ant
- sentence distance between m_i and ant. The distance is binned into one of the buckets [0, 1, 2, 3+].
- whether a pair of m_i and ant has an entry in a synonym dictionary.

When a candidate antecedent is $\texttt{NA}_{\texttt{CR}}$, the input vector is just the embedding of a target mention m_i, and the same neural network with different weight matrices calculates a score.

The following margin objective is trained:

$$\mathcal{L}_{CR} = \sum_i^{N_m} \max_{ant \in \mathcal{ANT}(m_i)} (1 + s^m_{CR}(ant, m_i) - s^m_{CR}(\hat{t}_i, m_i)), \quad (6)$$

where N_m denotes the number of mentions in a document, $\mathcal{ANT}(m_i)$ denotes the set of candidate antecedents of m_i, and $\hat{t}_i$ denotes the highest scoring true antecedent of m_i defined as follows:

$$\hat{t}_i = \operatorname*{argmax}_{ant \in \mathcal{T}(m_i)} s^m_{CR}(ant, m_i), \quad (7)$$

where $\mathcal{T}(m_i)$ denotes the set of true antecedents of m_i.

5.3 Predicate Argument Structure Analysis

When a target phrase is a predicate phrase, PA is performed. For each case of a predicate, PA searches an appropriate argument among candidate arguments: i) basic phrases located in the sentence including the predicate and preceding sentences, ii) *author* and *reader*, iii) unspecified, and

[1]The superscript m of $s^m_{CR}(ant, m_i)$ represents a *mention*-based score, which contrasts with an *entity*-based score introduced in Section 6.

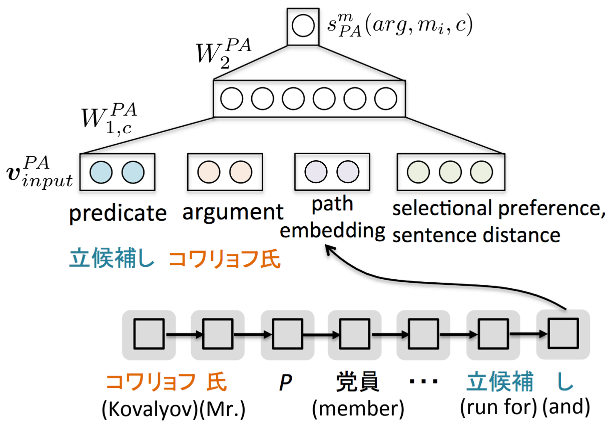

Figure 3: A neural network for PA.

iv) $\texttt{NA}_{\texttt{PA}}$ which means the predicate takes no argument of for the case.

The probability that the predicate m_i takes an argument arg for case c is defined as follows:

$$P(c = arg|m_i) = \frac{\exp(s^m_{PA}(arg, m_i, c))}{\sum_{\substack{carg \in \\ \mathcal{ARG}(m_i)}} \exp(s^m_{PA}(carg, m_i, c))}, \quad (8)$$

where $\mathcal{ARG}(m_i)$ denotes the set of candidate arguments of m_i, and a score $s^m_{PA}(arg, m_i, c)$ is calculated by a neural network as follows (Figure 3):

$$s^m_{PA}(arg, m_i, c) = W_2^{PA} \tanh(W_{1,c}^{PA} \boldsymbol{v}^{PA}_{input}), \quad (9)$$

where $W_{1,c}^{PA}$, W_2^{PA} are weight matrices, and $\boldsymbol{v}^{PA}_{input}$ is an input vector, a concatenation of the following vectors:

- embeddings of m_i and arg[2]
- path embedding: the dependency path between a predicate and an argument is an important clue. Roth and Lapata (2016) learn a representation of a lexicalized dependency path for SRL. An LSTM reads words[3] from an argument to a predicate along with a dependency path, and the final hidden state is adopted as the embedding of the dependency path.[4] For case analysis, the direct dependency relation between a predicate and its argument can be represented as the path embedding.

[2]An embedding for $\texttt{NA}_{\texttt{PA}}$ is assigned a trainable one.

[3]We add special words {Parent, Child}, which indicate a dependency direction between basic phrases.

[4]When an argument is an *inter* or *exophora*, the path embedding is set to be a zero vector.

- selectional preference: selectional preference is another important clue for PA. A selectional preference score is learned in an unsupervised manner from automatic parses of a raw corpus (Shibata et al., 2016).
- sentence distance between m_i and arg. The distance is binned in the same way as CR.

The objective is to minimize the cross entropy between predicted and true distributions:

$$\mathcal{L}_{PA} = -\sum_{i}^{N_p}\sum_{c} \log P(c = \widehat{arg}|p_i), \tag{10}$$

where N_p denotes the number of predicates in a document, and $\widehat{arg}$ denotes a true argument.

6 Entity-Centric Model

While the base model performs *mention*-based CR and PA, our proposed model performs *entity*-based analyses as shown in Figure 1.

6.1 Entity Embedding Update

The entity embeddings are managed in an entity buffer. First, let us introduce time stamp i for the entity embedding update. Time i corresponds to the analysis for the i-th basic phrase in a document. If an entity is referred to by the analysis, its embedding is updated. Let $\boldsymbol{e}_i^{(k)}$ be the embedding of an entity k at time i (after the entity embedding is updated).

In CR, following Wiseman et al. (2016), when a target phrase m_i refers to the entity k, $\boldsymbol{e}_i^{(k)}$ is updated as follows:

$$\boldsymbol{e}_i^{(k)} \leftarrow LSTM_e(\boldsymbol{h}_i, \boldsymbol{e}_{i-1}^{(k)}) \tag{11}$$

where $LSTM_e$ denotes an LSTM for the entity embedding update. When an antecedent is $\mathtt{NA}_{\mathrm{CR}}$, a new entity embedding is set up, initialized by a zero vector. The entity buffer maintains K LSTMs (K is the number of entities in a document), and their parameters are shared.

The proposed method updates the entity embedding not only in CR but also in PA. When the referent of a zero pronoun of case c of predicate p_i is entity k, the entity embedding is updated by using the predicate embedding $\boldsymbol{h}_i$ multiplied by a weight matrix W_c for case c as follows:

$$\boldsymbol{e}_i^{(k)} \leftarrow LSTM_e(W_c\boldsymbol{h}_i, \boldsymbol{e}_{i-1}^{(k)}). \tag{12}$$

In both CR and PA, the embeddings of entities other than the referred entity k are not updated ($\boldsymbol{e}_i^{(l)} \leftarrow \boldsymbol{e}_{i-1}^{(l)} (l \neq k)$).

6.2 Use of Entity Embedding in CR and PA

Both CR and PA are allowed to take the entity embeddings into consideration. In CR, let z_{ant} denote the id of an entity to which the candidate antecedent ant belongs. The *entity*-based score s_{CR}^{e} is calculated as follows:

$$s_{CR}^{e}(ant, m_i) = \begin{cases} \boldsymbol{h}_i^{\mathrm{T}}\boldsymbol{e}_{i-1}^{(z_{ant})} & (ant \neq \mathtt{NA}_{\mathrm{CR}}) \\ g_{NA}(m_i) & (ant = \mathtt{NA}_{\mathrm{CR}}). \end{cases} \tag{13}$$

The intuition behind the first case is that the dot-product of $\boldsymbol{h}_i$, the embedding of the target mention, and $\boldsymbol{e}_{i-1}^{(z_{ant})}$, the embedding of the entity that ant belongs to indicates the plausibility of their coreference. $g_{NA}(m_i)$ is defined as follows:

$$g_{NA}(m_i) = \boldsymbol{q}^{\mathrm{T}} \tanh(W_{NA}\left[\begin{smallmatrix} \boldsymbol{h}_i \\ \sum_k \boldsymbol{e}_{i-1}^{(k)} \end{smallmatrix}\right]), \tag{14}$$

where $\boldsymbol{q}$ is a weight vector, and W_{NA} is a weight matrix. The intuition is that whether a target phrase is $\mathtt{NA}_{\mathrm{CR}}$ can be judged from $\boldsymbol{h}_i$, the embedding of the target mention itself, and the sum of all the current entity embeddings. s_{CR}^{e} is added to s_{CR}^{m}, and the training objective is the same as the one described in Section 5.2.

In PA, the entity embedding corresponding to a candidate argument arg[5] is just added to the input vector $\boldsymbol{v}_{input}^{PA}$ described in Section 5.3, and *mention*- and *entity*-based score $s_{PA}^{m+e}(arg, m_i, c)$ is calculated in the same way as $s_{PA}^{m}(arg, m_i, c)$. The training objective is again the same as the one in Section 5.3.

In Wiseman et al. (2016), the oracle entity assignment is used for the entity embedding update in training, and the system output is used in a greedy manner in testing. Since the performance of PA is lower than that of English CR, there might be a more significant gap between training and testing. Therefore, scheduled sampling (Bengio et al., 2015) is adopted to bridge the gap: in training, the oracle entity assignment is used with probability ϵ_t (at the t-th iteration) and the system output otherwise. Exponential decay is used: $\epsilon_t = k^t$ (we set $k = 0.75$ for our experiments).

7 Experiments

7.1 Experimental Setting

The two kinds of evaluation sets were used for our experiments. One is the KWDLC (Kyoto Uni-

[5]When arg is $\mathtt{NA}_{\mathrm{PA}}$, the entity embedding is set to a zero vector.

versity Web Document Leads Corpus) evaluation set (Hangyo et al., 2012), and the other is Kyoto Corpus. KWDLC consists of the first three sentences of 5,000 Web documents (15,000 sentences) and Kyoto Corpus consists of 550 News documents (5,000 sentences). Word segmentations, POSs, dependencies, PASs, and coreferences were manually annotated (the closest referents and antecedents were annotated for zero anaphora and coreferences, respectively). Since we want to focus on the accuracy of CR and PA, gold segmentations, POSs, and dependencies were used. KWDLC (Web) was divided into 3,694 documents (11,558 sents.) for training, 512 documents (1,585 sents.) for development, and 700 documents (2,195 sents.) for testing; Kyoto Corpus (News) was divided into 360 documents (3,210 sents.) for training, 98 documents (971 sents.) for development, and 100 documents (967 sents.) for testing.

The evaluation measure is an F-measure, and the evaluation of both CR and PA was relaxed using a gold coreference chain, which leads to an entity-based evaluation. We did not use the conventional CR evaluation measures (MUC, B^3, CEAF and CoNLL) because our F-measure is almost the same as MUC, which is a link-based measure, and the other measures considering singletons get excessively high values[6], and thus they do not accord with the actual performance in our setting.[7]

7.2 Implementation Detail

The dimension of word embeddings was set to 100, and the word embeddings were initialized with pre-trained embeddings by Skip-gram with a negative sampling (Mikolov et al., 2013) on a Japanese Web corpus consisting of 100M sentences. The dimension of POS, sub-POS and conjugation were set to 10, respectively, and these embeddings were initialized randomly. The dimensions of the hidden layer in all the neural networks were set to 100. We used filter windows of 1,2,3 with 33 feature maps each for basic phrase CNN. Adam (Kingma and Ba, 2014) was adopted as the optimizer. F measures were averaged over four runs.

Checkpoint ensemble (Chen et al., 2017) was adopted, where the k best models were taken in terms of validation score, and then the parameters from the k models were averaged for testing. This method requires only one training process. In our experiments, k was set to 5, and the maximum number of epochs was set to 10.

We used a single-layer bi-LSTM for the input encoding (Section 5.1); preliminary experiments with stacked stacked bi-directional LSTM with residual connections were not favorable. Although we tried to use the character-level embedding of each word obtained with CNN, as the same way in the basic phrase embedding from the word sequences, the performance was not improved. The synonym dictionary used for CR (Section 5.2) was constructed from an ordinary dictionary and Web corpus, and has about 7,300 entries (Sasano et al., 2007).

7.3 Experimental Result

The following three methods were compared:

- Baseline: the method described in Section 5.
- "+entity (CR)": this method corresponds to (Wiseman et al., 2016). Entity embedding is updated based on the CR result, and CR takes the entity embedding into consideration.
- "+entity (CR,PA)" (**proposed method**): entity embedding is updated based on PA as well as CR result, and the CR and PA take the entity embedding into consideration.

The performance of CR and PA (case analysis and zero anaphora resolution (ZAR)) is shown in Table 1. The performance of CR and case analysis was almost the same for all the methods. For ZAR, "+entity (CR,PA)" improved the performance drastically.

CR surely benefits from the entity salience. Since entity embeddings are updated based on system outputs, its performance matters. The performance of Japanese CR is lower than that of English CR. Therefore, we assume there are improved/worsen examples, and our CR performance did not improve significantly. The performance of ZAR also matters. However, the performance of ZAR in our baseline model is extremely low, and thus there are few worsen examples and

[6]In Japanese, since zero pronouns are often used, there are many singletons. In example sentences (1) of the Introduction section, while "a car" and "It" form one cluster in English sentences (1-a), "a car" is a singleton in Japanese sentences (1-b) because a zero pronoun is used in the second sentence.

[7]For the Web evaluation set, the F-measure of our proposed method is 0.685, and the conventional evaluation measures are as follows; MUC: 69.1, B^3: 97.2, CEAF: 95.7, and CoNLL: 87.3.

	# of arguments	(1,971)	(2,949)	(559)	(675)	(1,715)	(1,049)	(1,436)	(591)	(546)	(299)

Table 2: Performance of case analysis and zero anaphora resolution for each case, and each argument position for zero anaphora resolution. The underlined values indicate the proposed method outperforms the baseline by a large margin.

a number of improved examples. Therefore, ZAR can benefit from the entity representation obtained by both CR and PA.

Table 2 shows performance of case analysis and zero anaphora resolution for each case, and each argument position. *Unspecified* was counted for *exophora*. Both for the News and Web evaluation sets, the performance for *inter* arguments of zero anaphora resolution, which was extremely difficult in the baseline method, was improved by a large margin by our proposed method.

7.4 Ablation Study

To reveal the importance of each clue for CR and PA, each clue was ablated. Table 3 shows the result on the development set. We found that, the path embedding was effective for PA, and the string match was effective for CR. The sentence distance for both CR and PA was effective for News, but not for Web since the Web evaluation corpus consists of three-sentence documents.

7.5 Comparison with Other Work

It is difficult to compare the performance of our method with other studies directly because there are no studies handling both CR and PA. The comparisons with other studies are summarized as follows:

- Shibata et al. (2016) proposed a neural-network based PA. Their target was *intra* and *exophora* for three major cases (NOM, ACC and DAT), and the performance was 0.534 on the same Web corpus as ours. The performance of our proposed method for the same three cases was 0.626. Furthermore, since their model assumes a static PA graph, their model is difficult to be extended to handle CR.
- Ouchi et al. (2017) proposed a grid-type RNN model for capturing the multi-predicate interaction. Their target was only *intra* on the NAIST text corpus (News), and the performance was 47.1. Since the NAIST text

	coreference resolution				zero anaphora resolution (ZAR)			
	Web		News		Web		News	
	F1	Δ	F1	Δ	F1	Δ	F1	Δ
Our proposed model	0.633		0.613		0.512		0.361	
CR								
- string match	0.212	-0.420	0.184	-0.429	0.474	-0.038	0.348	-0.013
- sentence distance	0.643	+0.011	0.588	-0.025	0.505	-0.007	0.343	-0.018
- synonym dictionary	0.643	+0.010	0.613	0.000	0.510	-0.002	0.348	-0.013
PA								
- path embedding	0.643	+0.010	0.625	+0.012	0.459	-0.054	0.268	-0.093
- selectional preference	0.638	+0.005	0.316	-0.297	0.507	-0.005	0.173	-0.188
- sentence distance	0.647	+0.014	0.606	-0.007	0.516	+0.004	0.327	-0.034

Table 3: Ablation study on the development set. The cells shaded gray represent they are not directly affected from the ablation, but from the counterpart analysis result.

corpus contains a lot of annotation errors as pointed out in Iida et al. (2016), we did not conduct our experiments on the NAIST text corpus.

- Iida et al. (2003) reported an F-measure of about 0.7 on News domain. The possible reason why our performance on News (0.541) is lower than theirs is that their basic unit is a compound noun while our basic unit is a noun, and thus our setting is difficult in comparison with theirs.

Since we handle *inter* as well as *intra* and *exophora* arguments in PA, together with CR, we can say that our experimental setting is more practical in comparison with other studies.

7.6 Error Analysis

In example (3), although the NOM argument of the predicate "通院ですよ!" (go to hospital) is *author*, our method wrongly classified it as *unspecified*.

(3) 毎日のように 通院ですよ！ 私自身は
every day go to hospital! I myself-TOP
とても 健康なんですけど。
very healthy.
((I) go to hospital every day!
(I am) very healthy, though.)

In the second sentence, our method correctly identified the antecedent of "私" (I) as *author*, and the NOM of "健康なんですけど" (healthy) as "私" (I). Our method adopts the greedy search so that it cannot exploit this handy information in the analysis of the first sentence. The global modeling using reinforcement learning (Clark and Manning, 2016a) for a whole document is our future work.

In example (4), although the NOM argument of "装飾されています" (be decorated) in the second sentence is "ドレス" (dress) in the first sentence, our method wrongly classified it as $\mathtt{NA}_{\mathtt{PA}}$.

(4) 大変 印象的な ドレスです。
very impressive dress-COPULA.
オーガンジーの 上に ラインを 描くように
organdie-GEN top-DAT line-ACC draw-as
小さな ビーズで 装飾されています。
small bead-INS decorated
((This is) a very impressive dress.
(The dress) is decorated by small beads as they draw a line on its organdy.)

"オーガンジー" (organdie) has a bridging relation to "ドレス", which might help capture the salience of "ドレス". The bridging reference resolution is our next target and must be easily incorporated into our model.

8 Conclusion

This paper has presented an entity-centric neural network-based joint model of coreference resolution and predicate argument structure analysis. Each entity has its embedding, and the embeddings are updated according to the result of both of these analyses dynamically. Both of these analyses took the entity embedding into consideration to access the global information of entities. The experimental results demonstrated that the proposed method could improve the performance of the inter-sentential zero anaphora resolution drastically, which has been regarded as a notoriously difficult task. We believe that our proposed method is also effective for other pro-drop languages such as Chinese and Korean.

Constraining MGbank: Agreement, L-Selection and Supertagging in Minimalist Grammars

John Torr
School of Informatics
University of Edinburgh
11 Crichton Street, Edinburgh, UK
john.torr@cantab.net

Abstract

This paper reports on two strategies that have been implemented for improving the efficiency and precision of wide-coverage Minimalist Grammar (MG) parsing. The first extends the formalism presented in Torr and Stabler (2016) with a mechanism for enforcing fine-grained selectional restrictions and agreements. The second is a method for factoring computationally costly null heads out from bottom-up MG parsing; this has the additional benefit of rendering the formalism fully compatible for the first time with highly efficient Markovian supertaggers. These techniques aided in the task of generating MGbank, the first wide-coverage corpus of Minimalist Grammar derivation trees.

1 Introduction

Parsers based on deep grammatical formalisms, such as CCG (Steedman and Baldridge, 2011) and HPSG (Pollard and Sag, 1994), exhibit superior performance on certain semantically crucial (unbounded) dependency types when compared to those with relatively shallow context free grammars (in the spirit of Collins (1997) and Charniak (2000)) or, in the case of modern dependency parsers (McDonald and Pereira (2006), Nivre et al. (2006)), no explicit formal grammar at all (Rimell et al. (2009), Nivre et al. (2010)). As parsing technology advances, the importance of correctly analysing these more complex construction types will also inevitably increase, making research into deep parsing technology an important goal within NLP.

One deep grammatical framework that has not so far been applied to NLP tasks is the Minimalist Grammar (MG) formalism (Stabler, 1997). Linguistically, MG is a computationally-oriented formalization of many aspects of Chomsky's (1995) Minimalist Program, arguably still the dominant framework in theoretical syntax, but so far conspicuously absent from NLP conferences. Part of the reason for this has been that until now no Minimalist treebank existed on which to train efficient statistical Minimalist parsers.

The Autobank (Torr, 2017) system was designed to address this issue. It provides a GUI for creating a wide-coverage MG together with a module for automatically generating MG trees for the sentences of the Wall Street Journal section of the Penn Treebank (PTB) (Marcus et al., 1993), which it does using an exhaustive bottom-up MG chart parser[1]. This system has been used to create MGbank, the first wide coverage (precision-oriented) Minimalist Grammar and MG treebank of English, which consists of 1078 hand-crafted MG lexical categories (355 of which are phonetically null) and currently covers approximately half of the WSJ PTB sentences. A problem which arose during its construction was that without any statistical model to constrain the derivation, MG parsing had to be exhaustive, and this presented some significant efficiency challenges once the grammar grew beyond a certain size[2], mainly because of the problem of identifying the location and category of phonetically silent heads (equivalent to type-changing unary rules) allowed by the theory. This problem was particularly acute for the MGbank grammar, which makes extensive use of such heads to multiply out the lexicon during pars-

[1]The parser is based on Harkema's (2001) CKY variant.

[2]As Cramer and Zhang (2010) (who pursue a similar treebanking strategy for HPSG) observe, there is very often considerable tension between the competing goals of efficiency and coverage for deep, hand-written and precision-oriented parsers, which aim not only to provide detailed linguistic analyses for grammatical sentences, but also to reject ungrammatical ones wherever possible.

ing. This approach reduces the amount of time needed for manual annotation, and also enables the parser to better generalise to unseen constructions, but it can quickly lead to an explosion in the search space if left unconstrained.

This paper provides details on two strategies that were developed for constraining the hypothesis space for wide-coverage MG parsing. The first of these is an implementation of the sorts of selectional restrictions[3] standardly used by other formalisms, which allow a head to specify certain fine-grained properties about its arguments. Pesetsky (1991) refers to this type of fine-grained selection as *l(exical)-selection*, in contrast to coarser-grained *c(ategory)-selection* and semantic *s-selection*. The same system is also used here to enforce morphosyntactic agreements, such as subject-verb agreement[4] and case 'assignment'. It is simpler and flatter than the structured feature value matrices one finds in formalisms such as HPSG and LFG, which arguably makes it less linguistically plausible. However, it is also considerably easier to read and to annotate, which greatly facilitated the manual treebanking task.

The second technique to be presented is a method for extracting a set of complex overt categories from a corpus of MG derivation trees which has the dual effect of factoring computationally costly null heads out from parsing (but not from the resulting parse trees) and rendering MGs fully compatible for the first time with existing supertagging techniques. Supertagging was originally introduced in Bangalore and Joshi (1999) for the Lexicalised Tree Adjoining Grammar (LTAG) formalism (Schabes et al., 1988), and involves applying Markovian part-of-speech tagging techniques to strongly lexicalised tag sets that are much larger and richer than the 45 tags used by the PTB. Because each supertag contains a great deal of information about the syntactic environment of the word it labels, such as its subcategorization frame, supertagging is sometimes referred to as 'almost parsing'. It has proven highly effective at making CCG (Clark and Curran, 2007; Lewis et al., 2016; Xu, 2016; Wu et al., 2017) parsing in particular efficient enough to support large-scale NLP tasks, making it desirable to apply this technique to MGs. However, existing supertaggers can only tag what they can see, presenting a problem for MGs, which include phonetically unpronounced heads. Our extraction algorithm addresses this by anchoring null heads to overt ones within complex LTAG-like supertag categories.

The paper is arranged as follows: section 2 gives an informal overview of MGs; section 3 introduces the selectional mechanisms and shows how these are used in MGbank to enforce case 'assignment' (3.1), l-selection (3.2) and subject-verb agreement (3.3); section 4 presents the algorithm for extracting supertags from a corpus of MG derivation trees (4.1), gives details of how a standard CKY MG parser can straightforwardly be adapted to make use of these complex tags (4.2), and presents some preliminary supertagging results (4.3) and a discussion of these (4.4); section 5 concludes the paper.

2 Minimalist Grammars

For a more detailed and formal account of the MG formalism assumed in this paper, see Torr and Stabler (2016) (henceforth T&S); here we give only an informal overview. MG is introduced in Stabler (1997); it is a strongly lexicalised formalism in which categories are comprised of lists of structure building features ordered from left to right. These features must be checked against each other and deleted during the derivation, except for a single c feature on the complementizer (C) heading the sentence, which survives intact (equivalent to reaching the S root in classical CFG parsing). Features are checked and deleted via the application of a small set of abstract Merge and Move rules. Two simple MG lexical entries are given below (The :: is a type identifier[5]):

him :: d
helps :: d= v

The structure building features themselves can be categorized into four classes: selector =x/x= features, selectee x features, licensor +y features, and licensee -y features. In a directional MG, such as that presented in T&S, the = symbol on the selector can appear on either side of the x category symbol, and this indicates whether selection is to the left or to the right. For instance, in our toy lexicon *helps*'s first feature is a d= selector, indicating that it is looking for a DP on its right. Since the

[3]These were briefly introduced in Torr (2017), but are expounded here in much greater depth.

[4]The approach to agreement adopted here differs in various respects from the operation Agree (Chomsky (2000) (2001)) assumed in current mainstream Minimalism.

[5]:: indicates a non-derived item and : a derived one.

first feature of *him* is a d selectee, we can merge these two words to obtain the following VP category, where ϵ is the empty string (The reason for the commas separating the left and right dependent string components from the head string component is to allow for subsequent head movement of the latter (see Stabler (2001)):

ϵ, *helps, him* : v

The strings of the two merged elements have been here been concatenated, but this will not always be the case. In particular, if the selected item has additional features behind its selectee, then it will need to check these in subsequent derivational steps via applications of Move. In that case the two constituents must be kept separate within a single expression following Merge. To illustrate this, we will update the lexicon as follows:

him :: d -case
helps :: d= +CASE v

Merging these two items results in the following expression:

ϵ, *helps*, ϵ : +CASE v, *him* : -case

The two subconstituents, separated above by the rightmost comma, are referred to as *chains*; the leftmost chain in any expression is the head of the expression; all other chains are movers. The +CASE licensor on the head chain must now attract a chain within the expression with a matching -case licensee as its first feature to move overtly to its left dependent (specifier) position[6]. Exactly one moving chain *must* satisfy this condition, or this expression will be unable to enter into any further operations (if more than one chain has the same licensee feature, it will violate a constraint on MG derivations known as the *Shortest Move Constraint* (SMC) and automatically be discarded). As this condition is satisfied by just *him*'s -case feature, we can perform the unary operation Move on this expression, resulting in the following new, single-chained expression:

him, helps, ϵ : v

We can represent these binary Merge and unary Move operations using the MG derivation tree in fig 1a. Derivation trees such as this are used frequently in work on Stablerian Minimalist Grammars, but they can be deterministically mapped into phrase structure trees like fig 1b[7].

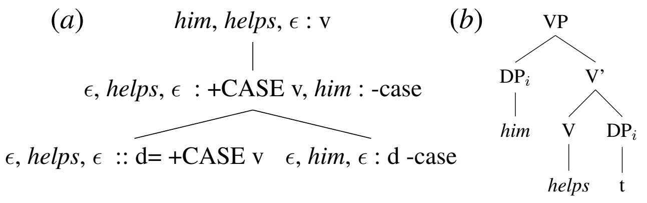

Figure 1: An MG Derivation tree for the VP *him, helps* (a); and its corresponding Xbar phrase structure tree (b). At this stage in the derivation the verb and its object are incorrectly ordered. This will be rectified by subsequent V-to-v head movement placing the verb to the left of its object.

To continue this derivation and derive the transitive sentence *he helps him*, we will expand our lexicon with the following categories, where square brackets indicate a null head and a $>$ diacritic on a selector feature indicates that a variant of Merge is triggered in which the head string of the selected constituent undergoes head movement to the left of the selecting constituent's head string:

he :: d -case
[trans] :: $>$v= =d lv[8]
[pres] :: lv= +CASE t
[decl] :: t= c

The full derivation tree and corresponding Xbar phrase structure tree for the sentence are given in fig 2 and fig 3 respectively.

3 Case, L-selection and Agreement

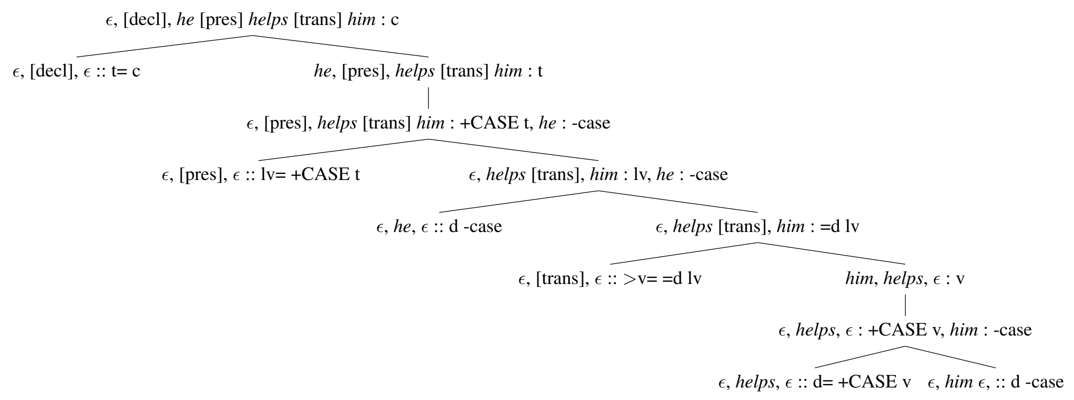
3.1 Case 'Assignment'

Notice that at present both the nominative and accusative forms of the masculine personal pronoun

[6]Uppercase licensors specify overt movement; lowercase licensors, by contrast, trigger covert movement, where only the features move, not the string (see T&S). Note that the MGbank grammar follows Chomsky's (2008) suggestion that it is the lexical verb V, rather than the null 'little v' head governing it, which checks the object's features, having inherited the relevant licensors (offline we assume) from v. This unifies the analysis of standard transitives with ECM constructions (*Jack expected Mary to help*), which in MGbank involve overt raising of the subject of the embedded infinitival clause to spec-VP to check accusative case (object control *Jack persuaded Mary to help* involves two such movements, the first for theta and the second for case).

[7]MGbank includes MG derivation tree, MG derived (bare phrase structure) tree, and Xbar tree formats.

[8]Note that little v is written as lv in MGbank derivation trees because upper vs lowercase letters are used to trigger different rules. In the corresponding MGbank Xbar trees, however, v has been converted to V and lv to v, to make these trees more familiar.



ϵ, [decl], he [pres] helps [trans] him : c
ϵ, [decl], ϵ :: t= c
he, [pres], helps [trans] him : t
ϵ, [pres], helps [trans] him : +CASE t, he : -case
ϵ, [pres], ϵ :: lv= +CASE t
ϵ, helps [trans], him : lv, he : -case
ϵ, he, ϵ :: d -case
ϵ, helps [trans], him : =d lv
ϵ, [trans], ϵ :: >v= =d lv
him, helps, ϵ : v
ϵ, helps, ϵ : +CASE v, him : -case
ϵ, helps, ϵ :: d= +CASE v
ϵ, him ϵ, :: d -case

Figure 2: MG derivation tree for the sentence *he helps him*.

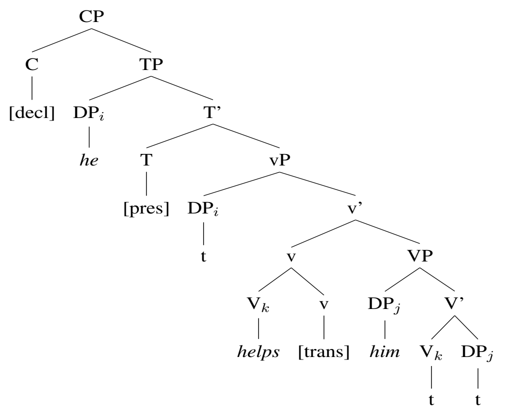


Figure 3: Xbar phrase structure tree for the sentence *he helps him*.

in our lexicon have the same feature sequence. This means that as well as correctly generating *he helps him*, our grammar also overgenerates *him helps he*. One way to solve this would be to split +/-case features into +/-nom and +/-acc. However, many items of category d in English (e.g. *the*, *a*, *you*, *there*, *it*) are syncretised (i.e. have the same phonetic form) for nominative vs. accusative case. This solution therefore lacks elegance as it expands the lexicon with duplicate homophonic entries differing in just a single (semantically meaningless) feature. Furthermore, increasing the size of the set k of licensees could adversely impact parsing efficiency, given that the worst case theoretical time complexity of MG chart parsing is known to be n^{2k+3} (Fowlie and Koller, 2017), where k is the number of moving chains allowed in any single expression by the grammar.

Instead, we will retain the single -case licensee feature and introduce NOM and ACC as subcategories, or *selectional properties*, of this feature. We will also subcategorize licensor features using *selectional requirements* of the form +X and -X, where X is some selectional property. Positive +X features require the presence of the specified property on the licensee feature being checked, while -X features require its absence. For example, consider the following updated lexical entries, where individual selectional features are separated by the . symbol:

him :: d -case{ACC}

he :: d -case{NOM}

helps :: d= +CASE{+ACC} v{PRES.TRANS}

[pres] :: lv{+PRES}= +CASE{+NOM} t{FIN.PRES}

[trans] :: >v{+TRANS}= =d lv

The +ACC selectional requirement on the V head's +CASE licensor specifies that the object's licensee feature must bear an ACC selectional property, while +NOM on the T(ense) head indicates that the subject's licensee must have a NOM property. For SMC purposes, however, these two different subcategories of -case will still block one another, meaning that k remains unaffected. The reader should satisfy themselves that our grammar now correctly blocks the ungrammatical *him helps he*.

We can now also address the aforementioned syncretism issue without increasing the size of the grammar. To do this, we simply allow features to bear multiple selectional properties from the same paradigm. For example, representing the pronoun *it* as follows will allow it to appear in either a nominative or an accusative case licensing position:

it :: d -case{ACC.NOM}

3.2 L-selection

As well as constraining Move, selectional restrictions can also constrain Merge. For instance, we can ensure that a subject control verb like *want* subcategorizes for a *to*-infinitival CP complement, and thereby avoid overgenerating *Jack wants that she help(s)*, simply by using the following categories for *want* and *that*:

want :: c{+INF}= v{TRANS}
that :: t{+FIN}= c{DECL.FIN}

Because *that* lacks the INF feature required by *want*, the ungrammatical derivation is blocked. We also need to block **Jack wants she help(s)*, where the overt C head is omitted. Minimalists assume that finite embedded declaratives lacking an overt C are nevertheless headed by a null C - a silent counterpart of *that*. A complicating factor is that a null complementizer is also assumed to head certain types of embedded infinitivals, including the embedded *help* clause in *Jack wants* [$_{CP}$ *to help*]. Given that these null C heads are (trivially) homophones and that they arguably exist to encode the same illocutionary force[9], an elegant approach would be to minimize the size of the lexicon - and hence the grammar - by treating them as one and the same item. On the other hand, using a single null C head syncretised with both FIN and INF will fail to block **Jack wants she help(s)*.

At present both C and T are specified as FIN, suggesting a redundancy. Instead, therefore, we will assume that T, being the locus of tense, is also the sole locus of inherent finiteness, but that C's selectee may inherit FIN or INF from its TP complement as the derivation proceeds[10]. Only a null C which inherits INF from a *to*-TP complement will be selectable by a verb like *want*, blocking the ungrammatical **Jack wants she help(s)*. However, although lacking inherent tense *properties*, certain C heads continue to bear inherent tense *requirements*[11]; for instance, *that*'s selector will retain its inherent +FIN, identifying it as a *finite* complementizer.

To implement this percolation[12] mechanism, we now introduce *selectional variables*, which we write as x, y, z etc. A variable on a selector or licensor feature will cause all the selectional properties and requirements (but not other variables) contained on the selectee or licensee feature that it checks to be copied onto all other instances of that variable on the selecting or licensing category's remaining unchecked feature sequence. Consider the following:

[trans] :: >v{+TRANS.x}= =d lv{x}
[pres] :: lv{+PRES.x}= +CASE{+NOM.x} t{FIN.x}
to :: lv{+BARE.x}= t{INF.x}
[decl] :: t{x}= c{DECL.x}
that :: t{+FIN.x}= c{DECL.x}

The [pres] T head has an x variable on its lv= selector feature and this same variable also appears to the right on its +CASE licensor and t selectee; any selectional properties or requirements contained on the lv selectee of its vP complement will thus percolate onto these two features (see fig 4). The x's on the two C heads will percolate the FIN property from the t selectee of [pres] to the c selectee of [decl], where it can be selected for by a verb like *say*, but not *want*, which requires INF (contained on the *to* T head); this will correctly block **Jack wants (that) she help(s)*.

Although we will not discuss the details here, it is worth noting that the MGbank grammar also uses this same percolation mechanism to capture long distance subcategorization in English subjunctives, thereby allowing *Jack demanded that she be there on time* while also blocking **Jack demanded that she is there on time*.

[9]Infinitival complementizers are sometimes assumed to encode *irrealis* force (see e.g. Radford (2004)) in contrast to *that* and its null counterpart which encode declarative force. However, the fact that *Jack expects her to help* is (on one reading) virtually synonymous with *Jack expects that she will help* suggests that in both cases the C head is encoding the same semantic property, with any subtle difference in meaning attributable to the contents of the Tense (T) head (i.e. *to* vs. *will*). Consider also *Mary wondered whether to help* vs. *Mary wondered whether she should help*, where the embedded infinitival and finite clauses are both clearly interrogative.

[10]If Grimshaw (1991) is correct that functional projections like DP, TP and CP are part of *extended projections* of the N and V heads they most closely c-command, then we should not be surprised to find instances where fine-grained syntactic properties are projected up through these functional layers.

[11]The property vs. requirement distinction mirrors Chomsky's (1995) interpretable vs. uninterpretable one.

[12]Note that because we are only allowing selectional properties and requirements to percolate, rather than the structure building feature themselves, this system is fundamentally different from that described in Kobele (2005), where it was shown that allowing licensee features to be percolated leads to type 0 MGs. Furthermore, by unifying any multiple instances of the same selectional property or requirement that arise on a structure building feature owing to percolation, we can ensure that the set of MG terminals and non-terminals remains finite and thus that the weak equivalence to MCFG (Michaelis, 1998; Harkema, 2001) is maintained.

ϵ, [pres], *helps* [trans] *him* : +CASE{+NOM.PRES.TRANS.+3SG} t{FIN.PRES.TRANS.+3SG}, *he* : -case{NOM.3SG}

ϵ, [pres], ϵ :: lv{+PRES.x}= +CASE{+NOM.x} t{FIN.x} ϵ, *helps* [trans], *him* : lv{PRES.TRANS.+3SG}, *he* : -case{NOM.3SG}

Figure 4: Merge of T with vP with percolation of selectional properties and requirements.

3.3 Subject-Verb Agreement

The percolation mechanism introduced above can also be used to capture agreement between the subject and the inflected verb. In Minimalist theory, this agreement is only indirect: the subject actually agrees directly with T when it moves to become the latter's specifier, having been initially selected for either by V (in the case of non-agent arguments) or by v (in the case of agent subjects - see fig 3)[13]. There is also assumed to be some sort of syntactic agreement (Roberts (2010)) and/or phonetic (Chomsky (2001)) process operating between T and the inflected verb, resulting in any tense/agreement inflectional material generated in T(ense) being suffixed onto the finite verb.

In MGbank, tense agreement is enforced between T and the finite verb by percolating a PRES or PAST selectional property from the selectee of the latter up through the tree so that it can be selected for by the [pres] or [past] T head. Subject-verb agreement, meanwhile, is enforced by also placing an agreement selectional restriction (+3SG, +1PL, -3SG etc) on the finite verb's selectee, and then percolating this up to the +CASE licensor of the T head. We thus have the following updated entries:

him :: d -case{ACC.3SG}
he :: d -case{NOM.3SG}
helps :: d= +CASE{+ACC} v{+3SG.PRES}

The percolation step from little v (lv) to T is shown in fig 4; lv has already inherited PRES and +3SG from V (*helps*) at this point, and these features now percolate to T's licensor and selectee[14] owing to the x variables; the PRES feature inherited from V by v is selected for by T, enforcing non-local tense agreement between T and V, while the +3SG enforces subject verb agreement[15].

4 MG Supertagging

The above selectional system restricts the parser's search space sufficiently well that it is feasible to generate an initial MG treebank for many of the sentences in the PTB, particularly the shorter ones and those longer ones which do not require the full range of null heads to be allowed into the chart[16]. However, for longer sentences requiring null heads such as extraposers, topicalizers or focalizers, parsing remains impractically slow. In this section we show how computationally costly null heads can be factored out from MG parsing al-

[13]A reviewer asks why all subjects are not directly selected for by V, suggesting that this appears to be a deviation from semantics, and more generally calls for some explanation of the underlying modelling decisions adopted here (e.g. head movements, case movements, null heads etc) which clearly deviate from the more surface oriented analyses of other formalisms used in NLP. In many cases these decisions rest on decades of research which we cannot hope to summarise here; for good introductions to Minimalism, see Radford (2004) and Hornstein et al. (2005). It is worth noting, however, that the null v head in fig 3 is essentially a valency increasing causative morpheme which ends up suffixed to the main verb (via head movement of the latter), effectively enabling it to take an additional 'external' argument. We can therefore view the V-v complex as a single synthetic verbal head, so that just as in a language like Turkish the verb *öl* meaning 'to die' can be transformed from an intransitive to a transitive (meaning 'to kill') by appending to it the causative suffix *dür*, in English a verb like *break* can be transformed from an intransitive (*the window broke*) to a transitive (*he broke the window*) by applying a null version of this morpheme. This cross-linguistic perspective (which makes this formalism potentially very relevant for machine translation) reflects a central goal of Minimalism, which is to show that at a relevant level of abstract representation, all languages share a common syntax (making them easier for children to learn). Most of the analyses adopted here are standard ones from the literature (see e.g. Larson's (1988) VP Shell Hypothesis, Baker's (1988) Uniform Theta Assignment Hypothesis, Koopman and Sportiche's (1991) Verb Phrase Internal Subject Hypothesis, and Chomsky (1995; 2008) on little v).

[14]Note that selectional requirements are entirely inert on selectee and licensee features while, conversely, selectional properties are inert on selectors and licensors.

[15]For non-3SG present tense verbs, MGbank uses a -3SG negative selectional requirement; for verbs with more complex paradigms, however, the grammar allows for inclusive disjunctive selectional requirements. For example, the selectee feature of the *was* form of the verb *be* bears the feature [+1SG|+3SG], allowing it to take either a first or third singular subject.

[16]The Autobank parser holds certain costly null heads back from the chart and only introduces these incrementally if it fails to parse the sentence without them. The advantage of this strategy is that it improves efficiency for many sentences, but the disadvantage is that it can also result in correct analyses being bled by incorrect ones. The supertagging approach introduced in this section eliminates this problem, since null heads are now anchored to overt ones as part of complex categories, any of which may freely be assigned by the supertagger.

together by anchoring them to overt heads within complex overt categories extracted from this initial treebank. This allows much more of the disambiguation work to be undertaken by a statistical Markovian supertagger[17], a strategy which has proven highly effective at rendering CCG parsing in particular efficient enough for large-scale NLP tasks. We also show how a standard CKY MG parser can be adapted to make use of these complex categories, and present some preliminary supertagging results.

4.1 Factoring null heads out from MG parsing

Consider again the lexical items which appear along the spine of the clause in fig 2.

[decl] :: t= c
[pres] :: lv= +CASE t
[trans] :: >v= =d lv
helps :: d= +CASE v

Recall that the null [trans] little v merges with the VP headed by overt *helps*, while the null [pres] T head merges with the vP, and the null [decl] C with TP. If we view each of these head-complement merge operations as a link in a chain, then all of these null heads are either directly (in the case of v) or indirectly (in the case of T and C) linked to the overt verb. All of the information represented on V, v, T and C heads in Minimalism is in LTAG represented on a single overt lexical category (known as an initial tree). We can adopt this perspective for Minimalist parsing if we view chains of merges that start with some null head and end with some overt head as constituting complex overt categories. Given a corpus of derivation trees, it is possible to extract all such chains appearing in the corpus, essentially precompiling all of the attested combinations of null heads with their overt anchors into the lexicon. A very simple algorithm for doing this is given below.

```
for each derivation tree $\tau$:
  for each null head $\eta$ in $\tau$:
     if $\eta$ is a proform:
        linkWithGovernor($\eta$);
     else:
        linkWithHeadOfComplement($\eta$);
  groupLinksIntoSupertags()
```

[17]During treebank generation we used the C&C (Clark and Curran, 2007) supertagger retrained to take gold CCGbank categories and words as input and output MGbank supertags.

For each derivation tree, we first anchor all null heads either directly or indirectly to some overt head; this is achieved by extracting a set of links, each of which represents one merge operation in the tree. Each link is comprised of the two atomic MG lexical categories that are the arguments to the merge operation along with matching indices indicating which features are checked by the operation. Applying the algorithm to our example sentence would result in the following 3 links:

link1: [decl] :: t=^{1} c, [pres] :: lv= +CASE t^1
link2: [pres] :: lv=^{2} +CASE t, [trans] :: v= =d lv^2
link3: [trans] :: v=^{3} =d lv, *helps* :: d= +CASE v^3

The majority of null heads are simply linked with the head of their complement, the only exception being that null proforms, such as PRO in arbitrary control constructions[18] (named [pro-d] in MGbank) and the null verbal heads used for VP ellipsis ([pro-v] in MGbank), are linked to whichever head selects for them (i.e. their governor). Assuming that null proforms are the only null heads appearing at the bottom of any extended projection (ep)[19] in the corpus, this ensures that all of the lexical items inside a given supertag are part of the same ep, except for PRO, which is trivially an ep in its own right and must therefore be anchored to the verb that selects it. Note that some atomic overt heads (such as *he* and *him* in our example sentence) will not be involved in any links and will therefore form simplex supertags.

Once the merge links and unattached overt heads are extracted, the algorithm then groups them together in such a way that any lexical items which are chained together either directly or indirectly by merge links are contained in the same group. Because links are only formed between null heads and their complements (except in the case of the null proform heads), and not between heads and specifiers or adjuncts, each chain ends with the first overt head encountered, so that every (null or overt) head is guaranteed to appear in just one group and each group is guaranteed to contain at most one overt lexical item.

The above merge links would form one group, or supertag, represented compactly as follows:

[18]Other instances of control are treated as cases of A-movement following Boeckx et al. (2010).

[19]Here, we define the clausal extended projection as running from V up to the closest CP (or TP if CP is absent, as in ECM constructions), and for nominals from N up to the closest PP (or DP if PP is absent).

[decl] :: t=^{1} c
[pres] :: lv=^{2} +CASE t^1
[trans] :: v=^{3} =d lv^2
helps :: d= +CASE v^3

All of the subcategorization information of the main verb is contained within this supertag, but unlike in the case of LTAG categories, this is not always the case: if an auxiliary verb were present between little vP and TP, for instance, then only little v would be anchored to the main verb, while T and C would be anchored to the structurally higher auxiliary. C is the head triggering A'-movements, such as wh-movement and topicalization. A consequence of this is that, although like LTAG (but unlike CCG) A'-movement is lexicalised onto an overt category here, that overt category is often structurally and linearly much closer to the A'-moved element than in LTAG. For instance, in the sentence *what did she say that Pete eats for breakfast?*, an LTAG would precompile the wh-movement onto the supertag for *eats*, whereas here the [int] C head licensing this movement would be precompiled onto *did*.

As noted in Kasai et al. (2017), LTAG's lexicalisation of unbounded A'-movement is one reason why supertagging has proven more difficult to apply successfully to TAG than to CCG, Markovian supertaggers being inherently better at identifying local dependencies. We hope that lexicalising A'-movement into a supertag that is linearly closer to the moved item will therefore ultimately prove advantageous.

4.2 Adapting an existing CKY MG parser to use MG supertags

The MG supertags can be integrated into an existing CKY MG parser quite straight forwardly as follows: first, for each supertag token assigned to each word in the sentence, we map the indices that indicate which features check each other into globally unique identifiers. This is necessary to ensure that different supertags and different instances of the same supertag assigned to different words are differentiated by the system. Then, whenever one of the constrained features is encountered, the parser ensures that it is only checked against the feature with the matching identifier. The parser otherwise operates as usual except that thousands of potential merge operations are now disallowed, with the result that the search space is drastically reduced (though this of course depends on the number of supertags assigned to each word).

One complication concerns the dynamic programming of the chart. In standard CKY MG parsing, as with classical CFG CKY, items with the same category spanning the same substring are combined into a single chart entry during parsing. This prevents the system having to create identical tree fragments multiple times. But the current approach complicates this because many items now have different predetermined futures (i.e. their unchecked features are differentially constrained), and when the system later attempts to reconstruct the trees by following the backpointers, things can become very complicated. We can avoid this issue, however, simply by treating the unique identifiers that were assigned to certain selector features as part of the category. This has the effect of splitting the categories and will, for instance, prevent two single chain categories =d^1 d= v and =d^2 d= v from being treated as a single chart entry until their =d features have been checked.

4.3 Preliminary Results

An LSTM supertagger similar to that in (Lewis et al., 2016) was trained on 13,000 sentences randomly chosen from MGbank, extracting various types of (super)tag from the derivation trees. A further 742 sentences were used for development, and 753 for testing, again randomly chosen. We tried training on just the automatically generated corpus and testing on the hand-crafted trees, but this hurt 1-best performances by 2-4%, no doubt owing to the fact that this hand-crafted set deliberately contains many of the rarer constructions in the Zipfian tail which didn't make it into the automatically generated corpus[20]. With more data this effect should lessen. The results for n-best supertagging accuracies are given in table 1.

4.4 Discussion

Unsurprisingly, the accuracies improve as the number of tags decreases. The CCGbank data contains by far the least tag types and has the highest performance. However, it is worth noting that the MG supertags contain a lot more information than their CCGbank counterparts, even once A'-movement and selectional restrictions are removed. For example, MGbank encodes all predicate-argument relations directly in the syntax, distinguishing for instance between subject

[20]There are 831 category types in the automatically generated corpus from a total of 1078 for the entire treebank.

	rei	ab	rei-A’	ab-A’	ov	ccg
|tags|	3087	2087	1883	1181	717	342
1-best	79.1	81.1	83.0	84.2	88.0	92.4
2-best	88.4	90.2	91.1	91.9	95.3	97.1
3-best	91.6	93.5	94.1	94.8	97.1	98.3
10-best	96.4	97.4	97.9	98.2	99.2	99.5
25-best	97.6	98.5	98.9	99.1	99.7	99.7
40-best	98.0	98.7	99.0	99.4	99.8	99.8

Table 1: Accuracies on different MG (super)tag types showing the % of cases where the correct tag appears in the n-best list. The first row gives the number of different (super)tag types in the data; rei(fied) is supertags with all selectional properties and requirements; ab(stract) is supertags with all but 5 of these features removed[22]; -A’ indicates that null C heads, and [focalizer], [topicalizer], [wh] and [relativizer] heads were not included in the supertags, thereby delexicalising A’-movement and moving the formalism towards CCG; ov(ert) is the (reified) atomic overt tags; ccg is the ccgbank supertags.

raising and subject control verbs, and between object raising (ECM) and object control verbs, whereas CCGbank itself does not. For a fairer comparison, therefore, we would need to combine CCGbank syntactic types with the semantic types of Bos (Bos et al., 2004). There are also many types of dependencies, such as those for rightward movement and correlative focus (*either..or, neither..nor, both..and*), which could be delixicalised to reduce the size of the supertag sets further. Of course, the more null heads that are allowed freely into the chart, the stronger the statistical model of the derivation itself must be. Finally, the MGbank grammar (particularly in its reified versions) is precision-oriented, in the sense that it blocks many ungrammatical sentence types (agreement/l-selection violations, binding theory violations, (anti)*that*-trace violations, wh-island violations etc). The extra information needed to attain this precision expands the tag set but should also ultimately help in pruning the search space, enabling the parser to try more tags. The CCGbank grammar, meanwhile, is much more flexible (making it very robust), and therefore leaves a much greater proportion of the task of constraining the search space to the probability model.

The 1-best accuracies are clearly not high enough to be practical for wide-coverage MG parsing at present. By the time the 3-best supertags per word are considered, however, the accuracies are in all cases quite high, and by the 25-best they are very high, although it is difficult to say at this point what level will be sufficient for wide-coverage parsing. The overt atomic tagging is much better, achieving high accuracy by the 3-best, but these tags contain the least information and therefore leave much more disambiguation to the parsing model. Clearly, using MG supertags will require an algorithm that navigates the search space as efficiently as possible and allows the supertagger to try as many tags for each word as possible. We are in the process of re-implementing the A* search algorithm of (Lewis and Steedman, 2014), which allows their CCG parser to consider the complete distribution of 425 supertags for each word.

The potential efficiency advantages of parsing with MG supertags are considerable: reparsing the seed set of 960 trees (which includes 207 sentences which were added to cover some constructions not found in the Penn Treebank) takes over 8 hours on a 1.4GHz Intel Core i5 Macbook Air with a perfect oracle providing the 1-best overt atomic tag, but just over 6 minutes using reified supertags.

5 Conclusion

We presented two methods for constraining the parser’s search space and improving efficiency during wide-coverage MG parsing. The first extends the formalism with mechanisms for enforcing morphosyntactic agreements and selectional restrictions. The second anchors computationally costly null heads to overt heads inside complex overt categories, rendering the formalism fully compatible with Markovian supertagging techniques. Both techniques have proven useful for the generation of MGbank. We are now working on an A* MG parser which can consider the full distribution of supertags for each word and exploit the potential of these rich lexical categories.

Acknowledgments

A big thank you is due to Mark Steedman, as well as to the four anonymous reviewers for all their helpful comments and suggestions. Most especially, I would like to thank Miloš Stanojević, who coded up the LSTM supertagger, ran the experiments reported in this paper and made some very helpful suggestions regarding the supertagging method described above. This project was supported by the Engineering and Physical Sciences Research Council (EPSRC) and an ERC H2020 Advanced Fellowship GA 742137 SEMANTAX and a Google Faculty Award.

Not that much power: Linguistic alignment is influenced more by low-level linguistic features rather than social power

Abstract

Linguistic alignment between dialogue partners has been claimed to be affected by their relative social power. A common finding has been that interlocutors of higher power tend to receive more alignment than those of lower power. However, these studies overlook some low-level linguistic features that can also affect alignment, which casts doubts on these findings. This work characterizes the effect of power on alignment with logistic regression models in two datasets, finding that the effect vanishes or is reversed after controlling for low-level features such as utterance length. Thus, linguistic alignment is explained better by low-level features than by social power. We argue that a wider range of factors, especially cognitive factors, need to be taken into account for future studies on observational data when social factors of language use are in question.

1 Introduction

The effect of social power on language use in conversations has been widely studied. The Communication Accommodation Theory (Giles, 2008) states that the *social power* of speakers influence the extent to which conversation partners accommodate (or align, coordinate) their communicating styles towards them. This theory is supported by findings from qualitative studies on employment interviews (Willemyns et al., 1997), classroom talks (Jones et al., 1999), and the more recent data-driven studies on large online communities and court conversations (Danescu-Niculescu-Mizil et al., 2012; Jones et al., 2014; Noble and Fernández, 2015). In particular, Danescu-Niculescu-Mizil et al. (2012) uses a probability-based measure of linguistic alignment to demonstrate that people align more towards conversation partners of higher power, i.e., the admin users in Wikipedia talk-page, and the justices in U.S. supreme court conversations, than those of lower power, i.e., the non-admin users and the lawyers.

However, while these results find sound explanations from socio-linguistic theories, they are still somewhat surprising from the perspective of cognitive mechanisms of language production, because the mutual alignment between interlocutors of in natural dialogue can be explained by an automatic and low-level priming process (Pickering and Garrod, 2004). It is known that the strength of alignment is sensitive to low-level linguistic features (e.g., words, syntactic structures etc.), such as temporal clustering properties (Myslín and Levy, 2016), syntactic surprisal measured by prediction error (Jaeger and Snider, 2013), and lexical information density (Xu and Reitter, 2018).

Then why, or under what mechanisms, can alignment be affected by the relatively high-level social perceptions of power as reported? Could it be the case that the effect of power on alignment is actually due to the other low level features in language, such as the ones mentioned above? Is the effect of power still observable, if we control for other factors? How large is the effect? Is it significant enough to be captured by computational measures of alignment? Answering these questions will help clarify the role of social factors in linguistic alignment, and improve our understanding of language production in general.

In this study, we conduct a two-step model analysis. First, we use a basic model that has two predictors, *count* (number of a certain linguistic marker in the preceding utterance) and *power* (power status of the preceding speaker), to predict the occurrence of the same marker in the following utterance. Here, the linguistic markers are derived from 11 Linguistic Inquiry and Word Count (LIWC; Pennebaker et al., 2001) categories (e.g., *article*, *adverb*, etc.). With the basic model, the main effect of *count* characterizes the strength of alignment, and the interaction between *count* and *power* characterizes the effect of power on alignment (Section 3). Second, we use an extended model that includes a third predictor, *utterance length* (It is chosen as a typical low-level linguistic feature, discussed in Section 2.3), on top of the basic model. With the extended model, we aim to examine whether the inclusion of *utterance length* will influence the interaction between *count* and *power* (Section 4). Therefore, we can examine the extent to which the effect of power on alignment is confounded by low-level linguistic features.

To clarify, our goal is not to disprove the existence of social accommodation in dialogue. Nonetheless, it is important to distinguish between what is caused by automatic priming-based alignment and what is caused by high-level, intentional accommodation. As we will discuss, these are different processes with different predictions. Throughout this paper we use the term *alignment* to refer to the priming-based process, and accommodation to refer to the intentional process.

2 Related Work

2.1 Social power and linguistic alignment

The social factors of language use have been widely studied. Communication Accommodation Theory (Giles, 2008) posits that individuals adapt their communication styles to increase or decrease the social distance from their interlocutors. One factor that affects the adaptation of linguistic styles is *social power*. Typically, people of lower power converge their linguistic styles to those of higher power; for example, interviewees towards interviewers (Willemyns et al., 1997), or students towards teachers (Jones et al., 1999).

More recently, sensitive quantitative methods have been applied to this line of inquiry. Danescu-Niculescu-Mizil et al. (2012) computed the probability-based linguistic coordination measure among Wikipedia editors and participants of the US supreme court, and they showed that people with low power (e.g., lawyers, non-admins) exhibit greater coordination than people with high power (Justices, admins). Using the same data, Noble and Fernández (2015) found that linguistic coordination is positively correlated with social network centrality, and this effect is even greater than the effect of power status distinction.

The aforementioned studies do not include low-level language features in their analysis and thus overlook the possibility that cognitive mechanisms may be able to more readily explain the data. Importantly, as we will later discuss, these studies use a measurement of alignment that we believe is more appropriately measuring the automatic process, rather than the intentional one.

2.2 Quantifying linguistic alignment

A variety of computational measures of linguistic alignment have been developed. Some quantify the increase in conditional probability of certain elements (words or word types) given that they have appeared earlier (Church, 2000; Danescu-Niculescu-Mizil et al., 2012). Some compute the proportion of repeated lexical entries or syntactic rules between two pieces of text (Fusaroli et al., 2012; Wang et al., 2014; Xu and Reitter, 2015). Some use the coefficients returned by generalized linear models (McCullagh, 1984; Breslow and Clayton, 1993; Lindstrom and Bates, 1990) as an index of alignment (Reitter and Moore, 2014). A large body of the existing computational measures intensively use LIWC (Pennebaker et al., 2001) to construct representations of language users' styles, which can be used to measure alignment with distance-like metrics (Niederhoffer and Pennebaker, 2002; Jones et al., 2014). Many of these approaches do not distinguish between different levels of linguistic analysis and different psycholinguistic processes (phonological, lexical, syntactic, etc.), and neither do we. Alignment is consistently present across these levels and processes, although it is not as clear in naturalistic language as it is in the constrained utterances of experiments, particularly at the syntactic level (Healey et al., 2014). We are concerned with the question of whether alignment is a socially linked, intentional adaptation process, as opposed to addressing any particular cognitive model.

More recently, Doyle et al. (2016) pointed out that most existing measures are difficult to compare, and emphasized the need for a universal measure. The Hierarchical Alignment Model (HAM; Doyle et al., 2016) and Word-Based HAM (WHAM; Doyle and Frank, 2016) use statistical inference techniques, which out-perform other measures in terms of robustness of capturing linguistic alignment in social media conversations.

In this study, we choose to use generalized linear models to quantify linguistic alignment, avoiding issues with more complex, and less inspectable models. For instance, the commonly used probability based methods and their more advanced variants (HAM and WHAM) lack the flexibility to jointly examine multiple factors (e.g., speaker groups, utterance length etc.) that influence alignment. Another issue is that they do not take into account the number of occurrences of linguistic markers, which is known to affect alignment (see Section 2.3). Conversely, though linear models do not give an accurate per-speaker estimate of alignment (which we do not need for the purpose of this study), they do provide the ability to examine multiple factors that influence alignment by simply including multiple predictors in the model. As should be clear, a generalized linear model also already takes into account baseline usage with a fitted intercept. Given these considerations, we use generalized linear models for quantitative analysis. The formulation of our models is described in Sections 3.2 and 4.1.

2.3 Cognitive constraints on linguistic alignment: why utterance length matters

There are many, at times competing, cognitive explanations of linguistic alignment in both comprehension and production. Jaeger and Snider (2013) explained alignment as a consequence of expectation adaptation, and they found that stronger alignment is associated with syntactic structures that have higher surprisal (roughly speaking, less common). Alignment in language production can also be modeled as a general memory phenomenon (Reitter et al., 2011), which explains a number of known interaction effects. Myslín and Levy (2016) found that sentence comprehension is faster when the same syntactic structure clusters in time in prior experience than when it is evenly spaced in time. Myslín and Levy (2016) cast comprehension priming as the rational expectation for repetition of stimuli. Though this result is not directly related to comprehension-to-production priming, it makes sense to anticipate that production could also be sensitive to the clustering patterns of linguistic elements, because comprehension and production are closely coupled processes (Pickering and Garrod, 2007).

Utterance length, i.e., the number of words in utterance, is a feature that closely relates to both surprisal and clustering properties. Longer utterances tend to have higher syntactic surprisal (Xu and Reitter, 2016a), and it is reasonable to assume they tend to contain more evenly distributed stimuli. Thus, utterance length is a low-level linguistic feature that correlates with many of the causes of alignment. In this way, we use utterance length as a stand-in for low-level linguistic features as a whole when comparing it with social power, a much higher-level feature. Examining alignment (in social science research and elsewhere) therefore calls for controlling sentence length.

3 Experiment 1: Basic model

In Experiment 1, we justify the practice of using generalized linear models to quantify linguistic alignment. We compare two ways of characterizing the occurrence of LIWC-derived markers in a preceding utterance, binary presence and numeric count, to determine which results in better model. We use an interaction term in the model to quantify the effect of the power status of speakers on linguistic alignment, which serves as the basis for the following sections.

3.1 Corpus data

We use two datasets compiled by Danescu-Niculescu-Mizil et al. (2012): Wikipedia talk-page corpus (*Wiki*) and a corpus of United States supreme court conversations (*SC*). Wiki is a collection of conversations from Wikipedia editor's talk Pages[1], which contains 125,292 conversations contributed by 30,732 editors. SC is a collection of conversations from the U.S. Supreme Court Oral Arguments[2], with 51,498 utterances making up 50,389 conversational exchanges, from 204 cases involving 11 Justices and 311 other participants (lawyers or amici curiae).

A conversation consists of a sequence of utterances, $\{u_i\}(i = 1, 2, \ldots, N)$, where N is the total number of utterances in the conversation. Because people take turns to talk in conversation, u_i and u_{i+1} are always from different speakers. Since our interest here is the alignment between different speakers (as opposed to within the same speaker), we use a sliding window of size 2 to go through

[1]http://en.wikipedia.org/wiki/Wikipedia:Talk_page_guidelines

[2]http://www.supremecourt.gov/oral_arguments/

the whole conversation, generating a sequence of adjacent utterance pairs, $\{\langle prime_i, target_i\rangle\}(i = 1, 2 \ldots N - 1)$.

Next, we process each utterance u_i by counting the number of occurrences of 14 linguistic markers that are derived from LIWC categories, resulting in 14 counts for each utterance. These 14 linguistic markers are: high frequency adverbs (*adv*), articles (*art*), auxiliary verbs (*auxv*), certainty (*certain*), conjunctions (*conj*), discrepancy (*discrep*), exclusion (*excl*), inclusion (*incl*), impersonal pronouns (*ipron*), negations (*negate*), personal pronouns (*ppron*), prepositions (*prep*), quantifiers (*quant*), and tentativeness (*tentat*). These fourteen markers come from taking the union of the 8 markers used by Danescu-Niculescu-Mizil et al. (2012) and the 11 markers used by Doyle and Frank (2016), which are the main studies we wanted to compare with.

3.2 Statistical models

We formulate alignment as the impact of using certain linguistic elements in the preceding utterance on their chance to appear again in the following utterance. In the language of generalized linear models, we use the occurrence of linguistic markers in *target* as the response variable and the predictor is their occurrence in *prime*. These occurrences can be represented as either a boolean or a count. Thus alignment is characterized by the β coefficient of the predictor, which allows the model to distinguish the prevalence of *Occurrence* or another feature in primed situations as compared to its prior in the corpus. Factors that may influence alignment (e.g., social power) can then be examined by adding a corresponding interaction term to the model.

Our first step, then, is to replicate the previous studies' findings of the effect of social power on alignment. Two models were fitted, predicting the *presence* of the linguistic marker *m* in *target* utterance over its absence. We fit models both corresponding to a binary predictor (C_{presence}) and a count-based one (C_{count}). Both models include a second binary predictor, C_{power}, indicating the power status of the *prime* speaker (*high* vs. *low*), and its interaction with C_{presence} and C_{count}, respectively. Additionally, random intercepts on linguistic marker and *target* speaker are fitted, based on the consideration that individuals might have different levels of alignment towards different markers. C_{count} is log-transformed to maximize model fit according to Bayesian Information Criterion; this is commensurate with standard psycholinguistic practice and known cumulative priming and memory effects. Equation (1) shows the count-based model. To reiterate, the interaction term $C_{\text{count}} * C_{\text{power}}$ characterizes the effect of power on alignment.

$$\begin{aligned}\text{logit}(m) &= \ln \frac{p(m \text{ in } \textit{target})}{p(m \text{ not in } \textit{target})} \\ &= \beta_0 + \beta_1 C_{\text{count}} + \beta_2 C_{\text{power}} \\ &+ \beta_3 \mathbf{C_{count}} * \mathbf{C_{power}}\end{aligned} \tag{1}$$

3.3 Model coefficients

The main effects of C_{presence} and C_{count} are significant ($p < 0.001$) and positive in both corpora (SC: $\beta_{\text{presence}} = 0.439$, $\beta_{\text{count}} = 0.291$; Wiki: $\beta_{\text{presence}} = 0.440$, $\beta_{\text{count}} = 0.395$), which captures the linguistic alignment from *prime* to *target*. However, there is difference in how alignment is influenced by power between the two corpora: In SC, $C_{\text{count}} * C_{\text{power}}$ is significant ($\beta = 0.078$, $p < 0.001$), but $C_{\text{presence}} * C_{\text{power}}$ is non-significant; In Wiki, on the contrary, $C_{\text{presence}} * C_{\text{power}}$ is marginally significant ($\beta = 0.014$, $p = .055$), but $C_{\text{count}} * C_{\text{power}}$ in not significant. No collinearity is found between C_{count} (or C_{presence}) and C_{power} (Pearson correlation $r < 0.2$).

To explore why using C_{presence} vs. C_{count} results in different significance levels for SC and Wiki, we fit a individual linear model for each linguistic marker, using 14 *disjoint* subsets of each corpus. We present the z scores and significance levels of the two interaction terms are reported in Table 1. First, in SC the interaction term $C_{\text{presence}} * C_{\text{power}}$ is significant for 9 out of 14 markers. In Wiki, $C_{\text{count}} * C_{\text{power}}$ is significant for 5 out of 14 markers. This suggests that the interaction between the occurrence of linguistic markers and the power status of speakers exists within a subset of the linguistic categories, but not across all of them. Thus, we consider this first experiment a replication of past findings of the effect of social power on alignment: social power has a significant effect across certain markers, but its overall effect is neutralized in the full model since some markers at not significant. This analysis also revealed that $C_{\text{count}} * C_{\text{power}}$ is more reliable in capturing this effect, which is what we will use in the following experiment.

Table 1: Summary of the 14 models that fit individual markers on disjoint data subsets. Wald's z-score and significance level (*** for $p < 0.001$, ** for $p < 0.01$, * for $p < 0.05$, and † for $0.05 < p < 0.1$) of the interaction terms ($C_{\text{presence}} * C_{\text{power}}$ or $C_{\text{count}} * C_{\text{power}}$) are reported.

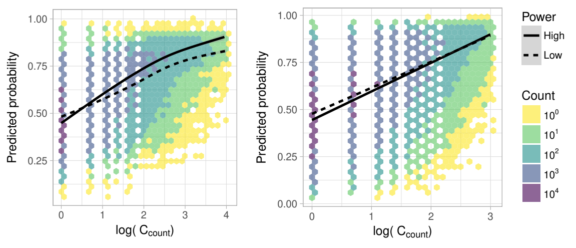
3.4 Visualizing the effect of power

To better understand the interaction term $C_{\text{count}} * C_{\text{power}}$, we divide the data into two groups by whether C_{power} is *high* or *low*, and fit a model on each of the groups. In the models we include only one predictor C_{count} (see Equation (2)). Then we compare the main effects (β_1 coefficients) from the two groups.

$$\text{logit}(m) = \beta_0 + \beta_1 C_{\text{count}} \tag{2}$$

Unsurprisingly, the main effects of C_{count} are significant for both groups ($p < 0.001$). But more importantly, the β_1 coefficients of the high power group are larger than those of the low power group. For SC, the difference is very salient: $\beta_1^{\text{high}} = 0.416$ ($SE = 0.006$), $\beta_1^{\text{low}} = 0.272$ ($SE = 0.005$). For Wiki, the difference is smaller: $\beta_1^{\text{high}} = 0.424$ ($SE = 0.007$), $\beta_1^{\text{low}} = 0.386$ ($SE = 0.005$). This is in line with the non-significant coefficient of $C_{\text{count}} * C_{\text{power}}$ in Wiki. In fact, the models of Wiki are fitted on a subset of data that contain the 5 (out of 14) markers that have significant coefficients of $C_{\text{count}} * C_{\text{power}}$ in the individual models shown in Table 1 (*certain*, *excl*, *incl*, *ipron*, *negate*), so that the difference in slopes is presented at maximal degree.

In Figure 1 we illustrate the β_{high} and β_{low} coefficients of C_{count} by plotting the predicted probability (the reversed logit transformation of the left-hand side term of Equation (2)) against C_{count} (log-transformed). It is obvious that the slope of β_{high} is larger than that of β_{low} (more salient in SC), indicating the significant interaction between C_{count} and C_{power}.



(a) Supreme Court (b) Wikipedia

Figure 1: The predicted probability of marker appearing in *target* (the reverse logit transform of the left hand side of Equation (2)) against the number of markers in *prime*, i.e., C_{count} (log-transformed), grouped by the power of *prime* speaker, i.e., *high* vs. *low*. Divergent slopes indicate significant interactions. Colored hexagons indicate the number of data points within that region.

3.5 Discussion

The occurrence of linguistic markers in *prime* is a strong predictor of whether the same marker will appear again in *target*. The coefficients of C_{count} can be viewed as indicators of the linguistic alignment between interlocutors: larger positive βs indicate stronger alignment, while smaller or even negative βs indicate weaker and reverse alignment, respectively (not found in our data).

Our results confirm the previously reported effect of power on linguistic alignment. The significant β' coefficient of $C_{\text{count}} * C_{\text{power}}$ means that the β of C_{count} is dependent on C_{power}. In other words, the strength of alignment varies significantly depending on different power levels (i.e., *high* vs. *low*) of the *prime* speaker (reflected by the different slopes in Figure 1). However, we need to keep in mind that this affirmative finding is *not* safe, because it based on a simple model that has only one key predictor, C_{power}. According to our hypothesis, the strength of alignment can be influenced by a lot of low-level linguistic features, and we are not sure yet if the effect of power will still be visible after we includes more predictors representing those features. This will be the next step experiment.

Additionally, the results also suggest that the influence of power on linguistic alignment is better characterized by the more fine-grained cumulative effect of linguistic markers than when it is simply explained by the mere difference between their *absence* or *presence*. Thus, we will discard C_{presence} and proceed with C_{count}.

4 Experiment 2: Extended model

In our first experiment, we replicated the effect of *prime* speakers' power status on the linguistic alignment from *target* speakers, from the significant interaction term $C_{\text{count}} * C_{\text{power}}$. Now, we want to determine if the effect of power remains significant after taking into account utterance length. As discussed, our hypothesis is that alignment (as measured by changes in probability of using LIWC categories) is best explained by low-level linguistic features that would be taken into account by an automatic priming process.

4.1 Statistical models

We add a new predictor to Equation (1), C_{pLen}, which is the number of words in *prime*, resulting in an extended model shown in Equation (3). We are interested to see if β_4 remains significant when the other interaction terms (with corresponding coefficients β_5, β_6 and β_7) are added.

$$\begin{aligned}\text{logit}(m) &= \ln \frac{p(m \text{ in } \textit{target})}{p(m \text{ not in } \textit{target})} \\ &= \beta_0 + \beta_1 C_{\text{count}} + \beta_2 C_{\text{power}} + \beta_3 C_{\text{pLen}} \\ &+ \boldsymbol{\beta_4 C_{\textbf{count}} * C_{\textbf{power}}} \\ &+ \boldsymbol{\beta_5 C_{\textbf{count}} * C_{\textbf{pLen}}} \\ &+ \boldsymbol{\beta_6 C_{\textbf{power}} * C_{\textbf{pLen}}} \\ &+ \boldsymbol{\beta_7 C_{\textbf{count}} * C_{\textbf{power}} * C_{\textbf{pLen}}}\end{aligned} \tag{3}$$

Note that we used the same subset of Wiki as used in Section 3.4 (using the five most significant LIWC categories), so that the strongest effect of $C_{\text{count}} * C_{\text{power}}$ is considered.

4.2 Model coefficients

The coefficients of the full model are in Table 2. Surprisingly, the coefficient of $C_{\text{count}} * C_{\text{power}}$ is significantly *negative* in SC, and non-significant in Wiki (see highlighted rows), which are in contrast to the *positive* coefficients of the same term in Table 1. It indicates that the observed effect of power on alignment depends on the presence of C_{pLen} in the model. No collinearity is found between C_{power} and other predictors: Pearson correlation $r < 0.2$; Variance inflation factor (VIF) is low (< 2.0) (O'brien, 2007).

Table 2: Summary of the model described in Equation (3): β coefficients, Wald's z-score and significance level (*** for $p < 0.001$, ** for $p < 0.01$, * for $p < 0.05$) for all predictors and interactions.

Corpus	Predictor	β	z
SC	Intercept	0.360	2.40*
	C_{count}	0.213	26.92***
	C_{power}	-0.060	-3.39***
	C_{pLen}	0.080	13.03***
	$\boldsymbol{C_{\textbf{count}} * C_{\textbf{power}}}$	**-0.103**	**-9.95*** **
	$C_{\text{count}} * C_{\text{pLen}}$	-0.066	-15.35***
	$C_{\text{power}} * C_{\text{pLen}}$	0.231	25.25***
	$C_{\text{count}} * C_{\text{power}} * C_{\text{pLen}}$	0.036	4.79***
Wiki	Intercept	0.330	1.40
	C_{count}	0.149	31.11***
	C_{power}	-0.074	-10.52***
	C_{pLen}	0.179	40.80***
	$\boldsymbol{C_{\textbf{count}} * C_{\textbf{power}}}$	**0.001**	**0.14**
	$C_{\text{count}} * C_{\text{pLen}}$	0.022	6.13***
	$C_{\text{power}} * C_{\text{pLen}}$	0.042	5.52***
	$C_{\text{count}} * C_{\text{power}} * C_{\text{pLen}}$	-0.010	-1.61

To further demonstrate how the coefficient of $C_{\text{power}} * C_{\text{count}}$ is dependent on C_{pLen}, we remove $C_{\text{count}} * C_{\text{pLen}}$, $C_{\text{power}} * C_{\text{pLen}}$ and $C_{\text{count}} * C_{\text{power}} * C_{\text{pLen}}$ from Equation (3) stepwisely, and examine $C_{\text{count}} * C_{\text{power}}$ in the corresponding remaining models. z-scores, significance levels, and the Akaike information criterion (AIC) score (Akaike, 1998) of the remainder models are reported in Table 3. In the full model, and when $C_{\text{count}} * C_{\text{power}} * C_{\text{pLen}}$ or $C_{\text{count}} * C_{\text{pLen}}$ is removed from the model, the coefficients of $C_{\text{power}} * C_{\text{count}}$ are significantly negative in SC and non-significant in Wiki. Only when $C_{\text{power}} * C_{\text{pLen}}$ is removed, the coefficients of $C_{\text{count}} * C_{\text{power}}$ become significantly positive (the last two rows in Table 3). However, the models that have negative or non-significant coefficient for $C_{\text{power}} * C_{\text{count}}$ have lower AIC scores than those that have positive coefficient (The full model has the lowest AIC score), which indicates that the former ones have higher quality. Altogether, the stepwise analysis not only indicates that the positive interaction between C_{power} and C_{count} shown in our basic model (Section 3) is unreliable, but also suggests that a negative interaction (SC) or non-significant interaction is more preferable.

4.3 Visualizing interaction effect

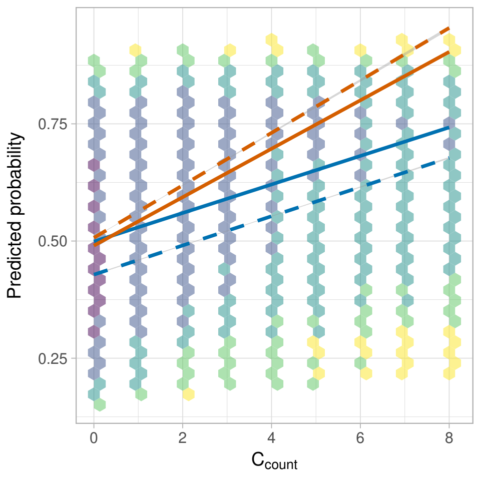
To illustrate how the interaction $C_{\text{power}} * C_{\text{count}}$ diminishes after adding C_{pLen} into the extended model, we cluster different ranges of C_{pLen} and determine how the amount of priming changes with C_{count} w.r.t. different combinations of C_{power} and C_{pLen}. This is a common practice to interpret linear models with three-way interactions (Houslay, 2014).

To cluster, we first compute the mean of C_{pLen} (i.e., the average utterance length), M_{pLen}. Then we divide the data by whether C_{pLen} is above or below M_{pLen}. Then we compute the mean of C_{pLen} for the upper and lower parts of data, resulting in M^L_{pLen} and M^S_{pLen} respectively (L for long and S for short). Now, we can replace the continuous variable C_{pLen} to a categorical and ordinal one that has two values, $\{M^S_{\text{pLen}}, M^L_{\text{pLen}}\}$, which represent the length of relatively short and long utterances respectively. Together with the other categorical variable, C_{power}, which has two values, *high* and *low*, we have four combinations: $C_{\text{pLen}} = M^S_{\text{pLen}}$ and $C_{\text{power}} = high$ (SH), $C_{\text{pLen}} = M^L_{\text{pLen}}$ and $C_{\text{power}} = high$ (LH), $C_{\text{pLen}} = M^S_{\text{pLen}}$ and $C_{\text{power}} = low$ (SL), $C_{\text{pLen}} = M^L_{\text{pLen}}$ and $C_{\text{power}} = low$ (LL). In Figure 2 we plot the smoothed regression lines of predicted probability against C_{count}, w.r.t. the above four groups of C_{pLen} and C_{power} combinations. Here C_{count} is not log-transformed, because it better demonstrates the trend of the fitted regression lines.

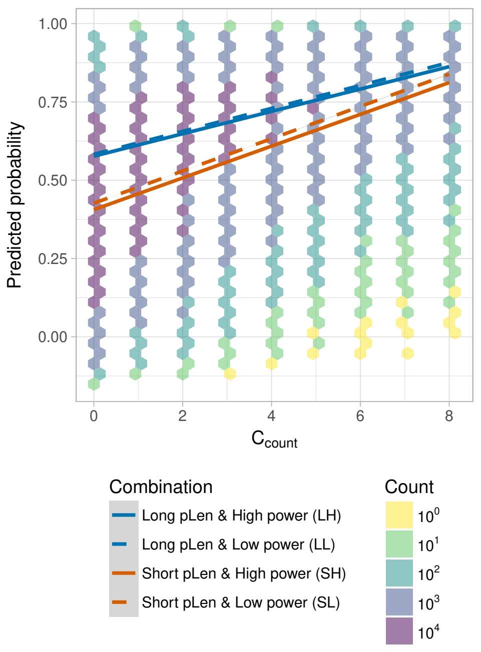
Figure 2 intuitively shows that C_{pLen} is a more determinant predictor than C_{power}. Division by power, i.e., *high* (SH and LH groups) vs. *low* (SL and LL groups), does not result in a salient difference in slopes, as it can be seen that the slopes of *high* (solid) and *low* (dashed) power lines do not differ much from each other within the same *prime* utterance length group (indicated by color). However, division by *prime* utterance length, i.e. *short* (SH and SL) vs. *long* (LH and LL), results in very significant differences in slopes: in Figure 2a, *short* C_{pLen} group (orange) has larger slopes than *long* C_{pLen} group (blue), while in Figure 2b, *short* group has smaller slopes than *long* group.

4.4 Discussion

Adding C_{pLen} to the model has strong impact on the previous conclusion about the effect of power



(a) Supreme Court



(b) Wikipedia

Figure 2: The predicted probability of marker appearing in *target* against C_{count}, grouped by the four combinations of C_{pLen} (*long* vs. *short*, indicated by color) and C_{power} (*high* vs. *low*, indicated by line type): LH, LL, SH, and SL. Colored hexagon indicates the number of data points.

on alignment. First of all, we find a negative interaction between C_{count} and C_{power} in SC and a non-significant effect in Wiki, which is contrary to the previous findings reported by Danescu-Niculescu-Mizil et al. (2012). Moreover, we doubt the reliability of a positive interaction because the valence of its β varies when other interaction terms (associated with C_{pLen}) are removed or added, and a negative or non-significant interaction is preferred

Table 3: Wald's z-score and significance level (*** for $p < 0.001$) of the $C_{\text{count}} * C_{\text{power}}$ term, and the AIC scores of the remainder models after removing other interaction terms from the full model stepwisely. The full model is described in Equation (3).

Remainder model	SC		Wiki	
	z-score	AIC	z-score	AIC
Full	-9.95***	697588	0.14	890685
Full $- C_{\text{count}} * C_{\text{power}} * C_{\text{pLen}}$	-8.75***	697609	-0.62	890686
Full $- C_{\text{count}} * C_{\text{power}} * C_{\text{pLen}}$ $- C_{\text{count}} * C_{\text{pLen}}$	-5.61***	697838.9	-0.74	890723.5
Full $- C_{\text{count}} * C_{\text{power}} * C_{\text{pLen}}$ $- C_{\text{power}} * C_{\text{pLen}}$	10.90***	698254.7	3.85***	890726.7
Full $- C_{\text{count}} * C_{\text{power}} * C_{\text{pLen}}$ $- C_{\text{count}} * C_{\text{pLen}}$ $- C_{\text{power}} * C_{\text{pLen}}$	15.02***	698461.8	3.72***	890763.8

by a simple model selection criterion.

Second, there is a significant interaction between C_{count} and C_{pLen}, though it is in different directions for the two corpora: negative β in SC and positive β in Wiki. Both observations have some theoretical justification from previous studies. Myslín and Levy (2016)'s work is in favor of the negative β: language comprehension is facilitated by the clustering of linguistic stimuli in time. In our case, the linguistic markers in the utterance of speaker A function as stimuli to speaker B. A longer utterance means that all the stimuli span wider in time, and thus demonstrate less clustering, which make the stimuli less salient features for speaker B to adapt to. This in turn causes speaker B to be less likely reuse those stimuli in the near future. Meanwhile, evidence from the line of works on surprisal and syntactic priming supports the positive β. In syntactic alignment, structures with higher surprisal (less common) are associated with stronger alignment (Jaeger and Snider, 2013; Reitter and Moore, 2014). Since surprisal has been found to be closely related with utterance length in dialogue (Genzel and Charniak, 2003; Xu and Reitter, 2016b,a), it is reasonable to expect that longer utterances receive stronger alignment because they contain content of higher surprisal.

The discrepancy between Wiki and SC in terms of the direction of $C_{\text{count}} * C_{\text{pLen}}$ is an interesting phenomenon to explore, because it can tell us something about how the form of dialogue (Wiki consists of online conversations and SC consists of face-to-face ones) affects the underlying cognitive mechanism of language production.

Regardless, our main finding is that low-level linguistic features, such as utterance length, have a strong effect on linguistic alignment. These effects are an important confound to take into account when examining higher-level features, such as social power. In particular, the effect of social power cannot be reliably detected by linear models once introducing utterance length.

Another interesting piece of result is the significant interaction term $C_{\text{power}} * C_{\text{pLen}}$, which implies that the power status of speaker and how long he/she tends to speak are not totally unrelated. Significant but weak correlation are found between C_{power} and C_{pLen} (using Pearson's correlation score): $r = -0.059$ in SC; $r = -0.018$ in Wiki. This correlation may show some kind of a linguistic manifestation of social power, but since it is not directly related to the alignment process, we do not further discuss it in this paper.

In summary of the results, we conjecture that the previously reported effect of power (Danescu-Niculescu-Mizil et al., 2012) is likely to be caused by the correlation between power status and utterance length, though further investigation is needed to confirm this. Moreover, utterance length is just one simple factor, and there are many more other linguistic features that can correlate with social power: e.g., the surprisal based measure of lexical information etc.

5 Conclusion

To sum up, our findings suggest that the previously reported effect of power on linguistic alignment is not reliable. Instead, we consistently align towards language that shares certain low-level features. We call for the inclusion of a wider range of factors in future studies of social influences on language use, especially low-level but interpretable cognitive factors. Perhaps in most scenarios, alignment is primarily influenced by linguistic features themselves, rather than social power.

We are not denying the existence of accommodation caused by the social distance between interlocutors. However, we want to stress the difference between the priming-induced alignment at lower linguistic levels and the intentional accommodation that is caused by higher-level perception of social power. The latter should be a relatively stable effect that is independent on the low-level linguistic features. In particular, our findings suggest that the probability change of LIWC categories is more likely to be a case of automatic alignment, rather than an intentional accommodation, because it is better explained by lower-level linguistic features (utterance length). Therefore, we suggest that future work on social power and language use should consider other (maybe higher-level) linguistic elements.

Abstract

The field of Natural Language Processing (NLP) is growing rapidly, with new research published daily along with an abundance of tutorials, codebases and other online resources. In order to learn this dynamic field or stay up-to-date on the latest research, students as well as educators and researchers must constantly sift through multiple sources to find valuable, relevant information. To address this situation, we introduce TutorialBank, a new, publicly available dataset which aims to facilitate NLP education and research. We have manually collected and categorized over 6,300 resources on NLP as well as the related fields of Artificial Intelligence (AI), Machine Learning (ML) and Information Retrieval (IR). Our dataset is notably the largest manually-picked corpus of resources intended for NLP education which does not include only academic papers. Additionally, we have created both a search engine [1] and a command-line tool for the resources and have annotated the corpus to include lists of research topics, relevant resources for each topic, prerequisite relations among topics, relevant subparts of individual resources, among other annotations. We are releasing the dataset and present several avenues for further research.

1 Introduction

NLP has seen rapid growth over recent years. A Google search of "Natural Language Processing" returns over 100 million hits with papers, tutorials, blog posts, codebases and other related online resources. Additionally, advances in related fields such as Artificial Intelligence and Deep Learning are strongly influencing current NLP research. With these developments, an increasing number of tutorials and online references are being published daily. As a result, the task of students, educators and researchers of tracking the changing landscape in this field has become increasingly difficult.

Recent work has studied the educational aspect of mining text for presenting scientific topics. One goal has been to develop concept maps of topics, graphs showing which topics are prerequisites for learning a given topic (Gordon et al., 2016; Liu et al., 2016; Pan et al., 2017a,b; Liang et al., 2017). Another goal has been to automatically create reading lists for a subject either by building upon concept graphs (Gordon et al., 2017) or through an unstructured approach (Jardine, 2014).

Additionally, other work has aimed to automatically summarize scientific topics, either by extractively summarizing academic papers (Jha et al., 2013, 2015; Jaidka et al., 2016) or by producing Wikipedia articles on these topics from multiple sources (Sauper and Barzilay, 2009; Liu et al., 2018). Scientific articles constitute primary texts which describe an author's work on a particular subject, while Wikipedia articles can be viewed as tertiary sources which summarize both results from primary works as well as explanations from secondary sources. Tang and McCalla (2004, 2009) and Sheng et al. (2017) explore the pedagogical function among the types of sources.

To address the problem of the scientific education of NLP more directly, we focus on the annotation and utilization of secondary sources presented in a manner immediately useful to the NLP community. We introduce the TutorialBank corpus, a manually-collected dataset of links to over

[1] `http://aan.how`

6,300 high-quality resources on NLP and related fields. The corpus's magnitude, manual collection and focus on annotation for education in addition to research differentiates it from other corpora. Throughout this paper we use the general term "resource" to describe any tutorial, research survey, blog post, codebase or other online source with a focus on educating on a particular subject. We have created a search engine for these resources and have annotated them according to a taxonomy to facilitate their sharing. Additionally, we have annotated for pedagogical role, prerequisite relations and relevance of resources to hand-selected topics and provide a command-line interface for our annotations.

Our main contribution is the manual collection of good quality resources related to NLP and the annotation and presentation of these resources in a manner conducive to NLP education. Additionally, we show initial work on topic modeling and resource recommendation. We present a variant of standard reading-list generation which recommends resources based on a title and abstract pair and demonstrate additional uses and research directions for the corpus.

2 Related Work

2.1 Pedagogical Value of Resources

Online resources are found in formats which vary in their roles in education. Sheng et al. (2017) identify seven types of pedagogical roles found in technical works: Tutorial, Survey, Software Manual, Resource, Reference Work, Empirical Results, and Other. They annotate a dataset of over 1,000 resources according to these types. Beyond these types, resources differ in their pedagogical value, which they define as "the estimate of how useful a document is to an individual who seeks to learn about specific concepts described in the document". Tang and McCalla (2004, 2009) discuss the pedagogical value of a single type, academic papers, in relation to a larger recommendation system.

2.2 Prerequisite Chains

Prerequisite chains refer to edges in a graph describing which topics are dependent on the knowledge of another topic. Prerequisite chains play an important role in curriculum planning and reading list generation. Liu et al. (2016) propose "Concept Graph Learning" in order to induce a graph from which they can predict prerequisite relations among university courses. Their framework consists of two graphs: (1) a higher-level graph which consists of university courses and (2) a lower-level graph which consists of induced concepts and pair-wise sequential preferences in learning or teaching the concept.

Liang et al. (2017) experiment with prerequisite chains on education data but focus on the recovery of a concept graph rather than on predicting unseen course relations as in Liu et al. (2016). They introduce both a synthetic dataset as well as one scraped from 11 universities which includes course prerequisites as well as concept-prerequisite labels. Concept graphs are also used in (Gordon et al., 2016) to address the problem of developing reading lists for students. The concept graph in this case is a labeled graph where nodes represent both documents and concepts (determined using Latent Dirichlet Allocation (LDA) (Blei et al., 2003)), and edges represent dependencies. They propose methods based on cross entropy and information flow for determining edges in the graph. Finally, finding prerequisite relationships has also been used in other contexts such as Massive Open Online Courses (MOOCs) (Pan et al., 2017a,b).

2.3 Reading List Generation

Jardine (2014) generates recommended reading lists from a corpus of technical papers in an unstructured manner in which a topic model weighs the relevant topics and relevant papers are chosen through his ThemedPageRank approach. He also provides a set of expert-generated reading lists. Conversely, Gordon et al. (2017) approach reading list generation from a structured perspective, first generating a concept graph from the corpus and then traversing the graph to select the most relevant document.

2.4 Survey Extraction

Recent work on survey generation for scientific topics has focused on creating summaries from academic papers (Jha et al., 2013, 2015; Jaidka et al., 2016). Jha et al. (2013) present a system that generates summaries given a topic keyword. From a base corpus of papers found by query matching, they expand the corpus via a citation network using a heuristic called Restricted Expansion. This process is repeated for seven standard NLP topics. In a similar manner, Jha et al. (2015) experiment with fifteen topics in computational linguistics and collect at least surveys written by experts on each topic, also making use of citation networks to expand their corpus. They introduce a content model as well as a discourse model and perform a qualitative comparisons of coherence with a standard summarization model.

The task of creating surveys for specified topics has also been viewed in the multi-document summarization setting of generating Wikipedia articles (Sauper and Barzilay, 2009; Liu et al., 2018). Sauper and Barzilay (2009) induce domain-specific templates from Wikipedia and fill these templates with content from the Internet. More recently Liu et al. (2018) explore a diverse set of domains for summarization and are the first to attempt abstractive summarization of the first section of Wikipedia articles, by combining extractive and abstractive summarization methods.

3 Dataset Collection

3.1 An Overview of TutorialBank

As opposed to other collections like the ACL Anthology (Bird et al., 2008; Radev et al., 2009, 2013, 2016), which contain solely academic papers, our corpus focuses mainly on resources other than academic papers. The main goal in our decision process of what to include in our corpus has been the quality-control of resources which can be used for an educational purpose. Initially, the resources collected were conference tutorials as well as surveys, books and longer papers on broader topics, as these genres contain an inherent amount of quality-control. Later on, other online resources were added to the corpus, as explained below. Student annotators, described later on, as well as the professor examined resources which they encountered in their studies. The resources were added to the corpus if deemed of good quality. Important to note is that not all resources which were found on the Internet were added to TutorialBank; one could scrape the web according to search terms, but quality control of the results would be largely missing. The quality of a resource is a somewhat subjective measure, but we aimed to find resources which would serve a pedagogical function to either students or researchers, with a professor of NLP making the final decision. This collection of resources and meta-data annotation has been done over multiple years, while this year we created the search engine and added additional annotations mentioned below.

Table 1: Top-level Taxonomy Topics

Topic Category	Count
Introduction to Neural Networks and Deep Learning	635
Tools for Deep Learning	475
Miscellaneous Deep Learning	287
Machine Learning	225
Word Embeddings	139
Recurrent Neural Networks	134
Python Basics	133
Reinforcement learning	132
Convolutional Neural Networks	129
Introduction to AI	89

Table 2: Corpus count by taxonomy topic for the most frequent topics (excluding topic "Other").

3.1.1 TutorialBank Taxonomy

In order to facilitate the sharing of resources about NLP, we developed a taxonomy of 305 topics of varying granularity. The top levels of our taxonomy tree are shown in Table 1. The backbone of our Taxonomy corresponds to the syllabus of a university-level NLP course and was expanded to include related topics from other courses in ML, IR and AI. As a result, there is a bias in the corpus towards NLP resources and resources from other fields in so far as they are relevant to NLP. However, this bias is planned, as our focus remains teaching NLP. The resource count for the most frequent taxonomy topics is shown in Table 2.

3.2 Data Preprocessing

For each resource in the corpus, we downloaded the corresponding PDF, PowerPoint presentations and other source formats and used PDFBox to perform OCR in translating the files to textual format. For HTML pages we downloaded both the raw HTML with all images as well as a formatted text version of the pages. For copyright purposes we release only the meta data such as urls and annotations and provide scripts for reproducing the dataset.

Resource Category	Count
corpus	131
lecture	126
library	1014
link set	1186
naclo	154
paper	1176
survey	390
tutorial	2079

Table 3: Corpus count by pedagogical feature.

4 Dataset Annotation

Annotations were performed by a group of 3 PhD students in NLP, and 6 undergraduate Computer Science students who have taken at least one course in AI or NLP.

4.1 Pedagogical Function

When collecting resources from the Internet, each item was labeled according to the medium in which it was found, analogous to the pedagogical function of (Sheng et al., 2017). We will use this term throughout the paper to describe this categorization. The categories along with their counts are shown in Table 3:

- **Corpus:** A corpus provides access to and a description of a scientific dataset.
- **Lecture:** A lecture consists of slides/notes from a university lecture.
- **Library:** A library consists of github pages and other codebases which aid in the implementation of algorithms.
- **NACLO:** NACLO problems refer to linguistics puzzles from the North American Computational Linguistics Olympiad.
- **Paper:** A paper is a short/long conference paper taken from sites such as https://arxiv.org/ and which is not included in the ACL Anthology.
- **Link set:** A link set provides a collection of helpful links in one location.
- **Survey:** A survey is a long paper or book which describes a broader subject.
- **Tutorial:** A tutorial is a slide deck from a conference tutorial or an HTML page that describes a contained topic.

4.2 Topic to Resource Collection

We first identified by hand 200 potential topics for survey generation in the fields of NLP, ML, AI and IR. Topics were added according to the following criteria:

1. It is conceivable that someone would write a Wikipedia page on this topic (an actual page may or may not exist).
2. The topic is not overly general (e.g., "Natural Language Processing") or too obscure or narrow.
3. In order to write a survey on the topic, one would need to include information from a number of sources.

Capsule Networks
Domain Adaptation
Document Representation
Matrix factorization
Natural language generation
Q Learning
Recursive Neural Networks
Shift-Reduce Parsing
Speech Recognition
Word2Vec

Table 4: Random sample of the list of 200 topics used for prerequisite chains, readling lists and survey extraction.

While some of the topics come from our taxonomy, many of the taxonomy topics have a different granularity than we desired, which motivated our topic collection. Topics were added to the list along with their corresponding Wikipedia pages, if they exist. A sample of the topics selected is shown in 4. Once the list of topics was compiled, annotators were assigned topics and asked to search that topic in the TutorialBank search engine and find relevant resources. In order to impose some uniformity on the dataset, we chose to only include resources which consisted of PowerPoint slides as well as HTML pages labeled as tutorials. We divided the topics among the annotators and asked them to choose five resources per topic using our search engine. The resource need not solely focus on the given topic; the resource may be on a more general topic and include a section on the given topic. As in general searching for resources, often resources include related information, so we believe this setting is fitting. For some topics the annotators chose fewer than five resources (partially due to the constraint we impose on the form of the resources). We noted topics for which no resources were found, and rather than replace the topics to reflect TutorialBank coverage, we leave these topics in and plan to add additional resources in a future release.

4.3 Prerequisite Chains

Even with a collection of resources and a list of topics, a student may not know where to begin studying a topic of interest. For example, in order to understand sentiment analysis the student should be familiar with Bayes' Theorem, the basics of ML as well as other topics. For this purpose, the annotators annotated which topics are prerequisites of others for the given topics from their reading lists. We expanded our list of potential prerequisites to include eight additional topics which were too broad for survey generation (e.g., Linear Algebra) but which are important prerequisites to capture. Following the method of (Gordon et al., 2016), we define labeling a topic Y as a prerequisite of X according to the following question:

- Would understanding Topic Y help you to understand Topic X?

As in (Gordon et al., 2016), the annotators can answer this question as "no", "somewhat" or "yes."

4.4 Reading Lists

When annotators were collecting relevant resources for a particular topic, we asked them to order the resources they found in terms of the usefulness of the resource for learning that particular topic. We also include the Wikipedia pages corresponding to the topics, when available, as an additional source of information. We do not perform additional annotation of the order of the resources or experiment in automatically reproducing these ordered lists but rather offer this annotation as a pedagogical tool for students and educators. We plan the expansion of these lists and analysis in future experiments.

4.5 Survey Extraction

We frame the task of creating surveys of scientific topics as a document retrieval task. A student searching for resources in order to learn about a topic such as Recurrent Neural Networks (RNN's) may encounter resources 1) which solely cover RNN's as well as 2) resources which cover RNN's within the context of a larger topic (e.g., Deep Learning). Within the first type, not every piece of content (a single PowerPoint slide or section in a blog post) contributes equally well to an understanding of RNN's; the content may focus on background information or may not clearly explain the topic. Within the second type, larger tutorials may contain valuable information on the topic, but may also contain much information not immediately relevant to the query. Given a query topic and a set of parsed documents we want to retrieve the parts most relevant to the topic.

In order to prepare the dataset for extracting surveys of topics, we first divide resources into units of content which we call "cards". PowerPoint slides inherently contain a division in the form of each individual slide, so we divide PowerPoint presentations into individual slides/cards. For HTML pages, the division is less clear. However, we convert the HTML pages to a markdown file and then automatically split the markdown file using header markers. We believe this is a reasonable heuristic as tutorials and similar content tend to be broken up into sections signalled by headers.

For each of the resources which the annotators gathered for the reading lists on a given topic, that same annotator was presented with each card from that resource and asked to rate the usefulness of the card. The annotator could rate the card from 0-2, with 0 meaning the card is not useful for learning the specified topic, 1 meaning the card is somewhat useful and 2 meaning the card is useful. We chose a 3-point scale as initial trials showed a 5-point scale to be too subjective. The annotators also had the option in our annotation interface to drop cards which were parsed incorrectly or were repeated one after the other as well as skip cards and return to score a card.

4.6 Illustrations

Whether needed for understanding a subject more deeply or for preparing a blog post on a subject, images play an important role in presenting concepts more concretely. Simply extracting the text from HTML pages leaves behind this valuable information, and OCR software often fails to parse complex graphs and images in a non-destructive fashion. To alleviate this problem and promote the sharing of images, we extracted all images from our collected HTML pages. Since many images were simply HTML icons and other extraneous images, we manually checked the images and selected those which are of value to the NLP student. We collected a total of 2,000 images and matched them with the taxonomy topic name of the resource it came from as well as the url of the resource. While we cannot outdo the countless images from Google search, we believe illustrations can be an additional feature of our search engine, and we describe an interface for this collection below.

5 Additional Features and Analysis

5.1 Search Engine

In order to present our corpus in a user-friendly manner, we created a search engine using Apache Lucene[2]. We allow the user to query key words to search our resource corpus, and the results can then be sorted based on relevance, year, topic, medium, and other meta data. In addition to searching by term, users can browse the resources by topic according to our taxonomy. For each child topic from the top-level taxonomy downward, we display resources according to their pedagogical functions. In addition to searching for general resources, we also provide search functionality for a corpus of papers, where the user can search by keyword as well as by author and venue.

While the search engine described above provides access to our base corpus and meta data, we also provide a command-line interface tool with our release so that students and researchers can easily use our annotations for prerequisite topics, illustrations and survey generation for educational purposes. The tool allows the user to input a topic from the taxonomy and retrieve all images related to that topic according to our meta data. Additionally, the user can input a topic from our list of 200 topics, and our tool outputs the prerequisites of that topic according to our annotation as well as the cards labelled as relevant for that topic.

5.2 Resource Recommendation from Title and Abstract Pairs

In addition to needing to search for a general term, often a researcher begins with an idea for a project which is already focused on a nuanced sub-task. An employee at an engineering company may be starting a project on image captioning. Ideas about the potential direction of this project may be clear, but what resources may be helpful or what papers have already been published on the subject may not be immediately obvious. To this end we propose the task of recommending resources from title and abstract pairs. The employee will input the title and abstract of the project and obtain a list of resources which can help complete the project. This task is analogous to reproducing the reference section of a paper, however, with a focus on tutorials and other resources rather than solely on papers. As an addition to our search engine, we allow a user to input a title and an abstract of variable length. We then propose taxonomy topics based on string matches with the query as well as a list of resources and papers and their scores as determined by the search engine. We later explore two baseline models for recommending resources based on document and topic modeling.

[2]http://lucene.apache.org/

5.3 Dataset and Annotation Statistics

We created reading lists for 182 of the 200 topics we identify in Section 4.2. Resources were not found for 18 topics due to the granularity of the topic (e.g., Radial Basis Function Networks) as well as our intended restriction of the chosen resources to PowerPoint presentations and HTML pages. The average number of resources per reading list for the 182 topics is 3.94. As an extension to the reading lists we collected Wikipedia pages for 184 of the topics and present these urls as part of the dataset.

We annotated prerequisite relations for the 200 topics described above. We present a subset of our annotations in Figure 1, which shows the network of topic relations (nodes without incoming edges were not annotated for their prerequisites as part of this shown inter-annotation round). Our network consists of 794 unidirectional edges and 33 bidirectional edges. The presence of bidirectional edges stems from our definition of a prerequisite, which does not preclude bidirectionality (one topic can help explain another and vice-versa) as well as the similarity of the topics. The set of bidirectional edges consists of topic pairs (BLEU - ROUGE; Word Embedding - Distributional Semantics; Backpropagation - Gradient descent) which could be collapsed into one topic to create a directed acyclic graph in the future.

For survey extraction, we automatically split 313 resources into content cards which we annotated for usefulness in survey extraction. These resources are a subset of the reading lists limited in number due to constraints in downloading urls and parsing to our annotation interface. The total number of cards which were not marked as repeats/mis-parsed totals 17,088, with 54.59 per resource. 6,099 cards were labeled as somewhat relevant or relevant for the target topic. The resources marked as non-relevant may be poorly

Annotation	Kappa
Pedagogical Function	0.69
Prerequisites	0.30
Survey Extraction	0.33

Table 5: Inter-annotator agreement.

presented or may not pertain fully to the topic of that survey. These numbers confirm the appropriateness of this survey corpus as a non-trivial information retrieval task.

To better understand the difficulty of our annotation tasks, we performed inter-annotator agreement experiments for each of our annotations. We randomly sampled twenty-five resources and had annotators label for pedagogical function. Additionally, we sampled twenty-five topics for prerequisite annotations and five topics with reading list lengths of five for survey annotation. We used Fleiss's Kappa (Fleiss et al., 2004), a variant of Cohen's Kappa (Cohen, 1960) designed to measure annotator agreement for more than two annotators. The results are shown in Table 5. Using the scale as defined in Landis and Koch (1977), pedagogical function annotation exhibits *substantial agreement* while prerequisite annotation and survey extraction annotation show *fair agreement*. The Kappa score for pedagogical function is comparable to that of Sheng et al. (2017) (0.68) while the prerequisite annotation is slightly lower than the agreement metric used in Gordon et al. (2016) (0.36) although they measure agreement through Pearson correlation. We believe that the sparsity of the labels plays a role in these scores.

5.4 Comparison to Similar Datasets

Our corpus distinguishes itself in its magnitude, manual collection and focus on annotation for educational purposes in addition to research tasks. We use similar categories for classifying pedagogical function as Sheng et al. (2017), but our corpus is hand-picked and over four-times larger, while exhibiting similar annotation agreement.

Gordon et al. (2016) present a corpus for prerequisite relations among topics, but this corpus differs in coverage. They used LDA topic modeling to generate a list of 300 topics, while we manually create a list of 200 topics based on criteria described above. Although their topics are generated from the ACL Anthology and related to NLP, we find less than a 40% overlap in topics. Additionally, they only annotate a subset of the topics for prerequisite annotations while we focus on broad coverage, annotating two orders of magnitude larger in terms of prerequisite edges while exhibiting fair inter-annotator agreement.

Previous work and datasets on generating surveys for scientific topics have focused on scientific articles (Jha et al., 2013, 2015; Jaidka et al., 2016) and Wikipedia pages (Sauper and Barzilay, 2009; Liu et al., 2018) as a summarization task. We, on the other hand, view this problem as an information retrieval task and focus on extracting content from manually-collected PowerPoint slides and online tutorials. Sauper and Barzilay (2009) differ in their domain coverage, and while the surveys of Jha et al. (2013, 2015) focus on NLP, we collect resources for an order of magnitude larger set of topics. Finally, our focus here in creating surveys, as well as the other annotations, is first and foremost to create a useful tool for students and researchers. Websites such as the ACL Anthology[3] and arXiv[4] provide an abundance of resources, but do not focus on the pedagogical aspect of their content. Meanwhile, websites such as Wikipedia which aim to create a survey of a topic may not reflect the latest trends in rapidly changing fields.

6 Topic Modeling and Resource Recommendation

As an example usage of our corpus, we experimented with topic modeling and its extension to

[3]http://aclweb.org/anthology/
[4]https://arxiv.org/

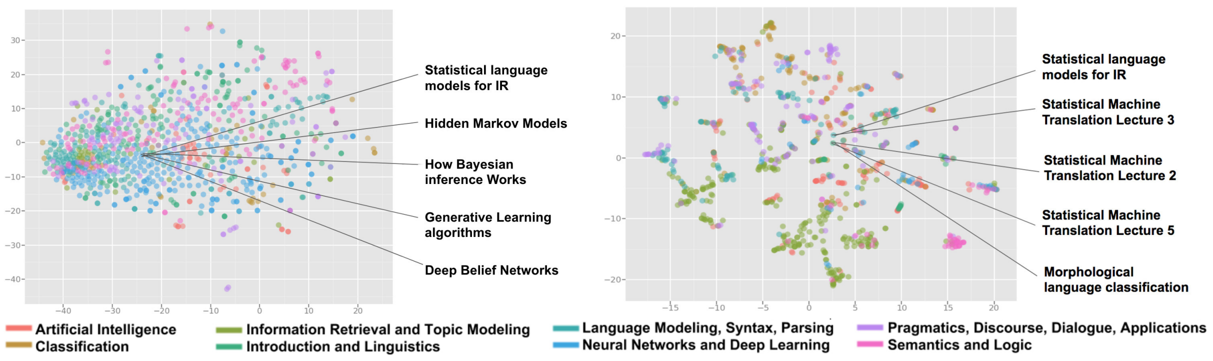

Figure 2: Plot showing a query document with title "Statistical language models for IR" and its neighbour document clusters as obtained through tSNE dimension reduction for Doc2Vec (left) and LDA topic modeling (right). Nearest neighbor documents titles are shown to the right of each plot.

resource recommendation. We restricted our corpus for this study to non-HTML files to examine the single domain of PDF's and PowerPoint presentations. This set consists of about 1,480 files with a vocabulary size 191,446 and a token count of 9,134,452. For each file, the tokens were processed, stop tokens were stripped, and then each token was stemmed. Words with counts less than five across the entire corpus were dropped. We experimented with two models: LDA, a generative probabilistic model mentioned earlier, and Doc2Vec (Le and Mikolov, 2014), an extension of Word2Vec (Mikolov et al., 2013) which creates representations of arbitrarily-sized documents. Figure 2 shows the document representations obtained with Doc2Vec as well as the topic clusters created with LDA. The grouping of related resources around a point demonstrates the clustering abilities of these models. We applied LDA in an unsupervised way, using 60 topics over 300 iterations as obtained through experimentation, and then colored each document dot with its category to observe the distribution. Our Doc2Vec model used hidden dimension 300, a window size of 10 and a constant learning rate of 0.025. Then, the model was trained for 10 epochs.

We tested these models for the task of resource recommendation from title+abstract pairs. We collected 10 random papers from ACL 2017. For LDA, the document was classified to a topic, and then the top resources from that topic were chosen, while Doc2Vec computed the similarity between the query document and the training set and chose the most similar documents. We concatenated the title and abstract as input and had our models predict the top 20 documents. We then had five annotators rate the recommendations for

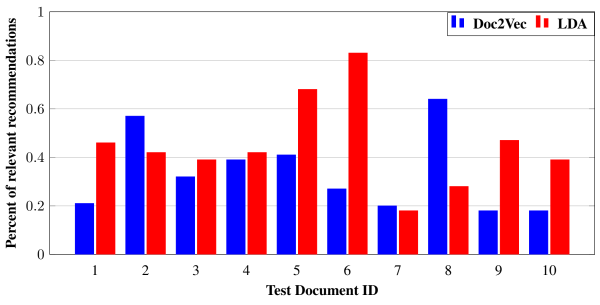

Figure 3: Relevance accuracies of the Doc2Vec and LDA resource recommendation models.

helpfulness as 0 (not helpful) or 1 (helpful). Recommended resources were rated according to the criterion of whether reading this resource would be useful in doing a project as described in the title and abstract. The results are found in Figure 3. Averaging the performance over each test case, the LDA model performed better than Doc2Vec (0.45 to 0.34), although both leave large room for improvements. LDA recommended resources notably better for cases 5 and 6, which correspond to papers with very well defined topics areas (Question Answering and Machine Translation) while Doc2Vec was able to find similar documents for cases 2 and 8 which are a mixture of topics, yet are well-represented in our corpus (Reinforcement Learning with dialog agents and emotion (sentiment) detection with classification). The low performance for both models also corresponds to differences in corpus coverage, and we plan to explore this bias in the future. We believe that this variant of reading list generation as well as the relationship between titles and abstracts is an unexplored and exciting area for future research.

7 Conclusion and Future Work

In this paper we introduce the TutorialBank Corpus, a collection of over 6,300 hand-collected resources on NLP and related fields. Our corpus is notably larger than similar datasets which deal with pedagogical resources and topic dependencies and unique in use as an educational tool. To this point, we believe that this dataset, with its multiple layers of annotation and usable interface, will be an invaluable tool to the students, educators and researchers of NLP. Additionally, the corpus promotes research on tasks not limited to pedagogical function classification, topic modeling and prerequisite relation labelling. Finally, we formulate the problem of recommending resources for a given title and abstract pair as a new way to approach reading list generation and propose two baseline models. For future work we plan to continue the collection and annotation of resources and to separately explore each of the above research tasks.

Acknowledgments

We would like to thank all those who worked on the development of the search engine and website as well as those whose discussion and annotated greatly helped this work, especially Jungo Kasai, Alexander Strzalkowski, Michihiro Yasunaga and Rui Zhang.

Abstract

While argument persuasiveness is one of the most important dimensions of argumentative essay quality, it is relatively little studied in automated essay scoring research. Progress on scoring argument persuasiveness is hindered in part by the scarcity of annotated corpora. We present the first corpus of essays that are simultaneously annotated with argument components, argument persuasiveness scores, and attributes of argument components that impact an argument's persuasiveness. This corpus could trigger the development of novel computational models concerning argument persuasiveness that provide useful feedback to students on *why* their arguments are (un)persuasive in addition to *how* persuasive they are.

1 Introduction

The vast majority of existing work on automated essay scoring has focused on *holistic* scoring, which summarizes the quality of an essay with a single score and thus provides very limited feedback to the writer (see Shermis and Burstein (2013) for the state of the art). While recent attempts address this problem by scoring a particular dimension of essay quality such as coherence (Miltsakaki and Kukich, 2004), technical errors, relevance to prompt (Higgins et al., 2004; Persing and Ng, 2014), organization (Persing et al., 2010), and thesis clarity (Persing and Ng, 2013), argument persuasiveness is largely ignored in existing automated essay scoring research despite being one of the most important dimensions of essay quality.

Nevertheless, scoring the persuasiveness of arguments in student essays is by no means easy. The difficulty stems in part from the scarcity of persuasiveness-annotated corpora of student essays. While persuasiveness-annotated corpora exist for other domains such as online debates (e.g., Habernal and Gurevych (2016a; 2016b)), to our knowledge only one corpus of persuasiveness-annotated student essays has been made publicly available so far (Persing and Ng, 2015).

Though a valuable resource, Persing and Ng's (2015) (P&N) corpus has several weaknesses that limit its impact on automated essay scoring research. First, P&N assign only *one* persuasiveness score to each essay that indicates the persuasiveness of the argument an essay makes for its *thesis*. However, multiple arguments are typically made in a persuasive essay. Specifically, the arguments of an essay are typically structured as an argument tree, where the major claim, which is situated at the root of the tree, is supported by one or more claims (the children of the root node), each of which is in turn supported by one or more premises. Hence, each node and its children constitute an argument. In P&N's dataset, only the persuasiveness of the overall argument (i.e., the argument represented at the root and its children) of each essay is scored. Hence, any system trained on their dataset cannot provide any feedback to students on the persuasiveness of any arguments other than the overall argument. Second, P&N's corpus does not contain annotations that explain *why* the overall argument is not persuasive if its score is low. This is undesirable from a feedback perspective, as a student will not understand why her argument is not persuasive if its score is low.

Our goal in this paper is to annotate and make publicly available a corpus of persuasive student essays that addresses the aforementioned weaknesses via designing appropriate annotation schemes and scoring rubrics. Specifically, not only do we score the persuasiveness of *each* argument in each essay (rather than simply the persuasiveness of the overall argument), but we also identify a set of attributes that can explain an argument's persuasiveness and annotate each argument with the values of these attributes. These annotations enable the development of systems that can provide useful feedback to students, as the attribute values predicted by these systems can help a student understand why her essay receives a particular persuasiveness score. To our knowledge, this is the first corpus of essays that are simultaneously annotated with argument components, persuasiveness scores, and related attributes.[1]

2 Related Work

While argument mining research has traditionally focused on determining the argumentative structure of a text document (i.e., identifying its major claim, claims, and premises, as well as the relationships between these argument components) (Stab and Gurevych, 2014b, 2017a; Eger et al., 2017), researchers have recently begun to study new argument mining tasks, as described below.

Persuasiveness-related tasks. Most related to our study is work involving argument persuasiveness. For instance, Habernal and Gurevych (2016b) and Wei et al. (2016) study the persuasiveness *ranking* task, where the goal is to rank two internet debate arguments written for the same topic w.r.t. their persuasiveness. As noted by Habernal and Gurevych, ranking arguments is a relatively easier task than scoring an argument's persuasiveness: in ranking, a system simply determines whether one argument is more persuasive than the other, but not *how much more* persuasive one argument is than the other; in scoring, however, a system has to determine how persuasive an argument is on an absolute scale. Note that ranking is not an acceptable evaluation setting for studying argument persuasiveness in the essay domain, as feedback for an essay has to be provided *independently* of other essays.

In contrast, there are studies that focus on factors affecting argument persuasiveness in internet debates. For instance, Lukin et al. (2017) examine how audience variables (e.g., personalities) interact with argument style (e.g., factual vs. emotional arguments) to affect argument persuasiveness. Persing and Ng (2017) identify factors that *negatively* impact persuasiveness, so their factors, unlike ours, cannot explain what makes an argument persuasive.

Other argument mining tasks. Some of the attributes that we annotate our corpus with have been studied. For instance, Hidey et al. (2017) examine the different semantic types of claims and premises, whereas Higgins and Walker (2012) investigate persuasion strategies (i.e., ethos, pathos, logos). Unlike ours, these studies use data from online debate forums and social/environment reports. Perhaps more importantly, they study these attributes independently of persuasiveness.

Several argument mining tasks have recently been proposed. For instance, Stab and Gurevych (2017b) examine the task of whether an argument is sufficiently supported. Al Khatib et al. (2016) identify and annotate a news editorial corpus with fine-grained argumentative discourse units for the purpose of analyzing the argumentation strategies used to persuade readers. Wachsmuth et al. (2017) focus on identifying and annotating 15 logical, rhetorical, and dialectical dimensions that would be useful for automatically accessing the quality of an argument. Most recently, the Argument Reasoning Comprehension task organized as part of SemEval 2018 has focused on selecting the correct warrant that explains reasoning of an argument that consists of a claim and a reason.[2]

3 Corpus

The corpus we chose to annotate is composed of 102 essays randomly chosen from the Argument Annotated Essays corpus (Stab and Gurevych, 2014a). This collection of essays was taken from *essayforum*[3], a site offering feedback to students wishing to improve their ability to write persuasive essays for tests. Each essay is written in response to a topic such as "should high school make music lessons compulsory?" and has already been annotated by Stab and Gurevych with an argument tree. Hence, rather than annotate everything from scratch, we annotate the persuasiveness score of each argument in the already-annotated argument trees in this essay collection as well as the attributes that potentially impact persuasiveness.

Each argument tree is composed of three types of tree nodes that correspond to argument compo-

Essays: 102	Sentences: 1462	Tokens: 24518
Major Claims: 185	Claims: 567	Premises: 707
Support Relations: 3615	Attack Relations: 219	

Table 1: Corpus statistics.

nents. The three annotated argument component types include: **MajorClaim**, which expresses the author's stance with respect to the essay's topic; **Claims**, which are controversial statements that should not be accepted by readers without additional support; and **Premises**, which are reasons authors give to persuade readers about the truth of another argument component statement. The two relation types include: **Support**, which indicates that one argument component supports another, and **Attack**, which indicates that one argument component attacks another.

Each argument tree has three to four levels. The root is a major claim. Each node in the second level is a claim that supports or attacks its parent (i.e., the major claim). Each node is the third level is a premise that supports or attacks its parent (i.e., a claim). There is an optional fourth level consisting of nodes that correspond to premises. Each of these premises either supports or attacks its (premise) parent. Stab and Gurevych (2014a) report high inter-annotator agreement on these annotations: for the annotations of major claims, claims, and premises, the Krippendorff's α values (Krippendorff, 1980) are 0.77, 0.70, and 0.76 respectively, and for the annotations of support and attack relations, the α values are both 0.81.

Note that Stab and Gurevych (2014a) determine premises and claims by their position in the argument tree and not by their semantic meaning. Due to the difficulty of treating an opinion as a non-negotiable unit of evidence, we convert all subjective premises into claims to demonstrate that they are subjective and require backing. At the end of this process, several essays contain argument trees that violate the scheme used by Stab and Gurevych, due to some premises supported by opinion premises, now converted to claims. Although the ideal argument should not violate the canonical structure, students attempting to improve their persuasive writing skills may not understand this, and mistakenly support evidence with their own opinions.

Statistics of this corpus are shown in Table 1. Its extensive use in argument mining research in recent years together with its reliably annotated argument trees makes it an ideal corpus to use for our annotation task.

4 Annotation

4.1 Definition

Since persuasiveness is defined on an argument, in order to annotate persuasiveness we need to define precisely what an argument is. Following van Eemeren et al. (2014), we define an argument as consisting of a conclusion that may or may not be supported/attacked by a set of evidences. Given an argument tree, a non-leaf node can be interpreted as a "conclusion" that is supported or attacked by its children, which can therefore be interpreted as "evidences" for the conclusion. In contrast, a leaf node can be interpreted as an unsupported conclusion. Hence, for the purposes of our work, an argument is composed of a node in an argument tree and all of its children, if any.

4.2 Annotation Scheme

Recall that the goal of our annotation is to score each argument w.r.t. its persuasiveness (see Table 2 for the rubric for scoring persuasiveness) and annotate each of its components with a set of predefined attributes that could impact the argument's persuasiveness. Table 3 presents a summary of the attributes we annotate. The rest of this subsection describes these attributes.

Each component type (MajorClaim, Claim, Premise) has a distinct set of attributes. All component types have three attributes in common: Eloquence, Specificity, and Evidence. *Eloquence* is how well the author uses language to convey ideas, similar to clarity and fluency. *Specificity* refers to the narrowness of a statement's scope. Statements that are specific are more believable because they indicate an author's confidence and depth of knowledge about a subject matter. Argument assertions (major claims and claims) need not be believable on their own since that is the job of the supporting evidence. The *Evidence* score describes how well the supporting components support the parent component. The rubrics for scoring Eloquence, Evidence, Claim/MajorClaim Specificity, and Premise Specificity are shown in Tables 4, 5, 6, and 7 respectively.

MajorClaim Since the major claim represents the overall argument of the essay, it is in this component that we annotate the persuasive strategies employed (i.e., *Ethos, Pathos* and *Logos*). These

Score	Description
6	A very strong, clear argument. It would persuade most readers and is devoid of errors that might detract from its strength or make it difficult to understand.
5	A strong, pretty clear argument. It would persuade most readers, but may contain some minor errors that detract from its strength or understandability.
4	A decent, fairly clear argument. It could persuade some readers, but contains errors that detract from its strength or understandability.
3	A poor, understandable argument. It might persuade readers who are already inclined to agree with it, but contains severe errors that detract from its strength or understandability.
2	It is unclear what the author is trying to argue or the argument is poor and just so riddled with errors as to be completely unpersuasive.
1	The author does not appear to make any argument (e.g. he may just describe some incident without explaining why it is important). It could not persuade any readers because there is nothing to be persuaded of. It may or may not contain detectable errors, but errors are moot since there is not an argument for them to interfere with.

Table 2: Description of the Persuasiveness scores.

Attribute	Possible Values	Applicability	Description
Specificity	1–5	MC,C,P	How detailed and specific the statement is
Eloquence	1–5	MC,C,P	How well the idea is presented
Evidence	1–6	MC,C,P	How well the supporting statements support their parent
Logos/Pathos/Ethos	yes,no	MC,C	Whether the argument uses the respective persuasive strategy
Relevance	1–6	C,P	The relevance of the statement to the parent statement
ClaimType	value,fact,policy	C	The category of what is being claimed
PremiseType	see Section 4.2	P	The type of Premise, e.g. statistics, definition, real example, etc.
Strength	1–6	P	How well a single statement contributes to persuasiveness

Table 3: Summary of the attributes together with their possible values, the argument component type(s) each attribute is applicable to (**MC**: MajorClaim, **C**: Claim, **P**: Premise), and a brief description.

Score	Description
5	Demonstrates mastery of English. There are no grammatical errors that distract from the meaning of the sentence. Exhibits a well thought out, flowing sentence structure that is easy to read and conveys the idea exceptionally well.
4	Demonstrates fluency in English. If there are any grammatical or syntactical errors, their affect on the meaning is negligible. Word choice suggests a broad vocabulary.
3	Demonstrates competence in English. There might be a few errors that are noticeable but forgivable, such as an incorrect verb tense or unnecessary pluralization. Demonstrates a typical vocabulary and a simple sentence structure.
2	Demonstrates poor understanding of sentence composition and/or poor vocabulary. The choice of words or grammatical errors force the reader to reread the sentence before moving on.
1	Demonstrates minimal eloquence. The sentence contains errors so severe that the sentence must be carefully analyzed to deduce its meaning.

Table 4: Description of the Eloquence scores.

Score	Description
6	A very strong, very persuasive argument body. There are many supporting components that have high Relevance scores. There may be a few attacking child components, but these components must be used for either concession or refuting counterarguments as opposed to making the argument indecisive or contradictory.
5	A strong, persuasive argument body. There are sufficient supporting components with respectable scores.
4	A decent, fairly persuasive argument body.
3	A poor, possibly persuasive argument body.
2	A totally unpersuasive argument body.
1	There is no argument body for the given component.

Table 5: Description of the Evidence scores.

three attributes are not inherent to the text identifying the major claim but instead summarize the child components in the argument tree.

Claim The claim argument component possesses all of the attributes of a major claim in addition to a *Relevance* score and a *ClaimType*. In order for an argument to be persuasive, all supporting components must be relevant to the component that they support/attack. The scoring rubric for Relevance is shown in Table 8. The ClaimType can be *value* (e.g., something is good or bad, important or not important, etc.), *fact* (e.g. something

Score	Description
5	The claim summarizes the argument well and has a qualifier that indicates the extent to which the claim holds true. Claims that summarize the argument well must reference most or all of the supporting components.
4	The claim summarizes the argument very well by mentioning most or all of the supporting components, but does not have a qualifier indicating the conditions under which the claim holds true. Alternatively, the claim may moderately summarize the argument by referencing a minority of supporting components and contain qualifier.
3	The claim has a qualifier clause or references a minority of the supporting components, but not both.
2	The claim does not make an attempt to summarize the argument nor does it contain a qualifier clause.
1	Simply rephrases the major claim or is outside scope of the major claim (argument components were annotated incorrectly: major claim could be used to support claim).

Table 6: Description of the Claim and MajorClaim Specificity scores.

Score	Description
5	An elaborate, very specific statement. The statement contains numerical data, or a historical example from the real world. There is (1) both a sufficient qualifier indicating the extent to which the statement holds true and an explanation of why the statement is true, or (2) at least one real world example, or (3) a sufficient description of a hypothetical situation that would evoke a mental image of the situation in the minds of most readers.
4	A more specific statement. It is characterized by either an explanation of why the statement is true, or a qualifier indicating when/to what extent the statement is true. Alternatively, it may list examples of items that do not qualify as historical events.
3	A sufficiently specific statement. It simply states a relationship or a fact with little ambiguity.
2	A broad statement. A statement with hedge words and without other redeeming factors such as explicit examples, or elaborate reasoning. Additionally, there are few adjectives or adverbs.
1	An extremely broad statement. There is no underlying explanation, qualifiers, or real-world examples.

Table 7: Description of the Premise Specificity scores.

Score	Description
6	Anyone can see how the support relates to the parent claim. The relationship between the two components is either explicit or extremely easy to infer. The relationship is thoroughly explained in the text because the two components contain the same words or exhibit coreference.
5	There is an implied relationship that is obvious, but it could be improved upon to remove all doubt. If the relationship is obvious, both relating components must have high Eloquence and Specificity scores.
4	The relationship is fairly clear. The relationship can be inferred from the context of the two statements. One component must have a high Eloquence and Specificity scores and the other must have lower but sufficient Eloquence and Specificity scores for the relationship to be fairly clear.
3	Somewhat related. It takes some thinking to imagine how the components relate. The parent component or the child component have low clarity scores. The two statements are about the same topic but unrelated ideas within the domain of said topic.
2	Mostly unrelated. It takes some major assumptions to relate the two components. A component may also receive this score if both components have low clarity scores.
1	Totally unrelated. Very few people could see how the two components relate to each other. The statement was annotated to show that it relates to the claim, but this was clearly in error.

Table 8: Description of the Relevance scores.

is true or false), or *policy* (claiming that some action should or should not be taken).

Premise The attributes exclusive to premises are *PremiseType* and *Strength*. To understand Strength, recall that only premises can persuade readers, but also that an argument can be composed of a premise and a set of supporting/attacking premises. In an argument of this kind, Strength refers to how well the parent premise contributes to the persuasiveness independently of the contributions from its children. The scoring rubric for Strength is shown in Table 9. PremiseType takes on a discrete value from one of the following: real_example, invented_instance, analogy, testimony, statistics, definition, common_knowledge, and warrant. Analogy, testimony, statistics, and definition are self-explanatory. A premise is labeled *invented_instance* when it describes a hypothetical situation, and *definition* when it provides a definition to be used elsewhere in the argument. A premise has type *warrant* when it does not fit any other type, but serves a functional purpose to explain the relationship between two entities or clarify/quantify another statement. The *real_example* premise type indicates that the statement is a historical event that actually occurred, or something that is verfiably true about the real world.

Score	Description
6	A very strong premise. Not much can be improved in order to contribute better to the argument.
5	A strong premise. It contributes to the persuasiveness of the argument very well on its own.
4	A decent premise. It is a fairly strong point but lacking in one or more areas possibly affecting its perception by the audience.
3	A fairly weak premise. It is not a strong point and might only resonate with a minority of readers.
2	A totally weak statement. May only help to persuade a small number of readers.
1	The statement does not contribute at all.

Table 9: Description of the Strength scores.

4.3 Annotation Procedure

Our 102 essays were annotated by two native speakers of English. We first familiarized them with the rubrics and definitions and then trained them on five essays (not included in our corpus). After that, they were both asked to annotate a randomly selected set of 30 essays and discuss the resulting annotations to resolve any discrepancies. Finally, the remaining essays were partitioned into two sets, and each annotator received one set to annotate. The resulting distributions of scores/classes for persuasiveness and the attributes are shown in Table 10.

4.4 Inter-Annotator Agreement

We use Krippendorff's α to measure inter-annotator agreement. Results are shown in Table 11. As we can see, all attributes exhibit an agreement above 0.5, showing a correlation much more significant than random chance. Persuasiveness has an agreement of 0.688, which suggests that it can be agreed upon in a reasonably general sense. The MajorClaim components have the highest Persuasiveness agreement, and it declines as the type changes to Claim and then to Premise. This would indicate that persuasiveness is easier to articulate in a wholistic sense, but difficult to explain as the number of details involved in the explanation increases.

The agreement scores that immediately stand out are the perfect 1.0's for Logos and Ethos. The perfect Logos score is explained by the fact that every major claim was marked to use logos. Although ethos is far less common, both annotators easily recognized it. This is largely due to the indisputability of recognizing a reference to an accepted authority on a given subject. Very few authors utilize this approach, so when they do it is extremely apparent. Contrary to Persuasiveness, Evidence agreement exhibits an upward trend as the component scope narrows. Even with this pattern, the Evidence agreement is always higher than Persuasiveness agreement, which suggests that it is not the only determiner of persuasiveness.

In spite of a rubric defining how to score Eloquence, it remains one of the attributes with the lowest agreement. This indicates that it is difficult to agree on exact eloquence levels beyond basic English fluency. Additionally, Specificity produced unexpectedly low agreement in claims and major claims. Precisely quantifying how well a claim summarizes its argument turned out to be a complicated and subjective task. Relevance agreement for premises is one of the lowest, partly because there are multiple scores for high relevance, and no examples were given in the rubric.

All attributes but those with the highest agreement are plagued by inherent subjectivity, regardless of how specific the rubric is written. There are often multiple interpretations of a given sentence, sometimes due to the complexity of natural language, and sometimes due to the poor writing of the author. Naturally, this makes it difficult to identify certain attributes such as Pathos, ClaimType, and PremiseType.

Although great care was taken to make each attribute as independent of the others as possible, they are all related to each other to a minuscule degree (e.g., Eloquence and Specificity). While annotators generally agree on what makes a persuasive argument, the act of assigning blame to the persuasiveness (or lack thereof) is tainted by this overlapping of attributes.

4.5 Analysis of Annotations

To understand whether the attributes we annotated are indeed useful for predicting persuasiveness, we compute the Pearson's Correlation Coefficient (PC) between persuasiveness and each of the attributes along with the corresponding p-values. Results are shown in Table 12. Among the correlations that are statistically significant at the $p < .05$ level, we see, as expected, that Persuasiveness is positively correlated with Specificity, Evidence, Eloquence, and Strength. Neither is it surprising that support provided by a premise in the form of statistics and examples is positively correlated with Persuasiveness. While Logos and invented_instance also have significant correlations with Persuasiveness, the correlation is very weak.

Attribute	PC	p**-value**
Specificity	.5680	0
Relevance	−.0435	.163
Eloquence	.4723	0
Evidence	.2658	0
Strength	.9456	0
Logos	−.1618	0
Ethos	−.0616	.1666
Pathos	−.0835	.0605
ClaimType:fact	.0901	.1072
ClaimType:value	−.0858	.1251
ClaimType:policy	−.0212	.7046
PremiseType:real_example	.2414	0
PremiseType:invented_instance	.0829	.0276
PremiseType:analogy	.0300	.4261
PremiseType:testimony	.0269	.4746
PremiseType:statistics	.1515	0
PremiseType:definition	.0278	.4608
PremiseType:common_knowledge	−.2948	1.228
PremiseType:warrant	.0198	.6009

	MC	**C**	**P**	**Avg**
PC	.9688	.9400	.9494	.9495
ME	.0710	.1486	.0954	.1061

Table 13: Persuasiveness scoring using gold attributes.

Next, we conduct an oracle experiment in an attempt to understand how well these attributes, when used together, can explain the persuasiveness of an argument. Specifically, we train three linear SVM regressors (using the SVM^{light} software (Joachims, 1999) with default learning parameters except for C (the regularization parameter), which is tuned on development data using grid search) to score an argument's persuasiveness using the *gold* attributes as features. The three regressors are trained on arguments having MajorClaims, Claims, and Premises as parents. For instance, to train the regressor involving MajorClaims, each instance corresponds to an argument represented by all and only those attributes involved in the major claim and all of its children.[4]

Five-fold cross-validation results, which are

[4]There is a caveat. If we define features for each of the children, the number of features will be proportional to the number of children. However, SVMs cannot handle a variable number of features. Hence, all of the children will be represented by one set of features. For instance, the Specificity feature value of the children will be the Specificity values averaged over all of the children.

Prompt: Government budget focus, young children or university?

Education plays a significant role in a country's long-lasting prosperity. It is no wonder that governments throughout the world lay special emphasis on education development. As for the two integral components within the system, elementary and advanced education, there's no doubt that a government is supposed to offer sufficient financial support for both.

Concerning that elementary education is the fundamental requirement to be a qualified citizen in today's society, government should guarantee that all people have equal and convenient access to it. So a lack of well-established primary education goes hand in hand with a high rate of illiteracy, and this interplay compromises a country's future development. In other words, if countries, especially developing ones, are determined to take off, one of the key points governments should set on agenda is to educate more qualified future citizens through elementary education.
...

Table 14: An example essay. Owing to space limitations, only its first two paragraphs are shown.

		P	E	S	Ev	R	St	Lo	Pa	Et	cType	pType
M1	government is supposed to offer sufficient financial support for both	3	4	2	3			T	F	F		
C1	if countries, especially developing ones, are determined to take off, one of the key points governments should set on agenda is to educate more qualified future citizens through elementary education	4	5	4	4	6		T	F	F	policy	
P1	elementary education is the fundamental requirement to be a qualified citizen in today's society	4	5	3	1	6	4					A
C2	government should guarantee that all people have equal and convenient access to it	2	3	1	1	6		F	F	F	policy	
P2	a lack of well-established primary education goes hand in hand with a high rate of illiteracy, and this interplay compromises a country's future development	4	5	3	1	6	4					C

Table 15: The argument components in the example in Table 14 and the scores of their associated attributes: **P**ersuasiveness, **E**loquence, **S**pecificity, **Ev**idence, **R**elevance, **St**rength, **Lo**gos, **Pa**thos, **Et**hos, **c**laim**Type**, and **p**remise**Type**.

shown in Table 13, are expressed in terms of two evaluation metrics, PC and ME (the mean absolute distance between a system's prediction and the gold score). Since PC is a *correlation* metric, higher correlation implies better performance. In contrast, ME is an *error* metric, so lower scores imply better performance. As we can see, the large PC values and the relatively low ME values provide suggestive evidence that these attributes, when used in combination, can largely explain the persuasiveness of an argument.

What these results imply in practice is that models that are trained on these attributes for persuasiveness scoring could provide useful feedback to students on *why* their arguments are (un)persuasive. For instance, one can build a pipeline system for persuasiveness scoring as follows. Given an argument, this system first predicts its attributes and then scores its persuasiveness using the predicted attribute values computed in the first step. Since the persuasiveness score of an argument is computed using its predicted attributes, these attributes can explain the persuasiveness score. Hence, a student can figure out which aspect of persuasiveness needs improvements by examining the values of the predicted attributes.

4.6 Example

To better understand our annotation scheme, we use the essay in Table 14 to illustrate how we obtain the attribute values in Table 15. In this essay, Claim **C1**, which supports MajorClaim **M1**, is supported by three children, Premises **P1** and **P2** as well as Claim **C2**.

After reading the essay in its entirety and acquiring a holistic impression of the argument's strengths and weaknesses, we begin annotating the atomic argument components bottom up, starting with the leaf nodes of the argument tree. First, we consider **P2**. Its Evidence score is 1 because it is a leaf node with no supporting evidence. Its Eloquence score is 5 because the sentence has no serious grammatical or syntactic errors, has a flowing, well thought out sentence structure, and uses articulate vocabulary. Its Specificity score is 3 because it is essentially saying that poor primary education causes illiteracy and consequently inhibits a country's development. It does not state why or to what extent, so we cannot assign a score of 4. However, it does explain a simple relationship with little ambiguity due to the lack of hedge words, so we can assign a score of 3. Its PremiseType is *common_knowledge* because it is reasonable to assume most people would agree that poor primary education causes illiteracy, and also that illiteracy inhibits a country's development. Its Relevance score is 6: its relationship with its parent is clear because the two components exhibit coreference. Specifically, **P2** contains a reference to primary/elementary education and shows how this affects a country's inability to transition from developing to developed. Its Strength is 4: though eloquent and relevant, **P2** is lacking substance in order to be considered for a score of 5 or 6. The PremiseType is *common_knowledge*, which is mediocre compared to statistics and real_example. In order for a premise that is not grounded in the real world to be strong, it must be very specific. **P2** only scored a 3 in Specificity, so we assign a Strength score of 4. Finally, the argument headed by **P2**, which does not have any children, has a Persuasiveness score of 4, which is obtained by summarizing the inherent strength of the premise and the supporting evidence. Although there is no supporting evidence for this premise, this does not adversely affect persuasiveness due to the standalone nature of premises. In this case the persuasiveness is derived totally from the strength.

Next, the annotator would score **C2** and **P1**, but for demonstration purposes we will examine the scoring of **C1**. **C1**'s Eloquence score is 5 because it shows fluency, broad vocabulary, and attention to how well the sentence structure reads. Its ClaimType is *policy* because it specifically says that the government should put something on their agenda. Its Specificity score is 4: while it contains information relevant to all the child premises (i.e., creating qualified citizens, whose role it is to provide the education, and the effect of education on a country's development), it does not contain a qualifier stating the extent to which the assertion holds true. Its Evidence score is 4: **C1** has two premises with decent persuasiveness scores and one claim with a poor persuasiveness score, and there are no attacking premises, so intuitively, we may say that this is a midpoint between many low quality premises and few high quality premises. We mark Logos as true, Pathos as false, and Ethos as false: rather than use an emotional appeal or an appeal to authority of any sort, the author attempts to use logical reasoning in order to prove their point. Its Persuasiveness score is 4: this score is mainly determined by the strength of the supporting evidence, given that the assertion is precise and clear as determined by the specificity and eloquence. Its Relevance score is 6, as anyone can see how endorsement of elementary education in **C1** relates to the endorsement of elementary and university education in its parent (i.e., **M1**).

After all of the claims have been annotated in the bottom-up method, the annotator moves on to the major claim, **M1**. **M1**'s Eloquence score is 4: while it shows fluency and a large vocabulary, it is terse and does not convey the idea exceptionally well. Its persuasion strategies are obtained by simply taking the logical disjunction of those used in its child claims. Since every claim in this essay relied on logos and did not employ pathos nor ethos, **M1** is marked with Logos as true, Pathos as false, and Ethos as false. Its Evidence score is 3: in this essay there are two other supporting claims not in the excerpt, with persuasiveness scores of only 3 and 2, so **M1**'s evidence has one decently persuasive claim, one claim that is poor but understandable, and one claim that is so poor as to be completely unpersuasive (in this case it has no supporting premises). Its Specificity score is 2 because it does not have a quantifier nor does it attempt to summarize the main points of the evidence. Finally, its Persuasiveness score is 3: all supporting claims rely on logos, so there is no added persuasiveness from a variety of persuasion strategies, and since the eloquence and specificity are adequate, they do not detract from the Evidence score.

5 Conclusion

We presented the first corpus of 102 persuasive student essays that are simultaneously annotated with argument trees, persuasiveness scores, and attributes of argument components that impact these scores. We believe that this corpus will push the frontiers of research in content-based essay grading by triggering the development of novel computational models concerning argument persuasiveness that could provide useful feedback to students on why their arguments are (un)persuasive in addition to how persuasive they are.

Inherent Biases in Reference-based Evaluation for Grammatical Error Correction and Text Simplification

Leshem Choshen[1] and Omri Abend[2]
[1]School of Computer Science and Engineering, [2] Department of Cognitive Sciences

leshem.choshen@mail.huji.ac.il, oabend@cs.huji.ac.il

Abstract

The prevalent use of too few references for evaluating text-to-text generation is known to bias estimates of their quality (henceforth, *low coverage bias* or LCB). This paper shows that overcoming LCB in Grammatical Error Correction (GEC) evaluation cannot be attained by re-scaling or by increasing the number of references in any feasible range, contrary to previous suggestions. This is due to the long-tailed distribution of valid corrections for a sentence. Concretely, we show that LCB incentivizes GEC systems to avoid correcting even when they can generate a valid correction. Consequently, existing systems obtain comparable or superior performance compared to humans, by making few but targeted changes to the input. Similar effects on Text Simplification further support our claims.

1 Introduction

Evaluation in monolingual translation (Xu et al., 2015; Mani, 2009) and in particular in GEC (Tetreault and Chodorow, 2008; Madnani et al., 2011; Felice and Briscoe, 2015; Bryant and Ng, 2015; Napoles et al., 2015) has gained notoriety for its difficulty, due in part to the heterogeneity and size of the space of valid corrections (Chodorow et al., 2012; Dreyer and Marcu, 2012). Reference-based evaluation measures (RBM) are the common practice in GEC, including the standard M^2 (Dahlmeier and Ng, 2012), GLEU (Napoles et al., 2015) and I-measure (Felice and Briscoe, 2015).

The Low Coverage Bias (LCB) was previously discussed by Bryant and Ng (2015), who showed that inter-annotator agreement in producing references is low, and concluded that RBMs underestimate the performance of GEC systems. To address this, they proposed a new measure, Ratio Scoring, which re-scales M^2 by the inter-annotator agreement (i.e., the score of a human corrector), interpreted as an upper bound.

We claim that the LCB has more far-reaching implications than previously discussed. First, while we agree with Bryant and Ng (2015) that a human correction should receive a perfect score, we show that LCB does not merely scale system performance by a constant factor, but rather that some correction policies are less prone to be biased against. Concretely, we show that by only correcting closed class errors, where few possible corrections are valid, systems can outperform humans. Indeed, in Section 2.3 we show that some existing systems outperform humans on M^2 and GLEU, while only applying few changes to the source.

We thus argue that the development of GEC systems against low coverage RBMs disincentivizes systems from making changes to the source in cases where there are plentiful valid corrections (open class errors), as necessarily only some of them are covered by the reference set. To support our claim we show that (1) existing GEC systems under-correct, often performing an order of magnitude less corrections than a human does (§3.2); (2) increasing the number of references alleviates under-correction (§3.3); and (3) under-correction is more pronounced in error types that are more varied in their valid corrections (§3.4).

A different approach for addressing LCB was taken by (Bryant and Ng, 2015; Sakaguchi et al., 2016), who propose to increase the number of references (henceforth, M). In Section 2 we estimate the distribution of corrections per sentence, and find that increasing M is unlikely to overcome LCB, due to the vast number of valid corrections for a sentence and their long-tailed distribution. Indeed, even short sentences have over 1000 valid corrections on average. Empirically assessing the effect of increasing M on the bias, we find diminishing returns using three standard GEC measures (M^2, accuracy and GLEU), underscoring the difficulty in this approach.

Similar trends are found when conducting such experiments to Text Simplification (TS) (§4). Specifically we show that (1) the distribution of valid simplifications for a given sentence is long-tailed; (2) common measures for TS dramatically under-estimate performance; (3) additional references alleviate this under-prediction.

To recap, we find that the LCB hinders the reliability of RBMs for GEC, and incentivizes systems developed to optimize these measures not to correct. LCB cannot be overcome by re-scaling or increasing M in any feasible range.

2 Coverage in RBMs

We begin by formulating a methodology for studying the distribution of valid corrections for a sentence (§2.1), and then turn to assessing the effect inadequate coverage has on common RBMs (§2.2). Finally, we compare human and system scores by common RBMs (§2.3).

Notation. We assume each ungrammatical sentence x has a set of valid corrections $Correct_x$, and a discrete distribution $\mathcal{D}_x$ over them, where $P_{\mathcal{D}_x}(y)$ for $y \in Correct_x$ is the probability a human annotator would correct x as y.

Let $X = x_1 \ldots x_N$ be the evaluated set of source sentences and denote $\mathcal{D}_i := \mathcal{D}_{x_i}$. Each x_i is independently sampled from some distribution $\mathcal{L}$ over input sentences, and is paired with M corrections $Y_i = \left\{y_i^1, \ldots, y_i^M\right\}$, which are independently sampled from $\mathcal{D}_i$. Our analysis assumes a fixed number of references across sentences, but generalizing to sentence-dependent M is straightforward. The *coverage* of a reference set Y_i of size M for a sentence x_i is defined as $P_{y \sim \mathcal{D}_i}(y \in Y_i)$.

A system C is a function from input sentences to proposed corrections (strings). An evaluation measure is a function $f\colon X \times Y \times C \to \mathbb{R}$. We use the term "true measure" to refer to a measure's output where the reference set includes all valid corrections, i.e., $\forall i\colon Y_i = Correct_i$.

Experimental Setup. We conduct all experiments on the NUCLE test dataset (Dahlmeier et al., 2013). NUCLE is a parallel corpus of essays written by language learners and their corrected versions, containing 1414 essays and 50 test essays, each of about 500 words.

We evaluate all participating systems in the CoNLL 2014 shared task, in addition to three of the best performing systems on this dataset, a hybrid system (Rozovskaya and Roth, 2016), a phrase-based MT system (Junczys-Dowmunt and Grundkiewicz, 2016) and a neural network system (Xie et al., 2016). Appendix A lists system names and abbreviations.

2.1 Estimating the Corrections Distribution

Data. We turn to estimating the number of corrections per sentence, and their histogram. The experiments in the following section are run on a random sample of 52 short sentences from the NUCLE test data, i.e. with 15 words or less. Through the length restriction, we avoid introducing too many independent errors that may drastically increase the number of annotation variants (as every combination of corrections for these errors is possible), thus resulting in unreliable estimation for $\mathcal{D}_x$.

Proven effective in GEC and related tasks such as MT (Zaidan and Callison-Burch, 2011; Madnani et al., 2011; Post et al., 2012), we use crowdsourcing to sample from $\mathcal{D}_x$ (see Appendix B). Aiming to judge grammaticality rather than fluency, we instructed the workers to correct only when necessary, not for styling. We begin by estimating the histogram of $\mathcal{D}_x$ for each sentence, using the crowdsourced corrections. We use UNSEENEST (Zou et al., 2016), a non-parametric algorithm to estimate a discrete distribution in which the individual values do not matter, only their probability. UNSEENEST aims to minimize the "earthmover distance", between the estimated histogram and the histogram of the distribution. Intuitively, if histograms are piles of dirt, UNSEENEST minimizes the amount of dirt moved times the distance it moved. UNSEENEST was originally developed and tested for estimating the histogram of variants a gene may have, including undiscovered ones, a setting similar to ours. Our manual tests of UNSEENEST with small artificially created datasets showed satisfactory results.[1]

[1]An implementation of UNSEENEST, the data we collected, the estimated distributions and efficient implementations of computations with Poisson binomial distributions can be found in `https://github.com/borgr/IBGEC`.

Our estimates show that most input sentences have a large number of infrequent corrections that account for much of the probability mass and a rather small number of frequent corrections. Table 1 presents the mean number of different corrections with frequency at least γ (for different γs), and their total probability mass. For instance, 74.34 corrections account for 75% of the probability mass, each occurring with frequency $\geq 0.1\%$.

	Frequency Threshold (γ)			
	0	0.001	0.01	0.1
Variants	1351.24	74.34	8.72	1.35
Mass	1	0.75	0.58	0.37

Table 1: Estimating the distribution of corrections $\mathcal{D}_x$. The table presents the mean number of corrections per sentence with probability more than γ (top row), as well as their total probability mass (bottom row).

The high number of rare corrections raises the question of whether these can be regarded as noise. To test this we conducted another crowd-sourcing experiment, where 3 annotators were asked to judge whether a correction produced in the first experiment, is indeed valid. We plot the validity of corrections against their frequencies, finding that frequency has little effect, where even the rarest corrections are judged valid 78% of the time. Details in Appendix C.

2.2 Under-estimation as a Function of M

After estimating the histogram of valid corrections for a sentence, we turn to estimating the resulting bias (LCB), for different M values. We study sentence-level accuracy, F-Score and GLEU.

Sentence-level Accuracy. Sentence-level accuracy is the percentage of corrections that exactly match one of the references. Accuracy is a basic, interpretable measure, used in GEC by, e.g., Rozovskaya and Roth (2010). It is also closely related to the 0-1 loss function commonly used for training in GEC (Chodorow et al., 2012; Rozovskaya and Roth, 2013).

Formally, given test sentences $X = \{x_1, \ldots, x_N\}$, their references $Y_1, \ldots, Y_N$ and a system C, we define C's accuracy to be

$$Acc\,(C; X, Y) = \frac{1}{N}\sum_{i=1}^{N} \mathbb{1}_{C(x_i)\in Y_i}. \tag{1}$$

Note that C's accuracy is, in fact, an estimate of C's *true accuracy*, the probability to produce a valid correction for a sentence. Formally:

$$TrueAcc\,(C) = P_{x\sim L}\left(C\,(x) \in Correct_x\right). \tag{2}$$

The bias of $Acc\,(C; X, Y)$ for a sample of N sentences, each paired with M references is then

$$\begin{aligned} &TrueAcc\,(C) - \mathbb{E}_{X,Y}\left[Acc\,(C; X, Y)\right] = && (3)\\ &TrueAcc\,(C) - P\left(C\,(x) \in Y\right) = && (4)\\ &P\left(C\,(x) \in Correct_x\right) \cdot && (5)\\ &\left(1 - P\left(C\,(x) \in Y | C\,(x) \in Correct_x\right)\right) && (6) \end{aligned}$$

We observe that the bias, denoted b_M, is not affected by N, only by M. As M grows, Y better approximates $Correct_x$, and b_M tends to 0.

In order to abstract away from the idiosyncrasies of specific systems, we consider an idealized learner, which, when correct, produces a valid correction with the same distribution as a human annotator (i.e., according to $\mathcal{D}_x$). Formally, we assume that, if $C(x) \in Correct_x$ then $C(x) \sim \mathcal{D}_x$. Hence the bias b_M (Eq. 6) can be re-written as

$$P(C(x) \in Correct_x) \cdot (1 - P_{Y\sim\mathcal{D}_x^M, y\sim\mathcal{D}_x}(y \in Y)).$$

We will henceforth assume that C is perfect (i.e., its *true accuracy* is 1). Note that assuming any other value for C's *true accuracy* would simply scale b_M by that accuracy. Similarly, assuming only a fraction p of the sentences require correction scales b_M by p.

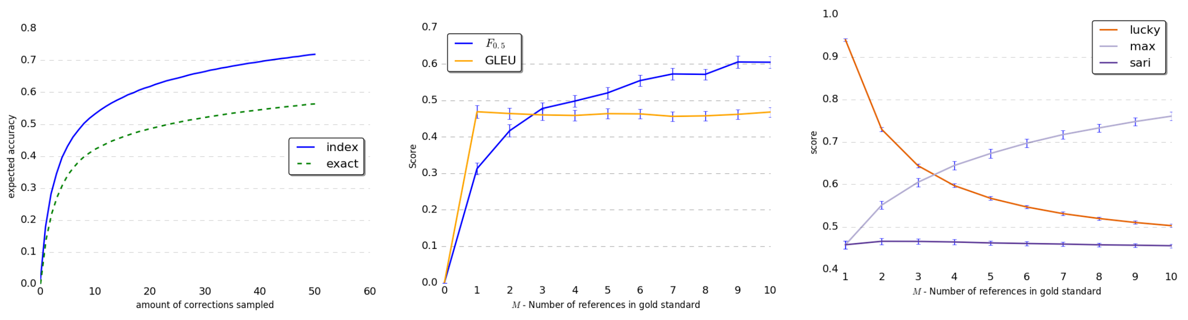
We estimate b_M empirically using its empirical mean on our experimental corpus:

$$\hat{b}_M = 1 - \frac{1}{N}\sum_{i=1}^{N} P_{Y\sim\mathcal{D}_i^M, y\sim\mathcal{D}_i}\left(y \in Y\right).$$

Using the UNSEENEST estimations of $\mathcal{D}_i$, we can compute $\hat{b}_M$ for any size of Y_i (M). However, as this is highly computationally demanding, we estimate it using sampling. Specifically, for every $M = 1, ..., 20$ and x_i, we sample Y_i 1000 times (with replacement), and estimate $P\left(y \in Y_i\right)$ as the covered probability mass $P_{\mathcal{D}_i}\{y : y \in Y_i\}$. Based on that we compute the accuracy distribution and expectation (see Appendix D).

We repeated all our experiments where Y_i is sampled without replacement, and find similar trends with a faster increase in accuracy reaching over 0.47 with $M = 10$.

Figure 1a presents the expected accuracy of a perfect system (i.e., 1-$\hat{b}_M$) for different Ms. Results show that even for M values which are much larger than the standard (e.g., $M = 20$), expected



(a) Accuracy and Exact Index Match.

(b) $F_{0.5}$ and GLEU

(c) (lucky) perfect SARI and MAX-SARI

Figure 1: The score obtained by perfect systems according to GEC accuracy (1a), GEC F-score and GLEU (1b). Figure 1c reports TS experimental results, namely the score of a perfect and lucky perfect system using SARI, and a perfect system using MAX-SARI. The y-axis corresponds to the measure values, and the x-axis to the number of references M. For bootstrapping experiments points are paired with a confidence interval ($p = .95$).

accuracy is only around 0.5. As M increases, the contribution of each additional correction diminishes sharply (the slope is 0.004 for $M = 20$).

We also experiment with a more relaxed measure, *Exact Index Match*, which is only sensitive to the identity of the changed words and not to what they were changed to. Formally, two corrections c and c' over a source sentence x match if for their word alignments with the source (computed as above) $a : \{1, ..., |x|\} \rightarrow \{1, ..., |c|, Null\}$ and $a' : \{1, ..., |x|\} \rightarrow \{1, ..., |c'|, Null\}$, it holds that $c_{a(i)} \neq x_i \Leftrightarrow c'_{a'(i)} \neq x_i$, where $c_{Null} = c'_{Null}$. Results, while somewhat higher, are still only 0.54 with $M = 10$. (Figure 1a)

F-Score. While accuracy is commonly used as a loss function for training GEC systems, F_α-score is standard for evaluating system performance. The score is computed in terms of *edit* overlap between edits that constitute a correction and ones that constitute a reference, where edits are substring replacements to the source. We use the standard M^2 scorer (Dahlmeier and Ng, 2012), which defines edits optimistically, maximizing over all possible annotations that generate the correction from the source. Since our crowdsourced corrections are not annotated for edits, we produce edits to the reference heuristically.

The complexity of the measure prohibits an analytic approach (Yeh, 2000). We instead use bootstrapping to estimate the bias incurred by not being able to exhaustively enumerate the set of valid corrections. As with accuracy, in order to avoid confounding our results with system-specific biases, we assume the evaluated system is perfect and sample its corrections from the human distribution of corrections $\mathcal{D}_x$.

Concretely, given a value for M and for N, we uniformly sample from our experimental corpus source sentences $x_1, ..., x_N$, and M corrections for each $Y_1, ..., Y_N$ (with replacement). Setting a realistic value for N in our experiments is important for obtaining comparable results to those obtained on the NUCLE corpus (see §2.3), as the expected value of F-score depends on N and the number of sentences that do not need correction (N_{cor}). Following the statistics of NUCLE's test set, we set $N = 1312$ and $N_{cor} = 136$.

Bootstrapping is carried out by the accelerated bootstrap procedure (Efron, 1987), with 1000 iterations. We also report confidence intervals ($p = .95$), computed using the same procedure.

Results (Figure 1b) again show the insufficiency of commonly-used M values for reliably estimating system performance. For instance, the $F_{0.5}$-score for our perfect system is only 0.42 with $M = 2$. The saturation effect, observed for accuracy, is even more pronounced in this setting.

GLEU. We repeat the procedure using the mean GLEU sentence score (Figure 1b), which was shown to better correlate with human judgments than M^2 (Napoles et al., 2016). Results are about 2% higher than M^2's with a similar saturation effect. Sakaguchi et al. (2016) observed a similar effect when evaluating against fluency-oriented references; this has led them to assume that saturation is due to covering most of the probability mass, which we now show is not the case.[2]

[2] We do not experiment with I-measure (Felice and Briscoe, 2015), as its run-time is prohibitively high for experimenting with bootstrapping that requires many applications of the measure (Choshen and Abend, 2018a), and as empirical validation studies showed that it has a low correlation with human judgments (Sakaguchi et al., 2016).

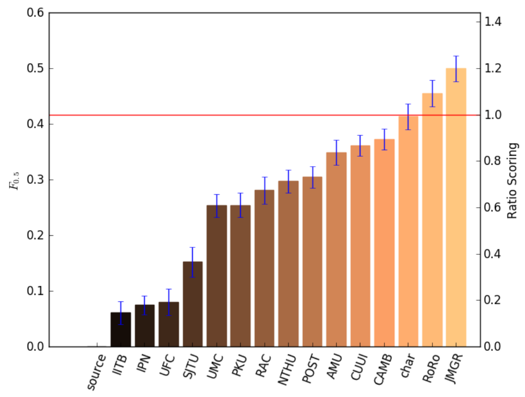


Figure 2: $F_{0.5}$ values with $M = 2$ for different systems, including confidence interval ($p = .95$). The left-most column ("source") presents the F-score of a system that doesn't make any changes to the source sentences. In red is human performance. See §2 for a legend of the systems.

2.3 Human and System Performance

The bootstrapping method for computing the significance of the F-score (§2.2) can also be used for assessing the significance of the differences in system performance reported in the literature. We compute confidence intervals of different systems on the NUCLE test data ($M = 2$).

Results (Figure 2) present mixed trends: some differences between previously reported F-scores are indeed significant and some are not. For example, the best performing system is significantly better than all but the second one.

Considering the F-score of the best-performing systems, and comparing them to the F-score of a perfect system with $M = 2$ (in accordance with systems' reported results), we find that their scores are comparable, where the systems RoRo and JMGR surpass a perfect system's F-score. Similar experiments with GLEU show that the two systems obtain comparable or superior performance to humans on this measure as well.

2.4 Discussion

In this section we have established that (1) as systems can surpass human performance on RBMs, re-scaling cannot be used to overcome the LCB, and that (2) as the distribution of valid corrections is long-tailed, the number of references needed for reliable RBMs is exceedingly high. Indeed, an average sentence has hundreds or more valid low-probability corrections, whose total probability mass is substantial. Our analysis with Exact Index Match suggests that similar effects are applicable to Grammatical Error Detection as well. The proposal of Sakaguchi et al. (2016), to emphasize fluency over grammaticality in reference corrections, only compounds this problem, as it results in a larger number of valid corrections.

3 Implications of the LCB

We discuss the adverse effects of LCB not only on the reliability of RBMs, but on the development of GEC systems. We argue that evaluation with inadequate reference coverage incentivizes systems to under-correct, and to mostly target errors that have few valid corrections (closed-class). We first show that low coverage can lead to under-correction (§3.1), then show that modern systems make far fewer corrections to the source, compared to humans (§3.2). §3.3 shows that increasing the number of references can alleviate this effect. §3.4 shows that open-class errors are more likely to be under-corrected than closed-class ones.

3.1 Motivating Analysis

For simplicity, we abstract away from the details of the learning model and assume that systems attempt to maximize an objective function, over some training or development data. We assume maximization is achieved by iterating over the samples, as with the Perceptron or SGD.

Assume the system is faced with a phrase it predicts to be ungrammatical. Assume p_{detect} is the probability this prediction is correct, and $p_{correct}$ is the probability it is able to predict a valid correction for this phrase (including correctly identifying it as erroneous). Finally, assume evaluation is against M references with coverage $p_{coverage}$ (the probability that a valid correction will be found among M randomly sampled references).

We will now assume that the system may either choose to correct with the correction it finds the most likely or not at all. If it chooses not to correct, its probability of being rewarded (i.e., its output is in the reference set) is $(1 - p_{detect})$. Otherwise, its probability of being rewarded is $p_{correct} \cdot p_{coverage}$. A system is disincentivized from altering the phrase in cases where:

$$p_{correct} \cdot p_{coverage} < 1 - p_{detect} \quad (7)$$

We expect Condition (7) to frequently hold in cases that require non-trivial changes, which are characterized both by low $p_{coverage}$ (as non-trivial changes are often open-class), and by lower system performance.

Corrector	Sentence
Source	This is especially to people who are overseas.
CHAR, UMC, JMGR	This is especially **for** people who are overseas.
IPN	This is especially to **peoples** who are overseas.
CUUI	This is especially to **the** people who are overseas.
NUCLE$_A$	This is especially **true for** people who are overseas.
NUCLE$_B$	This is especially **relevant** to people who are overseas.

Table 2: Example for a sentence and proposed corrections by different systems (top part) and by the two NUCLE annotators (bottom part). Systems not mentioned in the table retain the source. No system produces a new word as needed. The two references differ in their corrections.

Precision-oriented measures (e.g., $F_{0.5}$) penalize invalidly correcting more harshly than not correcting an ungrammatical sentence. In these cases, Condition (7) should be written as

$$p_{correct} \cdot p_{coverage} - (1 - p_{correct} \cdot p_{coverage})\,\alpha < 1 - p_{detect}$$

where α is the ratio between the penalty for introducing a wrong correction and the reward for a valid correction. The condition is even more likely to hold with such measures.

3.2 Under-correction in GEC Systems

In this section we compare the prevalence of changes made to the source by the systems, to their prevalence in the NUCLE references. To strengthen our claim, we exclude all non-alphanumeric characters, both within tokens or as separate tokens. See Table 2 for an example.

We consider three types of divergences between the source and the reference. First, we measure the extent to which *words* were changed: altered, deleted or added. To do so, we compute word alignment between the source and the reference, casting it as a weighted bipartite matching problem. Edge weights are assigned to be the token edit distances.[3] Following word alignment, we define WORDCHANGE as the number of aligned words and unaligned words changed. Second, we quantify word *order* differences using Spearman's ρ between the order of the words in the source sentence and the order of their corresponding-aligned words in the correction. $\rho = 0$ where the word order is uncorrelated, and $\rho = 1$ where the orders exactly match. We report the average ρ over all source sentence pairs. Third, we report how many source sentences were split and how many concatenated by the reference and by the systems. One annotator was arbitrarily selected for the figures.

Results. Results (Figure 3) show that humans make considerably more changes than systems according to all measures of under-correction, both in terms of the number of sentences modified and the number of modifications within them. Differences are often an order of magnitude large. For example, 36 reference sentences include 6 word changes, where the maximal number of sentences with 6 word changes by any system is 5. We find similar trends on the references of the TreeBank of Learner English (Yannakoudakis et al., 2011).

3.3 Higher M Alleviates Under-correction

This section reports an experiment for determining whether increasing the number of references in training indeed reduces under-correction. There is no corpus available with multiple references which is large enough for re-training a system. Instead, we simulate such a setting with an oracle reranking approach, and test whether the availability of increasingly more training references reduces a system's under-correction.

Concretely, given a set of sentences, each paired with M references, a measure and a system's k-best list, we define an oracle re-ranker that selects for each sentence the highest scoring correction. As a test case, we use the RoRo system with $k = 100$, and apply it to the largest available language learner corpus which is paired with a substantial amount of GEC references, namely the NUCLE test corpus. We use the standard F-score as the evaluation measure, examining the under-correction of the oracle re-ranker for different M values, averaging over the 1312 samples of M references from the available set of ten references provided by Bryant and Ng (2015).

As the argument is not trivial, we turn to explaining why decreased under-correction with an increase in M indicates that tuning against a small set of references (low coverage) yields under-correction. Assume an input sentence with some sub-string e. There are three cases: (1) e is an error, (2) e is valid but there are valid references that alter it, (3) e is uniquely valid. In case (3) or-

[3]Aligning words in GEC is much simpler than in MT, as most of the words are unchanged, deleted fully, added, or changed slightly.

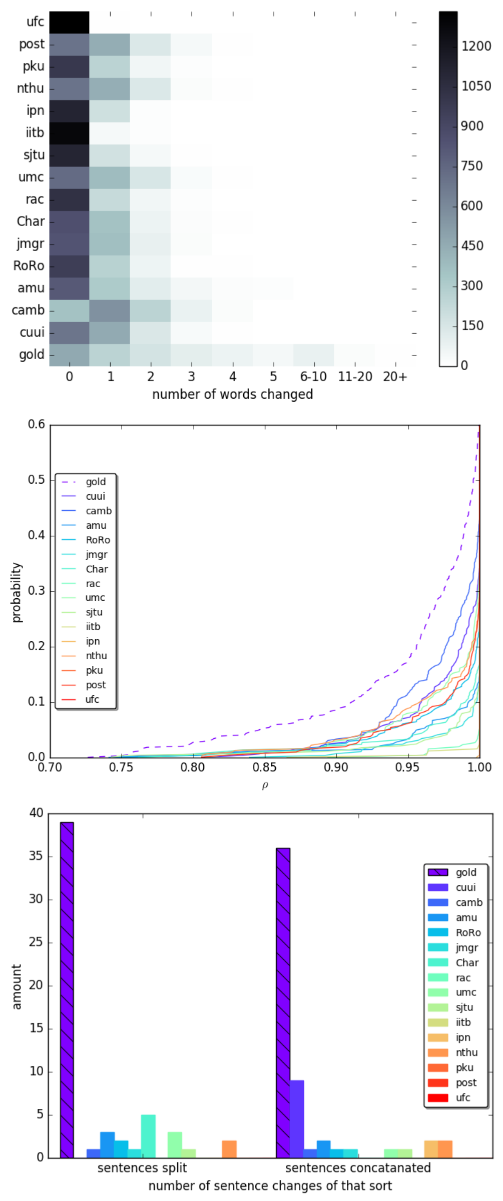

Figure 3: The prevalence of changes in system outputs and in the NUCLE reference. The top figure presents the number of sentences (heat) for each amount of word changes (x-axis; measured by WORDCHANGE) done by the outputs and the reference (y-axis). The middle figure presents the percentage of sentence pairs (y-axis) where the Spearman ρ values do not exceed a certain threshold (x-axis). The bottom figure presents the counts of source sentences (y-axis) concatenated (right bars) or split (left bars) by the references (striped column) and the outputs (coloured columns). See Appendix A for a legend of the systems. Under all measures, the gold standard references make substantially more changes to the source sentences than any of the systems, in some cases an order of magnitude more.

	L_{val} empty	L_{val} not empty	
		e valid	e error
Small M	0	$P_Y(\overline{e}, L_{val})$	$P_Y(L_{val})$
Large M	0	0	1
Correction Rate	=	$\downarrow$	$\uparrow$

Table 3: The expected effect of oracle re-ranking on under-correction. Values represent the probability of altering a substring of the input e, which is a proxy to the expected correction rate. L_{val} is the valid alterations in the k-best list. $P_Y(L_{val})$ is the probability that a valid correction from the list is also in the reference set Y, $P_Y(\overline{e}, L_{val})$ is the probability that, in addition, the reference that keeps e is not in Y. When M increases, the expected correction rate is expected to increase only if e is an error and a valid correction of it is found in the k-best list.

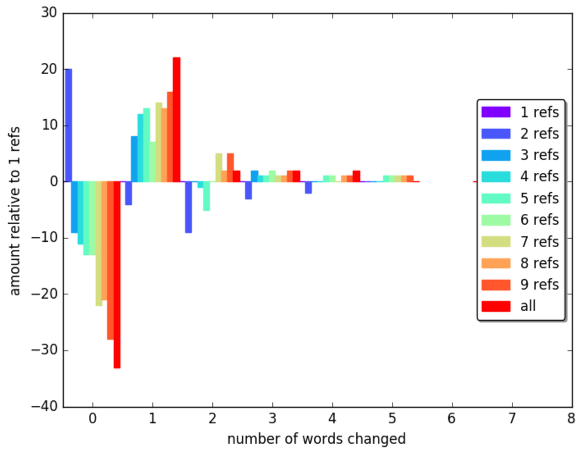

Figure 4: The amount of sentences (y-axis) with a given number of words changed (x-axis) following oracle reranking with different M values (column colors), where the amount for $M = 1$ is subtracted from them. All references are randomly sampled except the "all" column that contains all ten references. In conclusion, tuning against additional references indeed reduces under-correction.

acle re-ranking has no effect and can be ignored. The corrections in the k-best list can then be partitioned to those that keep e as it is; those that invalidly alter e; and those that validly alter e.

Table 3 presents the probability that e will be altered in the different cases. Analysis shows that under-correction is likely to decrease with M only in the case where e is an error and the k-best list contains a valid correction of it. Whenever the reference allows both keeping e and altering e, the re-ranker selects keeping e.

Indeed, our experimental results show that word changes increase with M (Figure 4), indicating that low coverage may play a role in the observed tendency of GEC systems to under-correct. No significant difference is found for word order.

3.4 Under-correction by Error Types

In this section we study the prevalence of under-correction according to edit types, finding that open-class types of errors (such as replacing a word with another word) are more starkly under-corrected, than closed-class errors. Evaluating with low coverage RBMs does not incentivize systems to address open-class errors (in fact, it disincentivizes them to). Therefore, even if LCB is not the cause for this trend, current evaluation procedures may perpetuate it.

We use the data of Bryant et al. (2017), which automatically assigned types to each edit in the output of all CoNLL 2014 systems on the NUCLE test set. As a measure of under-correction tendency, we take the ratio between the mean number of corrections produced by the systems and by the references. We note that this analysis does not consider whether the predicted correction is valid or not, but only how many of the errors of each type the systems attempted to correct.

We find that all edit types are under-predicted on average, but that the least under-predicted ones are mostly closed-class types. Concretely, the top quarter of error types consists of orthographical errors, plurality inflection of nouns, adjective inflections to superlative or comparative forms and determiner selection. The bottom quarter includes the categories verb selection, noun selection, particle/preposition selection, pronoun selection, and the type OTHER, which is a residual category. The only exception to this regularity is the closed-class punctuation selection type, which is found in the lower quarter. See Appendix E.

This trend cannot be explained by assuming that common error types are targeted more. Indeed, error type frequency is slightly negatively correlated with the under-correction ratio (ρ=-0.29 p-value=0.16). A more probable account of this effect is the disincentive of GEC systems to correct open-class error types, for which even valid corrections are unlikely to be rewarded.

4 Similar Effects on Simplification

We now turn to replicating our experiments on Text Simplification (TS). From a formal point of view, evaluation of the tasks is similar: the output is obtained by making zero or more edits to the source. RBMs are the standard for TS evaluation, much like they are in GEC.

Our experiments on TS demonstrate that similar trends recur in this setting as well. The tendency of TS systems to under-predict changes to the source has already been observed by previous work (Alva-Manchego et al., 2017), showing that TS systems under-predict word additions, deletions, substitutions, and sequence shifts (Zhang and Lapata, 2017), and have low edit distance from the source (Narayan and Gardent, 2016). Our experiments show that LCB may account for this under-prediction. Concretely, we show that (1) the distribution of valid references for a given sentence is long-tailed; (2) common evaluation measures suffer from LCB, taking SARI (Xu et al., 2016) as an example RBM (similar trends are obtained with Accuracy); (3) under-prediction is alleviated with M in oracle re-ranking experiments.

We crowd-sourced 2500 reference simplifications for 47 sentences, using the corpus and the annotation protocol of Xu et al. (2016), and applying UNSEENEST to estimate $\mathcal{D}_x$ (Appendix B). Table 4 shows that the expected number of references is even greater in this setting.

Assessing the effect of M on SARI, we find that SARI diverges from Accuracy and F-score in that its multi-reference version is not a maximum over the single-reference scores, but some combination of them. This can potentially increase coverage, but it also leads to an unintuitive situation: an output identical to a reference does not receive a perfect score, but rather the score depends on how similar the output is to the other references. A more in-depth analysis of SARI's handling of multiple references is found in Appendix F. In order to neutralize this effect of SARI, we also report results with MAX-SARI, which coincides with SARI on $M = 1$, and is defined as the maximum single-reference SARI score for $M > 1$.

Figure 1c presents the coverage of SARI and MAX-SARI of a perfect TS system that selects a random correction from the estimated distribution of corrections using the same bootstrapping protocol as in §2.1. We also include the SARI score of a "lucky perfect" system, that randomly selects one of the given references (the MAX-SARI score for such a system is 1). Results show that SARI has a coverage of about 0.45, and that this score is largely independent of M. The score of predicting one of the available references drops with the number of references, indicating that SARI scores may not be comparable across different M values.

We therefore restrict oracle re-ranking experi-

	Frequency Threshold (γ)

ments to MAX-SARI, conducting re-ranking experiments on k-best lists in two settings: Moses (Koehn et al., 2007) with $k = 100$, and a neural model (Nisioi et al., 2017) with $k = 12$. Our results indeed show that under-prediction is alleviated with M in both settings. For example, the least under-predicting model (the neural one) did not change 50 sentences with $M = 1$, but only 29 weren't changed with $M = 8$. See Appendix G.

5 Conclusion

We argue that using low-coverage reference sets has adverse effects on the reliability of reference-based evaluation, with GEC and TS as a test case, and consequently on the incentives offered to systems. We further argue that these effects cannot be overcome by re-scaling or increasing the number of references in a feasible way. The paper makes two methodological contributions to the monolingual translation evaluation literature: (1) a methodology for evaluating evaluation measures by the scores they assign a perfect system, using a bootstrapping procedure; (2) a methodology for assessing the distribution of valid monolingual translations. Our findings demonstrate how these tools can help characterize the biases of existing systems and evaluation measures. We believe our findings and methodologies can be useful for similar tasks such as style conversion and automatic post-editing of raw MT outputs.

We note that the LCB further jeopardizes the reliability of common validation experiments for RBMs, that assess the correlation between human and measure rankings of system outputs (Grundkiewicz et al., 2015). Indeed, if outputs all similarly under-correct, correlation studies will not be affected by whether an RBM is sensitive to under-correction. Therefore, the tendency of RBMs to reward under-correction cannot be detected by such correlation experiments (cf. Choshen and Abend, 2018a).

Our results underscore the importance of developing alternative evaluation measures that transcend n-gram overlap, and use deeper analysis tools, e.g., by comparing the semantics of the reference and the source to the output (cf. Lo and Wu, 2011). Napoles et al. (2016) have made progress towards this goal in proposing a reference-less grammaticality measure, using Grammatical Error Detection tools, as did Asano et al. (2017), who added a fluency measure to the grammaticality. In a recent project (Choshen and Abend, 2018b), we proposed a complementary measure that measures the semantic faithfulness of the output to the source, in order to form a combined semantic measure that bypasses the pitfalls of low coverage.

The price of debiasing automatic metrics in natural language evaluation

Abstract

For evaluating generation systems, automatic metrics such as BLEU cost nothing to run but have been shown to correlate poorly with human judgment, leading to systematic bias against certain model improvements. On the other hand, averaging human judgments, the unbiased gold standard, is often too expensive. In this paper, we use control variates to combine automatic metrics with human evaluation to obtain an unbiased estimator with lower cost than human evaluation alone. In practice, however, we obtain only a 7–13% cost reduction on evaluating summarization and open-response question answering systems. We then prove that our estimator is optimal: there is no unbiased estimator with lower cost. Our theory further highlights the two fundamental bottlenecks—the automatic metric and the prompt shown to human evaluators—both of which need to be improved to obtain greater cost savings.

1 Introduction

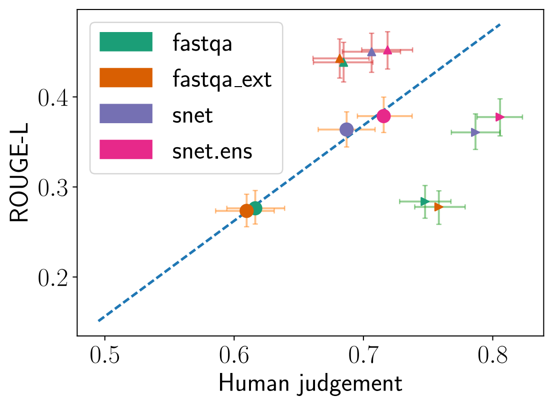
In recent years, there has been an increasing interest in tasks that require generating natural language, including abstractive summarization (Nallapati et al., 2016), open-response question answering (Nguyen et al., 2016; Kočisky et al., 2017), image captioning (Lin et al., 2014), and open-domain dialogue (Lowe et al., 2017b). Unfortunately, the evaluation of these systems remains a thorny issue because of the diversity of possible correct responses. As the gold standard of performing human evaluation is often too expensive, there has been a large effort developing automatic metrics such as BLEU (Papineni et al., 2002), ROUGE (Lin and Rey, 2004), METEOR (Lavie and Denkowski, 2009; Denkowski and Lavie, 2014) and CiDER (Vedantam et al., 2015). However, these have shown to be biased, correlating poorly with human metrics across different datasets and systems (Liu et al., 2016b; Novikova et al., 2017).

Can we combine automatic metrics and human evaluation to obtain an *unbiased* estimate at *lower cost* than human evaluation alone? In this paper, we propose a simple estimator based on control variates (Ripley, 2009), where we average differences between human judgments and automatic metrics rather than averaging the human judgments alone. Provided the two are correlated, our estimator will have lower variance and thus reduce cost.

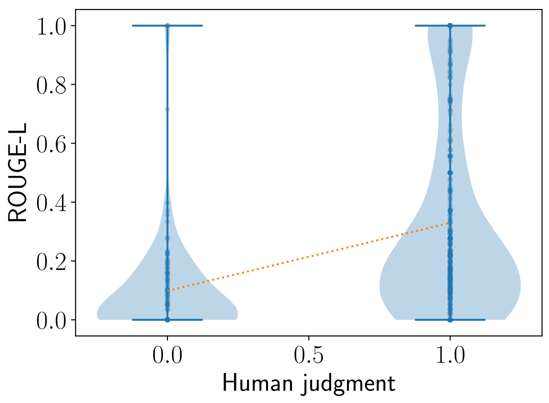
We prove that our estimator is *optimal* in the sense that no unbiased estimator using the same automatic metric can have lower variance. We also analyze its data efficiency (equivalently, cost savings)—the factor reduction in number of human judgments needed to obtain the same accuracy versus naive human evaluation—and show that it depends solely on two factors: (a) the annotator variance (which is a function of the human evaluation prompt) and (b) the correlation between human judgments and the automatic metric. This factorization allows us to calculate typical and best-case data efficiencies and accordingly refine the evaluation prompt or automatic metric.

Finally, we evaluate our estimator on state-of-the-art systems from two tasks, summarization on the CNN/Daily Mail dataset (Hermann et al., 2015; Nallapati et al., 2016) and open-response question answering on the MS MARCOv1.0 dataset (Nguyen et al., 2016). To study our estimators offline, we preemptively collected 10,000 human judgments which cover several

[*]Authors contributed equally.



(a) System-level correlation on the MS MARCO task



(b) Instance-level correlation for the `fastqa` system

Figure 1: (a) At a system-level, automatic metrics (ROUGE-L) and human judgment correlate well, but (b) the instance-level correlation plot (where each point is a system prediction) shows that the instance-level correlation is quite low ($\rho = 0.31$). As a consequence, if we try to locally improve systems to produce better answers ($\triangleright$ in (a)), they do not significantly improve ROUGE scores and vice versa ($\triangle$).

tasks and systems.[1] As predicted by the theory, we find that the data efficiency depends not only on the correlation between the human and automatic metrics, but also on the evaluation prompt. If the automatic metric had perfect correlation, our data efficiency would be around 3, while if we had noiseless human judgments, our data efficiency would be about 1.5. In reality, the reduction in cost we obtained was only about 10%, suggesting that improvements in both automatic metric and evaluation prompt are needed. As one case study in improving the latter, we show that, when compared to a Likert survey, measuring the amount of post-editing needed to fix a generated sentence reduced the annotator variance by three-fold.

2 Bias in automatic evaluation

It is well understood that current automatic metrics tend to correlate poorly with human judgment at the instance-level. For example, Novikova et al. (2017) report correlations less than 0.3 for a large suite of word-based and grammar-based evaluation methods on a generation task. Similarly, Liu et al. (2016b) find correlations less than 0.35 for automatic metrics on a dialog generation task in one domain, but find correlations with the same metric dropped significantly to less than 0.16 when used in another domain. Still, somewhat surprisingly, several automatic metrics have been found to have high *system-level* correlations (Novikova et al., 2017). What, then, are the implications of having a low instance-level correlation?

As a case study, consider the task of open-response question answering: here, a system receives a human-generated question and must *generate* an answer from some given context, e.g. a document or several webpages. We collected the responses of several systems on the MS MARCOv1 dataset (Nguyen et al., 2016) and crowd-sourced human evaluations of the system output (see Section 4 for details).

The instance-level correlation (Figure 1b) is only $\rho = 0.31$. A closer look at the instance-level correlation reveals that while ROUGE is able to correctly assign low scores to bad examples (lower left), it is bad at judging good examples and often assigns them low ROUGE scores (lower right)—see Table 1 for examples. This observation agrees with a finding reported in Novikova et al. (2017) that automatic metrics correlate better with human judgments on bad examples than average or good examples.

Thus, as Figure 1(a) shows, we can improve low-scoring ROUGE examples without improving their human judgment ($\triangle$) and vice versa ($\triangleright$). Indeed, Conroy and Dang (2008) report that summarization systems were optimized for ROUGE during the DUC challenge (Dang, 2006) until they were indistinguishable from the ROUGE scores of human-generated summaries, but the systems

(b) **CNN/Daily Mail.** Human judgment scores used are post-edit distance (`Edit`) (lower is better) and the automatic metric used is sentence vector similarity with the reference (higher is better).

Table 1: Examples highlighting the different modes in which the automatic metric and human judgments may agree or disagree. On the MS MARCO task, a majority of responses from systems were actually correct but poorly scored according to ROUGE-L. On the CNN/Daily Mail task, a significant number of examples which are scored highly by VecSim are poorly rated by humans, and likewise many examples scored poorly by VecSim are highly rated by humans.

had hardly improved on human evaluation. Hill-climbing on ROUGE can also lead to a system that does worse on human scores, e.g. in machine translation (Wu et al., 2016). Conversely, genuine quality improvements might not be reflected in improvements in ROUGE. This bias also appears in pool-based evaluation for knowledge base population (Chaganty et al., 2017). Thus the problems with automatic metrics clearly motivate the need for human evaluation, but can we still use the automatic metrics somehow to save costs?

3 Statistical estimation for unbiased evaluation

We will now formalize the problem of combining human evaluation with an automatic metric. Let $\mathcal{X}$ be a set of inputs (e.g., articles), and let S be the *system* (e.g. for summarization), which takes $x \in \mathcal{X}$ and returns output $S(x)$ (e.g. a summary). Let $\mathcal{Z} = \{(x, S(x)) : x \in \mathcal{X}\}$ be the set of system predictions. Let $Y(z)$ be the random variable representing the human judgment according to some evaluation prompt (e.g. grammaticality or correctness), and define $f(z) = \mathbb{E}[Y(z)]$ to be the (unknown) *human metric* corresponding to averaging over an infinite number of human judgments. Our goal is to estimate the average across all examples:

$$\mu \stackrel{\text{def}}{=} \mathbb{E}_z[f(z)] = \frac{1}{|\mathcal{Z}|}\sum_{z\in\mathcal{Z}} f(z) \qquad (1)$$

with as few queries to Y as possible.

Let g be an automatic metric (e.g. ROUGE), which maps z to a real number. We assume evaluating $g(z)$ is free. The central question is how to use g in conjunction with calls to Y to produce an unbiased estimate $\hat{\mu}$ (that is, $\mathbb{E}[\hat{\mu}] = \mu$). In this section, we will construct a simple estimator based on control variates (Ripley, 2009), and prove that it is minimax optimal.

3.1 Sample mean

We warm up with the most basic unbiased estimate, the sample mean. We sample $z^{(1)}, \dots, z^{(n)}$ independently with replacement from $\mathcal{Z}$. Then, we sample each human judgment $y^{(i)} = Y(z^{(i)})$ independently.[2] Define the estimator to be $\hat{\mu}_{\text{mean}} = \frac{1}{n}\sum_{i=1}^n y^{(i)}$. Note that $\hat{\mu}_{\text{mean}}$ is unbiased ($\mathbb{E}[\hat{\mu}_{\text{mean}}] = \mu$).

[2]Note that this independence assumption isn't quite true in practice since we do not control who annotates our data.

We can define $\sigma_f^2 \stackrel{\text{def}}{=} \text{Var}(f(z))$ as the variance of the human metric and $\sigma_a^2 \stackrel{\text{def}}{=} \mathbb{E}_z[\text{Var}(Y(z))]$ as the variance of human judgment averaged over $\mathcal{Z}$. By the law of total variance, the variance of our estimator is

$$\text{Var}(\hat{\mu}_{\text{mean}}) = \frac{1}{n}(\sigma_f^2 + \sigma_a^2). \qquad (2)$$

3.2 Control variates estimator

Now let us see how an automatic metric g can reduce variance. If there is no annotator variance ($\sigma_a^2 = 0$) so that $Y(z) = f(z)$, we should expect the variance of $f(z) - g(z)$ to be lower than the variance of $f(z)$, assuming g is correlated with f—see Figure 2 for an illustration.

The actual control variates estimator needs to handle noisy $Y(z)$ (i.e. $\sigma_a^2 > 0$) and guard against a $g(z)$ with low correlation. Let us standardize g to have zero mean and unit variance, because we have assumed it is free to evaluate. As before, let $z^{(1)}, \dots, z^{(n)}$ be independent samples from $\mathcal{Z}$ and draw $y^{(i)} = Y(z^{(i)})$ independently as well. We define the *control variates estimator* as

$$\hat{\mu}_{\text{cv}} = \frac{1}{n}\sum_{i=1}^{n} y^{(i)} - \alpha g(z^{(i)}), \qquad (3)$$

where

$$\alpha \stackrel{\text{def}}{=} \text{Cov}(f(z), g(z)). \qquad (4)$$

Intuitively, we have averaged over $y^{(i)}$ to handle the noise introduced by $Y(z)$, and scaled $g(z)$ to prevent an uncorrelated automatic metric from introducing too much noise.

An important quantity governing the quality of an automatic metric g is the correlation between $f(z)$ and $g(z)$ (recall that g has unit variance):

$$\rho \stackrel{\text{def}}{=} \frac{\alpha}{\sigma_f}. \qquad (5)$$

We can show that among all distributions with fixed σ_f^2, σ_a^2, and α (equivalently ρ), this estimator is minimax optimal, i.e. it has the least variance among all unbiased estimators:

Theorem 3.1. *Among all unbiased estimators that are functions of $y^{(i)}$ and $g(z^{(i)})$, and for all distributions with a given σ_f^2, σ_a^2, and α,*

$$\text{Var}(\hat{\mu}_{cv}) = \frac{1}{n}(\sigma_f^2(1-\rho^2) + \sigma_a^2), \qquad (6)$$

and no other estimator has a lower worst-case variance.

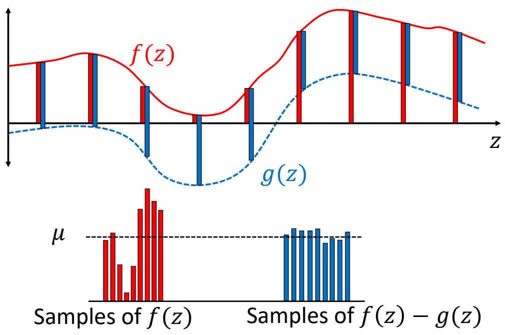

Figure 2: The samples from $f(z)$ have a higher variance than the samples from $f(z) - g(z)$ but the same mean. This is the key idea behind using control variates to reduce variance.

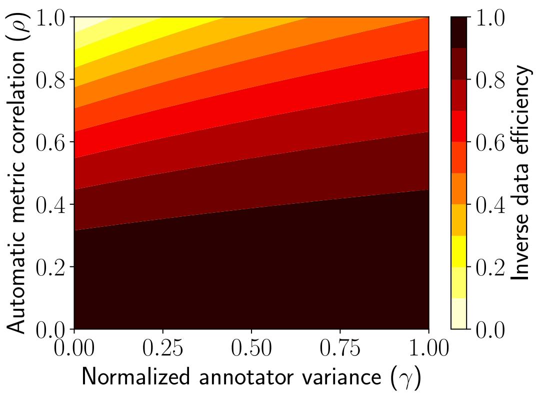

Figure 3: Inverse data efficiency for various values of γ and ρ. We need both low γ and high ρ to obtain significant gains.

Comparing the variances of the two estimators ((2) and (6)), we define the *data efficiency* as the ratio of the variances:

$$\mathrm{DE} \overset{\text{def}}{=} \frac{\mathrm{Var}(\hat{\mu}_{\text{mean}})}{\mathrm{Var}(\hat{\mu}_{\text{cv}})} = \frac{1+\gamma}{1-\rho^2+\gamma}, \qquad (7)$$

where $\gamma \overset{\text{def}}{=} \sigma_a^2/\sigma_f^2$ is the normalized annotator variance. Data efficiency is the key quantity in this paper: it is the multiplicative reduction in the number of samples required when using the control variates estimator $\hat{\mu}_{\text{cv}}$ versus the sample mean $\hat{\mu}_{\text{mean}}$. Figure 3 shows the inverse data efficiency contours as a function of the correlation ρ and γ.

When there is no correlation between human and automatic metrics ($\rho = 0$), the data efficiency is naturally 1 (no gain). In order to achieve a data efficiency of 2 (half the labeling cost), we need $|\rho| \geq \sqrt{2}/2 \approx 0.707$. Interestingly, even for an automatic metric with perfect correlation ($\rho = 1$), the data efficiency is still capped by $\frac{1+\gamma}{\gamma}$: unless $\gamma \to 0$ the data efficiency cannot increase unboundedly. Intuitively, even if we knew that $\rho = 1$, $f(z)$ would be undetermined up to a constant additive shift and just estimating the shift would incur a variance of $\frac{1}{n}\sigma_a^2$.

3.3 Using the control variates estimator

The control variates estimator can be easily integrated into an existing evaluation: we run human evaluation on a random sample of system outputs, automatic evaluation on all the system outputs, and plug in these results into Algorithm 1.

It is vital that we are able to evaluate the automatic metric on a significantly larger set of examples than those with human evaluations to reliably normalize $g(z)$: without these additional examples, it be can shown that the optimal minimax estimator for μ is simply the naive estimate $\hat{\mu}_{\text{mean}}$. Intuitively, this is because estimating the mean of $g(z)$ incurs an equally large variance as estimating μ. In other words, $g(z)$ is only useful if we have additional information about g beyond the samples $\{z^{(i)}\}$.

Algorithm 1 shows the estimator. In practice, we do not know $\alpha = \mathrm{Cov}(f(z), g(z))$, so we use a plug-in estimate $\hat{\alpha}$ in line 3 to compute the estimate $\widetilde{\mu}$ in line 4. We note that estimating α from data does introduce a $O(1/n)$ bias, but when compared to the standard deviation which decays as $\Theta(1/\sqrt{n})$, this bias quickly goes to 0.

Proposition 3.1. *The estimator $\widetilde{\mu}$ in Algorithm 1 has $O(1/n)$ bias.*

Algorithm 1 Control variates estimator

```
1: Input: $n$ human evaluations $y^{(i)}$ on system
   outputs $z^{(i)}$, normalized automatic metric $g$
2: $\bar{y} = \frac{1}{n}\sum_i y^{(i)}$
3: $\hat{\alpha} = \frac{1}{n}\sum_i (y^{(i)} - \bar{y}) g(z^{(i)})$
4: $\widetilde{\mu} = \frac{1}{n}\sum_i y^{(i)} - \hat{\alpha} g(z^{(i)})$
5: return $\widetilde{\mu}$
```

An additional question that arises when applying Algorithm 1 is figuring out how many samples n to use. Given a target variance, the number of samples can be estimated using (6) with conservative estimates of σ_f^2, σ_a^2 and ρ. Alternatively, our estimator can be combined with a dynamic stopping rule (Mnih et al., 2008) to stop data collection once we reach a target confidence interval.

Task	Eval.	σ_a^2	σ_f^2	$\gamma = \frac{\sigma_a^2}{\sigma_f^2}$
CDM	Fluency	0.32	0.26	1.23
CDM	Redund.	0.26	0.43	0.61
CDM	Overall	0.28	0.28	1.00
CDM	**Edit**	**0.07**	**0.18**	**0.36**
MS MARCO	AnyCorr.	0.14	0.15	0.95
MS MARCO	AvgCorr.	0.12	0.13	0.91

Table 2: A summary of the key statistics, human metric variance (σ_f^2) and annotator variance (σ_a^2) for different datasets, CNN/Daily Mail (CDM) and MS MARCO in our evaluation benchmark. We observe that the relative variance (γ) is fairly high for most evaluation prompts, upper bounding the data efficiency on these tasks. A notable exception is the `Edit` prompt wherein systems are compared on the number of post-edits required to improve their quality.

3.4 Discussion of assumptions

We will soon see that empirical instantiations of γ and ρ lead to rather underwhelming data efficiencies in practice. In light of our optimality result, does this mean there is no hope for gains? Let us probe our assumptions. We assumed that the human judgments are uncorrelated across different system outputs; it is possible that a more accurate model of human annotators (e.g. Passonneau and Carpenter (2014)) could offer improvements. Perhaps with additional information about $g(z)$ such as calibrated confidence estimates, we would be able to sample more adaptively. Of course the most direct routes to improvement involve increasing the correlation of g with human judgments and reducing annotator variance, which we will discuss more later.

4 Tasks and datasets

In order to compare different approaches to evaluating systems, we first collected human judgments for the output of several automatic summarization and open-response question answering systems using Amazon Mechanical Turk. Details of instructions provided and quality assurance steps taken are provided in Appendix A of the supplementary material. In this section, we'll briefly describe how we collected this data.

Evaluating language quality in automatic summarization. In automatic summarization, systems must generate a short (on average two or three sentence) summary of an article: for our study, we chose articles from the CNN/Daily Mail (CDM) dataset (Hermann et al., 2015; Nallapati et al., 2016) which come paired with reference summaries in the form of story highlights. We focus on the *language quality* of summaries and leave evaluating content selection to future work.

For each summary, we collected human judgments on a scale from 1–3 (Figure 4a) for fluency, (lack of) redundancy, and overall quality of the summary using guidelines from the DUC summarization challenge (Dang, 2006). As an alternate human metric, we also asked workers to post-edit the system's summary to improve its quality, similar to the post-editing step in MT evaluations (Snover et al., 2006). Obtaining judgments costs about \$0.15 per summary and this cost rises to about \$0.40 per summary for post-editing.

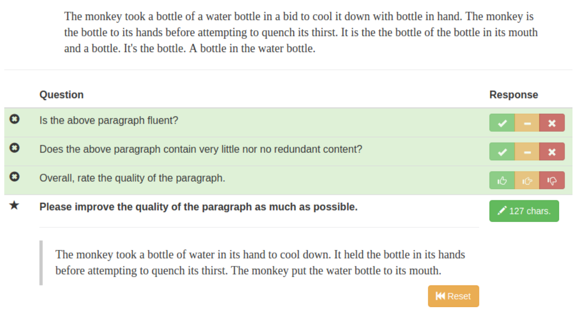
We collected judgments on the summaries generated by the `seq2seq` and `pointer` models of See et al. (2017), the `ml` and `ml+rl` models of Paulus et al. (2018), and the reference summaries.[3] Before presenting the summaries to human annotators, we performed some minimal post-processing: we true-cased and de-tokenized the output of `seq2seq` and `pointer` using Stanford CoreNLP (Manning et al., 2014) and replaced "unknown" tokens in each system with a special symbol (■).

Evaluating answer correctness. Next, we look at evaluating the correctness of system outputs in question answering using the MS MARCO question answering dataset (Nguyen et al., 2016). Here, each system is provided with a question and up to 10 paragraphs of context. The system generates open-response answers that do not need to be tied to a span in any paragraph.

We first ask annotators to judge if the output is even plausible for the question, and if yes, ask them identify if it is correct according to each context paragraph. We found that requiring annotators to highlight regions in the text that support their decision substantially improved the quality of the output without increasing costs. Annotations cost \$0.40 per system response.[4]

[3]All system output was obtained from the original authors through private communication.

[4]This cost could be significantly reduced if systems also

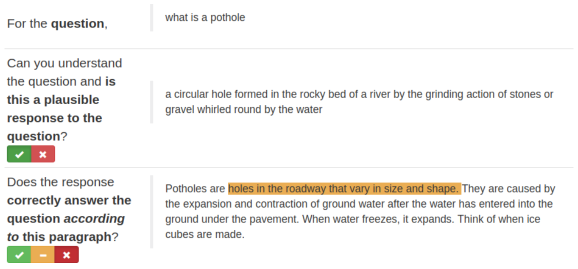


The monkey took a bottle of a water bottle in a bid to cool it down with bottle in hand. The monkey is the bottle to its hands before attempting to quench its thirst. It is the the bottle of the bottle in its mouth and a bottle. It's the bottle. A bottle in the water bottle.

	Question	Response
	Is the above paragraph fluent?	✓ – ✗
	Does the above paragraph contain very little nor no redundant content?	✓ – ✗
	Overall, rate the quality of the paragraph.	
★	**Please improve the quality of the paragraph as much as possible.**	127 chars.

The monkey took a bottle of water in its hand to cool down. It held the bottle in its hands before attempting to quench its thirst. The monkey put the water bottle to its mouth.

(a) Interface to evaluate language quality on CNN/Daily Mail



For the **question**,	what is a pothole
Can you understand the question and **is this a plausible response to the question**? ✓ ✗	a circular hole formed in the rocky bed of a river by the grinding action of stones or gravel whirled round by the water
Does the response **correctly answer the question *according to* this paragraph**? ✓ – ✗	Potholes are holes in the roadway that vary in size and shape. They are caused by the expansion and contraction of ground water after the water has entered into the ground under the pavement. When water freezes, it expands. Think of when ice cubes are made.

(b) Interface to judge answer correctness on MS MARCO

Figure 4: Screenshots of the annotation interfaces we used to measure (a) summary language quality on CNN/Daily Mail and (b) answer correctness on MS MARCO tasks.

While our goal is to evaluate the correctness of the provided answer, we found that there are often answers which may be correct or incorrect depending on the context. For example, the question "what is a pothole" is typically understood to refer to a hole in a roadway, but also refers to a geological feature (Figure 4b). This is reflected when annotators mark one context paragraph to support the given answer but mark another to contradict it. We evaluated systems based on both the average correctness (AvgCorrect) of their answers across all paragraphs as well as whether their answer is correct according to any paragraph (AnyCorrect).

We collected annotations on the systems generated by the `fastqa` and `fastqa_ext` from Weissenborn et al. (2017) and the `snet` and `snet.ens`(emble) models from Tan et al. (2018), along with reference answers. The answers generated by the systems were used without any post-processing. Surprisingly, we found that the correctness of the reference answers (according to the AnyCorrect metric) was only 73.5%, only 2% above that of the leading system (`snet.ens`). We manually inspected 30 reference answers which were annotated incorrectly and found that of those, about 95% were indeed incorrect. However, 62% are actually answerable from some paragraph, indicating that the real ceiling performance on this dataset is around 90% and that there is still room for improvement on this task.

5 Experimental results

We are now ready to evaluate the performance of our control variates estimator proposed in Section 3 using the datasets presented in Section 4.

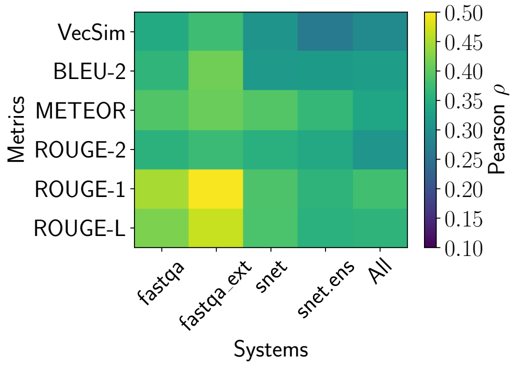
specify which passage they used to generate the answer.

Recall that our primary quantity of interest is *data efficiency*, the ratio of the number of human judgments required to estimate the overall human evaluation score for the control variates estimator versus the sample mean. We'll briefly review the automatic metrics used in our evaluation before analyzing the results.

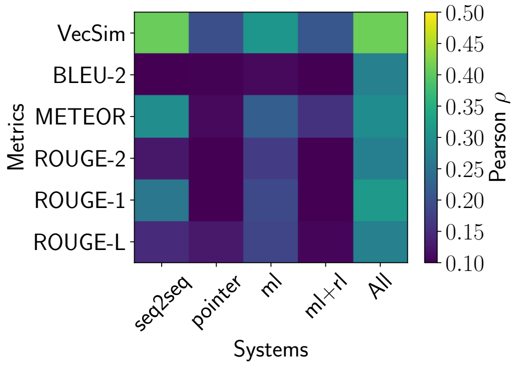
Automatic metrics. We consider the following frequently used automatic word-overlap based metrics in our work: **BLEU** (Papineni et al., 2002), **ROUGE** (Lin and Rey, 2004) and **METEOR** (Lavie and Denkowski, 2009). Following Novikova et al. (2017) and Liu et al. (2016b), we also compared a vector-based sentence-similarity using `sent2vec` (Pagliardini et al., 2017) to compare sentences (**VecSim**). Figure 5 shows how each of these metrics is correlated with human judgment for the systems being evaluated. Unsurprisingly, the correlation varies considerably across systems, with token-based metrics correlating more strongly for systems that are more extractive in nature (`fastqa` and `fastqa_ext`).

Results.[5] In Section 3 we proved that the control variates estimator is not only unbiased but also has the least variance among other unbiased estimators. Figure 6 plots the width of the 80% confidence interval, estimated using bootstrap, measured as a function of the number of samples collected for different tasks and prompts. As expected, the control variates estimator reduces the width of the confidence interval. We measure data efficiency by the averaging of the ratio of squared confidence intervals between the human baseline

[5]Extended results for other systems, metrics and prompts can be found at `https://bit.ly/price-of-debiasing/`.



(a) MS MARCO with the `AnyCorrect` prompt



(b) CNN/Daily Mail with the `Edit` prompt

Figure 5: Correlations of different automatic metrics on the MS MARCO and CNN/Daily Mail tasks. Certain systems are more correlated with certain automatic metrics than others, but overall the correlation is low to moderate for most systems and metrics.

and control variates estimates. We observe that the data efficiency depends on the task, prompt and system, ranging from about 1.08 (a 7% cost reduction) to 1.15 (a 13% cost reduction) using current automatic metrics.

As we showed in Section 3, further gains are fundamentally limited by the quality of the evaluation prompts and automatic metrics. Figures 6a and 6b show how improving the quality of the evaluation prompt from a Likert-scale prompt for quality (`Overall`) to using post-editing (`Edit`) noticeably decreases variance and hence allows better automatic metrics to increase data efficiency. Likewise, Figure 6c shows how using a better automatic metric (ROUGE-L instead of VecSim) also reduces variance.

Figure 6 also shows the conjectured confidence intervals if we were able to eliminate noise in human judgments (noiseless humans) or have a automatic metric that correlated perfectly with average human judgment (perfect metric). In particular, we use the mean of all (2–3) humans on each z for the perfect $g(z)$ and use the mean of all humans on each z for the "noiseless" $Y(z)$.

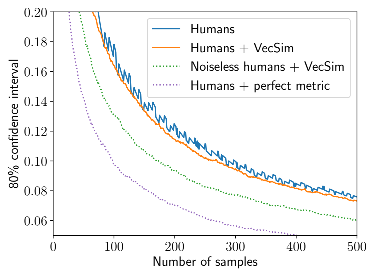
In both cases, we are able to significantly increase data efficiency (i.e. decrease estimator variance). With zero annotator variance and using existing automatic metrics, the data efficiency ranges from 1.42 to 1.69. With automatic metrics with perfect correlation and current variance of human judgments, it ranges from 2.38 to 7.25. Thus, we conclude that it is important not only to improve our automatic metrics but also the evaluation prompts we use during human evaluation.

6 Related work

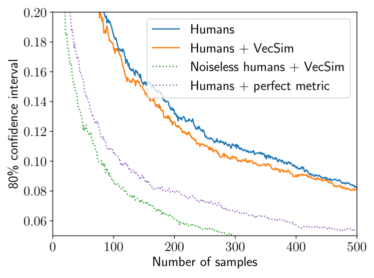
In this work, we focus on using existing automatic metrics to decrease the cost of human evaluations. There has been much work on improving the quality of automatic metrics. In particular, there is interest in learning models (Lowe et al., 2017a; Dusek et al., 2017) that are able to optimize for improved correlations with human judgment. However, in our experience, we have found that these learned automatic metrics have trouble generalizing to different systems. The framework we provide allows us to safely incorporate such models into evaluation, exploiting them when their correlation is high but also not introducing bias when it is low.

Our key technical tool is control variates, a standard statistical technique used to reduce the variance of Monte Carlo estimates (Ripley, 2009). The technique has also been used in machine learning and reinforcement learning to lower variance estimates of gradients (Greensmith et al., 2004; Paisley et al., 2012; Ranganath et al., 2014). To the best of our knowledge, we are the first to apply this technique in the context of language evaluation.

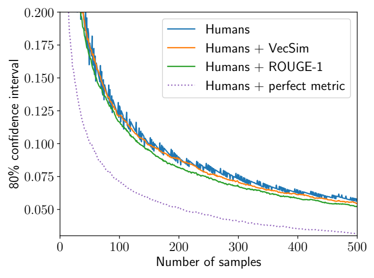
Our work also highlights the importance of human evaluation. Chaganty et al. (2017) identified a similar problem of systematic bias in evaluation metrics in the setting of knowledge base population and also propose statistical estimators that relies on human evaluation to correct bias. Unfortunately, their technique relies on having a structured output (relation triples) that are shared between



(a) `seq2seq` on CNN/Daily Mail using the `Overall`



(b) `seq2seq` on CNN/Daily Mail using `Edit`



(c) `fastqa_ext` on MS MARCO using `AnyCorrect`

Figure 6: 80% bootstrap confidence interval length as a function of the number of human judgments used when evaluating the indicated systems on their respective datasets and prompts. (a) We see a modest reduction in variance (and hence cost) relative to human evaluation by using the VecSim automatic metric with the proposed control variates estimator to estimate `Overall` scores on the CNN/Daily Mail task; the data efficiency (DE) is 1.06. (b) By improving the evaluation prompt to use `Edits` instead, it is possible to further reduce variance relative to humans (DE is 1.15). (c) Another way to reduce variance relative to humans is to improve the automatic metric evaluation; here using ROUGE-1 instead of VecSim improves the DE from 1.03 to 1.16.

systems and does not apply to evaluating natural language generation. In a similar vein, Chang et al. (2017) dynamically collect human feedback to learn better dialog policies.

7 Discussion

Prior work has shown that existing automatic metrics have poor instance-level correlation with mean human judgment and that they score many good quality responses poorly. As a result, the evaluation is systematically biased against genuine system improvements that would lead to higher human evaluation scores but not improve automatic metrics. In this paper, we have explored using an automatic metric to decrease the cost of human evaluation without introducing bias. In practice, we find that with current automatic metrics and evaluation prompts data efficiencies are only 1.08–1.15 (7–13% cost reduction). Our theory shows that further improvements are only possible by improving the correlation of the automatic metric and reducing the annotator variance of the evaluation prompt. As an example of how evaluation prompts could be improved, we found that using post-edits of summarizes decreased normalized annotator variance by a factor of three relative to using a Likert scale survey. It should be noted that changing the evaluation prompt also changes the underlying ground truth $f(z)$: it is up to us to find a prompt that still captures the essence of what we want to measure.

Without making stronger assumptions, the control variates estimator we proposed outlines the limitations of unbiased estimation. Where do we go from here? Certainly, we can try to improve the automatic metric (which is potentially as difficult as solving the task) and brainstorming alternative ways of soliciting evaluation (which has been less explored). Alternatively, we could give up on measuring absolute scores, and seek instead to find techniques stably rank methods and thus improve them. As the NLP community tackles increasingly difficult tasks, human evaluation will only become more important. We hope our work provides some clarity on to how to make it more cost effective.

Reproducibility

All code, data, and experiments for this paper are available on the CodaLab platform at `https://bit.ly/price-of-debiasing`.

Acknowledgments

We are extremely grateful to the authors of the systems we evaluated for sharing their systems' output with us. We also would like to thank Urvashi Khandelwal and Peng Qi for feedback on an earlier draft of the paper, the crowdworkers on Amazon Mechanical Turk and TurkNation for their work and feedback during the data collection process, and the anonymous reviewers for their constructive feedback.

Abstract

Sentence scoring and sentence selection are two main steps in extractive document summarization systems. However, previous works treat them as two separated subtasks. In this paper, we present a novel end-to-end neural network framework for extractive document summarization by jointly learning to score and select sentences. It first reads the document sentences with a hierarchical encoder to obtain the representation of sentences. Then it builds the output summary by extracting sentences one by one. Different from previous methods, our approach integrates the selection strategy into the scoring model, which directly predicts the relative importance given previously selected sentences. Experiments on the CNN/Daily Mail dataset show that the proposed framework significantly outperforms the state-of-the-art extractive summarization models.

1 Introduction

Traditional approaches to automatic text summarization focus on identifying important content, usually at sentence level (Nenkova and McKeown, 2011). With the identified important sentences, a summarization system can extract them to form an output summary. In recent years, *extractive methods* for summarization have proven effective in many systems (Carbonell and Goldstein, 1998; Mihalcea and Tarau, 2004; McDonald, 2007; Cao et al., 2015a). In previous works that use extractive methods, text summarization is decomposed into two subtasks, i.e., sentence scoring and sentence selection.

Sentence scoring aims to assign an importance score to each sentence, and has been broadly studied in many previous works. Feature-based methods are popular and have proven effective, such as word probability, TF*IDF weights, sentence position and sentence length features (Luhn, 1958; Hovy and Lin, 1998; Ren et al., 2017). Graph-based methods such as TextRank (Mihalcea and Tarau, 2004) and LexRank (Erkan and Radev, 2004) measure sentence importance using weighted-graphs. In recent years, neural network has also been applied to sentence modeling and scoring (Cao et al., 2015a; Ren et al., 2017).

For the second step, *sentence selection* adopts a particular strategy to choose content sentence by sentence. Maximal Marginal Relevance (Carbonell and Goldstein, 1998) based methods select the sentence that has the maximal score and is minimally redundant with sentences already included in the summary. Integer Linear Programming based methods (McDonald, 2007) treat sentence selection as an optimization problem under some constraints such as summary length. Submodular functions (Lin and Bilmes, 2011) have also been applied to solving the optimization problem of finding the optimal subset of sentences in a document. Ren et al. (2016) train two neural networks with handcrafted features. One is used to rank sentences, and the other one is used to model redundancy during sentence selection.

In this paper, we present a neural extractive document summarization (NeuSum) framework which jointly learns to score and select sentences. Different from previous methods that treat sentence scoring and sentence selection as two tasks, our method integrates the two steps into one end-to-end trainable model. Specifically, NeuSum is a neural network model without any handcrafted features that learns to identify the relative importance of sentences. The relative importance is

[*]Contribution during internship at Microsoft Research.

measured as the gain over previously selected sentences. Therefore, each time the proposed model selects one sentence, it scores the sentences considering both sentence saliency and previously selected sentences. Through the joint learning process, the model learns to predict the relative gain given the sentence extraction state and the partial output summary.

The proposed model consists of two parts, i.e., the document encoder and the sentence extractor. The document encoder has a hierarchical architecture, which suits the compositionality of documents. The sentence extractor is built with recurrent neural networks (RNN), which provides two main functionalities. On one hand, the RNN is used to remember the partial output summary by feeding the selected sentence into it. On the other hand, it is used to provide a sentence extraction state that can be used to score sentences with their representations. At each step during extraction, the sentence extractor reads the representation of the last extracted sentence. It then produces a new sentence extraction state and uses it to score the relative importance of the rest sentences.

We conduct experiments on the *CNN/Daily Mail* dataset. The experimental results demonstrate that the proposed NEUSUM by jointly scoring and selecting sentences achieves significant improvements over separated methods. Our contributions are as follows:

- We propose a joint sentence scoring and selection model for extractive document summarization.
- The proposed model can be end-to-end trained without handcrafted features.
- The proposed model significantly outperforms state-of-the-art methods and achieves the best result on *CNN/Daily Mail* dataset.

2 Related Work

Extractive document summarization has been extensively studied for years. As an effective approach, extractive methods are popular and dominate the summarization research. Traditional extractive summarization systems use two key techniques to form the summary, sentence scoring and sentence selection. Sentence scoring is critical since it is used to measure the saliency of a sentence. Sentence selection is based on the scores of sentences to determine which sentence should be extracted, which is usually done heuristically.

Many techniques have been proposed to model and score sentences. Unsupervised methods do not require model training or data annotation. In these methods, many surface features are useful, such as term frequency (Luhn, 1958), TF*IDF weights (Erkan and Radev, 2004), sentence length (Cao et al., 2015a) and sentence positions (Ren et al., 2017). These features can be used alone or combined with weights.

Graph-based methods (Erkan and Radev, 2004; Mihalcea and Tarau, 2004; Wan and Yang, 2006) are also applied broadly to ranking sentences. In these methods, the input document is represented as a connected graph. The vertices represent the sentences, and the edges between vertices have attached weights that show the similarity of the two sentences. The score of a sentence is the importance of its corresponding vertex, which can be computed using graph algorithms.

Machine learning techniques are also widely used for better sentence modeling and importance estimation. Kupiec et al. (1995) use a Naive Bayes classifier to learn feature combinations. Conroy and O'leary (2001) further use a Hidden Markov Model in document summarization. Gillick and Favre (2009) find that using bigram features consistently yields better performance than unigrams or trigrams for ROUGE (Lin, 2004) measures.

Carbonell and Goldstein (1998) proposed the Maximal Marginal Relevance (MMR) method as a heuristic in sentence selection. Systems using MMR select the sentence which has the maximal score and is minimally redundant with previous selected sentences. McDonald (2007) treats sentence selection as an optimization problem under some constraints such as summary length. Therefore, he uses Integer Linear Programming (ILP) to solve this optimization problem. Sentence selection can also be seen as finding the optimal subset of sentences in a document. Lin and Bilmes (2011) propose using submodular functions to find the subset.

Recently, deep neural networks based approaches have become popular for extractive document summarization. Cao et al. (2015b) develop a novel summary system called PriorSum, which applies enhanced convolutional neural networks to capture the summary prior features derived from length-variable phrases. Ren et al. (2017) use a two-level attention mechanism to measure the contextual relations of sentences. Cheng and Lapata (2016) propose treating document summarization as a sequence labeling task. They first encode the sentences in the document and then classify each sentence into two classes, i.e., extraction or not. Nallapati et al. (2017) propose a system called SummaRuNNer with more features, which also treat extractive document summarization as a sequence labeling task. The two works are both in the separated paradigm, as they first assign a probability of being extracted to each sentence, and then select sentences according to the probability until reaching the length limit. Ren et al. (2016) train two neural networks with handcrafted features. One is used to rank the sentences to select the first sentence, and the other one is used to model the redundancy during sentence selection. However, their model of measuring the redundancy only considers the redundancy between the sentence that has the maximal score, which lacks the modeling of all the selection history.

3 Problem Formulation

Extractive document summarization aims to extract informative sentences to represent the important meanings of a document. Given a document $\mathcal{D} = (S_1, S_2, \ldots, S_L)$ containing L sentences, an extractive summarization system should select a subset of $\mathcal{D}$ to form the output summary $\mathcal{S} = \{\hat{S}_i | \hat{S}_i \in \mathcal{D}\}$. During the training phase, the reference summary $\mathcal{S}^*$ and the score of an output summary $\mathcal{S}$ under a given evaluation function $r(\mathcal{S}|\mathcal{S}^*)$ are available. The goal of training is to learn a scoring function $f(\mathcal{S})$ which can be used to find the best summary during testing:

$$\begin{aligned} \arg\max_{\mathcal{S}} \quad & f(\mathcal{S}) \\ \text{s.t.} \quad & \mathcal{S} = \{\hat{S}_i | \hat{S}_i \in \mathcal{D}\} \\ & |\mathcal{S}| \leq l. \end{aligned}$$

where l is length limit of the output summary. In this paper, l is the sentence number limit.

Previous state-of-the-art summarization systems search the best solution using the learned scoring function $f(\cdot)$ with two methods, MMR and ILP. In this paper, we adopt the MMR method. Since MMR tries to maximize the relative gain given previous extracted sentences, we let the model to learn to score this gain. Previous works adopt ROUGE recall as the evaluation $r(\cdot)$ considering the DUC tasks have byte length limit for summaries. In this work, we adopt the *CNN/Daily Mail* dataset to train the neural network model, which does not have this length limit. To prevent the tendency of choosing longer sentences, we use ROUGE F1 as the evaluation function $r(\cdot)$, and set the length limit l as a fixed number of sentences.

Therefore, the proposed model is trained to learn a scoring function $g(\cdot)$ of the ROUGE F1 gain, specifically:

$$g(S_t | \mathbb{S}_{t-1}) = r\left(\mathbb{S}_{t-1} \cup \{S_t\}\right) - r(\mathbb{S}_{t-1}) \quad (1)$$

where $\mathbb{S}_{t-1}$ is the set of previously selected sentences, and we omit the condition $\mathcal{S}^*$ of $r(\cdot)$ for simplicity. At each time t, the summarization system chooses the sentence with maximal ROUGE F1 gain until reaching the sentence number limit.

4 Neural Document Summarization

Figure 1 gives the overview of NEUSUM, which consists of a hierarchical document encoder, and a sentence extractor. Considering the intrinsic hierarchy nature of documents, that words form a sentence and sentences form a document, we employ a hierarchical document encoder to reflect this hierarchy structure. The sentence extractor scores the encoded sentences and extracts one of them at each step until reaching the output sentence number limit. In this section, we will first introduce the hierarchical document encoder, and then describe how the model produces summary by joint sentence scoring and selection.

4.1 Document Encoding

We employ a hierarchical document encoder to represent the sentences in the input document. We encode the document in two levels, i.e., sentence level encoding and document level encoding. Given a document $\mathcal{D} = (S_1, S_2, \ldots, S_L)$ containing L sentences. The sentence level encoder reads the j-th input sentence $S_j = (x_1^{(j)}, x_2^{(j)}, \ldots, x_{n_j}^{(j)})$ and constructs the basic sentence representation $\widetilde{s}_j$. Here we employ a bidirectional GRU (BiGRU) (Cho et al., 2014) as the recurrent unit, where GRU is defined as:

$$z_i = \sigma(\mathbf{W}_z[x_i, h_{i-1}]) \quad (2)$$

$$r_i = \sigma(\mathbf{W}_r[x_i, h_{i-1}]) \quad (3)$$

$$\widetilde{h}_i = \tanh(\mathbf{W}_h[x_i, r_i \odot h_{i-1}]) \quad (4)$$

$$h_i = (1 - z_i) \odot h_{i-1} + z_i \odot \widetilde{h}_i \quad (5)$$

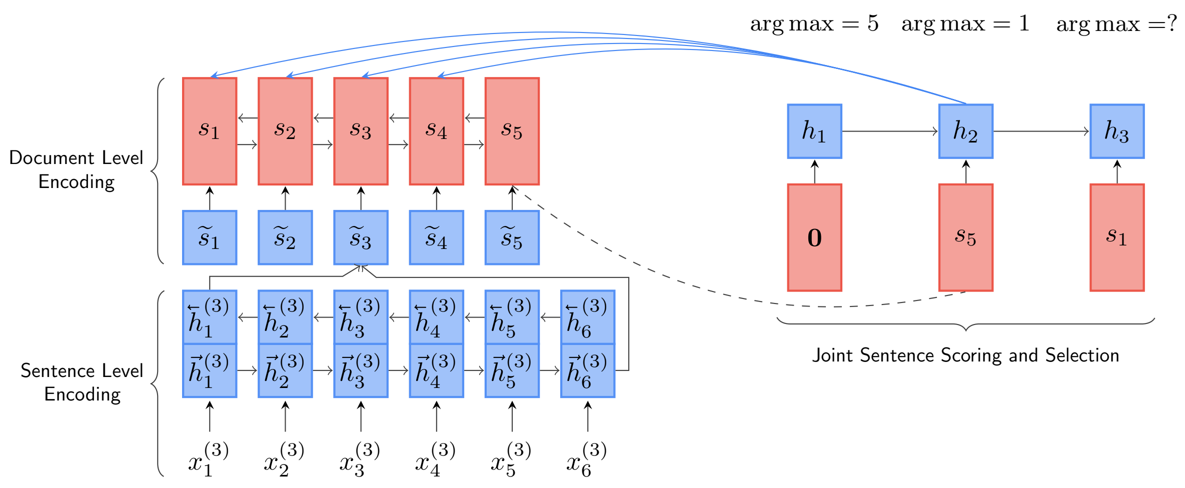

Figure 1: Overview of the NEUSUM model. The model extracts S_5 and S_1 at the first two steps. At the first step, we feed the model a zero vector $\mathbf{0}$ to represent empty partial output summary. At the second and third steps, the representations of previously selected sentences S_5 and S_1, i.e., s_5 and s_1, are fed into the extractor RNN. At the second step, the model only scores the first 4 sentences since the 5th one is already included in the partial output summary.

where $\mathbf{W}_z$, $\mathbf{W}_r$ and $\mathbf{W}_h$ are weight matrices.

The BiGRU consists of a forward GRU and a backward GRU. The forward GRU reads the word embeddings in sentence S_j from left to right and gets a sequence of hidden states, $(\vec{h}_1^{(j)}, \vec{h}_2^{(j)}, \ldots, \vec{h}_{n_j}^{(j)})$. The backward GRU reads the input sentence embeddings reversely, from right to left, and results in another sequence of hidden states, $(\overleftarrow{h}_1^{(j)}, \overleftarrow{h}_2^{(j)}, \ldots, \overleftarrow{h}_{n_j}^{(j)})$:

$$\vec{h}_i^{(j)} = \text{GRU}(x_i^{(j)}, \vec{h}_{i-1}^{(j)}) \tag{6}$$

$$\overleftarrow{h}_i^{(j)} = \text{GRU}(x_i^{(j)}, \overleftarrow{h}_{i+1}^{(j)}) \tag{7}$$

where the initial states of the BiGRU are set to zero vectors, i.e., $\vec{h}_1^{(j)} = 0$ and $\overleftarrow{h}_{n_j}^{(j)} = 0$.

After reading the words of the sentence S_j, we construct its sentence level representation $\widetilde{s}_j$ by concatenating the last forward and backward GRU hidden vectors:

$$\widetilde{s}_j = \begin{bmatrix} \overleftarrow{h}_1^{(j)} \\ \vec{h}_{n_j}^{(j)} \end{bmatrix} \tag{8}$$

We use another BiGRU as the document level encoder to read the sentences. With the sentence level encoded vectors $(\widetilde{s}_1, \widetilde{s}_2, \ldots, \widetilde{s}_L)$ as inputs, the document level encoder does forward and backward GRU encoding and produces two list of hidden vectors: $(\vec{s}_1, \vec{s}_2, \ldots, \vec{s}_L)$ and $(\overleftarrow{s}_1, \overleftarrow{s}_2, \ldots, \overleftarrow{s}_L)$. The document level representation s_i of sentence S_i is the concatenation of the forward and backward hidden vectors:

$$s_i = \begin{bmatrix} \vec{s}_i \\ \overleftarrow{s}_i \end{bmatrix} \tag{9}$$

We then get the final sentence vectors in the given document: $D = (s_1, s_2, \ldots, s_L)$. We use sentence S_i and its representative vector s_i interchangeably in this paper.

4.2 Joint Sentence Scoring and Selection

Since the separated sentence scoring and selection cannot utilize the information of each other, the goal of our model is to make them benefit each other. We couple these two steps together so that: a) sentence scoring can be aware of previously selected sentences; b) sentence selection can be simplified since the scoring function is learned to be the ROUGE score gain as described in section 3.

Given the last extracted sentence $\hat{S}_{t-1}$, the sentence extractor decides the next sentence $\hat{S}_t$ by scoring the remaining document sentences. To score the document sentences considering both their importance and partial output summary, the model should have two key abilities: 1) remembering the information of previous selected sentences; 2) scoring the remaining document sentences based on both the previously selected sentences and the importance of remaining sentences. Therefore, we employ another GRU as the recurrent unit to remember the partial output summary, and use a Multi-Layer Perceptron (MLP) to score the document sentences. Specifically, the GRU takes the document level representation s_{t-1} of the last extracted sentence $\hat{S}_{t-1}$ as input to produce its current hidden state h_t. The sentence scorer, which is a two-layer MLP, takes two input vectors, namely the current hidden state h_t and the sentence representation vector s_i, to calculate the score $\delta(S_i)$ of sentence S_i.

$$h_t = \mathrm{GRU}(s_{t-1}, h_{t-1}) \tag{10}$$

$$\delta(S_i) = \mathbf{W}_s \tanh\left(\mathbf{W}_q h_t + \mathbf{W}_d s_i\right) \tag{11}$$

where $\mathbf{W}_s$, $\mathbf{W}_q$ and $\mathbf{W}_d$ are learnable parameters, and we omit the bias parameters for simplicity.

When extracting the first sentence, we initialize the GRU hidden state h_0 with a linear layer with tanh activation function:

$$h_0 = \tanh\left(\mathbf{W}_m \overleftarrow{s}_1 + b_m\right) \tag{12}$$

$$S_0 = \varnothing \tag{13}$$

$$s_0 = \mathbf{0} \tag{14}$$

where$\mathbf{W}_m$ and b_m are learnable parameters, and $\overleftarrow{s}_1$ is the last backward state of the document level encoder BiGRU. Since we do not have any sentences extracted yet, we use a zero vector to represent the previous extracted sentence, i.e., $s_0 = \mathbf{0}$.

With the scores of all sentences at time t, we choose the sentence with maximal gain score:

$$\hat{S}_t = \underset{S_i \in \mathcal{D}}{\arg\max}\, \delta(S_i) \tag{15}$$

4.3 Objective Function

Inspired by Inan et al. (2017), we optimize the Kullback-Leibler (KL) divergence of the model prediction P and the labeled training data distribution Q. We normalize the predicted sentence score $\delta(S_i)$ with softmax function to get the model prediction distribution P:

$$P(\hat{S}_t = S_i) = \frac{\exp\left(\delta(S_i)\right)}{\sum_{k=1}^{L} \exp\left(\delta(S_k)\right)} \tag{16}$$

During training, the model is expected to learn the relative ROUGE F1 gain at time step t with previously selected sentences $\mathbb{S}_{t-1}$. Considering that the F1 gain value might be negative in the labeled data, we follow previous works (Ren et al., 2017) to use Min-Max Normalization to rescale the gain value to $[0, 1]$:

$$g(S_i) = r(\mathbb{S}_{t-1} \cup \{S_i\}) - r(\mathbb{S}_{t-1}) \tag{17}$$

$$\widetilde{g}(S_i) = \frac{g(S_i) - \min\left(g(S)\right)}{\max\left(g(S)\right) - \min\left(g(S)\right)} \tag{18}$$

We then apply a softmax operation with temperature τ (Hinton et al., 2015) [1] to produce the labeled data distribution Q as the training target. We apply the temperature τ as a smoothing factor to produce a smoothed label distribution Q:

$$Q(S_i) = \frac{\exp\left(\tau \widetilde{g}(S_i)\right)}{\sum_{k=1}^{L} \exp\left(\tau \widetilde{g}(S_k)\right)} \tag{19}$$

Therefore, we minimize the *KL* loss function J:

$$J = D_{KL}(P \parallel Q) \tag{20}$$

5 Experiments

5.1 Dataset

A large scale dataset is essential for training neural network-based summarization models. We use the *CNN/Daily Mail* dataset (Hermann et al., 2015; Nallapati et al., 2016) as the training set in our experiments. The *CNN/Daily Mail* news contain articles and their corresponding highlights. The highlights are created by human editors and are abstractive summaries. Therefore, the highlights are not ready for training extractive systems due to the lack of supervisions.

We create an extractive summarization training set based on *CNN/Daily Mail* corpus. To determine the sentences to be extracted, we design a rule-based system to label the sentences in a given document similar to Nallapati et al. (2017). Specifically, we construct training data by maximizing the ROUGE-2 F1 score. Since it is computationally expensive to find the global optimal combination of sentences, we employ a greedy approach. Given a document with n sentences, we enumerate the candidates from 1-combination $\binom{n}{1}$ to n-combination $\binom{n}{n}$. We stop searching if the highest ROUGE-2 F1 score in $\binom{n}{k}$ is less than the best one in $\binom{n}{k-1}$. Table 1 shows the data statistics of the *CNN/Daily Mail* dataset.

We conduct data preprocessing using the same method[2] in See et al. (2017), including sentence splitting and word tokenization. Both Nallapati et al. (2016, 2017) use the *anonymized* version of the data, where the named entities are replaced by identifiers such as `entity4`. Following See et al. (2017), we use the *non-anonymized* version so we can directly operate on the original text.

[1]We set $\tau = 20$ empirically according to the model performance on the development set.

Table 1: Data statistics of *CNN/Daily Mail* dataset.

5.2 Implementation Details

Model Parameters The vocabulary is collected from the *CNN/Daily Mail* training data. We lower-case the text and there are 732,304 unique word types. We use the top 100,000 words as the model vocabulary since they can cover 98.23% of the training data. The size of word embedding, sentence level encoder GRU, document level encoder GRU are set to 50, 256, and 256 respectively. We set the sentence extractor GRU hidden size to 256.

Model Training We initialize the model parameters randomly using a Gaussian distribution with Xavier scheme (Glorot and Bengio, 2010). The word embedding matrix is initialized using pre-trained 50-dimension GloVe vectors (Pennington et al., 2014)[3]. We found that larger size GloVe does not lead to improvement. Therefore, we use 50-dim word embeddings for fast training. The pre-trained GloVe vectors contain 400,000 words and cover 90.39% of our model vocabulary. We initialize the rest of the word embeddings randomly using a Gaussian distribution with Xavier scheme. The word embedding matrix is not updated during training. We use Adam (Kingma and Ba, 2015) as our optimizing algorithm. For the hyperparameters of Adam optimizer, we set the learning rate $\alpha = 0.001$, two momentum parameters $\beta_1 = 0.9$ and $\beta_2 = 0.999$ respectively, and $\epsilon = 10^{-8}$. We also apply gradient clipping (Pascanu et al., 2013) with range $[-5, 5]$ during training. We use dropout (Srivastava et al., 2014) as regularization with probability $p = 0.3$ after the sentence level encoder and $p = 0.2$ after the document level encoder. We truncate each article to 80 sentences and each sentence to 100 words during both training and testing. The model is implemented with PyTorch (Paszke et al., 2017). We release the source code and related resources at `https://res.qyzhou.me`.

[3]`https://nlp.stanford.edu/projects/glove/`

Model Testing At test time, considering that LEAD3 is a commonly used and strong extractive baseline, we make NEUSUM and the baselines extract 3 sentences to make them all comparable.

5.3 Baseline

We compare NEUSUM model with the following state-of-the-art baselines:

LEAD3 The commonly used baseline by selecting the first three sentences as the summary.

TEXTRANK An unsupervised algorithm based on weighted-graphs proposed by Mihalcea and Tarau (2004). We use the implementation in Gensim (Řehůřek and Sojka, 2010).

CRSUM Ren et al. (2017) propose an extractive summarization system which considers the contextual information of a sentence. We train this baseline model with the same training data as our approach.

NN-SE Cheng and Lapata (2016) propose an extractive system which models document summarization as a sequence labeling task. We train this baseline model with the same training data as our approach.

SUMMARUNNER Nallapati et al. (2017) propose to add some interpretable features such as sentence absolute and relative positions.

PGN Pointer-Generator Network (PGN). A state-of-the-art abstractive document summarization system proposed by See et al. (2017), which incorporates copying and coverage mechanisms.

5.4 Evaluation Metric

We employ ROUGE (Lin, 2004) as our evaluation metric. ROUGE measures the quality of summary by computing overlapping lexical units, such as unigram, bigram, trigram, and longest common subsequence (LCS). It has become the standard evaluation metric for DUC shared tasks and popular for summarization evaluation. Following previous work, we use ROUGE-1 (unigram), ROUGE-2 (bigram) and ROUGE-L (LCS) as the evaluation metrics in the reported experimental results.

5.5 Results

We use the official ROUGE script[4] (version 1.5.5) to evaluate the summarization output. Table 2 summarizes the results on *CNN/Daily Mail* data set using full length ROUGE-F1[5] evaluation. It includes two unsupervised baselines, LEAD3 and TEXTRANK. The table also includes three state-of-the-art neural network based extractive models, i.e., CRSUM, NN-SE and SUMMARUNNER. In addition, we report the state-of-the-art abstractive PGN model. The result of SUMMARUNNER is on the *anonymized* dataset and not strictly comparable to our results on the *non-anonymized* version dataset. Therefore, we also include the result of LEAD3 on the *anonymized* dataset as a reference.

Models	ROUGE-1	ROUGE-2	ROUGE-L
LEAD3	40.24^{-}	17.70^{-}	36.45^{-}
TEXTRANK	40.20^{-}	17.56^{-}	36.44^{-}
CRSUM	40.52^{-}	18.08^{-}	36.81^{-}
NN-SE	41.13^{-}	18.59^{-}	37.40^{-}
PGN‡	39.53^{-}	17.28^{-}	36.38^{-}
LEAD3‡ *	39.2	15.7	35.5
SUMMARUNNER‡ *	39.6	16.2	35.3
NEUSUM	**41.59**	**19.01**	**37.98**

Table 2: Full length ROUGE F1 evaluation (%) on *CNN/Daily Mail* test set. Results with ‡ mark are taken from the corresponding papers. Those marked with * were trained and evaluated on the anonymized dataset, and so are not strictly comparable to our results on the original text. All our ROUGE scores have a 95% confidence interval of at most ± 0.22 as reported by the official ROUGE script. The improvement is statistically significant with respect to the results with superscript $^{-}$ mark.

NEUSUM achieves 19.01 ROUGE-2 F1 score on the *CNN/Daily Mail* dataset. Compared to the unsupervised baseline methods, NEUSUM performs better by a large margin. In terms of ROUGE-2 F1, NEUSUM outperforms the strong baseline LEAD3 by 1.31 points. NEUSUM also outperforms the neural network based models. Compared to the state-of-the-art extractive model NN-SE (Cheng and Lapata, 2016), NEUSUM performs significantly better in terms of ROUGE-1, ROUGE-2 and ROUGE-L F1 scores. Shallow features, such as sentence position, have proven effective in document summarization (Ren et al., 2017; Nallapati et al., 2017). Without any hand-crafted features, NEUSUM performs better than the CRSUM and SUMMARUNNER baseline models with features. As given by the 95% confidence interval in the official ROUGE script, our model achieves statistically significant improvements over all the baseline models. To the best of our knowledge, the proposed NEUSUM model achieves the best results on the *CNN/Daily Mail* dataset.

Models	Info	Rdnd	Overall
NN-SE	1.36	1.29	1.39
NEUSUM	**1.33**	**1.21**	**1.34**

Table 3: Rankings of NEUSUM and NN-SE in terms of informativeness (Info), redundancy (Rdnd) and overall quality by human participants (lower is better).

We also provide human evaluation results on a sample of test set. We random sample 50 documents and ask three volunteers to evaluate the output of NEUSUM and the NN-SE baseline models. They are asked to rank the output summaries from best to worst (with ties allowed) regarding informativeness, redundancy and overall quality. Table 3 shows the human evaluation results. NEUSUM performs better than the NN-SE baseline on all three aspects, especially in redundancy. This indicates that by jointly scoring and selecting sentences, NEUSUM can produce summary with less content overlap since it re-estimates the saliency of remaining sentences considering both their contents and previously selected sentences.

6 Discussion

6.1 Precision at Step-t

We analyze the accuracy of sentence selection at each step. Since we extract 3 sentences at test time, we show how NEUSUM performs when extracting each sentence. Given a document D in test set $\mathfrak{T}$, NEUSUM predicted summary $\mathcal{S}$, its reference summary $\mathcal{S}^*$, and the extractive oracle summary $\mathcal{O}$ with respect to D and $\mathcal{S}^*$ (we use the method described in section 5.1 to construct $\mathcal{O}$), we define the precision at step t as $p(@t)$:

$$p(@t) = \frac{1}{|\mathfrak{T}|} \sum_{D \in \mathfrak{T}} \mathbf{1}_{\mathcal{O}}(\mathcal{S}[t]) \qquad (21)$$

[4] http://www.berouge.com/

[5] The ROUGE evaluation option is, -m -n 2

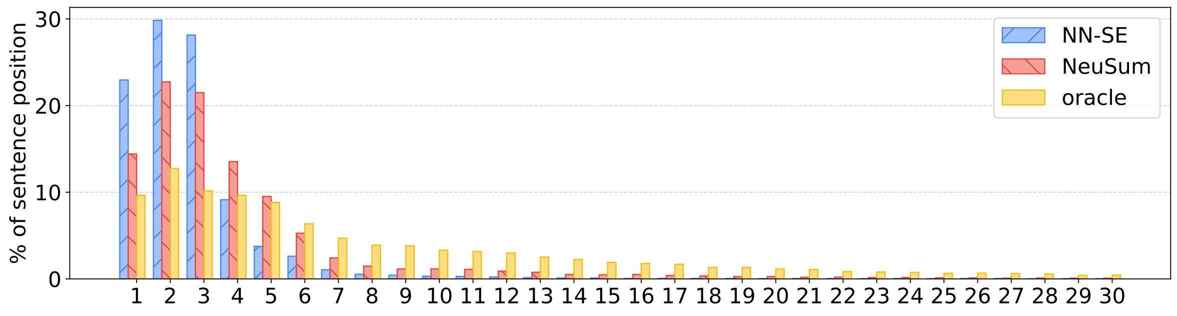

Figure 2: Position distribution of selected sentences of the NN-SE baseline, our NEUSUM model and oracle on the test set. We only draw the first 30 sentences since the average document length is 27.05.

where $\mathcal{S}[t]$ is the sentence extracted at step t, and $\mathbf{1}_{\mathcal{O}}$ is the indicator function defined as:

$$\mathbf{1}_{\mathcal{O}}(x) = \begin{cases} 1 & \text{if } x \in \mathcal{O} \\ 0 & \text{if } x \notin \mathcal{O} \end{cases} \tag{22}$$

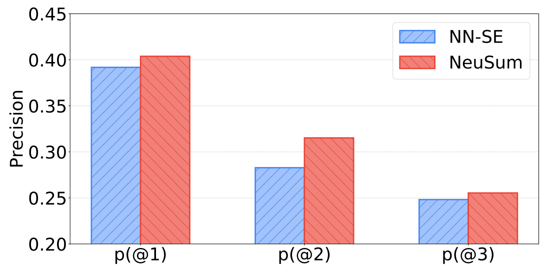

Figure 3: Precision of extracted sentence at step t of the NN-SE baseline and the NEUSUM model.

Figure 3 shows the precision at step t of NN-SE baseline and our NEUSUM. It can be observed that NEUSUM achieves better precision than the NN-SE baseline at each step. For the first sentence, both NEUSUM and NN-SE achieves good performance. The NN-SE baseline has 39.18% precision at the first step, and NEUSUM outperforms it by 1.2 points. At the second step, NEUSUM outperforms NN-SE by a large margin. In this step, the NEUSUM model extracts 31.52% sentences correctly, which is 3.24 percent higher than 28.28% of NN-SE. We think the second step selection benefits from the first step in NEUSUM since it can remember the selection history, while the separated models lack this ability.

However, we can notice the trend that the precision drops fast after each selection. We think this is due to two main reasons. First, we think that the error propagation leads to worse selection for the third selection. As shown in Figure 2, the $p(@1)$ and $p(@2)$ are 40.38% and 31.52% respectively, so the history is less reliable for the third selection. Second, intuitively, we think the later selections are more difficult compared to the previous ones since the most important sentences are already selected.

6.2 Position of Selected Sentences

Early works (Ren et al., 2017; Nallapati et al., 2017) have shown that sentence position is an important feature in extractive document summarization. Figure 2 shows the position distributions of the NN-SE baseline, our NEUSUM model and oracle on the *CNN/Daily Mail* test set. It can be seen that the NN-SE baseline model tends to extract large amount of leading sentences, especially the leading three sentences. According to the statistics, about 80.91% sentences selected by NN-SE baseline are in leading three sentences.

In the meanwhile, our NEUSUM model selects 58.64% leading three sentences. We can notice that in the oracle, the percentage of selecting leading sentences (sentence 1 to 5) is moderate, which is around 10%. Compared to NN-SE, the position of selected sentences in NEUSUM is closer to the oracle. Although NEUSUM also extracts more leading sentences than the oracle, it selects more tailing ones. For example, our NEUSUM model extracts more than 30% of sentences in the range of sentence 4 to 6. In the range of sentence 7 to 13, NN-SE barely extracts any sentences, but our NEUSUM model still extract sentences in this range. Therefore, we think this is one of the reasons why NEUSUM performs better than NN-SE.

We analyze the sentence position distribution and offer an explanation for these observations.

Intuitively, leading sentences are important for a well-organized article, especially for newswire articles. It is also well known that LEAD3 is a very strong baseline. In the training data, we found that 50.98% sentences labeled as “should be extracted” belongs to the first 5 sentences, which may cause the trained model tends to select more leading sentences. One possible situation is that one sentence in the tail of a document is more important than the leading sentences, but the margin between them is not large enough. The models which separately score and select sentences might not select sentences in the tail whose scores are not higher than the leading ones. These methods may choose the safer leading sentences as a fallback in such confusing situation because there is no direct competition between the leading and tailing candidates. In our NEUSUM model, the scoring and selection are jointly learned, and at each step the tailing candidates can compete directly with the leading ones. Therefore, NEUSUM can be more discriminating when dealing with this situation.

7 Conclusion

Conventional approaches to extractive document summarization contain two separated steps: sentence scoring and sentence selection. In this paper, we present a novel neural network framework for extractive document summarization by jointly learning to score and select sentences to address this issue. The most distinguishing feature of our approach from previous methods is that it combines sentence scoring and selection into one phase. Every time it selects a sentence, it scores the sentences according to the partial output summary and current extraction state. ROUGE evaluation results show that the proposed joint sentence scoring and selection approach significantly outperforms previous separated methods.

Abstract

We introduce a novel graph-based framework for abstractive meeting speech summarization that is fully unsupervised and does not rely on any annotations. Our work combines the strengths of multiple recent approaches while addressing their weaknesses. Moreover, we leverage recent advances in word embeddings and graph degeneracy applied to NLP to take exterior semantic knowledge into account, and to design custom diversity and informativeness measures. Experiments on the AMI and ICSI corpus show that our system improves on the state-of-the-art. Code and data are publicly available[1], and our system can be interactively tested[2].

1 Introduction

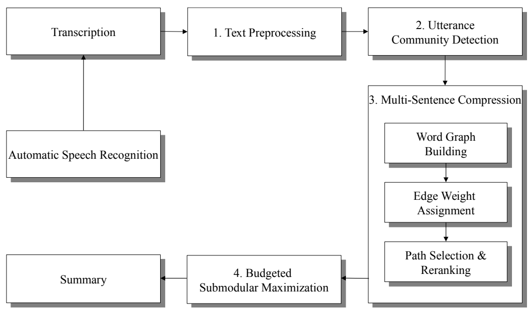
People spend a lot of their time in meetings. The ubiquity of web-based meeting tools and the rapid improvement and adoption of Automatic Speech Recognition (ASR) is creating pressing needs for effective meeting speech summarization mechanisms.

Spontaneous multi-party meeting speech transcriptions widely differ from traditional documents. Instead of grammatical, well-segmented *sentences*, the input is made of often ill-formed and ungrammatical text fragments called *utterances*. On top of that, ASR transcription and segmentation errors inject additional noise into the input.

In this paper, we combine the strengths of 6 approaches that had previously been applied to 3 different tasks (keyword extraction, multi-sentence compression, and summarization) into a unified, fully unsupervised end-to-end meeting speech summarization framework that can generate readable summaries despite the noise inherent to ASR transcriptions. We also introduce some novel components. Our method reaches state-of-the-art performance and can be applied to languages other than English in an almost out-of-the-box fashion.

2 Framework Overview

As illustrated in Figure 1, our system is made of 4 modules, briefly described in what follows.



Transcription
1. Text Preprocessing
2. Utterance Community Detection
3. Multi-Sentence Compression
Word Graph Building
Edge Weight Assignment
Path Selection & Reranking
Automatic Speech Recognition
Summary
4. Budgeted Submodular Maximization

Figure 1: Overarching system pipeline.

The first module pre-processes text. The goal of the second *Community Detection* step is to group together the utterances that should be summarized by a common abstractive sentence (Murray et al., 2012). These utterances typically correspond to a topic or subtopic discussed during the meeting. A single abstractive sentence is then separately generated for each community, using an extension of the Multi-Sentence Compression Graph (MSCG) of Filippova (2010). Finally, we generate a summary by selecting the best elements from the set of abstractive sentences under a budget constraint. We cast this problem as the maximization of a custom submodular quality function.

* Work done as part of 3rd year project, with equal contribution.

[2] http://datascience.open-paas.org/abs_summ_app

Note that our approach is fully unsupervised and does not rely on any annotations. Our input simply consists in a list of utterances without any metadata. All we need in addition to that is a part-of-speech tagger, a language model, a set of pre-trained word vectors, a list of stopwords and fillerwords, and optionally, access to a lexical database such as WordNet. Our system can work out-of-the-box in most languages for which such resources are available.

3 Related Work and Contributions

As detailed below, our framework combines the strengths of 6 recent works. It also includes novel components.

3.1 Multi-Sentence Compression Graph (MSCG) (Filippova, 2010)

Description: a fully unsupervised, simple approach for generating a short, self-sufficient sentence from a cluster of related, overlapping sentences. As shown in Figure 5, a word graph is constructed with special edge weights, the K-shortest weighted paths are then found and re-ranked with a scoring function, and the best path is used as the compression. The assumption is that redundancy alone is enough to ensure informativeness and grammaticality.
Limitations: despite making great strides and showing promising results, Filippova (2010) reported that 48% and 36% of the generated sentences were missing important information and were not perfectly grammatical.
Contributions: to respectively improve informativeness and grammaticality, we combine ideas found in Boudin and Morin (2013) and Mehdad et al. (2013), as described next.

3.2 More informative MSCG (Boudin and Morin, 2013)

Description: same task and approach as in Filippova (2010), except that a word co-occurrence network is built from the cluster of sentences, and that the PageRank scores of the nodes are computed in the manner of Mihalcea and Tarau (2004). The scores are then injected into the path re-ranking function to favor informative paths.
Limitations: PageRank is not state-of-the-art in capturing the importance of words in a document. Grammaticality is not considered.
Contributions: we take grammaticality into account as explained in subsection 3.4. We also follow recent evidence (Tixier et al., 2016a) that *spreading influence*, as captured by graph degeneracy-based measures, is better correlated with "keywordedness" than PageRank scores, as explained in the next subsection.

3.3 Graph-based word importance scoring (Tixier et al., 2016a)

Word co-occurrence network. As shown in Figure 2, we consider a word co-occurrence network as an undirected, weighted graph constructed by sliding a fixed-size window over text, and where edge weights represent co-occurrence counts (Tixier et al., 2016b; Mihalcea and Tarau, 2004).

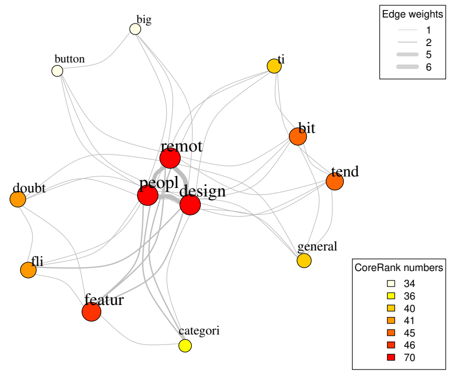

Figure 2: Word co-occurrence graph example, for the input text shown in Figure 5.

Important words are influential nodes. In social networks, it was shown that *influential spreaders*, that is, those individuals that can reach the largest part of the network in a given number of steps, are better identified via their core numbers rather than via their PageRank scores or degrees (Kitsak et al., 2010). See Figure 3 for the intuition. Similarly, in NLP, Tixier et al. (2016a) have shown that keywords are better identified via their core numbers rather than via their TextRank scores, that is, keywords are *influencers* within their word co-occurrence network.
Graph degeneracy (Seidman, 1983). Let $G(V, E)$ be an undirected, weighted graph with $n = |V|$ nodes and $m = |E|$ edges. A k-core of G is a maximal subgraph of G in which every vertex v has at least weighted degree k. As shown in Figures 3 and 4, the k-core decomposition of G forms a hierarchy of nested subgraphs whose cohesiveness and size respectively increase and decrease with k. The higher-level cores can be viewed as a *filtered version* of the graph that

excludes noise. This property is highly valuable when dealing with graphs constructed from noisy text, like utterances. The core number of a node is the highest order of a core that contains this node.

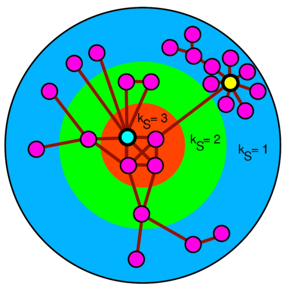

Figure 3: k-core decomposition. The blue and the yellow nodes have same degree and similar PageRank numbers. However, the blue node is a much more influential spreader as it is strategically placed in the core of the network, as captured by its higher core number.

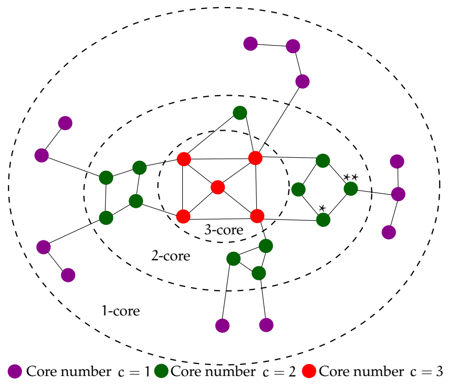
The CoreRank number of a node (Tixier et al., 2016a; Bae and Kim, 2014) is defined as the sum of the core numbers of its neighbors. As shown in Figure 4, CoreRank more finely captures the structural position of each node in the graph than raw core numbers. Also, stabilizing scores across node neighborhoods enhances the inherent noise robustness property of graph degeneracy, which is desirable when working with noisy speech-to-text output.



$\star\star$
$\star$
3-core
2-core
1-core
● Core number $c = 1$ ● Core number $c = 2$ ● Core number $c = 3$

Figure 4: Value added by CoreRank: while nodes $\star$ and $\star\star$ have the same core number (=2), node $\star$ has a greater CoreRank score (3+2+2=7 vs 2+2+1=5), which better reflects its more central position in the graph.

Time complexity. Building a graph-of-words is $\mathcal{O}(nW)$, and computing the weighted k-core decomposition of a graph requires $\mathcal{O}(m \log(n))$ (Batagelj and Zaveršnik, 2002). For small pieces of text, this two step process is so affordable that it can be used in real-time (Meladianos et al., 2017). Finally, computing CoreRank scores can be done with only a small overhead of $\mathcal{O}(n)$, provided that the graph is stored as a hash of adjacency lists. Getting the CoreRank numbers from scratch for a community of utterances is therefore very fast, especially since typically in this context, $n \sim 10$ and $m \sim 100$.

3.4 Fluency-aware, more abstractive MSCG (Mehdad et al., 2013)

Description: a *supervised* end-to-end framework for abstractive meeting summarization. Community Detection is performed by (1) building an utterance graph with a logistic regression classifier, and (2) applying the CONGA algorithm. Then, before performing sentence compression with the MSCG, the authors also (3) build an entailment graph with a SVM classifier in order to eliminate redundant and less informative utterances. In addition, the authors propose the use of WordNet (Miller, 1995) during the MSCG building phase to capture lexical knowledge between words and thus generate more abstractive compressions, and of a language model when re-ranking the shortest paths, to favor fluent compressions.
Limitations: this effort was a significant advance, as it was the first application of the MSCG to the meeting summarization task, to the best of our knowledge. However, steps (1) and (3) above are complex, based on handcrafted features, and respectively require annotated training data in the form of links between human-written abstractive sentences and original utterances and multiple external datasets (e.g., from the Recognizing Textual Entailment Challenge). Such annotations are costly to obtain and very seldom available in practice.
Contributions: while we retain the use of WordNet and of a language model, we show that, without deteriorating the quality of the results, steps (1) and (2) above (Community Detection) can be performed in a much more simple, completely unsupervised way, and that step (3) can be removed. That is, the MSCG is powerful enough to remove redundancy and ensure informativeness, should proper edge weights and path re-ranking function be used.

In addition to the aforementioned contributions, we also introduce the following novel components into our abstractive summarization pipeline:

• we inject global exterior knowledge into the edge weights of the MSCG, by using the *Word Attraction Force* of Wang et al. (2014), based on distance in the word embedding space,

- we add a diversity term to the path re-ranking function, that measures how many unique clusters in the embedding space are visited by each path,
- rather than using all the abstractive sentences as the final summary like in Mehdad et al. (2013), we maximize a custom submodular function to select a subset of abstractive sentences that is near-optimal given a budget constraint (summary size). A brief background of submodularity in the context of summarization is provided next.

3.5 Submodularity for summarization (Lin and Bilmes, 2010; Lin, 2012)

Selecting an optimal subset of abstractive sentences from a larger set can be framed as a budgeted submodular maximization task:

$$\underset{S \subseteq \mathcal{S}}{\operatorname{argmax}}\, f(S) | \sum_{s \in S} c_s \leq \mathcal{B} \tag{1}$$

where S is a summary, c_s is the cost (word count) of sentence s, $\mathcal{B}$ is the desired summary size in words (budget), and f is a summary quality scoring set function, which assigns a single numeric score to a summary S.

This combinatorial optimization task is NP-hard. However, near-optimal performance can be guaranteed with a modified greedy algorithm (Lin and Bilmes, 2010) that iteratively selects the sentence s that maximizes the ratio of quality function gain to scaled cost $f(S \cup s) - f(S) / c_s^r$ (where S is the current summary and $r \geq 0$ is a scaling factor).

In order for the performance guarantees to hold however, f has to be *submodular* and *monotone non-decreasing*. Our proposed f is described in subsection 4.4.

4 Our Framework

We detail next each of the four modules in our architecture (shown in Figure 1).

4.1 Text preprocessing

We adopt preprocessing steps tailored to the characteristics of ASR transcriptions. Consecutive repeated unigrams and bigrams are reduced to single terms. Specific ASR tags, such as {*vocalsound*}, {*pause*}, *and* {*gap*} are filtered out. In addition, filler words, such as *uh-huh*, *okay*, *well*, and *by the way* are also discarded. Consecutive stopwords at the beginning and end of utterances are stripped. In the end, utterances that contain less than 3 non-stopwords are pruned out. The surviving utterances are used for the next steps.

4.2 Utterance community detection

The goal here is to cluster utterances into communities that should be summarized by a common abstractive sentence.

We initially experimented with techniques capitalizing on word vectors, such as k-means and hierarchical clustering based on the Euclidean distance or the Word Mover's Distance (Kusner et al., 2015). We also tried graph-based approaches, such as community detection in a complete graph where nodes are utterances and edges are weighted based on the aforementioned distances.

Best results were obtained, however, with a simple approach in which utterances are projected into the vector space and assigned standard TF-IDF weights. Then, the dimensionality of the utterance-term matrix is reduced with Latent Semantic Analysis (LSA), and finally, the k-means algorithm is applied. Note that LSA is only used here, during the utterance community detection phase, to remove noise and stabilize clustering. We do not use a topic graph in our approach.

We think using word embeddings was not effective, because in meeting speech, as opposed to traditional documents, participants tend to use the same term to refer to the same thing throughout the entire conversation, as noted by Riedhammer et al. (2010), and as verified in practice. This is probably why, for clustering utterances, capturing synonymy is counterproductive, as it artificially reduces the distance between every pair of utterances and blurs the picture.

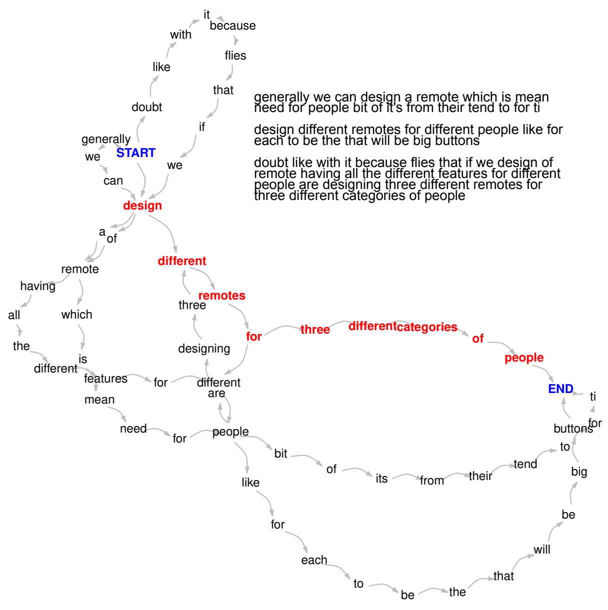
4.3 Multi-Sentence Compression

The following steps are performed separately for each community.

Word importance scoring

From a processed version of the community (stemming and stopword removal), we construct an undirected, weighted word co-occurrence network as described in subsection 3.3. We use a sliding window of size $W = 6$ not overspanning utterances. Note that stemming is performed only here, and for the sole purpose of building the word co-occurrence network.

We then compute the CoreRank numbers of the nodes as described in subsection 3.3.



generally we can design a remote which is mean need for people bit of it's from their tend to for ti

design different remotes for different people like for each to be the that will be big buttons

doubt like with it because flies that if we design of remote having all the different features for different people are designing three different remotes for three different categories of people

Figure 5: Compressed sentence (in **bold red**) generated by our multi-sentence compression graph (MSCG) for a 3-utterance community from meeting IS1009b of the AMI corpus. Using Filippova (2010)'s weighting and re-ranking scheme here would have selected another path: *design different remotes for different people bit of it's from their tend to for ti*. Note that the compressed sentence does not appear in the initial set of utterances, and is compact and grammatical, despite the redundancy, transcription and segmentation errors of the input. The *abstractive* and *robust* nature of the MSCG makes it particularly well-suited to the meeting domain.

We finally reweigh the CoreRank scores, indicative of word importance within a given community, with a quantity akin to an *Inverse Document Frequency*, where communities serve as documents and the full meeting as the collection. We thus obtain something equivalent to the TW-IDF weighting scheme of Rousseau and Vazirgiannis (2013), where the CoreRank scores are the term weights TW:

$$TW\text{-}IDF(t,d,D) = TW(t,d) \times IDF(t,D) \tag{2}$$

where t is a term belonging to community d, and D is the set of all utterance communities. We compute the IDF as $IDF(t,D) = 1 + \log|D|/D_t$, where $|D|$ is the number of communities and D_t the number of communities containing t.

The intuition behind this reweighing scheme is that a term should be considered important within a given meeting if it has a high CoreRank score within its community *and* if the number of communities in which the term appears is relatively small.

Word graph building

The backbone of the graph is laid out as a directed sequence of nodes corresponding to the words in the first utterance, with special `START` and `END` nodes at the beginning and at the end (see Figure 5). Edge direction follows the natural flow of text. Words from the remaining utterances are then iteratively added to the graph (between the `START` and `END` nodes) based on the following rules:

1) if the word is a **non-stopword**, the word is mapped onto an existing node if it has the same lowercased form and the same part-of-speech tag[3]. In case of multiple matches, we check the immediate context (the preceding and following words in the utterance and the neighboring nodes in the graph), and we pick the node with the largest context overlap or which has the greatest number of words already mapped to it (when no overlap). When there is no match, we use WordNet as described in Appendix A.

2) if the word is a **stopword** and there is a match, it is mapped only if there is an overlap of at least one non-stopword in the immediate context. Otherwise, a new node is created.

Finally, note that any two words appearing within the same utterance cannot be mapped to the same node. This ensures that every utterance is a loopless path in the graph. Of course, there are many more paths in the graphs than original utterances.

Edge Weight Assignment

Once the word graph is constructed, we assign weights to its edges as:

$$w'''(p_i, p_j) = \frac{w'(p_i, p_j)}{w''(p_i, p_j)} \tag{3}$$

where p_i and p_j are two neighbors in the MSCG. As detailed next, those weights combine *local co-occurrence statistics* (numerator) with *global exterior knowledge* (denominator). Note that the lower

[3]We used NLTK's averaged perceptron tagger, available at: http://www.nltk.org/api/nltk.tag.html#module-nltk.tag.perceptron

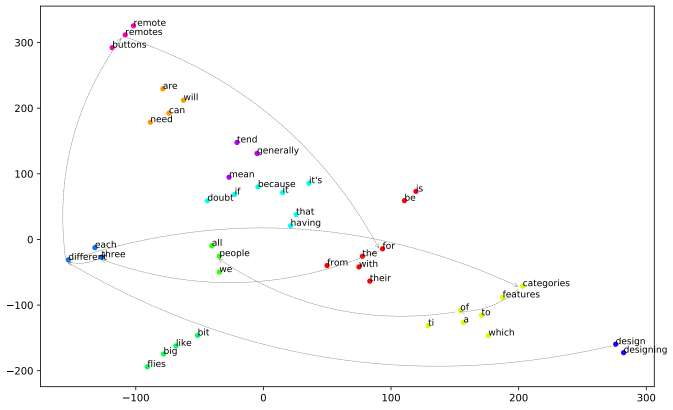


Figure 6: t-SNE visualization (Maaten and Hinton, 2008) of the Google News vectors of the words in the utterance community shown in Figure 5. Arrows join the words in the best compression path shown in Figure 5. Movements in the embedding space, as measured by the number of unique clusters covered by the path (here, 6/11), provide a sense of the diversity of the compressed sentence, as formalized in Equation 10.

the weight of an edge, the better.

Local co-occurrence statistics.
We use Filippova (2010)'s formula:

$$w'(p_i, p_j) = \frac{f(p_i) + f(p_j)}{\sum_{P \in G', p_i, p_j \in P} \text{diff}(P, p_i, p_j)^{-1}} \tag{4}$$

where $f(p_i)$ is the number of words mapped to node p_i in the MSCG G', and $\text{diff}(P, p_i, p_j)^{-1}$ is the inverse of the distance between p_i and p_j in a path P (in number of hops). This weighting function favors edges between infrequent words that frequently appear close to each other in the text (the lower, the better).

Global exterior knowledge.
We introduce a second term based on the *Word Attraction Force score* of Wang et al. (2014):

$$w''(p_i, p_j) = \frac{f(p_i) \times f(p_j)}{d^2_{p_i, p_j}} \tag{5}$$

where d_{p_i,p_j} is the Euclidean distance between the words mapped to p_i and p_j in a word embedding space[4]. This component favor paths going through salient words that have *high semantic similarity* (the higher, the better). The goal is to ensure readability of the compression, by avoiding to generate a sentence jumping from one word to a completely unrelated one.

Path re-ranking

As in Boudin and Morin (2013), we use a shortest weighted path algorithm to find the K paths between the `START` and `END` symbols having the lowest cumulative edge weight:

$$W(P) = \sum_{i=1}^{|P|-1} w'''(p_i, p_{i+1}) \tag{6}$$

Where $|P|$ is the number of nodes in the path. Paths having less than z words or that do not contain a verb are filtered out (z is a tuning parameter). However, unlike in Boudin and Morin (2013), we rerank the K best paths with the following novel weighting scheme (the lower, the better), and the path with the lowest score is used as the compression:

$$\text{score}(P) = \frac{W(P)}{|P| \times F(P) \times C(P) \times D(P)} \tag{7}$$

The denominator takes into account the length of the path, and its fluency (F), coverage (C), and diversity (D). F, C, and D are detailed in what follows.

Fluency. We estimate the grammaticality of a path with an n-gram language model. In our experiments, we used a trigram model[5]:

$$F(P) = \frac{\sum_{i=1}^{|P|} \log Pr(p_i | p_{i-n+1}^{i-1})}{\#n\text{-}gram} \tag{8}$$

where $|P|$ denote path length, and p_i and $\#n\text{-}gram$ are respectively the words and number of n-grams in the path.

Coverage. We reward the paths that visit important nouns, verbs and adjectives:

$$C(P) = \frac{\sum_{p_i \in P} \text{TW-IDF}(p_i)}{\#p_i} \tag{9}$$

where $\#p_i$ is the number of nouns, verbs and adjectives in the path. The TW-IDF scores are computed as explained in subsection 4.3.

Diversity. We cluster all words from the MSCG in the word embedding space by applying the k-means algorithm. We then measure the diversity of the vocabulary contained in a path as the number

[4]GoogleNews vectors `https://code.google.com/archive/p/word2vec`

[5]CMUSphinx English LM: `https://cmusphinx.github.io`

of unique clusters visited by the path, normalized by the length of the path:

$$D(P) = \frac{\sum_{j=1}^{k} 1_{\exists p_i \in P | p_i \in \text{cluster}_j}}{|P|} \tag{10}$$

The graphical intuition for this measure is provided in Figure 6. Note that we do not normalize D by the total number of clusters (only by path length) because k is fixed for all candidate paths.

4.4 Budgeted submodular maximization

We apply the previous steps separately for all utterance communities, which results in a set $\mathcal{S}$ of abstractive sentences (one for each community). This set of sentences can already be considered to be a summary of the meeting. However, it might exceed the maximum size allowed, and still contain some redundancy or off-topic sections unrelated to the general theme of the meeting (e.g., chit-chat).

Therefore, we design the following *submodular* and *monotone non-decreasing* objective function:

$$f(S) = \sum_{s_i \in S} n_{s_i} w_{s_i} + \lambda \sum_{j=1}^{k} 1_{\exists s_i \in S | s_i \in group_j} \tag{11}$$

where $\lambda \geq 0$ is the trade-off parameter, n_{s_i} is the number of occurrences of word s_i in S, and w_{s_i} is the CoreRank score of s_i.

Then, as explained in subsection 3.5, we obtain a near-optimal subset of abstractive sentences by maximizing f with a greedy algorithm. CoreRank scores and clusters are found as previously described, except that this time they are obtained from the full processed meeting transcription rather than from a single utterance community.

5 Experimental setup

5.1 Datasets

We conducted experiments on the widely-used AMI (McCowan et al., 2005) and ICSI (Janin et al., 2003) benchmark datasets. We used the traditional test sets of 20 and 6 meetings respectively for the AMI and ICSI corpora (Riedhammer et al., 2008). Each meeting in the AMI test set is associated with a human abstractive summary of 290 words on average, whereas each meeting in the ICSI test set is associated with 3 human abstractive summaries of respective average sizes 220, 220 and 670 words. For parameter tuning, we constructed development sets of 47 and 25 meetings, respectively for AMI and ICSI, by randomly sampling from the training sets. The word error rate of the ASR transcriptions is respectively of 36% and 37% for AMI and ICSI.

5.2 Baselines

We compared our system against 7 baselines, which are listed below and more thoroughly detailed in Appendix B. Note that preprocessing was exactly the same for our system and all baselines.

• **Random** and **Longest Greedy** are basic baselines recommended by (Riedhammer et al., 2008),
• **TextRank** (Mihalcea and Tarau, 2004),
• **ClusterRank** (Garg et al., 2009),
• **CoreRank & PageRank submodular** (Tixier et al., 2017),
• **Oracle** is the same as the random baseline, but uses the human extractive summaries as input.

In addition to the baselines above, we included in our comparison 3 variants of our system using different MSCGs: **Our System (Baseline)** uses the original MSCG of Filippova (2010), **Our System (KeyRank)** uses that of Boudin and Morin (2013), and **Our System (FluCovRank)** that of Mehdad et al. (2013). Details about each approach were given in Section 3.

5.3 Parameter tuning

For *Our System* and each of its variants, we conducted a grid search on the development sets of each corpus, for fixed summary sizes of 350 and 450 words (AMI and ICSI). We searched the following parameters:

• n: number of utterance communities (see Section 4.2). We tested values of n ranging from 20 to 60, with steps of 5. This parameter controls how much abstractive should the summary be. If all utterances are assigned to their own singleton community, the MSCG is of no utility, and our framework is extractive. It becomes more and more abstractive as the number of communities decreases.
• z: minimum path length (see Section 4.3). We searched values in the range $[6, 16]$ with steps of 2. If a path is shorter than a certain minimum number of words, it often corresponds to an invalid sentence, and should thereby be filtered out.
• λ and r, the trade-off parameter and the scaling factor (see Section 4.4). We searched $[0, 1]$ and $[0, 2]$ (respectively) with steps of 0.1. The parameter λ plays a regularization role favoring diversity.

The scaling factor makes sure the quality function gain and utterance cost are comparable.

The best parameter values for each corpus are summarized in Table 1. λ is mostly non-zero, indicating that it is necessary to include a regularization term in the submodular function. In some cases though, r is equal to zero, which means that utterance costs are not involved in the greedy decision heuristic. These observations contradict the conclusion of Lin (2012) that $r = 0$ cannot give best results.

System	AMI	ICSI
Our System	50, 8, (0.7, 0.5)	40, 14, (0.0, 0.0)
Our System (Baseline)	50, 12, (0.3, 0.5)	45, 14, (0.1, 0.0)
Our System (KeyRank)	50, 10, (0.2, 0.9)	45, 12, (0.3, 0.4)
Our System (FluCovRank)	35, 6, (0.4, 1.0)	50, 10, (0.2, 0.3)

Table 1: Optimal parameter values $n, z, (\lambda, r)$.

Apart from the tuning parameters, we set the number of LSA dimensions to 30 and 60 (resp. on AMI and ISCI). The small number of LSA dimensions retained can be explained by the fact that the AMI and ICSI transcriptions feature 532 and 1126 unique words on average, which is much smaller than traditional documents. This is due to relatively small meeting duration, and to the fact that participants tend to stick to the same terms throughout the entire conversation. For the k-means algorithm, k was set equal to the minimum path length z when doing MSCG path re-ranking (see Equation 10), and to 60 when generating the final summary (see Equation 11).

Following Boudin and Morin (2013), the number of shortest weighted paths K was set to 200, which is greater than the $K = 100$ used by Filippova (2010). Increasing K from 100 improves performance with diminishing returns, but significantly increases complexity. We empirically found 200 to be a good trade-off.

6 Results and Interpretation

Metrics. We evaluated performance with the widely-used ROUGE-1, ROUGE-2 and ROUGE-SU4 metrics (Lin, 2004). These metrics are respectively based on unigram, bigram, and unigram plus skip-bigram overlap with maximum skip distance of 4, and have been shown to be highly correlated with human evaluations (Lin, 2004). ROUGE-2 scores can be seen as a measure of summary readability (Lin and Hovy, 2003; Ganesan et al., 2010). ROUGE-SU4 does not require consecutive matches but is still sensitive to word order.

Macro-averaged results for summaries generated from automatic transcriptions can be seen in Figure 7 and Table 2. Table 2 provides detailed comparisons over the fixed budgets that we used for parameter tuning, while Figure 7 shows the performance of the models for budgets ranging from 150 to 500 words. The same information for summaries generated from manual transcriptions is available in Appendix C. Finally, summary examples are available in Appendix D.

ROUGE-1. Our systems outperform all baselines on AMI (including *Oracle*) and all baselines on ICSI (except *Oracle*). Specifically, *Our System* is best on ICSI, while *Our System (KeyRank)* is superior on AMI. We can also observe on Figure 7 that our systems are consistently better throughout the different summary sizes, even though their parameters were tuned for specific sizes only. This shows that the best parameter values are quite robust across the entire budget range.

ROUGE-2. Again, our systems (except *Our System (Baseline)*) outperform all baselines, except *Oracle*. In addition, *Our System* and *Our System (FluCovRank)* consistently improve on *Our System (Baseline)*, which proves that the novel components we introduce improve summary fluency.

ROUGE-SU4. ROUGE-SU4 was used to measure the amount of in-order word pairs overlapping. Our systems are competitive with all baselines, including *Oracle*. Like with ROUGE-1, *Our System* is better than *Our System (KeyRank)* on ICSI, whereas the opposite is true on AMI.

General remarks.

• The summaries of all systems except *Oracle* were generated from noisy ASR transcriptions, but were compared against human abstractive summaries. ROUGE being based on word overlap, it makes it very difficult to reach very high scores, because many words in the ground truth summaries do not appear in the transcriptions at all.

• The scores of all systems are lower on ICSI than on AMI. This can be explained by the fact that on ICSI, the system summaries have to jointly match 3 human abstractive summaries of different content and size, which is much more difficult than matching a single summary.

• Our framework is very competitive to *Oracle*, which is notable since the latter has direct access to the human extractive summaries. Note that *Or-*

acle does not reach very high ROUGE scores because the overlap between the human extractive and abstractive summaries is low (19% and 29%, respectively on AMI and ICSI test sets).

7 Conclusion and Next Steps

Our framework combines the strengths of 6 approaches that had previously been applied to 3 different tasks (keyword extraction, multi-sentence compression, and summarization) into a unified, fully unsupervised end-to-end summarization framework, and introduces some novel components. Rigorous evaluation on the AMI and ICSI corpora shows that we reach state-of-the-art performance, and generate reasonably grammatical abstractive summaries despite taking noisy utterances as input and not relying on any annotations or training data. Finally, thanks to its fully unsupervised nature, our method is applicable to other languages than English in an almost out-of-the-box manner.

Our framework was developed for the meeting domain. Indeed, our generative component, the multi-sentence compression graph (MSCG), needs redundancy to perform well. Such redundancy is typically present in meeting speech but not in traditional documents. In addition, the MSCG is by design robust to noise, and our custom path re-ranking strategy, based on graph degeneracy, makes it even more robust to noise. As a result, our framework is advantaged on ASR input. Finally, we use a language model to favor fluent paths, which is crucial when working with (meeting) speech but not that important when dealing with well-formed input.

Future efforts should be dedicated to improving the community detection phase and generating more abstractive sentences, probably by harnessing Deep Learning. However, the lack of large training sets for the meeting domain is an obstacle to the use of neural approaches.

Fast Abstractive Summarization with Reinforce-Selected Sentence Rewriting

Yen-Chun Chen and **Mohit Bansal**
UNC Chapel Hill
{yenchun, mbansal}@cs.unc.edu

Abstract

Inspired by how humans summarize long documents, we propose an accurate and fast summarization model that first selects salient sentences and then rewrites them abstractively (i.e., compresses and paraphrases) to generate a concise overall summary. We use a novel sentence-level policy gradient method to bridge the non-differentiable computation between these two neural networks in a hierarchical way, while maintaining language fluency. Empirically, we achieve the new state-of-the-art on all metrics (including human evaluation) on the CNN/Daily Mail dataset, as well as significantly higher abstractiveness scores. Moreover, by first operating at the sentence-level and then the word-level, we enable *parallel decoding* of our neural generative model that results in substantially faster (10-20x) inference speed as well as 4x faster training convergence than previous long-paragraph encoder-decoder models. We also demonstrate the generalization of our model on the test-only DUC-2002 dataset, where we achieve higher scores than a state-of-the-art model.

1 Introduction

The task of document summarization has two main paradigms: extractive and abstractive. The former method directly chooses and outputs the salient sentences (or phrases) in the original document (Jing and McKeown, 2000; Knight and Marcu, 2000; Martins and Smith, 2009; Berg-Kirkpatrick et al., 2011). The latter abstractive approach involves rewriting the summary (Banko et al., 2000; Zajic et al., 2004), and has seen substantial recent gains due to neural sequence-to-sequence models (Chopra et al., 2016; Nallapati et al., 2016; See et al., 2017; Paulus et al., 2018). Abstractive models can be more concise by performing generation from scratch, but they suffer from slow and inaccurate encoding of very long documents, with the attention model being required to look at all encoded words (in long paragraphs) for decoding each generated summary word (slow, one by one sequentially). Abstractive models also suffer from redundancy (repetitions), especially when generating multi-sentence summary.

To address both these issues and combine the advantages of both paradigms, we propose a hybrid extractive-abstractive architecture, with policy-based reinforcement learning (RL) to bridge together the two networks. Similar to how humans summarize long documents, our model first uses an *extractor agent* to select salient sentences or highlights, and then employs an *abstractor network* to rewrite (i.e., compress and paraphrase) each of these extracted sentences. To overcome the non-differentiable behavior of our extractor and train on available document-summary pairs without saliency label, we next use actor-critic policy gradient with sentence-level metric rewards to connect these two neural networks and to learn sentence saliency. We also avoid common language fluency issues (Paulus et al., 2018) by preventing the policy gradients from affecting the abstractive summarizer's word-level training, which is supported by our human evaluation study. Our sentence-level reinforcement learning takes into account the word-sentence hierarchy, which better models the language structure and makes parallelization possible. Our extractor combines reinforcement learning and pointer networks, which is inspired by Bello et al. (2017)'s attempt to solve the Traveling Salesman Problem. Our abstractor is a simple encoder-aligner-decoder model (with copying) and is trained on pseudo document-summary sentence pairs obtained via simple automatic matching criteria.

Thus, our method incorporates the abstractive paradigm's advantages of concisely rewriting sentences and generating novel words from the full vocabulary, yet it adopts intermediate extractive behavior to improve the overall model's quality, speed, and stability. Instead of encoding and attending to every word in the long input document sequentially, our model adopts a human-inspired *coarse-to-fine* approach that first extracts all the salient sentences and then decodes (rewrites) them (*in parallel*). This also avoids almost all redundancy issues because the model has already chosen non-redundant salient sentences to abstractively summarize (but adding an optional final reranker component does give additional gains by removing the fewer across-sentence repetitions).

Empirically, our approach is the new state-of-the-art on all ROUGE metrics (Lin, 2004) as well as on METEOR (Denkowski and Lavie, 2014) of the CNN/Daily Mail dataset, achieving statistically significant improvements over previous models that use complex long-encoder, copy, and coverage mechanisms (See et al., 2017). The test-only DUC-2002 improvement also shows our model's better generalization than this strong abstractive system. In addition, we surpass the popular lead-3 baseline on all ROUGE scores with an abstractive model. Moreover, our sentence-level abstractive rewriting module also produces substantially more (3x) novel N-grams that are not seen in the input document, as compared to the strong flat-structured model of See et al. (2017). This empirically justifies that our RL-guided extractor has learned sentence saliency, rather than benefiting from simply copying longer sentences. We also show that our model maintains the same level of fluency as a conventional RNN-based model because the reward does not leak to our abstractor's word-level training. Finally, our model's training is 4x and inference is more than 20x faster than the previous state-of-the-art. The optional final reranker gives further improvements while maintaining a 7x speedup.

Overall, our contribution is three fold: First we propose a novel sentence-level RL technique for the well-known task of abstractive summarization, effectively utilizing the word-then-sentence hierarchical structure without annotated matching sentence-pairs between the document and ground truth summary. Next, our model achieves the new state-of-the-art on all metrics of multiple versions of a popular summarization dataset (as well as a test-only dataset) both extractively and abstractively, without loss in language fluency (also demonstrated via human evaluation and abstractiveness scores). Finally, our parallel decoding results in a significant 10-20x speed-up over the previous best neural abstractive summarization system with even better accuracy.[1]

2 Model

In this work, we consider the task of summarizing a given long text document into several (ordered) highlights, which are then combined to form a multi-sentence summary. Formally, given a training set of document-summary pairs $\{x_i, y_i\}_{i=1}^N$, our goal is to approximate the function $h : X \to Y, X = \{x_i\}_{i=1}^N, Y = \{y_i\}_{i=1}^N$ such that $h(x_i) = y_i, 1 \leq i \leq N$. Furthermore, we assume there exists an abstracting function g defined as: $\forall s \in S_i, \exists d \in D_i$ such that $g(d) = s, 1 \leq i \leq N$, where S_i is the set of summary sentences in x_i and D_i the set of document sentences in y_i. i.e., in any given pair of document and summary, every summary sentence can be produced from some document sentence. For simplicity, we omit subscript i in the remainder of the paper. Under this assumption, we can further define another latent function $f : X \to D^n$ that satisfies $f(x) = \{d_t\}_{j=1}^n$ and $y = h(x) = [g(d_1), g(d_2), \ldots, g(d_n)]$, where $[,]$ denotes sentence concatenation. This latent function f can be seen as an extractor that chooses the salient (ordered) sentences in a given document for the abstracting function g to rewrite. Our overall model consists of these two submodules, the *extractor agent* and the *abstractor network*, to approximate the above-mentioned f and g, respectively.

2.1 Extractor Agent

The extractor agent is designed to model f, which can be thought of as extracting salient sentences from the document. We exploit a hierarchical neural model to learn the sentence representations of the document and a 'selection network' to extract sentences based on their representations.

[1]We are releasing our code, best pretrained models, as well as output summaries, to promote future research: `https://github.com/ChenRocks/fast_abs_rl`

Figure 1: Our extractor agent: the convolutional encoder computes representation r_j for each sentence. The RNN encoder (blue) computes context-aware representation h_j and then the RNN decoder (green) selects sentence j_t at time step t. With j_t selected, h_{j_t} will be fed into the decoder at time $t + 1$.

2.1.1 Hierarchical Sentence Representation

We use a temporal convolutional model (Kim, 2014) to compute r_j, the representation of each individual sentence in the documents (details in supplementary). To further incorporate global context of the document and capture the long-range semantic dependency between sentences, a bidirectional LSTM-RNN (Hochreiter and Schmidhuber, 1997; Schuster et al., 1997) is applied on the convolutional output. This enables learning a strong representation, denoted as h_j for the j-th sentence in the document, that takes into account the context of all previous and future sentences in the same document.

2.1.2 Sentence Selection

Next, to select the extracted sentences based on the above sentence representations, we add another LSTM-RNN to train a *Pointer Network* (Vinyals et al., 2015), to extract sentences recurrently. We calculate the extraction probability by:

$$u_j^t = \begin{cases} v_p^\top \tanh(W_{p1}h_j + W_{p2}e_t) & \text{if } j_t \neq j_k \\ & \forall k < t \\ -\infty & \text{otherwise} \end{cases} \tag{1}$$

$$P(j_t|j_1, \dots, j_{t-1}) = \text{softmax}(u^t) \tag{2}$$

where e_t's are the output of the *glimpse* operation (Vinyals et al., 2016):

$$a_j^t = v_g^\top \tanh(W_{g1}h_j + W_{g2}z_t) \tag{3}$$

$$\alpha^t = \text{softmax}(a^t) \tag{4}$$

$$e_t = \sum_j \alpha_j^t W_{g1}h_j \tag{5}$$

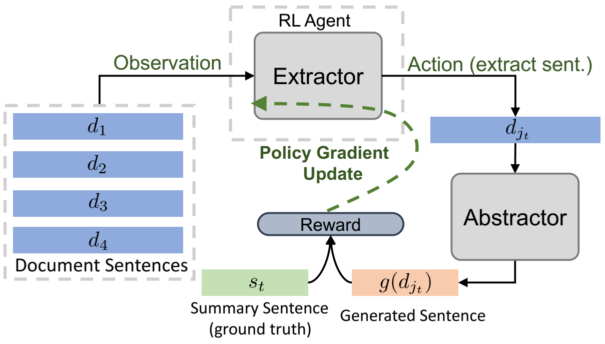

Figure 2: Reinforced training of the extractor (for one extraction step) and its interaction with the abstractor. For simplicity, the critic network is not shown. Note that all d's and s_t are raw sentences, *not* vector representations.

In Eqn. 3, z_t is the output of the added LSTM-RNN (shown in green in Fig. 1) which is referred to as the *decoder*. All the W's and v's are trainable parameters. At each time step t, the decoder performs a 2-hop attention mechanism: It first attends to h_j's to get a context vector e_t and then attends to h_j's again for the extraction probabilities.[2] This model is essentially classifying all sentences of the document at each extraction step. An illustration of the whole extractor is shown in Fig. 1.

2.2 Abstractor Network

The abstractor network approximates g, which compresses and paraphrases an extracted document sentence to a concise summary sentence. We

[2]Note that we force-zero the extraction prob. of already extracted sentences so as to prevent the model from using repeating document sentences and suffering from redundancy. This is non-differentiable and hence only done in RL training.

use the standard encoder-aligner-decoder (Bahdanau et al., 2015; Luong et al., 2015). We add the copy mechanism[3] to help directly copy some out-of-vocabulary (OOV) words (See et al., 2017). For more details, please refer to the supplementary.

3 Learning

Given that our extractor performs a non-differentiable *hard* extraction, we apply standard policy gradient methods to bridge the back-propagation and form an end-to-end trainable (stochastic) computation graph. However, simply starting from a randomly initialized network to train the whole model in an end-to-end fashion is infeasible. When randomly initialized, the extractor would often select sentences that are not relevant, so it would be difficult for the abstractor to learn to abstractively rewrite. On the other hand, without a well-trained abstractor the extractor would get noisy reward, which leads to a bad estimate of the policy gradient and a sub-optimal policy. We hence propose optimizing each sub-module separately using maximum-likelihood (ML) objectives: train the extractor to select salient sentences (fit f) and the abstractor to generate shortened summary (fit g). Finally, RL is applied to train the full model end-to-end (fit h).

3.1 Maximum-Likelihood Training for Submodules

Extractor Training: In Sec. 2.1.2, we have formulated our sentence selection as classification. However, most of the summarization datasets are end-to-end document-summary pairs without extraction (saliency) labels for each sentence. Hence, we propose a simple similarity method to provide a 'proxy' target label for the extractor. Similar to the extractive model of Nallapati et al. (2017), for each ground-truth summary sentence, we find the most similar document sentence d_{j_t} by:[4]

$$j_t = \text{argmax}_i(\text{ROUGE-L}_{recall}(d_i, s_t)) \tag{6}$$

Given these proxy training labels, the extractor is then trained to minimize the cross-entropy loss.

Abstractor Training: For the abstractor training, we create training pairs by taking each summary sentence and pairing it with its extracted document sentence (based on Eqn. 6). The network is trained as an usual sequence-to-sequence model to minimize the cross-entropy loss $L(\theta_{abs}) = -\frac{1}{M}\sum_{m=1}^{M} \log P_{\theta_{abs}}(w_m|w_{1:m-1})$ of the decoder language model at each generation step, where θ_{abs} is the set of trainable parameters of the abstractor and w_m the m^{th} generated word.

3.2 Reinforce-Guided Extraction

Here we explain how policy gradient techniques are applied to optimize the whole model. To make the extractor an RL agent, we can formulate a Markov Decision Process (MDP)[5]: at each extraction step t, the agent observes the current state $c_t = (D, d_{j_{t-1}})$, samples an action $j_t \sim \pi_{\theta_a,\omega}(c_t, j) = P(j)$ from Eqn. 2 to extract a document sentence and receive a reward[6]

$$r(t+1) = \text{ROUGE-L}_{F_1}(g(d_{j_t}), s_t) \tag{7}$$

after the abstractor summarizes the extracted sentence d_{j_t}. We denote the trainable parameters of the extractor agent by $\theta = \{\theta_a, \omega\}$ for the decoder and hierarchical encoder respectively. We can then train the extractor with policy-based RL. We illustrate this process in Fig. 2.

The vanilla policy gradient algorithm, REINFORCE (Williams, 1992), is known for high variance. To mitigate this problem, we add a critic network with trainable parameters θ_c to predict the state-value function $V^{\pi_{\theta_a,\omega}}(c)$. The predicted value of critic $b_{\theta_c,\omega}(c)$ is called the 'baseline', which is then used to estimate the *advantage function*: $A^{\pi_\theta}(c,j) = Q^{\pi_{\theta_a,\omega}}(c,j) - V^{\pi_{\theta_a,\omega}}(c)$ because the total return R_t is an estimate of action-value function $Q(c_t, j_t)$. Instead of maximizing $Q(c_t, j_t)$ as done in REINFORCE, we maximize $A^{\pi_\theta}(c,j)$ with the following policy gradient:

$$\begin{aligned} \nabla_{\theta_a,\omega} J(\theta_a,\omega) = \\ \mathbb{E}[\nabla_{\theta_a,\omega} \log\pi_\theta(c,j) A^{\pi_\theta}(c,j)] \end{aligned} \tag{8}$$

And the critic is trained to minimize the square loss: $L_c(\theta_c, \omega) = (b_{\theta_c,\omega}(c_t) - R_t)^2$. This is

[3]We use the terminology of *copy mechanism* (originally named *pointer-generator*) in order to avoid confusion with the *pointer network* (Vinyals et al., 2015).

[4]Nallapati et al. (2017) selected sentences greedily to maximize the global summary-level ROUGE, whereas we match exactly 1 document sentence for each GT summary sentence based on the *individual* sentence-level score.

[5]Strictly speaking, this is a *Partially Observable Markov Decision Process* (POMDP). We approximate it as an MDP by assuming that the RNN hidden state contains all past info.

[6]In Eqn. 6, we use ROUGE-recall because we want the extracted sentence to contain as much information as possible for rewriting. Nevertheless, for Eqn. 7, ROUGE-F_1 is more suitable because the abstractor g is supposed to rewrite the extracted sentence d to be as *concise* as the ground truth s.

known as the *Advantage Actor-Critic* (A2C), a synchronous variant of A3C (Mnih et al., 2016). For more A2C details, please refer to the supp.

Intuitively, our RL training works as follow: If the extractor chooses a good sentence, after the abstractor rewrites it the ROUGE match would be high and thus the action is encouraged. If a bad sentence is chosen, though the abstractor still produces a compressed version of it, the summary would not match the ground truth and the low ROUGE score discourages this action. Our RL with a sentence-level agent is a novel attempt in neural summarization. We use RL as a saliency guide without altering the abstractor's language model, while previous work applied RL on the word-level, which could be prone to gaming the metric at the cost of language fluency.[7]

Learning how many sentences to extract: In a typical RL setting like game playing, an episode is usually terminated by the environment. On the other hand, in text summarization, the agent does not know in advance how many summary sentence to produce for a given article (since the desired length varies for different downstream applications). We make an important yet simple, intuitive adaptation to solve this: by adding a 'stop' action to the policy action space. In the RL training phase, we add another set of trainable parameters v_{EOE} (EOE stands for 'End-Of-Extraction') with the same dimension as the sentence representation. The pointer-network decoder treats v_{EOE} as one of the extraction candidates and hence naturally results in a stop action in the stochastic policy. We set the reward for the agent performing EOE to ROUGE-$1_{F_1}([\{g(d_{j_t})\}_t], [\{s_t\}_t])$; whereas for any extraneous, unwanted extraction step, the agent receives zero reward. The model is therefore encouraged to extract when there are still remaining ground-truth summary sentences (to accumulate intermediate reward), and learn to stop by optimizing a global ROUGE and avoiding extra extraction.[8] Overall, this modification allows dynamic decisions of number-of-sentences based on the input document, eliminates the need for tuning a fixed number of steps, and enables a data-driven adaptation for any specific dataset/application.

3.3 Repetition-Avoiding Reranking

Existing abstractive summarization systems on long documents suffer from generating repeating and redundant words and phrases. To mitigate this issue, See et al. (2017) propose the coverage mechanism and Paulus et al. (2018) incorporate tri-gram avoidance during beam-search at test-time. Our model without these already performs well because the summary sentences are generated from mutually exclusive document sentences, which naturally avoids redundancy. However, we do get a small further boost to the summary quality by removing a few 'across-sentence' repetitions, via a simple reranking strategy: At sentence-level, we apply the same beam-search tri-gram avoidance (Paulus et al., 2018). We keep all k sentence candidates generated by beam search, where k is the size of the beam. Next, we then rerank all k^n combinations of the n generated summary sentence beams. The summaries are reranked by the number of repeated N-grams, the smaller the better. We also apply the diverse decoding algorithm described in Li et al. (2016) (which has almost no computation overhead) so as to get the above approach to produce useful diverse reranking lists. We show how much the redundancy affects the summarization task in Sec. 6.2.

4 Related Work

Early summarization works mostly focused on extractive and compression based methods (Jing and McKeown, 2000; Knight and Marcu, 2000; Clarke and Lapata, 2010; Berg-Kirkpatrick et al., 2011; Filippova et al., 2015). Recent large-sized corpora attracted neural methods for abstractive summarization (Rush et al., 2015; Chopra et al., 2016). Some of the recent success in neural abstractive models include hierarchical attention (Nallapati et al., 2016), coverage (Suzuki and Nagata, 2016; Chen et al., 2016; See et al., 2017), RL based metric optimization (Paulus et al., 2018), graph-based attention (Tan et al., 2017), and the copy mechanism (Miao and Blunsom, 2016; Gu et al., 2016; See et al., 2017).

[7]During this RL training of the extractor, we keep the abstractor parameters fixed. Because the input sentences for the abstractor are extracted by an intermediate stochastic policy of the extractor, it is impossible to find the correct target summary for the abstractor to fit g with ML objective. Though it is possible to optimize the abstractor with RL, in out preliminary experiments we found that this does not improve the overall ROUGE, most likely because this RL optimizes at a sentence-level and can add across-sentence redundancy. We achieve SotA results without this abstractor-level RL.

[8]We use ROUGE-1 for terminal reward because it is a better measure of bag-of-words information (i.e., has all the important information been generated); while ROUGE-L is used as intermediate rewards since it is known for better measurement of language fluency within a local sentence.

Our model shares some high-level intuition with extract-then-compress methods. Earlier attempts in this paradigm used Hidden Markov Models and rule-based systems (Jing and McKeown, 2000), statistical models based on parse trees (Knight and Marcu, 2000), and integer linear programming based methods (Martins and Smith, 2009; Gillick and Favre, 2009; Clarke and Lapata, 2010; Berg-Kirkpatrick et al., 2011). Recent approaches investigated discourse structures (Louis et al., 2010; Hirao et al., 2013; Kikuchi et al., 2014; Wang et al., 2015), graph cuts (Qian and Liu, 2013), and parse trees (Li et al., 2014; Bing et al., 2015). For neural models, Cheng and Lapata (2016) used a second neural net to select words from an extractor's output. Our abstractor does not merely 'compress' the sentences but generatively produce novel words. Moreover, our RL bridges the extractor and the abstractor for end-to-end training.

Reinforcement learning has been used to optimize the non-differential metrics of language generation and to mitigate exposure bias (Ranzato et al., 2016; Bahdanau et al., 2017). Henß et al. (2015) use Q-learning based RL for extractive summarization. Paulus et al. (2018) use RL policy gradient methods for abstractive summarization, utilizing sequence-level metric rewards with curriculum learning (Ranzato et al., 2016) or weighted ML+RL mixed loss (Paulus et al., 2018) for stability and language fluency. We use sentence-level rewards to optimize the extractor while keeping our ML trained abstractor decoder fixed, so as to achieve the best of both worlds.

Training a neural network to use another fixed network has been investigated in machine translation for better decoding (Gu et al., 2017a) and real-time translation (Gu et al., 2017b). They used a fixed pretrained *translator* and applied policy gradient techniques to train another task-specific network. In question answering (QA), Choi et al. (2017) extract one sentence and then generate the answer from the sentence's vector representation with RL bridging. Another recent work attempted a new coarse-to-fine attention approach on summarization (Ling and Rush, 2017) and found desired sharp focus properties for scaling to larger inputs (though without metric improvements). Very recently (concurrently), Narayan et al. (2018) use RL for ranking sentences in pure extraction-based summarization and Çelikyilmaz et al. (2018) investigate multiple communicating encoder agents to enhance the copying abstractive summarizer.

Finally, there are some loosely-related recent works: Zhou et al. (2017) proposed *selective gate* to improve the attention in abstractive summarization. Tan et al. (2018) used an *extract-then-synthesis* approach on QA, where an extraction model predicts the important spans in the passage and then another synthesis model generates the final answer. Swayamdipta et al. (2017) attempted cascaded non-recurrent small networks on extractive QA, resulting a scalable, parallelizable model. Fan et al. (2017) added controlling parameters to adapt the summary to length, style, and entity preferences. However, none of these used RL to bridge the non-differentiability of neural models.

5 Experimental Setup

Please refer to the supplementary for full training details (all hyperparameter tuning was performed on the validation set). We use the CNN/Daily Mail dataset (Hermann et al., 2015) modified for summarization (Nallapati et al., 2016). Because there are two versions of the dataset, original text and entity anonymized, we show results on both versions of the dataset for a fair comparison to prior works. The experiment runs training and evaluation for each version separately. Despite the fact that the 2 versions have been considered separately by the summarization community as 2 different datasets, we use same hyper-parameter values for both dataset versions to show the generalization of our model. We also show improvements on the DUC-2002 dataset in a *test-only* setup.

5.1 Evaluation Metrics

For all the datasets, we evaluate standard ROUGE-1, ROUGE-2, and ROUGE-L (Lin, 2004) on full-length F_1 (with stemming) following previous works (Nallapati et al., 2017; See et al., 2017; Paulus et al., 2018). Following See et al. (2017), we also evaluate on METEOR (Denkowski and Lavie, 2014) for a more thorough analysis.

5.2 Modular Extractive vs. Abstractive

Our hybrid approach is capable of both extractive and abstractive (i.e., rewriting every sentence) summarization. The extractor alone performs extractive summarization. To investigate the effect of the recurrent extractor (rnn-ext), we implement a feed-forward extractive baseline ff-ext (details in supplementary). It is also possible to apply RL

Models	ROUGE-1	ROUGE-2	ROUGE-L	METEOR
Extractive Results				
lead-3 (See et al., 2017)	40.34	17.70	36.57	22.21
Narayan et al. (2018)	40.0	18.2	36.6	-
ff-ext	40.63	18.35	36.82	**22.91**
rnn-ext	40.17	18.11	36.41	22.81
rnn-ext + RL	**41.47**	**18.72**	**37.76**	22.35
Abstractive Results				
See et al. (2017) (w/o coverage)	36.44	15.66	33.42	16.65
See et al. (2017)	39.53	17.28	36.38	18.72
Fan et al. (2017) (controlled)	39.75	17.29	36.54	-
ff-ext + abs	39.30	17.02	36.93	20.05
rnn-ext + abs	38.38	16.12	36.04	19.39
rnn-ext + abs + RL	40.04	17.61	37.59	**21.00**
rnn-ext + abs + RL + rerank	**40.88**	**17.80**	**38.54**	20.38

Table 1: Results on the original, non-anonymized CNN/Daily Mail dataset. Adding RL gives statistically significant improvements for all metrics over non-RL rnn-ext models (and over the state-of-the-art See et al. (2017)) in both extractive and abstractive settings with $p < 0.01$. Adding the extra reranking stage yields statistically significant better results in terms of all ROUGE metrics with $p < 0.01$.

to extractor without using the abstractor (rnn-ext + RL).[9] Benefiting from the high modularity of our model, we can make our summarization system abstractive by simply applying the abstractor on the extracted sentences. Our abstractor rewrites each sentence and generates novel words from a large vocabulary, and hence every word in our overall summary is generated from scratch; making our full model categorized into the abstractive paradigm.[10] We run experiments on separately trained extractor/abstractor (ff-ext + abs, rnn-ext + abs) and the reinforced full model (rnn-ext + abs + RL) as well as the final reranking version (rnn-ext + abs + RL + rerank).

6 Results

For easier comparison, we show separate tables for the original-text vs. anonymized versions – Table 1 and Table 2, respectively. Overall, our model achieves strong improvements and the new state-of-the-art on both extractive and abstractive settings for both versions of the CNN/DM dataset (with some comparable results on the anonymized version). Moreover, Table 3 shows the generalization of our abstractive system to an out-of-domain test-only setup (DUC-2002), where our model achieves better scores than See et al. (2017).

6.1 Extractive Summarization

In the extractive paradigm, we compare our model with the extractive model from Nallapati et al. (2017) and a strong lead-3 baseline. For producing our summary, we simply concatenate the extracted sentences from the extractors. From Table 1 and Table 2, we can see that our feed-forward extractor out-performs the lead-3 baseline, empirically showing that our hierarchical sentence encoding model is capable of extracting salient sentences.[11] The reinforced extractor performs the best, because of the ability to get the summary-level reward and the reduced train-test mismatch of feeding the previous extraction decision. The improvement over lead-3 is consistent across both tables. In Table 2, it outperforms the previous best neural extractive model (Nallapati et al., 2017). In Table 1, our model also outperforms a recent, con-

Models	R-1	R-2	R-L
Extractive Results

rnn-ext + abs + RL + rerank	39.66	**15.85**	**37.34**

Table 2: ROUGE for anonymized CNN/DM.

[9]In this case the abstractor function $g(d) = d$.

[10]Note that the abstractive CNN/DM dataset does *not* include any human-annotated extraction label, and hence our models do not receive any direct extractive supervision.

[11]The ff-ext model outperforms rnn-ext possibly because it does not predict sentence ordering; thus is easier to optimize and the n-gram based metrics do not consider sentence ordering. Also note that in our MDP formulation, we cannot apply RL on ff-ext due to its historyless nature. Even if applied naively, there is no mean for the feed-forward model to learn the EOE described in Sec. 3.2.

Models	R-1	R-2	R-L
See et al. (2017)	37.22	15.78	33.90
rnn-ext + abs + RL	39.46	17.34	36.72

Table 3: Generalization to DUC-2002 (F1).

current work by Narayan et al. (2018), showing that our pointer-network extractor and reward formulations are very effective when combined with A2C RL.

6.2 Abstractive Summarization

After applying the abstractor, the ff-ext based model still out-performs the rnn-ext model. Both combined models exceed the pointer-generator model (See et al., 2017) without coverage by a large margin for all metrics, showing the effectiveness of our 2-step hierarchical approach: our method naturally avoids repetition by extracting multiple sentences with different keypoints.[12]

Moreover, after applying reinforcement learning, our model performs better than the best model of See et al. (2017) and the best ML trained model of Paulus et al. (2018). Our reinforced model outperforms the ML trained rnn-ext + abs baseline with statistical significance of $p < 0.01$ on all metrics for both version of the dataset, indicating the effectiveness of the RL training. Also, rnn-ext + abs + RL is statistically significant better than See et al. (2017) for all metrics with $p < 0.01$.[13] In the supplementary, we show the learning curve of our RL training, where the average reward goes up quickly after the extractor learns the End-of-Extract action and then stabilizes. For all the above models, we use standard greedy decoding and find that it performs well.

Reranking and Redundancy Although the extract-then-abstract approach inherently will not generate repeating sentences like other neural-decoders do, there might still be across-sentence redundancy because the abstractor is not aware of other extracted sentences when decoding one. Hence, we incorporate an optional reranking strategy described in Sec. 3.3. The improved ROUGE scores indicate that this successfully removes some remaining redundancies and hence produces more concise summaries. Our best abstractive model (rnn-ext + abs + RL + rerank) is clearly superior than the one of See et al. (2017). We are comparable on R-1 and R-2 but a 0.4 point improvement on R-L w.r.t. Paulus et al. (2018).[14] We also outperform the results of Fan et al. (2017) on both original and anonymized dataset versions. Several previous works have pointed out that extractive baselines are very difficult to beat (in terms of ROUGE) by an abstractive system (See et al., 2017; Nallapati et al., 2017). Note that our best model is one of the first abstractive models to outperform the lead-3 baseline on the original-text CNN/DM dataset. Our extractive experiment serves as a complementary analysis of the effect of RL with extractive systems.

[12]A trivial *lead-3* + *abs* baseline obtains ROUGE of (37.37, 15.59, 34.82), which again confirms the importance of our reinforce-based sentence selection.

[13]We calculate statistical significance based on the bootstrap test (Noreen, 1989; Efron and Tibshirani, 1994) with 100K samples. Output of Paulus et al. (2018) is not available so we couldn't test for statistical significance there.

	Relevance	Readability	Total
See et al. (2017)	120	128	248
rnn-ext + abs + RL + rerank	**137**	**133**	**270**
Equally good/bad	43	39	82

Table 4: Human Evaluation: pairwise comparison between our final model and See et al. (2017).

6.3 Human Evaluation

We also conduct human evaluation to ensure robustness of our training procedure. We measure *relevance* and *readability* of the summaries. Relevance is based on the summary containing important, salient information from the input article, being correct by avoiding contradictory/unrelated information, and avoiding repeated/redundant information. Readability is based on the summarys fluency, grammaticality, and coherence. To evaluate both these criteria, we design the following Amazon MTurk experiment: we randomly select 100 samples from the CNN/DM test set and ask the human testers (3 for each sample) to rank between summaries (for relevance and readability) produced by our model and that of See et al. (2017) (the models were anonymized and randomly shuffled), i.e. A is better, B is better, both are equally good/bad. Following previous work, the input article and ground truth summaries are also shown to the human participants in addition to the two model summaries.[15] From the results shown in Table 4, we can see that our model is better in both relevance and readability w.r.t. See et al. (2017).

[14]We do not list the scores of their pure RL model because they discussed its bad readability.

[15]We selected human annotators that were located in the US, had an approval rate greater than 95%, and had at least 10,000 approved HITs on record.

	Speed	
Models	total time (hr)	words / sec
(See et al., 2017)	12.9	14.8
rnn-ext + abs + RL	0.68	361.3
rnn-ext + abs + RL + rerank	2.00 (1.46 +0.54)	109.8

Table 5: Speed comparison with See et al. (2017).

6.4 Speed Comparison

Our two-stage extractive-abstractive hybrid model is not only the SotA on summary quality metrics, but more importantly also gives a significant speed-up in both train and test time over a strong neural abstractive system (See et al., 2017).[16]

Our full model is composed of a extremely fast extractor and a parallelizable abstractor, where the computation bottleneck is on the abstractor, which has to generate summaries with a large vocabulary from scratch.[17] The main advantage of our abstractor at decoding time is that we can first compute all the extracted sentences for the document, and then abstract every sentence concurrently (*in parallel*) to generate the overall summary. In Table 5, we show the substantial test-time speed-up of our model compared to See et al. (2017).[18] We calculate the total decoding time for producing all summaries for the test set.[19] Due to the fact that the main test-time speed bottleneck of RNN language generation model is that the model is constrained to generate one word at a time, the total decoding time is dependent on the number of total words generated; we hence also report the decoded words per second for a fair comparison. Our model without reranking is extremely fast. From Table 5 we can see that we achieve a speed up of 18x in time and 24x in word generation rate. Even after adding the (optional) reranker, we still maintain a 6-7x speed-up (and hence a user can choose to use the reranking component depending on their downstream application's speed requirements).[20]

[16]The only publicly available code with a pretrained model for neural summarization which we can test the speed.

[17]The time needed for extractor is negligible w.r.t. the abstractor because it does not require large matrix multiplication for generating every word. Moreover, with convolutional encoder at word-level made parallelizable by the hierarchical rnn-ext, our model is scalable for very long documents.

[18]For details of training speed-up, please see the supp.

[19]We time the model of See et al. (2017) using beam size of 4 (used for their best-reported scores). Without beam-search, it gets significantly worse ROUGE of (36.62, 15.12, 34.08), so we do not compare speed-ups w.r.t. that version.

[20]Most of the recent neural abstractive summarization systems are of similar algorithmic complexity to that of See et al. (2017). The main differences such as the training objective (ML vs. RL) and copying (soft/hard) has negligible test runtime compared to the slowest component: the long-summary attentional-decoder's sequential generation; and this is the component that we substantially speed up via our parallel sentence decoding with sentence-selection RL.

	Novel N-gram (%)			
Models	1-gm	2-gm	3-gm	4-gm
See et al. (2017)	0.1	2.2	6.0	9.7
rnn-ext + abs + RL + rerank	0.3	10.0	21.7	31.6
reference summaries	10.8	47.5	68.2	78.2

Table 6: Abstractiveness: novel n-gram counts.

7 Analysis

7.1 Abstractiveness

We compute an abstractiveness score (See et al., 2017) as the ratio of novel n-grams in the generated summary that are not present in the input document. The results are shown in Table 6: our model rewrites substantially more abstractive summaries than previous work. A potential reason for this is that when trained with individual sentence-pairs, the abstractor learns to drop more document words so as to write individual summary sentences as concise as human-written ones; thus the improvement in multi-gram novelty.

7.2 Qualitative Analysis on Output Examples

We show examples of how our best model selects sentences and then rewrites them. In the supplementary Figure 2 and Figure 3, we can see how the abstractor rewrites the extracted sentences concisely while keeping the mentioned facts. Adding the reranker makes the output more compact globally. We observe that when rewriting longer text, the abstractor would have many facts to choose from (Figure 3 sentence 2) and this is where the reranker helps avoid redundancy across sentences.

8 Conclusion

We propose a novel sentence-level RL model for abstractive summarization, which makes the model aware of the word-sentence hierarchy. Our model achieves the new state-of-the-art on both CNN/DM versions as well a better generalization on test-only DUC-2002, along with a significant speed-up in training and decoding.

Soft Layer-Specific Multi-Task Summarization with Entailment and Question Generation

Han Guo[*] **Ramakanth Pasunuru**[*] **Mohit Bansal**

{hanguo, ram, mbansal}@cs.unc.edu

Abstract

An accurate abstractive summary of a document should contain all its salient information and should be logically entailed by the input document. We improve these important aspects of abstractive summarization via multi-task learning with the auxiliary tasks of question generation and entailment generation, where the former teaches the summarization model how to look for salient questioning-worthy details, and the latter teaches the model how to rewrite a summary which is a directed-logical subset of the input document. We also propose novel multi-task architectures with high-level (semantic) layer-specific sharing across multiple encoder and decoder layers of the three tasks, as well as soft-sharing mechanisms (and show performance ablations and analysis examples of each contribution). Overall, we achieve statistically significant improvements over the state-of-the-art on both the CNN/DailyMail and Gigaword datasets, as well as on the DUC-2002 transfer setup. We also present several quantitative and qualitative analysis studies of our model's learned saliency and entailment skills.

1 Introduction

Abstractive summarization is the challenging NLG task of compressing and rewriting a document into a short, relevant, salient, and coherent summary. It has numerous applications such as summarizing storylines, event understanding, etc. As compared to extractive or compressive summarization (Jing and McKeown, 2000; Knight and Marcu, 2002; Clarke and Lapata, 2008; Filippova et al., 2015; Henß et al., 2015), abstractive summaries are based on rewriting as opposed to selecting. Recent end-to-end, neural sequence-to-sequence models and larger datasets have allowed substantial progress on the abstractive task, with ideas ranging from copy-pointer mechanism and redundancy coverage, to metric reward based reinforcement learning (Rush et al., 2015; Chopra et al., 2016; Nallapati et al., 2016; See et al., 2017).

Despite these strong recent advancements, there is still a lot of scope for improving the summary quality generated by these models. A good rewritten summary is one that contains all the salient information from the document, is logically followed (entailed) by it, and avoids redundant information. The redundancy aspect was addressed by coverage models (Suzuki and Nagata, 2016; Chen et al., 2016; Nallapati et al., 2016; See et al., 2017), but we still need to teach these models about how to better detect salient information from the input document, as well as about better logically-directed natural language inference skills.

In this work, we improve abstractive text summarization via soft, high-level (semantic) layer-specific multi-task learning with two relevant auxiliary tasks. The first is that of document-to-question generation, which teaches the summarization model about what are the right questions to ask, which in turn is directly related to what the salient information in the input document is. The second auxiliary task is a premise-to-entailment generation task to teach it how to rewrite a summary which is a directed-logical subset of (i.e., logically follows from) the input document, and contains no contradictory or unrelated information. For the question generation task, we use the SQuAD dataset (Rajpurkar et al., 2016), where we learn to generate a question given a sentence containing the answer, similar to the recent work

[*] Equal contribution.

by Du et al. (2017). Our entailment generation task is based on the recent SNLI classification dataset and task (Bowman et al., 2015), converted to a generation task (Pasunuru and Bansal, 2017).

Further, we also present novel multi-task learning architectures based on multi-layered encoder and decoder models, where we empirically show that it is substantially better to share the higher-level semantic layers between the three aforementioned tasks, while keeping the lower-level (lexico-syntactic) layers unshared. We also explore different ways to optimize the shared parameters and show that 'soft' parameter sharing achieves higher performance than hard sharing.

Empirically, our soft, layer-specific sharing model with the question and entailment generation auxiliary tasks achieves statistically significant improvements over the state-of-the-art on both the CNN/DailyMail and Gigaword datasets. It also performs significantly better on the DUC-2002 transfer setup, demonstrating its strong generalizability as well as the importance of auxiliary knowledge in low-resource scenarios. We also report improvements on our auxiliary question and entailment generation tasks over their respective previous state-of-the-art. Moreover, we significantly decrease the training time of the multi-task models by initializing the individual tasks from their pretrained baseline models. Finally, we present human evaluation studies as well as detailed quantitative and qualitative analysis studies of the improved saliency detection and logical inference skills learned by our multi-task model.

2 Related Work

Automatic text summarization has been progressively improving over the time, initially more focused on extractive and compressive models (Jing and McKeown, 2000; Knight and Marcu, 2002; Clarke and Lapata, 2008; Filippova et al., 2015; Kedzie et al., 2015), and moving more towards compressive and abstractive summarization based on graphs and concept maps (Giannakopoulos, 2009; Ganesan et al., 2010; Falke and Gurevych, 2017) and discourse trees (Gerani et al., 2014), syntactic parse trees (Cheung and Penn, 2014; Wang et al., 2013), and Abstract Meaning Representations (AMR) (Liu et al., 2015; Dohare and Karnick, 2017). Recent work has also adopted machine translation inspired neural seq2seq models for abstractive summarization with advances in hierarchical, distractive, saliency, and graph-attention modeling (Rush et al., 2015; Chopra et al., 2016; Nallapati et al., 2016; Chen et al., 2016; Tan et al., 2017). Paulus et al. (2018) and Henß et al. (2015) incorporated recent advances from reinforcement learning. Also, See et al. (2017) further improved results via pointer-copy mechanism and addressed the redundancy with coverage mechanism.

Multi-task learning (MTL) is a useful paradigm to improve the generalization performance of a task with related tasks while sharing some common parameters/representations (Caruana, 1998; Argyriou et al., 2007; Kumar and Daumé III, 2012). Several recent works have adopted MTL in neural models (Luong et al., 2016; Misra et al., 2016; Hashimoto et al., 2017; Pasunuru and Bansal, 2017; Ruder et al., 2017; Kaiser et al., 2017). Moreover, some of the above works have investigated the use of shared vs unshared sets of parameters. On the other hand, we investigate the importance of soft parameter sharing and high-level versus low-level layer-specific sharing.

Our previous workshop paper (Pasunuru et al., 2017) presented some preliminary results for multi-task learning of textual summarization with entailment generation. This current paper has several major differences: (1) We present question generation as an additional effective auxiliary task to enhance the important complementary aspect of saliency detection; (2) Our new high-level layer-specific sharing approach is significantly better than alternative layer-sharing approaches (including the decoder-only sharing by Pasunuru et al. (2017)); (3) Our new soft sharing parameter approach gives stat. significant improvements over hard sharing; (4) We propose a useful idea of starting multi-task models from their pretrained baselines, which significantly speeds up our experiment cycle[1]; (5) For evaluation, we show diverse improvements of our soft, layer-specific MTL model (over state-of-the-art pointer+coverage baselines) on the CNN/DailyMail, Gigaword, as well as DUC datasets; we also report human evaluation plus analysis examples of learned saliency and entailment skills; we also report improvements on the auxiliary question and entailment generation tasks over their respective previous state-of-the-art.

[1]About 4-5 days for Pasunuru et al. (2017) approach vs. only 10 hours for us. This will allow the community to try many more multi-task training and tuning ideas faster.

In our work, we use a question generation task to improve the saliency of abstractive summarization in a multi-task setting. Using the SQuAD dataset (Rajpurkar et al., 2016), we learn to generate a question given the sentence containing the answer span in the comprehension (similar to Du et al. (2017)). For the second auxiliary task of entailment generation, we use the generation version of the RTE classification task (Dagan et al., 2006; Lai and Hockenmaier, 2014; Jimenez et al., 2014; Bowman et al., 2015). Some previous work has explored the use of RTE for redundancy detection in summarization by modeling graph-based relationships between sentences to select the most non-redundant sentences (Mehdad et al., 2013; Gupta et al., 2014), whereas our approach is based on multi-task learning.

3 Models

First, we introduce our pointer+coverage baseline model and then our two auxiliary tasks: question generation and entailment generation (and finally the multi-task learning models in Sec. 4).

3.1 Baseline Pointer+Coverage Model

We use a sequence-attention-sequence model with a 2-layer bidirectional LSTM-RNN encoder and a 2-layer uni-directional LSTM-RNN decoder, along with Bahdanau et al. (2015) style attention. Let $x = \{x_1, x_2, ..., x_m\}$ be the source document and $y = \{y_1, y_2, ..., y_n\}$ be the target summary. The output summary generation vocabulary distribution conditioned over the input source document is $P_v(y|x;\theta) = \prod_{t=1}^{n} p_v(y_t|y_{1:t-1}, x; \theta)$. Let the decoder hidden state be s_t at time step t and let c_t be the context vector which is defined as a weighted combination of encoder hidden states. We concatenate the decoder's (last) RNN layer hidden state s_t and context vector c_t and apply a linear transformation, and then project to the vocabulary space by another linear transformation. Finally, the conditional vocabulary distribution at each time step t of the decoder is defined as:

$$p_v(y_t|y_{1:t-1}, x; \theta) = \text{sfm}(V_p(W_f[s_t; c_t]+b_f)+b_p) \tag{1}$$

where, W_f, V_p, b_f, b_p are trainable parameters, and $\text{sfm}(\cdot)$ is the softmax function.

Pointer-Generator Networks Pointer mechanism (Vinyals et al., 2015) helps in directly copying the words from the source sequence during target sequence generation, which is a good fit for a task like summarization. Our pointer mechanism approach is similar to See et al. (2017), who use a soft switch based on the generation probability $p_g = \sigma(W_g c_t + U_g s_t + V_g e_{w_{t-1}} + b_g)$, where $\sigma(\cdot)$ is a sigmoid function, W_g, U_g, V_g and b_g are parameters learned during training. $e_{w_{t-1}}$ is the previous time step output word embedding. The final word distribution is $P_f(y) = p_g \cdot P_v(y) + (1-p_g) \cdot P_c(y)$, where P_v vocabulary distribution is as shown in Eq. 1, and copy distribution P_c is based on the attention distribution over source document words.

Coverage Mechanism Following previous work (See et al., 2017), coverage helps alleviate the issue of word repetition while generating long summaries. We maintain a coverage vector $\hat{c}_t = \sum_{t=0}^{t-1} \alpha_t$ that sums over all of the previous time steps attention distributions α_t, and this is added as input to the attention mechanism. Coverage loss is $L_{cov}(\theta) = \sum_t \sum_i min(\alpha_{t,i}, \hat{c}_{t,i})$. Finally, the total loss is a weighted combination of cross-entropy loss and coverage loss:

$$L(\theta) = -\log P_f(y) + \lambda L_{cov}(\theta) \tag{2}$$

where λ is a tunable hyperparameter.

3.2 Two Auxiliary Tasks

Despite the strengths of the strong model described above with attention, pointer, and coverage, a good summary should also contain maximal salient information and be a directed logical entailment of the source document. We teach these skills to the abstractive summarization model via multi-task training with two related auxiliary tasks: question generation task and entailment generation.

Question Generation The task of question generation is to generate a question from a given input sentence, which in turn is related to the skill of being able to find the important salient information to ask questions about. First the model has to identify the important information present in the given sentence, then it has to frame (generate) a question based on this salient information, such that, given the sentence and the question, one has to be able to predict the correct answer (salient information in this case). A good summary should also be able to find and extract all the salient information in the given source document, and hence we incorporate such capabilities into our abstractive text summarization model by multi-task learning it with a question generation task, sharing some common parameters/representations (see more details in Sec. 4). For setting up the question generation task, we follow Du et al. (2017) and use the SQuAD dataset to extract sentence-question pairs. Next, we use the same sequence-to-sequence model architecture as our summarization model. Note that even though our question generation task is generating one question at a time[2], our multi-task framework (see Sec. 4) is set up in such a way that the sentence-level knowledge from this auxiliary task can help the document-level primary (summarization) task to generate multiple salient facts – by sharing high-level semantic layer representations. See Sec. 7 and Table 10 for a quantitative evaluation showing that the multi-task model can find multiple (and more) salient phrases in the source document. Also see Sec. 7 (and supp) for challenging qualitative examples where baseline and SotA models only recover a small subset of salient information but our multi-task model with question generation is able to detect more of the important information.

Entailment Generation The task of entailment generation is to generate a hypothesis which is entailed by (or logically follows from) the given premise as input. In summarization, the generation decoder also needs to generate a summary that is entailed by the source document, i.e., does not contain any contradictory or unrelated/extraneous information as compared to the input document. We again incorporate such inference capabilities into the summarization model via multi-task learning, sharing some common representations/parameters between our summarization and entailment generation model (more details in Sec. 4). For this task, we use the entailment-labeled pairs from the SNLI dataset (Bowman et al., 2015) and set it up as a generation task (using the same strong model architecture as our abstractive summarization model). See Sec. 7 and Table 9 for a quantitative evaluation showing that the multi-task model is better entailed by the source document and has fewer extraneous facts. Also see Sec. 7 and supplementary for qualitative examples of how our multi-task model with the entailment auxiliary task is able to generate more logically-entailed summaries than the baseline and SotA models, which instead produce extraneous, unrelated words not present (in any paraphrased form) in the source document.

[2]We also tried to generate all the questions at once from the full document, but we obtained low accuracy because of this task's challenging nature and overall less training data.

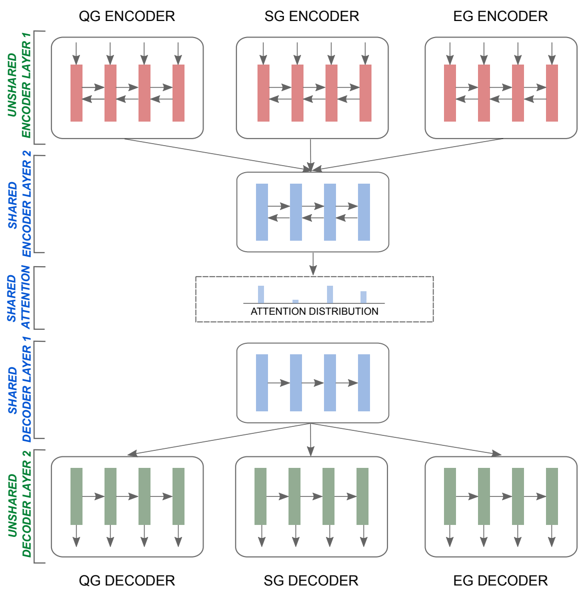

Figure 1: Overview of our multi-task model with parallel training of three tasks: abstractive summary generation (SG), question generation (QG), and entailment generation (EG). We share the 'blue' color representations across all the three tasks, i.e., second layer of encoder, attention parameters, and first layer of decoder.

4 Multi-Task Learning

We employ multi-task learning for parallel training of our three tasks: abstractive summarization, question generation, and entailment generation. In this section, we describe our novel layer-specific, soft-sharing approaches and other multi-task learning details.

4.1 Layer-Specific Sharing Mechanism

Simply sharing all parameters across the related tasks is not optimal, because models for different tasks have different input and output distributions, esp. for low-level vs. high-level parameters. Therefore, related tasks should share some common representations (e.g., high-level information), as well as need their own individual task-specific representations (esp. low-level information). To this end, we allow different components of model parameters of related tasks to be shared vs. unshared, as described next.

Encoder Layer Sharing: Belinkov et al. (2017) observed that lower layers (i.e., the layers closer to the input words) of RNN cells in a seq2seq machine translation model learn to represent word structure, while higher layers (farther from input) are more focused on high-level semantic meanings (similar to findings in the computer vision community for image features (Zeiler and Fergus, 2014)). We believe that while textual summarization, question generation, and entailment generation have different training data distributions and low-level representations, they can still benefit from sharing their models' high-level components (e.g., those that capture the skills of saliency and inference). Thus, we keep the lower-level layer (i.e., first layer closer to input words) of the 2-layer encoder of all three tasks unshared, while we share the higher layer (second layer in our model as shown in Fig. 1) across the three tasks.

Decoder Layer Sharing: Similarly for the decoder, lower layers (i.e., the layers closer to the output words) learn to represent word structure for generation, while higher layers (farther from output) are more focused on high-level semantic meaning. Hence, we again share the higher level components (first layer in the decoder far from output as show in Fig. 1), while keeping the lower layer (i.e., second layer) of decoders of all three tasks unshared.

Attention Sharing: As described in Sec. 3.1, the attention mechanism defines an attention distribution over high-level layer encoder hidden states and since we share the second, high-level (semantic) layer of all the encoders, it is intuitive to share the attention parameters as well.

4.2 Soft vs. Hard Parameter Sharing

Hard-sharing: In the most common multi-task learning hard-sharing approach, the parameters to be shared are forced to be the same. As a result, gradient information from multiple tasks will directly pass through shared parameters, hence forcing a common space representation for all the related tasks. **Soft-sharing**: In our soft-sharing approach, we encourage shared parameters to be close in representation space by penalizing their l_2 distances. Unlike hard sharing, this approach gives more flexibility for the tasks by only loosely coupling the shared space representations. We minimize the following loss function for the primary task in soft-sharing approach:

$$L(\theta) = -\log P_f(y) + \lambda L_{cov}(\theta) + \gamma \|\theta_s - \psi_s\| \quad (3)$$

where γ is a hyperparameter, θ represents the primary summarization task's full parameters, while θ_s and ψ_s represent the shared parameter subset between the primary and auxiliary tasks.

4.3 Fast Multi-Task Training

During multi-task learning, we alternate the mini-batch optimization of the three tasks, based on a tunable 'mixing ratio' $\alpha_s : \alpha_q : \alpha_e$; i.e., optimizing the summarization task for α_s mini-batches followed by optimizing the question generation task for α_q mini-batches, followed by entailment generation task for α_e mini-batches (and for 2-way versions of this, we only add one auxiliary task at a time). We continue this process until all the models converge. Also, importantly, instead of training from scratch, we start the primary task (summarization) from a 90%-converged model of its baseline to make the training process faster. We observe that starting from a fully-converged baseline makes the model stuck in a local minimum. In addition, we also start all auxiliary models from their 90%-converged baselines, as we found that starting the auxiliary models from scratch has a chance to pull the primary model's shared parameters towards randomly-initialized auxiliary model's shared parameters.

5 Experimental Setup

Datasets: We use CNN/DailyMail dataset (Hermann et al., 2015; Nallapati et al., 2016) and Gigaword (Rush et al., 2015) datasets for summarization, and the Stanford Natural Language Inference (SNLI) corpus (Bowman et al., 2015) and the Stanford Question Answering Dataset (SQuAD) (Rajpurkar et al., 2016) datasets for our entailment and question generation tasks, resp. We also show generalizability/transfer results on DUC-2002 with our CNN/DM trained models. Supplementary contains dataset details.

Evaluation Metrics: We use the standard ROUGE evaluation package (Lin, 2004) for reporting the results on all of our summarization models. Following previous work (Chopra et al., 2016; Nallapati et al., 2016), we use ROUGE full-length F1 variant for all our results. Following See et al. (2017), we also report METEOR (Denkowski and Lavie, 2014) using the MS-COCO evaluation script (Chen et al., 2015).

Human Evaluation Criteria: We used Amazon MTurk to perform human evaluation of summary *relevance* and *readability*. We selected human annotators that were located in the US, had an ap-

proval rate greater than 95%, and had at least 10,000 approved HITs. For the pairwise model comparisons discussed in Sec. 6.2, we showed the annotators the input article, the ground truth summary, and the two model summaries (randomly shuffled to anonymize model identities) – we then asked them to choose the better among the two model summaries or choose 'Not-Distinguishable' if both summaries are equally good/bad. Instructions for relevance were defined based on the summary containing salient/important information from the given article, being correct (i.e., avoiding contradictory/unrelated information), and avoiding redundancy. Instructions for readability were based on the summary's fluency, grammaticality, and coherence.

Training Details All our soft/hard and layer-specific sharing decisions were made on the validation/development set. Details of RNN hidden state sizes, Adam optimizer, mixing ratios, etc. are provided in the supplementary for reproducibility.

6 Results

6.1 Summarization (Primary Task) Results

Pointer+Coverage Baseline We start from the strong model of See et al. (2017).[3] Table 1 shows that our baseline model performs better than or comparable to See et al. (2017).[4] On Gigaword dataset, our baseline model (with pointer only, since coverage not needed for this single-sentence summarization task) performs better than all previous works, as shown in Table 2.

Multi-Task with Entailment Generation We first perform multi-task learning between abstractive summarization and entailment generation with soft-sharing of parameters as discussed in Sec. 4. Table 1 and Table 2 shows that this multi-task setting is better than our strong baseline models and the improvements are statistically significant on all metrics[5] on both CNN/DailyMail ($p < 0.01$ in ROUGE-1/ROUGE-L/METEOR and $p < 0.05$ in ROUGE-2) and Gigaword ($p < 0.01$ on all metrics) datasets, showing that entailment generation task is inducing useful inference skills to the summarization task (also see analysis examples in Sec. 7).

Multi-Task with Question Generation For multi-task learning with question generation, the improvements are statistically significant in ROUGE-1 ($p < 0.01$), ROUGE-L ($p < 0.05$), and METEOR ($p < 0.01$) for CNN/DailyMail and in all metrics ($p < 0.01$) for Gigaword, compared to the respective baseline models. Also, Sec. 7 presents quantitative and qualitative analysis of this model's improved saliency.[6]

[3]We use two layers so as to allow our high- versus low-level layer sharing intuition. Note that this does not increase the parameter size much (23M versus 22M for See et al. (2017)).

[4]As mentioned in the github for See et al. (2017), their publicly released pretrained model produces the lower scores that we represent by † in Table 1.

[5]Stat. significance is computed via bootstrap test (Noreen, 1989; Efron and Tibshirani, 1994) with 100K samples.

[6]In order to verify that our improvements were from the auxiliary tasks' specific character/capabilities and not just due to adding more data, we separately trained word embeddings on each auxiliary dataset (i.e., SNLI and SQuAD) and incorporated them into the summarization model. We found that both our 2-way multi-task models perform sig-

Models	Relevance	Readability	Total

Models	Relevance	Readability	Total
MTL wins	33	32	65
Baseline wins	22	22	44
Non-distinguish.	45	46	91

Table 4: Gigaword Human Evaluation: pairwise comparison between our 3-way multi-task (MTL) model w.r.t. our baseline.

Multi-Task with Entailment and Question Generation Finally, we perform multi-task learning with all three tasks together, achieving the best of both worlds (inference skills and saliency). Table 1 and Table 2 show that our full multi-task model achieves the best scores on CNN/DailyMail and Gigaword datasets, and the improvements are statistically significant on all metrics on both CNN/DailyMail ($p < 0.01$ in ROUGE-1/ROUGE-L/METEOR and $p < 0.02$ in ROUGE-2) and Gigaword ($p < 0.01$ on all metrics). Finally, our 3-way multi-task model (with both entailment and question generation) outperforms the publicly-available pretrained result (†) of the previous SotA (See et al., 2017) with stat. significance ($p < 0.01$), as well the higher-reported results ($\star$) on ROUGE-1/ROUGE-2 ($p < 0.01$).

6.2 Human Evaluation

We also conducted a blind human evaluation on Amazon MTurk for relevance and readability, based on 100 samples, for both CNN/DailyMail and Gigaword (see instructions in Sec. 5). Table. 3 shows the CNN/DM results where we do pairwise comparison between our 3-way multi-task model's output summaries w.r.t. our baseline summaries and w.r.t. See et al. (2017) summaries. As shown, our 3-way multi-task model achieves both higher relevance and higher readability scores w.r.t. the baseline. W.r.t. See et al. (2017), our MTL model is higher in relevance scores but a bit lower in readability scores (and is higher in terms of total aggregate scores). One potential reason for this lower readability score is that our entailment generation auxiliary task encourages our summarization model to rewrite more and to be more abstractive than See et al. (2017) – see abstractiveness results in Table 11.

We also show human evaluation results on the Gigaword dataset in Table 4 (again based on pairwise comparisons for 100 samples), where we see that our MTL model is better than our state-of-the-art baseline on both relevance and readability.[7]

nificantly better than these models using the auxiliary word-embeddings, suggesting that merely adding more data in not enough.

Models	R-1	R-2	R-L
See et al. (2017)	34.30	14.25	30.82
Baseline	35.96	15.91	32.92
Multi-Task (EG + QG)	36.73	16.15	33.58

Table 5: ROUGE F1 scores on DUC-2002.

6.3 Generalizability Results (DUC-2002)

Next, we also tested our model's generalizability/transfer skills, where we take the models trained on CNN/DailyMail and directly test them on DUC-2002. We take our baseline and 3-way multi-task models, plus the pointer-coverage model from See et al. (2017).[8] We only re-tune the beam-size for each of these three models separately (based on DUC-2003 as the validation set).[9] As shown in Table 5, our multi-task model achieves statistically significant improvements over the strong baseline ($p < 0.01$ in ROUGE-1 and ROUGE-L) and the pointer-coverage model from See et al. (2017) ($p < 0.01$ in all metrics). This demonstrates that our model is able to generalize well and that the auxiliary knowledge helps more in low-resource scenarios.

6.4 Auxiliary Task Results

In this section, we discuss the individual/separated performance of our auxiliary tasks.

Entailment Generation We use the same architecture as described in Sec. 3.1 with pointer mech-

[7]Note that we did not have output files of any previous work's model on Gigaword; however, our baseline is already a strong state-of-the-art model as shown in Table 2.

[8]We use the publicly-available pretrained model from See et al. (2017)'s github for these DUC transfer results, which produces the † results in Table 1. All other comparisons and analysis in our paper are based on their higher $\star$ results.

[9]We follow previous work which has shown that larger beam values are better and feasible for DUC corpora. However, our MTL model still achieves stat. significant improvements ($p < 0.01$ in all metrics) over See et al. (2017) without beam retuning (i.e., with beam $= 4$).

Models	M	C	R	B
Pasunuru&Bansal (2017)	29.6	117.8	62.4	40.6
Our 1-layer pointer EG	32.4	139.3	65.1	43.6
Our 2-layer pointer EG	32.3	140.0	64.4	43.7

Models	M	C	R	B
Du et al. (2017)	15.2	-	38.0	10.8
Our 1-layer pointer QG	15.4	75.3	36.2	9.2
Our 2-layer pointer QG	17.5	95.3	40.1	13.8

Table 7: Performance of our pointer-based question generation (QG) model w.r.t. previous work.

anism, and Table 6 compares our model's performance to Pasunuru and Bansal (2017). Our pointer mechanism gives a performance boost, since the entailment generation task involves copying from the given premise sentence, whereas the 2-layer model seems comparable to the 1-layer model. Also, the supplementary shows some output examples from our entailment generation model.

Question Generation Again, we use same architecture as described in Sec. 3.1 along with pointer mechanism for the task of question generation. Table 7 compares the performance of our model w.r.t. the state-of-the-art Du et al. (2017). Also, the supplementary shows some output examples from our question generation model.

7 Ablation and Analysis Studies

Soft-sharing vs. Hard-sharing As described in Sec. 4.2, we choose soft-sharing over hard-sharing because of the more expressive parameter sharing it provides to the model. Empirical results in Table. 8 prove that soft-sharing method is statistically significantly better than hard-sharing with $p < 0.001$ in all metrics.[10]

Comparison of Different Layer-Sharing Methods We also conducted ablation studies among various layer-sharing approaches. Table 8 shows results for soft-sharing models with decoder-only sharing (D1+D2; similar to Pasunuru et al. (2017)) as well as lower-layer sharing (encoder layer 1 + decoder layer 2, with and without attention shared). As shown, our final model (high-level semantic layer sharing E2+Attn+D1) outperforms

Models	R-1	R-2	R-L	M
Final Model	**39.81**	**17.64**	**36.54**	**18.54**
SOFT-VS.-HARD SHARING				
Hard-sharing	39.51	17.44	36.33	18.21
LAYER SHARING METHODS				
D1+D2	39.62	17.49	36.44	18.34
E1+D2	39.51	17.51	36.37	18.15
E1+Attn+D2	39.32	17.36	36.11	17.88

Table 8: Ablation studies comparing our final multi-task model with hard-sharing and different alternative layer-sharing methods. Here E1, E2, D1, D2, Attn refer to parameters of the first/second layer of encoder/decoder, and attention parameters. Improvements of final model upon ablation experiments are all stat. signif. with $p < 0.05$.

Models	Average Entailment Probability
Baseline	0.907
Multi-Task (EG)	0.912

Table 9: Entailment classification results of our baseline vs. EG-multi-task model ($p < 0.001$).

these alternate sharing methods in all metrics with statistical significance ($p < 0.05$).[11]

Quantitative Improvements in Entailment We employ a state-of-the-art entailment classifier (Chen et al., 2017), and calculate the average of the entailment probability of each of the output summary's sentences being entailed by the input source document. We do this for output summaries of our baseline and 2-way-EG multi-task model (with entailment generation). As can be seen in Table 9, our multi-task model improves upon the baseline in the aspect of being entailed by the source document (with statistical significance $p < 0.001$). Further, we use the Named Entity Recognition (NER) module from CoreNLP (Manning et al., 2014) to compute the number of times the output summary contains extraneous facts (i.e., named entities as detected by the NER system) that are not present in the source documents, based on the intuition that a well-entailed summary should not contain unrelated information not followed from the input premise. We found that our 2-way MTL model with entailment generation reduces this extraneous count by 17.2% w.r.t. the baseline. The qualitative examples below further discuss this issue of generating unrelated information.

Quantitative Improvements in Saliency Detection For our saliency evaluation, we used the

[10]In the interest of space, most of the analyses are shown for CNN/DailyMail experiments, but we observed similar trends for the Gigaword experiments as well.

[11]Note that all our soft and layer sharing decisions were strictly made on the dev/validation set (see Sec. 5).

Models	Average Match Rate
Baseline	27.75 %
Multi-Task (QG)	28.06 %

Table 10: Saliency classification results of our baseline vs. QG-multi-task model ($p < 0.01$).

Models	2-gram	3-gram	4-gram
See et al. (2017)	2.24	6.03	9.72
MTL (3-way)	2.84	6.83	10.66

Table 11: Abstractiveness: novel n-gram percent.

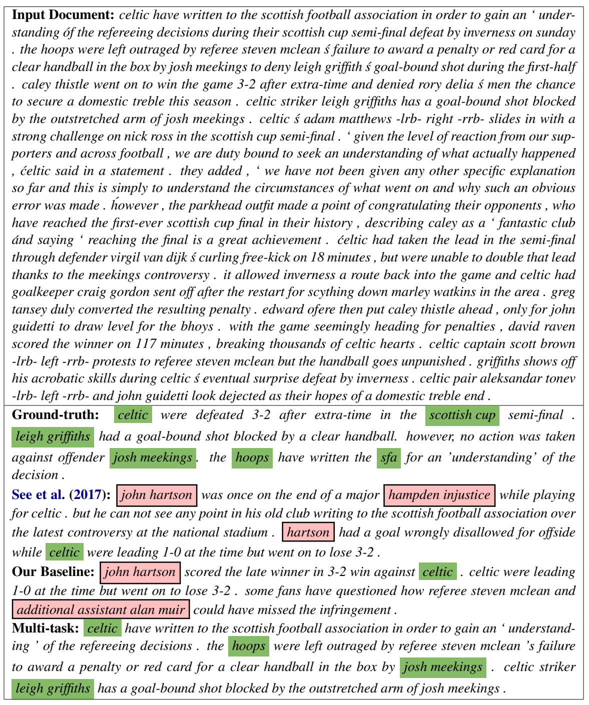
answer-span prediction classifier from Pasunuru and Bansal (2018) trained on SQuAD (Rajpurkar et al., 2016) as the keyword detection classifier. We then annotate the ground-truth and model summaries with this keyword classifier and compute the % match, i.e., how many salient words from the ground-truth summary were also generated in the model summary. The results are shown in Table 10, where the 2-way-QG MTL model (with question generation) versus baseline improvement is stat. significant ($p < 0.01$). Moreover, we found 93 more cases where our 2-way-QG MTL model detects 2 or more additional salient keywords than the pointer baseline model (as opposed to vice versa), showing that sentence-level question generation task is helping the document-level summarization task in finding more salient terms.

Qualitative Examples on Entailment and Saliency Improvements Fig. 2 presents an example of output summaries generated by See et al. (2017), our baseline, and our 3-way multi-task model. See et al. (2017) and our baseline models generate phrases like "john hartson" and "hampden injustice" that don't appear in the input document, hence they are not entailed by the input.[12] Moreover, both models missed salient information like "josh meekings", "leigh griffiths", and "hoops", that our multi-task model recovers.[13] Hence, our 3-way multi-task model generates summaries that are both better at logical entailment and contain more salient information. We refer to supplementary Fig. 3 for more details and similar examples for separated 2-way multi-task models (supplementary Fig. 1, Fig. 2).

Abstractiveness Analysis As suggested in See et al. (2017), we also compute the abstractiveness score as the number of novel n-grams between the model output summary and source document. As shown in Table 11, our multi-task model (EG + QG) is more abstractive than See et al. (2017).

[12]These extra, non-entailed unrelated/contradictory information are not present at all in any paraphrase form in the input document.

[13]We consider the fill-in-the-blank highlights annotated by human on CNN/DailyMail dataset as salient information.



Input Document: *celtic have written to the scottish football association in order to gain an ‘ understanding ́of the refereeing decisions during their scottish cup semi-final defeat by inverness on sunday . the hoops were left outraged by referee steven mclean ś failure to award a penalty or red card for a clear handball in the box by josh meekings to deny leigh griffith ś goal-bound shot during the first-half . caley thistle went on to win the game 3-2 after extra-time and denied rory delia ś men the chance to secure a domestic treble this season . celtic striker leigh griffiths has a goal-bound shot blocked by the outstretched arm of josh meekings . celtic ś adam matthews -lrb- right -rrb- slides in with a strong challenge on nick ross in the scottish cup semi-final . ‘ given the level of reaction from our supporters and across football , we are duty bound to seek an understanding of what actually happened , ćeltic said in a statement . they added , ‘ we have not been given any other specific explanation so far and this is simply to understand the circumstances of what went on and why such an obvious error was made . h́owever , the parkhead outfit made a point of congratulating their opponents , who have reached the first-ever scottish cup final in their history , describing caley as a ‘ fantastic club ánd saying ‘ reaching the final is a great achievement . ćeltic had taken the lead in the semi-final through defender virgil van dijk ś curling free-kick on 18 minutes , but were unable to double that lead thanks to the meekings controversy . it allowed inverness a route back into the game and celtic had goalkeeper craig gordon sent off after the restart for scything down marley watkins in the area . greg tansey duly converted the resulting penalty . edward ofere then put caley thistle ahead , only for john guidetti to draw level for the bhoys . with the game seemingly heading for penalties , david raven scored the winner on 117 minutes , breaking thousands of celtic hearts . celtic captain scott brown -lrb- left -rrb- protests to referee steven mclean but the handball goes unpunished . griffiths shows off his acrobatic skills during celtic ś eventual surprise defeat by inverness . celtic pair aleksandar tonev -lrb- left -rrb- and john guidetti look dejected as their hopes of a domestic treble end .*

Ground-truth: *celtic were defeated 3-2 after extra-time in the scottish cup semi-final . leigh griffiths had a goal-bound shot blocked by a clear handball. however, no action was taken against offender josh meekings. the hoops have written the sfa for an 'understanding' of the decision .*

See et al. (2017): *john hartson was once on the end of a major hampden injustice while playing for celtic . but he can not see any point in his old club writing to the scottish football association over the latest controversy at the national stadium . hartson had a goal wrongly disallowed for offside while celtic were leading 1-0 at the time but went on to lose 3-2 .*

Our Baseline: *john hartson scored the late winner in 3-2 win against celtic . celtic were leading 1-0 at the time but went on to lose 3-2 . some fans have questioned how referee steven mclean and additional assistant alan muir could have missed the infringement .*

Multi-task: *celtic have written to the scottish football association in order to gain an ‘ understanding ’ of the refereeing decisions . the hoops were left outraged by referee steven mclean 's failure to award a penalty or red card for a clear handball in the box by josh meekings . celtic striker leigh griffiths has a goal-bound shot blocked by the outstretched arm of josh meekings .*

Figure 2: Example summary from our 3-way MTL model. The boxed-red highlights are extraneously-generated words not present/paraphrased in the input document. The unboxed-green highlights show salient phrases.

8 Conclusion

We presented a multi-task learning approach to improve abstractive summarization by incorporating the ability to detect salient information and to be logically entailed by the document, via question generation and entailment generation auxiliary tasks. We propose effective soft and high-level (semantic) layer-specific parameter sharing and achieve significant improvements over the state-of-the-art on two popular datasets, as well as a generalizability/transfer DUC-2002 setup.

{godiaz,vince}@hlt.utdallas.edu

Abstract

As the popularity of free-form user-generated reviews in e-commerce and review websites continues to increase, there is a growing need for automatic mechanisms that sift through the vast number of reviews and identify quality content. Online review helpfulness modeling and prediction is a task which studies the factors that determine review helpfulness and attempts to accurately predict it. This survey paper provides an overview of the most relevant work on product review helpfulness prediction and understanding in the past decade, discusses gained insights, and provides guidelines for future research.

1 Introduction

Research on the computational modeling and prediction of online review helpfulness has generally proceeded in two directions. One concerns the automatic prediction of the helpfulness of a review, where helpfulness is typically defined as the fraction of "helpful" votes it receives. Review helpfulness research in the NLP and text mining communities has largely focused on identifying textual content features of a review that are useful for automatic helpfulness prediction. The other direction concerns understanding the nature of helpfulness, where researchers seek to understand the process of human evaluation of review helpfulness and the factors that influence it.

The increasing popularity of modeling and prediction of review helpfulness since its inception more than a decade ago can be attributed to its practical significance. Nowadays, customers regularly rely on different kinds of user reviews (e.g., hotels, restaurants, products, movies) to decide what to spend their money on. Given the large number of reviews available in web platforms, a review helpfulness prediction system could substantially save people's time by allowing them to focus on the most helpful reviews. Hence, a successful review helpfulness prediction system could be as useful as a product recommender system.

Unfortunately, unlike in many key areas of research in NLP, it is by no means easy to determine the state of the art in automatic helpfulness prediction. Empirical comparisons are complicated for at least two reasons. First, historically, systems have been trained on different datasets, not all of which are publicly available. Second, researchers have not built on the successes of each other, evaluating their ideas against baselines that are not necessarily the state of the art. Worse still, new features are not always properly evaluated. This somewhat disorganized situation can be attributed in part to the lack of a common forum for researchers to discuss a long-term vision and a roadmap for research in this area.

Our goal in this survey is to present an overview of the current state of research on computational modeling and prediction of product review helpfulness. Our focus on product reviews is motivated by the fact that they are the most widely studied type of review. Despite this focus, it is by no means the case that our work is only applicable to product reviews. While online platforms differ in objectives and review domains (e.g., Amazon is an online product store, Yelp is a business review website, and TripAdvisor is a booking website for a variety of travel activities), the principles that govern the helpfulness voting process are robust across platforms and domains. This means that most, if not all, of our findings are transferable to other kinds of online reviews. We believe that this survey will be useful to researchers and developers interested in a better understanding of the mechanisms behind review helpfulness.

2 Datasets

The main source of product reviews used in past research is Amazon.com, but interesting work has been done on data from Ciao.com (a now defunct product review website). The main difference between these two sources is the metadata associated with them: Amazon.com offers anonymous voting information, whereas Ciao attaches userIDs to helpfulness votes. Ciao also uses helpfulness votes in the range of 0 to 5, whereas Amazon votes are binary. Furthermore, Ciao offers information on a social trust network, where users choose to connect to reviewers if they find their reviews consistently helpful, unlike Amazon.com, which does not offer any such social trust network. These differences have allowed researchers to make observations on Ciao.com data that cannot be made on Amazon.com.

Datasets are collected from the aforementioned sources through web scraping or APIs. When it comes to Amazon datasets, researchers can choose one of two pre-collected datasets: the Multi-Domain Sentiment Dataset[1](Blitzer et al., 2007) (MDSD) and the Amazon Review Dataset[2] (McAuley et al., 2015; He and McAuley, 2016) (ARD). These datasets have a similar number of product categories (25 and 24, respectively). However, the latest version of MDSD contains 1,422,530 reviews, while ARD contains 142.8 million reviews. Furthermore, ARD offers a variety of metadata that is not present in MDSD (e.g., product salesrank). To the best of our knowledge, there is only one pre-collected Ciao dataset[3] (302,232 reviews, 43,666 users, and 8,894,899 helpfulness votes), which was made available by Tang et al. (2013). Few researchers have used these pre-collected datasets, however. Instead, most have relied on collecting their own datasets directly from websites. As mentioned before, the general lack of testing on pre-collected datasets has made system comparisons difficult.

The majority of researchers simply use helpfulness scores (the fraction of users who vote a review as helpful) as found in websites as ground truth for system training and evaluation. Given that these scores are volatile when reviews have few votes, researchers frequently filter out reviews that do not have a minimum number of votes. Some researchers have argued that helpfulness scores might not be good indicators of actual helpfulness, and have resorted to rating or ranking reviews themselves (Liu et al., 2007; Tsur and Rappoport, 2009; Yang et al., 2015), but these approaches are not the norm.

Votes : [97, 102]
Text : I'm a much bigger fan of the Targus folding keyboard. For starters it folds into the size of a handspring. Second of all the Landware version's keys are incredibly small. The one feature benefit of landware is that it's a rigid design so it can be used on your lap - while the Targus version is very flexible and needs to be placed on a flat surface to type.

Figure 1: Example Review

Researchers have observed interesting patterns in review datasets. For instance, positive reviews are more likely to have high helpfulness scores (O'Mahony et al., 2010; Huang et al., 2015), top ranking reviews hold a disproportionate amount of votes when compared to lower-ranked reviews (Liu et al., 2007), and more recent reviews tend to get fewer votes than older reviews (Liu et al., 2007). Although some of these effects may be the consequence of website voting mechanisms (e.g., Amazon shows reviews based on their helpfulness), they should be taken in consideration when selecting and pre-processing datasets.

Perhaps the most important observation is that helpfulness scores may not be strongly correlated to review quality (Liu et al., 2007; Danescu-Niculescu-Mizil et al., 2009; Tsur and Rappoport, 2009; Ghose and Ipeirotis, 2011; Yang et al., 2015). In at least one study, independent annotators agreed more frequently (85%) with an alternate helpfulness ranking than with one based on helpfulness scores (Tsur and Rappoport, 2009). The example review in Figure 1 shows discrepancies between quality and score. While this review is relatively short and contains only a couple of judgments on its product, 97 out of 102 people voted it as helpful (0.95 score). The quality of this review does not seem to match its near-perfect score. As we will see in Section 4, these discrepancies could be explained as the consequence of several *moderating factors*, which have a direct influence on the helpfulness voting process but are largely ignored in current helpfulness prediction systems.

3 Helpfulness Prediction

Helpfulness prediction tasks include score *regression* (predicting the helpfulness score $h \in [0, 1]$ of a review), binary review *classification* (classifying a review as helpful or not), and review *ranking* (ordering a set of reviews by their helpfulness). In this section, we present the evaluation measures and approaches explored in past work.

3.1 Performance Measures

Regarding performance measures, classification tasks have used Precision, Recall, and F-measure. Regression tasks have mostly used mean squared error (MSE), which measures the average of the sum of the squared error, and root mean squared error (RMSE), which is defined as the square root of MSE. Ranking systems have used Normalized Discounted Cumulative Gain (NDCG), which is popularly used to measure the relevance of search results in information retrieval (here, helpfulness is used as a measure of relevance), and NDCG@k, a special version of NDCG that only takes into account the top k items in a ranking (this is used because users only read a limited number of reviews). Researchers have also used Pearson and Spearman correlations to measure model fit and ranking performance.

3.2 Approaches

Next, we provide a high-level overview of the approaches that have been employed to predict the helpfulness of online product reviews.

Regression has primarily been attempted through support vector regression (Kim et al., 2006; Zhang and Varadarajan, 2006; Yang et al., 2015). However, probabilistic matrix factorization (Tang et al., 2013), linear regression (Lu et al., 2010), and extended tensor factorization models (Moghaddam et al., 2012) have successfully been used to integrate sophisticated constraints into the learning process and have achieved improvements over regular regression models. Multi-layer neural networks have also been used towards this purpose (Lee and Choeh, 2014). In particular, there seems to be progress toward more sophisticated models. For instance, Mukherjee et al. (2017) used a HMM-LDA based model to jointly infer reviewer expertise, predict aspects, and review helpfulness, which showed significant improvement over simpler models. *Classification* approaches have mostly been based on SVMs (Kim et al., 2006; Hong et al., 2012; Zeng et al., 2014; Krishnamoorthy, 2015), but thresholded linear regression models (Ghose and Ipeirotis, 2011), Naive Bayes, Random Forests, J48 and JRip have also been used (O'Mahony et al., 2010; Ghose and Ipeirotis, 2011; Krishnamoorthy, 2015). Recent work has also approached this task with neural networks (Malik and Hussain, 2017; Chen et al., 2018). Regarding *ranking*, some researchers have used ranking-specific methods such as SVM ranking (Tsur and Rappoport, 2009; Hong et al., 2012), but others have attempted to recover rankings from classification (O'Mahony and Smyth, 2009, 2010) or regression (Mukherjee et al., 2017) outputs.

Table 1 provides an overview of some of the most relevant features used in helpfulness prediction systems, explains the intuition behind them and, whenever possible, their correlation to helpfulness and impact on performance. Here, we differentiate primarily between *content* and *context* features. *Content features* focus on information directly derived from the review, such as review text and star rating, whereas *context features* focus on information from outside the review, such as reviewer/user information.

Content features include *Review Length Features*, which are based on the intuition that longer reviews have more information and are thus more helpful; *Readability Features*, which are based on the conjecture that if a review is easier to read, it will be found helpful by more users; *Word-Based Features*, which are based on the idea of identifying key words whose presence indicates the importance of the information found in a review; *Word-Category Features*, which identify the presence of words belonging to specific word lists; and *Content Divergence Features*, which measure how different the contents of the review are from specific reference texts. Context features include *Reviewer Features*, which collect meaningful reviewer historical information to predict future helpfulness scores; and *User-Reviewer Idiosyncrasy Features*, which attempt to capture the similarity between users and reviewers. We also include a couple of *Miscellaneous Features*, which are based on metadata and sentiment analysis; these features are better understood in the context of the moderating factors presented in Section 4.

Researchers have managed to mostly agree on some observations regarding which features are

Feature	Description	Comments
Content Features		
Review Length Features: Measure review length using different metrics.		
Average Sentence Length	-	Used in Liu et al. (2007), Lu et al. (2010), and Yang et al. (2015) without studying its individual predictive power.
No. of Sentences	-	Used in Liu et al. (2007), Lu et al. (2010), Yang et al. (2015)
Number of Words	-	Positive correlation (Mudambi and Schuff, 2010); shown to subdue sentence features (Kim et al., 2006).
Readability Features: Measure how easy a review is to read.		
Readability	Measures how easy a text is to read	Ghose and Ipeirotis (2011) and Korfiatis et al. (2012) found a positive correlation.
Spelling Errors	-	Ghose and Ipeirotis (2011) found a negative correlation.
Paragraph Metrics	Avg. paragraph length, no. of paragraphs	Kim et al. (2006) found an insignificant difference when included in a binary classifier.
Word-Based Features: Indicate the presence of meaningful key words.		
Unigram TF-IDF	Degree of word importance in relation to all reviews for a product	Kim et al. (2006) observed a positive correlation and performance improvement when combined with review length.
Dominant Terms	Presence of particularly important terms for a specific book	Tsur and Rappoport (2009) based entire system on this metric. Tailored for book reviews: similar to UGR TF-IDF.
Word-Category Features: Indicate the presence of words of lists of semantically related words in review.		
Product features	Attempt to identify the presence of important topics	Liu et al. (2007) showed 2.89-3.22% improvement. Hong et al. (2012) presented a system which improves $\sim$ 8% accuracy over Kim et al. (2006) and Liu et al. (2007) but the individual predictive power of the feature was not analyzed. Kim et al. (2006) found it inferior to UGR TF-IDF.
Subjective Tokens	Words taken from lists of subjective adjectives and nouns	Zhang and Varadarajan (2006) found it "barely" correlated with helpfulness. No significant performance improvement.
Sentiment Words	Attempt to capture the presence of opinions, analyses, emotions etc.	Kim et al. (2006) found these features inferior to UGR TF-IDF; Yang et al. (2015) found the opposite and significant improvement over simple text features regression.
Syntactic tokens	A variety of tokens including nouns, adjectives, adverbs, wh- determiners etc.	Kim et al. (2006) found no performance gains; Hong et al. (2012) built a system with volition auxiliaries and sentence tense which showed $\sim$ 8% accuracy improvement over Kim et al. (2006) and Liu et al. (2007), but the individual predictive power of these features was not studied.
Content Divergence Features: Measure the difference between reviews and some reference text.		
Review-product descr. divergence	Helpful reviews should echo the contents of product description	Zhang and Varadarajan (2006) found no significant improvement in model correlation.
Sentiment divergence	The mainstream opinion polarity for a product and its strength are compared to those of the review	Hong et al. (2012) presented a system which improved $\sim$ 8% accuracy over Kim et al. (2006) and Liu et al. (2007) but the individual predictive power of the feature was not analyzed.
KL average review divergence	Divergence between the unigram language model of the review and aggregated product reviews	Lu et al. (2010) introduced it in their baseline model along with a variety of features; the individual predictive power of the feature was not studied.
Miscellaneous Features		
Star rating	The review-assigned product star rating	Positively correlated to helpfulness (Huang et al., 2015). Influence explained by Danescu-Niculescu-Mizil et al. (2009) and Mudambi and Schuff (2010) (see Sections 4.4, 4.2).
Subjectivity	The probability of a review and its sentences being subjective	Based on the conjecture that readers prefer subjective or objective info. based on product type. Empirical evidence found in Ghose and Ipeirotis (2011) (see Section 4.5).
Context Features		
Reviewer Features: Capture reviewer statistics.		
# Past Reviews	Previous reviews written by reviewer	No influence found by Huang et al. (2015).
# Helpful Votes	Previous votes received by reviewer	No influence found by Huang et al. (2015).
Avg. Helpfulness	Reviewer avg. past helpfulness	Positive correlation found by Huang et al. (2015). Mixed effects found by Ghose and Ipeirotis (2011).
User-Reviewer Idiosyncrasy: Capture the similarity between users and reviewers.		
Connection Strength	User-Reviewer connection strength in a social network using the metric introduced in Tang et al. (2012)	Relative performance increase of 1.15-28.38% (Lu et al., 2010; Tang et al., 2013) (see Section 4.3)
User-Reviewer Product Rating Similarity	User-Reviewer product rating history similarity	Relative performance increase of 28.38% (Tang et al., 2013) (see Section 4.3)

Table 1: Summary of Observed Features on Helpfulness

useful for helpfulness prediction[4]. *Review length* has been shown multiple times to be strongly (positively) correlated to helpfulness (Kim et al., 2006; Liu et al., 2007; Otterbacher, 2009; Mudambi and Schuff, 2010; Cao et al., 2011; Pan and Zhang, 2011; Yang et al., 2015; Bjering et al., 2015; Huang et al., 2015; Salehan and Kim, 2016) with only few researchers disagreeing on the existence of the correlation (Zhang and Varadarajan, 2006; Korfiatis et al., 2012). There is general agreement that a review's *star rating* can also be useful for helpfulness prediction. Some researchers use the extremity of the rating (positive, negative, neutral) as a feature (positive and negative reviews are seen as more useful than neutral reviews) (Ghose and Ipeirotis, 2011), while others use star ratings directly (Kim et al., 2006; Mudambi and Schuff, 2010; Pan and Zhang, 2011; Zeng et al., 2014; Huang et al., 2015; Bjering et al., 2015). Some researchers argue that star rating is useful because of the presence of *positivity bias* (i.e., reviews with positive star ratings are seen as more helpful), while few researchers disagree on the existence of a connection between star ratings and helpfulness (Otterbacher, 2009). *Review readability metrics*, which measure how "easy" it is to read a review, have been found to have a positive correlation to helpfulness (Ghose and Ipeirotis, 2011; Korfiatis et al., 2012), but have not been as thoroughly tested as other features. A recurrent idea is that of capturing *review content relevance*: unigram TF-IDF statistics (the relative importance of the words in a review when compared to other reviews of the same product) (Kim et al., 2006), dominant terms (computed using a custom metric similar to TF-IDF, but tailored for book reviews) (Tsur and Rappoport, 2009), and latent review topics (the themes present in the review) (McAuley and Leskovec, 2013; Mukherjee et al., 2017) stand out particularly.

3.3 The State of Helpfulness Prediction

The classical approach to helpfulness prediction has consisted of finding new hand-crafted features that can improve system performance. Although many interesting features continue to be found (e.g., emotion (Martin and Pu, 2014), aspect (Yang et al., 2016), and argument (Liu et al., 2017) based features), advances have been hindered by the lack of standard datasets, which are needed for performance comparisons, and feature ablation studies, which are needed to properly evaluate the contribution of newly proposed features.

Even so, as in many other areas of NLP, recent systems based on neural network architectures have shown performance increases both when using hand-crafted features (Lee and Choeh, 2014; Malik and Hussain, 2017) and when performing raw-text predictions (Chen et al., 2018). Moreover, recent systems have been shown to be able to tackle domain knowledge transfer considerably well (Chen et al., 2018). Although these systems were not compared against a robust hand-crafted feature baseline, the fact that authors are beginning to use pre-collected datasets (ARD) enables fairer comparisons. Intuitively, we expect models based on neural network architectures to be better at capturing latent semantics, as well as some of the feature interactions we will present in Section 4. In parallel, systems that have incorporated user and reviewer features, particularly those that learn from individual user votes (Tang et al., 2013), have shown large performance increases over extensive hand-crafted-only feature baselines (Lu et al., 2010; Tang et al., 2013), and more sophisticated models focused on review semantics (Mukherjee et al., 2017) have also outperformed hand-crafted-only feature baselines significantly.

4 The Helpfulness Voting Process: Entities and Moderating Factors

So far we have presented an overview of the features used in helpfulness prediction systems. With a few exceptions (Mudambi and Schuff, 2010; Ghose and Ipeirotis, 2011; Tang et al., 2013), past work on helpfulness prediction has focused exclusively on *non-moderating factors* (i.e., observable features which can contribute towards helpfulness scores, but cannot alter or influence the voting process itself). Even so, researchers have gained key insights on certain *moderating factors* (i.e., mechanisms and properties that can influence the voting process outcome). These findings are relevant not only because they can be used to enhance helpfulness prediction, but because, when put together, they constitute arguments in favor of reconsidering the helpfulness prediction task and its focus. In this section, we will present a variety of moderating factors.

[4]We do not discuss features that are not helpful since, in general, they are not as thoroughly tested as those mentioned here.

4.1 The Voting Process and its Entities

To start our discussion on moderating factors, let us provide a brief, intuitive definition of the steps involved in the helpfulness voting process and outline the entities involved in it[5]:

1. A reviewer, a, writes a review r on product p
2. A user, u, reads the review by reviewer a on product p and internally assigns it a score s using some criterion c.
3. If the score s is over some threshold t, the user votes the review as "helpful". Otherwise, the user votes it as "not helpful".

Intuitively, one can expect these four entities — reviewers, users, reviews, and products — to play a role in determining the outcome of the voting process. Moreover, it is reasonable to expect both the nature of these entities and the interactions between them to be sometimes expressed through hidden features/variables. For instance, one cannot directly observe a user's opinion of a product unless he/she writes a review, and one cannot directly observe a particular user's information needs or a product's nature, which would indicate what kind of review is most helpful for it. In the next subsections, we will discuss different moderating factors that have been discovered for each of these entities, the observable features that have been used to approximate them, and their effects on the voting process.

4.2 User-Product Predispositions

Danescu-Niculescu-Mizil et al. (2009) showed that the difference between user and reviewer opinions can influence helpfulness votes. Since user opinions are hidden, based on the assumption that star ratings are good indicators of opinion, Danescu et al. studied the interplay between review star rating deviation from the mean (the divergence between the reviewer's opinion and the average opinion of the product) and star rating variance (the level of opinion consensus for a product) for 1 million Amazon US book reviews, making the following observations:

1. When star rating variance is very low, the most helpful reviews are those with the average star rating.
2. With moderate variance, the most helpful reviews are those with a slightly-above-average star rating.
3. As variance becomes large, reviews with star ratings both above and below the average are more helpful (positive reviews still deemed somewhat more helpful).

These observations held when controlling for review text, and constitute one of the most straightforward pieces of evidence against text-only review helpfulness understanding and prediction. Although these observations show only aggregated user behavior, they have a theoretical backing by past research (Wilson and Peterson, 1989), and hint that a deeper understanding of user opinions can lead to better prediction systems.

4.3 User-Reviewer Idiosyncrasy

Tang et al. (2013) found that, by observing users' actions, user-reviewer idiosyncrasy similarity could be measured and used to enhance helpfulness prediction. They showed that the existence and strength of connections between reviewers and users in a social network, along with product rating history similarity, moderated the general user opinion of a particular reviewer's reviews. Specifically, they analyzed *social network connections* in Ciao's *circle of trust*, a social network where a user *connects* to a reviewer if they consistently find their reviews helpful, along with users' and reviewers' product rating histories, and made the following observations:

1. Users are likely to think of reviews from their connected reviewers as more helpful.
2. The more strongly users connect to a reviewer, the more helpful users consider the reviews from the reviewer.[6]
3. Users are likely to consider the reviews from reviewers with similar product ratings as more helpful.
4. The more similar the product ratings of users and reviewers, the more helpful users consider the reviews from the reviewer.

As Tang et al. proposed that differences in helpfulness scores are not necessarily a consequence of review quality, but of differences of opinion between users (if everyone thought the same way, all reviews would have a score of either 0 or 1), they were among the first to advocate for user-specific helpfulness prediction, which aims to predict how a specific user will vote, instead of predicting the

[5]Here we assume voting participation and do not attempt to reconcile it with polarity, but a deeper understanding of participation could lead to better interpretations of votes.

[6]Connection strength is measured with the metric introduced in Tang et al. (2012).

aggregated votes of the community. Under this approach, Tang et al. implemented their observations in a probabilistic matrix factorization framework and achieved a 28.38% relative improvement over a text-reviewer-based baseline that included an extensive set of text features present in other systems (Lu et al., 2010).

This suggests that the similarity between reviewers' idiosyncrasy as expressed in reviews and that of users can be approximated by studying user and reviewer actions. Further, the information used by Tang et al. (2013) towards this purpose is not the only kind that could prove useful. It could easily be extended to include the vast amount of user information stored by current day e-commerce websites such as Amazon. Users' age, gender, purchase history, location, browsing and purchase patterns, and review history (both writing and rating) could be used to define prior probabilities on some user x liking the review of a reviewer y.[7] As some of this information has already been used in recommender systems, it would be of interest to explore the extent to which techniques from this field (specifically those from collaborative filtering) can be applied to helpfulness prediction.

4.4 Product Nature

Product nature moderates users' information needs and the criteria of a helpful review. Online stores now have an astoundingly large catalog of products, which can be very different in price, use, target market, complexity, popularity, etc. Hence, it is reasonable to expect the information needs of users to depend at least somewhat on the product in question. Consider the task of *buying a house vs buying a TV*. We can easily see that the amount and nature of information needed to buy a TV or a house is considerably different. Further, the quality of these products stems from different sources: a TV's perceived quality depends mostly on its technical features, whereas the perceived quality of a house depends to some degree on the potential buyer. Therefore, it is perfectly sensible to expect helpful reviews for products of different "types" to be different. Below we show that the nature of a product moderates the effects of star ratings, review length, and subjectivity on helpfulness scores.

[7]Since a reviewer's idiosyncrasy is embodied in his/her reviews, we do not rule out the possibility that more complex text representations can also be used to approximate it. Regardless, these sources of information should still be able to complement prediction systems.

Researchers have proven the influence of product nature on the helpfulness voting process by differentiating between *search* and *experience* goods. According to Nelson (1970, 1974), the quality of search goods is derived from objective attributes (e.g., a camera), whereas the quality of experience goods is based on subjective attributes (e.g., a music CD). Mudambi and Schuff (2010) first identified that review length (word count) is positively correlated to review helpfulness, and then made the following observations:

- For experience goods, reviews with extreme star ratings (high or low) are associated with lower levels of helpfulness than reviews with moderate star ratings.
- Review depth has a greater positive effect on the helpfulness of the review for search goods than experience goods.

These observations make it clear that the nature of a product can impact the way a user will judge a review's helpfulness. However, approximating the nature of a product is not a trivial task. As stated by Mudambi and Schuff, even if these observations hold, classifying products as search or experience goods is a complicated task, since products fall at some point along a spectrum and commonly have aspects of both search and experience goods. This means that finding methods of automatically discovering product features or classifications that influence the helpfulness voting process is an important task for future research.

What other product categorizations are there that could influence helpfulness and be easily collected/computed? We propose to start by using categories already present in e-commerce websites. Intuitively, it would make sense for products under the "computers" category to be similar in their information needs. And as such, systems trained on computer reviews should learn similar parameters. As most e-commerce websites use a hierarchical product categorization system, by starting at the most specific subcategories one could potentially generalize subcategory-learned parameters into category-wide trends.

4.5 Review Nature

A review's style influences the properties that make it helpful. It is well known that when it comes to expressing opinions, the way information is presented can be almost as important as the information itself. Even if two reviewers have a similar opinion on a product, the way they frame their opinion can make a big difference when it comes to how helpful their reviews are. Consider the task of deciding whether to buy a specific car. What advice could prove useful for this decision? We could consider *regular* advice that is mostly concerned with the car itself, *comparative* advice that relates various aspects of the car with its alternatives, and *suggestive* advice, which focuses on usage recommendations.

Qazi et al. (2016) used these three types of advice to classify hotel reviews from TripAdvisor.com and made the following observations:

- For comparative reviews, longer reviews are considered more helpful.
- For suggestive and regular reviews, shorter reviews are more helpful.

Similar findings on the influence of review nature were made by Huang et al. (2015): when differentiating between reviews written by regular and top Amazon reviewers, they made the following observations:

- The influence of word count on review helpfulness is bounded (after 144 words, the effect stops) for regular reviewers.
- For top reviewers, the effect is nonexistent.

Similarly to product nature, an important research question for future work is how to identify and exploit review categories for effective helpfulness prediction. We expect more sophisticated textual features to be necessary to differentiate between meaningful styles of reviews.

4.6 Review Context

Sipos et al. (2014) found evidence that helpfulness votes are the consequence of judgments of *relative quality* (i.e., how the review compares to its neighbors) and that aggregate user voting polarity is influenced by the specific review ranking that websites display at any given point in time. To prove this, they collected daily snapshots of the top 50 reviews of 595 Amazon products over a 5 month period. Four months after the data collection period ended, they collected the full review rankings for all 595 products. This final review ranking was taken to be the "true" ranking. They studied daily changes and observed that:

- A review receives more positive votes when it is under-ranked (under its final ranking).
- A review receives more positive votes when it is superior to its neighbors.
- A review receives fewer positive votes when it is over-ranked (over its final ranking).
- A review receives fewer positive votes when it is locally inferior to its neighbors.

Sipos et al. noted that these observations are consistent with the interpretation that users vote to correct "misorderings" in the ranking. This has important consequences for user-specific helpfulness prediction systems. Recall that votes may express judgments over a set of reviews. If researchers build training sets that identify user votes and contain sufficient information to replicate context at the time of voting, systems could learn more about user preferences: a vote would no longer inform solely on a user's perceived helpfulness of a review x, but on the user's perceived helpfulness of x with respect to its neighbors. This could be particularly useful in sparsity scenarios, and could lead to better helpfulness predictions.

5 Conclusions and Recommendations

Online product review helpfulness modeling and prediction is a multi-faceted task that involves using content and context information to understand and predict helpfulness scores. Researchers now have at their disposal at least three public, pre-collected product review datasets — MDSD, ARD, and Ciao — to build and test systems. Although significant advances have been made on finding hand-crafted features for helpfulness prediction, effective comparisons between proposed approaches have been hindered by the lack of standard evaluation datasets, well-defined baselines, and feature ablation studies. However, there have been exciting developments in helpfulness prediction: systems that have attempted to exploit user and reviewer information, along with those based on sophisticated models (e.g., probabilistic matrix factorization, HMM-LDA) and neural network architectures, are promising prospects for future work. Furthermore, a variety of insightful observations have been made on moderating factors. In particular, product opinions, user idiosyncrasy, product and review nature, along with review voting context have been shown to influence the way users vote. This provides suggestive evidence that researchers should adopt a holistic view of the helpfulness voting process, which may require information not present in current datasets.

We conclude our survey with several recommendations for future work on computational modeling and prediction of review helpfulness.

Task If one acknowledges the role that users play in determining whether a review is helpful or not, it seems contradictory to insist on predicting helpfulness scores, which represent the average perception of a subset of users that (1) may not be representative of the entire population and (2) may not serve users well if their perceptions do not align with the subset of users that voted (even if the subset consisted of the entire population). This is why we consider that user-specific helpfulness prediction, first presented in Moghaddam et al. (2012) and Tang et al. (2013), should be the goal of future work, as it allows systems to tailor their predictions to users' preferences and needs (much like a recommender system). Note that pursuing user-specific helpfulness prediction is not enough. A substantial amount of work must still be done to find, approximate, and implement moderating factors in helpfulness prediction systems, as well as build models that can adequately reflect the effects of these factors.

Data Given that we recommend user-specific helpfulness prediction, we propose the development of a gold standard that contains information that can facilitate the design of user-specific models (e.g., records of who voted and how, data relevant to user-profiling recommendations such as age, location, social networks, purchase and browsing history and patterns, product reviews written, and review and product rating histories). Furthermore, as users frequently vote on reviews in a different context (scores and neighboring reviews can vary over time), this dataset should include temporal information, which would allow researchers to reconstruct the context under which votes are cast. To build this dataset, we recommend that researchers work with companies such as Amazon, which may have such information.

Features and knowledge sources While we encourage the development of user-specific helpfulness prediction, we by no means imply that a model should be trained for each user. In fact, this may not be feasible if a user has cast only a small number of votes. There are multiple ways to approach this task. One is to train a user-specific model for each *cluster* of "similar" users. Taking inspirations from collaborative filtering, we could define or learn user similarity based on their purchasing/browsing/review and product rating histories (Liu et al., 2014) as well as profiling information (Krulwich, 1997), which should be available in the aforementioned dataset. Further, "similar" reviews (i.e., reviews on which users vote similarly) could be exploited (Sarwar et al., 2001; Linden et al., 2003). Once product and user/reviewer factors are incorporated into a model, it may become feasible to use past instances to predict helpfulness votes (how similar is a test instance to past situations where a user has voted "helpful"?).

Baseline systems To design a strong baseline system, first, researchers should consider all proposed features so far, including content features, context features, and features used to approach moderating factors. Second, combinations of these features should be systematically tested on the different models proposed by researchers. As we have seen that product nature influences the voting process, these tests should be conducted over different products and product categories. We recommend identifying specific experience and search products, since the effects of product nature have already been proven for them. Although ideally, these tests would be carried out on our proposed gold-standard dataset, we believe that the Ciao dataset introduced in Tang et al. (2013) and ARD (McAuley et al., 2015) can prove useful to define a baseline in the short term. Towards this purpose, the systems proposed in Tang et al. (2013), Mukherjee et al. (2017), Malik and Hussain (2017), and Chen et al. (2018) could serve as baselines after being enriched with extra features.

Other platforms, review domains and languages While we focused on Amazon product reviews written in English, the majority of the features discussed in Section 3 are platform-, domain- and language-independent, and the existence and importance of moderating factors described in Section 4 is by no means limited to product reviews. Consequently, we encourage researchers to evaluate the usefulness of these features and study these moderating factors in different domains, platforms, and languages, possibly identifying new features and moderating factors.

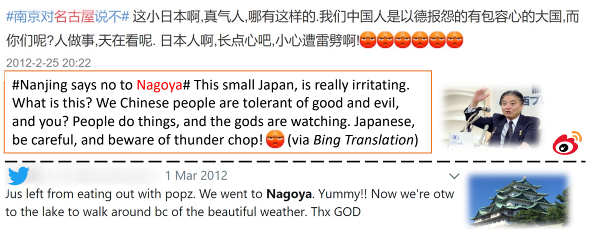
Abstract

Cross-cultural differences and similarities are common in cross-lingual natural language understanding, especially for research in social media. For instance, people of distinct cultures often hold different opinions on a single named entity. Also, understanding slang terms across languages requires knowledge of cross-cultural similarities. In this paper, we study the problem of computing such cross-cultural differences and similarities. We present a lightweight yet effective approach, and evaluate it on two novel tasks: 1) mining cross-cultural differences of named entities and 2) finding similar terms for slang across languages. Experimental results show that our framework substantially outperforms a number of baseline methods on both tasks. The framework could be useful for machine translation applications and research in computational social science.

1 Introduction

Computing similarities between terms is one of the most fundamental computational tasks in natural language understanding. Much work has been done in this area, most notably using the distributional properties drawn from large monolingual textual corpora to train vector representations of words or other linguistic units (Pennington et al., 2014; Le and Mikolov, 2014). However, computing cross-cultural similarities of terms between different cultures is still an open research question, which is important in cross-lingual natural language understanding. In this paper, we address cross-cultural research questions such as these:



#南京对名古屋说不# 这小日本啊,真气人,哪有这样的.我们中国人是以德报怨的有包容心的大国,而你们呢?人做事,天在看呢. 日本人啊,长点心吧,小心遭雷劈啊!😡😡😡😡😡😡
2012-2-25 20:22

#Nanjing says no to Nagoya# This small Japan, is really irritating. What is this? We Chinese people are tolerant of good and evil, and you? People do things, and the gods are watching. Japanese, be careful, and beware of thunder chop! 😡 (via *Bing Translation*)

[redacted] 1 Mar 2012
Jus left from eating out with popz. We went to **Nagoya**. Yummy!! Now we're otw to the lake to walk around bc of the beautiful weather. Thx GOD

Figure 1: Two social media messages about Nagoya from different cultures in 2012

1. *Were there any cross-cultural differences between Nagoya (a city in Japan) for native English speakers and 名古屋 (Nagoya in Chinese) for Chinese people in 2012?*
2. *What English terms can be used to explain "浮云" (a Chinese slang term)?*

These kinds of questions about cross-cultural differences and similarities are important in cross-cultural social studies, multi-lingual sentiment analysis, culturally sensitive machine translation, and many other NLP tasks, especially in social media. We propose two novel tasks in mining them from social media.

The first task (Section 4) is to mine cross-cultural differences in the perception of named entities (e.g., persons, places and organizations). Back in 2012, in the case of "Nagoya", many native English speakers posted their pleasant travel experiences in Nagoya on Twitter. However, Chinese people overwhelmingly greeted the city with anger and condemnation on *Weibo* (a Chinese version of Twitter), because the city mayor denied the truthfulness of the Nanjing Massacre. Figure 1 illustrates two example microblog messages about Nagoya in Twitter and Weibo respectively.

The second task (Section 5) is to find similar terms for slang across cultures and languages. Social media is always a rich soil where slang terms emerge in many cultures. For example,

*Both authors contributed equally.

"浮云" literally means "floating clouds", but now almost equals to "nothingness" on the Chinese web. Our experiments show that well-known online machine translators such as *Google Translate* are only able to translate such slang terms to their literal meanings, even under clear contexts where slang meanings are much more appropriate.

Enabling intelligent agents to understand such cross-cultural knowledge can benefit their performances in various cross-lingual language processing tasks. Both tasks share the same core problem, which is **how to compute cross-cultural differences (or similarities) between two terms from different cultures.** A term here can be either an ordinary word, an entity name, or a slang term. We focus on names and slang in this paper for they convey more social and cultural connotations.

There are many works on cross-lingual word representation (Ruder et al., 2017) to compute general cross-lingual similarities (Camacho-Collados et al., 2017). Most existing models require bilingual supervision such as aligned parallel corpora, bilingual lexicons, or comparable documents (Sarath et al., 2014; Kočiský et al., 2014; Upadhyay et al., 2016). However, they do not purposely preserve social or cultural characteristics of named entities or slang terms, and the required parallel corpora are rare and expensive.

In this paper, we propose a lightweight yet effective approach to project two incompatible monolingual word vector spaces into a single bilingual word vector space, known as social vector space (*SocVec*). A key element of SocVec is the idea of "bilingual social lexicon", which contains bilingual mappings of selected words reflecting psychological processes, which we believe are central to capturing the socio-linguistic characteristics. Our contribution in this paper is two-fold:

(a) We present an effective approach (SocVec) to mine cross-cultural similarities and differences of terms, which could benefit research in machine translation, cross-cultural social media analysis, and other cross-lingual research in natural language processing and computational social science.

(b) We propose two novel and important tasks in cross-cultural social studies and social media analysis. Experimental results on our annotated datasets show that the proposed method outperforms many strong baseline methods.

2 The *SocVec* Framework

In this section, we first discuss the intuition behind our model, the concept of "social words" and our notations. Then, we present the overall workflow of our approach. We finally describe the *SocVec* framework in detail.

2.1 Problem Statement

We choose (English, Chinese) to be the target language pair throughout this paper for the salient cross-cultural differences between the east and the west[1]. Given an English term W and a Chinese term U, the core research question is how to compute a similarity score, $ccsim(W, U)$, to represent the *cross-cultural similarities* between them.

We cannot directly calculate the similarity between the monolingual word vectors of W and U, because they are trained separately and the semantics of dimension are not aligned. Thus, the challenge is to devise a way to compute similarities across two different vector spaces while retaining their respective cultural characteristics.

A very intuitive solution is to firstly translate the Chinese term U to its English counterpart U' through a Chinese-English bilingual lexicon, and then regard $ccsim(W, U)$ as the (cosine) similarity between W and U' with their monolingual word embeddings. However, this solution is not promising in some common cases for three reasons:

(a) if U is an OOV (Out of Vocabulary) term, e.g., a novel slang term, then there is probably no translation U' in bilingual lexicons.

(b) if W and U are names referring to the same named entity, then we have $U' = W$. Therefore, $ccsim(W, U)$ is just the similarity between W and itself, and we cannot capture any cross-cultural differences with this method.

(c) this approach does not explicitly preserve the cultural and social contexts of the terms.

To overcome the above problems, our intuition is to project both English and Chinese word vectors into a single third space, known as *SocVec*, and the projection is supposed to purposely carry cultural features of terms.

2.2 Social Words and Our Notations

Some research in psychology and sociology (Kitayama et al., 2000; Gareis and Wilkins, 2011)

[1]Nevertheless, the techniques are language independent and thus can be utilized for any language pairs so long as the necessary resources outlined in Section 2.3 are available.

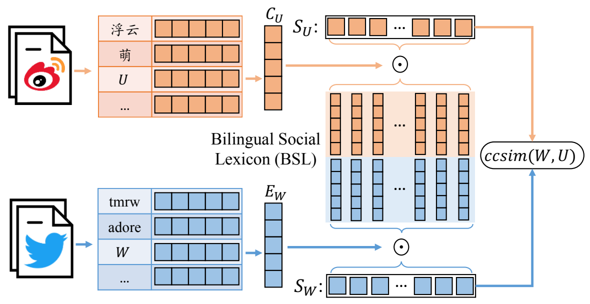


Figure 2: Workflow for computing the cross-cultural similarity between an English word *W* and a Chinese word *U*, denoted by $ccsim(W, U)$

show that culture can be highly related to emotions and opinions people express in their discussions. As suggested by Tausczik and Pennebaker (2009), we thus define the concept of "**social word**" as the words directly reflecting opinion, sentiment, cognition and other human psychological processes[2], which are important to capturing cultural and social characteristics. Both Elahi and Monachesi (2012) and Garimella et al. (2016a) find such *social words* are most effective culture/socio-linguistic features in identifying cross-cultural differences.

We use these notations throughout the paper: *CnVec* and *EnVec* denote the Chinese and English word vector space, respectively; *CSV* and *ESV* denote the Chinese and English social word vocab; *BL* means Bilingual Lexicon, and *BSL* is short for Bilingual Social Lexicon; finally, we use $\mathbf{E_x}$, $\mathbf{C_x}$ and $\mathbf{S_x}$ to denote the word vectors of the word x in *EnVec*, *CnVec* and *SocVec* spaces respectively.

2.3 Overall Workflow

Figure 2 shows the workflow of our framework to construct the *SocVec* and compute $ccsim(W, U)$. Our proposed *SocVec* model attacks the problem with the help of three low-cost external resources: (i) an English corpus and a Chinese corpus from social media; (ii) an English-to-Chinese bilingual lexicon (*BL*); (iii) an English social word vocabulary (*ESV*) and a Chinese one (*CSV*).

We train English and Chinese word embeddings (*EnVec* and *CnVec*) on the English and Chinese social media corpus respectively. Then, we build a *BSL* from the *CSV*, *ESV* and *BL* (see Section 2.4). The *BSL* further maps the previously incompatible *EnVec* and *CnVec* into a single common vector space *SocVec*, where two new vectors, S_W for W and S_U for U, are finally comparable.

2.4 Building the BSL

The process of building the *BSL* is illustrated in Figure 3. We first extract our bilingual lexicon (*BL*), where confidence score w_i represents the probability distribution on the multiple translations for each word. Afterwards, we use BL to translate each social word in the *ESV* to a set of Chinese words and then filter out all the words that are not in the *CSV*. Now, we have a set of Chinese social words for each English social word, which is denoted by a "translation set". The final step is to generate a Chinese "pseudo-word" for each English social word using their corresponding translation sets. A "pseudo-word" can be either a real word that is the most representative word in the translation set, or an imaginary word whose vector is a certain combination of the vectors of the words in the translation set.

For example, in Figure 3, the English social word "*fawn*" has three Chinese translations in the bilingual lexicon, but only two of them (underlined) are in the CSV. Thus, we only keep these two in the translation set in the filtered bilingual lexicon. The pseudo-word generator takes the word vectors of the two words (in the black box), namely 奉承 (flatter) and 谄媚 (toady), as input, and generates the pseudo-word vector denoted by "*fawn**". Note that the direction of building *BSL* can also be from Chinese to English, in the same manner. However, we find that the current direction gives better results due to the better translation quality of our *BL* in this direction.

Given an English social word, we denote $\mathbf{t_i}$ as the i^{th} Chinese word of its translation set consisting of N social words. We design four intuitive types of pseudo-word generator as follows, which are tested in the experiments:

(1) Max. Maximum of the values in each dimension, assuming dimensionality is K:

$$\text{Pseudo}(\mathbf{C_{t_1}}, ..., \mathbf{C_{t_N}}) = \begin{bmatrix} max(C_{t_1}^{(1)}, ..., C_{t_N}^{(1)}) \\ \vdots \\ max(C_{t_1}^{(K)}, ..., C_{t_N}^{(K)}) \end{bmatrix}^{\mathrm{T}}$$

(2) Avg. Average of the values in every dimension:

$$\text{Pseudo}(\mathbf{C_{t_1}}, ..., \mathbf{C_{t_N}}) = \frac{1}{N}\sum_{i}^{N} \mathbf{C_{t_i}}$$

[2]Example social words in English include *fawn, inept, tremendous, gratitude, terror, terrific, loving, traumatic*, etc. We discuss the sources of such social words in Section 3.

inept: inept*:
terror: terror*:
fawn: fawn*:
Pseudo-word Generator

Figure 3: Generating an entry in the BSL for “*fawn*” and its pseudo-word “*fawn**”

(3) WAvg. Weighted average value of every dimension with respect to the translation confidence:

$$\text{Pseudo}(\mathbf{C_{t_1}}, ..., \mathbf{C_{t_N}}) = \frac{1}{N}\sum_{i}^{N} w_i \mathbf{C_{t_i}}$$

(4) Top. The most confident translation:

$$\text{Pseudo}(\mathbf{C_{t_1}}, ..., \mathbf{C_{t_N}}) = \mathbf{C_{t_k}}, k = \operatorname*{argmax}_i w_i$$

Finally, the *BSL* contains a set of English-Chinese word vector pairs, where each entry represents an English social word and its Chinese pseudo-word based on its “translation set”.

2.5 Constructing the SocVec Space

Let B_i denote the English word of the i^{th} entry of the *BSL*, and its corresponding Chinese pseudo-word is denoted by B_i^*. We can project the English word vector $\mathbf{E_W}$ into the *SocVec* space by computing the cosine similarities between $\mathbf{E_W}$ and each English word vector in *BSL* as values on SocVec dimensions, effectively constructing a new vector $\mathbf{S_W}$ of size L. Similarly, we map a Chinese word vector $\mathbf{C_U}$ to be a new vector $\mathbf{S_U}$. $\mathbf{S_W}$ and $\mathbf{S_U}$ belong to the same vector space *SocVec* and are comparable. The following equation illustrates the projection, and how to compute *ccsim*[3].

$$\begin{aligned} &ccsim(W, U) := f(\mathbf{E_W}, \mathbf{C_U}) \\ &= sim\left(\begin{bmatrix} cos(\mathbf{E_W}, \mathbf{E_{B_1}}) \\ \vdots \\ cos(\mathbf{E_W}, \mathbf{E_{B_L}}) \end{bmatrix}^{\mathrm{T}}, \begin{bmatrix} cos(\mathbf{C_U}, \mathbf{C_{B_1^*}}) \\ \vdots \\ cos(\mathbf{C_U}, \mathbf{C_{B_L^*}}) \end{bmatrix}^{\mathrm{T}}\right) \\ &= sim(\mathbf{S_W}, \mathbf{S_U}) \end{aligned}$$

For example, if W is “Nagoya” and U is “名古屋”, we compute the cosine similarities between “Nagoya” and each English social word in the *BSL* with their monolingual word embeddings in English. Such similarities compose $\mathbf{S}_{\text{nagoya}}$. Similarly, we compute the cosine similarities between “名古屋” and each Chinese pseudo-word, and compose the social word vector $\mathbf{S}_{名古屋}$.

In other words, for each culture/language, the new word vectors like S_W are constructed based on the monolingual similarities of each word to the vectors of a set of task-related words (“social words” in our case). This is also a significant part of the novelty of our transformation method.

3 Experimental Setup

Prior to evaluating *SocVec* with our two proposed tasks in Section 4 and Section 5, we present our preparation steps as follows.

Social Media Corpora Our English Twitter corpus is obtained from Archive Team’s Twitter stream grab[4]. The Chinese Weibo corpus comes from Open Weiboscope Data Access[5] (Fu et al., 2013). Both corpora cover the whole year of 2012. We then randomly down-sample each corpus to 100 million messages where each message contains at least 10 characters, normalize the text (Han et al., 2012), lemmatize the text (Manning et al., 2014) and use LTP (Che et al., 2010) to perform word segmentation for the Chinese corpus.

Entity Linking and Word Embedding Entity linking is a preprocessing step which links various entity mentions (surface forms) to the identity of corresponding entities. For the Twitter corpus, we use Wikifier (Ratinov et al., 2011; Cheng and Roth, 2013), a widely used entity linker in English. Because no sophisticated tool for Chinese short text is available, we implement our own tool that is greedy for high precision. We train English and Chinese monolingual word embedding respectively using *word2vec*’s skip-gram method with a window size of 5 (Mikolov et al., 2013b).

Bilingual Lexicon Our bilingual lexicon is collected from *Microsoft Translator*[6], which translates English words to multiple Chinese words

[3]The function *sim* is a generic similarity function, for which several metrics are considered in experiments.

[4]`https://archive.org/details/twitterstream`
[5]`http://weiboscope.jmsc.hku.hk/datazip/`
[6]`http://www.bing.com/translator/api/Dictionary/Lookup?from=en&to=zh-CHS&text=<input_word>`

with confidence scores. Note that all named entities and slang terms used in the following experiments are excluded from this bilingual lexicon.

Social Word Vocabulary Our social word vocabularies come from *Empath* (Fast et al., 2016) and *OpinionFinder* (Choi et al., 2005) for English, and *TextMind* (Gao et al., 2013) for Chinese. Empath is similar to LIWC (Tausczik and Pennebaker, 2009), but has more words and more categories and is publicly available. We manually select 91 categories of words that are relevant to human perception and psychological processes following Garimella et al. (2016a). OpinionFinder consists of words relevant to opinions and sentiments, and TextMind is a Chinese counterpart for Empath. In summary, we obtain 3,343 words from Empath, 3,861 words from OpinionFinder, and 5,574 unique social words in total.

4 Task 1: Mining cross-cultural differences of named entities

Task definition: This task is to discover and quantify cross-cultural differences of concerns towards named entities. Specifically, the input in this task is a list of 700 named entities of interest and two monolingual social media corpora; the output is the scores for the 700 entities indicating the cross-cultural differences of the concerns towards them between two corpora. The ground truth is from the labels collected from human annotators.

4.1 Ground Truth Scores

Harris (1954) states that the meaning of words is evidenced by the contexts they occur with. Likewise, we assume that the cultural properties of an entity can be captured by the terms they always co-occur within a large social media corpus. Thus, for each of randomly selected 700 named entities, we present human annotators with two lists of 20 most co-occurred terms within Twitter and Weibo corpus respectively.

Our annotators are instructed to rate the topic-relatedness between the two word lists using one of following labels: “very different”, “different”, “hard to say”, “similar” and “very similar”. We do this for efficiency and avoiding subjectivity. As the word lists presented come from social media messages, the social and cultural elements are already embedded in their chances of occurrence. All four annotators are native Chinese speakers but have excellent command of English and lived in the US extensively, and they are trained with many selected examples to form shared understanding of the labels. The inter-annotator agreement is 0.67 by Cohen’s kappa coefficient, suggesting substantial correlation (Landis and Koch, 1977).

4.2 Baseline and Our Methods

We propose eight baseline methods for this novel task: **distribution-based** methods (BL-JS, E-BL-JS, and WN-WUP) compute cross-lingual relatedness between two lists of the words surrounding the input English and Chinese terms respectively ($\mathcal{L}_E$ and $\mathcal{L}_C$); **transformation-based** methods (LTrans and BLex) compute the vector representation in English and Chinese corpus respectively, and then train a transformation; MCCA, MCluster and Duong are three typical **bilingual word representation models** for computing general cross-lingual word similarities.

The $\mathcal{L}_E$ and $\mathcal{L}_C$ in the BL-JS and WN-WUP methods are the same as the lists that annotators judge. **BL-JS** (*Bilingual Lexicon Jaccard Similarity*) uses the bilingual lexicon to translate $\mathcal{L}_E$ to a Chinese word list $\mathcal{L}_E^*$ as a medium, and then calculates the Jaccard Similarity between $\mathcal{L}_E^*$ and $\mathcal{L}_C$ as J_{EC}. Similarly, we compute J_{CE}. Finally, we regard $(J_{EC} + J_{CE})/2$ as the score of this named entity. **E-BL-JS** (*Embedding-based Jaccard Similarity*) differs from BL-JS in that it instead compares the two lists of words gathered from the rankings of word embedding similarities between the name of entities and all English words and Chinese words respectively. **WN-WUP** (*WordNet Wu-Palmer Similarity*) uses Open Multilingual Wordnet (Wang and Bond, 2013) to compute the average similarities over all English-Chinese word pairs constructed from the $\mathcal{L}_E$ and $\mathcal{L}_C$.

We follow the steps of Mikolov et al. (2013a) to train a linear transformation (**LTrans**) matrix between *EnVec* and *CnVec*, using 3,000 translation pairs with maximum confidences in the bilingual lexicon. Given a named entity, this solution simply calculates the cosine similarity between the vector of its English name and the *transformed* vector of its Chinese name. **BLex** (*Bilingual Lexicon Space*) is similar to our *SocVec* but it does not use any social word vocabularies but uses bilingual lexicon entries as pivots instead.

MCCA (Ammar et al., 2016) takes two trained monolingual word embeddings with a bilingual lexicon as input, and develop a bilingual word em-

Entity	Twitter topics	Weibo topics
Maldives	coup, president Nasheed quit, political crisis	holiday, travel, honeymoon, paradise, beach
Nagoya	tour, concert, travel, attractive, Osaka	Mayor Takashi Kawamura, Nanjing Massacre, denial of history
Quebec	Conservative Party, Liberal Party, politicians, prime minister, power failure	travel, autumn, maples, study abroad, immigration, independence
Philippines	gunman attack, police, quake, tsunami	South China Sea, sovereignty dispute, confrontation, protest
Yao Ming	NBA, Chinese, good player, Asian	patriotism, collective values, Jeremy Lin, Liu Xiang, Chinese Law maker, gold medal superstar
USC	college football, baseball, Stanford, Alabama, win, lose	top destination for overseas education, Chinese student murdered, scholars, economics, Sino American politics

Table 1: Selected culturally different entities with summarized Twitter and Weibo's trending topics

bedding space. It is extended from the work of Faruqui and Dyer (2014), which performs slightly worse in the experiments. **MCluster** (Ammar et al., 2016) requires re-training the bilingual word embeddings from the two mono-lingual corpora with a bilingual lexicon. Similarly, **Duong** (Duong et al., 2016) retrains the embeddings from mono-lingual corpora with an EM-like training algorithm. We also use our BSL as the bilingual lexicon in these methods to investigate its effectiveness and generalizability. The dimensionality is tuned from $\{50, 100, 150, 200\}$ in all these bilingual word embedding methods.

With our constructed ***SocVec*** space, given a named entity with its English and Chinese names, we can simply compute the similarity between their *SocVec*s as its cross-cultural difference score. Our method is based on monolingual word embeddings and a BSL, and thus does not need the time-consuming re-training on the corpora.

4.3 Experimental Results

For qualitative evaluation, Table 1 shows some of the most culturally different entities mined by the SocVec method. The hot and trendy topics on Twitter and Weibo are manually summarized to help explain the cross-cultural differences. The perception of these entities diverges widely between English and Chinese social media, thus suggesting significant cross-cultural differences. Note that some cultural differences are time-specific. We believe such temporal variations of cultural differences can be valuable and beneficial for social studies as well. Investigating temporal factors of cross-cultural differences in social media can be an interesting future research topic in this task.

In Table 2, we evaluate the benchmark methods and our approach with three metrics: Spearman and Pearson, where correlation is computed between truth averaged scores (quantifying the labels from 1.0 to 5.0) and computed cultural difference scores from different methods; Mean Average Precision (MAP), which converts averaged scores as binary labels, by setting 3.0 as the threshold. The ***SocVec:opn*** considers only OpinionFinder as the ESV, while ***SocVec:all*** uses the union of Empath and OpinionFinder vocabularies[7].

Method	Spearman	Pearson	MAP

Table 2: Comparison of Different Methods

Lexicon Ablation Test. To show the effectiveness of social words versus other type of words as the bridge between the two cultures, we also compare the results using sets of nouns (***SocVec:noun***), verbs (***SocVec:verb***) and adjectives (***SocVec:adj.***). All vocabularies under comparison are of similar sizes (around 5,000), indicating that the improvement of our method is significant. Results show that our *SocVec* models, and in particular, the *SocVec* model using the social words as cross-lingual media, performs the best.

[7]The following tuned parameters are used in *SocVec* methods: 5-word context window, 150 dimensions monolingual word vectors, cosine similarity as the *sim* function, and "*Top*" as the pseudo-word generator.

Similarity	Spearman	Pearson	MAP
PCorr.	0.631	0.625	0.806
L1 + M	0.666	0.656	0.824

15.29	14.97	15.13	**17.31**	

(b) English Slang to Chinese

Table 5: ACS Sum Results of Slang Translation

Similarity Options. We also evaluate the effectiveness of four different similarity options in *SocVec*, namely, Pearson Correlation Coefficient (*PCorr.*), L1-normalized Manhattan distance (*L1+M*), Cosine Similarity (*Cos*) and L2-normalized Euclidean distance (*L2+E*). From Table 3, we conclude that among these four options, *Cos* and *L2+E* perform the best.

Pseudo-word Generators. Table 4 shows effect of using four pseudo-word generator functions, from which we can infer that "*Top*" generator function performs best for it reduces some noisy translation pairs.

5 Task 2: Finding most similar words for slang across languages

Task Description: This task is to find the most similar English words of a given Chinese slang term in terms of its slang meanings and sentiment, and vice versa. The input is a list of English/Chinese slang terms of interest and two monolingual social media corpora; the output is a list of Chinese/English word sets corresponding to each input slang term. Simply put, for each given slang term, we want to find a set of the words in a different language that are most similar to itself and thus can help people understand it across languages. We propose Average Cosine Similarity (Section 5.3) to evaluate a method's performance with the ground truth (presented below).

5.1 Ground Truth

Slang Terms. We collect the Chinese slang terms from an online Chinese slang glossary[8] consisting of 200 popular slang terms with English explanations. For English, we resort to a slang word list from OnlineSlangDictionary[9] with explanations and downsample the list to 200 terms.

Truth Sets. For each Chinese slang term, its truth set is a set of words extracted from its English explanation. For example, we construct the truth set of the Chinese slang term "二百五" by manually extracting significant words about its slang meanings (bold) in the glossary:

二百五: A ***foolish*** person who is lacking in sense but still ***stubborn***, ***rude***, and ***impetuous***.

Similarly, for each English slang term, its Chinese word sets are the translation of the words hand picked from its English explanation.

5.2 Baseline and Our Methods

We propose two types of baseline methods for this task. The first is based on well-known *online translators*, namely Google (Gg), Bing (Bi) and Baidu (Bd). Note that experiments using them are done in August, 2017. Another baseline method for Chinese is CC-CEDICT[10] (CC), an online public Chinese-English dictionary, which is constantly updated for popular slang terms.

Considering situations where many slang terms have literal meanings, it may be unfair to retrieve target terms from such machine translators by solely inputing slang terms without specific contexts. Thus, we utilize example sentences of their slang meanings from some websites (mainly from Urban Dictionary[11]). The following example shows how we obtain the target translation terms for the slang word "fruitcake" (an insane person):

Input sentence: *Oh man, you don't want to date that girl. She's always drunk and yelling. She is a total* ***fruitcake***.[12]

[8] https://www.chinasmack.com/glossary

[9] http://onlineslangdictionary.com/word-list/

[10] https://cc-cedict.org/wiki/

[11] http://www.urbandictionary.com/

[12] http://www.englishbaby.com/lessons/4349/slang/fruitcake

Slang	Explanation	Google	Bing	Baidu	Ours
浮云	something as ephemeral and unimportant as “passing clouds”	clouds	nothing	floating clouds	nothingness, illusion
水军	“water army”, people paid to slander competitors on the Internet and to help shape public opinion	Water army	Navy	Navy	propaganda, complicit, fraudulent
floozy	a woman with a reputation for promiscuity	N/A	劣根性 (depravity)	荡妇(slut)	骚货(slut),妖精(promiscuous)
fruitcake	a crazy person, someone who is completely insane	水果蛋糕 (fruit cake)	水果蛋糕 (fruit cake)	水果蛋糕 (fruit cake)	怪诞(bizarre),厌烦(annoying)

Table 6: Bidirectional Slang Translation Examples Produced by SocVec

Google Translation: 哦, 男人, 你不想约会那个女孩。她总是喝醉了, 大喊大叫。她是一个水果蛋糕。

Another lines of baseline methods is scoring-based. The basic idea is to score all words in our bilingual lexicon and consider the top K words as the target terms. Given a source term to be translated, the Linear Transform (LT), MCCA, MCluster and Duong methods score the candidate target terms by computing cosine similarities in their constructed bilingual vector space (with the tuned best settings in previous evaluation). A more sophisticated baseline (TransBL) leverages the bilingual lexicon: for each candidate target term w in the target language, we first obtain its translations T_w back into the source language and then calculate the average word similarities between the source term and the translations T_w as w's score.

Our *SocVec-based method* (**SV**) is also scoring-based. It simply calculates the cosine similarities between the source term and each candidate target term within *SocVec* space as their scores.

5.3 Experimental Results

To quantitatively evaluate our methods, we need to measure similarities between a produced word set and the ground truth set. Exact-matching Jaccard similarity is too strict to capture valuable relatedness between two word sets. We argue that average cosine similarity (ACS) between two sets of word vectors is a better metric for evaluating the similarity between two word sets.

$$\text{ACS}(A,B) = \frac{1}{|A||B|}\sum_{i=1}^{|A|}\sum_{j=1}^{|B|}\frac{\mathbf{A_i}\cdot\mathbf{B_j}}{\|\mathbf{A_i}\|\|\mathbf{B_j}\|}$$

The above equation illustrates such computation, where A and B are the two word sets: A is the truth set and B is a similar list produced by each method. In the previous case of “二百五” (Section 5.1), A is {foolish, stubborn, rude, impetuous} while B can be {imbecile, brainless, scumbag, imposter}. $\mathbf{A_i}$ and $\mathbf{B_j}$ denote the word vector of the i^{th} word in A and j^{th} word in B respectively. The embeddings used in ACS computations are pre-trained *GloVe* word vectors[13] and thus the computation is fair among different methods.

Chinese Slang	English Slang	Explanation
萌	adorbz, adorb, adorbs, tweeny, attractiveee	cute, adorable
二百五	shithead, stupidit, douchbag	A foolish person
鸭梨	antsy, stressy, fidgety, grouchy, badmood	stress, pressure, burden

Table 7: Slang-to-Slang Translation Examples

Experimental results of Chinese and English slang translation in terms of the sum of *ACS* over 200 terms are shown in Table 5. The performance of online translators for slang typically depends on human-set rules and supervised learning on well-annotated parallel corpora, which are rare and costly, especially for social media where slang emerges the most. This is probably the reason why they do not perform well. The Linear Transformation (LT) model is trained on highly confident translation pairs in the bilingual lexicon, which lacks OOV slang terms and social contexts around them. The TransBL method is competitive because its similarity computations are within monolingual semantic spaces and it makes great use of the bilingual lexicon, but it loses the information from the related words that are not in the bilingual lexicon. Our method (SV) outperforms baselines by directly using the distances in the *SocVec* space, which proves that the *SocVec* well captures the cross-cultural similarities between terms.

To qualitatively evaluate our model, in Table 6, we present several examples of our translations for Chinese and English slang terms as well as their

[13] https://nlp.stanford.edu/projects/glove/

explanations from the glossary. Our results are highly correlated with these explanations and capture their significant semantics, whereas most online translators just offer literal translations, even within obviously slang contexts. We take a step further to directly translate Chinese slang terms to English slang terms by filtering out ordinary (non-slang) words in the original target term lists, with examples shown in Table 7.

6 Related Work

Although social media messages have been essential resources for research in computational social science, most works based on them only focus on a single culture and language (Petrovic et al., 2010; Paul and Dredze, 2011; Rosenthal and McKeown, 2015; Wang and Yang, 2015; Zhang et al., 2015; Lin et al., 2017). Cross-cultural studies have been conducted on the basis of a questionnaire-based approach for many years. There are only a few of such studies using NLP techniques.

Nakasaki et al. (2009) present a framework to visualize the cross-cultural differences in concerns in multilingual blogs collected with a topic keyword. Elahi and Monachesi (2012) show that cross-cultural analysis through language in social media data is effective, especially using emotion terms as culture features, but the work is restricted in monolingual analysis and a single domain (love and relationship). Garimella et al. (2016a) investigate the cross-cultural differences in word usages between Australian and American English through their proposed "socio-linguistic features" (similar to our social words) in a supervised way. With the data of social network structures and user interactions, Garimella et al. (2016b) study how to quantify the controversy of topics within a culture and language. Gutiérrez et al. (2016) propose an approach to detect differences of word usage in the cross-lingual topics of multilingual topic modeling results. To the best of our knowledge, our work for Task 1 is among the first to mine and quantify the cross-cultural differences in concerns about named entities across different languages.

Existing research on slang mainly focuses on automatic discovering of slang terms (Elsahar and Elbeltagy, 2014) and normalization of noisy texts (Han et al., 2012) as well as slang formation. Ni and Wang (2017) are among the first to propose an automatic supervised framework to monolingually explain slang terms using external resources. However, research on automatic translation or cross-lingually explanation for slang terms is missing from the literature. Our work in Task 2 fills the gap by computing cross-cultural similarities with our bilingual word representations (*SocVec*) in an unsupervised way. We believe this application is useful in machine translation for social media (Ling et al., 2013).

Many existing cross-lingual word embedding models rely on expensive parallel corpora with word or sentence alignments (Klementiev et al., 2012; Kočiský et al., 2014). These works often aim to improve the performance on monolingual tasks and cross-lingual model transfer for document classification, which does not require cross-cultural signals. We position our work in a broader context of "monolingual mapping" based cross-lingual word embedding models in the survey of Ruder et al. (2017). The SocVec uses only lexicon resource and maps monolingual vector spaces into a common high-dimensional third space by incorporating social words as pivot, where orthogonality is approximated by setting clear meaning to each dimension of the *SocVec* space.

7 Conclusion

We present the SocVec method to compute cross-cultural differences and similarities, and evaluate it on two novel tasks about mining cross-cultural differences in named entities and computing cross-cultural similarities in slang terms. Through extensive experiments, we demonstrate that the proposed lightweight yet effective method outperforms a number of baselines, and can be useful in translation applications and cross-cultural studies in computational social science. Future directions include: 1) mining cross-cultural differences in general concepts other than names and slang, 2) merging the mined knowledge into existing knowledge bases, and 3) applying the SocVec in downstream tasks like machine translation.[14]

Classification of Moral Foundations in Microblog Political Discourse

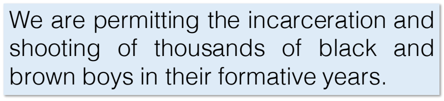
Kristen Johnson and Dan Goldwasser
Department of Computer Science
Purdue University, West Lafayette, IN 47907
{john1187, dgoldwas}@purdue.edu

Abstract

Previous works in computer science, as well as political and social science, have shown correlation in text between political ideologies and the moral foundations expressed within that text. Additional work has shown that policy frames, which are used by politicians to bias the public towards their stance on an issue, are also correlated with political ideology. Based on these associations, this work takes a first step towards modeling both the language and how politicians frame issues on Twitter, in order to predict the moral foundations that are used by politicians to express their stances on issues. The contributions of this work includes a dataset annotated for the moral foundations, annotation guidelines, and probabilistic graphical models which show the usefulness of jointly modeling abstract political slogans, as opposed to the unigrams of previous works, with policy frames for the prediction of the morality underlying political tweets.

1 Introduction

Social media microblogging platforms, specifically Twitter, have become highly influential and relevant to current political events. Such platforms allow politicians to communicate with the public as events are unfolding and shape public discourse on various issues. Furthermore, politicians are able to express their stances on issues and by selectively using certain political slogans, reveal their underlying political ideologies and moral views on an issue. Previous works in political and social science have shown a correlation between political ideology, stances on political issues, and the moral convictions used to justify these stances (Graham et al., 2009). For example, Figure 1 presents a tweet, by a prominent member of the U.S. Congress, which expresses concern

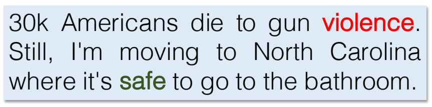


We are permitting the incarceration and shooting of thousands of black and brown boys in their formative years.

Figure 1: Example Tweet Highlighting Classification Difficulty.

about the fate of young individuals (i.e., *incarceration, shooting*), specifically for vulnerable members of minority groups. The Moral Foundations Theory (MFT) (Haidt and Joseph, 2004; Haidt and Graham, 2007) provides a theoretical framework for explaining these nuanced distinctions. The theory suggests that there are five basic moral values which underlie human moral perspectives, emerging from evolutionary, social, and cultural origins. These are referred to as the moral foundations (MF) and include *Care/Harm, Fairness/Cheating, Loyalty/Betrayal, Authority/Subversion*, and *Purity/Degradation* (Table 1 provides a more detailed explanation). The above example reflects the moral foundations that shape the author's perspective on the issue: *Harm* and *Cheating*.

Traditionally, analyzing text based on the MFT has relied on the use of a lexical resource, the Moral Foundations Dictionary (MFD) (Haidt and Graham, 2007; Graham et al., 2009). The MFD, similar to LIWC (Pennebaker et al., 2001; Tausczik and Pennebaker, 2010), associates a list of related words with each one of the moral foundations. Therefore, analyzing text equates to counting the number of occurrences of words in the text which also match the words in the MFD. Given the highly abstract and generalized nature of the moral foundations, this approach often falls short of dealing with the highly ambiguous text politicians use to express their perspectives on specific issues. The following tweet, by another prominent member of the U.S. Congress, reflects the author's use of both the *Harm* and *Cheating* moral foundations.



30k Americans die to gun violence. Still, I'm moving to North Carolina where it's safe to go to the bathroom.

Figure 2: Example Tweet Highlighting Classification Difficulty.

While the first foundation (*Harm*) can be directly identified using a word match to the MFD (as shown in red), the second foundation requires first identifying the sarcastic expression referring to LGBTQ rights and then using extensive world knowledge to determine the appropriate moral foundation. [1] Relying on a match of *safe* to the MFD would indicate the *Care* MF is being used instead of the *Cheating* foundation.

In this paper, we aim to solve this challenge by suggesting a data-driven approach to moral foundation identification in tweets. Previous work (Garten et al., 2016) has looked at classification-based approaches over tweets specifically related to Hurricane Sandy, augmenting the textual content with background knowledge using entity linking (Lin et al., 2017). Different from this and similar works, we look at the tweets of U.S. politicians over a long period of time, discussing a large number of events, and touching on several different political issues. Our approach is guided by the intuition that the abstract moral foundations will manifest differently in text, depending on the specific characteristics of the events discussed in the tweet. As a result, it is necessary to correctly model the relevant contextualizing information.

Specifically, we are interested in exploring how political ideology, language, and framing interact to represent morality on Twitter. We examine the interplay of political slogans (for example *"repeal and replace"* when referring to the Affordable Care Act), and policy framing techniques (Boydstun et al., 2014; Johnson et al., 2017) as features for predicting the underlying moral values which are expressed in politicians' tweets. Additionally, we identify high-level themes characterizing the main point of the tweet, which allows the model to identify the author's perspective on specific issues and generalize over the specific wording used (for example, if the tweet mentions `Religion` or `Political Maneuvering`).

This information is incorporated into global probabilistic models using Probabilistic Soft Logic (PSL), a graphical probabilistic modeling framework (Bach et al., 2013). PSL specifies high level rules over a relational representation of these features, which are compiled into a graphical model called a hinge-loss Markov random field that is used to make the final prediction. Our experiments show the importance of modeling contextualizing information, leading to significant improvements over dictionary driven approaches and purely lexical methods.

In summary, this paper makes the following contributions: (1) This work is among the first to explore jointly modeling language and political framing techniques for the classification of moral foundations used in the tweets of U.S. politicians on Twitter. (2) We provide a description of our annotation guidelines and an annotated dataset of 2,050 tweets.[2] (3) We suggest computational models which easily adapt to new policy issues, for the classification of the moral foundations present in tweets.

2 Related Works

In this paper, we explore how political ideology, language, framing, and morality interact on Twitter. Previous works have studied framing in longer texts, such as congressional speeches and news (Fulgoni et al., 2016; Tsur et al., 2015; Card et al., 2015; Baumer et al., 2015), as well as issue-independent framing on Twitter (Johnson and Goldwasser, 2016; Johnson et al., 2017). Ideology measurement (Iyyer et al., 2014; Bamman and Smith, 2015; Sim et al., 2013; Djemili et al., 2014), political sentiment analysis (Pla and Hurtado, 2014; Bakliwal et al., 2013), and polls based on Twitter political sentiment (Bermingham and Smeaton, 2011; O'Connor et al., 2010; Tumasjan et al., 2010) are also related to the study of framing. The association between Twitter and framing in molding public opinion of events and issues (Burch et al., 2015; Harlow and Johnson, 2011; Meraz and Papacharissi, 2013; Jang and

[1]The tweet refers to legislation proposed in 2016 concerning transgender bathroom access restrictions.

[2]The data will be available at `http://purduenlp.cs.purdue.edu/projects/twittermorals`.

MORAL FOUNDATION AND BRIEF DESCRIPTION
1. Care/Harm: Care for others, generosity, compassion, ability to feel pain of others, sensitivity to suffering of others, prohibiting actions that harm others.
2. Fairness/Cheating: Fairness, justice, reciprocity, reciprocal altruism, rights, autonomy, equality, proportionality, prohibiting cheating.
3. Loyalty/Betrayal: Group affiliation and solidarity, virtues of patriotism, self-sacrifice for the group, prohibiting betrayal of one's group.
4. Authority/Subversion: Fulfilling social roles, submitting to authority, respect for social hierarchy/traditions, leadership, prohibiting rebellion against authority.
5. Purity/Degradation: Associations with the sacred and holy, disgust, contamination, religious notions which guide how to live, prohibiting violating the sacred.
6. Non-moral: Does not fall under any other foundations.

Table 1: Brief Descriptions of Moral Foundations.

Hart, 2015) has also been studied.

The connection between morality and political ideology has been explored in the fields of psychology and sociology (Graham et al., 2009, 2012). Moral foundations were also used to inform downstream tasks, by using the MFD to identify the moral foundations in partisan news sources (Fulgoni et al., 2016), or to construct features for other downstream tasks (Volkova et al., 2017). Several recent works have looked into using data-driven methods that go beyond the MFD to study tweets related to Hurricane Sandy (Garten et al., 2016; Lin et al., 2017).

3 Data Annotation

The Moral Foundations Theory (Haidt and Graham, 2007) was proposed by sociologists and psychologists as a way to understand how morality develops, as well as its similarities and differences across cultures. The theory consists of the five moral foundations shown in Table 1. The goal of this work is to classify the tweets of the Congressional Tweets Dataset (Johnson et al., 2017) with the moral foundation implied in the tweet.

We first attempted to use Amazon Mechanical Turk for annotation, but found that most Mechanical Turkers would choose the *Care/Harm* or *Fairness/Cheating* label a majority of the time. Additionally, annotators preferred choosing first the foundation branch (i.e., *Care/Harm*) and then its sentiment (positive or negative) as opposed to the choice of each foundation separately, i.e., given the choice between *Harm* or *Care/Harm and Negative*, annotators preferred the latter. Based on these observations, two annotators, one liberal and one conservative (self-reported), manually annotated a subset of tweets. This subset had an inter-annotator agreement of 67.2% using Cohen's Kappa coefficient. The annotators then discussed and agreed on general guidelines which were used to label the remaining tweets of the dataset. The resulting dataset has an inter-annotator agreement of 79.2% using Cohen's Kappa statistic. The overall distribution, distributions by political party, and distributions per issue of the labeled dataset are presented in Table 2. Table 3 lists the frames that most frequently co-occured with each MF. As expected, frames concerning Morality and Sympathy are highly correlated with the *Purity* foundation, while *Subversion* is highly correlated with the Legal and Political frames.

Labeling tweets presents several challenges. First, tweets are short and thus lack the context often necessary for choosing a moral viewpoint. Tweets are often ambiguous, e.g., a tweet may express care for people who are being harmed by a policy. Another major challenge was overcoming the political bias of the annotator. For example, if a tweet discusses opposing Planned Parenthood because it provides abortion services, the liberal annotator typically viewed this as *Harm* (i.e., hurting women by taking away services from them), while the conservative annotator tended to view this as *Purity* (i.e., all life is sacred and should be protected). To overcome this bias, annotators were given the political party of the politician who wrote the tweets and instructed to choose the moral foundation *from the politician's perspective*. To further simplify the annotation process, all tweets belonging to one political party were labeled together, i.e., all Republican tweets were labeled and then all Democrat tweets were labeled. Finally, tweets present a compound problem, often expressing two thoughts which can further be contradictory. This results in one tweet having multiple moral foundations. Annotators chose a primary moral foundation whenever possible, but were allowed a secondary foundation if the tweet presented two differing thoughts.

Several recurring themes continued to appear throughout the dataset including "thoughts and prayers" for victims of gun shooting events or rhetoric against the opposing political party. The annotators agreed to use the following moral foundation labels for these repeating topics as follows: (1) The *Purity* label is used for tweets that relate to

Morals	OVERALL	PARTY		ISSUE					
		REP	DEM	ABO	ACA	GUN	IMM	LGBTQ	TER
Care	524	156	368	37	123	215	33	34	113
Harm	355	151	204	26	64	141	19	34	101
Fairness	268	55	213	41	81	19	11	86	39
Cheating	82	37	45	14	27	11	10	9	13
Loyalty	303	63	240	28	29	128	36	38	58
Betrayal	53	25	28	10	4	9	6	3	22
Authority	192	62	130	24	44	50	38	10	34
Subversion	419	251	168	34	169	75	73	25	60
Purity	174	86	88	24	3	102	5	24	41
Degradation	66	34	32	5	0	31	0	4	31
Non-moral	334	198	136	17	143	28	47	7	96

Table 2: Distributions of Moral Foundations. Overall is across the entire dataset. Party is the Republican (REP) or Democrat (DEM) specific distributions. Issue lists the six issue-specific distributions (Abortion, ACA, Guns, Immigration, LGBTQ, Terrorism).

MORAL FOUNDATION AND CO-OCCURING FRAMES
Care: Capacity & Resources, Security & Defense, Health & Safety, Quality of Life, Public Sentiment, External Regulation & Reputation
Harm: Economic, Crime & Punishment
Fairness: Fairness & Equality
Loyalty: Cultural Identity
Subversion: Legality, Constitutionality, & Jurisdiction, Political Factors & Implications, Policy Description, Prescription, & Evaluation
Purity: Morality & Ethics, Personal Sympathy & Support
Non-moral: Factual, (Self) Promotion

Table 3: Foundations and Co-occuring Frames. *Cheating, Betrayal, Authority,* and *Degradation* did not co-occur frequently with any frames.

prayers or the fight against ISIL/ISIS. (2) *Loyalty* is for tweets that discuss "stand(ing) with" others, American values, troops, or allies, or reference a demographic that the politician belongs to, e.g. if the politician tweeting is a woman and she discusses an issue in terms of its effects on women. (3) At the time the dataset was collected, the President was Barack Obama and the Republican party controlled Congress. Therefore, any tweets specifically attacking Obama or Republicans (the controlling party) were labeled as *Subversion*. (4) Tweets discussing health or welfare were labeled as *Care*. (5) Tweets which discussed limiting or restricting laws or rights were labeled as *Cheating*. (6) Sarcastic attacks, typically against the opposing political party, were labeled as *Degradation*.

4 Feature Extraction for PSL Models

For this work, we designed extraction models and PSL models that were capable of adapting to the dynamic language used on Twitter and predicting the moral foundation of a given tweet. Our approach uses weakly supervised extraction models, whose only initial supervision is a set of unigrams and the political party of the tweet's author, to extract features for each PSL model. These features are represented as PSL predicates and combined into the probabilistic rules of each model, as shown in Table 4, which successively build upon the rules of the previous model.

4.1 Global Modeling Using PSL

PSL is a declarative modeling language which can be used to specify weighted, first-order logic rules that are compiled into a hinge-loss Markov random field. This field defines a probability distribution over possible continuous value assignments to the random variables of the model (Bach et al., 2015) and is represented as:

$$P(\mathbf{Y} \mid \mathbf{X}) = \frac{1}{Z} \exp\left(-\sum_{r=1}^{M} \lambda_r \phi_r(\mathbf{Y}\,,\mathbf{X})\right)$$

where Z is a normalization constant, λ is the weight vector, and

$$\phi_r(\mathbf{Y}, \mathbf{X}) = (\max\{l_r(\mathbf{Y}, \mathbf{X}), 0\})^{\rho_r}$$

is the hinge-loss potential specified by a linear function l_r. The exponent $\rho_r \in 1, 2$ is optional. Each potential represents the instantiation of a rule, which takes the following form:

$$\lambda_1 : P_1(x) \wedge P_2(x, y) \rightarrow P_3(y)$$
$$\lambda_2 : P_1(x) \wedge P_4(x, y) \rightarrow \neg P_3(y)$$

P_1, P_2, P_3, and P_4 are predicates (e.g., party, issue, and frame) and x, y are variables. Each rule has a weight λ to reflect its importance to the model. Using concrete constants *a, b* (e.g., tweets) which instantiate the variables x, y, model atoms are mapped to continuous [0,1] assignments.

MOD.	INFORMATION USED	EXAMPLE OF PSL RULE
M1	UNIGRAMS (MFD OR AR)	UNIGRAM$_M$(T, U) $\rightarrow$ MORAL(T, M)
M2	M1 + PARTY	UNIGRAM$_M$(T, U) $\wedge$ PARTY(T, P) $\rightarrow$ MORAL(T, M)
M3	M2 + ISSUE	UNIGRAM$_M$(T, U) $\wedge$ PARTY(T, P) $\wedge$ ISSUE(T, I) $\rightarrow$ MORAL(T, M)
M4	M3 + PHRASE	UNIGRAM$_M$(T, U) $\wedge$ PARTY(T, P) $\wedge$ PHRASE(T, PH) $\rightarrow$ MORAL(T, M)
M5	M4 + FRAME	UNIGRAM$_M$(T, U) $\wedge$ PHRASE(T, PH) $\wedge$ FRAME(T, F) $\rightarrow$ MORAL(T, M)
M6	M5 + PARTY-BIGRAMS	UNIGRAM$_M$(T, U) $\wedge$ PARTY(T, P) $\wedge$ BIGRAM$_P$(T, B) $\rightarrow$ MORAL(T, M)

M13	M12 + FRAME	TRIGRAM$_{PI}$(T, TG) $\wedge$ FRAME(T, F) $\rightarrow$ MORAL(T, M)

Table 4: Examples of PSL Moral Model Rules Using Gold Standard Frames. For these rules, the FRAME predicate is initialized with the known frame labels of the tweet. Each model builds successively on the rules of the previous model.

M2: UNIGRAMS + PARTY	UNIGRAM$_M$(T, U) $\wedge$ PARTY(T, P) $\wedge$ FRAME(T, F) $\rightarrow$ MORAL(T, M) UNIGRAM$_M$(T, U) $\wedge$ PARTY(T, P) $\wedge$ MORAL(T, M) $\rightarrow$ FRAME(T, F)
M13: ALL FEATURES	TRIGRAM$_{PI}$(T, TG) $\wedge$ PHRASE(T, PH) $\wedge$ FRAME(T, F) $\rightarrow$ MORAL(T, M) TRIGRAM$_{PI}$(T, TG) $\wedge$ UNIGRAM$_M$(T, U) $\wedge$ MORAL(T, M) $\rightarrow$ FRAME(T, F)

Table 5: Examples of PSL Joint Moral and Frame Model Rules. For these models, the FRAME predicate is *not initialized with known values*, but is predicted jointly with the MORAL predicate.

4.2 Feature Extraction Models

For each aspect of the tweets that composes the PSL models, scripts are written to first identify and then extract the correct information from the tweets. Once extracted, this information is formatted into PSL predicate notation and input to the PSL models. Table 4 presents the information that composes each PSL model, as well as an example of how rules in the PSL model are constructed.

Language: Works studying the Moral Foundations Theory typically assign a foundation to a body of text based on a majority match of the words in the text to the Moral Foundations Dictionary (MFD), a predefined list of unigrams associated with each foundation. These unigrams capture the conceptual idea behind each foundation. Annotators noted, however, that when choosing a foundation they typically used a small phrase or the entire tweet, not a single unigram. Based on this, we compiled all of the annotators' phrases per foundation into a unique set to create a new list of unigrams for each foundation. These unigrams are referred to as "Annotator's Rationale (AR)" throughout the remainder of this paper. The PSL predicate UNIGRAM$_M$(T, U) is used to input any unigram U from tweet T that matches the M list of unigrams (either from the MFD or AR lists) into the PSL models. An example of a rule using this predicate is shown in the first row of Table 4.

During annotation, we observed that often a tweet has only one match to a unigram, if any, and therefore a majority count approach may fail. Further, as shown in Figure 2, many tweets have one unigram that matches one foundation and another unigram that matches a different foundation. In such cases, the correct foundation cannot be determined from unigram counts alone. Based on these observations and the annotators' preference for using phrases, we incorporate the most frequent bigrams and trigrams for each political party (BIGRAM$_P$(T, B) and TRIGRAM$_P$(T, TG)) and for each party on each issue (BIGRAM$_{PI}$(T, B) and TRIGRAM$_{PI}$(T, TG)). These top 20 bigrams and trigrams contribute to a more accurate prediction than unigrams alone (Johnson et al., 2017).

Ideological Information: Previous works have shown a strong correlation between ideology and the moral foundations (Haidt and Graham, 2007), as well as between ideology and policy issues (Boydstun et al., 2014). Annotators were able to agree on labels when instructed to label from the ideological point of view of the tweet's author, even if it opposed their own views. Based on these positive correlations, we incorporate both the issue of the tweet (ISSUE(T, I)) and the political party of the author of the tweet (PARTY(T, P)) into the PSL models. Examples of how this information is represented in the PSL models are shown in rows two and three of Table 4.

Abstract Phrases: As described previously, annotators reported that phrases were more useful than unigrams in determining the moral foundation of the tweet. Due to the dynamic nature of language and trending issues on Twitter, it is impracticable to construct a list of all possible phrases one can expect to appear in tweets. However, because politicians are known for sticking to certain talking points, these phrases can be *abstracted* into higher-level phrases that are more stable and thus easier to identify and extract.

For example, a tweet discussing "President Obama's signing a bill" has two possible concrete phrases: *President Obama's signing* and *signing a bill*. Each phrase falls under two possible abstractions: political maneuvering (Obama's actions) and mentions legislation (signing of a bill). In this paper we use the following high-level abstractions: `legislation or voting`, `rights and equality`, `emotion`, `sources of danger or harm`, `positive benefits or effects`, `solidarity`, `political maneuvering`, `protection and prevention`, `American values or traditions`, `religion`, and `promotion`. For example, if a tweet mentions "civil rights" or "equal pay", then these phrases indicate that the `rights and equality` abstraction is being used to express morality. Some of these abstractions correlate with the corresponding MF or frame, e.g., the `religion` abstraction is highly correlated with the *Purity* foundation and `political maneuvering` is correlated with the Political Factors & Implications Frame.

To match phrases in tweets to these abstractions, we use the embedding-based model of Lee et al. (2017). This phrase similarity model was trained on the Paraphrase Database (PPDB) (Ganitkevitch et al., 2013) and incorporates a Convolutional Neural Network (CNN) to capture sentence structures. This model generates the embeddings of our abstract phrases and computes the cosine similarities between phrases and tweets as the scores. The input tweets and phrases are represented as the average word embeddings in the input layer, which are then projected into a convolutional layer, a max-pooling layer, and finally two fully-connected layers. The embeddings are thus represented in the final layer. The learning objective of this model is:

$$\begin{aligned}\min_{W_c,W_w}\Big(\sum_{<x_1,x_2>\in X} & max(0,\delta - cos(g(x_1),g(x_2)) \\ & + cos(g(x_1),g(t_1))) \\ & + max(0,\delta - cos(g(x_1),g(x_2))) \\ & + cos(g(x_2),g(t_2))\Big) \\ & + \lambda_c||W_c||^2 + \lambda_w||W_{init} - W_w||^2,\end{aligned}$$

where X is all the positive input pairs, δ is the margin, $g(\cdot)$ represents the network, λ_c and λ_w are the weights for L2-regularization, W_c is the network parameters, W_w is the word embeddings, W_{init} is the initial word embeddings, and t_1 and t_2 are negative examples that are randomly selected.

All tweet-phrase pairs with a cosine similarity over a given threshold are used as input to the PSL model via the predicate PHRASE(T, PH), which indicates that tweet T contains a phrase that is similar to an abstracted phrase (PH). [3] Rows four, eight, and twelve of Table 4 show examples of the phrase rules as used in our modeling procedure.

Nuanced Framing: Framing is a political strategy in which politicians carefully word their statements in order to bias public opinion towards their stance on an issue. This technique is a fine-grained view of how issues are expressed. Frames are associated with issue, political party, and ideologies. For example, if a politician emphasizes the economic burden a new bill would place on the public, then they are using the *Economic* frame. Different from this, if they emphasize how people's lives will improve because of this bill, then they are using the *Quality of Life* frame.

In this work, we explore frames in two settings: (1) where the actual frames of tweets are known and used to predict the moral foundation of the tweets and (2) when the frames are unknown and predicted jointly with the moral foundations. Using the Congressional Tweets Dataset as the true labels for 17 policy frames, this information is input to the PSL models using the FRAME(T, F) predicate as shown in Table 4. Conversely, the

[3] A threshold score of 0.45 provided the most accurate matches while minimizing noise.

same predicate can be used as a joint prediction target predicate, with no initialization, as shown in Table 5.

5 Experimental Results

In this section, we present an analysis of the results of our modeling approach. Table 6 summarizes our overall results and compares the traditional BoW SVM classifier[4] to several variations of our model. We provide an in-depth analysis, broken down by the different types of moral foundations, in Tables 7 and 8.

We also study the relationship between moral foundations, policy framing, and political ideology. Table 9 describes the results of a joint model for predicting moral foundations and policy frames. Finally, in Section 6 we discuss how moral foundations can be used for the downstream prediction of political party affiliation.

Model	MFD	AR
SVM BoW	18.70	—
PSL BoW	21.88	—
Majority Vote	12.50	10.86
M1 (Unigrams)	7.17	8.68
M3 (+ Political Info)	22.01	30.45
M5 (+ Frames)	28.94	37.44
M9 (+ Bigrams)	67.93	66.50
M13 (All features)	72.49	69.38

Table 6: Overview of Macro-weighted Average F_1 Scores of SVM and PSL Models. The top portion of the table shows the results of the three baselines. The bottom portion shows a subset of the PSL models (parentheses indicate features added onto the previous models).

Evaluation Metrics: Since each tweet can have more than one moral foundation, our prediction task is a multilabel classification task. The precision of a multilabel model is the ratio of how many predicted labels are correct:

$$Precision = \frac{1}{T}\sum_{t=1}^{T}\frac{|Y_t \cap h(x_t)|}{|h(x_t)|} \tag{1}$$

The recall of this model is the ratio of how many of the actual labels were predicted:

$$Recall = \frac{1}{T}\sum_{t=1}^{T}\frac{|Y_t \cap h(x_t)|}{|Y_t|} \tag{2}$$

[4]For this work, we used the SVM implementation provided by scikit-learn.

In both formulas, T is the number of tweets, Y_t is the true label for tweet *t*, x_t is a tweet example, and $h(x_t)$ are the predicted labels for that tweet. The F_1 score is computed as the harmonic mean of the precision and recall. Additionally, the last lines of Tables 7 and 8 provide the macro-weighted average F_1 score over all moral foundations.

Analysis of Supervised Experiments: We conducted supervised experiments using five-fold cross validation with randomly chosen splits. Table 6 shows an overview of the average results of our supervised experiments for five of the PSL models. The first column lists the SVM or PSL model. The second column presents the results of a given model when using the MFD as the source of the unigrams for the initial model (M1). The final column shows the results when the AR unigrams are used as the initial source of supervision. The first two rows show the results of predicting the morals present in tweets using a bag-of-words (BoW) approach. Both the SVM and PSL models perform poorly due to the eleven predictive classes and noisy input features. The third row shows the results when taking a majority vote over the presence of MFD unigrams, similar to previous works. This approach is simpler and less noisy than M1, the PSL model closest to this approach.

The last five lines of this table also show the overall trends of the full results shown in Tables 7 and 8. As can be seen in all three tables, as we add more information with each PSL model, the overall results continue to improve, with the final model (M13) achieving the highest F_1 score for both sources of unigrams.

An interesting trend to note is that the AR unigrams based models result in better average performance for most of the models until M9. Models M9 and above incorporate the most powerful features: bigrams and trigrams with phrases and frames. This suggests that the AR unigrams, designed specifically for the political Twitter domain, are more useful than the MFD unigrams, *when only unigrams are available*. Conversely, the MFD unigrams are designed to *conceptually* capture morality, and therefore have weaker performance in the unigram-based models, but achieve higher performance when combined with the more powerful features of the higher models. For all models, incorporating phrases and frames results in a more accurate prediction than when using unigrams alone.

Table 8: F_1 Scores of PSL Models Using Annotator's Rationale (AR). The highest prediction per moral foundation is marked in bold.

Analysis of Joint Experiments: In addition to studying the effects of each feature on the models' ability to predict moral foundations, we also explored jointly predicting both policy frames and moral foundations. These tasks are highly related as shown by the large increase in score between the baseline and skyline measurements in Table 9 once frames are incorporated into the models.

Both moral foundations and frame classification are challenging multilabel classification tasks, the former using 11 possible foundations and the latter consisting of 17 possible frames. Furthermore, joint learning problems are harder to learn due to a larger numbers of parameters, which in turn also affects learning and inference.

Table 9 shows the macro-weighted average F_1 scores for three different models. The Baseline model shows the results of predicting only the Moral of the tweet using the non-joint model M13, which uses all features with frames initialized. The Joint model is designed to predict both the moral foundation and frame of a tweet simultaneously (as shown in Table 5), with no frame initialization. Finally, the Skyline model is M13 with all features, where the frames are initialized with their known values.

The joint model using AR unigrams outperforms the baseline, showing that there is some benefit to modeling moral foundations and frames together, as well as using domain-specific unigrams. However, it is unable to beat the MFD-based unigrams model. This is likely due to the large amount of noise introduced by incorrect frame predictions into the joint model. As expected, the joint model does not outperform the skyline model which is able to use the known values of the frames in order to accurately classify the moral foundations associated with the tweets.

Finally, the predictions for the frames in the joint model were quite low, going from an average F_1 score of 26.09 in M1 to an average F_1 score of 27.99 in M13. This likely has two causes: (1) frame prediction is a challenging 17-label classification task, with a random baseline of 6% (which our approach is able to exceed) and (2) the lower performance is because the frames are predicted with *no initialization*. In previous works, the frame prediction models are initialized with a set of unigrams expected to occur for each frame. Different from this approach, the only information our models provide to the frames are political party, issue, associated bigrams and trigrams, and the *predicted values for the moral foundations* from using this information. The F_1 score of 27.99 with such minimal initialization indicates that there is indeed a relationship between policy frames and the moral foundations expressed in tweets worth exploring in future work.

PSL MODEL	MFD	AR
BASELINE	55.49	55.88
JOINT	51.22	58.75
SKYLINE	72.49	69.38

Table 9: Overview of Macro-weighted Average F_1 Scores of Joint PSL Model M13. BASELINE is the MORAL prediction result. JOINT is the result of jointly predicting the MORAL and uninitialized FRAME predicates. SKYLINE shows the results when using all features with initialized frames.

6 Qualitative Results

Previous works (Makazhanov and Rafiei, 2013; Preoţiuc-Pietro et al., 2017) have shown the usefulness of moral foundations for the prediction of political party preference and the political ideologies of Twitter users. The moral foundation information used in these tasks is typically represented as word-level features extracted from the MFD. Unfortunately, these dictionary-based features are often too noisy to contribute to highly accurate predictions.

Recall the example tweets shown in Figures 1 and 2. Both figures are examples of tweets that are mislabeled by the traditional MFD-based approach, but correctly labeled using PSL Model M13. Using the MFD, Figure 1 is labeled as *Authority* due to "permit", the only matching unigram, while Figure 2 is incorrectly labeled as *Care*, even though there is one matching unigram for *Harm* and one for *Care*. To further demonstrate this point we compare the dictionary features to features extracted from the MORAL predictions of our PSL model.

Table 10 shows the results of using the different feature sets for the prediction of political affiliation of the author of a given tweet. All three models use moral information for prediction, but this information is represented differently in each of the models. The MFD model (line 1) uses the MFD unigrams to directly predict the political party of the author. The PSL model (line 2) uses the MF *prediction* made by the best performing model (M13) as features. Finally, the GOLD model (line 3) uses the actual MF annotations.

The difference in performance between the GOLD and MFD results shows that directly mapping the expected MFD unigrams to politicians' tweets is not informative enough for party affiliation prediction. However, by using abstract representations of language, the PSL model is able to achieve results closer to that which can be attained when using the *actual annotations* as features.

PSL MODEL	REP	DEM
MFD	48.72	51.28
PSL	61.25	66.92
GOLD	68.57	71.43

Table 10: Accuracy of Author Political Party Prediction. REP represents Republican and DEM represents Democrat.

7 Conclusion

Moral foundations and policy frames are employed as political strategies by politicians to garner support from the public. Politicians carefully word their statements to express their moral and social positions on issues, while maximizing their base's response to their message. In this paper we present PSL models for the classification of moral foundations expressed in political discourse on the microblog, Twitter. We show the benefits and drawbacks of traditionally used MFD unigrams and domain-specific unigrams for initialization of the models. We also provide an initial approach to the joint modeling of frames and moral foundations. In future works, we will exploit the interesting connections between moral foundations and frames for the analysis of more detailed ideological leanings and stance prediction.

Abstract

Semantic parsing aims at mapping natural language utterances into structured meaning representations. In this work, we propose a structure-aware neural architecture which decomposes the semantic parsing process into two stages. Given an input utterance, we first generate a rough sketch of its meaning, where low-level information (such as variable names and arguments) is glossed over. Then, we fill in missing details by taking into account the natural language input and the sketch itself. Experimental results on four datasets characteristic of different domains and meaning representations show that our approach consistently improves performance, achieving competitive results despite the use of relatively simple decoders.

1 Introduction

Semantic parsing maps natural language utterances onto machine interpretable meaning representations (e.g., executable queries or logical forms). The successful application of recurrent neural networks to a variety of NLP tasks (Bahdanau et al., 2015; Vinyals et al., 2015) has provided strong impetus to treat semantic parsing as a sequence-to-sequence problem (Jia and Liang, 2016; Dong and Lapata, 2016; Ling et al., 2016). The fact that meaning representations are typically structured objects has prompted efforts to develop neural architectures which explicitly account for their structure. Examples include tree decoders (Dong and Lapata, 2016; Alvarez-Melis and Jaakkola, 2017), decoders constrained by a grammar model (Xiao et al., 2016; Yin and Neubig, 2017; Krishnamurthy et al., 2017), or modular decoders which use syntax to dynamically compose various submodels (Rabinovich et al., 2017).

In this work, we propose to decompose the decoding process into two stages. The first decoder focuses on predicting a rough *sketch* of the meaning representation, which omits low-level details, such as arguments and variable names. Example sketches for various meaning representations are shown in Table 1. Then, a second decoder fills in missing details by conditioning on the natural language input and the sketch itself. Specifically, the sketch constrains the generation process and is encoded into vectors to guide decoding.

We argue that there are at least three advantages to the proposed approach. Firstly, the decomposition disentangles high-level from low-level semantic information, which enables the decoders to model meaning at different levels of granularity. As shown in Table 1, sketches are more compact and as a result easier to generate compared to decoding the entire meaning structure in one go. Secondly, the model can explicitly share knowledge of coarse structures for the examples that have the same sketch (i.e., basic meaning), even though their actual meaning representations are different (e.g., due to different details). Thirdly, after generating the sketch, the decoder knows what the basic meaning of the utterance looks like, and the model can use it as global context to improve the prediction of the final details.

Our framework is flexible and not restricted to specific tasks or any particular model. We conduct experiments on four datasets representative of various semantic parsing tasks ranging from logical form parsing, to code generation, and SQL query generation. We adapt our architecture to these tasks and present several ways to obtain sketches from their respective meaning representations. Experimental results show that our framework achieves competitive performance compared

Dataset	Length	Example
	7.6	x : *which state has the most rivers running through it?*

with previous systems, despite employing relatively simple sequence decoders.

2 Related Work

Various models have been proposed over the years to learn semantic parsers from natural language expressions paired with their meaning representations (Tang and Mooney, 2000; Ge and Mooney, 2005; Zettlemoyer and Collins, 2007; Wong and Mooney, 2007; Lu et al., 2008; Kwiatkowski et al., 2011; Andreas et al., 2013; Zhao and Huang, 2015). These systems typically learn lexicalized mapping rules and scoring models to construct a meaning representation for a given input.

More recently, neural sequence-to-sequence models have been applied to semantic parsing with promising results (Dong and Lapata, 2016; Jia and Liang, 2016; Ling et al., 2016), eschewing the need for extensive feature engineering. Several ideas have been explored to enhance the performance of these models such as data augmentation (Kočiský et al., 2016; Jia and Liang, 2016), transfer learning (Fan et al., 2017), sharing parameters for multiple languages or meaning representations (Susanto and Lu, 2017; Herzig and Berant, 2017), and utilizing user feedback signals (Iyer et al., 2017). There are also efforts to develop structured decoders that make use of the syntax of meaning representations. Dong and Lapata (2016) and Alvarez-Melis and Jaakkola (2017) develop models which generate tree structures in a top-down fashion. Xiao et al. (2016) and Krishnamurthy et al. (2017) employ the grammar to constrain the decoding process. Cheng et al. (2017) use a transition system to generate variable-free queries. Yin and Neubig (2017) design a grammar model for the generation of abstract syntax trees (Aho et al., 2007) in depth-first, left-to-right order. Rabinovich et al. (2017) propose a modular decoder whose submodels are dynamically composed according to the generated tree structure.

Our own work also aims to model the structure of meaning representations more faithfully. The flexibility of our approach enables us to easily apply sketches to different types of meaning representations, e.g., trees or other structured objects. Coarse-to-fine methods have been popular in the NLP literature, and are perhaps best known for syntactic parsing (Charniak et al., 2006; Petrov, 2011). Artzi and Zettlemoyer (2013) and Zhang et al. (2017) use coarse lexical entries or macro grammars to reduce the search space of semantic parsers. Compared with coarse-to-fine inference for lexical induction, sketches in our case are abstractions of the final meaning representation.

The idea of using sketches as intermediate representations has also been explored in the field of program synthesis (Solar-Lezama, 2008; Zhang and Sun, 2013; Feng et al., 2017). Yaghmazadeh et al. (2017) use SEMPRE (Berant et al., 2013) to map a sentence into SQL sketches which are completed using program synthesis techniques and iteratively repaired if they are faulty.

3 Problem Formulation

Our goal is to learn semantic parsers from instances of natural language expressions paired with their structured meaning representations.

Figure 1: We first generate the meaning sketch a for natural language input x. Then, a fine meaning decoder fills in the missing details (shown in red) of meaning representation y. The coarse structure a is used to guide and constrain the output decoding.

Let $x = x_1 \cdots x_{|x|}$ denote a natural language expression, and $y = y_1 \cdots y_{|y|}$ its meaning representation. We wish to estimate $p(y|x)$, the conditional probability of meaning representation y given input x. We decompose $p(y|x)$ into a two-stage generation process:

$$p(y|x) = p(y|x, a)\, p(a|x) \tag{1}$$

where $a = a_1 \cdots a_{|a|}$ is an abstract sketch representing the meaning of y. We defer detailed description of how sketches are extracted to Section 4. Suffice it to say that the extraction amounts to stripping off arguments and variable names in logical forms, schema specific information in SQL queries, and substituting tokens with types in source code (see Table 1).

As shown in Figure 1, we first predict sketch a for input x, and then fill in missing details to generate the final meaning representation y by conditioning on both x and a. The sketch is encoded into vectors which in turn guide and constrain the decoding of y. We view the input expression x, the meaning representation y, and its sketch a as sequences. The generation probabilities are factorized as:

$$p(a|x) = \prod_{t=1}^{|a|} p(a_t | a_{<t}, x) \tag{2}$$

$$p(y|x, a) = \prod_{t=1}^{|y|} p(y_t | y_{<t}, x, a) \tag{3}$$

where $a_{<t} = a_1 \cdots a_{t-1}$, and $y_{<t} = y_1 \cdots y_{t-1}$. In the following, we will explain how $p(a|x)$ and $p(y|x, a)$ are estimated.

3.1 Sketch Generation

An *encoder* is used to encode the natural language input x into vector representations. Then, a *decoder* learns to compute $p(a|x)$ and generate the sketch a conditioned on the encoding vectors.

Input Encoder Every input word is mapped to a vector via $\mathbf{x}_t = \mathbf{W}_x \mathbf{o}(x_t)$, where $\mathbf{W}_x \in \mathbb{R}^{n \times |\mathcal{V}_x|}$ is an embedding matrix, $|\mathcal{V}_x|$ is the vocabulary size, and $\mathbf{o}(x_t)$ a one-hot vector. We use a bi-directional recurrent neural network with long short-term memory units (LSTM, Hochreiter and Schmidhuber 1997) as the input encoder. The encoder recursively computes the hidden vectors at the t-th time step via:

$$\overrightarrow{\mathbf{e}}_t = \mathrm{f}_{\mathrm{LSTM}}\left(\overrightarrow{\mathbf{e}}_{t-1}, \mathbf{x}_t\right), t = 1, \cdots, |x| \tag{4}$$

$$\overleftarrow{\mathbf{e}}_t = \mathrm{f}_{\mathrm{LSTM}}\left(\overleftarrow{\mathbf{e}}_{t+1}, \mathbf{x}_t\right), t = |x|, \cdots, 1 \tag{5}$$

$$\mathbf{e}_t = [\overrightarrow{\mathbf{e}}_t, \overleftarrow{\mathbf{e}}_t] \tag{6}$$

where $[\cdot, \cdot]$ denotes vector concatenation, $\mathbf{e}_t \in \mathbb{R}^n$, and $\mathrm{f}_{\mathrm{LSTM}}$ is the LSTM function.

Coarse Meaning Decoder The decoder's hidden vector at the t-th time step is computed by $\mathbf{d}_t = \mathrm{f}_{\mathrm{LSTM}}(\mathbf{d}_{t-1}, \mathbf{a}_{t-1})$, where $\mathbf{a}_{t-1} \in \mathbb{R}^n$ is the embedding of the previously predicted token. The hidden states of the first time step in the decoder are initialized by the concatenated encoding vectors $\mathbf{d}_0 = [\overrightarrow{\mathbf{e}}_{|x|}, \overleftarrow{\mathbf{e}}_1]$. Additionally, we use an attention mechanism (Luong et al., 2015) to learn soft alignments. We compute the attention score for the current time step t of the decoder, with the k-th hidden state in the encoder as:

$$s_{t,k} = \exp\{\mathbf{d}_t \cdot \mathbf{e}_k\} / Z_t \tag{7}$$

where $Z_t = \sum_{j=1}^{|x|} \exp\{\mathbf{d}_t \cdot \mathbf{e}_j\}$ is a normalization term. Then we compute $p(a_t|a_{<t}, x)$ via:

$$\mathbf{e}_t^d = \sum_{k=1}^{|x|} s_{t,k}\mathbf{e}_k \tag{8}$$

$$\mathbf{d}_t^{att} = \tanh\left(\mathbf{W}_1\mathbf{d}_t + \mathbf{W}_2\mathbf{e}_t^d\right) \tag{9}$$

$$p(a_t|a_{<t}, x) = \text{softmax}_{a_t}\left(\mathbf{W}_o\mathbf{d}_t^{att} + \mathbf{b}_o\right) \tag{10}$$

where $\mathbf{W}_1, \mathbf{W}_2 \in \mathbb{R}^{n\times n}$, $\mathbf{W}_o \in \mathbb{R}^{|\mathcal{V}_a|\times n}$, and $\mathbf{b}_o \in \mathbb{R}^{|\mathcal{V}_a|}$ are parameters. Generation terminates once an end-of-sequence token "*</s>*" is emitted.

3.2 Meaning Representation Generation

Meaning representations are predicted by conditioning on the input x and the generated sketch a. The model uses the encoder-decoder architecture to compute $p(y|x, a)$, and decorates the sketch a with details to generate the final output.

Sketch Encoder As shown in Figure 1, a bi-directional LSTM encoder maps the sketch sequence a into vectors $\{\mathbf{v}_k\}_{k=1}^{|a|}$ as in Equation (6), where $\mathbf{v}_k$ denotes the vector of the k-th time step.

Fine Meaning Decoder The final decoder is based on recurrent neural networks with an attention mechanism, and shares the input encoder described in Section 3.1. The decoder's hidden states $\{\mathbf{h}_t\}_{t=1}^{|y|}$ are computed via:

$$\mathbf{i}_t = \begin{cases} \mathbf{v}_k & y_{t-1} \text{ is determined by } a_k \\ \mathbf{y}_{t-1} & \text{otherwise} \end{cases} \tag{11}$$

$$\mathbf{h}_t = \text{f}_{\text{LSTM}}\left(\mathbf{h}_{t-1}, \mathbf{i}_t\right)$$

where $\mathbf{h}_0 = [\overrightarrow{\mathbf{e}}_{|x|}, \overleftarrow{\mathbf{e}}_1]$, and $\mathbf{y}_{t-1}$ is the embedding of the previously predicted token. Apart from using the embeddings of previous tokens, the decoder is also fed with $\{\mathbf{v}_k\}_{k=1}^{|a|}$. If y_{t-1} is determined by a_k in the sketch (i.e., there is a one-to-one alignment between y_{t-1} and a_k), we use the corresponding token's vector $\mathbf{v}_k$ as input to the next time step.

The sketch constrains the decoding output. If the output token y_t is already in the sketch, we force y_t to conform to the sketch. In some cases, sketch tokens will indicate what information is missing (e.g., in Figure 1, token "*flight@1*" indicates that an argument is missing for the predicate "*flight*"). In other cases, sketch tokens will not reveal the number of missing tokens (e.g., "STRING" in DJANGO) but the decoder's output will indicate whether missing details have been generated (e.g., if the decoder emits a closing quote token for "STRING"). Moreover, type information in sketches can be used to constrain generation. In Table 1, sketch token "NUMBER" specifies that a numeric token should be emitted.

For the missing details, we use the hidden vector $\mathbf{h}_t$ to compute $p(y_t|y_{<t}, x, a)$, analogously to Equations (7)–(10).

3.3 Training and Inference

The model's training objective is to maximize the log likelihood of the generated meaning representations given natural language expressions:

$$\max \sum_{(x,a,y)\in\mathcal{D}} \log p(y|x, a) + \log p(a|x)$$

where $\mathcal{D}$ represents training pairs.

At test time, the prediction for input x is obtained via $\hat{a} = \arg\max_{a'} p(a'|x)$ and $\hat{y} = \arg\max_{y'} p(y'|x, \hat{a})$, where a' and y' represent coarse- and fine-grained meaning candidates. Because probabilities $p(a|x)$ and $p(y|x, a)$ are factorized as shown in Equations (2)–(3), we can obtain best results approximately by using greedy search to generate tokens one by one, rather than iterating over all candidates.

4 Semantic Parsing Tasks

In order to show that our framework applies across domains and meaning representations, we developed models for three tasks, namely parsing natural language to logical form, to Python source code, and to SQL query. For each of these tasks we describe the datasets we used, how sketches were extracted, and specify model details over and above the architecture presented in Section 3.

4.1 Natural Language to Logical Form

For our first task we used two benchmark datasets, namely GEO (880 language queries to a database of U.S. geography) and ATIS (5,410 queries to a flight booking system). Examples are shown in Table 1 (see the first and second block). We used standard splits for both datasets: 600 training and 280 test instances for GEO (Zettlemoyer and Collins, 2005); 4,480 training, 480 development, and 450 test examples for ATIS. Meaning representations in these datasets are based on λ-calculus (Kwiatkowski et al., 2011). We use brackets to linearize the hierarchical structure.

Algorithm 1 Sketch for GEO and ATIS

```
Input: t: Tree-structure λ-calculus expression
       t.pred: Predicate name, or operator name
Output: a: Meaning sketch
  ▷ (count $0 (< (fare $0) 50:do))→(count#1 (< fare@1 ?))
  function SKETCH(t)
      if t is leaf then                    ▷ No nonterminal in arguments
          return "%s@%d" % (t.pred, len(t.args))
      if t.pred is λ operator, or quantifier then ▷ e.g., count
          Omit variable information defined by t.pred
          t.pred ← "%s#%d" % (t.pred, len(variable))
      for c ← argument in t.args do
          if c is nonterminal then
              c ← SKETCH(c)
          else
              c ← "?"                      ▷ Placeholder for terminal
      return t
```

The first element between a pair of brackets is an operator or predicate name, and any remaining elements are its arguments.

Algorithm 1 shows the pseudocode used to extract sketches from λ-calculus-based meaning representations. We strip off arguments and variable names in logical forms, while keeping predicates, operators, and composition information. We use the symbol "@" to denote the number of missing arguments in a predicate. For example, we extract "*from@2*" from the expression "*(from $0 dallas:ci)*" which indicates that the predicate "*from*" has two arguments. We use "*?*" as a placeholder in cases where only partial argument information can be omitted. We also omit variable information defined by the lambda operator and quantifiers (e.g., *exists*, *count*, and *argmax*). We use the symbol "#" to denote the number of omitted tokens. For the example in Figure 1, "*lambda $0 e*" is reduced to "*lambda#2*".

The meaning representations of these two datasets are highly compositional, which motivates us to utilize the hierarchical structure of λ-calculus. A similar idea is also explored in the tree decoders proposed in Dong and Lapata (2016) and Yin and Neubig (2017) where parent hidden states are fed to the input gate of the LSTM units. On the contrary, parent hidden states serve as input to the softmax classifiers of both fine and coarse meaning decoders.

Parent Feeding Taking the meaning sketch "*(and flight@1 from@2)*" as an example, the parent of "*from@2*" is "*(and*". Let p_t denote the parent of the t-th time step in the decoder. Compared with Equation (10), we use the vector $\mathbf{d}_t^{att}$ and the hidden state of its parent $\mathbf{d}_{p_t}$ to compute the probability $p(a_t|a_{<t}, x)$ via:

$$p(a_t|a_{<t}, x) = \text{softmax}_{a_t}\left(\mathbf{W}_o[\mathbf{d}_t^{att}, \mathbf{d}_{p_t}] + \mathbf{b}_o\right)$$

where $[\cdot, \cdot]$ denotes vector concatenation. The parent feeding is used for both decoding stages.

4.2 Natural Language to Source Code

Our second semantic parsing task used DJANGO (Oda et al., 2015), a dataset built upon the Python code of the Django library. The dataset contains lines of code paired with natural language expressions (see the third block in Table 1) and exhibits a variety of use cases, such as iteration, exception handling, and string manipulation. The original split has $16,000$ training, $1,000$ development, and $1,805$ test instances.

We used the built-in lexical scanner of Python[1] to tokenize the code and obtain token types. Sketches were extracted by substituting the original tokens with their token types, except delimiters (e.g., "[", and ":"), operators (e.g., "+", and "*"), and built-in keywords (e.g., "True", and "while"). For instance, the expression "if s[:4].lower() == 'http':" becomes "if NAME [: NUMBER] . NAME ( ) == STRING :", with details about names, values, and strings being omitted.

DJANGO is a diverse dataset, spanning various real-world use cases and as a result models are often faced with out-of-vocabulary (OOV) tokens (e.g., variable names, and numbers) that are unseen during training. We handle OOV tokens with a copying mechanism (Gu et al., 2016; Gulcehre et al., 2016; Jia and Liang, 2016), which allows the fine meaning decoder (Section 3.2) to directly copy tokens from the natural language input.

Copying Mechanism Recall that we use a softmax classifier to predict the probability distribution $p(y_t|y_{<t}, x, a)$ over the pre-defined vocabulary. We also learn a copying gate $g_t \in [0, 1]$ to decide whether y_t should be copied from the input or generated from the vocabulary. We compute the modified output distribution via:

$$\begin{aligned} g_t &= \text{sigmoid}(\mathbf{w}_g \cdot \mathbf{h}_t + b_g) \\ \tilde{p}(y_t|y_{<t}, x, a) &= (1 - g_t) p(y_t|y_{<t}, x, a) \\ &\quad + \mathbb{1}_{[y_t \notin \mathcal{V}_y]} g_t \sum_{k: x_k = y_t} s_{t,k} \end{aligned}$$

[1] https://docs.python.org/3/library/tokenize

where $\mathbf{w}_g \in \mathbb{R}^n$ and $b_g \in \mathbb{R}$ are parameters, and the indicator function $\mathbb{1}_{[y_t \notin \mathcal{V}_y]}$ is 1 only if y_t is not in the target vocabulary $\mathcal{V}_y$; the attention score $s_{t,k}$ (see Equation (7)) measures how likely it is to copy y_t from the input word x_k.

4.3 Natural Language to SQL

The WIKISQL (Zhong et al., 2017) dataset contains $80,654$ examples of questions and SQL queries distributed across $24,241$ tables from Wikipedia. The goal is to generate the correct SQL query for a natural language question and table schema (i.e., table column names), without using the content values of tables (see the last block in Table 1 for an example). The dataset is partitioned into a training set (70%), a development set (10%), and a test set (20%). Each table is present in one split to ensure generalization to unseen tables.

WIKISQL queries follow the format "`SELECT agg_op agg_col WHERE (cond_col cond_op cond) AND ...`", which is a subset of the SQL syntax. `SELECT` identifies the column that is to be included in the results after applying the aggregation operator `agg_op`[2] to column `agg_col`. `WHERE` can have zero or multiple conditions, which means that column `cond_col` must satisfy the constraints expressed by the operator `cond_op`[3] and the condition value `cond`. Sketches for SQL queries are simply the (sorted) sequences of condition operators `cond_op` in `WHERE` clauses. For example, in Table 1, sketch "`WHERE > AND =`" has two condition operators, namely ">" and "=".

The generation of SQL queries differs from our previous semantic parsing tasks, in that the table schema serves as input in addition to natural language. We therefore modify our input encoder in order to render it table-aware, so to speak. Furthermore, due to the formulaic nature of the SQL query, we only use our decoder to generate the `WHERE` clause (with the help of sketches). The `SELECT` clause has a fixed number of slots (i.e., aggregation operator `agg_op` and column `agg_col`), which we straightforwardly predict with softmax classifiers (conditioned on the input). We briefly explain how these components are modeled below.

Table-Aware Input Encoder Given a table schema with M columns, we employ the special token "$\|$" to concatenate its header names

[2] `agg_op` $\in \{empty,$ `COUNT`, `MIN`, `MAX`, `SUM`, `AVG`$\}$.
[3] `cond_op` $\in \{=, <, >\}$.

as "$\|c_{1,1} \cdots c_{1,|c_1|}\| \cdots \|c_{M,1} \cdots c_{M,|c_M|}\|$", where the k-th column ("$c_{k,1} \cdots c_{k,|c_k|}$") has $|c_k|$ words. As shown in Figure 2, we use bi-directional LSTMs to encode the whole sequence. Next, for column c_k, the LSTM hidden states at positions $c_{k,1}$ and $c_{k,|c_k|}$ are concatenated. Finally, the concatenated vectors are used as the encoding vectors $\{\mathbf{c}_k\}_{k=1}^{M}$ for table columns.

As mentioned earlier, the meaning representations of questions are dependent on the tables. As shown in Figure 2, we encode the input question x into $\{\mathbf{e}_t\}_{t=1}^{|x|}$ using LSTM units. At each time step t, we use an attention mechanism towards table column vectors $\{\mathbf{c}_k\}_{k=1}^{M}$ to obtain the most relevant columns for $\mathbf{e}_t$. The attention score from $\mathbf{e}_t$ to $\mathbf{c}_k$ is computed via $u_{t,k} \propto \exp\{\alpha(\mathbf{e}_t) \cdot \alpha(\mathbf{c}_k)\}$, where $\alpha(\cdot)$ is a one-layer neural network, and $\sum_{k=1}^{M} u_{t,k} = 1$. Then we compute the context vector $\mathbf{c}_t^e = \sum_{k=1}^{M} u_{t,k}\mathbf{c}_k$ to summarize the relevant columns for $\mathbf{e}_t$. We feed the concatenated vectors $\{[\mathbf{e}_t, \mathbf{c}_t^e]\}_{t=1}^{|x|}$ into a bi-directional LSTM encoder, and use the new encoding vectors $\{\tilde{\mathbf{e}}_t\}_{t=1}^{|x|}$ to replace $\{\mathbf{e}_t\}_{t=1}^{|x|}$ in other model components. We define the vector representation of input x as:

$$\tilde{\mathbf{e}} = [\overrightarrow{\tilde{\mathbf{e}}}_{|x|}, \overleftarrow{\tilde{\mathbf{e}}}_1] \tag{12}$$

analogously to Equations (4)–(6).

`SELECT` Clause We feed the question vector $\tilde{\mathbf{e}}$ into a softmax classifier to obtain the aggregation operator `agg_op`. If `agg_col` is the k-th table column, its probability is computed via:

$$\sigma(\mathbf{x}) = \mathbf{w}_3 \cdot \tanh(\mathbf{W}_4\mathbf{x} + \mathbf{b}_4) \tag{13}$$

$$p(\texttt{agg\_col} = k|x) \propto \exp\{\sigma([\tilde{\mathbf{e}}, \mathbf{c}_k])\} \tag{14}$$

where $\sum_{j=1}^{M} p(\texttt{agg\_col} = j|x) = 1$, $\sigma(\cdot)$ is a scoring network, and $\mathbf{W}_4 \in \mathbb{R}^{2n \times m}$, $\mathbf{w}_3, \mathbf{b}_4 \in \mathbb{R}^m$ are parameters.

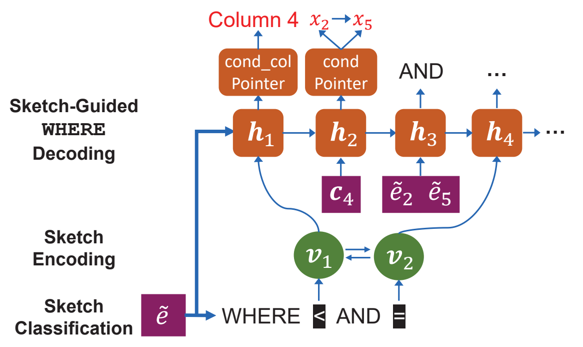

Figure 3: Fine meaning decoder of the WHERE clause used for WIKISQL.

WHERE Clause We first generate sketches whose details are subsequently decorated by the fine meaning decoder described in Section 3.2. As the number of sketches in the training set is small (35 in total), we model sketch generation as a classification problem. We treat each sketch a as a category, and use a softmax classifier to compute $p(a|x)$:

$$p(a|x) = \text{softmax}_a (\mathbf{W}_a \tilde{\mathbf{e}} + \mathbf{b}_a)$$

where $\mathbf{W}_a \in \mathbb{R}^{|\mathcal{V}_a| \times n}$, $\mathbf{b}_a \in \mathbb{R}^{|\mathcal{V}_a|}$ are parameters, and $\tilde{\mathbf{e}}$ is the table-aware input representation defined in Equation (12).

Once the sketch is predicted, we know the condition operators and number of conditions in the WHERE clause which follows the format "WHERE (cond_op cond_col cond) AND ...". As shown in Figure 3, our generation task now amounts to populating the sketch with condition columns cond_col and their values cond.

Let $\{\mathbf{h}_t\}_{t=1}^{|y|}$ denote the LSTM hidden states of the fine meaning decoder, and $\{\mathbf{h}_t^{att}\}_{t=1}^{|y|}$ the vectors obtained by the attention mechanism as in Equation (9). The condition column cond_col_{y_t} is selected from the table's headers. For the k-th column in the table, we compute $p(\text{cond\_col}_{y_t} = k | y_{<t}, x, a)$ as in Equation (14), but use different parameters and compute the score via $\sigma([\mathbf{h}_t^{att}, \mathbf{c}_k])$. If the k-th table column is selected, we use $\mathbf{c}_k$ for the input of the next LSTM unit in the decoder.

Condition values are typically mentioned in the input questions. These values are often phrases with multiple tokens (e.g., *Mikhail Snitko* in Table 1). We therefore propose to select a *text span* from input x for each condition value cond_{y_t} rather than copying tokens one by one. Let $x_l \cdots x_r$ denote the text span from which cond_{y_t} is copied. We factorize its probability as:

$$\begin{aligned} & p(\text{cond}_{y_t} = x_l \cdots x_r | y_{<t}, x, a) \\ & \quad = p\left([\![l]\!]_{y_t}^L | y_{<t}, x, a\right) p\left([\![r]\!]_{y_t}^R | y_{<t}, x, a, [\![l]\!]_{y_t}^L\right) \\ & p\left([\![l]\!]_{y_t}^L | y_{<t}, x, a\right) \propto \exp\{\sigma([\mathbf{h}_t^{att}, \tilde{\mathbf{e}}_l])\} \\ & p\left([\![r]\!]_{y_t}^R | y_{<t}, x, a, [\![l]\!]_{y_t}^L\right) \propto \exp\{\sigma([\mathbf{h}_t^{att}, \tilde{\mathbf{e}}_l, \tilde{\mathbf{e}}_r])\} \end{aligned}$$

where $[\![l]\!]_{y_t}^L / [\![r]\!]_{y_t}^R$ represents the first/last copying index of cond_{y_t} is l/r, the probabilities are normalized to 1, and $\sigma(\cdot)$ is the scoring network defined in Equation (13). Notice that we use different parameters for the scoring networks $\sigma(\cdot)$. The copied span is represented by the concatenated vector $[\tilde{\mathbf{e}}_l, \tilde{\mathbf{e}}_r]$, which is fed into a one-layer neural network and then used as the input to the next LSTM unit in the decoder.

5 Experiments

We present results on the three semantic parsing tasks discussed in Section 4. Our implementation and pretrained models are available at https://github.com/donglixp/coarse2fine.

5.1 Experimental Setup

Preprocessing For GEO and ATIS, we used the preprocessed versions provided by Dong and Lapata (2016), where natural language expressions are lowercased and stemmed with NLTK (Bird et al., 2009), and entity mentions are replaced by numbered markers. We combined predicates and left brackets that indicate hierarchical structures to make meaning representations compact. We employed the preprocessed DJANGO data provided by Yin and Neubig (2017), where input expressions are tokenized by NLTK, and quoted strings in the input are replaced with place holders. WIKISQL was preprocessed by the script provided by Zhong et al. (2017), where inputs were lowercased and tokenized by Stanford CoreNLP (Manning et al., 2014).

Configuration Model hyperparameters were cross-validated on the training set for GEO, and were validated on the development split for the other datasets. Dimensions of hidden vectors and word embeddings were selected from $\{250, 300\}$ and $\{150, 200, 250, 300\}$, respectively. The dropout rate was selected from $\{0.3, 0.5\}$. Label smoothing (Szegedy et al., 2016) was employed for GEO and ATIS. The smoothing parameter was set to 0.1. For WIKISQL, the hidden size of $\sigma(\cdot)$

and $\alpha(\cdot)$ in Equation (13) was set to 64. Word embeddings were initialized by GloVe (Pennington et al., 2014), and were shared by table encoder and input encoder in Section 4.3. We appended 10-dimensional part-of-speech tag vectors to embeddings of the question words in WIKISQL. The part-of-speech tags were obtained by the spaCy toolkit. We used the RMSProp optimizer (Tieleman and Hinton, 2012) to train the models. The learning rate was selected from $\{0.002, 0.005\}$. The batch size was 200 for WIKISQL, and was 64 for other datasets. Early stopping was used to determine the number of epochs.

Evaluation We use accuracy as the evaluation metric, i.e., the percentage of the examples that are correctly parsed to their gold standard meaning representations. For WIKISQL, we also execute generated SQL queries on their corresponding tables, and report the execution accuracy which is defined as the proportion of correct answers.

5.2 Results and Analysis

We compare our model (COARSE2FINE) against several previously published systems as well as various baselines. Specifically, we report results with a model which decodes meaning representations in one stage (ONESTAGE) without leveraging sketches. We also report the results of several ablation models, i.e., without a sketch encoder and without a table-aware input encoder.

Table 2 presents our results on GEO and ATIS. Overall, we observe that COARSE2FINE outperforms ONESTAGE, which suggests that disentangling high-level from low-level information during decoding is beneficial. The results also show that removing the sketch encoder harms performance since the decoder loses access to additional contextual information. Compared with previous neural models that utilize syntax or grammatical information (SEQ2TREE, ASN; the second block in Table 2), our method performs competitively despite the use of relatively simple decoders. As an upper bound, we report model accuracy when gold meaning sketches are given to the fine meaning decoder (+oracle sketch). As can be seen, predicting the sketch correctly boosts performance. The oracle results also indicate the accuracy of the fine meaning decoder.

Table 3 reports results on DJANGO where we observe similar tendencies. COARSE2FINE outperforms ONESTAGE by a wide margin. It is also superior to the best reported result in the literature (SNM+COPY; see the second block in the table). Again we observe that the sketch encoder is beneficial and that there is an 8.9 point difference in accuracy between COARSE2FINE and the oracle.

Results on WIKISQL are shown in Table 4. Our model is superior to ONESTAGE as well as to previous best performing systems. COARSE2FINE's accuracies on aggregation `agg_op` and `agg_col` are 90.2% and 92.0%, respectively, which is comparable to SQLNET (Xu et al., 2017). So the most gain is obtained by the improved decoder of the `WHERE` clause. We also find that a table-aware input encoder is critical for doing well on this task, since the same question might lead to different SQL queries depending on the table schemas. Consider the question "*how many presidents are graduated from A*". The SQL query over table "‖*President*‖*College*‖" is "`SELECT`

Method	Accuracy	Execution Accuracy
SEQ2SEQ	23.4	35.9
Aug Ptr Network	43.3	53.3
SEQ2SQL (Zhong et al., 2017)	48.3	59.4
SQLNET (Xu et al., 2017)	61.3	68.0
ONESTAGE	68.8	75.9
COARSE2FINE	71.7	78.5
− sketch encoder	70.8	77.7
− table-aware input encoder	68.6	75.6
+ oracle sketch	73.0	79.6

Table 4: Evaluation results on WIKISQL. Accuracies in the first block are taken from Zhong et al. (2017) and Xu et al. (2017).

Method	GEO	ATIS	DJANGO	WIKISQL
ONESTAGE	85.4	85.9	73.2	95.4
COARSE2FINE	89.3	88.0	77.4	95.9

Table 5: Sketch accuracy. For ONESTAGE, sketches are extracted from the meaning representations it generates.

COUNT(*President*) WHERE (*College* = *A*)", but the query over table "‖*College*‖*Number of Presidents*‖" would be "SELECT *Number of Presidents* WHERE (*College* = *A*)".

We also examine the predicted sketches themselves in Table 5. We compare sketches generated by COARSE2FINE against ONESTAGE. The latter model generates meaning representations without an intermediate sketch generation stage. Nevertheless, we can extract sketches from the output of ONESTAGE following the procedures described in Section 4. Sketches produced by COARSE2FINE are more accurate across the board. This is not surprising because our model is trained explicitly to generate compact meaning sketches. Taken together (Tables 2–4), our results show that better sketches bring accuracy gains on GEO, ATIS, and DJANGO. On WIKISQL, the sketches predicted by COARSE2FINE are marginally better compared with ONESTAGE. Performance improvements on this task are mainly due to the fine meaning decoder. We conjecture that by decomposing decoding into two stages, COARSE2FINE can better match table columns and extract condition values without interference from the prediction of condition operators. Moreover, the sketch provides a canonical order of condition operators, which is beneficial for the decoding process (Vinyals et al., 2016; Xu et al., 2017).

6 Conclusions

In this paper we presented a coarse-to-fine decoding framework for neural semantic parsing. We first generate meaning sketches which abstract away from low-level information such as arguments and variable names and then predict missing details in order to obtain full meaning representations. The proposed framework can be easily adapted to different domains and meaning representations. Experimental results show that coarse-to-fine decoding improves performance across tasks. In the future, we would like to apply the framework in a weakly supervised setting, i.e., to learn semantic parsers from question-answer pairs and to explore alternative ways of defining meaning sketches.

Acknowledgments We would like to thank Pengcheng Yin for sharing with us the preprocessed version of the DJANGO dataset. We gratefully acknowledge the financial support of the European Research Council (award number 681760; Dong, Lapata) and the AdeptMind Scholar Fellowship program (Dong).

Abstract

In this work we focus on confidence modeling for neural semantic parsers which are built upon sequence-to-sequence models. We outline three major causes of uncertainty, and design various metrics to quantify these factors. These metrics are then used to estimate confidence scores that indicate whether model predictions are likely to be correct. Beyond confidence estimation, we identify which parts of the input contribute to uncertain predictions allowing users to interpret their model, and verify or refine its input. Experimental results show that our confidence model significantly outperforms a widely used method that relies on posterior probability, and improves the quality of interpretation compared to simply relying on attention scores.

1 Introduction

Semantic parsing aims to map natural language text to a formal meaning representation (e.g., logical forms or SQL queries). The neural sequence-to-sequence architecture (Sutskever et al., 2014; Bahdanau et al., 2015) has been widely adopted in a variety of natural language processing tasks, and semantic parsing is no exception. However, despite achieving promising results (Dong and Lapata, 2016; Jia and Liang, 2016; Ling et al., 2016), neural semantic parsers remain difficult to interpret, acting in most cases as a black box, not providing any information about what made them arrive at a particular decision. In this work, we explore ways to estimate and interpret the model's confidence in its predictions, which we argue can provide users with immediate and meaningful feedback regarding uncertain outputs.

An explicit framework for confidence modeling would benefit the development cycle of neural semantic parsers which, contrary to more traditional methods, do not make use of lexicons or templates and as a result the sources of errors and inconsistencies are difficult to trace. Moreover, from the perspective of application, semantic parsing is often used to build natural language interfaces, such as dialogue systems. In this case it is important to know whether the system understands the input queries with high confidence in order to make decisions more reliably. For example, knowing that some of the predictions are uncertain would allow the system to generate clarification questions, prompting users to verify the results before triggering unwanted actions. In addition, the training data used for semantic parsing can be small and noisy, and as a result, models do indeed produce uncertain outputs, which we would like our framework to identify.

A widely-used confidence scoring method is based on posterior probabilities $p(y|x)$ where x is the input and y the model's prediction. For a linear model, this method makes sense: as more positive evidence is gathered, the score becomes larger. Neural models, in contrast, learn a complicated function that often overfits the training data. Posterior probability is effective when making decisions about model output, but is no longer a good indicator of confidence due in part to the nonlinearity of neural networks (Johansen and Socher, 2017). This observation motivates us to develop a confidence modeling framework for sequence-to-sequence models. We categorize the causes of uncertainty into three types, namely *model uncertainty*, *data uncertainty*, and *input uncertainty* and design different metrics to characterize them.

[*] Work carried out during an internship at Microsoft Research.

We compute these confidence metrics for a given prediction and use them as features in a regression model which is trained on held-out data to fit prediction F1 scores. At test time, the regression model's outputs are used as confidence scores. Our approach does not interfere with the training of the model, and can be thus applied to various architectures, without sacrificing test accuracy. Furthermore, we propose a method based on backpropagation which allows to interpret model behavior by identifying which parts of the input contribute to uncertain predictions.

Experimental results on two semantic parsing datasets (IFTTT, Quirk et al. 2015; and DJANGO, Oda et al. 2015) show that our model is superior to a method based on posterior probability. We also demonstrate that thresholding confidence scores achieves a good trade-off between coverage and accuracy. Moreover, the proposed uncertainty backpropagation method yields results which are qualitatively more interpretable compared to those based on attention scores.

2 Related Work

Confidence Estimation Confidence estimation has been studied in the context of a few NLP tasks, such as statistical machine translation (Blatz et al., 2004; Ueffing and Ney, 2005; Soricut and Echihabi, 2010), and question answering (Gondek et al., 2012). To the best of our knowledge, confidence modeling for semantic parsing remains largely unexplored. A common scheme for modeling uncertainty in neural networks is to place distributions over the network's weights (Denker and Lecun, 1991; MacKay, 1992; Neal, 1996; Blundell et al., 2015; Gan et al., 2017). But the resulting models often contain more parameters, and the training process has to be accordingly changed, which makes these approaches difficult to work with. Gal and Ghahramani (2016) develop a theoretical framework which shows that the use of dropout in neural networks can be interpreted as a Bayesian approximation of Gaussian Process. We adapt their framework so as to represent uncertainty in the encoder-decoder architectures, and extend it by adding Gaussian noise to weights.

Semantic Parsing Various methods have been developed to learn a semantic parser from natural language descriptions paired with meaning representations (Tang and Mooney, 2000; Zettlemoyer and Collins, 2007; Lu et al., 2008; Kwiatkowski et al., 2011; Andreas et al., 2013; Zhao and Huang, 2015). More recently, a few sequence-to-sequence models have been proposed for semantic parsing (Dong and Lapata, 2016; Jia and Liang, 2016; Ling et al., 2016) and shown to perform competitively whilst eschewing the use of templates or manually designed features. There have been several efforts to improve these models including the use of a tree decoder (Dong and Lapata, 2016), data augmentation (Jia and Liang, 2016; Kočiský et al., 2016), the use of a grammar model (Xiao et al., 2016; Rabinovich et al., 2017; Yin and Neubig, 2017; Krishnamurthy et al., 2017), coarse-to-fine decoding (Dong and Lapata, 2018), network sharing (Susanto and Lu, 2017; Herzig and Berant, 2017), user feedback (Iyer et al., 2017), and transfer learning (Fan et al., 2017). Current semantic parsers will by default generate some output for a given input even if this is just a random guess. System results can thus be somewhat unexpected inadvertently affecting user experience. Our goal is to mitigate these issues with a confidence scoring model that can estimate how likely the prediction is correct.

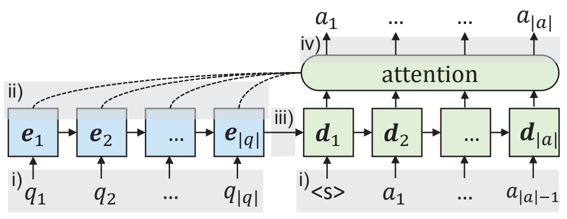
3 Neural Semantic Parsing Model

In the following section we describe the neural semantic parsing model (Dong and Lapata, 2016; Jia and Liang, 2016; Ling et al., 2016) we assume throughout this paper. The model is built upon the sequence-to-sequence architecture and is illustrated in Figure 1. An *encoder* is used to encode natural language input $q = q_1 \cdots q_{|q|}$ into a vector representation, and a *decoder* learns to generate a logical form representation of its meaning $a = a_1 \cdots a_{|a|}$ conditioned on the encoding vectors. The encoder and decoder are two different recurrent neural networks with long short-term memory units (LSTMs; Hochreiter and Schmidhuber 1997) which process tokens sequentially. The probability of generating the whole sequence $p(a|q)$ is factorized as:

$$p(a|q) = \prod_{t=1}^{|a|} p(a_t|a_{<t}, q) \tag{1}$$

where $a_{<t} = a_1 \cdots a_{t-1}$.

Let $\mathbf{e}_t \in \mathbb{R}^n$ denote the hidden vector of the encoder at time step t. It is computed via $\mathbf{e}_t = \mathrm{f}_{\mathrm{LSTM}}(\mathbf{e}_{t-1}, \mathbf{q}_t)$, where $\mathrm{f}_{\mathrm{LSTM}}$ refers to the LSTM unit, and $\mathbf{q}_t \in \mathbb{R}^n$ is the word embedding



a_1 ... ... $a_{|a|}$
iv)
attention
ii)
e_1 e_2 ... $e_{|q|}$
iii)
d_1 d_2 ... $d_{|a|}$
i) q_1 q_2 ... $q_{|q|}$
i) <s> a_1 ... $a_{|a|-1}$

Figure 1: We use dropout as approximate Bayesian inference to obtain model uncertainty. The dropout layers are applied to i) token vectors; ii) the encoder's output vectors; iii) bridge vectors; and iv) decoding vectors.

of q_t. Once the tokens of the input sequence are encoded into vectors, $\mathbf{e}_{|q|}$ is used to initialize the hidden states of the first time step in the decoder.

Similarly, the hidden vector of the decoder at time step t is computed by $\mathbf{d}_t = \mathrm{f}_{\mathrm{LSTM}}(\mathbf{d}_{t-1}, \mathbf{a}_{t-1})$, where $\mathbf{a}_{t-1} \in \mathbb{R}^n$ is the word vector of the previously predicted token. Additionally, we use an attention mechanism (Luong et al., 2015a) to utilize relevant encoder-side context. For the current time step t of the decoder, we compute its attention score with the k-th hidden state in the encoder as:

$$r_{t,k} \propto \exp\{\mathbf{d}_t \cdot \mathbf{e}_k\} \tag{2}$$

where $\sum_{j=1}^{|q|} r_{t,j} = 1$. The probability of generating a_t is computed via:

$$\mathbf{c}_t = \sum_{k=1}^{|q|} r_{t,k}\mathbf{e}_k \tag{3}$$

$$\mathbf{d}_t^{att} = \tanh(\mathbf{W}_1\mathbf{d}_t + \mathbf{W}_2\mathbf{c}_t) \tag{4}$$

$$p(a_t|a_{<t}, q) = \mathrm{softmax}_{a_t}\left(\mathbf{W}_o\mathbf{d}_t^{att}\right) \tag{5}$$

where $\mathbf{W}_1, \mathbf{W}_2 \in \mathbb{R}^{n\times n}$ and $\mathbf{W}_o \in \mathbb{R}^{|V_a|\times n}$ are three parameter matrices.

The training objective is to maximize the likelihood of the generated meaning representation a given input q, i.e., maximize $\sum_{(q,a)\in\mathcal{D}} \log p(a|q)$, where $\mathcal{D}$ represents training pairs. At test time, the model's prediction for input q is obtained via $\hat{a} = \arg\max_{a'} p(a'|q)$, where a' represents candidate outputs. Because $p(a|q)$ is factorized as shown in Equation (1), we can use beam search to generate tokens one by one rather than iterating over all possible results.

4 Confidence Estimation

Given input q and its predicted meaning representation a, the confidence model estimates score $s(q,a) \in (0,1)$. A large score indicates the model is confident that its prediction is correct. In order to gauge confidence, we need to estimate "what we do not know". To this end, we identify three causes of uncertainty, and design various metrics characterizing each one of them. We then feed these metrics into a regression model in order to predict $s(q,a)$.

Algorithm 1 Dropout Perturbation

```
Input: $q, a$: Input and its prediction
       $\mathcal{M}$: Model parameters
1: for $i \leftarrow 1, \cdots, F$ do
2:     $\hat{\mathcal{M}}^i \leftarrow$ Apply dropout layers to $\mathcal{M}$        ▷ Figure 1
3:     Run forward pass and compute $\hat{p}(a|q; \hat{\mathcal{M}}^i)$
4: Compute variance of $\{\hat{p}(a|q; \hat{\mathcal{M}}^i)\}_{i=1}^F$        ▷ Equation (6)
```

4.1 Model Uncertainty

The model's parameters or structures contain uncertainty, which makes the model less confident about the values of $p(a|q)$. For example, noise in the training data and the stochastic learning algorithm itself can result in model uncertainty. We describe metrics for capturing uncertainty below:

Dropout Perturbation Our first metric uses dropout (Srivastava et al., 2014) as approximate Bayesian inference to estimate model uncertainty (Gal and Ghahramani, 2016). Dropout is a widely used regularization technique during training, which relieves overfitting by randomly masking some input neurons to zero according to a Bernoulli distribution. In our work, we use dropout at *test time*, instead. As shown in Algorithm 1, we perform F forward passes through the network, and collect the results $\{\hat{p}(a|q; \hat{\mathcal{M}}^i)\}_{i=1}^F$ where $\hat{\mathcal{M}}^i$ represents the perturbed parameters. Then, the uncertainty metric is computed by the variance of results. We define the metric on the sequence level as:

$$\mathrm{var}\{\hat{p}(a|q; \hat{\mathcal{M}}^i)\}_{i=1}^F. \tag{6}$$

In addition, we compute uncertainty u_{a_t} at the token-level a_t via:

$$u_{a_t} = \mathrm{var}\{\hat{p}(a_t|a_{<t}, q; \hat{\mathcal{M}}^i)\}_{i=1}^F \tag{7}$$

where $\hat{p}(a_t|a_{<t}, q; \hat{\mathcal{M}}^i)$ is the probability of generating token a_t (Equation (5)) using perturbed model $\hat{\mathcal{M}}^i$. We operationalize token-level uncertainty in two ways, as the average score $\mathrm{avg}\{u_{a_t}\}_{t=1}^{|a|}$ and the maximum score

$\max\{u_{a_t}\}_{t=1}^{|a|}$ (since the uncertainty of a sequence is often determined by the most uncertain token). As shown in Figure 1, we add dropout layers in i) the word vectors of the encoder and decoder $\mathbf{q}_t, \mathbf{a}_t$; ii) the output vectors of the encoder $\mathbf{e}_t$; iii) bridge vectors $\mathbf{e}_{|q|}$ used to initialize the hidden states of the first time step in the decoder; and iv) decoding vectors $\mathbf{d}_t^{att}$ (Equation (4)).

Gaussian Noise Standard dropout can be viewed as applying noise sampled from a Bernoulli distribution to the network parameters. We instead use Gaussian noise, and apply the metrics in the same way discussed above. Let $\mathbf{v}$ denote a vector perturbed by noise, and $\mathbf{g}$ a vector sampled from the Gaussian distribution $\mathcal{N}(0, \sigma^2)$. We use $\hat{\mathbf{v}} = \mathbf{v} + \mathbf{g}$ and $\hat{\mathbf{v}} = \mathbf{v} + \mathbf{v} \odot \mathbf{g}$ as two noise injection methods. Intuitively, if the model is more confident in an example, it should be more robust to perturbations.

Posterior Probability Our last class of metrics is based on posterior probability. We use the log probability $\log p(a|q)$ as a sequence-level metric. The token-level metric $\min\{p(a_t|a_{<t}, q)\}_{t=1}^{|a|}$ can identify the most uncertain predicted token. The perplexity per token $-\frac{1}{|a|}\sum_{t=1}^{|a|} \log p\left(a_t|a_{<t}, q\right)$ is also employed.

4.2 Data Uncertainty

The coverage of training data also affects the uncertainty of predictions. If the input q does not match the training distribution or contains unknown words, it is difficult to predict $p\left(a|q\right)$ reliably. We define two metrics:

Probability of Input We train a language model on the training data, and use it to estimate the probability of input $p(q|\mathcal{D})$ where $\mathcal{D}$ represents the training data.

Number of Unknown Tokens Tokens that do not appear in the training data harm robustness, and lead to uncertainty. So, we use the number of unknown tokens in the input q as a metric.

4.3 Input Uncertainty

Even if the model can estimate $p\left(a|q\right)$ reliably, the input itself may be ambiguous. For instance, the input *the flight is at 9 o'clock* can be interpreted as either `flight_time(9am)` or `flight_time(9pm)`. Selecting between these predictions is difficult, especially if they are both highly likely. We use the following metrics to measure uncertainty caused by ambiguous inputs.

Variance of Top Candidates We use the variance of the probability of the top candidates to indicate whether these are similar. The sequence-level metric is computed by:

$$\mathrm{var}\{p(a^i|q)\}_{i=1}^{K}$$

where $a^1 \dots a^K$ are the K-best predictions obtained by the beam search during inference (Section 3).

Entropy of Decoding The sequence-level entropy of the decoding process is computed via:

$$H[a|q] = -\sum_{a'} p(a'|q) \log p(a'|q)$$

which we approximate by Monte Carlo sampling rather than iterating over all candidate predictions. The token-level metrics of decoding entropy are computed by $\mathrm{avg}\{H[a_t|a_{<t}, q]\}_{t=1}^{|a|}$ and $\max\{H[a_t|a_{<t}, q]\}_{t=1}^{|a|}$.

4.4 Confidence Scoring

The sentence- and token-level confidence metrics defined in Section 4 are fed into a gradient tree boosting model (Chen and Guestrin, 2016) in order to predict the overall confidence score $s\left(q, a\right)$. The model is wrapped with a logistic function so that confidence scores are in the range of $(0, 1)$.

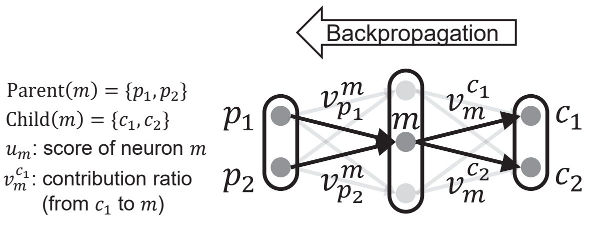
Because the confidence score indicates whether the prediction is likely to be correct, we can use the prediction's F1 (see Section 6.2) as target value. The training loss is defined as:

$$\sum_{(q,a)\in\mathcal{D}} \ln(1+e^{-\hat{s}(q,a)})^{y_{q,a}} + \ln(1+e^{\hat{s}(q,a)})^{(1-y_{q,a})}$$

where $\mathcal{D}$ represents the data, $y_{q,a}$ is the target F1 score, and $\hat{s}(q, a)$ the predicted confidence score. We refer readers to Chen and Guestrin (2016) for mathematical details of how the gradient tree boosting model is trained. Notice that we learn the confidence scoring model on the held-out set (rather than on the training data of the semantic parser) to avoid overfitting.

5 Uncertainty Interpretation

Confidence scores are useful in so far they can be traced back to the inputs causing the uncertainty in the first place. For semantic parsing, identifying



Backpropagation
Parent(m) = {p_1, p_2}
Child(m) = {c_1, c_2}
u_m: score of neuron m
$v_m^{c_1}$: contribution ratio (from c_1 to m)
p_1
p_2
$v_{p_1}^m$
$v_{p_2}^m$
m
$v_m^{c_1}$
$v_m^{c_2}$
c_1
c_2

Figure 2: Uncertainty backpropagation at the neuron level. Neuron m's score u_m is collected from child neurons c_1 and c_2 by $u_m = v_m^{c_1} u_{c_1} + v_m^{c_2} u_{c_2}$. The score u_m is then redistributed to its parent neurons p_1 and p_2, which satisfies $v_{p_1}^m + v_{p_2}^m = 1$.

which input words contribute to uncertainty would be of value, e.g., these could be treated explicitly as special cases or refined if they represent noise.

In this section, we introduce an algorithm that backpropagates token-level uncertainty scores (see Equation (7)) from predictions to input tokens, following the ideas of Bach et al. (2015) and Zhang et al. (2016). Let u_m denote neuron m's uncertainty score, which indicates the degree to which it contributes to uncertainty. As shown in Figure 2, u_m is computed by the summation of the scores backpropagated from its child neurons:

$$u_m = \sum_{c \in \text{Child}(m)} v_m^c u_c$$

where Child(m) is the set of m's child neurons, and the non-negative contribution ratio v_m^c indicates how much we backpropagate u_c to neuron m. Intuitively, if neuron m contributes more to c's value, ratio v_m^c should be larger.

After obtaining score u_m, we redistribute it to its parent neurons in the same way. Contribution ratios from m to its parent neurons are normalized to 1:

$$\sum_{p \in \text{Parent}(m)} v_p^m = 1$$

where Parent(m) is the set of m's parent neurons.

Given the above constraints, we now define different backpropagation rules for the operators used in neural networks. We first describe the rules used for fully-connected layers. Let $\mathbf{x}$ denote the input. The output is computed by $\mathbf{z} = \sigma(\mathbf{W}\mathbf{x}+\mathbf{b})$, where σ is a nonlinear function, $\mathbf{W} \in \mathbb{R}^{|\mathbf{z}|*|\mathbf{x}|}$ is the weight matrix, $\mathbf{b} \in \mathbb{R}^{|\mathbf{z}|}$ is the bias, and neuron $\mathbf{z}_i$ is computed via $\mathbf{z}_i = \sigma(\sum_{j=1}^{|\mathbf{x}|} \mathbf{W}_{i,j}\mathbf{x}_j + \mathbf{b}_i)$. Neuron $\mathbf{x}_k$'s uncertainty score u_{x_k} is gathered from the next layer:

Algorithm 2 Uncertainty Interpretation

```
Input: $q, a$: Input and its prediction
Output: $\{\hat{u}_{q_t}\}_{t=1}^{|q|}$: Interpretation scores for input tokens
Function: TokenUnc: Get token-level uncertainty
 1: ▷ Get token-level uncertainty for predicted tokens
 2: $\{u_{a_t}\}_{t=1}^{|a|} \leftarrow$ TokenUnc$(q, a)$
 3: ▷ Initialize uncertainty scores for backpropagation
 4: for $t \leftarrow 1, \cdots, |a|$ do
 5:     Decoder classifier's output neuron $\leftarrow u_{a_t}$
 6: ▷ Run backpropagation
 7: for $m \leftarrow$ neuron in backward topological order do
 8:     ▷ Gather scores from child neurons
 9:     $u_m \leftarrow \sum_{c \in \text{Child}(m)} v_m^c u_c$
10: ▷ Summarize scores for input words
11: for $t \leftarrow 1, \cdots, |q|$ do
12:     $u_{q_t} \leftarrow \sum_{c \in \mathbf{q}_t} u_c$
13: $\{\hat{u}_{q_t}\}_{t=1}^{|q|} \leftarrow$ normalize $\{u_{q_t}\}_{t=1}^{|q|}$
```

$$u_{x_k} = \sum_{i=1}^{|\mathbf{z}|} v_{x_k}^{z_i} u_{z_i} = \sum_{i=1}^{|\mathbf{z}|} \frac{|\mathbf{W}_{i,k}\mathbf{x}_k|}{\sum_{j=1}^{|\mathbf{x}|} |\mathbf{W}_{i,j}\mathbf{x}_j|} u_{z_i}$$

ignoring the nonlinear function σ and the bias $\mathbf{b}$. The ratio $v_{x_k}^{z_i}$ is proportional to the contribution of $\mathbf{x}_k$ to the value of $\mathbf{z}_i$.

We define backpropagation rules for element-wise vector operators. For $\mathbf{z} = \mathbf{x} \pm \mathbf{y}$, these are:

$$u_{x_k} = \frac{|\mathbf{x}_k|}{|\mathbf{x}_k|+|\mathbf{y}_k|} u_{z_k} \quad u_{y_k} = \frac{|\mathbf{y}_k|}{|\mathbf{x}_k|+|\mathbf{y}_k|} u_{z_k}$$

where the contribution ratios $v_{x_k}^{z_k}$ and $v_{y_k}^{z_k}$ are determined by $|\mathbf{x}_k|$ and $|\mathbf{y}_k|$. For multiplication, the contribution of two elements in $\frac{1}{3} * 3$ should be the same. So, the propagation rules for $\mathbf{z} = \mathbf{x} \odot \mathbf{y}$ are:

$$u_{x_k} = \frac{|\log|\mathbf{x}_k||}{|\log|\mathbf{x}_k||+|\log|\mathbf{y}_k||} u_{z_k} \; u_{y_k} = \frac{|\log|\mathbf{y}_k||}{|\log|\mathbf{x}_k||+|\log|\mathbf{y}_k||} u_{z_k}$$

where the contribution ratios are determined by $|\log|\mathbf{x}_k||$ and $|\log|\mathbf{y}_k||$.

For scalar multiplication, $\mathbf{z} = \lambda\mathbf{x}$ where λ denotes a constant. We directly assign $\mathbf{z}$'s uncertainty scores to $\mathbf{x}$ and the backpropagation rule is $u_{x_k} = u_{z_k}$.

As shown in Algorithm 2, we first initialize uncertainty backpropagation in the decoder (lines 1–5). For each predicted token a_t, we compute its uncertainty score u_{a_t} as in Equation (7). Next, we find the dimension of a_t in the decoder's softmax classifier (Equation (5)), and initialize the neuron with the uncertainty score u_{a_t}. We then backpropagate these uncertainty scores through

Dataset	Example
IFTTT	*turn android phone to full volume at 7am monday to friday* `date_time−every_day_of_the_week_at−((time_of_day (07)(:)(00)) (days_of_the_week (1)(2)(3)(4)(5))) THEN android_device−set_ringtone_volume−(volume ({'volume_level':1.0,'name':'100%'}))`
DJANGO	*for every key in sorted list of user_settings* `for key in sorted(user_settings):`

the network (lines 6–9), and finally into the neurons of the input words. We summarize them and compute the token-level scores for interpreting the results (line 10–13). For input word vector $\mathbf{q}_t$, we use the summation of its neuron-level scores as the token-level score:

$$\hat{u}_{q_t} \propto \sum_{c \in \mathbf{q}_t} u_c$$

where $c \in \mathbf{q}_t$ represents the neurons of word vector $\mathbf{q}_t$, and $\sum_{t=1}^{|q|} \hat{u}_{q_t} = 1$. We use the normalized score $\hat{u}_{q_t}$ to indicate token q_t's contribution to prediction uncertainty.

6 Experiments

In this section we describe the datasets used in our experiments and various details concerning our models. We present our experimental results and analysis of model behavior. Our code is publicly available at https://github.com/donglixp/confidence.

6.1 Datasets

We trained the neural semantic parser introduced in Section 3 on two datasets covering different domains and meaning representations. Examples are shown in Table 1.

IFTTT This dataset (Quirk et al., 2015) contains a large number of if-this-then-that programs crawled from the IFTTT website. The programs are written for various applications, such as home security (e.g., "*email me if the window opens*"), and task automation (e.g., "*save instagram photos to dropbox*"). Whenever a program's trigger is satisfied, an action is performed. Triggers and actions represent functions with arguments; they are selected from different channels (160 in total) representing various services (e.g., Android). There are 552 trigger functions and 229 action functions. The original split contains 77,495 training, 5,171 development, and 4,294 test instances. The subset that removes non-English descriptions was used in our experiments.

DJANGO This dataset (Oda et al., 2015) is built upon the code of the Django web framework. Each line of Python code has a manually annotated natural language description. Our goal is to map the English pseudo-code to Python statements. This dataset contains diverse use cases, such as iteration, exception handling, and string manipulation. The original split has 16,000 training, 1,000 development, and 1,805 test examples.

6.2 Settings

We followed the data preprocessing used in previous work (Dong and Lapata, 2016; Yin and Neubig, 2017). Input sentences were tokenized using NLTK (Bird et al., 2009) and lowercased. We filtered words that appeared less than four times in the training set. Numbers and URLs in IFTTT and quoted strings in DJANGO were replaced with place holders. Hyperparameters of the semantic parsers were validated on the development set. The learning rate and the smoothing constant of RMSProp (Tieleman and Hinton, 2012) were 0.002 and 0.95, respectively. The dropout rate was 0.25. A two-layer LSTM was used for IFTTT, while a one-layer LSTM was employed for DJANGO. Dimensions for the word embedding and hidden vector were selected from $\{150, 250\}$. The beam size during decoding was 5.

For IFTTT, we view the predicted trees as a set of productions, and use balanced F1 as evaluation metric (Quirk et al., 2015). We do not measure accuracy because the dataset is very noisy and there rarely is an exact match between the predicted output and the gold standard. The F1 score of our neural semantic parser is 50.1%, which is comparable to Dong and Lapata (2016). For DJANGO, we measure the fraction of exact matches, where F1 score is equal to accuracy. Because there are unseen variable names at test time, we use attention scores as alignments to replace unknown to-

kens in the prediction with the input words they align to (Luong et al., 2015b). The accuracy of our parser is 53.7%, which is better than the result (45.1%) of the sequence-to-sequence model reported in Yin and Neubig (2017).

To estimate model uncertainty, we set dropout rate to 0.1, and performed 30 inference passes. The standard deviation of Gaussian noise was 0.05. The language model was estimated using KenLM (Heafield et al., 2013). For input uncertainty, we computed variance for the 10-best candidates. The confidence metrics were implemented in batch mode, to take full advantage of GPUs. Hyperparameters of the confidence scoring model were cross-validated. The number of boosted trees was selected from $\{20, 50\}$. The maximum tree depth was selected from $\{3, 4, 5\}$. We set the subsample ratio to 0.8. All other hyperparameters in XGBoost (Chen and Guestrin, 2016) were left with their default values.

6.3 Results

Confidence Estimation We compare our approach (CONF) against confidence scores based on posterior probability $p(a|q)$ (POSTERIOR). We also report the results of three ablation variants (−MODEL, −DATA, −INPUT) by removing each group of confidence metrics described in Section 4. We measure the relationship between confidence scores and F1 using Spearman's ρ correlation coefficient which varies between -1 and 1 (0 implies there is no correlation). High ρ indicates that the confidence scores are high for correct predictions and low otherwise.

As shown in Table 2, our method CONF outperforms POSTERIOR by a large margin. The ablation results indicate that model uncertainty plays the most important role among the confidence metrics. In contrast, removing the metrics of data uncertainty affects performance less, because most examples in the datasets are in-domain. Improvements for each group of metrics are significant with $p < 0.05$ according to bootstrap hypothesis testing (Efron and Tibshirani, 1994).

Tables 3 and 4 show the correlation matrix for F1 and individual confidence metrics on the IFTTT and DJANGO datasets, respectively. As can be seen, metrics representing model uncertainty and input uncertainty are more correlated to each other compared with metrics capturing data uncertainty. Perhaps unsurprisingly metrics of the same group are highly inter-correlated since they model the same type of uncertainty. Table 5 shows the relative importance of individual metrics in the regression model. As importance score we use the average gain (i.e., loss reduction) brought by the confidence metric once added as feature to the branch of the decision tree (Chen and Guestrin, 2016). The results indicate that model uncertainty (Noise/Dropout/Posterior/Perplexity) plays

Metric	Dout	Noise	PR	PPL	LM	#UNK	Var	Ent
IFTTT	0.39	**1.00**	**0.89**	0.27	0.26	0.46	0.43	0.34
DJANGO	**1.00**	**0.59**	0.22	**0.58**	0.49	0.14	0.24	0.25

Table 5: Importance scores of confidence metrics (normalized by maximum value on each dataset). Best results are shown in **bold**. Same shorthands apply as in Table 3.

the most important role. On IFTTT, the number of unknown tokens (#UNK) and the variance of top candidates (var(K-best)) are also very helpful because this dataset is relatively noisy and contains many ambiguous inputs.

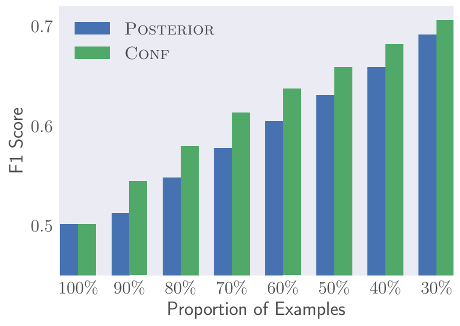
Finally, in real-world applications, confidence scores are often used as a threshold to trade-off precision for coverage. Figure 3 shows how F1 score varies as we increase the confidence threshold, i.e., reduce the proportion of examples that we return answers for. F1 score improves monotonically for POSTERIOR and our method, which, however, achieves better performance when coverage is the same.

Uncertainty Interpretation We next evaluate how our backpropagation method (see Section 5) allows us to identify input tokens contributing to uncertainty. We compare against a method that interprets uncertainty based on the attention mechanism (ATTENTION). As shown in Equation (2), attention scores $r_{t,k}$ can be used as soft alignments between the time step t of the decoder and the k-th input token. We compute the normalized uncertainty score $\hat{u}_{q_t}$ for a token q_t via:

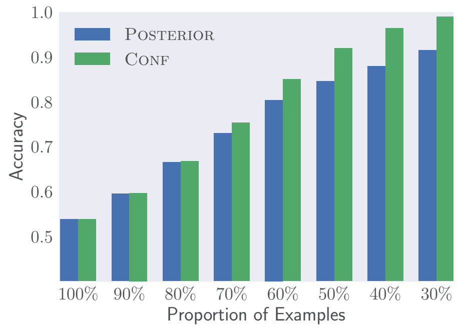
$$\hat{u}_{q_t} \propto \sum_{t=1}^{|a|} r_{t,k} u_{a_t} \tag{8}$$

where u_{a_t} is the uncertainty score of the predicted token a_t (Equation (7)), and $\sum_{t=1}^{|q|} \hat{u}_{q_t} = 1$.

Unfortunately, the evaluation of uncertainty interpretation methods is problematic. For our semantic parsing task, we do not a priori know which tokens in the natural language input contribute to uncertainty and these may vary depending on the architecture used, model parameters, and so on. We work around this problem by creating a proxy gold standard. We inject noise to the vectors representing tokens in the encoder (see Section 4.1) and then estimate the uncertainty caused by each token q_t (Equation (6)) under the assumption that



(a) IFTTT



(b) DJANGO

Figure 3: Confidence scores are used as threshold to filter out uncertain test examples. As the threshold increases, performance improves. The horizontal axis shows the proportion of examples beyond the threshold.

addition of noise should only affect genuinely uncertain tokens. Notice that here we inject noise to one token at a time[1] instead of all parameters (see Figure 1). Tokens identified as uncertain by the above procedure are considered gold standard and compared to those identified by our method. We use Gaussian noise to perturb vectors in our experiments (dropout obtained similar results).

We define an evaluation metric based on the overlap ($overlap@K$) among tokens identified as uncertain by the model and the gold standard. Given an example, we first compute the interpretation scores of the input tokens according to our method, and obtain a list τ_1 of K tokens with highest scores. We also obtain a list τ_2 of K tokens with highest ground-truth scores and measure the degree of overlap between these two lists:

$$\text{overlap}@K = \frac{|\tau_1 \cap \tau_2|}{K}$$

[1]Noise injection as described above is used for evaluation purposes only since we need to perform forward passes multiple times (see Section 4.1) for each token, and the running time increases linearly with the input length.

where $K \in \{2, 4\}$ in our experiments. For example, the overlap@4 metric of the lists $\tau_1 = [q_7, q_8, q_2, q_3]$ and $\tau_2 = [q_7, q_8, q_3, q_4]$ is $3/4$, because there are three overlapping tokens.

Table 6 reports results with overlap@2 and overlap@4. Overall, BACKPROP achieves better interpretation quality than the attention mechanism. On both datasets, about 80% of the top-4 tokens identified as uncertain agree with the ground truth. Table 7 shows examples where our method has identified input tokens contributing to the uncertainty of the output. We highlight token a_t if its uncertainty score u_{a_t} is greater than $0.5 * \text{avg}\{u_{a_{t'}}\}_{t'=1}^{|a|}$. The results illustrate that the parser tends to be uncertain about tokens which are function arguments (e.g., URLs, and message content), and ambiguous inputs. The examples show that BACKPROP is qualitatively better compared to ATTENTION; attention scores often produce inaccurate alignments while BACKPROP can utilize information flowing through the LSTMs rather than only relying on the attention mechanism.

7 Conclusions

In this paper we presented a confidence estimation model and an uncertainty interpretation method for neural semantic parsing. Experimental results show that our method achieves better performance than competitive baselines on two datasets. Directions for future work are many and varied. The proposed framework could be applied to a variety of tasks (Bahdanau et al., 2015; Schmaltz et al., 2017) employing sequence-to-sequence architectures. We could also utilize the confidence estimation model within an active learning framework for neural semantic parsing.

Acknowledgments

We would like to thank Pengcheng Yin for sharing with us the preprocessed version of the DJANGO dataset. We gratefully acknowledge the financial support of the European Research Council (award number 681760; Dong, Lapata) and the Adept-Mind Scholar Fellowship program (Dong).

STRUCTVAE: Tree-structured Latent Variable Models for Semi-supervised Semantic Parsing

Abstract

Semantic parsing is the task of transducing natural language (NL) utterances into formal meaning representations (MRs), commonly represented as tree structures. Annotating NL utterances with their corresponding MRs is expensive and time-consuming, and thus the limited availability of labeled data often becomes the bottleneck of data-driven, supervised models. We introduce STRUCTVAE, a variational auto-encoding model for semi-supervised semantic parsing, which learns both from limited amounts of parallel data, and readily-available unlabeled NL utterances. STRUCTVAE models latent MRs not observed in the unlabeled data as tree-structured latent variables. Experiments on semantic parsing on the ATIS domain and Python code generation show that with extra unlabeled data, STRUCTVAE outperforms strong supervised models.[1]

1 Introduction

Semantic parsing tackles the task of mapping natural language (NL) utterances into structured formal meaning representations (MRs). This includes parsing to general-purpose logical forms such as λ-calculus (Zettlemoyer and Collins, 2005, 2007) and the abstract meaning representation (AMR, Banarescu et al. (2013); Misra and Artzi (2016)), as well as parsing to computer-executable programs to solve problems such as question answering (Berant et al., 2013; Yih et al., 2015; Liang et al., 2017), or generation of domain-specific (*e.g.*, SQL) or general purpose programming languages (*e.g.*, Python) (Quirk et al., 2015; Yin and Neubig, 2017; Rabinovich et al., 2017).

Figure 1: Graphical Representation of STRUCTVAE

While these models have a long history (Zelle and Mooney, 1996; Tang and Mooney, 2001), recent advances are largely attributed to the success of neural network models (Xiao et al., 2016; Ling et al., 2016; Dong and Lapata, 2016; Iyer et al., 2017; Zhong et al., 2017). However, these models are also extremely *data hungry*: optimization of such models requires large amounts of training data of parallel NL utterances and manually annotated MRs, the creation of which can be expensive, cumbersome, and time-consuming. Therefore, the limited availability of parallel data has become the bottleneck of existing, purely supervised-based models. These data requirements can be alleviated with *weakly-supervised* learning, where the denotations (*e.g.*, answers in question answering) of MRs (*e.g.*, logical form queries) are used as indirect supervision (Clarke et al. (2010); Liang et al. (2011); Berant et al. (2013), *inter alia*), or *data-augmentation techniques* that automatically generate pseudo-parallel corpora using hand-crafted or induced grammars (Jia and Liang, 2016; Wang et al., 2015).

In this work, we focus on *semi-supervised* learning, aiming to learn from both limited amounts of parallel NL-MR corpora, and *unlabeled* but readily-available NL utterances. We draw inspiration from recent success in applying variational auto-encoding (VAE) models in semi-supervised sequence-to-sequence learning (Miao and Blunsom, 2016; Kociský et al., 2016), and propose STRUCTVAE — a principled deep generative approach for semi-supervised learning with tree-structured latent variables (Fig. 1). STRUCTVAE is based on a generative story where the surface NL utterances are generated from tree-structured latent MRs following the standard VAE architecture: (1) an off-the-shelf semantic parser functions as the *inference model*, parsing an observed NL utterance into latent meaning representations (§ 3.2); (2) a *reconstruction model* decodes the latent MR into the original observed utterance (§ 3.1). This formulation enables our model to perform both standard supervised learning by optimizing the inference model (*i.e.*, the parser) using parallel corpora, and unsupervised learning by maximizing the variational lower bound of the likelihood of the unlabeled utterances (§ 3.3).

In addition to these contributions to semi-supervised semantic parsing, STRUCTVAE contributes to generative model research as a whole, providing a recipe for training VAEs with *structured* latent variables. Such a structural latent space is contrast to existing VAE research using *flat* representations, such as continuous distributed representations (Kingma and Welling, 2013), discrete symbols (Miao and Blunsom, 2016), or hybrids of the two (Zhou and Neubig, 2017).

We apply STRUCTVAE to semantic parsing on the ATIS domain and Python code generation. As an auxiliary contribution, we implement a transition-based semantic parser, which uses Abstract Syntax Trees (ASTs, § 3.2) as intermediate MRs and achieves strong results on the two tasks. We then apply this parser as the inference model for semi-supervised learning, and show that with extra unlabeled data, STRUCTVAE outperforms its supervised counterpart. We also demonstrate that STRUCTVAE is compatible with different structured latent representations, applying it to a simple sequence-to-sequence parser which uses λ-calculus logical forms as MRs.

2 Semi-supervised Semantic Parsing

In this section we introduce the objectives for semi-supervised semantic parsing, and present high-level intuition in applying VAEs for this task.

2.1 Supervised and Semi-supervised Training

Formally, semantic parsing is the task of mapping utterance $\boldsymbol{x}$ to a meaning representation $\boldsymbol{z}$. As noted above, there are many varieties of MRs that can be represented as either graph structures (*e.g.*, AMR) or tree structures (*e.g.*, λ-calculus and ASTs for programming languages). In this work we specifically focus on tree-structured MRs (see Fig. 2 for a running example Python AST), although application of a similar framework to graph-structured representations is also feasible.

Traditionally, purely supervised semantic parsers train a probabilistic model $p_\phi(\boldsymbol{z}|\boldsymbol{x})$ using parallel data $\mathbb{L}$ of NL utterances and annotated MRs (*i.e.*, $\mathbb{L} = \{\langle \boldsymbol{x}, \boldsymbol{z} \rangle\}$). As noted in the introduction, one major bottleneck in this approach is the lack of such parallel data. Hence, we turn to semi-supervised learning, where the model additionally has access to a relatively large amount of unlabeled NL utterances $\mathbb{U} = \{\boldsymbol{x}\}$. Semi-supervised learning then aims to maximize the log-likelihood of examples in both $\mathbb{L}$ and $\mathbb{U}$:

$$\mathcal{J} = \underbrace{\sum_{\langle \boldsymbol{x}, \boldsymbol{z} \rangle \in \mathbb{L}} \log p_\phi(\boldsymbol{z}|\boldsymbol{x})}_{\text{supervised obj. } \mathcal{J}_s} + \alpha \underbrace{\sum_{\boldsymbol{x} \in \mathbb{U}} \log p(\boldsymbol{x})}_{\text{unsupervised obj. } \mathcal{J}_u} \quad (1)$$

The joint objective consists of two terms: (1) a supervised objective $\mathcal{J}_s$ that maximizes the conditional likelihood of annotated MRs, as in standard supervised training of semantic parsers; and (2) a unsupervised objective $\mathcal{J}_u$, which maximizes the marginal likelihood $p(\boldsymbol{x})$ of unlabeled NL utterances $\mathbb{U}$, controlled by a tuning parameter α. Intuitively, if the modeling of $p_\phi(\boldsymbol{z}|\boldsymbol{x})$ and $p(\boldsymbol{x})$ is coupled (*e.g.*, they share parameters), then optimizing the marginal likelihood $p(\boldsymbol{x})$ using the unsupervised objective $\mathcal{J}_u$ would help the learning of the semantic parser $p_\phi(\boldsymbol{z}|\boldsymbol{x})$ (Zhu, 2005). STRUCTVAE uses the variational auto-encoding framework to jointly optimize $p_\phi(\boldsymbol{z}|\boldsymbol{x})$ and $p(\boldsymbol{x})$, as outlined in § 2.2 and detailed in § 3.

2.2 VAEs for Semi-supervised Learning

From Eq. (1), our semi-supervised model must be able to calculate the probability $p(\boldsymbol{x})$ of unlabeled NL utterances. To model $p(\boldsymbol{x})$, we use VAEs, which provide a principled framework for generative models using neural networks (Kingma and Welling, 2013). As shown in Fig. 1, VAEs define a *generative story* (bold arrows in Fig. 1, explained in § 3.1) to model $p(\boldsymbol{x})$, where a latent MR $\boldsymbol{z}$ is sampled from a prior, and then passed to the *reconstruction* model to decode into the surface utterance $\boldsymbol{x}$. There is also an *inference* model $q_\phi(\boldsymbol{z}|\boldsymbol{x})$ that allows us to infer the most probable latent MR $\boldsymbol{z}$ given the input $\boldsymbol{x}$ (dashed arrows in Fig. 1, explained in § 3.2). In our case, the inference process is equivalent to the task of semantic parsing if we set $q_\phi(\cdot) \triangleq p_\phi(\cdot)$. VAEs also provide a framework to compute an approximation of $p(\boldsymbol{x})$ using the inference and reconstruction models, allowing us to effectively optimize the unsupervised and supervised objectives in Eq. (1) in a joint fashion (Kingma et al. (2014), explained in § 3.3).

3 StructVAE: VAEs with Tree-structured Latent Variables

3.1 Generative Story

StructVAE follows the standard VAE architecture, and defines a generative story that explains how an NL utterance is generated: a latent meaning representation $\boldsymbol{z}$ is sampled from a prior distribution $p(\boldsymbol{z})$ over MRs, which encodes the latent semantics of the utterance. A *reconstruction* model $p_\theta(\boldsymbol{x}|\boldsymbol{z})$ then decodes the sampled MR $\boldsymbol{z}$ into the observed NL utterance $\boldsymbol{x}$.

Both the prior $p(\boldsymbol{z})$ and the reconstruction model $p(\boldsymbol{x}|\boldsymbol{z})$ takes tree-structured MRs as inputs. To model such inputs with rich internal structures, we follow Konstas et al. (2017), and model the distribution over a sequential surface representation of $\boldsymbol{z}$, $\boldsymbol{z}^s$ instead. Specifically, we have $p(\boldsymbol{z}) \triangleq p(\boldsymbol{z}^s)$ and $p_\theta(\boldsymbol{x}|\boldsymbol{z}) \triangleq p_\theta(\boldsymbol{x}|\boldsymbol{z}^s)$[2]. For code generation, $\boldsymbol{z}^s$ is simply the surface source code of the AST $\boldsymbol{z}$. For semantic parsing, $\boldsymbol{z}^s$ is the linearized s-expression of the logical form. Linearization allows us to use standard sequence-to-sequence networks to model $p(\boldsymbol{z})$ and $p_\theta(\boldsymbol{x}|\boldsymbol{z})$. As we will explain in § 4.3, we find these two components perform well with linearization.

Specifically, the prior is parameterized by a Long Short-Term Memory (LSTM) language model over $\boldsymbol{z}^s$. The reconstruction model is an attentional sequence-to-sequence network (Luong et al., 2015), augmented with a copying mechanism (Gu et al., 2016), allowing an out-of-vocabulary (OOV) entity in $\boldsymbol{z}^s$ to be copied to $\boldsymbol{x}$ (*e.g.*, the variable name `my_list` in Fig. 1 and its AST in Fig. 2). We refer readers to Appendix B for details of the neural network architecture.

[2]Linearizion is used by the prior and the reconstruction model only, and not by the inference model.

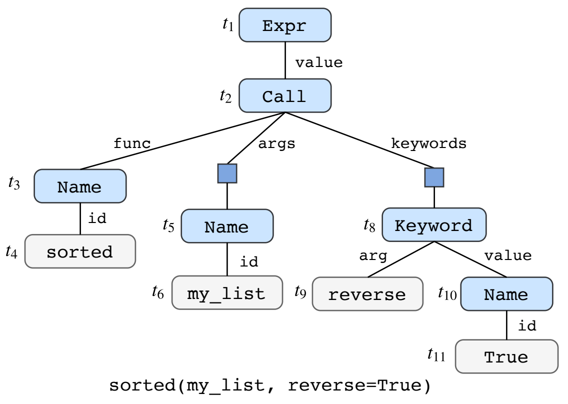
3.2 Inference Model

StructVAE models the semantic parser $p_\phi(\boldsymbol{z}|\boldsymbol{x})$ as the inference model $q_\phi(\boldsymbol{z}|\boldsymbol{x})$ in VAE (§ 2.2), which maps NL utterances $\boldsymbol{x}$ into tree-structured meaning representations $\boldsymbol{z}$. $q_\phi(\boldsymbol{z}|\boldsymbol{x})$ can be any trainable semantic parser, with the corresponding MRs forming the structured latent semantic space. In this work, we primarily use a semantic parser based on the Abstract Syntax Description Language (ASDL) framework (Wang et al., 1997) as the inference model. The parser encodes $\boldsymbol{x}$ into ASTs (Fig. 2). ASTs are the native meaning representation scheme of source code in modern programming languages, and can also be adapted to represent other semantic structures, like λ-calculus logical forms (see § 4.2 for details). We remark that StructVAE works with other semantic parsers with different meaning representations as well (*e.g.*, using λ-calculus logical forms for semantic parsing on Atis, explained in § 4.3).

Our inference model is a transition-based parser inspired by recent work in neural semantic parsing and code generation. The transition system is an adaptation of Yin and Neubig (2017) (hereafter YN17), which decomposes the generation process of an AST into sequential applications of tree-construction actions following the ASDL grammar, thus ensuring the syntactic well-formedness of generated ASTs. Different from YN17, where ASTs are represented as a Context Free Grammar learned from a parsed corpus, we follow Rabinovich et al. (2017) and use ASTs defined under the ASDL formalism (§ 3.2.1).

3.2.1 Generating ASTs with ASDL Grammar

First, we present a brief introduction to ASDL. An AST can be generated by applying typed *constructors* in an ASDL grammar, such as those in Fig. 3 for the Python ASDL grammar. Each constructor specifies a language construct, and is assigned to a particular *composite type*. For example, the constructor `Call` has type `expr` (expression), and it denotes function calls. Constructors are associated with multiple *fields*. For instance, the `Call` constructor and has three fields: *func*, *args* and *keywords*. Like constructors, fields are also strongly typed. For example, the *func* field of `Call` has `expr` type. Fields with composite types are instantiated by constructors of the same type, while fields with *primitive* types store values (*e.g.*, identifier names or string literals). Each field also has



t	Frontier Field	Action
t_1	`stmt root`	`Expr(expr value)`
t_2	`expr value`	`Call(expr func, expr* args, keyword* keywords)`
t_3	`expr func`	`Name(identifier id)`
t_4	`identifier id`	GENTOKEN[*sorted*]
t_5	`expr* args`	`Name(identifier id)`
t_6	`identifier id`	GENTOKEN[*my_list*]
t_7	`expr* args`	REDUCE (close the frontier field)
t_8	`keyword* keywords`	`keyword(identifier arg, expr value)`
t_9	`identifier arg`	GENTOKEN[*reverse*]
t_{10}	`expr value`	`Name(identifier id)`
t_{11}	`identifier id`	GENTOKEN[*True*]
t_{12}	`keyword* keywords`	REDUCE (close the frontier field)

Figure 2: ***Left*** An example ASDL AST with its surface source code. Field names are labeled on upper arcs. Blue squares denote fields with *sequential* cardinality. Grey nodes denote primitive identifier fields, with annotated values. Fields are labeled with time steps at which they are generated. ***Right*** Action sequences used to construct the example AST. Frontier fields are denoted by their signature `(type name)`. Each constructor in the Action column refers to an APPLYCONSTR action.

```
stmt  ↦ FunctionDef(identifier name,
                             arguments args, stmt* body)
      | ClassDef(identifier name, expr* bases, stmt* body)
      | Expr(expr value)
      | Return(expr? value)

expr  ↦ Call(expr func, expr* args, keyword* keywords)
      | Name(identifier id)
      | Str(string s)
```

Figure 3: Excerpt of the python abstract syntax grammar (Python Software Foundation, 2016)

a cardinality (single, optional ?, and sequential $*$), specifying the number of values the field has.

Each node in an AST corresponds to a typed field in a constructor (except for the root node). Depending on the cardinality of the field, an AST node can be instantiated with one or multiple constructors. For instance, the *func* field in the example AST has single cardinality, and is instantiated with a `Name` constructor; while the *args* field with sequential cardinality could have multiple constructors (only one shown in this example).

Our parser employs a transition system to generate an AST using three types of actions. Fig. 2 (Right) lists the sequence of actions used to generate the example AST. The generation process starts from an initial derivation with only a root node of type `stmt` (statement), and proceeds according to the top-down, left-to-right traversal of the AST. At each time step, the parser applies an action to the *frontier field* of the derivation:

APPLYCONSTR$[c]$ actions apply a constructor c to the frontier composite field, expanding the derivation using the fields of c. For fields with single or optional cardinality, an APPLYCONSTR action instantiates the empty frontier field using the constructor, while for fields with sequential cardinality, it appends the constructor to the frontier field. For example, at t_2 the `Call` constructor is applied to the *value* field of `Expr`, and the derivation is expanded using its three child fields.

REDUCE actions complete generation of a field with optional or multiple cardinalities. For instance, the *args* field is instantiated by `Name` at t_5, and then closed by a REDUCE action at t_7.

GENTOKEN$[v]$ actions populate an empty primitive frontier field with token v. A primitive field whose value is a single token (*e.g.*, identifier fields) can be populated with a single GENTOKEN action. Fields of `string` type can be instantiated using multiple such actions, with a final GENTOKEN[`</f>`] action to terminate the generation of field values.

3.2.2 Modeling $q_\phi(\boldsymbol{z}|\boldsymbol{x})$

The probability of generating an AST $\boldsymbol{z}$ is naturally decomposed into the probabilities of the actions $\{a_t\}$ used to construct $\boldsymbol{z}$:

$$q_\phi(\boldsymbol{z}|\boldsymbol{x}) = \prod_t p(a_t|a_{<t}, \boldsymbol{x}).$$

Following YN17, we parameterize $q_\phi(\boldsymbol{z}|\boldsymbol{x})$ using a sequence-to-sequence network with auxiliary recurrent connections following the topology of the AST. Interested readers are referred to Appendix B and Yin and Neubig (2017) for details of the neural network architecture.

3.3 Semi-supervised Learning

In this section we explain how to optimize the semi-supervised learning objective Eq. (1) in STRUCTVAE.

Supervised Learning For the supervised learning objective, we modify $\mathcal{J}_s$, and use the labeled data to optimize both the inference model (the semantic parser) and the reconstruction model:

$$\mathcal{J}_s \triangleq \sum_{(\boldsymbol{x},\boldsymbol{z})\in\mathbb{L}} \big(\log q_\phi(\boldsymbol{z}|\boldsymbol{x}) + \log p_\theta(\boldsymbol{x}|\boldsymbol{z})\big) \quad (2)$$

Unsupervised Learning To optimize the unsupervised learning objective $\mathcal{J}_u$ in Eq. (1), we maximize the variational lower-bound of $\log p(\boldsymbol{x})$:

$$\log p(\boldsymbol{x}) \geq \mathbb{E}_{\boldsymbol{z}\sim q_\phi(\boldsymbol{z}|\boldsymbol{x})}\big(\log p_\theta(\boldsymbol{x}|\boldsymbol{z})\big) - \lambda \cdot \mathrm{KL}[q_\phi(\boldsymbol{z}|\boldsymbol{x})||p(\boldsymbol{z})] = \mathcal{L} \quad (3)$$

where $\mathrm{KL}[q_\phi||p]$ is the Kullback-Leibler (KL) divergence. Following common practice in optimizing VAEs, we introduce λ as a tuning parameter of the KL divergence to control the impact of the prior (Miao and Blunsom, 2016; Bowman et al., 2016).

To optimize the parameters of our model in the face of non-differentiable discrete latent variables, we follow Miao and Blunsom (2016), and approximate $\frac{\partial\mathcal{L}}{\partial\phi}$ using the score function estimator (a.k.a. REINFORCE, Williams (1992)):

$$\begin{aligned}\frac{\partial\mathcal{L}}{\partial\phi} &= \frac{\partial}{\partial\phi}\mathbb{E}_{\boldsymbol{z}\sim q_\phi(\boldsymbol{z}|\boldsymbol{x})} \\ &\quad \underbrace{\Big(\log p_\theta(\boldsymbol{x}|\boldsymbol{z}) - \lambda\big(\log q_\phi(\boldsymbol{z}|\boldsymbol{x}) - \log p(\boldsymbol{z})\big)\Big)}_{\text{learning signal}} \\ &= \frac{\partial}{\partial\phi}\mathbb{E}_{\boldsymbol{z}\sim q_\phi(\boldsymbol{z}|\boldsymbol{x})} l'(\boldsymbol{x},\boldsymbol{z}) \\ &\approx \frac{1}{|\mathcal{S}(\boldsymbol{x})|}\sum_{\boldsymbol{z}_i\in\mathcal{S}(\boldsymbol{x})} l'(\boldsymbol{x},\boldsymbol{z}_i)\frac{\partial \log q_\phi(\boldsymbol{z}_i|\boldsymbol{x})}{\partial\phi} \qquad (4)\end{aligned}$$

where we approximate the gradient using a set of samples $\mathcal{S}(\boldsymbol{x})$ drawn from $q_\phi(\cdot|\boldsymbol{x})$. To ensure the quality of sampled latent MRs, we follow Guu et al. (2017) and use beam search. The term $l'(\boldsymbol{x},\boldsymbol{z})$ is defined as the *learning signal* (Miao and Blunsom, 2016). The learning signal weights the gradient for each latent sample $\boldsymbol{z}$. In REINFORCE, to cope with the high variance of the learning signal, it is common to use a baseline $b(\boldsymbol{x})$ to stabilize learning, and re-define the learning signal as

$$l(\boldsymbol{x},\boldsymbol{z}) \triangleq l'(\boldsymbol{x},\boldsymbol{z}) - b(\boldsymbol{x}). \quad (5)$$

Specifically, in STRUCTVAE, we define

$$b(\boldsymbol{x}) = a \cdot \log p(\boldsymbol{x}) + c, \quad (6)$$

where $\log p(\boldsymbol{x})$ is a pre-trained LSTM language model. This is motivated by the empirical observation that $\log p(\boldsymbol{x})$ correlates well with the reconstruction score $\log p_\theta(\boldsymbol{x}|\boldsymbol{z})$, hence with $l'(\boldsymbol{x},\boldsymbol{z})$.

Finally, for the reconstruction model, its gradient can be easily computed:

$$\frac{\partial\mathcal{L}}{\partial\theta} \approx \frac{1}{|\mathcal{S}(\boldsymbol{x})|}\sum_{\boldsymbol{z}_i\in\mathcal{S}(\boldsymbol{x})}\frac{\partial \log p_\theta(\boldsymbol{x}|\boldsymbol{z}_i)}{\partial\theta}.$$

Discussion Perhaps the most intriguing question here is why semi-supervised learning could improve semantic parsing performance. While the underlying theoretical exposition still remains an active research problem (Singh et al., 2008), in this paper we try to empirically test some likely hypotheses. In Eq. (4), the gradient received by the inference model from each latent sample $\boldsymbol{z}$ is weighed by the learning signal $l(\boldsymbol{x},\boldsymbol{z})$. $l(\boldsymbol{x},\boldsymbol{z})$ can be viewed as the reward function in REINFORCE learning. It can also be viewed as weights associated with pseudo-training examples $\{\langle\boldsymbol{x},\boldsymbol{z}\rangle : \boldsymbol{z} \in \mathcal{S}(\boldsymbol{x})\}$ sampled from the inference model. Intuitively, a sample $\boldsymbol{z}$ with higher rewards should: (1) have $\boldsymbol{z}$ adequately encode the input, leading to high reconstruction score $\log p_\theta(\boldsymbol{x}|\boldsymbol{z})$; and (2) have $\boldsymbol{z}$ be succinct and natural, yielding high prior probability. Let $\boldsymbol{z}^*$ denote the gold-standard MR of $\boldsymbol{x}$. Consider the ideal case where $\boldsymbol{z}^* \in \mathcal{S}(\boldsymbol{x})$ and $l(\boldsymbol{x},\boldsymbol{z}^*)$ is positive, while $l(\boldsymbol{x},\boldsymbol{z}')$ is negative for other imperfect samples $\boldsymbol{z}' \in \mathcal{S}(\boldsymbol{x})$, $\boldsymbol{z}' \neq \boldsymbol{z}^*$. In this ideal case, $\langle\boldsymbol{x},\boldsymbol{z}^*\rangle$ would serve as a positive training example and other samples $\langle\boldsymbol{x},\boldsymbol{z}'\rangle$ would be treated as negative examples. Therefore, the inference model would receive informative gradient updates, and learn to discriminate between gold and imperfect MRs. This intuition is similar in spirit to recent efforts in interpreting gradient update rules in reinforcement learning (Guu et al., 2017). We will present more empirical statistics and observations in § 4.3.

4 Experiments

4.1 Datasets

In our semi-supervised semantic parsing experiments, it is of interest how STRUCTVAE could further improve upon a supervised parser with extra unlabeled data. We evaluate on two datasets:

Semantic Parsing We use the ATIS dataset, a collection of 5,410 telephone inquiries of flight booking (*e.g.*, *"Show me flights from ci0 to ci1"*). The target MRs are defined using λ-calculus logical forms (*e.g.*, "`lambda $0 e (and (flight $0) (from $ci0) (to $ci1))`"). We use the pre-processed dataset released by Dong and Lapata (2016), where entities (*e.g.*, cities) are canonicalized using typed slots (*e.g.*, `ci0`). To predict λ-

calculus logical forms using our transition-based parser, we use the ASDL grammar defined by Rabinovich et al. (2017) to convert between logical forms and ASTs (see Appendix C for details).

Code Generation The DJANGO dataset (Oda et al., 2015) contains 18,805 lines of Python source code extracted from the Django web framework. Each line of code is annotated with an NL utterance. Source code in the DJANGO dataset exhibits a wide variety of real-world use cases of Python, including IO operation, data structure manipulation, class/function definition, *etc*. We use the pre-processed version released by Yin and Neubig (2017) and use the `astor` package to convert ASDL ASTs into Python source code.

4.2 Setup

Labeled and Unlabeled Data STRUCTVAE requires access to extra unlabeled NL utterances for semi-supervised learning. However, the datasets we use do not accompany with such data. We therefore simulate the semi-supervised learning scenario by randomly sub-sampling K examples from the training split of each dataset as the labeled set $\mathbb{L}$. To make the most use of the NL utterances in the dataset, we construct the unlabeled set $\mathbb{U}$ using all NL utterances in the training set[3,4].

Training Procedure Optimizing the unsupervised learning objective Eq. (3) requires sampling structured MRs from the inference model $q_\phi(\boldsymbol{z}|\boldsymbol{x})$. Due to the complexity of the semantic parsing problem, we cannot expect any valid samples from randomly initialized $q_\phi(\boldsymbol{z}|\boldsymbol{x})$. We therefore pre-train the inference and reconstruction models using the supervised objective Eq. (2) until convergence, and then optimize using the semi-supervised learning objective Eq. (1). Throughout all experiments we set α (Eq. (1)) and λ (Eq. (3)) to 0.1. The sample size $|\mathcal{S}(\boldsymbol{x})|$ is 5. We observe that the variance of the learning signal could still be high when low-quality samples are drawn from the inference model $q_\phi(\boldsymbol{z}|\boldsymbol{x})$. We therefore clip all learning signals lower than $k = -20.0$. Early-stopping is used to avoid over-fitting. We also pre-train the prior $p(\boldsymbol{z})$ (§ 3.3) and the baseline function Eq. (6). Readers are referred to Appendix D for more detail of the configurations.

[3]We also tried constructing $\mathbb{U}$ using the disjoint portion of the NL utterances not presented in the labeled set $\mathbb{L}$, but found this yields slightly worse performance, probably due to lacking enough unlabeled data. Interpreting these results would be an interesting avenue for future work.

[4]While it might be relatively easy to acquire additional unlabeled utterances in practical settings (*e.g.*, through query logs of a search engine), unfortunately most academic semantic parsing datasets, like the ones used in this work, do not feature large sets of in-domain unlabeled data. We therefore perform simulated experiments instead.

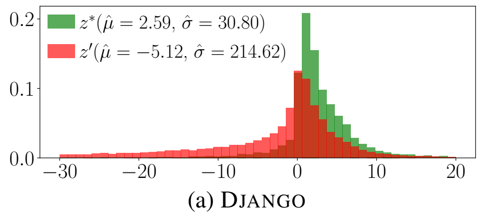
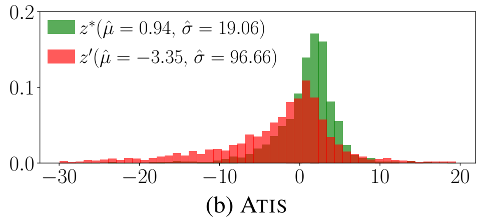
4.3 Main Results

Tab. 1 and Tab. 2 list the results on ATIS and DJANGO, resp, with varying amounts of labeled data $\mathbb{L}$. We also present results of training the transition-based parser using only the supervised objective (**SUP.**, Eq. (2)). We also compare STRUCTVAE with self-training (**SELFTRAIN**), a semi-supervised learning baseline which uses the supervised parser to predict MRs for unlabeled utterances in $\mathbb{U} - \mathbb{L}$, and adds the predicted examples to the training set to fine-tune the supervised model. Results for STRUCTVAE are averaged over four runs to account for the additional fluctuation caused by REINFORCE training.

Supervised System Comparison First, to highlight the effectiveness of our transition parser based on ASDL grammar (hence the reliability of



(a) DJANGO



(b) ATIS

Figure 4: Histograms of learning signals on DJANGO ($|\mathbb{L}| = 5000$) and ATIS ($|\mathbb{L}| = 2000$). Difference in sample means is statistically significant ($p < 0.05$).

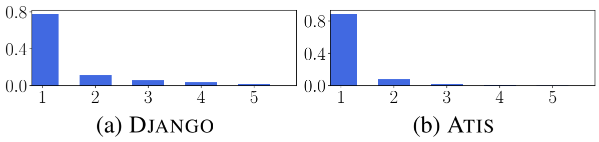


Figure 5: Distribution of the rank of $l(\boldsymbol{x}, \boldsymbol{z}^*)$ in sampled set

our supervised baseline), we compare the supervised version of our parser with existing parsing models. On ATIS, our supervised parser trained on the full data is competitive with existing neural network based models, surpassing the SEQ2TREE model, and on par with the Abstract Syntax Network (ASN) without using extra supervision. On DJANGO, our model significantly outperforms the YN17 system, probably because the transition system used by our parser is defined natively to construct ASDL ASTs, reducing the number of actions for generating each example. On DJANGO, the average number of actions is 14.3, compared with 20.3 reported in YN17.

Semi-supervised Learning Next, we discuss our main comparison between STRUCTVAE with the supervised version of the parser (recall that the supervised parser is used as the inference model in STRUCTVAE, § 3.2). First, comparing our proposed STRUCTVAE with the supervised parser when there are extra unlabeled data (*i.e.*, $|\mathbb{L}| < 4,434$ for ATIS and $|\mathbb{L}| < 16,000$ for DJANGO), semi-supervised learning with STRUCTVAE consistently achieves better performance. Notably, on DJANGO, our model registers results as competitive as previous state-of-the-art method (YN17) using only *half* the training data (71.5 when $|\mathbb{L}| = 8000$ v.s. 71.6 for YN17). This demonstrates that STRUCTVAE is capable of learning from unlabeled NL utterances by inferring high quality, structurally rich latent meaning representations, further improving the performance of its supervised counterpart that is already competitive. Second, comparing STRUCTVAE with self-training, we find STRUCTVAE outperforms SELFTRAIN in eight out of ten settings, while SELFTRAIN under-performs the supervised parser in four out of ten settings. This shows self-training does not necessarily yield stable gains while STRUCTVAE does. Intuitively, STRUCTVAE would perform better since it benefits from the additional signal of the quality of MRs from the reconstruction model (§ 3.3), for which we present more analysis in our next set of experiments.

For the sake of completeness, we also report the results of STRUCTVAE when $\mathbb{L}$ is the full training set. Note that in this scenario there is no extra unlabeled data disjoint with the labeled set, and not surprisingly, STRUCTVAE does not outperform the supervised parser. In addition to the supervised objective Eq. (2) used by the supervised parser, STRUCTVAE has the extra unsupervised objective Eq. (3), which uses sampled (probably incorrect) MRs to update the model. When there is no extra unlabeled data, those sampled (incorrect) MRs add noise to the optimization process, causing STRUCTVAE to under-perform.

Study of Learning Signals As discussed in § 3.3, in semi-supervised learning, the gradient received by the inference model from each sampled latent MR is weighted by the learning signal. Empirically, we would expect that on average, the learning signals of gold-standard samples $\boldsymbol{z}^*$, $l(\boldsymbol{x}, \boldsymbol{z}^*)$, are positive, larger than those of other (imperfect) samples $\boldsymbol{z}'$, $l(\boldsymbol{x}, \boldsymbol{z}')$. We therefore study the statistics of $l(\boldsymbol{x}, \boldsymbol{z}^*)$ and $l(\boldsymbol{x}, \boldsymbol{z}')$ for all utterances $\boldsymbol{x} \in \mathbb{U} - \mathbb{L}$, *i.e.*, the set of utterances which are not included in the labeled set.[5] The statistics are obtained by performing inference using trained models. Figures 4a and 4b depict the histograms of learning signals on DJANGO and ATIS, resp. We observe that the learning signals for gold samples concentrate on positive intervals. We also show the mean and variance of the learning signals. On average, we have $l(\boldsymbol{x}, \boldsymbol{z}^*)$ being positive and $l(\boldsymbol{x}, \boldsymbol{z})$ negative. Also note that the distribution of $l(\boldsymbol{x}, \boldsymbol{z}^*)$ has smaller variance and is more concentrated. Therefore the inference model receives informative gradient updates to discriminate between gold and imperfect

[5]We focus on cases where $\boldsymbol{z}^*$ is in the sample set $\mathcal{S}(\boldsymbol{x})$.

	$\log p(\boldsymbol{z}) = -20.41$	$l(\boldsymbol{x}, \boldsymbol{z}) = -2.60$

Table 3: Inferred latent MRs on DJANGO ($|\mathbb{L}| = 5000$). For simplicity we show the surface representation of MRs ($\boldsymbol{z}^s$, source code) instead.

samples. Next, we plot the distribution of the rank of $l(\boldsymbol{x}, \boldsymbol{z}^*)$, among the learning signals of all samples of $\boldsymbol{x}$, $\{l(\boldsymbol{x}, \boldsymbol{z}_i) : \boldsymbol{z}_i \in \mathcal{S}(\boldsymbol{x})\}$. Results are shown in Fig. 5. We observe that the gold samples $\boldsymbol{z}^*$ have the largest learning signals in around 80% cases. We also find that when $\boldsymbol{z}^*$ has the largest learning signal, its average difference with the learning signal of the highest-scoring incorrect sample is 1.27 and 0.96 on DJANGO and ATIS, respectively.

Finally, to study the relative contribution of the reconstruction score $\log p(\boldsymbol{x}|\boldsymbol{z})$ and the prior $\log p(\boldsymbol{z})$ to the learning signal, we present examples of inferred latent MRs during training (Tab. 3). Examples 1&2 show that the reconstruction score serves as an informative quality measure of the latent MR, assigning the correct samples $\boldsymbol{z}_1^s$ with high $\log p(\boldsymbol{x}|\boldsymbol{z})$, leading to positive learning signals. This is in line with our assumption that a good latent MR should adequately encode the semantics of the utterance. Example 3 shows that the prior is also effective in identifying "unnatural" MRs (*e.g.*, it is rare to add a function and a string literal, as in $\boldsymbol{z}_2^s$). These results also suggest that the prior and the reconstruction model perform well with linearization of MRs. Finally, note that in Examples 2&3 the learning signals for the correct samples $\boldsymbol{z}_1^s$ are positive even if their inference scores $q(\boldsymbol{z}|\boldsymbol{x})$ are lower than those of $\boldsymbol{z}_2^s$.

Table 5: Comparison of STRUCTVAE with different baseline functions $b(\boldsymbol{x})$, *italic*†: semi-supervised learning with the MLP baseline is worse than supervised results.

This result further demonstrates that learning signals provide informative gradient weights for optimizing the inference model.

Generalizing to Other Latent MRs Our main results are obtained using a strong AST-based semantic parser as the inference model, with copy-augmented reconstruction model and an LSTM language model as the prior. However, there are many other ways to represent and infer structure in semantic parsing (Carpenter, 1998; Steedman, 2000), and thus it is of interest whether our basic STRUCTVAE framework generalizes to other semantic representations. To examine this, we test STRUCTVAE using λ-calculus logical forms as latent MRs for semantic parsing on the ATIS domain. We use standard sequence-to-sequence networks with attention (Luong et al., 2015) as inference and reconstruction models. The inference model is trained to construct a tree-structured logical form using the transition actions defined in Cheng et al. (2017). We use a classical tri-gram Kneser-Ney language model as the prior. Tab. 4 lists the results for this STRUCTVAE-SEQ model.

We can see that even with this very different model structure STRUCTVAE still provides significant gains, demonstrating its compatibility with different inference/reconstruction networks and priors. Interestingly, compared with the results in Tab. 1, we found that the gains are especially larger with few labeled examples — STRUCTVAE-SEQ achieves improvements of 8-10 points when $|\mathbb{L}| < 1000$. These results suggest that semi-supervision is especially useful in improving a mediocre parser in low resource settings.

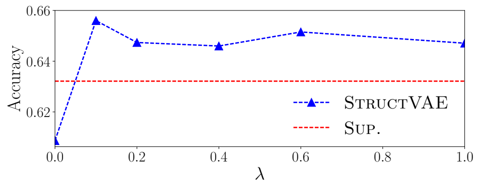

Figure 6: Performance on Django ($|\mathbb{L}| = 5000$) w.r.t. the KL weight λ

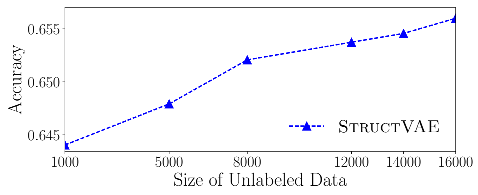

Figure 7: Performance on Django ($|\mathbb{L}| = 5000$) w.r.t. the size of unlabeled data $\mathbb{U}$

Impact of Baseline Functions In § 3.3 we discussed our design of the baseline function $b(\boldsymbol{x})$ incorporated in the learning signal (Eq. (4)) to stabilize learning, which is based on a language model (LM) over utterances (Eq. (6)). We compare this baseline with a commonly used one in REINFORCE training: the multi-layer perceptron (MLP). The MLP takes as input the last hidden state of the utterance given by the encoding LSTM of the inference model. Tab. 5 lists the results over sampled settings. We found that although StructVAE with the MLP baseline sometimes registers better performance on Atis, in most settings it is worse than our LM baseline, and could be even worse than the supervised parser. On the other hand, our LM baseline correlates well with the learning signal, yielding stable improvements over the supervised parser. This suggests the importance of using carefully designed baselines in REINFORCE learning, especially when the reward signal has large range (*e.g.*, log-likelihoods).

Impact of the Prior $p(\boldsymbol{z})$ Fig. 6 depicts the performance of StructVAE as a function of the KL term weight λ in Eq. (3). When StructVAE degenerates to a vanilla auto-encoder without the prior distribution (*i.e.*, $\lambda = 0$), it under-performs the supervised baseline. This is in line with our observation in Tab. 3 showing that the prior helps identify unnatural samples. The performance of the model also drops when $\lambda > 0.1$, suggesting that empirically controlling the influence of the prior to the inference model is important.

Impact of Unlabeled Data Size Fig. 7 illustrates the accuracies w.r.t. the size of unlabeled data. StructVAE yields consistent gains as the size of the unlabeled data increases.

5 Related Works

Semi-supervised Learning for NLP Semi-supervised learning comes with a long history (Zhu, 2005), with applications in NLP from early work of self-training (Yarowsky, 1995), and graph-based methods (Das and Smith, 2011), to recent advances in auto-encoders (Cheng et al., 2016; Socher et al., 2011; Zhang et al., 2017) and deep generative methods (Xu et al., 2017). Our work follows the line of neural variational inference for text processing (Miao et al., 2016), and resembles Miao and Blunsom (2016), which uses VAEs to model summaries as discrete latent variables for semi-supervised summarization, while we extend the VAE architecture for more complex, tree-structured latent variables.

Semantic Parsing Most existing works alleviate issues of limited parallel data through weakly-supervised learning, using the denotations of MRs as indirect supervision (Reddy et al., 2014; Krishnamurthy et al., 2016; Neelakantan et al., 2016; Pasupat and Liang, 2015; Yin et al., 2016). For semi-supervised learning of semantic parsing, Kate and Mooney (2007) first explore using transductive SVMs to learn from a semantic parser's predictions. Konstas et al. (2017) apply self-training to bootstrap an existing parser for AMR parsing. Kociský et al. (2016) employ VAEs for semantic parsing, but in contrast to StructVAE's structured representation of MRs, they model NL utterances as flat latent variables, and learn from unlabeled MR data. There have also been efforts in unsupervised semantic parsing, which exploits external linguistic analysis of utterances (*e.g.*, dependency trees) and the schema of target knowledge bases to infer the latent MRs (Poon and Domingos, 2009; Poon, 2013). Another line of research is domain adaptation, which seeks to transfer a semantic parser learned from a source domain to the target domain of interest, therefore alleviating the need of parallel data from the target domain (Su and Yan, 2017; Fan et al., 2017; Herzig and Berant, 2018).

6 Conclusion

We propose StructVAE, a deep generative model with tree-structured latent variables for semi-supervised semantic parsing. We apply StructVAE to semantic parsing and code generation tasks, and show it outperforms a strong supervised parser using extra unlabeled data.

Abstract

This paper proposes a neural semantic parsing approach – Sequence-to-Action, which models semantic parsing as an end-to-end semantic graph generation process. Our method simultaneously leverages the advantages from two recent promising directions of semantic parsing. Firstly, our model uses a semantic graph to represent the meaning of a sentence, which has a tight-coupling with knowledge bases. Secondly, by leveraging the powerful representation learning and prediction ability of neural network models, we propose a RNN model which can effectively map sentences to action sequences for semantic graph generation. Experiments show that our method achieves state-of-the-art performance on OVERNIGHT dataset and gets competitive performance on GEO and ATIS datasets.

1 Introduction

Semantic parsing aims to map natural language sentences to logical forms (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Wong and Mooney, 2007; Lu et al., 2008; Kwiatkowski et al., 2013). For example, the sentence "*Which states border Texas?*" will be mapped to `answer (A, (state (A), next_to (A, stateid ( texas ))))`.

A semantic parser needs two functions, one for structure prediction and the other for semantic grounding. Traditional semantic parsers are usually based on compositional grammar, such as CCG (Zettlemoyer and Collins, 2005, 2007), DCS (Liang et al., 2011), etc. These parsers compose structure using manually designed grammars, use lexicons for semantic grounding, and exploit features for candidate logical forms ranking. Unfortunately, it is challenging to design grammars and learn accurate lexicons, especially in wide-open domains. Moreover, it is often hard to design effective features, and its learning process is not end-to-end. To resolve the above problems, two promising lines of work have been proposed: Semantic graph-based methods and Seq2Seq methods.

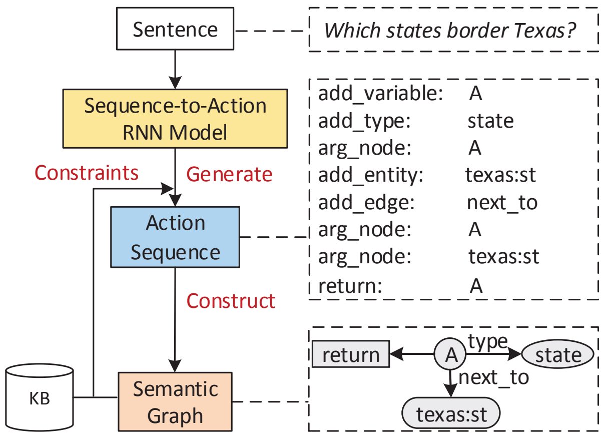

Figure 1: Overview of our method, with a demonstration example.

Semantic graph-based methods (Reddy et al., 2014, 2016; Bast and Haussmann, 2015; Yih et al., 2015) represent the meaning of a sentence as a semantic graph (i.e., a sub-graph of a knowledge base, see example in Figure 1) and treat semantic parsing as a semantic graph matching/generation process. Compared with logical forms, semantic graphs have a tight-coupling with knowledge bases (Yih et al., 2015), and share many commonalities with syntactic structures (Reddy et al., 2014). Therefore both the structure and semantic constraints from knowledge bases can be easily exploited during parsing (Yih et al., 2015). The main challenge of semantic graph-based parsing is how to effectively construct the semantic graph of a sentence. Currently, semantic graphs are either constructed by matching with patterns (Bast and Haussmann, 2015), transforming from dependency tree (Reddy et al., 2014, 2016), or via a staged heuristic search algorithm (Yih et al., 2015). These methods are all based on manually-designed, heuristic construction processes, making them hard to handle open/complex situations.

In recent years, RNN models have achieved success in sequence-to-sequence problems due to its strong ability on both representation learning and prediction, e.g., in machine translation (Cho et al., 2014). A lot of Seq2Seq models have also been employed for semantic parsing (Xiao et al., 2016; Dong and Lapata, 2016; Jia and Liang, 2016), where a sentence is parsed by translating it to linearized logical form using RNN models. There is no need for high-quality lexicons, manually-built grammars, and hand-crafted features. These models are trained end-to-end, and can leverage attention mechanism (Bahdanau et al., 2014; Luong et al., 2015) to learn soft alignments between sentences and logical forms.

In this paper, we propose a new neural semantic parsing framework – Sequence-to-Action, which can simultaneously leverage the advantages of semantic graph representation and the strong prediction ability of Seq2Seq models. Specifically, we model semantic parsing as an end-to-end semantic graph generation process. For example in Figure 1, our model will parse the sentence "*Which states border Texas*" by generating a sequence of actions [`add_variable:A`, `add_type:state`, ...]. To achieve the above goal, we first design an action set which can encode the generation process of semantic graph (including node actions such as `add_variable`, `add_entity`, `add_type`, edge actions such as `add_edge`, and operation actions such as `argmin`, `argmax`, `count`, `sum`, etc.). And then we design a RNN model which can generate the action sequence for constructing the semantic graph of a sentence. Finally we further enhance parsing by incorporating both structure and semantic constraints during decoding.

Compared with the manually-designed, heuristic generation algorithms used in traditional semantic graph-based methods, our sequence-to-action method generates semantic graphs using a RNN model, which is learned end-to-end from training data. Such a learnable, end-to-end generation makes our approach more effective and can fit to different situations.

Compared with the previous Seq2Seq semantic parsing methods, our sequence-to-action model predicts a sequence of semantic graph generation actions, rather than linearized logical forms. We find that the action sequence encoding can better capture structure and semantic information, and is more compact. And the parsing can be enhanced by exploiting structure and semantic constraints. For example, in GEO dataset, the action `add_edge:next_to` must subject to the semantic constraint that its arguments must be of type `state` and `state`, and the structure constraint that the edge `next_to` must connect two nodes to form a valid graph.

We evaluate our approach on three standard datasets: GEO (Zelle and Mooney, 1996), ATIS (He and Young, 2005) and OVERNIGHT (Wang et al., 2015b). The results show that our method achieves state-of-the-art performance on OVERNIGHT dataset and gets competitive performance on GEO and ATIS datasets.

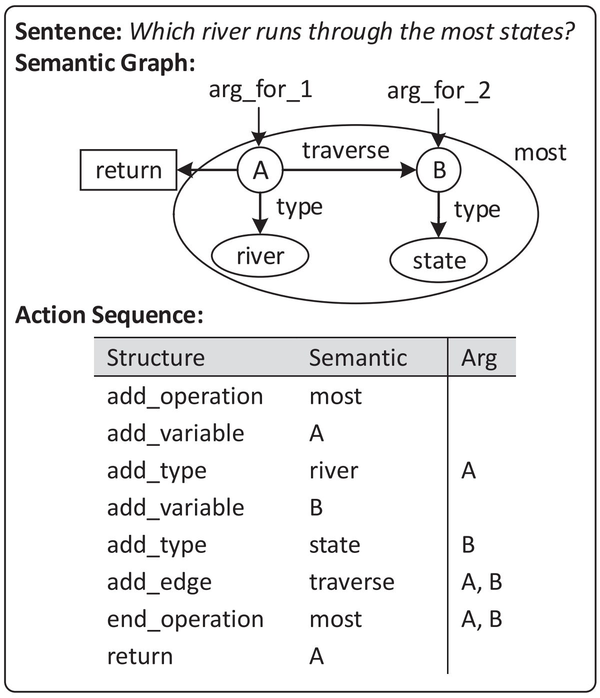
The main contributions of this paper are summarized as follows:

- We propose a new semantic parsing framework – Sequence-to-Action, which models semantic parsing as an end-to-end semantic graph generation process. This new framework can synthesize the advantages of semantic graph representation and the prediction ability of Seq2Seq models.

- We design a sequence-to-action model, including an action set encoding for semantic graph generation and a Seq2Seq RNN model for action sequence prediction. We further enhance the parsing by exploiting structure and semantic constraints during decoding. Experiments validate the effectiveness of our method.

2 Sequence-to-Action Model for End-to-End Semantic Graph Generation

Given a sentence $X = x_1, ..., x_{|X|}$, our sequence-to-action model generates a sequence of actions $Y = y_1, ..., y_{|Y|}$ for constructing the correct semantic graph. Figure 2 shows an example. The conditional probability $P(Y|X)$ used in our



Sentence: *Which river runs through the most states?*

Semantic Graph:

Action Sequence:

Structure	Semantic	Arg
add_operation	most	
add_variable	A	
add_type	river	A
add_variable	B	
add_type	state	B
add_edge	traverse	A, B
end_operation	most	A, B
return	A	

Figure 2: An example of a sentence paired with its semantic graph, together with the action sequence for semantic graph generation.

model is decomposed as follows:

$$P(Y|X) = \prod_{t=1}^{|Y|} P(y_t|y_{<t}, X) \tag{1}$$

where $y_{<t} = y_1, ..., y_{t-1}$.

To achieve the above goal, we need: 1) an action set which can encode semantic graph generation process; 2) an encoder which encodes natural language input X into a vector representation, and a decoder which generates $y_1, ..., y_{|Y|}$ conditioned on the encoding vector. In following we describe them in detail.

2.1 Actions for Semantic Graph Generation

Generally, a semantic graph consists of nodes (including variables, entities, types) and edges (semantic relations), with some universal operations (e.g., `argmax`, `argmin`, `count`, `sum`, and `not`). To generate a semantic graph, we define six types of actions as follows:

Add Variable Node: This kind of actions denotes adding a variable node to semantic graph. In most cases a variable node is a return node (e.g., *which*, *what*), but can also be an intermediate variable node. We represent this kind of action as `add_variable:A`, where `A` is the identifier of the variable node.

Add Entity Node: This kind of actions denotes adding an entity node (e.g., *Texas*, *New York*) and is represented as `add_entity_node:texas`. An entity node corresponds to an entity in knowledge bases.

Add Type Node: This kind of actions denotes adding a type node (e.g., *state*, *city*). We represent them as `add_type_node:state`.

Add Edge: This kind of actions denotes adding an edge between two nodes. An edge is a binary relation in knowledge bases. This kind of actions is represented as `add_edge:next_to`.

Operation Action: This kind of actions denotes adding an operation. An operation can be `argmax`, `argmin`, `count`, `sum`, `not`, et al. Because each operation has a scope, we define two actions for an operation, one is operation start action, represented as `start_operation:most`, and the other is operation end action, represented as `end_operation:most`. The subgraph within the start and end operation actions is its scope.

Argument Action: Some above actions need argument information. For example, which nodes the `add_edge:next_to` action should connect to. In this paper, we design argument actions for `add_type`, `add_edge` and `operation` actions, and the argument actions should be put directly after its main action.

For `add_type` actions, we put an argument action to indicate which node this type node should constrain. The argument can be a variable node or an entity node. An argument action for a type node is represented as `arg:A`.

For `add_edge` action, we use two argument actions: `arg1_node` and `arg2_node`, and they are represented as `arg1_node:A` and `arg2_node:B`.

We design argument actions for different operations. For `operation:sum`, there are three arguments: `arg-for`, `arg-in` and `arg-return`. For `operation:count`, they are `arg-for` and `arg-return`. There are two `arg-for` arguments for `operation:most`.

We can see that each action encodes both structure and semantic information, which makes it easy to capture more information for parsing and can be tightly coupled with knowledge base. Furthermore, we find that action sequence encoding is more compact than linearized logical form (See Section 4.4 for more details).

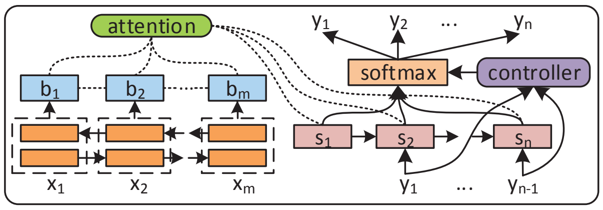


Figure 3: Our attention-based Sequence-to-Action RNN model, with a controller for incorporating constraints.

2.2 Neural Sequence-to-Action Model

Based on the above action encoding mechanism, this section describes our encoder-decoder model for mapping sentence to action sequence. Specifically, similar to the RNN model in Jia and Liang (2016), this paper employs the attention-based sequence-to-sequence RNN model. Figure 3 presents the overall structure.

Encoder: The encoder converts the input sequence $x_1, ..., x_m$ to a sequence of context-sensitive vectors $b_1, ..., b_m$ using a bidirectional RNN (Bahdanau et al., 2014). Firstly each word x_i is mapped to its embedding vector, then these vectors are fed into a forward RNN and a backward RNN. The sequence of hidden states $h_1, ..., h_m$ are generated by recurrently applying the recurrence:

$$h_i = LSTM(\phi^{(x)}(x_i), h_{i-1}). \tag{2}$$

The recurrence takes the form of LSTM (Hochreiter and Schmidhuber, 1997). Finally, for each input position i, we define its context-sensitive embedding as $b_i = [h_i^F, h_i^B]$.

Decoder: This paper uses the classical attention-based decoder (Bahdanau et al., 2014), which generates action sequence $y_1, ..., y_n$, one action at a time. At each time step j, it writes y_j based on the current hidden state s_j, then updates the hidden state to s_{j+1} based on s_j and y_j. The decoder is formally defined by the following equations:

$$s_1 = \tanh(W^{(s)}[h_m^F, h_1^B]) \tag{3}$$

$$e_{ji} = s_j^T W^{(a)} b_i \tag{4}$$

$$a_{ji} = \frac{\exp(e_{ji})}{\sum_{i'=1}^{m} \exp(e_{ji'})} \tag{5}$$

$$c_j = \sum_{i=1}^{m} a_{ji} b_i \tag{6}$$

$$P(y_j = w | x, y_{1:j-1}) \propto \exp(U_w[s_j, c_j]) \tag{7}$$

$$s_{j+1} = LSTM([\phi^{(y)}(y_j), c_j], s_j) \tag{8}$$

where the normalized attention scores a_{ji} defines the probability distribution over input words, indicating the attention probability on input word i at time j; e_{ji} is un-normalized attention score. To incorporate constraints during decoding, an extra controller component is added and its details will be described in Section 3.3.

Action Embedding. The above decoder needs the embedding of each action. As described above, each action has two parts, one for structure (e.g., `add_edge`), and the other for semantic (e.g., `next_to`). As a result, actions may share the same structure or semantic part, e.g., `add_edge:next_to` and `add_edge:loc` have the same structure part, and `add_node:A` and `arg_node:A` have the same semantic part. To make parameters more compact, we first embed the structure part and the semantic part independently, then concatenate them to get the final embedding. For instance, $\phi^{(y)}($`add_edge:next_to` $) = [\ \phi^{(y)}_{strut}($ `add_edge` $), \phi^{(y)}_{sem}($ `next_to` $)]$. The action embeddings $\phi^{(y)}$ are learned during training.

3 Constrained Semantic Parsing using Sequence-to-Action Model

In this section, we describe how to build a neural semantic parser using sequence-to-action model. We first describe the training and the inference of our model, and then introduce how to incorporate structure and semantic constraints during decoding.

3.1 Training

Parameter Estimation. The parameters of our model include RNN parameters $W^{(s)}$, $W^{(a)}$, U_w, word embeddings $\phi^{(x)}$, and action embeddings $\phi^{(y)}$. We estimate these parameters from training data. Given a training example with a sentence X and its action sequence Y, we maximize the likelihood of the generated sequence of actions given X. The objective function is:

$$\sum_{i=1}^{n} \log P(Y_i|X_i) \tag{9}$$

Standard stochastic gradient descent algorithm is employed to update parameters.

Logical Form to Action Sequence. Currently, most datasets of semantic parsing are labeled with logical forms. In order to train our model, we

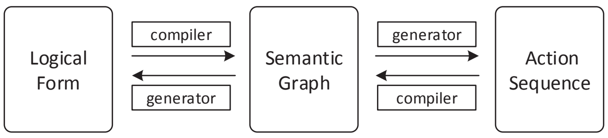

Figure 4: The procedure of converting between logical form and action sequence.

convert logical forms to action sequences using semantic graph as an intermediate representation (See Figure 4 for an overview). Concretely, we transform logical forms into semantic graphs using a depth-first-search algorithm from root, and then generate the action sequence using the same order. Specifically, entities, variables and types are nodes; relations are edges. Conversely we can convert action sequence to logical form similarly. Based on the above algorithm, action sequences can be transformed into logical forms in a deterministic way, and the same for logical forms to action sequences.

Mechanisms for Handling Entities. Entities play an important role in semantic parsing (Yih et al., 2015). In Dong and Lapata (2016), entities are replaced with their types and unique IDs. In Jia and Liang (2016), entities are generated via attention-based copying mechanism helped with a lexicon. This paper implements both mechanisms and compares them in experiments.

3.2 Inference

Given a new sentence X, we predict action sequence by:

$$Y^* = \underset{Y}{\text{argmax}} P(Y|X) \qquad (10)$$

where Y represents action sequence, and $P(Y|X)$ is computed using Formula (1). Beam search is used for best action sequence decoding. Semantic graph and logical form can be derived from Y^* as described in above.

3.3 Incorporating Constraints in Decoding

For decoding, we generate action sequentially. It is obviously that the next action has a strong correlation with the partial semantic graph generated to current, and illegal actions can be filtered using structure and semantic constraints. Specifically, we incorporate constraints in decoding using a controller. This procedure has two steps: 1) the controller constructs partial semantic graph using the actions generated to current; 2) the controller checks whether a new generated action can meet

	Structure	Semantic	Arg	Validity
Generated Actions	add_variable	A		
	add_type	state	A	
	add_entity	texas:st		
Candidate Next Action	add_type	city	texas:st	✗
	add_edge	loc	A, texas:st	✗
	add_edge	next_to	A, A	✗
	add_edge	next_to	A, texas:st	✓
	⋮	⋮	⋮	⋮

Figure 5: A demonstration of illegal action filtering using constraints. The graph in color is the constructed semantic graph to current.

all structure/semantic constraints using the partial semantic graph.

Structure Constraints. The structure constraints ensure action sequence will form a connected acyclic graph. For example, there must be two argument nodes for an edge, and the two argument nodes should be different (The third candidate next action in Figure 5 violates this constraint). This kind of constraints are domain-independent. The controller encodes structure constraints as a set of rules.

Semantic Constraints. The semantic constraints ensure the constructed graph must follow the schema of knowledge bases. Specifically, we model two types of semantic constraints. One is selectional preference constraints where the argument types of a relation should follow knowledge base schemas. For example, in GEO dataset, relation `next_to`'s `arg1` and `arg2` should both be a `state`. The second is type conflict constraints, i.e., an entity/variable node's type must be consistent, i.e., a node cannot be both of type `city` and `state`. Semantic constraints are domain-specific and are automatically extracted from knowledge base schemas. The controller encodes semantic constraints as a set of rules.

4 Experiments

In this section, we assess the performance of our method and compare it with previous methods.

4.1 Datasets

We conduct experiments on three standard datasets: GEO, ATIS and OVERNIGHT.

GEO contains natural language questions about US geography paired with corresponding Prolog database queries. Following Zettlemoyer and Collins (2005), we use the standard 600/280 instance splits for training/test.

ATIS contains natural language questions of a flight database, with each question is annotated with a lambda calculus query. Following Zettlemoyer and Collins (2007), we use the standard 4473/448 instance splits for training/test.

OVERNIGHT contains natural language paraphrases paired with logical forms across eight domains. We evaluate on the standard train/test splits as Wang et al. (2015b).

4.2 Experimental Settings

Following the experimental setup of Jia and Liang (2016): we use 200 hidden units and 100-dimensional word vectors for sentence encoding. The dimensions of action embedding are tuned on validation datasets for each corpus. We initialize all parameters by uniformly sampling within the interval [-0.1, 0.1]. We train our model for a total of 30 epochs with an initial learning rate of 0.1, and halve the learning rate every 5 epochs after epoch 15. We replace word vectors for words occurring only once with an universal word vector. The beam size is set as 5. Our model is implemented in Theano (Bergstra et al., 2010), and the codes and settings are released on Github: https://github.com/dongpobeyond/Seq2Act.

We evaluate different systems using the standard accuracy metric, and the accuracies on different datasets are obtained as same as Jia and Liang (2016).

4.3 Overall Results

We compare our method with state-of-the-art systems on all three datasets. Because all systems using the same training/test splits, we directly use the reported best performances from their original papers for fair comparison.

For our method, we train our model with three settings: the first one is the basic sequence-to-action model without constraints – Seq2Act; the second one adds structure constraints in decoding – Seq2Act (+C1); the third one is the full model which adds both structure and semantic constraints – Seq2Act (+C1+C2). Semantic constraints (C2) are stricter than structure constraints (C1). Therefore we set that C1 should be first met for C2 to be met. So in our experiments we add constraints incrementally. The overall results are shown in Table 1-2. From the overall results, we can see that:

	GEO	ATIS

Seq2Act (+C1+C2)	88.9	85.5

Table 1: Test accuracies on GEO and ATIS datasets, where * indicates systems with extra-resources are used.

1) By synthetizing the advantages of semantic graph representation and the prediction ability of Seq2Seq model, our method achieves state-of-the-art performance on OVERNIGHT dataset, and gets competitive performance on GEO and ATIS dataset. In fact, on GEO our full model (Seq2Act+C1+C2) also gets the best test accuracy of 88.9 if under the same settings, which only falls behind Liang et al. (2011)* which uses extra handcrafted lexicons and Jia and Liang (2016)* which uses extra augmented training data. On ATIS our full model gets the second best test accuracy of 85.5, which only falls behind Rabinovich et al. (2017) which uses a supervised attention strategy. On OVERNIGHT, our full model gets state-of-the-art accuracy of 79.0, which even outperforms Jia and Liang (2016)* with extra augmented training data.

2) Compared with the linearized logical form representation used in previous Seq2Seq baselines, our action sequence encoding is more effective for semantic parsing. On all three datasets,

	Soc.	Blo.	Bas.	Res.	Cal.	Hou.	Pub.	Rec.	Avg.
Previous Work									
Wang et al. (2015b)	48.2	41.9	46.3	75.9	74.4	54.0	59.0	70.8	58.8
Seq2Seq Models									
Xiao et al. (2016)	80.0	55.6	80.5	80.1	75.0	61.9	75.8	–	72.7
Jia and Liang (2016)	81.4	58.1	85.2	76.2	78.0	71.4	76.4	79.6	75.8
Jia and Liang (2016)* (+data)	79.6	60.2	87.5	79.5	81.0	72.5	78.3	81.0	77.5
Our Models									
Seq2Act	81.4	60.4	87.5	79.8	81.0	73.0	79.5	81.5	78.0
Seq2Act (+C1)	81.8	60.9	88.0	80.1	81.0	73.5	80.1	82.0	78.4
Seq2Act (+C1+C2)	**82.1**	**61.4**	**88.2**	**80.7**	**81.5**	**74.1**	**80.7**	**82.9**	**79.0**

Table 2: Test accuracies on OVERNIGHT dataset, which includes eight domains: Social, Blocks, Basketball, Restaurants, Calendar, Housing, Publications, and Recipes.

our basic Seq2Act model gets better results than all Seq2Seq baselines. On GEO, the Seq2Act model achieve test accuracy of 87.5, better than the best accuracy 87.1 of Seq2Seq baseline. On ATIS, the Seq2Act model obtains a test accuracy of 84.6, the same as the best Seq2Seq baseline. On OVERNGIHT, the Seq2Act model gets a test accuracy of 78.0, better than the best Seq2Seq baseline gets 77.5. We argue that this is because our action sequence encoding is more compact and can capture more information.

3) Structure constraints can enhance semantic parsing by ensuring the validity of graph using the generated action sequence. In all three datasets, Seq2Act (+C1) outperforms the basic Seq2Act model. This is because a part of illegal actions will be filtered during decoding.

4) By leveraging knowledge base schemas during decoding, semantic constraints are effective for semantic parsing. Compared to Seq2Act and Seq2Act (+C1), the Seq2Act (+C1+C2) gets the best performance on all three datasets. This is because semantic constraints can further filter semantic illegal actions using selectional preference and consistency between types.

4.4 Detailed Analysis

Effect of Entity Handling Mechanisms. This paper implements two entity handling mechanisms – *Replacing* (Dong and Lapata, 2016) which identifies entities and then replaces them with their types and IDs, and attention-based *Copying* (Jia and Liang, 2016). To compare the above two mechanisms, we train and test with our full model and the results are shown in Table 3. We can see that, *Replacing* mechanism outperforms *Copying* in all three datasets. This is because *Replacing* is done in preprocessing, while attention-based *Copying* is done during parsing and needs additional copy mechanism.

	Replacing	*Copying*
GEO	88.9	88.2
ATIS	85.5	84.0
OVERNIGHT	79.0	77.9

Table 3: Test accuracies of Seq2Act (+C1+C2) on GEO, ATIS, and OVERNIGHT of two entity handling mechanisms.

	Logical Form	Action Sequence
GEO	28.2	18.2
ATIS	28.4	25.8
OVERNIGHT	46.6	33.3

Table 4: Average length of logical forms and action sequences on three datasets. On OVERNIGHT, we average across all eight domains.

Linearized Logical Form vs. Action Sequence. Table 4 shows the average length of linearized logical forms used in previous Seq2Seq models and the action sequences of our model on all three datasets. As we can see, action sequence encoding is more compact than linearized logical form encoding: action sequence is shorter on all three datasets, 35.5%, 9.2% and 28.5% reduction in length respectively. The main advantage of a shorter/compact encoding is that it will reduce the influence of long distance dependency problem.

4.5 Error Analysis

We perform error analysis on results and find there are mainly two types of errors.

Unseen/Informal Sentence Structure. Some test sentences have unseen syntactic structures. For example, the first case in Table 5 has an unseen

Error Types	Examples
Un-covered Sentence Structure	Sentence: *Iowa borders how many states?* (Formal Form: *How many states does Iowa border?*) Gold Parse: `answer(A, count(B, (const (C, stateid(iowa)), next_to(C, B), state (B)), A))` Predicted Parse: `answer (A, count(B, state(B), A))`
Under-Mapping	Sentence: *Please show me **first class** flights from indianapolis to memphis one way leaving before 10am* Gold Parse: `(lambda x (and (flight x) (oneway x) (class_type x first:cl) (< (departure_time x) 1000:ti) (from x indianapolis:ci) (to x memphis:ci)))` Predicted Parse: `(lambda x (and (flight x) (oneway x) (< (departure_time x) 1000:ti) (from x indianapolis:ci) (to x memphis:ci)))`

Table 5: Some examples for error analysis. Each example includes the sentence for parsing, with gold parse and predicted parse from our model.

and informal structure, where entity word "*Iowa*" and relation word "*borders*" appear ahead of the question words "*how many*". For this problem, we can employ sentence rewriting or paraphrasing techniques (Chen et al., 2016; Dong et al., 2017) to transform unseen sentence structures into normal ones.

Under-Mapping. As Dong and Lapata (2016) discussed, the attention model does not take the alignment history into consideration, makes some words are ignored during parsing. For example in the second case in Table 5, "*first class*" is ignored during the decoding process. This problem can be further solved using explicit word coverage models used in neural machine translation (Tu et al., 2016; Cohn et al., 2016)

5 Related Work

Semantic parsing has received significant attention for a long time (Kate and Mooney, 2006; Clarke et al., 2010; Krishnamurthy and Mitchell, 2012; Artzi and Zettlemoyer, 2013; Berant and Liang, 2014; Quirk et al., 2015; Artzi et al., 2015; Reddy et al., 2017). Traditional methods are mostly based on the principle of compositional semantics, which first trigger predicates using lexicons and then compose them using grammars. The prominent grammars include SCFG (Wong and Mooney, 2007; Li et al., 2015), CCG (Zettlemoyer and Collins, 2005; Kwiatkowski et al., 2011; Cai and Yates, 2013), DCS (Liang et al., 2011; Berant et al., 2013), etc. As discussed above, the main drawback of grammar-based methods is that they rely on high-quality lexicons, manually-built grammars, and hand-crafted features.

In recent years, one promising direction of semantic parsing is to use semantic graph as representation. Thus semantic parsing is modeled as a semantic graph generation process. Ge and Mooney (2009) build semantic graph by transforming syntactic tree. Bast and Haussmann (2015) identify the structure of a semantic query using three pre-defined patterns. Reddy et al. (2014, 2016) use Freebase-based semantic graph representation, and convert sentences to semantic graphs using CCG or dependency tree. Yih et al. (2015) generate semantic graphs using a staged heuristic search algorithm. These methods are all based on manually-designed, heuristic generation process, which may suffer from syntactic parse errors (Ge and Mooney, 2009; Reddy et al., 2014, 2016), structure mismatch (Chen et al., 2016), and are hard to deal with complex sentences (Yih et al., 2015).

One other direction is to employ neural Seq2Seq models, which models semantic parsing as an end-to-end, sentence to logical form machine translation problem. Dong and Lapata (2016), Jia and Liang (2016) and Xiao et al. (2016) transform word sequence to linearized logical forms. One main drawback of these methods is that it is hard to capture and exploit structure and semantic constraints using linearized logical forms. Dong and Lapata (2016) propose a Seq2Tree model to capture the hierarchical structure of logical forms.

It has been shown that structure and semantic constraints are effective for enhancing semantic parsing. Krishnamurthy et al. (2017) use type constraints to filter illegal tokens. Liang et al. (2017) adopt a Lisp interpreter with pre-defined functions to produce valid tokens. Iyyer et al. (2017) adopt type constraints to generate valid actions. Inspired by these approaches, we also incorporate both structure and semantic constraints in our neural sequence-to-action model.

Transition-based approaches are important in both dependency parsing (Nivre, 2008; Henderson et al., 2013) and AMR parsing (Wang et al., 2015a). In semantic parsing, our method has a tight-coupling with knowledge bases, and constraints can be exploited for more accurate decoding. We believe this can also be used to enhance previous transition based methods and may also be used in other parsing tasks, e.g., AMR parsing.

6 Conclusions

This paper proposes Sequence-to-Action, a method which models semantic parsing as an end-to-end semantic graph generation process. By leveraging the advantages of semantic graph representation and exploiting the representation learning and prediction ability of Seq2Seq models, our method achieved significant performance improvements on three datasets. Furthermore, structure and semantic constraints can be easily incorporated in decoding to enhance semantic parsing.

For future work, to solve the problem of the lack of training data, we want to design weakly supervised learning algorithm using denotations (QA pairs) as supervision. Furthermore, we want to collect labeled data by designing an interactive UI for annotation assist like (Yih et al., 2016), which uses semantic graphs to annotate the meaning of sentences, since semantic graph is more natural and can be easily annotated without the need of expert knowledge.

Abstract

Unsupervised machine translation—i.e., not assuming *any* cross-lingual supervision signal, whether a dictionary, translations, or comparable corpora—seems impossible, but nevertheless, Lample et al. (2018a) recently proposed a fully unsupervised machine translation (MT) model. The model relies heavily on an adversarial, unsupervised alignment of word embedding spaces for *bilingual dictionary induction* (Conneau et al., 2018), which we examine here. Our results identify the limitations of current unsupervised MT: unsupervised bilingual dictionary induction performs much worse on morphologically rich languages that are not dependent marking, when monolingual corpora from different domains or different embedding algorithms are used. We show that a simple trick, exploiting a weak supervision signal from identical words, enables more robust induction, and establish a near-perfect correlation between unsupervised bilingual dictionary induction performance and a previously unexplored graph similarity metric.

1 Introduction

Cross-lingual word representations enable us to reason about word meaning in multilingual contexts and facilitate cross-lingual transfer (Ruder et al., 2018). Early cross-lingual word embedding models relied on large amounts of parallel data (Klementiev et al., 2012; Mikolov et al., 2013a), but more recent approaches have tried to minimize the amount of supervision necessary (Vulić and Korhonen, 2016; Levy et al., 2017; Artetxe et al., 2017). Some researchers have even presented *unsupervised* methods that do not rely on any form of cross-lingual supervision at all (Barone, 2016; Conneau et al., 2018; Zhang et al., 2017).

Unsupervised cross-lingual word embeddings hold promise to induce bilingual lexicons and machine translation models in the absence of dictionaries and translations (Barone, 2016; Zhang et al., 2017; Lample et al., 2018a), and would therefore be a major step toward machine translation to, from, or even between low-resource languages.

Unsupervised approaches to learning cross-lingual word embeddings are based on the assumption that monolingual word embedding graphs are approximately isomorphic, that is, after removing a small set of vertices (words) (Mikolov et al., 2013b; Barone, 2016; Zhang et al., 2017; Conneau et al., 2018). In the words of Barone (2016):

> *. . . we hypothesize that, if languages are used to convey thematically similar information in similar contexts, these random processes should be approximately isomorphic between languages, and that this isomorphism can be learned from the statistics of the realizations of these processes, the monolingual corpora, in principle without any form of explicit alignment.*

Our results indicate this assumption is not true in general, and that approaches based on this assumption have important limitations.

Contributions We focus on the recent state-of-the-art unsupervised model of Conneau et al. (2018).[1] Our contributions are: (a) In §2, we show that the monolingual word embeddings used in Conneau et al. (2018) are *not* approximately isomorphic, using the VF2 algorithm (Cordella et al., 2001) and we therefore introduce a metric for quantifying the similarity of word embeddings, based on Laplacian eigenvalues. (b) In §3, we identify circumstances under which the unsupervised bilingual

[1]Our motivation for this is that Artetxe et al. (2017) use small dictionary seeds for supervision, and Barone (2016) seems to obtain worse performance than Conneau et al. (2018). Our results should extend to Barone (2016) and Zhang et al. (2017), which rely on very similar methodology.

Figure 1: Nearest neighbor graphs.

dictionary induction (BDI) algorithm proposed in Conneau et al. (2018) does not lead to good performance. (c) We show that a simple trick, exploiting a weak supervision signal from words that are identical across languages, makes the algorithm much more robust. Our main finding is that the performance of unsupervised BDI depends heavily on all three factors: the language pair, the comparability of the monolingual corpora, and the parameters of the word embedding algorithms.

2 How similar are embeddings across languages?

As mentioned, recent work focused on unsupervised BDI assumes that monolingual word embedding spaces (or at least the subgraphs formed by the most frequent words) are approximately isomorphic. In this section, we show, by investigating the nearest neighbor graphs of word embedding spaces, that word embeddings are far from isomorphic. We therefore introduce a method for computing the similarity of non-isomorphic graphs. In §4.7, we correlate our similarity metric with performance on unsupervised BDI.

Isomorphism To motivate our study, we first establish that word embeddings are far from graph isomorphic[2]—even for two closely related languages, English and German, and using embeddings induced from comparable corpora (Wikipedia) with the same hyper-parameters.

If we take the top k most frequent words in English, and the top k most frequent words in German, and build nearest neighbor graphs for English and German using the monolingual word embeddings used in Conneau et al. (2018), the graphs are of course very different. This is, among other things, due to German case and the fact that *the* translates into *der*, *die*, and *das*, but unsupervised alignment does not have access to this kind of information. *Even* if we consider the top k most frequent English words *and their translations* into German, the nearest neighbor graphs are not isomorphic. Figure 1a-b shows the nearest neighbor graphs of the top 10 most frequent English words on Wikipedia, and their German translations.

Word embeddings are particularly good at capturing relations between nouns, but even if we consider the top k most frequent English *nouns* and their translations, the graphs are not isomorphic; see Figure 1c-d. We take this as evidence that word embeddings are not approximately isomorphic across languages. We also ran graph isomorphism checks on 10 random samples of frequent English nouns and their translations into Spanish, and only in 1/10 of the samples were the corresponding nearest neighbor graphs isomorphic.

Eigenvector similarity Since the nearest neighbor graphs are not isomorphic, even for frequent translation pairs in neighboring languages, we want to quantify the potential for unsupervised BDI using a metric that captures varying degrees of graph similarity. Eigenvalues are compact representations of global properties of graphs, and we introduce a spectral metric based on Laplacian eigenvalues (Shigehalli and Shettar, 2011) that quantifies the extent to which the nearest neighbor graphs are *isospectral*. Note that (approximately) isospectral graphs need not be (approximately) isomorphic, but (approximately) isomorphic graphs are always (approximately) isospectral (Gordon et al., 1992). Let A_1 and A_2 be the adjacency matrices of the nearest neighbor graphs G_1 and G_2 of our two word embeddings, respectively. Let $L_1 = D_1 - A_1$ and $L_2 = D_2 - A_2$ be the Laplacians of the nearest neighbor graphs, where D_1 and D_2 are the corresponding diagonal matrices of degrees. We now

[2]Two graphs that contain the same number of graph vertices connected in the same way are said to be isomorphic. In the context of weighted graphs such as word embeddings, a weak version of this is to require that the underlying nearest neighbor graphs for the most frequent k words are isomorphic.

compute the eigensimilarity of the Laplacians of the nearest neighbor graphs, L_1 and L_2. For each graph, we find the smallest k such that the sum of the k largest Laplacian eigenvalues is <90% of the Laplacian eigenvalues. We take the smallest k of the two, and use the sum of the squared differences between the largest k Laplacian eigenvalues Δ as our similarity metric.

$$\Delta = \sum_{i=1}^{k} (\lambda_{1_i} - \lambda_{2_i})^2$$

where k is chosen s.t.

$$\min_j \{ \frac{\sum_{i=1}^{k} \lambda_{ji}}{\sum_{i=1}^{n} \lambda_{ji}} > 0.9 \}$$

Note that $\Delta = 0$ means the graphs are isospectral, and the metric goes to infinite. Thus, the higher Δ is, the *less* similar the graphs (i.e., their Laplacian spectra). We discuss the correlation between unsupervised BDI performance and approximate isospectrality or eigenvector similarity in §4.7.

3 Unsupervised cross-lingual learning

3.1 Learning scenarios

Unsupervised neural machine translation relies on BDI using cross-lingual embeddings (Lample et al., 2018a; Artetxe et al., 2018), which in turn relies on the assumption that word embedding graphs are approximately isomorphic. The work of Conneau et al. (2018), which we focus on here, also makes several implicit assumptions that may or may not be necessary to achieve such isomorphism, and which may or may not scale to low-resource languages. The algorithms are not intended to be limited to learning scenarios where these assumptions hold, but since they do in the reported experiments, it is important to see to what extent these assumptions are necessary for the algorithms to produce useful embeddings or dictionaries.

We focus on the work of Conneau et al. (2018), who present a fully unsupervised approach to aligning monolingual word embeddings, induced using *fastText* (Bojanowski et al., 2017). We describe the learning algorithm in §3.2. Conneau et al. (2018) consider a specific set of learning scenarios:

(a) The authors work with the following **languages**: English-{French, German, Chinese, Russian, Spanish}. These languages, except French, are dependent marking (Table 1).[3] We evaluate Conneau et al. (2018) on (English to) Estonian (ET), Finnish (FI), Greek (EL), Hungarian (HU), Polish (PL), and Turkish (TR) in §4.2, to test whether the selection of languages in the original study introduces a bias.

(b) The monolingual corpora in their experiments are comparable; Wikipedia corpora are used, except for an experiment in which they include Google Gigawords. We evaluate across different **domains**, i.e., on all combinations of Wikipedia, EuroParl, and the EMEA medical corpus, in §4.3. We believe such scenarios are more realistic for low-resource languages.

(c) The monolingual embedding models are induced using the same **algorithms** with the same **hyper-parameters**. We evaluate Conneau et al. (2018) on pairs of embeddings induced with different hyper-parameters in §4.4. While keeping hyper-parameters fixed is always possible, it is of practical interest to know whether the unsupervised methods work on any set of pre-trained word embeddings.

We also investigate the sensitivity of unsupervised BDI to the **dimensionality** of the monolingual word embeddings in §4.5. The motivation for this is that dimensionality reduction will alter the geometric shape and remove characteristics of the embedding graphs that are important for alignment; but on the other hand, lower dimensionality introduces regularization, which will make the graphs more similar. Finally, in §4.6, we investigate the impact of different types of query **test words** on performance, including how performance varies across part-of-speech word classes and on shared vocabulary items.

3.2 Summary of Conneau et al. (2018)

We now introduce the method of Conneau et al. (2018).[4] The approach builds on existing work on learning a mapping between monolingual word embeddings (Mikolov et al., 2013b; Xing et al., 2015) and consists of the following steps: 1) **Monolingual word embeddings:** An off-the-shelf word embedding algorithm (Bojanowski et al., 2017) is used to learn source and target language spaces X

[3] A dependent-marking language marks agreement and case more commonly on dependents than on heads.

[4] https://github.com/facebookresearch/MUSE

and Y. 2) **Adversarial mapping:** A translation matrix W is learned between the spaces X and Y using adversarial techniques (Ganin et al., 2016). A discriminator is trained to discriminate samples from the translated source space WX from the target space Y, while W is trained to prevent this. This, again, is motivated by the assumption that source and target language word embeddings are approximately isomorphic. 3) **Refinement (Procrustes analysis):** W is used to build a small bilingual dictionary of frequent words, which is pruned such that only bidirectional translations are kept (Vulić and Korhonen, 2016). A new translation matrix W that translates between the spaces X and Y of these frequent word pairs is then induced by solving the Orthogonal Procrustes problem:

$$W^* = \text{argmin}_W \|WX - Y\|_\text{F} = UV^\top \quad \text{s.t. } U\Sigma V^\top = \text{SVD}(YX^\top) \tag{1}$$

This step can be used iteratively by using the new matrix W to create new seed translation pairs. It requires frequent words to serve as reliable anchors for learning a translation matrix. In the experiments in Conneau et al. (2018), as well as in ours, the iterative Procrustes refinement improves performance across the board. 4) **Cross-domain similarity local scaling** (CSLS) is used to expand high-density areas and condense low-density ones, for more accurate nearest neighbor calculation, CSLS reduces the hubness problem in high-dimensional spaces (Radovanović et al., 2010; Dinu et al., 2015). It relies on the mean similarity of a source language embedding x to its K target language nearest neighbours ($K = 10$ suggested) $nn_1, \ldots, nn_K$:

$$mnn_T(x) = \frac{1}{K}\sum_{i=1}^{K} cos(x, nn_i) \tag{2}$$

where cos is the cosine similarity. $mnn_S(y)$ is defined in an analogous manner for any target language embedding y. $CSLS(x, y)$ is then calculated as follows:

$$2cos(x, y) - mnn_T(x) - mnn_S(y) \tag{3}$$

3.3 A simple supervised method

Instead of learning cross-lingual embeddings completely without supervision, we can extract inexpensive supervision signals by harvesting identically spelled words as in, e.g. (Artetxe et al., 2017; Smith et al., 2017). Specifically, we use identically spelled words that occur in the vocabularies of both languages as bilingual seeds, without employing any additional transliteration or lemmatization/normalization methods. Using this seed dictionary, we then run the refinement step using Procrustes analysis of Conneau et al. (2018).

4 Experiments

In the following experiments, we investigate the robustness of unsupervised cross-lingual word embedding learning, varying the language pairs, monolingual corpora, hyper-parameters, etc., to obtain a better understanding of when and why unsupervised BDI works.

Task: Bilingual dictionary induction After the shared cross-lingual space is induced, given a list of N source language words $x_{u,1}, \ldots, x_{u,N}$, the task is to find a target language word t for each *query word* x_u relying on the representations in the space. t_i is the target language word closest to the source language word $x_{u,i}$ in the induced cross-lingual space, also known as the *cross-lingual nearest neighbor*. The set of learned N $(x_{u,i}, t_i)$ pairs is then run against a gold standard dictionary.

We use bilingual dictionaries compiled by Conneau et al. (2018) as gold standard, and adopt their evaluation procedure: each test set in each language consists of 1500 gold translation pairs. We rely on CSLS for retrieving the nearest neighbors, as it consistently outperformed the cosine similarity in all our experiments. Following a standard evaluation practice (Vulić and Moens, 2013; Mikolov et al., 2013b; Conneau et al., 2018), we report *Precision at 1* scores (P@1): how many times one of the correct translations of a source word w is retrieved as the nearest neighbor of w in the target language.

4.1 Experimental setup

Our default experimental setup closely follows the setup of Conneau et al. (2018). For each language we induce monolingual word embeddings for all languages from their respective tokenized and lowercased Polyglot Wikipedias (Al-Rfou et al., 2013) using *fastText* (Bojanowski et al., 2017). Only words with more than 5 occurrences are retained for training. Our *fastText* setup relies on skip-gram with negative sampling (Mikolov et al., 2013a) with standard hyper-parameters: bag-of-words contexts with the window size 2, 15 negative samples, subsampling rate 10^{-4}, and character n-gram length

	Marking	**Type**	**# Cases**
English (EN)	dependent	isolating	None
French (FR)	mixed	fusional	None
German (DE)	dependent	fusional	4
Chinese (ZH)	dependent	isolating	None
Russian (RU)	dependent	fusional	6–7
Spanish (ES)	dependent	fusional	None
Estonian (ET)	mixed	agglutinative	10+
Finnish (FI)	mixed	agglutinative	10+
Greek (EL)	double	fusional	3
Hungarian (HU)	dependent	agglutinative	10+
Polish (PL)	dependent	fusional	6–7
Turkish (TR)	dependent	agglutinative	6–7

Table 1: Languages in Conneau et al. (2018) and in our experiments (lower half)

	Unsupervised (Adversarial)	**Supervised** (Identical)	**Similarity** (Eigenvectors)
EN-ES	81.89	**82.62**	2.07

Table 2: Bilingual dictionary induction scores (P@1$\times$100%) using **a)** the unsupervised method with adversarial training; **b)** the supervised method with a bilingual seed dictionary consisting of identical words (shared between the two languages). The third columns lists eigenvector similarities between 10 randomly sampled source language nearest neighbor subgraphs of 10 nodes and the subgraphs of their translations, all from the benchmark dictionaries in Conneau et al. (2018).

3-6. All embeddings are 300-dimensional.

As we analyze the impact of various modeling assumptions in the following sections (e.g., domain differences, algorithm choices, hyper-parameters), we also train monolingual word embeddings using other corpora and different hyper-parameter choices. Quick summaries of each experimental setup are provided in the respective subsections.

4.2 Impact of language similarity

Conneau et al. (2018) present results for several target languages: Spanish, French, German, Russian, Chinese, and Esperanto. All languages but Esperanto are isolating or exclusively concatenating languages from a morphological point of view. All languages but French are dependent-marking. Table 1 lists three important morphological properties of the languages involved in their/our experiments.

Agglutinative languages with mixed or double marking show more morphological variance with content words, and we speculate whether unsupervised BDI is challenged by this kind of morphological complexity. To evaluate this, we experiment with Estonian and Finnish, and we include Greek, Hungarian, Polish, and Turkish to see how their approach fares on combinations of these two morphological traits.

We show results in the left column of Table 2. The results are quite dramatic. The approach achieves impressive performance for Spanish, one of the languages Conneau et al. (2018) include in their paper. For the languages we add here, performance is less impressive. For the languages with dependent marking (Hungarian, Polish, and Turkish), P@1 scores are still reasonable, with Turkish being slightly lower (0.327) than the others. However, for Estonian and Finnish, the method fails completely. Only in less than 1/1000 cases does a nearest neighbor search in the induced embeddings return a correct translation of a query word.[5]

The sizes of Wikipedias naturally vary across languages: e.g., *fastText* trains on approximately 16M sentences and 363M word tokens for Spanish, while it trains on 1M sentences and 12M words for Finnish. However, the difference in performance cannot be explained by the difference in training data sizes. To verify that near-zero performance in Finnish is not a result of insufficient training data, we have conducted another experiment using the large **Finnish WaC corpus** (Ljubešić et al., 2016) containing 1.7B words in total (this is similar in size to the English Polyglot Wikipedia). However, even with this large Finnish corpus, the model does not induce anything useful: P@1 equals 0.0.

We note that while languages with mixed marking may be harder to align, it seems unsupervised BDI is possible between similar, mixed marking languages. So while unsupervised learning fails for English-Finnish and English-Estonian, performance is reasonable and stable for the more similar Estonian-Finnish pair (Table 2). In general, unsupervised BDI, using the approach in Conneau et al. (2018), seems challenged when pairing En-

[5]We note, though, that varying our random seed, performance for Estonian, Finnish, and Greek is sometimes (approximately 1 out of 10 runs) *on par* with Turkish. Detecting main causes and remedies for the inherent instability of adversarial training is one the most important avenues for future research.

glish with languages that are not isolating and do not have dependent marking.[6]

The promise of zero-supervision models is that we can learn cross-lingual embeddings even for low-resource languages. On the other hand, a similar distribution of embeddings requires languages to be similar. This raises the question whether we need fully unsupervised methods at all. In fact, our supervised method that relies on very naive supervision in the form of identically spelled words leads to competitive performance for similar language pairs and better results for dissimilar pairs. The fact that we can reach competitive and more robust performance with such a simple heuristic questions the true applicability of fully unsupervised approaches and suggests that it might often be better to rely on available weak supervision.

4.3 Impact of domain differences

Monolingual word embeddings used in Conneau et al. (2018) are induced from Wikipedia, a near-parallel corpus. In order to assess the sensitivity of unsupervised BDI to the comparability and domain similarity of the monolingual corpora, we replicate the experiments in Conneau et al. (2018) using combinations of word embeddings extracted from three different domains: **1)** parliamentary proceedings from EuroParl.v7 (Koehn, 2005), **2)** Wikipedia (Al-Rfou et al., 2013), and **3)** the EMEA corpus in the medical domain (Tiedemann, 2009). We report experiments with three language pairs: English-{Spanish, Finnish, Hungarian}.

To control for the corpus size, we restrict each corpus in each language to 1.1M sentences in total (i.e., the number of sentences in the smallest, EMEA corpus). 300-dim *fastText* vectors are induced as in §4.1, retaining all words with more than 5 occurrences in the training data. For each pair of monolingual corpora, we compute their domain (dis)similarity by calculating the Jensen-Shannon divergence (El-Gamal, 1991), based on term distributions.[7] The domain similarities are displayed in Figures 2a–c.[8]

We show the results of unsupervised BDI in Figures 2g–i. For Spanish, we see good performance in all three cases where the English and Spanish corpora are from the same domain. *When the two corpora are from different domains, performance is close to zero.* For Finnish and Hungarian, performance is always poor, suggesting that more data is needed, even when domains are similar. This is in sharp contrast with the results of our minimally supervised approach (Figures 2d–f) based on identical words, which achieves decent performance in many set-ups.

We also observe a strong decrease in P@1 for English-Spanish (from 81.19% to 46.52%) when using the smaller Wikipedia corpora. This result indicates the importance of procuring large monolingual corpora from similar domains in order to enable unsupervised dictionary induction. However, resource-lean languages, for which the unsupervised method was designed in the first place, cannot be guaranteed to have as large monolingual training corpora as available for English, Spanish or other major resource-rich languages.

4.4 Impact of hyper-parameters

Conneau et al. (2018) use the same hyper-parameters for inducing embeddings for all languages. This is of course always practically possible, but we are interested in seeing whether their approach works on pre-trained embeddings induced with possibly very different hyper-parameters. We focus on two hyper-parameters: context window-size (*win*) and the parameter controlling the number of n-gram features in the *fastText* model (*chn*), while at the same time varying the underlying algorithm: *skip-gram* vs. *cbow*. The results for English-Spanish are listed in Table 3.

The small variations in the hyper-parameters with the same underlying algorithm (i.e., using *skip-gram* or *cbow* for both EN and ES) yield only slight drops in the final scores. Still, the best scores are obtained with the same configuration on both sides. Our main finding here is that unsupervised BDI fails (even) for EN-ES when the two monolingual embedding spaces are induced by two different algorithms (see the results of the entire Spanish *cbow* column).[9] In sum, this means that *the unsupervised approach is unlikely to work on pre-trained word embeddings unless they are induced on same-*

[6]One exception here is French, which they include in their paper, but French arguably has a relatively simple morphology.

[7]In order to get comparable term distributions, we translate the source language to the target language using the bilingual dictionaries provided by Conneau et al. (2018).

[8]We also computed $\mathcal{A}$-distances (Blitzer et al., 2007) and confirmed that trends were similar.

[9]We also checked if this result might be due to a lower-quality monolingual ES space. However, monolingual word similarity scores on available datasets in Spanish show performance comparable to that of Spanish *skip-gram* vectors: e.g., Spearman's ρ correlation is ≈ 0.7 on the ES evaluation set from SemEval-2017 Task 2 (Camacho-Collados et al., 2017).

Figure 2: Influence of language-pair *and* domain similarity on BLI performance, with three language pairs (en-es/fi/hu). **Top row, (a)-(c)**: Domain similarity (higher is more similar) computed as $dsim = 1 - JS$, where JS is Jensen-Shannon divergence; **Middle row, (d)-(f)**: baseline BLI model which learns a linear mapping between two monolingual spaces based on a set of identical (i.e., shared) words; **Bottom row, (g)-(i)**: fully unsupervised BLI model relying on the distribution-level alignment and adversarial training. Both BLI models apply the Procrustes analysis and use CSLS to retrieve nearest neighbours.

or comparable-domain, reasonably-sized training data using the same underlying algorithm.

4.5 Impact of dimensionality

We also perform an experiment on 40-dimensional monolingual word embeddings. This leads to reduced expressivity, and can potentially make the geometric shapes of embedding spaces harder to align; on the other hand, reduced dimensionality may also lead to less overfitting. We generally see worse performance (P@1 is 50.33 for Spanish, 21.81 for Hungarian, 20.11 for Polish, and 22.03 for Turkish) – but, very *interestingly*, we obtain *better performance* for Estonian (13.53), Finnish (15.33), and Greek (24.17) than we did with 300 dimensions. We hypothesize this indicates monolingual word embedding algorithms over-fit to some of the rarer peculiarities of these languages.

	English (skipgram, win=2, chn=3-6)	
	Spanish *(skipgram)*	Spanish *(cbow)*
==	81.89	00.00
≠ win=10	81.28	00.07
≠ chn=2-7	80.74	00.00
≠ win=10, chn=2-7	80.15	00.13

Table 3: Varying the underlying *fastText* algorithm and hyper-parameters. The first column lists differences in training configurations between English and Spanish monolingual embeddings.

	en-es	en-hu	en-fi
Noun	80.94	26.87	00.00
Verb	66.05	25.44	00.00
Adjective	85.53	53.28	00.00
Adverb	80.00	51.57	00.00
Other	73.00	53.40	00.00

Table 4: P@1 $\times$ 100% scores for query words with different parts-of-speech.

4.6 Impact of evaluation procedure

BDI models are evaluated on a held-out set of query words. Here, we analyze the performance of the unsupervised approach across different parts-of-speech, frequency bins, and with respect to query words that have orthographically identical counterparts in the target language with the same or a different meaning.

Part-of-speech We show the impact of the part-of-speech of the query words in Table 4; again on a representative subset of our languages. The results indicate that performance on verbs is lowest across the board. This is consistent with research on distributional semantics and verb meaning (Schwartz et al., 2015; Gerz et al., 2016).

Frequency We also investigate the impact of the frequency of query words. We calculate the word frequency of English words based on Google's Trillion Word Corpus: query words are divided in groups based on their rank – i.e., the first group contains the top 100 most frequent words, the second one contains the 101th-1000th most frequent words, etc. – and plot performance (P@1) relative to rank in Figure 3. For EN-FI, P@1 was 0 across all frequency ranks. The plot shows sensitivity to frequency for HU, but less so for ES.

Homographs Since we use identical word forms (homographs) for supervision, we investigated whether these are representative or harder to align than other words. Table 5 lists performance for three sets of query words: (a) source words that have homographs (words that are spelled the same way) with the same meaning (homonyms) in the target language, e.g., many proper names; (b) source words that have homographs that are not homonyms in the target language, e.g., many short words; and (c) other words. Somewhat surprisingly, words which have translations that are homographs, are associated with *lower* precision than other words. This is probably due to loan words and proper names, but note that using homographs as supervision for alignment, we achieve high precision for this part of the vocabulary *for free*.

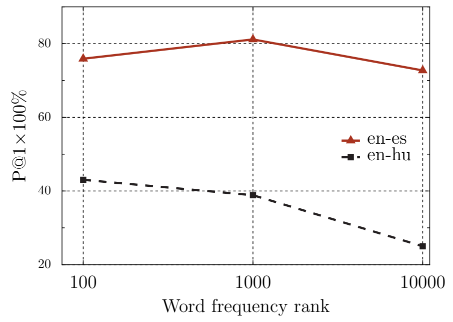

Figure 3: P@1 scores for EN-ES and EN-HU for queries with different frequency ranks.

Spelling	Meaning	en-es	en-hu	en-fi
Same	Same	45.94	18.07	00.00
Same	Diff	39.66	29.97	00.00
Diff	Diff	62.42	34.45	00.00

Table 5: Scores (P@1 $\times$ 100%) for query words with same and different spellings and meanings.

4.7 Evaluating eigenvector similarity

Finally, in order to get a better understanding of the limitations of unsupervised BDI, we correlate the graph similarity metric described in §2 (right column of Table 2) with performance across languages (left column). Since we already established that the monolingual word embeddings are far from isomorphic—in contrast with the intuitions motivating previous work (Mikolov et al., 2013b; Barone, 2016; Zhang et al., 2017; Conneau et al., 2018)—we would like to establish another diagnostic metric that identifies embedding spaces for which the approach in Conneau et al. (2018) is likely to work. Differences in morphology, domain, or embedding parameters seem to be predictive of poor performance, but a metric that is independent of linguistic

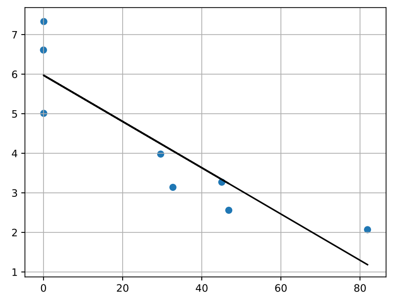

Figure 4: Strong correlation ($\rho = 0.89$) between BDI performance (x) and graph similarity (y)

categorizations and the characteristics of the monolingual corpora would be more widely applicable. We plot the values in Table 2 in Figure 4. Recall that our graph similarity metric returns a value in the half-open interval $[0, \infty)$. The correlation between BDI performance and graph similarity is strong ($\rho \sim 0.89$).

5 Related work

Cross-lingual word embeddings Cross-lingual word embedding models typically, unlike Conneau et al. (2018), require aligned words, sentences, or documents (Levy et al., 2017). Most approaches based on word alignments learn an explicit mapping between the two embedding spaces (Mikolov et al., 2013b; Xing et al., 2015). Recent approaches try to minimize the amount of supervision needed (Vulić and Korhonen, 2016; Artetxe et al., 2017; Smith et al., 2017). See Upadhyay et al. (2016) and Ruder et al. (2018) for surveys.

Unsupervised cross-lingual learning Haghighi et al. (2008) were first to explore unsupervised BDI, using features such as context counts and orthographic substrings, and canonical correlation analysis. Recent approaches use adversarial learning (Goodfellow et al., 2014) and employ a discriminator, trained to distinguish between the translated source and the target language space, and a generator learning a translation matrix (Barone, 2016). Zhang et al. (2017), in addition, use different forms of regularization for convergence, while Conneau et al. (2018) uses additional steps to refine the induced embedding space.

Unsupervised machine translation Research on unsupervised machine translation (Lample et al., 2018a; Artetxe et al., 2018; Lample et al., 2018b) has generated a lot of interest recently with a promise to support the construction of MT systems for and between resource-poor languages. All unsupervised NMT methods critically rely on accurate unsupervised BDI and back-translation. Models are trained to reconstruct a corrupted version of the source sentence and to translate its translated version back to the source language. Since the crucial input to these systems are indeed cross-lingual word embedding spaces induced in an unsupervised fashion, in this paper we also implicitly investigate one core limitation of such unsupervised MT techniques.

6 Conclusion

We investigated when unsupervised BDI (Conneau et al., 2018) is possible and found that differences in morphology, domains or word embedding algorithms may challenge this approach. Further, we found eigenvector similarity of sampled nearest neighbor subgraphs to be predictive of unsupervised BDI performance. We hope that this work will guide further developments in this new and exciting field.

Abstract

Recent work has managed to learn cross-lingual word embeddings without parallel data by mapping monolingual embeddings to a shared space through adversarial training. However, their evaluation has focused on favorable conditions, using comparable corpora or closely-related languages, and we show that they often fail in more realistic scenarios. This work proposes an alternative approach based on a fully unsupervised initialization that explicitly exploits the structural similarity of the embeddings, and a robust self-learning algorithm that iteratively improves this solution. Our method succeeds in all tested scenarios and obtains the best published results in standard datasets, even surpassing previous supervised systems. Our implementation is released as an open source project at `https://github.com/artetxem/vecmap`.

1 Introduction

Cross-lingual embedding mappings have shown to be an effective way to learn bilingual word embeddings (Mikolov et al., 2013; Lazaridou et al., 2015). The underlying idea is to independently train the embeddings in different languages using monolingual corpora, and then map them to a shared space through a linear transformation. This allows to learn high-quality cross-lingual representations without expensive supervision, opening new research avenues like unsupervised neural machine translation (Artetxe et al., 2018b; Lample et al., 2018).

While most embedding mapping methods rely on a small seed dictionary, adversarial training has recently produced exciting results in fully unsupervised settings (Zhang et al., 2017a,b; Conneau et al., 2018). However, their evaluation has focused on particularly favorable conditions, limited to closely-related languages or comparable Wikipedia corpora. When tested on more realistic scenarios, we find that they often fail to produce meaningful results. For instance, none of the existing methods works in the standard English-Finnish dataset from Artetxe et al. (2017), obtaining translation accuracies below 2% in all cases (see Section 5).

On another strand of work, Artetxe et al. (2017) showed that an iterative self-learning method is able to bootstrap a high quality mapping from very small seed dictionaries (as little as 25 pairs of words). However, their analysis reveals that the self-learning method gets stuck in poor local optima when the initial solution is not good enough, thus failing for smaller training dictionaries.

In this paper, we follow this second approach and propose a new unsupervised method to build an initial solution without the need of a seed dictionary, based on the observation that, given the similarity matrix of all words in the vocabulary, each word has a different distribution of similarity values. Two equivalent words in different languages should have a similar distribution, and we can use this fact to induce the initial set of word pairings (see Figure 1). We combine this initialization with a more robust self-learning method, which is able to start from the weak initial solution and iteratively improve the mapping. Coupled together, we provide a fully unsupervised cross-lingual mapping method that is effective in realistic settings, converges to a good solution in all cases tested, and sets a new state-of-the-art in bilingual lexicon extraction, even surpassing previous supervised methods.

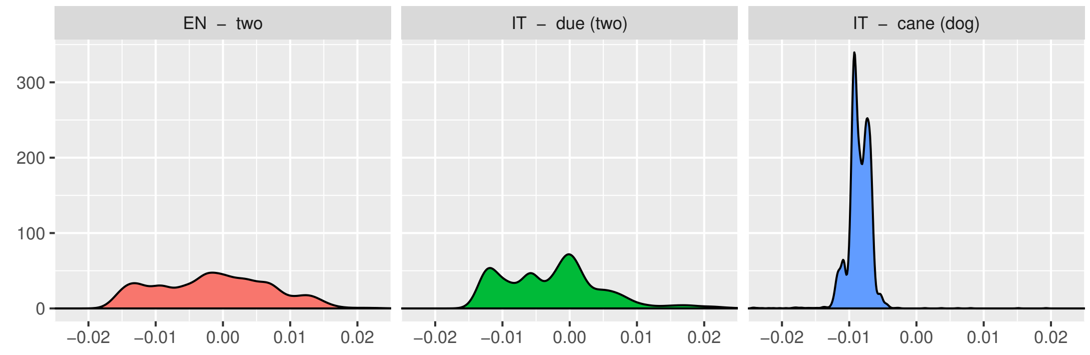

Figure 1: Motivating example for our unsupervised initialization method, showing the similarity distributions of three words (corresponding to the smoothed density estimates from the normalized square root of the similarity matrices as defined in Section 3.2). Equivalent translations (two and *due*) have more similar distributions than non-related words (two and *cane* - meaning dog). This observation is used to build an initial solution that is later improved through self-learning.

2 Related work

Cross-lingual embedding mapping methods work by independently training word embeddings in two languages, and then mapping them to a shared space using a linear transformation.

Most of these methods are **supervised**, and use a bilingual dictionary of a few thousand entries to learn the mapping. Existing approaches can be classified into regression methods, which map the embeddings in one language using a least-squares objective (Mikolov et al., 2013; Shigeto et al., 2015; Dinu et al., 2015), canonical methods, which map the embeddings in both languages to a shared space using canonical correlation analysis and extensions of it (Faruqui and Dyer, 2014; Lu et al., 2015), orthogonal methods, which map the embeddings in one or both languages under the constraint of the transformation being orthogonal (Xing et al., 2015; Artetxe et al., 2016; Zhang et al., 2016; Smith et al., 2017), and margin methods, which map the embeddings in one language to maximize the margin between the correct translations and the rest of the candidates (Lazaridou et al., 2015). Artetxe et al. (2018a) showed that many of them could be generalized as part of a multi-step framework of linear transformations.

A related research line is to adapt these methods to the **semi-supervised** scenario, where the training dictionary is much smaller and used as part of a bootstrapping process. While similar ideas where already explored for traditional count-based vector space models (Peirsman and Padó, 2010; Vulić and Moens, 2013), Artetxe et al. (2017) brought this approach to pre-trained low-dimensional word embeddings, which are more widely used nowadays. More concretely, they proposed a self-learning approach that alternates the mapping and dictionary induction steps iteratively, obtaining results that are comparable to those of supervised methods when starting with only 25 word pairs.

A practical approach for reducing the need of bilingual supervision is to design **heuristics to build the seed dictionary**. The role of the seed lexicon in learning cross-lingual embedding mappings is analyzed in depth by Vulić and Korhonen (2016), who propose using document-aligned corpora to extract the training dictionary. A more common approach is to rely on shared words and cognates (Peirsman and Padó, 2010; Smith et al., 2017), while Artetxe et al. (2017) go further and restrict themselves to shared numerals. However, while these approaches are meant to eliminate the need of bilingual data in practice, they also make strong assumptions on the writing systems of languages (e.g. that they all use a common alphabet or Arabic numerals). Closer to our work, a recent line of **fully unsupervised** approaches drops these assumptions completely, and attempts to learn cross-lingual embedding mappings based on distributional information alone. For that purpose, existing methods rely on adversarial training. This was first proposed by Miceli Barone (2016), who combine an encoder that maps source language embeddings into the target language, a decoder that reconstructs the source language embeddings from the mapped embeddings, and a discriminator that discriminates between the mapped embeddings and the true target language embeddings. Despite promising, they conclude that their model "is not competitive with other cross-lingual representation approaches". Zhang et al. (2017a) use a very similar architecture, but incorporate additional techniques like noise injection to aid training and report competitive results on bilingual lexicon extraction. Conneau et al. (2018) drop the reconstruction component, regularize the mapping to be orthogonal, and incorporate an iterative refinement process akin to self-learning, reporting very strong results on a large bilingual lexicon extraction dataset. Finally, Zhang et al. (2017b) adopt the earth mover's distance for training, optimized through a Wasserstein generative adversarial network followed by an alternating optimization procedure. However, all this previous work used comparable Wikipedia corpora in most experiments and, as shown in Section 5, face difficulties in more challenging settings.

3 Proposed method

Let X and Z be the word embedding matrices in two languages, so that their ith row X_{i*} and Z_{i*} denote the embeddings of the ith word in their respective vocabularies. Our goal is to learn the linear transformation matrices W_X and W_Z so the mapped embeddings XW_X and ZW_Z are in the same cross-lingual space. At the same time, we aim to build a dictionary between both languages, encoded as a sparse matrix D where $D_{ij} = 1$ if the jth word in the target language is a translation of the ith word in the source language.

Our proposed method consists of four sequential steps: a pre-processing that normalizes the embeddings (§3.1), a fully unsupervised initialization scheme that creates an initial solution (§3.2), a robust self-learning procedure that iteratively improves this solution (§3.3), and a final refinement step that further improves the resulting mapping through symmetric re-weighting (§3.4).

3.1 Embedding normalization

Our method starts with a pre-processing that length normalizes the embeddings, then mean centers each dimension, and then length normalizes them again. The first two steps have been shown to be beneficial in previous work (Artetxe et al., 2016), while the second length normalization guarantees the final embeddings to have a unit length. As a result, the dot product of any two embeddings is equivalent to their cosine similarity and directly related to their Euclidean distance[1], and can be taken as a measure of their similarity.

3.2 Fully unsupervised initialization

The underlying difficulty of the mapping problem in its unsupervised variant is that the word embedding matrices X and Z are unaligned across both axes: neither the ith vocabulary item X_{i*} and Z_{i*} nor the jth dimension of the embeddings X_{*j} and Z_{*j} are aligned, so there is no direct correspondence between both languages. In order to overcome this challenge and build an initial solution, we propose to first construct two alternative representations X' and Z' that are aligned across their jth dimension X'_{*j} and Z'_{*j}, which can later be used to build an initial dictionary that aligns their respective vocabularies.

Our approach is based on a simple idea: while the axes of the original embeddings X and Z are different in nature, both axes of their corresponding similarity matrices $M_X = XX^T$ and $M_Z = ZZ^T$ correspond to words, which can be exploited to reduce the mismatch to a single axis. More concretely, assuming that the embedding spaces are perfectly isometric, the similarity matrices M_X and M_Z would be equivalent up to a permutation of their rows and columns, where the permutation in question defines the dictionary across both languages. In practice, the isometry requirement will not hold exactly, but it can be assumed to hold approximately, as the very same problem of mapping two embedding spaces without supervision would otherwise be hopeless. Based on that, one could try every possible permutation of row and column indices to find the best match between M_X and M_Z, but the resulting combinatorial explosion makes this approach intractable.

In order to overcome this problem, we propose to first sort the values in each row of M_X and M_Z, resulting in matrices $\text{sorted}(M_X)$ and $\text{sorted}(M_Z)$[2]. Under the strict isometry condition, equivalent words would get the exact same vector across languages, and thus, given a word and its row in $\text{sorted}(M_X)$, one could apply nearest neighbor retrieval over the rows of $\text{sorted}(M_Z)$ to find its corresponding translation.

On a final note, given the singular value decomposition $X = USV^T$, the similarity matrix

[1]Given two length normalized vectors u and v, $u \cdot v = \cos(u, v) = 1 - ||u - v||^2/2$.

[2]Note that the values in each row are sorted independently from other rows.

is $M_X = US^2U^T$. As such, its square root $\sqrt{M_X} = USU^T$ is closer in nature to the original embeddings, and we also find it to work better in practice. We thus compute $\mathrm{sorted}(\sqrt{M_X})$ and $\mathrm{sorted}(\sqrt{M_Z})$ and normalize them as described in Section 3.1, yielding the two matrices X' and Z' that are later used to build the initial solution for self-learning (see Section 3.3).

In practice, the isometry assumption is strong enough so the above procedure captures some cross-lingual signal. In our English-Italian experiments, the average cosine similarity across the gold standard translation pairs is 0.009 for a random solution, 0.582 for the optimal supervised solution, and 0.112 for the mapping resulting from this initialization. While the latter is far from being useful on its own (the accuracy of the resulting dictionary is only 0.52%), it is substantially better than chance, and it works well as an initial solution for the self-learning method described next.

3.3 Robust self-learning

Previous work has shown that self-learning can learn high-quality bilingual embedding mappings starting with as little as 25 word pairs (Artetxe et al., 2017). In this method, training iterates through the following two steps until convergence:

1. Compute the optimal orthogonal mapping maximizing the similarities for the current dictionary D:

$$\arg\max_{W_X, W_Z} \sum_i \sum_j D_{ij}((X_{i*}W_X) \cdot (Z_{j*}W_Z))$$

   An optimal solution is given by $W_X = U$ and $W_Z = V$, where $USV^T = X^TDZ$ is the singular value decomposition of X^TDZ.

2. Compute the optimal dictionary over the similarity matrix of the mapped embeddings $XW_XW_Z^TZ^T$. This typically uses nearest neighbor retrieval from the source language into the target language, so $D_{ij} = 1$ if $j = \mathrm{argmax}_k\,(X_{i*}W_X) \cdot (Z_{k*}W_Z)$ and $D_{ij} = 0$ otherwise.

The underlying optimization objective is independent from the initial dictionary, and the algorithm is guaranteed to converge to a local optimum of it. However, the method does not work if starting from a completely random solution, as it tends to get stuck in poor local optima in that case. For that reason, we use the unsupervised initialization procedure at Section 3.2 to build an initial solution. However, simply plugging in both methods did not work in our preliminary experiments, as the quality of this initial method is not good enough to avoid poor local optima. For that reason, we next propose some key improvements in the dictionary induction step to make self-learning more robust and learn better mappings:

- **Stochastic dictionary induction**. In order to encourage a wider exploration of the search space, we make the dictionary induction stochastic by randomly keeping some elements in the similarity matrix with probability p and setting the remaining ones to 0. As a consequence, the smaller the value of p is, the more the induced dictionary will vary from iteration to iteration, thus enabling to escape poor local optima. So as to find a fine-grained solution once the algorithm gets into a good region, we increase this value during training akin to simulated annealing, starting with $p = 0.1$ and doubling this value every time the objective function at step 1 above does not improve more than $\epsilon = 10^{-6}$ for 50 iterations.

- **Frequency-based vocabulary cutoff**. The size of the similarity matrix grows quadratically with respect to that of the vocabularies. This does not only increase the cost of computing it, but it also makes the number of possible solutions grow exponentially[3], presumably making the optimization problem harder. Given that less frequent words can be expected to be noisier, we propose to restrict the dictionary induction process to the k most frequent words in each language, where we find $k = 20{,}000$ to work well in practice.

- **CSLS retrieval**. Dinu et al. (2015) showed that nearest neighbor suffers from the hubness problem. This phenomenon is known to occur as an effect of the curse of dimensionality, and causes a few points (known as *hubs*) to be nearest neighbors of many other points (Radovanović et al., 2010a,b). Among the existing solutions to penalize the similarity score of hubs, we adopt the Cross-domain

[3]There are m^n possible combinations that go from a source vocabulary of n entries to a target vocabulary of m entries.

Similarity Local Scaling (CSLS) from Conneau et al. (2018). Given two mapped embeddings x and y, the idea of CSLS is to compute $\mathrm{r_T}(x)$ and $\mathrm{r_S}(y)$, the average cosine similarity of x and y for their k nearest neighbors in the other language, respectively. Having done that, the corrected score $\mathrm{CSLS}(x, y) = 2\cos(x, y) - \mathrm{r_T}(x) - \mathrm{r_S}(y)$. Following the authors, we set $k = 10$.

- **Bidirectional dictionary induction**. When the dictionary is induced from the source into the target language, not all target language words will be present in it, and some will occur multiple times. We argue that this might accentuate the problem of local optima, as repeated words might act as strong attractors from which it is difficult to escape. In order to mitigate this issue and encourage diversity, we propose inducing the dictionary in both directions and taking their corresponding concatenation, so $D = D_{X \to Z} + D_{Z \to X}$.

In order to build the **initial dictionary**, we compute X' and Z' as detailed in Section 3.2 and apply the above procedure over them. As the only difference, this first solution does not use the stochastic zeroing in the similarity matrix, as there is no need to encourage diversity (X' and Z' are only used once), and the threshold for vocabulary cutoff is set to $k = 4,000$, so X' and Z' can fit in memory. Having computed the initial dictionary, X' and Z' are discarded, and the remaining iterations are performed over the original embeddings X and Z.

3.4 Symmetric re-weighting

As part of their multi-step framework, Artetxe et al. (2018a) showed that re-weighting the target language embeddings according to the cross-correlation in each component greatly improved the quality of the induced dictionary. Given the singular value decomposition $USV^T = X^T DZ$, this is equivalent to taking $W_X = U$ and $W_Z = VS$, where X and Z are previously whitened applying the linear transformations $(X^T X)^{-\frac{1}{2}}$ and $(Z^T Z)^{-\frac{1}{2}}$, and later de-whitened applying $U^T (X^T X)^{\frac{1}{2}} U$ and $V^T (Z^T Z)^{\frac{1}{2}} V$.

However, re-weighting also accentuates the problem of local optima when incorporated into self-learning as, by increasing the relevance of dimensions that best match for the current solution, it discourages to explore other regions of the search space. For that reason, we propose using it as a final step once self-learning has converged to a good solution. Unlike Artetxe et al. (2018a), we apply re-weighting symmetrically in both languages, taking $W_X = US^{\frac{1}{2}}$ and $W_Z = VS^{\frac{1}{2}}$. This approach is neutral in the direction of the mapping, and gives good results as shown in our experiments.

4 Experimental settings

Following common practice, we evaluate our method on **bilingual lexicon extraction**, which measures the accuracy of the induced dictionary in comparison to a gold standard.

As discussed before, **previous evaluation** has focused on favorable conditions. In particular, existing unsupervised methods have almost exclusively been tested on Wikipedia corpora, which is comparable rather than monolingual, exposing a strong cross-lingual signal that is not available in strictly unsupervised settings. In addition to that, some datasets comprise unusually small embeddings, with only 50 dimensions and around 5,000-10,000 vocabulary items (Zhang et al., 2017a,b). As the only exception, Conneau et al. (2018) report positive results on the English-Italian dataset of Dinu et al. (2015) in addition to their main experiments, which are carried out in Wikipedia. While this dataset does use strictly monolingual corpora, it still corresponds to a pair of two relatively close indo-european languages.

In order to get a wider picture of how our method compares to previous work in different conditions, including more challenging settings, we carry out our experiments in the widely used **dataset** of Dinu et al. (2015) and the subsequent extensions of Artetxe et al. (2017, 2018a), which together comprise English-Italian, English-German, English-Finnish and English-Spanish. More concretely, the dataset consists of 300-dimensional CBOW embeddings trained on WacKy crawling corpora (English, Italian, German), Common Crawl (Finnish) and WMT News Crawl (Spanish). The gold standards were derived from dictionaries built from Europarl word alignments and available at OPUS (Tiedemann, 2012), split in a test set of 1,500 entries and a training set of 5,000 that we do not use in our experiments. The datasets are freely available. As a non-european agglutinative language, the English-Finnish pair is particularly challeng-

ing due to the linguistic distance between them. For completeness, we also test our method in the Spanish-English, Italian-English and Turkish-English datasets of Zhang et al. (2017a), which consist of 50-dimensional CBOW embeddings trained on Wikipedia, as well as gold standard dictionaries[4] from Open Multilingual WordNet (Spanish-English and Italian-English) and Google Translate (Turkish-English). The lower dimensionality and comparable corpora make an easier scenario, although it also contains a challenging pair of distant languages (Turkish-English).

Our method is implemented in Python using NumPy and CuPy. Together with it, we also test the **methods** of Zhang et al. (2017a) and Conneau et al. (2018) using the publicly available implementations from the authors[5]. Given that Zhang et al. (2017a) report using a different value of their hyperparameter λ for different language pairs ($\lambda = 10$ for English-Turkish and $\lambda = 1$ for the rest), we test both values in all our experiments to better understand its effect. In the case of Conneau et al. (2018), we test both the default hyperparameters in the source code as well as those reported in the paper, with iterative refinement activated in both cases. Given the instability of these methods, we perform 10 runs for each, and report the best and average accuracies, the number of successful runs (those with >5% accuracy) and the average runtime. All the experiments were run in a single Nvidia Titan Xp.

5 Results and discussion

We first present the main results (§5.1), then the comparison to the state-of-the-art (§5.2), and finally ablation tests to measure the contribution of each component (§5.3).

5.1 Main results

We report the results in the dataset of Zhang et al. (2017a) at Table 1. As it can be seen, the proposed method performs at par with that of Conneau et al. (2018) both in Spanish-English and Italian-English, but gets substantially better results in the more challenging Turkish-English pair. While we are able to reproduce the results reported by Zhang et al. (2017a), their method gets the worst results of all by a large margin. Another disadvantage of that model is that different

[4]The test dictionaries were obtained through personal communication with the authors. The rest of the language pairs were left out due to licensing issues.

[5]Despite our efforts, Zhang et al. (2017b) was left out because: 1) it does not create a one-to-one dictionary, thus difficulting direct comparison, 2) it depends on expensive proprietary software 3) its computational cost is orders of magnitude higher (running the experiments would have taken several months).

Table 3: Accuracy (%) of the proposed method in comparison with previous work. [*]Results obtained with the official implementation from the authors. [†]Results obtained with the framework from Artetxe et al. (2018a). The remaining results were reported in the original papers. For methods that do not require supervision, we report the average accuracy across 10 runs. [‡]For meaningful comparison, runs with <5% accuracy are excluded when computing the average, but note that, unlike ours, their method often gives a degenerated solution (see Table 2).

language pairs require different hyperparameters: $\lambda = 1$ works substantially better for Spanish-English and Italian-English, but only $\lambda = 10$ works for Turkish-English.

The results for the more challenging dataset from Dinu et al. (2015) and the extensions of Artetxe et al. (2017, 2018a) are given in Table 2. In this case, our proposed method obtains the best results in all metrics for all the four language pairs tested. The method of Zhang et al. (2017a) does not work at all in this more challenging scenario, which is in line with the negative results reported by the authors themselves for similar conditions (only %2.53 accuracy in their large Gigaword dataset). The method of Conneau et al. (2018) also fails for English-Finnish (only 1.62% in the best run), although it is able to get positive results in some runs for the rest of language pairs. Between the two configurations tested, the default hyperparameters in the code show a more stable behavior.

These results confirm the robustness of the proposed method. While the other systems succeed in some runs and fail in others, our method converges to a good solution in all runs without exception and, in fact, it is the only one getting positive results for English-Finnish. In addition to being more robust, our method also obtains substantially better accuracies, surpassing previous methods by at least 1-3 points in all but the easiest pairs. Moreover, our method is not sensitive to hyperparameters that are difficult to tune without a development set, which is critical in realistic unsupervised conditions.

At the same time, our method is significantly faster than the rest. In relation to that, it is interesting that, while previous methods perform a fixed number of iterations and take practically the same time for all the different language pairs, the runtime of our method adapts to the difficulty of the task thanks to the dynamic convergence criterion of our stochastic approach. This way, our method tends to take longer for more challenging language pairs (1.7 vs 0.6 minutes for es-en and tr-en in one dataset, and 12.9 vs 7.3 minutes for en-fi and en-de in the other) and, in fact, our (relative) execution times correlate surprisingly well with the linguistic distance with English (closest/fastest is German, followed by Italian/Spanish, followed by Turkish/Finnish).

Table 4: Ablation test on the dataset of Dinu et al. (2015) and the extensions of Artetxe et al. (2017, 2018a). We perform 10 runs for each method and report the best and average accuracies (%), the number of successful runs (those with >5% accuracy) and the average runtime (minutes).

5.2 Comparison with the state-of-the-art

Table 3 shows the results of the proposed method in comparison to previous systems, including those with different degrees of supervision. We focus on the widely used English-Italian dataset of Dinu et al. (2015) and its extensions. Despite being fully unsupervised, our method achieves the best results in all language pairs but one, even surpassing previous supervised approaches. The only exception is English-Finnish, where Artetxe et al. (2018a) gets marginally better results with a difference of 0.3 points, yet ours is the only unsupervised system that works for this pair. At the same time, it is remarkable that the proposed system gets substantially better results than Artetxe et al. (2017), the only other system based on self-learning, with the additional advantage of being fully unsupervised.

5.3 Ablation test

In order to better understand the role of different aspects in the proposed system, we perform an ablation test, where we separately analyze the effect of initialization, the different components of our robust self-learning algorithm, and the final symmetric re-weighting. The obtained results are reported in Table 4.

In concordance with previous work, our results show that self-learning does not work with random initialization. However, the proposed unsupervised initialization is able to overcome this issue without the need of any additional information, performing at par with other character-level heuristics that we tested (e.g. shared numerals).

As for the different self-learning components, we observe that the stochastic dictionary induction is necessary to overcome the problem of poor local optima for English-Finnish, although it does not make any difference for the rest of easier language pairs. The frequency-based vocabulary cutoff also has a positive effect, yielding to slightly better accuracies and much faster runtimes. At the same time, CSLS plays a critical role in the system, as hubness severely accentuates the problem of local optima in its absence. The bidirectional dictionary induction is also beneficial, contributing to the robustness of the system as shown by English-Finnish and yielding to better accuracies in all cases.

Finally, these results also show that symmetric re-weighting contributes positively, bringing an improvement of around 1-2 points without any cost in the execution time.

6 Conclusions

In this paper, we show that previous unsupervised mapping methods (Zhang et al., 2017a; Conneau et al., 2018) often fail on realistic scenarios involving non-comparable corpora and/or distant languages. In contrast to adversarial methods, we propose to use an initial weak mapping that exploits the structure of the embedding spaces in combination with a robust self-learning approach. The results show that our method succeeds in all cases, providing the best results with respect to all previous work on unsupervised and supervised mappings.

The ablation analysis shows that our initial solution is instrumental for making self-learning work without supervision. In order to make self-learning robust, we also added stochasticity to dictionary induction, used CSLS instead of nearest neighbor, and produced bidirectional dictionaries. Results also improved using smaller intermediate vocabularies and re-weighting the final solution. Our implementation is available as an open source project at `https://github.com/artetxem/vecmap`.

In the future, we would like to extend the method from the bilingual to the multilingual scenario, and go beyond the word level by incorporating embeddings of longer phrases.

Abstract

We propose a multi-lingual multi-task architecture to develop supervised models with a minimal amount of labeled data for sequence labeling. In this new architecture, we combine various transfer models using two layers of parameter sharing. On the first layer, we construct the basis of the architecture to provide universal word representation and feature extraction capability for all models. On the second level, we adopt different parameter sharing strategies for different transfer schemes. This architecture proves to be particularly effective for low-resource settings, when there are less than 200 training sentences for the target task. Using Name Tagging as a target task, our approach achieved 4.3%-50.5% absolute F-score gains compared to the mono-lingual single-task baseline model. [1]

1 Introduction

When we use supervised learning to solve Natural Language Processing (NLP) problems, we typically train an individual model for each task with task-specific labeled data. However, our target task may be intrinsically linked to other tasks. For example, Part-of-speech (POS) tagging and Name Tagging can both be considered as sequence labeling; Machine Translation (MT) and Abstractive Text Summarization both require the ability to understand the source text and generate natural language sentences. Therefore, it is valuable to transfer knowledge from related tasks to the target task. Multi-task Learning (MTL) is one of the most effective solutions for knowledge transfer across tasks. In the context of neural network architectures, we usually perform MTL by sharing parameters across models (Ruder, 2017).

Previous studies (Collobert and Weston, 2008; Dong et al., 2015; Luong et al., 2016; Liu et al., 2018; Yang et al., 2017) have proven that MTL is an effective approach to boost the performance of related tasks such as MT and parsing. However, most of these previous efforts focused on tasks and languages which have sufficient labeled data but hit a performance ceiling on each task alone. Most NLP tasks, including some well-studied ones such as POS tagging, still suffer from the lack of training data for many low-resource languages. According to Ethnologue[2], there are 7,099 living languages in the world. It is an unattainable goal to annotate data in all languages, especially for tasks with complicated annotation requirements. Furthermore, some special applications (e.g., disaster response and recovery) require rapid development of NLP systems for extremely low-resource languages. Therefore, in this paper, we concentrate on enhancing supervised models in low-resource settings by borrowing knowledge learned from related high-resource languages and tasks.

In (Yang et al., 2017), the authors simulated a low-resource setting for English and Spanish by downsampling the training data for the target task. However, for most low-resource languages, the data sparsity problem also lies in related tasks and languages. Under such circumstances, a single transfer model can only bring limited improvement. To tackle this issue, we propose a *multi-lingual multi-task* architecture which combines different transfer models within a unified architecture through two levels of parameter sharing. In the first level, we share character embeddings,

[*] Part of this work was done when the first author was on an internship at Facebook.

[1] The code of our model is available at https://github.com/limteng-rpi/mlmt

[2] https://www.ethnologue.com/guides/how-many-languages

character-level convolutional neural networks, and word-level long-short term memory layer across all models. These components serve as a basis to connect multiple models and transfer universal knowledge among them. In the second level, we adopt different sharing strategies for different transfer schemes. For example, we use the same output layer for all Name Tagging tasks to share task-specific knowledge (e.g., I-PER[3] should not be assigned to the first word in a sentence).

To illustrate our idea, we take *sequence labeling* as a case study. In the NLP context, the goal of sequence labeling is to assign a categorical label (e.g., POS tag) to each token in a sentence. It underlies a range of fundamental NLP tasks, including POS Tagging, Name Tagging, and chunking.

Experiments show that our model can effectively transfer various types of knowledge from different auxiliary tasks and obtains up to 50.5% absolute F-score gains on Name Tagging compared to the mono-lingual single-task baseline. Additionally, our approach does not rely on a large amount of auxiliary task data to achieve the improvement. Using merely 1% auxiliary data, we already obtain up to 9.7% absolute gains in F-score.

2 Model

2.1 Basic Architecture

The goal of sequence labeling is to assign a categorical label to each token in a given sentence. Though traditional methods such as Hidden Markov Models (HMMs) and Conditional Random Fields (CRFs) (Lafferty et al., 2001; Ratinov and Roth, 2009; Passos et al., 2014) achieved high performance on sequence labeling tasks, they typically relied on hand-crafted features, therefore it is difficult to adapt them to new tasks or languages. To avoid task-specific engineering, (Collobert et al., 2011) proposed a feed-forward neural network model that only requires word embeddings trained on a large scale corpus as features. After that, several neural models based on the combination of long-short term memory (LSTM) and CRFs (Ma and Hovy, 2016; Lample et al., 2016; Chiu and Nichols, 2016) were proposed and achieved better performance on sequence labeling tasks.

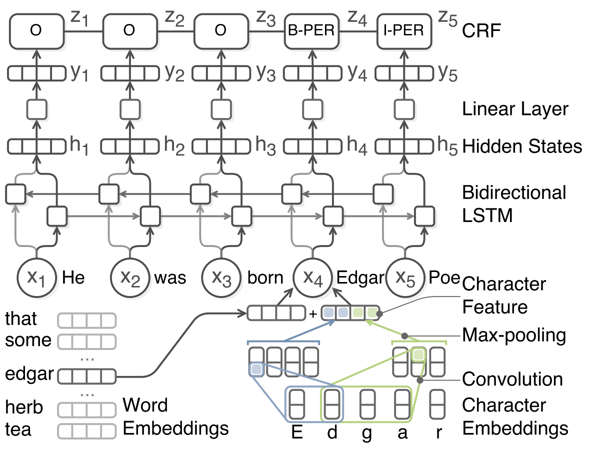

Figure 1: LSTM-CNNs: an LSTM-CRFs-based model for Sequence Labeling

LSTM-CRFs-based models are well-suited for multi-lingual multi-task learning for three reasons: (1) They learn features from word and character embeddings and therefore require little feature engineering; (2) As the input and output of each layer in a neural network are abstracted as vectors, it is fairly straightforward to share components between neural models; (3) Character embeddings can serve as a bridge to transfer morphological and semantic information between languages with identical or similar scripts, without requiring cross-lingual dictionaries or parallel sentences.

Therefore, we design our multi-task multi-lingual architecture based on the LSTM-CNNs model proposed in (Chiu and Nichols, 2016). The overall framework is illustrated in Figure 1. First, each word w_i is represented as the combination x_i of two parts, word embedding and character feature vector, which is extracted from character embeddings of the characters in w_i using convolutional neural networks (CharCNN). On top of that, a bidirectional LSTM processes the sequence $\boldsymbol{x} = \{x_1, x_2, ...\}$ in both directions and encodes each word and its context into a fixed-size vector h_i. Next, a linear layer converts h_i to a score vector y_i, in which each component represents the predicted score of a target tag. In order to model correlations between tags, a CRFs layer is added at the top to generate the best tagging path for the whole sequence. In the CRFs layer, given an input sentence $\boldsymbol{x}$ of length L and the output of the linear layer $\boldsymbol{y}$, the score of a sequence of tags $\boldsymbol{z}$ is

[3]We adopt the BIOES annotation scheme. Prefixes B-, I-, E-, and S- represent the beginning of a mention, inside of a mention, the end of a mention and a single-token mention respectively. The O tag is assigned to a word which is not part of any mention.

defined as:

$$S(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z}) = \sum_{t=1}^{L} (\boldsymbol{A}_{z_{t-1}, z_t} + \boldsymbol{y}_{t, z_t}),$$

where $\boldsymbol{A}$ is a transition matrix in which $\boldsymbol{A}_{p,q}$ represents the binary score of transitioning from tag p to tag q, and $\boldsymbol{y}_{t,z}$ represents the unary score of assigning tag z to the t-th word. Given the ground truth sequence of tags $\boldsymbol{z}$, we maximize the following objective function during the training phase:

$$\begin{aligned}\mathcal{O} &= \log P(\boldsymbol{z}|\boldsymbol{x}) \\ &= S(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z}) - \log \sum_{\tilde{\boldsymbol{z}} \in \boldsymbol{Z}} e^{S(\boldsymbol{x}, \boldsymbol{y}, \tilde{\boldsymbol{z}})},\end{aligned}$$

where $\boldsymbol{Z}$ is the set of all possible tagging paths.

We emphasize that our actual implementation differs slightly from the LSTM-CNNs model. We do not use additional word- and character-level explicit symbolic features (e.g., capitalization and lexicon) as they may require additional language-specific knowledge. Additionally, we transform character feature vectors using highway networks (Srivastava et al., 2015), which is reported to enhance the overall performance by (Kim et al., 2016) and (Liu et al., 2018). Highway networks is a type of neural network that can smoothly switch its behavior between transforming and carrying information.

2.2 Multi-task Multi-lingual Architecture

MTL can be employed to improve performance on multiple tasks at the same time, such as MT and parsing in (Luong et al., 2016). However, in our scenario, we only focused on enhancing the performance of a low-resource task, which is our target task or ***main task***. Our proposed architecture aims to transfer knowledge from a set of ***auxiliary tasks*** to the main task. For simplicity, we refer to a model of a main (auxiliary) task as a main (auxiliary) model.

To jointly train multiple models, we perform multi-task learning using parameter sharing. Let Θ_i be the set of parameters for model m_i and $\Theta_{i,j} = \Theta_i \cap \Theta_j$ be the shared parameters between m_i and m_j. When optimizing model m_i, we update Θ_i and hence $\Theta_{i,j}$. In this way, we can partially train model m_j as $\Theta_{i,j} \subseteq \Theta_j$. Previously, each MTL model generally uses a single transfer scheme. In order to merge different transfer models into a unified architecture, we employ two levels of parameter sharing as follows.

On the first level, we construct the basis of the architecture by sharing character embeddings, CharCNN and bidirectional LSTM among all models. This level of parameter sharing aims to provide universal word representation and feature extraction capability for all tasks and languages.

Character Embeddings and Character-level CNNs. Character features can represent morphological and semantic information; e.g., the English morpheme `dis-` usually indicates negation and reversal as in "*disagree*" and "*disapproval*". For low-resource languages lacking in data to suffice the training of high-quality word embeddings, character embeddings learned from other languages may provide crucial information for labeling, especially for rare and out-of-vocabulary words. Take the English word "*overflying*" (flying over) as an example. Even if it is rare or absent in the corpus, we can still infer the word meaning from its suffix `over-` (above), root `fly`, and prefix `-ing` (present participle form). In our architecture, we share character embeddings and the CharCNN between languages with identical or similar scripts to enhance word representation for low-resource languages.

Bidirectional LSTM. The bidirectional LSTM layer is essential to extract character, word, and contextual information from a sentence. However, with a large number of parameters, it cannot be fully trained only using the low-resource task data. To tackle this issue, we share the bidirectional LSTM layer across all models. Bear in mind that because our architecture does not require aligned cross-lingual word embeddings, sharing this layer across languages may confuse the model as it equally handles embeddings in different spaces. Nevertheless, under low-resource circumstances, data sparsity is the most critical factor that affects the performance.

On top of this basis, we adopt different parameter sharing strategies for different transfer schemes. For cross-task transfer, we use the same word embedding matrix across tasks so that they can mutually enhance word representations. For cross-lingual transfer, we share the linear layer and CRFs layer among languages to transfer task-specific knowledge, such as the transition score between two tags.

Word Embeddings. For most words, in addition to character embeddings, word embeddings are still crucial to represent semantic informa-

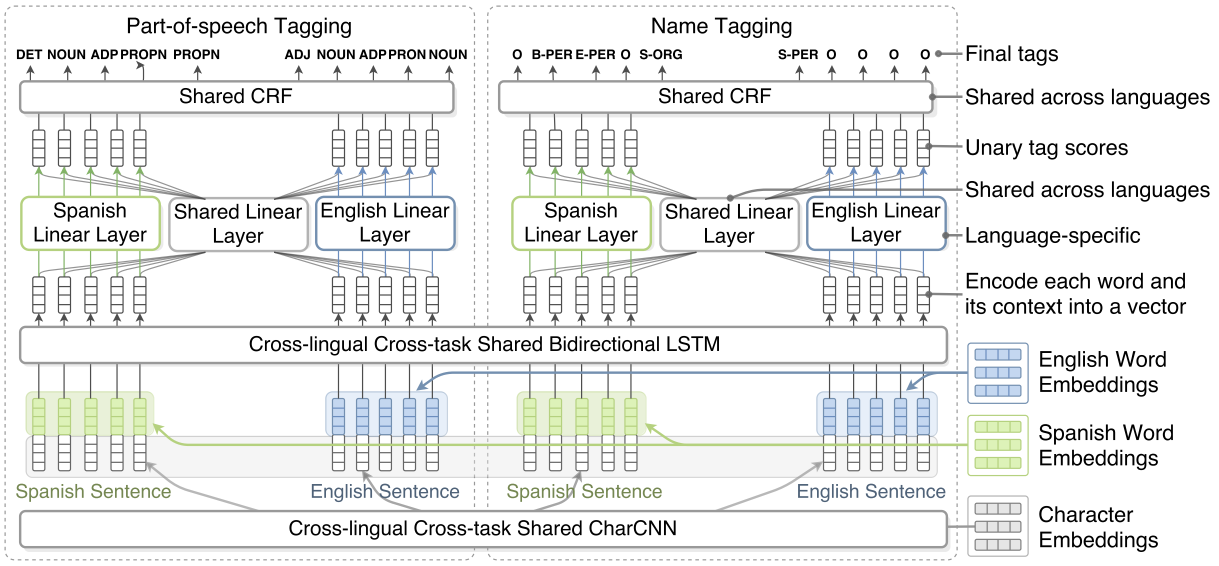

Figure 2: Multi-task Multi-lingual Architecture

tion. We use the same word embedding matrix for tasks in the same language. The matrix is initialized with pre-trained embeddings and optimized as parameters during training. Thus, task-specific knowledge can be encoded into the word embeddings by one task and subsequently utilized by another one. For a low-resource language even without sufficient raw text, we mix its data with a related high-resource language to train word embeddings. In this way, we merge both corpora and hence their vocabularies.

Recently, Conneau et al. (2017) proposed a domain-adversarial method to align two monolingual word embedding matrices without cross-lingual supervision such as a bilingual dictionary. Although cross-lingual word embeddings are not required, we evaluate our framework with aligned embeddings generated using this method. Experiment results show that the incorporation of cross-lingual embeddings substantially boosts the performance under low-resource settings.

Linear Layer and CRFs. As the tag set varies from task to task, the linear layer and CRFs can only be shared across languages. We share these layers to transfer task-specific knowledge to the main model. For example, our model corrects [S-PER Charles] [S-PER Picqué] to [B-PER Charles] [E-PER Picqué] because the CRFs layer fully trained on other languages assigns a low score to the rare transition S-PER→S-PER and promotes B-PER→E-PER. In addition to the shared linear layer, we add an unshared language-specific linear layer to allow the model to behave differently toward some features for different languages. For example, the suffix `-ment` usually indicates nouns in English whereas indicates adverbs in French.

We combine the output of the shared linear layer $\boldsymbol{y}^u$ and the output of the language-specific linear layer $\boldsymbol{y}^s$ using:

$$\boldsymbol{y} = \boldsymbol{g} \odot \boldsymbol{y}^s + (1 - \boldsymbol{g}) \odot \boldsymbol{y}^u,$$

where $\boldsymbol{g} = \sigma(\boldsymbol{W}_g \boldsymbol{h} + \boldsymbol{b}_g)$. $\boldsymbol{W}_g$ and $\boldsymbol{b}_g$ are optimized during training. $\boldsymbol{h}$ is the LSTM hidden states. As $\boldsymbol{W}_g$ is a square matrix, $\boldsymbol{y}$, $\boldsymbol{y}^s$, and $\boldsymbol{y}^u$ have the same dimension.

Although we only focus on sequence labeling in this work, our architecture can be adapted for many NLP tasks with slight modification. For example, for text classification tasks, we can take the last hidden state of the forward LSTM as the sentence representation and replace the CRFs layer with a Softmax layer.

In our model, each task has a separate object function. To optimize multiple tasks within one model, we adopt the alternating training approach in (Luong et al., 2016). At each training step, we sample a task d_i with probability $\frac{r_i}{\sum_j r_j}$, where r_i is the *mixing rate value* assigned to d_i. In our experiments, instead of tuning r_i, we estimate it by:

$$r_i = \mu_i \zeta_i \sqrt{N_i}\ ,$$

where μ_i is the task coefficient, ζ_i is the language coefficient, and N_i is the number of training examples. μ_i (or ζ_i) takes the value 1 if the task (or language) of d_i is the same as that of the target task; Otherwise it takes the value 0.1. For example, given English Name Tagging as the target task, the task coefficient μ and language coefficient ζ of Spanish Name Tagging are 0.1 and 1 respectively.

While assigning lower mixing rate values to auxiliary tasks, this formula also takes the amount of data into consideration. Thus, auxiliary tasks receive higher probabilities to reduce overfitting when we have a smaller amount of main task data.

3 Experiments

3.1 Data Sets

For Name Tagging, we use the following data sets: Dutch (NLD) and Spanish (ESP) data from the CoNLL 2002 shared task (Tjong Kim Sang, 2002), English (ENG) data from the CoNLL 2003 shared task (Tjong Kim Sang and De Meulder, 2003), Russian (RUS) data from LDC2016E95 (Russian Representative Language Pack), and Chechen (CHE) data from TAC KBP 2017 10-Language EDL Pilot Evaluation Source Corpus[4]. We select Chechen as another target language in addition to Dutch and Spanish because it is a truly under-resourced language and its related language, Russian, also lacks NLP resources.

Code	Train	Dev	Test
NLD	202,931 (13,344)	37,761 (2,616)	68,994 (3,941)
ESP	207,484 (18,797)	51,645 (4,351)	52,098 (3,558)
ENG	204,567 (23,499)	51,578 (5,942)	46,666 (5,648)
RUS	66,333 (3,143)	8,819 (413)	7,771 (407)
CHE	98,355 (2,674)	12,265 (312)	11,933 (366)

Table 1: Name Tagging data set statistics: #token and #name (between parentheses).

For POS Tagging, we use English, Dutch, Spanish, and Russian data from the CoNLL 2017 shared task (Zeman et al., 2017; Nivre et al., 2017). In this data set, each token is annotated with two POS tags, UPOS (universal POS tag) and XPOS (language-specific POS tag). We use UPOS because it is consistent throughout all languages.

3.2 Experimental Setup

We use 50-dimensional pre-trained word embeddings and 50-dimensional randomly initialized character embeddings. We train word embeddings using the word2vec package[5]. English, Spanish, and Dutch embeddings are trained on corresponding Wikipedia articles (2017-12-20 dumps). Russian embeddings are trained on documents in LDC2016E95. Chechen embeddings are trained on documents in TAC KBP 2017 10-Language EDL Pilot Evaluation Source Corpus. To learn a mapping between mono-lingual word embeddings and obtain cross-lingual embeddings, we use the unsupervised model in the MUSE library[6] (Conneau et al., 2017). Although word embeddings are fine-tuned during training, we update the embedding matrix in a sparse way and thus do not have to update a large number of parameters.

We optimize parameters using Stochastic Gradient Descent with momentum, gradient clipping and exponential learning rate decay. At step t, the learning rate α_t is updated using $\alpha_t = \alpha_0 * \rho^{t/T}$, where α_0 is the initial learning rate, ρ is the decay rate, and T is the decay step.[7] To reduce overfitting, we apply Dropout (Srivastava et al., 2014) to the output of the LSTM layer.

We conduct hyper-parameter optimization by exploring the space of parameters shown in Table 2 using random search (Bergstra and Bengio, 2012). Due to time constraints, we only perform parameter sweeping on the Dutch Name Tagging task with 200 training examples. We select the set of parameters that achieves the best performance on the development set and apply it to all models.

Layer	Range	Final
CharCNN Filter Number	$[10, 30]$	20
Highway Layer Number	$[1, 2]$	2
Highway Activation Function	ReLU, SeLU	SeLU
LSTM Hidden State Size	$[50, 200]$	171
LSTM Dropout Rate	$[0.3, 0.8]$	0.6
Learning Rate	$[0.01, 0.2]$	0.02
Batch Size	$[5, 25]$	19

Table 2: Hyper-parameter search space.

3.3 Comparison of Different Models

In Figure 3, 4, and 5, we compare our model with the mono-lingual single-task LSTM-CNNs model (denoted as *baseline*), cross-task transfer model, and cross-lingual transfer model in low-resource settings with Dutch, Spanish, and Chechen Name Tagging as the main task respectively. We use English as the related language for Dutch and Spanish, and use Russian as the related language for

[4]`https://tac.nist.gov/2017/KBP/data.html`

[5]`https://github.com/tmikolov/word2vec`

[6]`https://github.com/facebookresearch/MUSE`

[7]Momentum β, gradient clipping threshold, ρ, and T are set to 0.9, 5.0, 0.9, and 10000 in the experiments.

Chechen. For cross-task transfer, we take POS Tagging as the auxiliary task. Because the CoNLL 2017 data does not include Chechen, we only use Russian POS Tagging and Russian Name Tagging as auxiliary tasks for Chechen Name Tagging.

We take Name Tagging as the target task for three reasons: (1) POS Tagging has a much lower requirement for the amount of training data. For example, using only 10 training sentences, our baseline model achieves 75.5% and 82.9% prediction accuracy on Dutch and Spanish; (2) Compared to POS Tagging, Name Tagging has been considered as a more challenging task; (3) Existing POS Tagging resources are relatively richer than Name Tagging ones; e.g., the CoNLL 2017 data set provides POS Tagging training data for 45 languages. Name Tagging also has a higher annotation cost as its annotation guidelines are usually more complicated.

We can see that our model substantially outperforms the mono-lingual single-task baseline model and obtains visible gains over single transfer models. When trained with less than 50 main tasks training sentences, cross-lingual transfer consistently surpasses cross-task transfer, which is not surprising because in the latter scheme, the linear layer and CRFs layer of the main model are not shared with other models and thus cannot be fully trained with little data.

Because there are only 20,400 sentences in Chechen documents, we also experiment with the data augmentation method described in Section 2.2 by training word embeddings on a mixture of Russian and Chechen data. This method yields additional 3.5%-10.0% absolute F-score gains. We also experiment with transferring from English to Chechen. Because Chechen uses Cyrillic alphabet , we convert its data set to Latin script. Surprisingly, although these two languages are not close, we get more improvement by using English as the auxiliary language.

In Table 3, we compare our model with state-of-the-art models using all Dutch or Spanish Name Tagging data. Results show that although we design this architecture for low-resource settings, it also achieves good performance in high-resource settings. In this experiment, with sufficient training data for the target task, we perform another round of parameter sweeping. We increase the embedding sizes and LSTM hidden state size to 100 and 225 respectively.

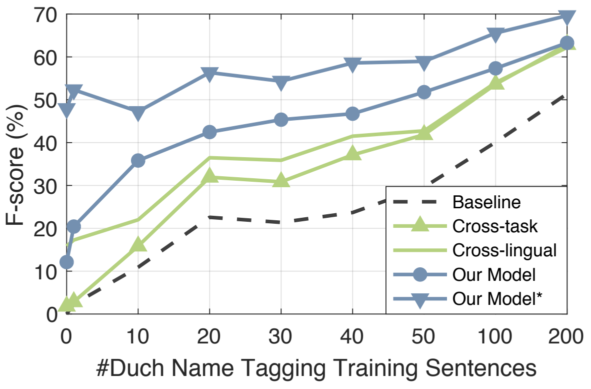

Figure 3: Performance on Dutch Name Tagging. We scale the horizontal axis to show more details under 100 sentences. Our Model*: our model with MUSE cross-lingual embeddings.

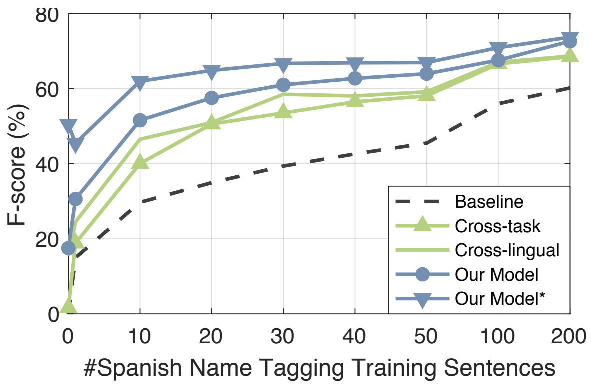

Figure 4: Performance on Spanish Name Tagging.

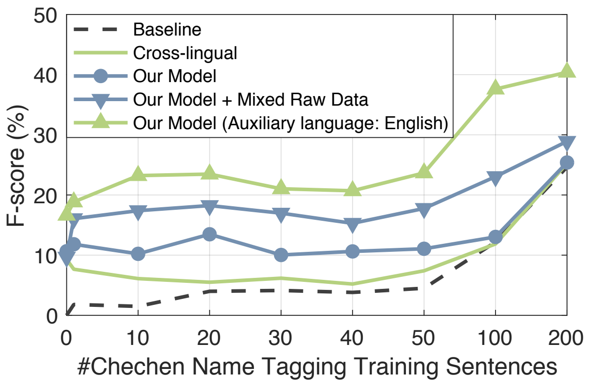

Figure 5: Performance on Chechen Name Tagging.

3.4 Qualitative Analysis

In Table 4, we compare Name Tagging results from the baseline model and our model, both trained with 100 main task sentences.

The first three examples show that shared character-level networks can transfer different levels of morphological and semantic information.

Language	Model	F-score
Dutch	Gillick et al. (2016)	82.84
	Lample et al. (2016)	81.74
	Yang et al. (2017)	85.19
	Baseline	85.14
	Cross-task	85.69
	Cross-lingual	85.71
	Our Model	**86.55**
Spanish	Gillick et al. (2016)	82.95
	Lample et al. (2016)	85.75
	Yang et al. (2017)	85.77
	Baseline	85.44
	Cross-task	85.37
	Cross-lingual	85.02
	Our Model	**85.88**

Table 3: Comparison with state-of-the-art models.

In example #1, the baseline model fails to identify "*Palestijnen*", an unseen word in the Dutch data, while our model can recognize it because the shared CharCNN represents it in a way similar to its corresponding English word "*Palestinians*", which occurs 20 times. In addition to mentions, the shared CharCNN can also improve representations of context words, such as "*staat*" (state) in the example. For some words dissimilar to corresponding English words, the CharCNN may enhance their word representations by transferring morpheme-level knowledge. For example, in sentence #2, our model is able to identify "*Rusland*" (Russia) as the suffix `-land` is usually associated with location names in the English data; e.g., Finland. Furthermore, the CharCNN is capable of capturing some word-level patterns, such as capitalized hyphenated compound and acronym as example #3 shows. In this sentence, neither "*PMS-centra*" nor "*MST*" can be found in auxiliary task data, while we observe a number of similar expressions, such as American-style and LDP.

The transferred knowledge also helps reduce overfitting. For example, in sentence #4, the baseline model mistakenly tags "*sección*" (section) and "*consellería*" (department) as organizations because their capitalized forms usually appear in Spanish organization names. With knowledge learned in auxiliary tasks that a lowercased word is rarely tagged as a proper noun, our model is able to avoid overfitting and correct these errors. Sentence #5 shows an opposite situation, where the capitalized word "*campesinos*" (farm worker) never appears in Spanish names.

In Table 5, we show differences between cross-lingual transfer and cross-task transfer. Although the cross-task transfer model recognizes "*Ingeborg Marx*" missed by the baseline model, it mistakenly assigns an S-PER tag to "*Marx*". Instead, from English Name Tagging, the cross-lingual transfer model borrows task-specific knowledge through the shared CRFs layer that (1) B-PER→S-PER is an invalid transition, and (2) even if we assign S-PER to "*Ingeborg*", it is rare to have continuous person names without any conjunction or punctuation. Thus, the cross-lingual model promotes the sequence B-PER→E-PER.

In Figure 6, we depict the change of tag distribution with the number of training sentences. When trained with less than 100 sentences, the baseline model only correctly predicts a few tags dominated by frequent types. By contrast, our model has a visibly higher recall and better predicts infrequent tags, which can be attributed to the implicit data augmentation and inductive bias introduced by MTL (Ruder, 2017). For example, if all location names in the Dutch training data are single-token ones, the baseline model will inevitably overfit to the tag S-LOC and possibly label "*Caldera de Taburiente*" as [S-LOC Caldera] [S-LOC de] [S-LOC Taburiente], whereas with the shared CRFs layer fully trained on English Name Tagging, our model prefers B-LOC→I-LOC→E-LOC, which receives a higher transition score.

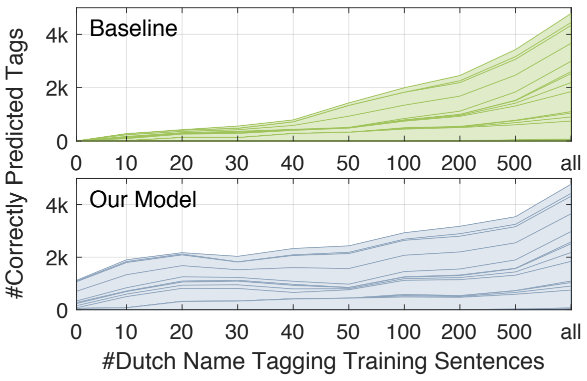

Figure 6: The distribution of correctly predicted tags on Dutch Name Tagging. The height of each stack indicates the number of a certain tag.

3.5 Ablation Studies

In order to quantify the contributions of individual components, we conduct ablation studies on Dutch Name Tagging with different numbers of training sentences for the target task. For the basic model, we we use separate LSTM layers and

Table 5: Comparing cross-task transfer and cross-lingual transfer on Dutch Name Tagging with 100 training sentences.

remove the character embeddings, highway networks, language-specific layer, and Dropout layer. As Table 6 shows, adding each component usually enhances the performance (F-score, %), while the impact also depends on the size of the target task data. For example, the language-specific layer slightly impairs the performance with only 10 training sentences. However, this is unsurprising as it introduces additional parameters that are only trained by the target task data.

Model	**0**	**10**	**100**	**200**	**All**

3.6 Effect of the Amount of Auxiliary Task Data

For many low-resource languages, their related languages are also low-resource. To evaluate our model's sensitivity to the amount of auxiliary task data, we fix the size of main task data and downsample all auxiliary task data with sample rates from 1% to 50%. As Figure 7 shows, the performance goes up when we raise the sample rate from

1% to 20%. However, we do not observe significant improvement when we further increase the sample rate. By comparing scores in Figure 3 and Figure 7, we can see that using only 1% auxiliary data, our model already obtains 3.7%-9.7% absolute F-score gains. Due to space limitations, we only show curves for Dutch Name Tagging, while we observe similar results on other tasks. Therefore, we may conclude that our model does not heavily rely on the amount of auxiliary task data.

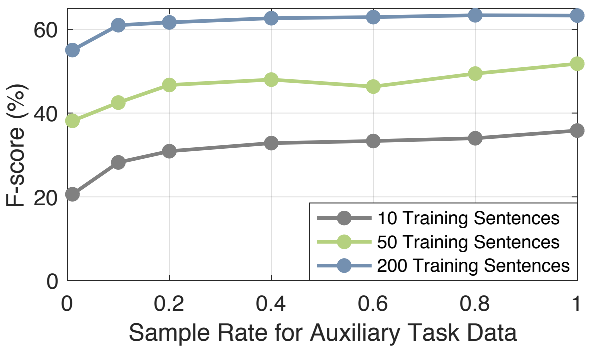

Figure 7: The effect of the amount of auxiliary task data on Dutch Name Tagging.

4 Related Work

Multi-task Learning has been applied in different NLP areas, such as machine translation (Luong et al., 2016; Dong et al., 2015; Domhan and Hieber, 2017), text classification (Liu et al., 2017), dependency parsing (Peng et al., 2017), textual entailment (Hashimoto et al., 2017), text summarization (Isonuma et al., 2017) and sequence labeling (Collobert and Weston, 2008; Søgaard and Goldberg, 2016; Rei, 2017; Peng and Dredze, 2017; Yang et al., 2017; von Däniken and Cieliebak, 2017; Aguilar et al., 2017; Liu et al., 2018)

Collobert and Weston (2008) is an early attempt that applies MTL to sequence labeling. The authors train a CNN model jointly on POS Tagging, Semantic Role Labeling, Name Tagging, chunking, and language modeling using parameter sharing. Instead of using other sequence labeling tasks, Rei (2017) and Liu et al. (2018) take language modeling as the secondary training objective to extract semantic and syntactic knowledge from large scale raw text without additional supervision. In (Yang et al., 2017), the authors propose three transfer models for cross-domain, cross-application, and cross-lingual transfer for sequence labeling, and also simulate a low-resource setting by downsampling the training data. By contrast, we combine cross-task transfer and cross-lingual transfer within a unified architecture to transfer different types of knowledge from multiple auxiliary tasks simultaneously. In addition, because our model is designed for low-resource settings, we share components among models in a different way (e.g., the LSTM layer is shared across all models). Differing from most MTL models, which perform supervisions for all tasks on the outermost layer, (Søgaard and Goldberg, 2016) proposes an MTL model which supervised tasks at different levels. It shows that supervising low-level tasks such as POS Tagging at lower layer obtains better performance.

5 Conclusions and Future Work

We design a multi-lingual multi-task architecture for low-resource settings. We evaluate the model on sequence labeling tasks with three language pairs. Experiments show that our model can effectively transfer different types of knowledge to improve the main model. It substantially outperforms the mono-lingual single-task baseline model, cross-lingual transfer model, and cross-task transfer model.

The next step of this research is to apply this architecture to other types of tasks, such as Event Extract and Semantic Role Labeling that involve structure prediction. We also plan to explore the possibility of integrating incremental learning into this architecture to adapt a trained model for new tasks rapidly.

Abstract

Bilingual tasks, such as bilingual lexicon induction and cross-lingual classification, are crucial for overcoming data sparsity in the target language. Resources required for such tasks are often out-of-domain, thus domain adaptation is an important problem here. We make two contributions. First, we test a delightfully simple method for *domain adaptation of bilingual word embeddings*. We evaluate these embeddings on two bilingual tasks involving different domains: cross-lingual twitter sentiment classification and medical bilingual lexicon induction. Second, we tailor a *broadly applicable semi-supervised classification* method from computer vision to these tasks. We show that this method also helps in low-resource setups. Using both methods together we achieve large improvements over our baselines, by using only additional unlabeled data.

1 Introduction

In this paper we study two bilingual tasks that strongly depend on bilingual word embeddings (BWEs). Previously, specialized domain adaptation approaches to such tasks were proposed. We instead show experimentally that a simple adaptation process involving only unlabeled text is highly effective. We then show that a semi-supervised classification method from computer vision can be applied successfully for further gains in cross-lingual classification.

Our BWE adaptation method is delightfully simple. We begin by adapting monolingual word embeddings to the target domain for source and target languages by simply building them using both general and target-domain unlabeled data. As a second step we use post-hoc mapping (Mikolov et al., 2013b), i.e., we use a seed lexicon to transform the word embeddings of the two languages into the same vector space. We show experimentally for the first time that the domain-adapted bilingual word embeddings we produce using this extremely simple technique are highly effective. We study two quite different tasks and domains, where resources are lacking, showing that our simple technique performs well for both of them: cross-lingual twitter sentiment classification and medical bilingual lexicon induction. In previous work, task-dependent approaches were used for this type of domain adaptation. Our approach is simple and task independent.

Second, we adapt the semi-supervised image classification system of Häusser et al. (2017) for NLP problems for the first time. This approach is broadly applicable to many NLP classification tasks where unlabeled data is available. We tailor it to both of our cross-lingual tasks. The system exploits unlabeled data during the training of classifiers by learning similar features for similar labeled and unlabeled training examples, thereby extracting information from unlabeled examples as well. As we show experimentally, the system further improves cross-lingual knowledge transfer for both of our tasks.

After combining both techniques, the results of sentiment analysis are competitive with systems that use annotated data in the target language, an impressive result considering that we require no target-language annotated data. The method also yields impressive improvements for bilingual lexicon induction compared with baselines trained on in-domain data. We show that this system requires the high-quality domain-adapted bilingual word embeddings we previously created to use unlabeled data well.

2 Previous Work

2.1 Bilingual Word Embeddings

Many approaches have been proposed for creating high quality BWEs using different bilingual signals. Following Mikolov et al. (2013b), many authors (Faruqui and Dyer, 2014; Xing et al., 2015; Lazaridou et al., 2015; Vulić and Korhonen, 2016) map monolingual word embeddings (MWEs) into the same bilingual space. Others leverage parallel texts (Hermann and Blunsom, 2014; Gouws et al., 2015) or create artificial cross-lingual corpora using seed lexicons or document alignments (Vulić and Moens, 2015; Duong et al., 2016) to train BWEs.

In contrast, our aim is not to improve the intrinsic quality of BWEs, but to adapt BWEs to specific domains to enhance their performance on bilingual tasks in these domains. Faruqui et al. (2015), Gouws and Søgaard (2015), Rothe et al. (2016) have previously studied domain adaptation of bilingual word embeddings, showing it to be highly effective for improving downstream tasks. However, importantly, their proposed methods are based on specialized domain lexicons (such as, e.g., sentiment lexicons) which contain task specific word relations. Our delightfully simple approach is, in contrast, effectively task independent (in that it only requires unlabeled in-domain text), which is an important strength.

2.2 Cross-Lingual Sentiment Analysis

Sentiment analysis is widely applied, and thus ideally we would have access to high quality supervised models in all human languages. Unfortunately, good quality labeled datasets are missing for many languages. Training models on resource rich languages and applying them to resource poor languages is therefore highly desirable. Cross-lingual sentiment classification (CLSC) tackles this problem (Mihalcea et al., 2007; Banea et al., 2010; Wan, 2009; Lu et al., 2011; Balamurali and Joshi, 2012; Gui et al., 2013). Recent CLSC approaches use BWEs as features of deep learning architectures which allows us to use a model for target-language sentiment classification, even when the model was trained only using source-language supervised training data. Following this approach we perform CLSC on Spanish tweets using English training data. Even though Spanish is not resource-poor we simulate this by using only English annotated data.

Xiao and Guo (2013) proposed a cross-lingual log-bilinear document model to learn distributed representations of words, which can capture both the semantic similarities of words across languages and the predictive information with respect to the classification task. Similarly, Tang and Wan (2014) jointly embedded texts in different languages into a joint semantic space representing sentiment. Zhou et al. (2014) employed aligned sentences in the BWE learning process, but in the sentiment classification process only representations in the source language are used for training, and representations in the target language are used for predicting labels. An important weakness of these three works was that aligned sentences were required.

Some work has trained sentiment-specific BWEs using annotated sentiment information in both languages (Zhou et al., 2015, 2016), which is desirable, but this is not applicable to our scenario. Our goal is to adapt BWEs to a specific domain without requiring additional task-specific engineering or knowledge sources beyond having access to plentiful target-language in-domain unlabeled text. Both of the approaches we study in this work fit this criterion, the delightfully simple method for adapting BWEs can improve the performance of any off-the-shelf classifier that is based on BWEs, while the broadly applicable semi-supervised approach of Häusser et al. (2017) can improve the performance of any off-the-shelf classifier.

2.3 Bilingual Lexicon Induction (BLI)

BLI is an important task that has been addressed by a large amount of previous work. The goal of BLI is to automatically extract word translation pairs using BWEs. While BLI is often used to provide an intrinsic evaluation of BWEs (Lazaridou et al., 2015; Vulić and Moens, 2015; Vulić and Korhonen, 2016) it is also useful for tasks such as machine translation (Madhyastha and España Bohnet, 2017). Most work on BLI using BWEs focuses on frequent words in high-resource domains such as parliament proceedings or news texts. Recently Heyman et al. (2017) tackled BLI of words in the medical domain. This task is useful for many applications such as terminology extraction or OOV mining for machine translation of medical texts. Heyman et al. (2017) show that when only a small amount of medical data is available, BLI using BWEs tends to perform poorly. Especially BWEs obtained using post-hoc mapping (Mikolov et al., 2013b; Lazaridou et al., 2015) fail on this task. Consequently, Heyman et al. (2017) build BWEs using aligned documents and then engineer a specialized classification-based approach to BLI. In contrast, our delightfully simple approach to create high-quality BWEs for the medical domain requires only monolingual data. We show that our adapted BWEs yield impressive improvements over non-adapted BWEs in this task with both cosine similarity and with the classifier of Heyman et al. (2017). In addition, we show that the broadly applicable method can push performance further using easily accessible unlabeled data.

3 Adaptation of BWEs

BWEs trained on *general domain* texts usually result in lower performance when used in a system for a *specific domain*. There are two reasons for this. (i) Vocabularies of specific domains contain words that are not used in the general case, e.g., names of medicines or diseases. (ii) The meaning of a word varies across domains; e.g., "apple" mostly refers to a fruit in general domains, but is an electronic device in many product reviews.

The delightfully simple method adapts general domain BWEs in a way that preserves the semantic knowledge from general domain data and leverages *monolingual* domain specific data to create domain-specific BWEs. Our domain-adaptation approach is applicable to any language-pair in which monolingual data is available. Unlike other methods, our approach is task independent: it only requires unlabeled in-domain target language text.

3.1 Approach

To create domain adapted BWEs, we first train MWEs (monolingual word embeddings) in both languages and then map those into the same space using post-hoc mapping (Mikolov et al., 2013b). We train MWEs for both languages by concatenating monolingual out-of-domain and in-domain data. The out-of-domain data allows us to create accurate distributed representations of common vocabulary while the in-domain data embeds domain specific words. We then map the two MWEs using a small seed lexicon to create the adapted BWEs. Because post-hoc mapping only requires a seed lexicon as bilingual signal it can easily be used with (cheap) monolingual data.

For **post-hoc mapping**, we use Mikolov et al. (2013b)'s approach. This model assumes a $W \in \mathbb{R}^{d_1 \times d_2}$ matrix which maps vectors from the source to the target MWEs where d_1 and d_2 are the embedding space dimensions. A seed lexicon of $(x_i, y_i) \in L \subseteq \mathbb{R}^{d_1} \times \mathbb{R}^{d_2}$ pairs is needed where x_i and y_i are source and target MWEs. W can be learned using ridge regression by minimizing the L_2-regularized mapping error between the source x_i and the target y_i vectors:

$$\min_W \sum_i ||Wx_i - y_i||_2^2 + \lambda ||W||_2^2 \qquad (1)$$

where λ is the regularization weight. Based on the source embedding x, we then compute a target embedding as Wx.

We create MWEs with word2vec skipgram (Mikolov et al., 2013a)[1] and estimate W with *scikit-learn* (Pedregosa et al., 2011). We use default parameters.

4 Cross-Lingual Sentiment Classification

In CLSC, an important application of BWEs, we train a supervised sentiment model on training data available in the source (a resource rich language) and apply it to the target (a resource poor language, for which there is typically no training data available). Because BWEs embed source and target words in the same space, annotations in the source (represented as BWEs) enable transfer learning. For CLSC of tweets, a drawback of BWEs trained on non-twitter data is that they do not produce embeddings for twitter-specific vocabulary, e.g., slang words like English *coool* and (Mexican) Spanish *chido*, resulting in lost information when a sentiment classifier uses them.

4.1 Training Data for Twitter Specific BWEs

As comparable non-twitter data we use OpenSubtitles (Lison and Tiedemann, 2016) which contains 49.2M English and Spanish subtitle sentences respectively (**Subtitle**). The reason behind choosing Subtitles is that although it is out-of-domain it contains slang words similar to tweets thus serving as a strong baseline in our setup. We experiment with two monolingual twitter data sets:

(i) **22M_tweets**: Downloaded[2] English (17.2M) and Spanish (4.8M) tweets using the public

[1]https://github.com/dav/word2vec
[2]We downloaded for a month starting on 2016-10-15.

Twitter Streaming API[3] with language filters *en* and *es*

(ii) a **BACKGROUND** corpus of 296K English and 150K Spanish (non-annotated) tweets released with the test data of the RepLab task (Amigó et al., 2013) described below

All twitter data was tokenized using Bird et al. (2009) and lowercased. User names, URLs, numbers, emoticons and punctuation were removed.

As lexicon for the mapping, we use the BNC word frequency list (Kilgarriff, 1997), a list of 6,318 frequent English lemmas and their Spanish translations, obtained from Google Translate. Note that we do not need a domain-specific lexicon in order to get good quality adapted BWEs.

4.2 Training Data for Sentiment Classifiers

For sentiment classification, we use data from the *RepLab 2013* shared task (Amigó et al., 2013). The data is annotated with positive, neutral and negative labels and contains English and Spanish tweets. We used the official English training set (26.6K tweets) and the Spanish test set (14.9K) in the resource-poor setup. We only use the 7.2K Spanish labeled training data for comparison reasons in §6.2, which we will discuss later.

The shared task was on target-level sentiment analysis, i.e., given a pair (document, target entity), the gold annotation is based on whether the sentiment expressed by the document is about the target. For example: *I cried on the back seat of my BMW!* where *BMW* is the target would be negative in the sentence-level scenario. However, it is neutral in the target-level case because the negative sentiment is not related to BMW. The reason for using this dataset is that it contains comparable English and Spanish tweets annotated for sentiment. There are other twitter datasets for English (Nakov et al., 2016) and Spanish (Garcıa-Cumbreras et al., 2016), but they were downloaded at different times and were annotated using different annotation methodologies, thus impeding a clean and consistent evaluation.

4.3 Sentiment Systems

For evaluating our adapted BWEs on the *RepLab* dataset we used a **target-aware** sentiment classifier introduced by Zhang et al. (2016). The network first embeds input words using pre-trained BWEs and feeds them to a bi-directional gated neural network. Pooling is applied on the hidden representations of the left and right context of the target mention respectively. Finally, gated neurons are used to model the interaction between the target mention and its surrounding context. During training we hold our pre-trained BWEs fixed and keep the default parameters of the model.

We also implement Kim (2014)'s *CNN-non-static* system, which does not use the target information in a given document (**target-ignorant**). The network first embeds input words using pre-trained BWEs and feeds them to a convolutional layer with multiple window sizes. Max pooling is applied on top of convolution followed by a fully connected network with one hidden layer. We used this system as well because it performed comparably to the target-aware system. The reason for this is that only 1% of the used data contains more than one target and out of these rare cases only 14% have differing sentiment labels in the same sentence, which are the difficult cases of target-level sentiment analysis. We used the default parameters as described in (Kim, 2014) with the exception of using 1000 feature maps and 30 epochs, based on our initial experiments. Word embeddings are fixed during the training just as for the target-aware classifier.

4.4 Results

As we previously explained we evaluate our adaptation method on the task of target-level sentiment classification using both target-aware and target-ignorant classifiers. For all experiments, our two baselines are off-the-shelf classifiers using non-adapted BWEs, i.e., BWEs trained only using Subtitles. Our goal is to show that our BWE adaptation method can improve the performance of such classifiers. We train our adapted BWEs on the concatenation of Subtitle and 22M_tweets or BACKGROUND respectively. In addition, we also report results with BWEs trained only on tweets.

To train the sentiment classifiers we use the English Replab training set and we evaluate on the Spanish test set. To show the performance that can be reached in a monolingual setup, we report results obtained by using annotated Spanish sentiment data instead of English (oracle). We train two oracle sentiment classifiers using (i) MWEs trained on only the Spanish part of Subtitle and (ii)

[3]dev.twitter.com/streaming/overview

			target-	
			aware	ignorant
oracle		MWE_Subtitle	62.17%	63.27%
oracle		BWE_Subtitle	62.46%	63.50%
domain adaptation		Baseline	55.14%	59.05%
domain adaptation	del. simple	BACKGROUND	56.79%	58.50%
domain adaptation	del. simple	22M_tweets	59.44%	61.14%
domain adaptation	del. simple	Subtitle+BACKGROUND	58.64%	59.34%
domain adaptation	del. simple	Subtitle+22M_tweets	60.99%	61.06%

Table 1: Accuracy of the BWE adaptation approach on the target-level sentiment classification task. The oracle systems used Spanish sentiment training data instead of English.

BWEs trained on Subtitle using posthoc mapping. The difference between the two is that the embeddings of (ii) are enriched with English words which can be beneficial for the classification of Spanish tweets because they often contain a few English words.

We do not compare with word embedding adaptation methods relying on specialized resources. The point of our work is to study task-independent methods and to the best of our knowledge ours is the first such attempt. Similarly, we do not compare against machine translation based sentiment classifiers (e.g., (Zhou et al., 2016)) because for their adaptation in-domain parallel data would be needed.

Table 1 gives results for both classifiers. It shows that the adaptation of Subtitle based BWEs with data from Twitter (22M_tweets and BACKGROUND) clearly outperforms the Baseline in all cases. The target-aware system performed poorly with the baseline BWEs and could benefit significantly from the adaptation approach. The target-ignorant performed better with the baseline BWEs but could also benefit from the adaptation. Comparing results with the Twitter-dataset-only based BWEs, the 22M_tweets performed better even though the BACKGROUND dataset is from the same topic as the RepLab train and test sets. Our conjecture is that the latter is too small to create good BWEs. In combination with Subtitles, 22M_tweets also yields better results than when combined with BACKGROUND. Although the best accuracy was reached using the 22M_tweets-only based BWEs, it is only slightly better then the adapted Subtitles+22M_tweets based BWEs. In §6 we show that both the semantic knowledge from Subtitles and the domain-specific information from tweets are needed to further improve results.

Comparing the two classifiers we can say that they performed similarly in terms of their best results. On the other hand, the target-ignorant system had better results on average. This might seem surprising at first because the system does not use the target as information. But considering the characteristics of RepLab, i.e., that the number of tweets that contains multiple targets is negligible, using the target offers no real advantage.

Although we did not focus on the impact of the seed lexicon size, we ran post-hoc mapping with different sizes during our preliminary experiments. With 1,000 and 100 word pairs in the lexicon the target-ignorant system suffered 0.5% and 4.0% drop in average of our setups respectively.

To summarize the result: using adapted BWEs for the Twitter CLSC task improves the performance of off-the-shelf classifiers.

5 Medical Bilingual Lexicon Induction

Another interesting downstream task for BWEs is bilingual lexicon induction. Given a list of words in a source language, the goal of BLI is to mine translations for each word in a chosen target language. The medical bilingual lexicon induction task proposed in (Heyman et al., 2017) aims to mine medical words using BWEs trained on a very small amount of English and Dutch monolingual medical data. Due to the lack of resources in this domain, good quality BWEs are hard to build using in-domain data only. We show that by enriching BWEs with general domain knowledge (in the form of general domain monolingual corpora) better results can be achieved on this medical domain task.

5.1 Experimental Setup

We evaluate our improved BWEs on the dataset provided by Heyman et al. (2017). The monolingual medical data consists of English and Dutch medical articles from Wikipedia. The English (resp. Dutch) articles contain 52,336 (resp. 21,374) sentences. A total of 7,368 manually annotated word translation pairs occurring in the English (source) and Dutch (target) monolingual corpora are provided as gold data. This set is split 64%/16%/20% into trn/dev/test. 20% of the English words have multiple translations. Given an English word, the task is to find the correct Dutch translation.

As monolingual general-domain data we use

	cosine similarity		classifier	
	F_1 (top)	F_1 (all)	F_1 (top)	F_1 (all)
Baseline	13.43	9.84	37.73	36.61
Baseline BNC lexicon	-	-	20.73	21.78
Adapted medical lexicon	14.18	14.15	40.71	38.09
Adapted BNC lexicon	16.29	16.71	22.10	21.50

Table 2: We report F_1 results for medical BLI with the cosine similarity and the classifier based systems. We present baseline and our proposed domain adaptation method using both general and medical lexicons.

the English and Dutch data from Europarl (v7) (Koehn, 2005), a corpus of 2 million sentence pairs. Although Europarl is a parallel corpus, we use it in a monolingual way and shuffle each side of the corpus before training. By using massive cheap data we create high-quality MWEs in each language which are still domain-specific (due to inclusion of medical data). To obtain an out-of-domain seed lexicon, we translated the English words in BNC to Dutch using Google Translate (just as we did before for the Twitter CLSC task). We then use the out-of-domain BNC and the in-domain medical seed lexicons in separate experiments to create BWEs with post-hoc mapping. Note, we did not concatenate the two lexicons because (i) they have a small common subset of source words which have different target words, thus having a negative effect on the mapping and (ii) we did not want to modify the medical seed lexicon because it was taken from previous work.

5.2 BLI Systems

To perform BLI we use two methods. Because BWEs represent words from different languages in a shared space, BLI can be performed via *cosine similarity* in this space. In other words, given a BWE representing two languages V_s and V_t, the translation of each word $s \in V_s$ can be induced by taking the word $t \in V_t$ whose representation $\vec{x_t}$ in the BWE is closest to the representation $\vec{x_s}$.

As the second approach we use a *classifier based system* proposed by Heyman et al. (2017). This neural network based system is comprised of two main modules. The first is a character-level LSTM which aims to learn orthographic similarity of word pairs. The other is the concatenation of the embeddings of the two words using embedding layers with the aim of learning the similarity among semantic representations of the words. Dense layers are applied on top of the two modules before the output soft-max layer. The classifier is trained using positive and negative word pair examples and a pre-trained word embedding model. Negative examples are randomly generated for each positive one in the training lexicon. We used default parameters as reported by Heyman et al. (2017) except for the t classification thresholds (used at prediction time). We fine-tuned these on dev. We note that the system works with pre-trained MWEs as well (and report these as official baseline results) but it requires BWEs for candidate generation at prediction time, thus we use BWEs for the system's input for all experiments. In preliminary work, we had found that MWE and BWE results are similar.

5.3 Results

Heyman et al. (2017)'s results are our *baseline*. Table 2 compares its performance with our adapted BWEs, with both cosine similarity and classification based systems. "top" F_1 scores are based on the most probable word as prediction only; "all" F_1 scores use all words as prediction whose probability is above the threshold. It can be seen that the cosine similarity based system using adapted BWEs clearly outperforms the non-adapted BWEs which were trained in a resource poor setup.[4] Moreover, the best performance was reached using the general seed lexicon for the mapping which is due to the fact that general domain words have better quality embeddings in the MWE models, which in turn gives a better quality mapping.

The classification based system performs significantly better comparing to cosine similarity by exploiting the seed lexicon better. Using adapted BWEs as input word embeddings for the system further improvements were achieved which shows the better quality of our BWEs. Simulating an even poorer setup by using a general lexicon, the

[4]The results for cosine similarity in (Heyman et al., 2017) are based on BWESG-based BWEs (Vulić and Moens, 2016) trained on a small document aligned parallel corpus without using a seed lexicon.

performance gain of the classifier is lower. This shows the significance of the medical seed lexicon for this system. On the other hand, adapted BWEs have better performance compared to non-adapted ones using the best translation while they have just slightly lower F_1 using multiple translations. This result shows that while with adapted BWEs the system predicts better "top" translations, it has a harder time when predicting "all" due to the increased vocabulary size.

To summarize: we have shown that adapted BWEs increase performance for this task and domain; and they do so independently of the task-specific system that is used.

6 Semi-Supervised Learning

In addition to the experiments that show our BWE-adaptation method's task and language independence, we investigate ways to further incorporate unlabeled data to overcome data sparsity.

Häusser et al. (2017) introduce a semi-supervised method for neural networks that makes associations from the vector representation of labeled samples to those of unlabeled ones and back. This lets the learning exploit unlabeled samples as well. While Häusser et al. (2017) use their model for image classification, we adapt it to CLSC of tweets and medical BLI. We show that our semi-supervised model requires adapted BWEs to be effective and yields significant improvements. This innovative method is general and can be applied to any classification when unlabeled text is available.

6.1 Model

Häusser et al. (2017)'s basic assumption is that the embeddings of labeled and unlabeled samples – i.e., the representations in the neural network on which the classification layer is applied – are similar within the same class. To achieve this, walking cycles are introduced: a cycle starts from a labeled sample, goes to an unlabeled one and ends at a labeled one. A cycle is correct if the start and end samples are in the same class. The probability of going from sample A to B is proportional to the cosine similarity of their embeddings. To maximize the number of correct cycles, two loss functions are employed: Walker loss and Visit loss.

Walker loss penalizes incorrect walks and encourages a uniform probability distribution of walks to the correct class. It is defined as:

$$\mathcal{L}_{walker} := H(T, P^{aba}) \tag{2}$$

where H is the cross-entropy function, P^{aba}_{ij} is the probability that a cycle starts from sample i and ends at j and T is the uniform target distribution:

$$T_{ij} := \begin{cases} 1/(\#c(i)) & \text{if } c(i) = c(j) \\ 0 & \text{otherwise} \end{cases} \tag{3}$$

where $c(i)$ is the class of sample i and $\#c(i)$ is the number of occurrences of $c(i)$ in the labeled set.

Visit loss encourages cycles to visit all unlabeled samples, rather than just those which are the most similar to labeled samples. It is defined as:

$$\mathcal{L}_{visit} := H(V, P^{visit})$$

$$P^{visit}_j := \langle P^{ab}_{ij} \rangle_i \tag{4}$$

$$V_j := \frac{1}{U}$$

where H is cross-entropy, P^{ab}_{ij} is the probability that a cycle starts from sample i and goes to j and U is the number of unlabeled samples.

The total loss during training is the sum of the walker, visit and classification (cross-entropy between predicted and gold labels) losses which is minimized using Adam (Kingma and Ba, 2015).

We adapt this model (including the two losses) to sentiment classification, focusing on the target-ignorant classifier, and the classifier based approach for BLI. We will call these systems **semisup**[5]. Due to the fact that we initialize the embedding layers for both classifiers with BWEs the models are able to make some correct cycles at the beginning of the training and improve them later on. We will describe the labeled and unlabeled datasets used in the subsequent sections below.

We use Häusser et al. (2017)'s implementation of the losses, with 1.0, 0.5 and 1.0 weights for the walker, visit and classification losses, respectively, for CLSC based on preliminary experiments. We fine-tuned the weights for BLI on dev for each experiment.

[5]We publicly release our implementation: https://github.com/hangyav/biadapt

		semisup
	Baseline	58.67% (-0.38%)
domain adaptation	BACKGROUND	57.41% (-1.09%)
	22M_tweets	60.19% (-0.95%)
	Subtitle+BACKGROUND	60.31% (0.97%)
	Subtitle+22M_tweets	63.23% (2.17%)

Table 3: Accuracy on CLSC of the adapted BWE approach with the semisup (target-ignorant with additional loss functions) system comparing to the target-ignorant in brackets.

6.2 Semi-Supervised CLSC

As in §4.4, we use pre-trained BWEs to initialize the classifier and use English sentiment training data as the labeled set. Furthermore, we use the Spanish sentiment training data as the unlabeled set, ignoring its annotation. This setup is very similar to real-word low-resource scenarios: unlabeled target-language tweets are easy to download while labeled English ones are available.

Table 3 gives results for adapted BWEs and shows that semisup helps only when word embeddings are adapted to the Twitter domain. As mentioned earlier, semisup compares labeled and unlabeled samples based on their vector representations. By using BWEs based on only Subtitles, we lose too many embeddings of similar English and Spanish tweets. On the other hand, if we use only tweet-based BWEs we lose good quality semantic knowledge which can be learned from more standard text domains. By combining the two domains we were able to capture both sides. For Subtitle+22M_tweets, we even get very close to the best oracle (BWE_Subtitle) in Table 1 getting only 0.27% less accuracy – an impressive result keeping in mind that we did not use labeled Spanish data.

The RepLab dataset contains tweets from 4 topics: automotive, banking, university, music. We manually analyzed similar tweets from the labeled and unlabeled sets. We found that when using semisup, English and Spanish tweets from the same topics are more similar in the embedding space than occurs without the additional losses. Topics differ in how they express sentiment – this may explain why semisup increases performance for RepLab.

Adding supervision. To show how well semisup can exploit the unlabeled data we used both English and Spanish sentiment training data together to train the sentiment classifiers. Table 4 shows that by using annotated data in both languages we get clearly better results than when using only one language. Tables 3 and 4 show that for Subtitle+22M_tweets based BWEs, the semisup approach achieved high improvement (2.17%) comparing to target-ignorant with English training data only, while it achieved lower improvement (0.97%) with the Subtitle+BACKGROUND based BWEs. On the other hand, adding labeled Spanish data caused just a slight increase comparing to semisup with Subtitle+22M_tweets based BWEs (0.59%), while in case of Subtitle+BACKGROUND we got significant additional improvement (2.61%). This means that with higher quality BWEs, unlabeled target-language data can be exploited better.

It can also be seen that the target-aware system outperformed the target-ignorant system using additional labeled target-language data. The reason could be that it is a more complex network and therefore needs more data to reach high performance.

The results in table 4 are impressive: our target-level system is strongly competitive with the official shared task results. We achieved high accuracy on the Spanish test set by using only English training data. Comparing our best system which used all training data to the official results (Amigó et al., 2013) we would rank 2nd even though our system is not fine-tuned for the RepLab dataset. Furthermore, we also outperformed the oracles when using annotated data from both languages which shows the additional advantage of using BWEs.

6.3 Semi-Supervised BLI

For BLI experiments with semisup we used word pairs from the medical seed lexicon as the labeled set (with negative word pairs generated as described in §5.2). As opposed to CLSC and the work of (Häusser et al., 2017), for this task we do not have an unlabeled set, and therefore we need to generate it. We developed two scenarios. For the first, **BNC**, we generate a general unlabeled set using English words from the **BNC** lexicon and generate 10 pairs out of each word by using the 5 most similar Dutch words based on the corresponding BWEs and 5 random Dutch words. For the second scenario, **medical**, we generate an in-domain unlabeled set by generating for each English word in the **medical** lexicon the 3 most similar Dutch

		lang	target-aware	target-ignorant
oracle	MWE_Subtitle	Es	62.17%	63.27%
	BWE_Subtitle	Es	62.46%	63.50%
domain adaptation	Subtitle+BACKGROUND	En	58.64%	59.34%
	Subtitle+BACKGROUND	En+Es	64.01%	62.92% (2.61%)
	Subtitle+22M_tweets	En	60.99%	61.06%
	Subtitle+22M_tweets	En+Es	64.24%	63.82% (0.59%)

Table 4: Accuracy on CLSC of both target-aware and target-ignorant systems using English or/and Spanish sentiment training data. Column *lang* shows the language of the used training data. Differences comparing to semisup are indicated in brackets.

	F_1 (top)	F_1 (all)
Baseline+BNC	35.04 (-0.66)	34.98 (-1.40)
Baseline+medical	36.20 (0.50)	36.55 (0.16)
Adapted+BNC	41.01 (0.30)	39.04 (0.95)
Adapted+medical	41.44 (0.73)	37.51 (-0.57)

Table 5: Results with the semi-supervised system for BLI. Differences comparing to previous results are indicated in brackets. Baseline results are compared to rerun experiments of Heyman et al. (2017) using BWEs instead of MWEs.

words based on BWEs and for each of these we use the 5 most similar English words (ignoring the words which are in the original medical lexicon) and 5 negative words. The idea behind these methods is to automatically generate an unlabeled set that hopefully has a similar positive and negative word pair distribution to the distribution in the labeled set.

Results in Table 5 show that adding semisup to the classifier further increases performance for BLI as well. For the baseline system, when using only in-domain text for creating BWEs, only the medical unlabeled set was effective, general domain word pairs could not be exploited due to the lack of general semantic knowledge in the BWE model. On the other hand, by using our domain adapted BWEs, which contain both general domain and in-domain semantical knowledge, we can exploit word pairs from both domains. Results for adapted BWEs increased in 3 out of 4 cases, where the only exception is when using multiple translations for a given source word (which may have been caused by the bigger vocabulary size).

These results show that adapted BWEs are needed to exploit unlabeled data well which leads to an impressive overall 3.71 increase compared with the best result in previous work (Heyman et al., 2017), by using only unlabeled data.

7 Conclusion

Bilingual word embeddings trained on general domain data yield poor results in out-of-domain tasks. We presented experiments on two different low-resource task/domain combinations. Our delightfully simple task independent method to adapt BWEs to a specific domain uses unlabeled monolingual data only. We showed that with the support of adapted BWEs the performance of off-the-shelf methods can be increased for both cross-lingual Twitter sentiment classification and medical bilingual lexicon induction. Furthermore, by adapting the broadly applicable semi-supervised approach of Häusser et al. (2017) (which until now has only been applied in computer vision) we were able to effectively exploit unlabeled data to further improve performance. We showed that, when also using high-quality adapted BWEs, the performance of the semi-supervised systems can be significantly increased by using unlabeled data at classifier training time. In addition, CLSC results are competitive with a system that uses target-language labeled data, even when we use no such target-language labeled data.

Knowledgeable Reader: Enhancing Cloze-Style Reading Comprehension with External Commonsense Knowledge

Todor Mihaylov and **Anette Frank**

Department of Computational Linguistics, Heidelberg University
Heidelberg, Germany
{mihaylov,frank}@cl.uni-heidelberg.de

Abstract

We introduce a neural reading comprehension model that integrates *external commonsense knowledge*, encoded as a key-value memory, in a cloze-style setting. Instead of relying on only document-to-question interaction or discrete features as in prior work, our model attends to relevant external knowledge and combines this knowledge with the context representation before inferring the answer. This allows the model to attract and imply knowledge from an external knowledge source that is not explicitly stated in the text, but that is relevant for inferring the answer. Our model improves results over a very strong baseline on a hard *Common Nouns* dataset, making it a strong competitor of much more complex models. By including knowledge *explicitly*, our model can also provide *evidence* about the background knowledge used in the RC process.

1 Introduction

Reading comprehension (RC) is a language understanding task similar to question answering, where a system is expected to read a given passage of text and answer questions about it. Cloze-style reading comprehension is a task setting where the question is formed by replacing a token in a sentence of the story with a placeholder (left part of Figure 1).

In contrast to many previous complex models (Weston et al., 2015; Dhingra et al., 2017; Cui et al., 2017; Munkhdalai and Yu, 2016; Sordoni et al., 2016) that perform *multi-turn reading* of a story and a question before inferring the correct answer, we aim to tackle the cloze-style RC task in a way that resembles how humans solve it: using, in addition, background knowledge. We develop

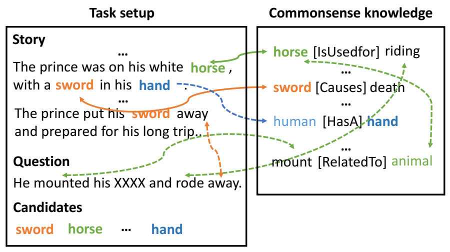

Figure 1: Cloze-style reading comprehension with external commonsense knowledge.

a neural model for RC that can successfully deal with tasks where most of the information to infer answers from is given in the document (story), but where additional information is needed to predict the answer, which can be retrieved from a knowledge base and added to the context representations explicitly.[1] An illustration is given in Figure 1.

Such knowledge may be *commonsense knowledge* or *factual background knowledge about entities and events* that is not explicitly expressed but can be found in a knowledge base such as ConceptNet (Speer et al., 2017), BabelNet (Navigli and Ponzetto, 2012), Freebase (Tanon et al., 2016) or domain-specific KBs collected with Information Extraction approaches (Fader et al., 2011; Mausam et al., 2012; Bhutani et al., 2016). Thus, we aim to define a neural model that encodes pre-selected knowledge in a memory, and that learns to include the available knowledge as an enrichment to the context representation.

The main difference of our model to prior state-of-the-art is that instead of relying only on document-to-question interaction or discrete features while performing multiple hops over the document, our model (i) *attends to relevant selected*

[1] *'Context representation'* refers to a vector representation computed from textual information only (i.e., document (story) or question).

external knowledge and (ii) *combines this knowledge with the context representation before inferring the answer*, in a single hop. This allows the model to explicitly imply knowledge that is not stated in the text, but is relevant for inferring the answer, and that can be found in an external knowledge source. Moreover, by including knowledge explicitly, our model *provides evidence and insight about the used knowledge in the RC.*

Our main contributions are: **(i)** We develop a method for integrating knowledge in a simple but effective reading comprehension model (*AS Reader*, Kadlec et al. (2016)) and improve its results significantly whereas other models employ features or multiple hops. **(ii)** We examine two sources of common knowledge: WordNet (Miller et al., 1990) and ConceptNet (Speer et al., 2017) and show that this type of knowledge is important for answering *common nouns* questions and also improves slightly the performance for *named entities*.

(iii) We show that knowledge facts can be added directly to the text-only representation, enriching the neural context encoding. **(iv)** We demonstrate the effectiveness of the injected knowledge by case studies and data statistics in a qualitative evaluation study.

2 Reading Comprehension with Background Knowledge Sources

In this work, we examine the impact of using external knowledge as supporting information for the task of *cloze style* reading comprehension.

We build a system with two modules. The first, *Knowledge Retrieval*, performs *fact retrieval* and selects a number of facts f_1, ..., f_p that might be relevant for connecting story, question and candidate answers. The second, main module, *the Knowledgeable Reader*, is a knowledge-enhanced neural module. It uses the input of the story context tokens $d_{1..m}$, the question tokens $q_{1..n}$, the set of answer candidates $a_{1..k}$ and a set of 'relevant' background knowledge facts $f_{1..p}$ in order to select the right answer. To include external knowledge for the RC task, we encode each fact $f_{1..p}$ and use attention to select the most relevant among them for each token in the story and question. We expect that enriching the text with additional knowledge about the mentioned concepts will improve the prediction of correct answers in a strong *single-pass* system. See Figure 1 for illustration.

2.1 Knowledge Retrieval

In our experiments we use knowledge from the Open Mind Common Sense (OMCS, Singh et al. (2002)) part of ConceptNet, a crowd-sourced resource of commonsense knowledge with a total of ∼630k facts. Each fact f_i is represented as a triple f_i=*(subject, relation, object)*, where *subject* and *object* can be multi-word expressions and *relation* is a relation type. An example is: *([bow]$_{subj}$, [IsUsedFor]$_{rel}$, [hunt, animals]$_{obj}$)*

We experiment with three set-ups: using (i) all facts from OMCS that pertain to ConceptNet, referred to as *CN5All*, (ii) using all facts from *CN5All* excluding some WordNet relations referred to as *CN5Sel(ected)* (see Section 3), and using (iii) facts from OMCS that have *source* set to *WordNet* (*CN5WN3*).

Retrieving relevant knowledge. For each instance (D, Q, $A_{1..10}$) we retrieve relevant commonsense background facts. We first retrieve facts that contain lemmas that can be looked up via tokens contained in any D(ocument), Q(uestion) or A(nswer candidates). We add a weight value for each node: 4, if it contains a lemma of a candidate token from A; 3, if it contains a lemma from the tokens of Q; and 2 if it contains a lemma from the tokens of D. The selected weights are chosen heuristically such that they model relative fact importance in different interactions as A+A > A+Q > A+D > D+Q > D+D. We weight the fact triples that contain these lemmas as nodes, by summing the weights of the subject and object arguments. Next, we sort the knowledge triples by this overall weight value. To limit the memory of our model, we run experiments with different sizes of the top number of facts (P) selected from all instance fact candidates, $P \in \{50, 100, 200\}$. As additional retrieval limitation, we force the number of facts per answer candidate to be the same, in order to avoid a frequency bias for an answer candidate that appears more often in the knowledge source. Thus, if we select the maximum 100 facts for each task instance and we have 10 answer candidates $a_{i=1..10}$, we retrieve the top 10 facts for each candidate a_i that has either a subject or an object lemma for a token in a_i. If the same fact contains lemmas of two candidates a_i and a_j ($j > i$), we add the fact once for a_i and do not add the same fact again for a_j. If several facts have the same weight, we take

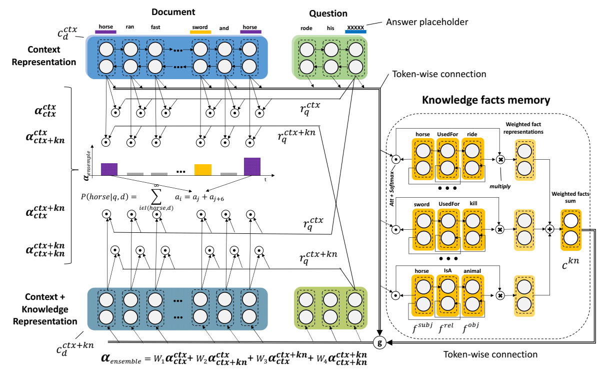

Figure 2: The Knowledgeable Reader combines plain *context* & *enhanced* (*context* + *knowledge*) repres. of *D* and *Q* and retrieved knowledge from the explicit memory with the *Key-Value* approach.

the first in the order of the list[2], i.e., the order of retrieval from the database. If one candidate has less than 10 facts, the overall fact candidates for the sample will be less than the maximum (100).

2.2 Neural Model: Extending the Attention Sum Reader with a Knowledge Memory

We implement our *Knowledgeable Reader (KnReader)* using as a basis the *Attention Sum Reader* as one of the strongest core models for single-hop RC. We extend it with a knowledge fact memory that is filled with pre-selected facts. Our aim is to examine how adding commonsense knowledge to a simple yet effective model can improve the RC process and to show some evidence of that by attending on the incorporated knowledge facts. The model architecture is shown in Figure 2.

Base Attention Model. The Attention-Sum Reader (Kadlec et al., 2016), our base model for RC reads the input of story tokens $d_{1..n}$, the question tokens $q_{1..m}$, and the set of candidates $a_{1..10}$ that occur in the story text. The model calculates the attention between the question representation r_q and the story token context encodings of the candidate tokens $a_{1..10}$ and sums the attention scores for the candidates that appear multiple times in the story. The model selects as answer the candidate that has the highest attention score.

Word Embeddings Layer. We represent input document and question tokens w by looking up their embedding representations $e_i = Emb(w_i)$, where Emb is an embedding lookup function. We apply dropout (Srivastava et al., 2014) with keep probability $p = 0.8$ to the output of the embeddings lookup layer.

Context Representations. To represent the document and question contexts, we first encode the tokens with a Bi-directional GRU (Gated Recurrent Unit) (Chung et al., 2014) to obtain context-encoded representations for document ($c^{ctx}_{d_1..n}$) and question ($c^{ctx}_{q_1..m}$) encoding:

$$c^{ctx}_{d_1..n} = BiGRU^{ctx}(e_{d_1..n}) \in \mathbb{R}^{n \times 2h} \quad (1)$$

$$c^{ctx}_{q_1..m} = BiGRU^{ctx}(e_{q_1..m}) \in \mathbb{R}^{m \times 2h} \quad (2)$$

, where d_i and q_i denote the ith token of a text sequence d (document) and q (question), respectively, n and m is the size of d and q and h the output hidden size (256) of a single GRU unit. $BiGRU$ is defined in (3), with e_i a word embedding vector

$$BiGRU^{ctx}(e_i, h_{i_{prev}}) = \begin{matrix}[\overrightarrow{GRU}(e_i, \overrightarrow{h_{i_{prev}}}), \\ \overleftarrow{GRU}(e_i, \overleftarrow{h_{i_{prev}}})]\end{matrix} \quad (3)$$

, where $h_{i_{prev}} = [\overrightarrow{h_{i_{prev}}}, \overleftarrow{h_{i_{prev}}}]$, and $\overrightarrow{h_{i_{prev}}}$ and $\overleftarrow{h_{i_{prev}}}$ are the previous hidden states of the forward and backward layers. Below we use $BiGRU^{ctx}(e_i)$ without the hidden state, for short.

Question Query Representation. For the question we construct a single vector representation r^{ctx}_q by retrieving the token representation at the placeholder (XXXX) index *pl* (cf. Figure 2):

$$r^{ctx}_q = c^{ctx}_{q_i..m}[pl] \in \mathbb{R}^{2h} \quad (4)$$

where $[pl]$ is an element pickup operation.

Our question vector representation is different from the original *AS Reader* that builds the question by concatenating the *last states* of a forward and backward layer $[\overrightarrow{GRU}(e_m), \overleftarrow{GRU}(e_1)]$. We changed the original representation as we observed some very long questions and in this way aim to prevent the context encoder from 'forgetting' where the placeholder is.

Answer Prediction: Q^{ctx} to D^{ctx} Attention. In order to predict the correct answer to the given question, we rank the given answer candidates $a_1..a_L$ according to the normalized attention sum score between the context (ctx) representation of the question placeholder r^{ctx}_q and the representation of the candidate tokens in the document:

$$P(a_i|q,d) = softmax(\sum \alpha_{i_j}) \quad (5)$$

$$\alpha_{i_j} = Att(r^{ctx}_q, c^{ctx}_{d_j}), i \in [1..L] \quad (6)$$

[2]We also experimented with re-ranking the facts with the same weight sums using tf-idf but we did not notice a difference in performance.

, where j is an index pointer from the list of indices that point to the candidate a_i token occurrences in the document context representation c_d. Att is a dot product.

Enriching Context Representations with Knowledge (Context+Knowledge). To enhance the representation of the context, we add knowledge, retrieved as a set of knowledge facts.

Knowledge Encoding. For each instance in the dataset, we retrieve a number of relevant facts (cf. Section 2.1). Each retrieved fact is represented as a triple $f = (w^{subj}_{1..L_{subj}}, w^{rel}_0, w^{obj}_{1..L_{obj}})$, where $w^{subj}_{1..L_{subj}}$ and $w^{obj}_{1..L_{obj}}$ are a multi-word expressions representing the $subject$ and $object$ with sequence lengths L_{subj} and L_{obj}, and w^{rel}_0 is a word token corresponding to a relation.[3] As a result of fact encoding, we obtain a separate knowledge memory for each instance in the data.

To encode the knowledge we use a $BiGRU$ to encode the triple argument tokens into the following context-encoded representations:

$$f^{subj}_{last} = BiGRU(Emb(w^{subj}_{1..L_{subj}}), 0) \quad (7)$$

$$f^{rel}_{last} = BiGRU(Emb(w^{rel}_0), f^{subj}_{last}) \quad (8)$$

$$f^{obj}_{last} = BiGRU(Emb(w^{obj}_{1..L_{subj}}), f^{rel}_{last}) \quad (9)$$

, where f^{subj}_{last}, f^{rel}_{last}, f^{obj}_{last} are the final hidden states of the context encoder $BiGRU$, that are also used as initial representations for the encoding of the next triple attribute in left-to-right order. See *Supplement* for comprehensive visualizations. The motivation behind this encoding is: (i) We encode the knowledge fact attributes in the same vector space as the plain tokens; (ii) we preserve the triple directionality; (iii) we use the relation type as a way of filtering the *subject* information to initialize the *object*.

Querying the Knowledge Memory. To enrich the context representation of the document and question tokens with the facts collected in the knowledge memory, we select a single *sum of weighted fact representations* for each token using Key-Value retrieval (Miller et al., 2016). In our model the *key* $M^{k(ey)}_i$ can be either f^{subj}_{last} or f^{obj}_{last} and the *value* $M^{v(alue)}_i$ is f^{obj}_{last}.

For each context-encoded token $c^{ctx}_{s_i}$ ($s = d, q$; i the token index) we attend over all knowledge memory keys M^k_i in the retrieved P knowledge facts. We use an attention function Att, scale the scalar attention value using $softmax$, multiply it with the value representation M^v_i and sum the result into a single vector value representation $c^{kn}_{s_i}$:

$$c^{kn}_{s_i} = \sum softmax(Att(c^{ctx}, M^k_{1..P}))^T M^v_{1..P} \quad (10)$$

Att is a dot product, but it can be replaced with another attention function. As a result of this operation, the context token representation $c^{ctx}_{s_i}$ and the corresponding retrieved knowledge $c^{kn}_{s_i}$ are in the same vector space $\in \mathbb{R}^{2h}$.

Combine Context and Knowledge $(ctx+kn)$**.** We combine the original context token representation $c^{ctx}_{s_i}$, with the acquired knowledge representation $c^{kn}_{s_i}$ to obtain $c^{ctx+kn}_{s_i}$:

$$c^{ctx+kn}_{s_i} = \gamma c^{ctx}_{s_i} + (1-\gamma) c^{kn}_{s_i} \quad (11)$$

, where $\gamma = 0.5$. We keep γ static but it can be replaced with a gating function.

Answer Prediction: $Q^{ctx(+kn)}$ **to** $D^{ctx(+kn)}$**.** To rank answer candidates $a_1..a_L$ we use attention sum similar to Eq.5 over an attention $\alpha^{ensemble}_{i_j}$ that combines attentions between context (ctx) and context+knowledge ($ctx+kn$) representations of the question ($r^{ctx(+kn)}_q$) and candidate token occurrences a_{i_j} in the document $c^{ctx(+kn)}_{d_j}$:

$$P(a_i|q,d) = softmax(\sum \alpha^{ensemble}_{i_j}) \quad (12)$$

$$\alpha^{ensemble}_{i_j} = \begin{array}{r} W_1 Att(r^{ctx}_q, c^{ctx}_{d_j}) \\ +W_2 Att(r^{ctx}_q, c^{ctx+kn}_{d_j}) \\ +W_3 Att(r^{ctx+kn}_q, c^{ctx}_{d_j}) \\ +W_4 Att(r^{ctx+kn}_q, c^{ctx+kn}_{d_j}) \end{array} \quad (13)$$

, where j is an index pointer from the list of indices that point to the candidate a_i token occurrences in the document context representation $c^{ctx(+kn)}_d$. $W_{1..4}$ are scalar weights initialized with 1.0 and optimized during training.[4] We propose the combination of ctx and $ctx + kn$ attentions because our task does not provide supervision whether the knowledge is needed or not.

[3]The 0 in w^{rel}_0 indicates that we encode the relation as a single *relation type* word. Ex. */r/IsUsedFor*.

[4]An example for learned $W_{1..4}$ is (2.13, 1.41, 1.49, 1.84) in setting (CBT CN, CN5Sel, Subj-Obj as k-v, 50 facts).

Table 1: Characteristics of Children Book Test datasets. CN: *Common Nouns*, NE: *Named Entities*. Cells for *Train, Dev, Test* show overall numbers of examples and average story size in tokens.

3 Data and Task Description

We experiment with knowledge-enhanced cloze-style reading comprehension using the *Common Nouns* and *Named Entities* partitions of the Children's Book Test (CBT) dataset (Hill et al., 2015).

In the CBT cloze-style task a system is asked to read a children story context of 20 sentences. The following 21st sentence involves a placeholder token that the system needs to predict, by choosing from a given set of 10 candidate words from the document. An example with suggested external knowledge facts is given in Figure 1. While in its *Common Nouns* setup, the task can be considered as a language modeling task, Hill et al. (2015) show that humans can answer the questions without the full context with an accuracy of only *64.4%* and a language model alone with *57.7%*. By contrast, the human performance when given the full context is at *81.6%*. Since the best neural model (Munkhdalai and Yu, 2016) achieves only *72.0%* on the task, we hypothesize that the task itself can benefit from external knowledge. The characteristics of the data are shown in Table 1.

Other popular cloze-style datasets such as CNN/Daily Mail (Hermann et al., 2015) or WhoDidWhat (Onishi et al., 2016) are mainly focused on finding *Named Entities* where the benefit of adding commonsense knowledge (as we show for the *NE* part of CBT) would be more limited.

Knowledge Source. As a source of commonsense knowledge we use the *Open Mind Common Sense* part of ConceptNet 5.0 that contains 630k fact triples. We refer to this entire source as *CN5All*. We conduct experiments with subparts of this data: *CN5WN3* which is the WordNet 3 part of *CN5All* (213k triples) and *CN5Sel*, which excludes the following WordNet relations: *RelatedTo, IsA, Synonym, SimilarTo, HasContext*.

4 Related Work

Cloze-Style Reading Comprehension. Following the original MCTest (Richardson et al., 2013) dataset multiple-choice version of cloze-style RC) recently several large-scale, automatically generated datasets for cloze-style reading comprehension gained a lot of attention, among others the 'CNN/Daily Mail' (Hermann et al., 2015; Onishi et al., 2016) and the Children's Book Test (CBTest) data set (Hill et al., 2015). Early work introduced simple but good *single turn models* (Hermann et al., 2015; Kadlec et al., 2016; Chen et al., 2016), that read the document once with the question representation 'in mind' and select an answer from a given set of candidates. More complex models (Weston et al., 2015; Dhingra et al., 2017; Cui et al., 2017; Munkhdalai and Yu, 2016; Sordoni et al., 2016) perform *multi-turn reading* of the story context and the question, before inferring the correct answer or use features (GA Reader, Dhingra et al. (2017). Performing multiple hops and *modeling a deeper relation between question and document* was further developed by several models (Seo et al., 2017; Xiong et al., 2016; Wang et al., 2016, 2017; Shen et al., 2016) on another generation of RC datasets, e.g. SQuAD (Rajpurkar et al., 2016), NewsQA (Trischler et al., 2017) or TriviaQA (Joshi et al., 2017).

Integrating Background Knowledge in Neural Models. Integrating background knowledge in a neural model was proposed in the *neural-checklist model* by Kiddon et al. (2016) for text generation of recipes. They copy words from a list of ingredients instead of inferring the word from a global vocabulary. Ahn et al. (2016) proposed a language model that copies fact attributes from a topic knowledge memory. The model predicts a fact in the knowledge memory using a gating mechanism and given this fact, the next word to be selected is copied from the fact attributes. The knowledge facts are encoded using embeddings obtained using *TransE* (Bordes et al., 2013). Yang et al. (2017) extended a *seq2seq* model with attention to external facts for dialogue and recipe generation and a co-reference resolution-aware language model. A similar model was adopted by He et al. (2017) for answer generation in dialogue. Incorporating external knowledge in a neural model has proven beneficial for several other tasks: Yang and Mitchell (2017) incorporated knowledge directly into the *LSTM* cell state to improve event and entity extraction. They used knowledge embeddings trained on WordNet (Miller et al., 1990) and NELL (Mitchell et al., 2015) using the *BILINEAR* (Yang et al., 2014) model.

Work similar to ours is by Long et al. (2017), who have introduced a new task of Rare Entity Prediction. The task is to read a paragraph from WikiLinks (Singh et al., 2012) and to fill a blank field in place of a missing entity. Each missing entity is characterized with a short description derived from Freebase, and the system needs to choose one from a set of pre-selected candidates to fill the field. While the task is superficially similar to cloze-style reading comprehension, it differs considerably: first, when considering the text without the externally provided entity information, it is clearly ambiguous. In fact, the task is more similar to Entity Linking tasks in the Knowledge Base Population (KBP) tracks at TAC 2013-2017, which aim at detecting specific entities from Freebase. Our work, by contrast, examines the impact of injecting external knowledge in a reading comprehension, or NLU task, where the knowledge is drawn from a commonsense knowledge base, ConceptNet in our case. Another difference is that in their setup, the reference knowledge for the candidates is explicitly provided as a single, fixed set of knowledge facts (the entity description), encoded in a single representation. In our work, we are retrieving (typically) distinct sets of knowledge facts that might (or might not) be relevant for understanding the story and answering the question. Thus, in our setup, we crucially depend on the ability of the attention mechanism to retrieve relevant pieces of knowledge. Our aim is to examine to what extent commonsense knowledge can contribute to and improve the cloze-style RC task, that in principle is supposed to be solvable without explicitly given additional knowledge. We show that by integrating external commonsense knowledge we achieve clear improvements in reading comprehension performance over a strong baseline, and thus we can speculate that humans, when solving this RC task, are similarly using commonsense knowledge as implicitly understood background knowledge.

Recent unpublished work in Weissenborn et al. (2017) is driven by similar intentions. The authors exploit knowledge from ConceptNet to improve the performance of a reading comprehension model, experimenting on the recent SQuAD (Rajpurkar et al., 2016) and TriviaQA (Joshi et al., 2017) datasets. While the source of the background knowledge is the same, the way of integrating this knowledge into the model and task is different. (i) We are using attention to select unordered fact triples using key-value retrieval and (ii) we integrate the knowledge that is considered relevant explicitly for each token in the context. The model of Weissenborn et al. (2017), by contrast, explicitly reads the acquired additional knowledge sequentially after reading the document and question, but transfers the background knowledge implicitly, by refining the word embeddings of the words in the document and the question with the words from the supporting knowledge that share the same lemma. In contrast to the implicit knowledge transfer of Weissenborn et al. (2017), our explicit attention over external knowledge facts can deliver insights about the used knowledge and how it interacts with specific context tokens (see Section 6).

5 Experiments and Results

We perform quantitative analysis through experiments. We study the impact of the used knowledge and different model components that employ the external knowledge. Some of the experiments below focus only on the *Common Nouns (CN)* dataset, as it has been shown to be more challenging than *Named Entities (NE)* in prior work.

5.1 Model Parameters

We experiment with different model parameters.

Number of facts. We explore different sizes of knowledge memories, in terms of number of acquired facts. If not stated otherwise, we use 50 facts per example.

Key-Value Selection Strategy. We use two strategies for defining key and value (Key/Value): *Subj/Obj* and *Obj/Obj*, where *Subj* and *Obj* are the subject and object attributes in the fact triples and they are selected as *Key* and *Value* for the KV memory *(see Section 2.2, Querying the Knowledge Memory)*. If not stated otherwise, we use the *Subj/Obj* strategy.

Answer Selection Components. If not stated otherwise, we use ensemble attention $\alpha_{ensemble}$ (combinations of *ctx* and *ctx+kn*) to rank the answers. We call this our *Full model* (see Sec. 2.2).

Source	Dev	Test
CN5All	71.40	66.72
CN5WN3 (WN3)	70.70	68.48
CN5Sel(ected)	**71.85**	67.64

Table 2: Results with different knowledge sources, for CBT-CN (Full model, 50 facts).

# facts	50	100	200	500
Dev	**71.85**	71.35	71.40	71.20
Test	67.64	67.44	**68.12**	67.24

Table 3: Results for CBT (CN) with different numbers of facts. (Full model, CN5Sel)

Hyper-parameters. For our experiments we use pre-trained Glove (Pennington et al., 2014) embeddings, *BiGRU* with hidden size 256, batch size of 64 and learning reate of 0.001 as they were shown (Kadlec et al., 2016) to perform good on the AS Reader.

5.2 Empirical Results

We perform experiments with the different model parameters described above. We report accuracy on the *Dev* and *Test* and use the results on *Dev* set for pruning the experiments.

Knowledge Sources. We experiment with different configuration of *ConceptNet* facts (see Section 3). Results on the *CBT CN* dataset are shown in Table 2. *CN5Sel* works best on the *Dev* set but *CN5WN3* works much better on *Test*. Further experiments use the *CN5Sel* setup.

Number of facts. We further experiment with different numbers of facts on the *Common Nouns* dataset (Table 3). The best result on the *Dev* set is for 50 facts so we use it for further experiments.

Component ablations. We ensemble the attentions from different combinations of the interaction between the question and document *context (ctx)* representations and *context+knowledge (ctx+kn)* representations in order to infer the right answer (see Section 2.2, Answer Ranking).

Table 4 shows that the combination of different interactions between *ctx* and *ctx+kn* representations leads to clear improvement over the *w/o knowledge* setup, in particular for the *Common Nouns* dataset. We also performed ablations for a model with 100 facts (see *Supplement*).

Key-Value Selection Strategy. Table 5 shows that for the *NE* dataset, the two strategies perform equally well on the *Dev* set, whereas the *Subj/Obj* strategy works slightly better on the *Test* set. For *Common Nouns*, *Subj/Obj* is better.

	NE		CN	
D_{repr} to Q_{repr} **interaction**	**Dev**	**Test**	**Dev**	**Test**

Table 6: Comparison of KnReader to existing end-to-end neural models on the benchmark datasets.

Comparison to Previous Work. Table 6 compares our model (*Knowledgeable Reader*) to previous work on the CBT datasets. We show the results of our model with the settings that performed best on the *Dev* sets of the two datasets *NE* and *CN*: for *NE*, (D_{ctx+kn}, Q_{ctx}) with 100 facts; for *CN* the *Full model* with *50 facts*, both with *CN5Sel*.

Note that our work focuses on the impact of external knowledge and employs a *single inter-*

action (single-hop) between the document context and the question so we primarily compare to and aim at improving over similar models. *KnReader* clearly outperforms prior single-hop models on both datasets. While we do not improve over the state of the art, our model stands well among other models that perform multiple hops. In the *Supplement* we also give comparison to ensemble models and some models that use re-ranking strategies.

6 Discussion and Analysis

6.1 Analysis of the empirical results.

Our experiments examined key parameters of the KnReader. As expected, injection of background knowledge yields only small improvements over the baseline model for *Named Entities*. However, on this dataset our single-hop model is competitive to most multi-hop neural architectures.

The integration of knowledge clearly helps for the *Common Nouns* task. The impact of knowledge sources (Table 2) is different on the *Dev* and *Test* sets which indicates that either the model or the data subsets are sensitive to different knowledge types and retrieved knowledge. Table 5 shows that attending over the *Subj* of the knowledge triple is slightly better than *Obj*. This shows that using a *Key-Value* memory is valuable. A reason for lower performance of *Obj/Obj* is that the model picks facts that are similar to the candidate tokens, not adding much new information. From the empirical results we see that training and evaluation with less facts is slightly better. We hypothesize that this is related to the lack of supervision on the retrieved and attended knowledge.

6.2 Interpreting Component Importance

Figure 3 shows the impact on prediction accuracy of individual components of the *Full model*, including the interaction between D and Q with ctx or $ctx + kn$ (w/o ctx-only). The values for each component are obtained from the attention weights, without retraining the model. The difference between blue (left) and orange (right) values indicates how much the module contributes to the model. Interestingly, the ranking of the contribution ($D_{ctx}, Q_{ctx+kn} > D_{ctx+kn}, Q_{ctx} > D_{ctx+kn}$, Q_{ctx+kn}) corresponds to the component importance ablation on the Dev set, lines 5-8, Table 4.

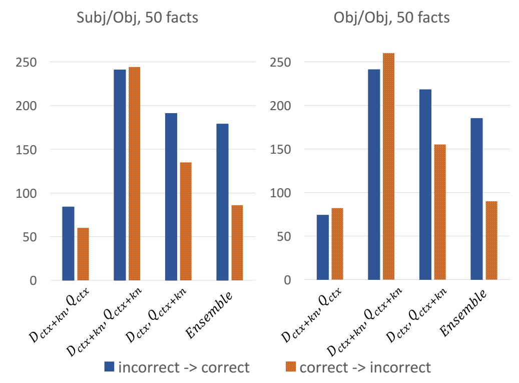

Figure 3: # of items with reversed prediction (±correct) for each combination of (*ctx+kn*, *ctx*) for Q and D. We report the number of *wrong* → *correct* (blue) and *correct* → *wrong* (orange) changes when switching from score w/o knowledge to score w/ knowledge. The best model type is *Ensemble*. (*Full model w/o* D_{ctx}, Q_{ctx}).

6.3 Qualitative Data Investigation

We will use the attention values of the interactions between $D_{ctx(+kn)}$ and $Q_{ctx(+kn)}$ and attentions to facts from each candidate token and the question placeholder to interpret how knowledge is employed to make a prediction for a single example.

Method: Interpreting Model Components. We manually inspect examples from the evaluation sets where *KnReader* improves prediction (blue (left) category, Fig. 3) or makes the prediction worse (orange (right) category, Fig. 3). Figure 4 shows the question with placeholder, followed by answer candidates and their associated attention weights as assigned by the model *w/o knowledge*. The matrix shows selected facts and their assigned weights for the question and the candidate tokens. Finally, we show the attention weights determined by the knowledge-enhanced D to Q interactions. The attention to the correct answer (*head*) is low when the model considers the text alone (*w/o knowledge*). When adding retrieved knowledge to the Q only (row $ctx, ctx + kn$) and to both Q and D (row $ctx + kn, ctx + kn$) the score improves, while when adding knowledge to D alone (row $ctx + kn, ctx$) the score remains ambiguous. The combined score *Ensemble* (see Eq. 13) then takes the final decision for the answer. In this example, the question can be answered without the story. The model tries to find knowledge that is related to *eyes*. The fact *eyes /r/PartOf head* is not contained in the retrieved knowledge but in-

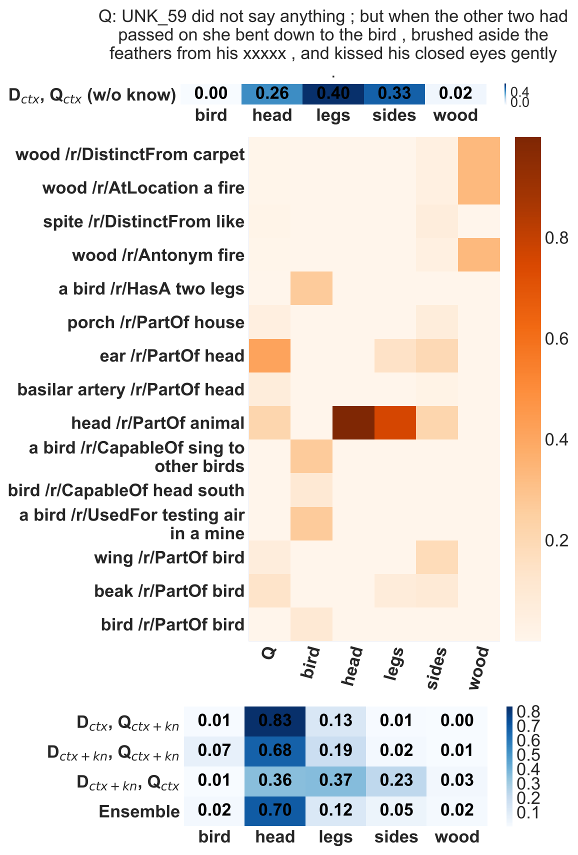

Figure 4: Interpreting the components of *KnReader*. Adding knowledge to Q and D increases the score for the correct answer. Results for top 5 candidates are shown. (*Full model, CN data, CN5Sel, Subj/Obj, 50 facts*)

stead the model selects the fact *ear /r/PartOf head* which receives the highest attention from Q. The weighted *Obj* representation (*head*) is added to the question with the highest weight, together with *animal* and *bird* from the next highly weighted facts This results in a high score for the Q_{ctx} to D_{ctx+kn} interaction with candidate *head*. See *Supplement for more details*.

Using the method described above, we analyze several example cases (presented in *Supplement*) that highlight different aspects of our model. Here we summarize our observations.

(i.) Answer prediction from Q or Q+D. In both human and machine RC, questions can be answered based on the question alone (Figure 4) or jointly with the story context (Case 2, *Suppl.*). We show that empirically, enriching the question with knowledge is crucial for the first type, while enrichment of Q and D is required for the second.

(ii.) Overcoming frequency bias.. We show that when appropriate knowledge is available and selected, the model is able to correct a frequency bias towards an incorrect answer (Cases 1 and 3).

(iii.) Providing appropriate knowledge. We observe a lack of knowledge regarding events (e.g. *take off* vs. *put on clothes*, Case 2; *climb up*, Case 5). Nevertheless relevant knowledge from CN5 can help predicting infrequent candidates (Case 2).

(iv.) Knowledge, Q and D encoding. The context encoding of facts allows the model to detect knowledge that is semantically related, but not surface near to phrases in Q and D (Case 2). The model finds facts to non-trivial paraphrases (e.g. *undressed–naked*, Case 2).

7 Conclusion and Future Work

We propose a neural cloze-style reading comprehension model that incorporates external commonsense knowledge, building on a single-turn neural model. Incorporating external knowledge improves its results with a relative error rate reduction of 9% on *Common Nouns*, thus the model is able to compete with more complex RC models. We show that the types of knowledge contained in ConceptNet are useful. We provide quantitative and qualitative evidence of the effectiveness of our model, that learns how to select relevant knowledge to improve RC. The attractiveness of our model lies in its *transparency and flexibility*: due to the attention mechanism, we can trace and analyze the facts considered in answering specific questions. This opens up for deeper investigation and future improvement of RC models in a targeted way, allowing us to investigate what knowledge sources are required for different data sets and domains. Since our model directly integrates background knowledge with the document and questioncontext representations, it can be adapted to very different task settings where we have a pair of two arguments (i.e. *entailment*, *question answering, etc.*) In future work, we will investigate even tighter integration of the attended knowledge and stronger reasoning methods.

Acknowledgments

This work has been supported by the German Research Foundation as part of the Research Training Group Adaptive Preparation of Information from Heterogeneous Sources (AIPHES) under grant No. GRK 1994/1. We thank the reviewers for their helpful questions and comments.

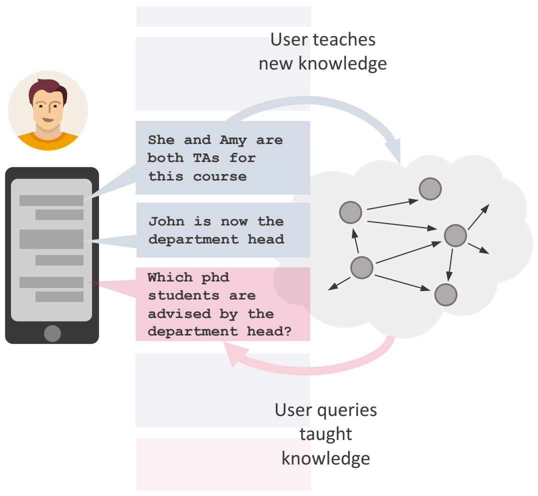
Abstract

Question Answering (QA), as a research field, has primarily focused on either knowledge bases (KBs) or free text as a source of knowledge. These two sources have historically shaped the kinds of questions that are asked over these sources, and the methods developed to answer them. In this work, we look towards a practical use-case of *QA over user-instructed knowledge* that uniquely combines elements of both *structured QA* over knowledge bases, and *unstructured QA* over narrative, introducing the task of *multi-relational QA over personal narrative*. As a first step towards this goal, we make three key contributions: (i) we generate and release TEXTWORLDSQA, a set of five diverse datasets, where each dataset contains dynamic narrative that describes entities and relations in a simulated world, paired with variably compositional questions over that knowledge, (ii) we perform a thorough evaluation and analysis of several state-of-the-art QA models and their variants at this task, and (iii) we release a lightweight Python-based framework we call TEXTWORLDS for easily generating arbitrary additional worlds and narrative, with the goal of allowing the community to create and share a growing collection of diverse worlds as a test-bed for this task.

1 Introduction

Personal devices that interact with users via natural language conversation are becoming ubiquitous (e.g., Siri, Alexa), however, very little of that conversation today allows the user to teach, and then query, new knowledge. Most of the focus in these personal devices has been on Question Answering (QA) over general world-knowledge (e.g., *“who was the president in 1980”* or *“how many ounces are in a cup”*). These devices open a new and exciting possibility of enabling end-users to teach machines in natural language, e.g., by expressing the state of their personal world to its virtual assistant (e.g., via narrative about people and events in that user’s life) and enabling the user to ask questions over that personal knowledge (e.g., *“which engineers in the QC team were involved in the last meeting with the director?”*).



User teaches new knowledge
She and Amy are both TAs for this course
John is now the department head
Which phd students are advised by the department head?
User queries taught knowledge

Figure 1: Illustration of our task: relational question answering from dynamic knowledge expressed via personal narrative

This type of questions highlight a unique blend of two conventional streams of research in Question Answering (QA) – QA over *structured* sources such as knowledge bases (KBs), and QA over *unstructured* sources such as free text. This blend is a natural consequence of our problem setting: (i) users may choose to express rich relational knowledge about their world, in turn enabling them to pose complex **composi-**

Academic Department World

```
1. There is an associate professor named Andy
2. He returned from a sabbatical
3. This professor currently has funding
4. There is a masters level course called G301
5. That course is taught by him
6. That class is part of the mechanical
   engineering department
7. Roslyn is a student in this course
8. U203 is a undergraduate level course
9. Peggy and that student are TAs for this
   course

Figure 2: Illustrative snippets from two sample worlds. We aim to generate natural-sounding first-person narratives from five diverse worlds, covering a range of different events, entities and relations.

tional queries (e.g., *"all CS undergrads who took my class last semester"*), while at the same time (ii) personal knowledge generally evolves through time and has an open and growing set of relations, making natural language the only practical interface for creating and maintaining that knowledge by non-expert users. In short, the task that we address in this work is: **multi-relational question answering from dynamic knowledge expressed via narrative**.

Although we hypothesize that question-answering over personal knowledge of this sort is ubiquitous (e.g., between a professor and their administrative assistant, or even if just in the user's head), such interactions are rarely recorded, presenting a significant practical challenge to collecting a sufficiently large real-world dataset of this type. At the same time, we hypothesize that the technical challenges involved in developing models for relational question answering from narrative would not be fundamentally impacted if addressed via sufficiently rich, but controlled simulated narratives. Such simulations also offer the advantage of enabling us to directly experiment with stories and queries of different complexity, potentially offering additional insight into the fundamental challenges of this task.

While our problem setting blends the problems of relational question answering over knowledge bases and question answering over text, our hypothesis is that end-to-end QA models may learn to answer such multisentential relational queries, without relying on an intermediate knowledge base representation. In this work, we conduct an extensive evaluation of a set of state-of-the-art end-to-end QA models on our task and analyze their results.

2 Related Work

Question answering has been mainly studied in two different settings: KB-based and text-based. KB-based QA mostly focuses on parsing questions to logical forms (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2012; Berant et al., 2013; Kwiatkowski et al., 2013; Yih et al., 2015) in order to better retrieve answer candidates from a knowledge base. Text-based QA aims to directly answer questions from the input text. This includes works on early information retrieval-based methods (Banko et al., 2002; Ahn et al., 2004) and methods that build on extracted structured representations from both the question and the input text (Sachan et al., 2015; Sachan and Xing, 2016; Khot et al., 2017; Khashabi et al., 2018b). Although these structured presentations make reasoning more effective, they rely on sophisticated

NLP pipelines and suffer from error propagation. More recently, end-to-end neural architectures have been successfully applied to text-based QA, including Memory-augmented neural networks (Sukhbaatar et al., 2015; Miller et al., 2016; Kumar et al., 2016) and attention-based neural networks (Hermann et al., 2015; Chen et al., 2016; Kadlec et al., 2016; Dhingra et al., 2017; Xiong et al., 2017; Seo et al., 2017; Chen et al., 2017). In this work, we focus on QA over text (where the text is generated from a supporting KB) and evaluate several state-of-the-art memory-augmented and attention-based neural architectures on our QA task. In addition, we consider a sequence-to-sequence model baseline (Bahdanau et al., 2015), which has been widely used in dialog (Vinyals and Le, 2015; Ghazvininejad et al., 2017) and recently been applied to generating answer values from Wikidata (Hewlett et al., 2016).

There are numerous datasets available for evaluating the capabilities of QA systems. For example, MCTest (Richardson et al., 2013) contains comprehension questions for fictional stories. Allen AI Science Challenge (Clark, 2015) contains science questions that can be answered with knowledge from text books. RACE (Lai et al., 2017) is an English exam dataset for middle and high school Chinese students. MULTIRC (Khashabi et al., 2018a) is a dataset that focuses on evaluating multi-sentence reasoning skills. These datasets all require humans to carefully design multiple-choice questions and answers, so that certain aspects of the comprehension and reasoning capabilities are properly evaluated. As a result, it is difficult to collect them at scale. Furthermore, as the knowledge required for answering each question is not clearly specified in these datasets, it can be hard to identify the limitations of QA systems and propose improvements.

Weston et al. (2015) proposes to use synthetic QA tasks (the BABI dataset) to better understand the limitations of QA systems. BABI builds on a simulated physical world similar to interactive fiction (Montfort, 2005) with simple objects and relations and includes 20 different reasoning tasks. Various types of end-to-end neural networks (Sukhbaatar et al., 2015; Lee et al., 2015; Peng et al., 2015) have demonstrated promising accuracies on this dataset. However, the performance can hardly translate to real-world QA datasets, as BABI uses a small vocabulary (150 words) and short sentences with limited language variations (e.g., nesting sentences, coreference). A more sophisticated QA dataset with a supporting KB is WIKIMOVIES (Miller et al., 2016), which contains 100k questions about movies, each of them is answerable by using either a KB or a Wikipedia article. However, WIKIMOVIES is highly domain-specific, and similar to BABI, the questions are designed to be in simple forms with little compositionality and hence limit the difficulty level of the tasks.

Our dataset differs in the above datasets in that (i) it contains five different realistic domains permitting cross-domain evaluation to test the ability of models to generalize beyond a fixed set of KB relations, (ii) it exhibits rich referring expressions and linguistic variations (vocabulary much larger than the BABI dataset), (iii) questions in our dataset are designed to be deeply compositional and can cover multiple relations mentioned across multiple sentences.

Other large-scale QA datasets include Cloze-style datasets such as CNN/Daily Mail (Hermann et al., 2015), Children's Book Test (Hill et al., 2015), and Who Did What (Onishi et al., 2016); datasets with answers being spans in the document, such as SQuAD (Rajpurkar et al., 2016), NewsQA (Trischler et al., 2016), and TriviaQA (Joshi et al., 2017); and datasets with human generated answers, for instance, MS MARCO (Nguyen et al., 2016) and SearchQA (Dunn et al., 2017). One common drawback of these datasets is the difficulty in accessing a system's capability of integrating information across a document context. Kočiskỳ et al. (2017) recently emphasized this issue and proposed NarrativeQA, a dataset of fictional stories with questions that reflect the complexity of narratives: characters, events, and evolving relations. Our dataset contains similar narrative elements, but it is created with a supporting KB and hence it is easier to analyze and interpret results in a controlled setting.

3 TEXTWORLDS: Simulated Worlds for Multi-Relational QA from Narratives

In this work, we synthesize narratives in five diverse worlds, each containing a thousand narratives and where each narrative describes the evolution of a simulated user's world from a first-person perspective. In each narrative, the simulated user may introduce new knowledge, update existing knowledge or express a state change (e.g., *"Homework 3 is now due on Friday"* or *"Samantha passed her thesis defense"*). Each narrative is interleaved with questions about the current state of the world, and questions range in complexity depending on the amount of knowledge that needs to be integrated to answer them. This allows us to benchmark a range of QA models at their ability to answer questions that require different extents of relational reasoning to be answered.

The set of worlds that we simulate as part of this work are as follows:

1. MEETING WORLD: This world describes situations related to professional meetings, e.g., meetings being set/cancelled, people attending meetings, topics of meetings.

2. HOMEWORK WORLD: This world describes situations from the first-person perspective of a student, e.g., courses taken, assignments in different courses, deadlines of assignments.

3. SOFTWARE ENGINEERING WORLD: This world describes situations from the first-person perspective of a software development manager, e.g., task assignment to different project team members, stages of software development, bug tickets.

4. ACADEMIC DEPARTMENT WORLD: This world describes situations from the first-person perspective of a professor, e.g., teaching assignments, faculty going/returning from sabbaticals, students from different departments taking/dropping courses.

5. SHOPPING WORLD: This world describes situations about a person shopping for various occasions, e.g., adding items to a shopping list, purchasing items at different stores, noting where items are on sale.

3.1 Narrative

Each world is represented by a set of entities $\mathcal{E}$ and a set of unary, binary or ternary relations $\mathcal{R}$. Formally, a single step in one simulation of a world involves a combination of instantiating new entities and defining new (or mutating existing) relations between entities. Practically, we implement each world as a collection of classes and methods, with each step of the simulation creating or mutating class instances by sampling entities and methods on those entities. By design, these classes and methods are easy to extend, to either enrich existing worlds or create new ones. Each simulation step is then expressed as a natural language statement, which is added to the narrative. In the process of generating a natural language expression, we employ a rich mechanism for generating anaphora, such as *"meeting with John about the performance review"* and *"meeting that I last added"*, in addition to simple pronoun references. This allows us to generate more natural and flowing narratives. These references are generated and composed automatically by the underlying TEXTWORLDS framework, significantly reducing the effort needed to build new worlds. Furthermore, all generated stories also provide additional annotation that maps all entities to underlying gold-standard KB ids, allowing to perform experiments that provide models with different degrees of access to the "simulation oracle".

Statistics	Value
# of total stories	5,000
# of total questions	1,207,022
Avg. # of entity mentions (per story)	217.4
Avg. # of correct answers (per question)	8.7
Avg. # of statements in stories	100
Avg. # of tok. in stories	837.5
Avg. # of tok. in questions	8.9
Avg. # of tok. in answers	1.5
Vocabulary size (tok.)	1,994
Vocabulary size (entity)	10,793

Table 1: TEXTWORLDSQA dataset statistics

We generate 1,000 narratives within each world, where each narrative consists of 100 sentences, plus up to 300 questions interleaved randomly within the narrative. See Figure 1 for two example narratives. Each story in a given world samples its entities from a large general pool of entity names collected from the web (e.g., *people names*, *university names*). Although some entities do overlap between stories, each story in a given world contains a unique flow of events and entities involved in those events. See Table 1 for the data statistics.

3.2 Questions

Formally, questions are queries over the knowledge-base in the state defined up to the point when the question is asked in the narrative. In the narrative, the questions are expressed

Dataset	**Questions**			
	Single Entity/Relation	Multiple entities		
		Single relation	Two relations	Three relations
MEETING	57,590 (41.16%)	46,373 (33.14%)	30,391 (21.72%)	5,569 (3.98%)
HOMEWORK	45,523 (24.10%)	17,964 (9.51%)	93,669 (49.59%)	31,743 (16.80%)
SOFTWARE	47,565 (20.59%)	51,302 (22.20%)	66,026 (28.58%)	66,150 (28.63%)
ACADEMIC	46,965 (24.81%)	54,581 (28.83%)	57,814 (30.53%)	29,982 (15.83%)
SHOPPING	111,522 (26.25%)	119,890 (28.22%)	107,418 (25.29%)	85,982 (20.24%)
All	309,165 (26.33%)	290,110 (24.71%)	355,318 (30.27%)	219,426 (18.69%)

Table 2: Dataset statistics by question type.

in natural language, employing the same anaphora mechanism used in generating the narrative (e.g., *"who is attending the last meeting I added?"*).

We categorize generated questions into four types, reflecting the number and types of facts required to answer them; questions that require more facts to answer are typically more compositional in nature. We categorize each question in our dataset into one of the following four categories:

Single Entity/Single Relation Answers to these questions are a single entity, e.g. *"what is John's email address?"*, or expressed in lambda-calculus notation:

$$\lambda x.\texttt{EmailAddress}(\texttt{John}, x)$$

The answers to these questions are found in a single sentence in the narrative, although it is possible that the answer may change through the course of the narrative (e.g., *"John's new office is GHC122"*).

Multi-Entity/Single Relation Answers to these questions can be multiple entities but involve a single relation, e.g., *"Who is enrolled in the Math class?"*, or expressed in lambda calculus notation:

$$\lambda x.\texttt{TakingClass}(x, \texttt{Math})$$

Unlike the previous category, answers to these questions can be sets of entities.

Multi-Entity/Two Relations Answers to these questions can be multiple entities and involve two relations, e.g., *"Who is enrolled in courses that I am teaching?"*, or expressed in lambda calculus:

$$\lambda x.\exists y.\texttt{EnrolledInClass}(x, y) \\ \wedge \texttt{CourseTaughtByMe}(y)$$

Multi-Entity/Three Relations Answers to these questions can be multiple entities and involve three relations, e.g., *"Which undergraduates are enrolled in courses that I am teaching?"*, or expressed in lambda calculus notation:

$$\lambda x.\exists y.\texttt{EnrolledInClass}(x, y) \\ \wedge \texttt{CourseTaughtByMe}(y) \\ \wedge \texttt{Undergrad}(x)$$

In the data that we generate, answers to questions are always sets of spans in the narrative (the reason for this constraint is for easier evaluation of several existing machine-reading models; this assumption can easily be relaxed in the simulation). In all of our evaluations, we will partition our results by one of the four question categories listed above, which we hypothesize correlates with the difficulty of a question.

4 Methods

We develop several baselines for our QA task, including a logistic regression model and four different neural network models: Seq2Seq (Bahdanau et al., 2015), MemN2N (Sukhbaatar et al., 2015), BiDAF (Seo et al., 2017), and DrQA (Chen et al., 2017). These models generate answers in different ways, e.g., predicting a single entity, predicting spans of text, or generating answer sequences. Therefore, we implement two experimental settings: ENTITY and RAW. In the ENTITY setting, given a question and a story, we treat all the entity spans in the story as candidate answers, and the prediction task becomes a classification problem. In the RAW setting, a model needs to predict the answer spans. For logistic regression and MemN2N, we adopt the ENTITY setting as they are naturally classification models. This ideally provides an upper bound on the performance when considering answer candidate generation. For all the other models, we can apply the RAW setting.

4.1 Logistic Regression

The logistic regression baseline predicts the likelihood of an answer candidate being a true answer.

For each answer candidate e and a given question, we extract the following features: (1) The frequency of e in the story; (2) The number of words within e; (3) Unigrams and bigrams within e; (4) Each non-stop question word combined with each non-stop word within e; (5) The average minimum distance between each non-stop question word and e in the story; (6) The common words (excluding stop words) between the question and the text surrounding of e (within a window of 10 words); (7) Sum of the frequencies of the common words to the left of e, to the right e, and both. These features are designed to help the model pick the correct answer spans. They have shown to be effective for answer prediction in previous work (Chen et al., 2016; Rajpurkar et al., 2016).

We associate each answer candidate with a binary label indicating whether it is a true answer. We train a logistic regression classifier to produce a probability score for each answer candidate. During test, we search for an optimal threshold that maximizes the F1 performance on the validation data. During training, we optimize the cross-entropy loss using Adam (Kingma and Ba, 2014) with an initial learning rate of 0.01. We use a batch size of $10,000$ and train with 5 epochs. Training takes roughly 10 minutes for each domain on a Titan X GPU.

4.2 Seq2Seq

The seq2seq model is based on the sequence to sequence model presented in (Bahdanau et al., 2015), which includes an attention model. Bahdanau et al. (Bahdanau et al., 2015) have used this model to build a neural based machine translation performing at the state-of-the-art. We adopt this model to fit our own domain by including a preprocessing step in which all statements are concatenated with a dedicated token, while eliminating all previously asked questions, and the current question is added at the end of the list of statements. The answers are treated as a sequence of words. We use word embeddings (Zou et al., 2013), as it was shown to improve accuracy. We use 3 GRU (Cho et al., 2014) connected layers, each with a capacity of 256. Our batch size was set to 16. We use gradient descent with an initial learning rate of 0.5 and a decay factor of 0.99, iterating on the data for $50,000$ steps (5 epochs). The training process for each domain took approximately 48 hours on a Titan X GPU.

4.3 MemN2N

End-To-End Memory Network (MemN2N) is a neural architecture that encodes both long-term and short-term context into a memory and iteratively reads from the memory (i.e., multiple hops) relevant information to answer a question (Sukhbaatar et al., 2015). It has been shown to be effective for a variety of question answering tasks (Weston et al., 2015; Sukhbaatar et al., 2015; Hill et al., 2015).

In this work, we directly apply MemN2N to our task with a small modification. Originally, MemN2N was designed to produce a single answer for a question, so at the prediction layer, it uses softmax to select the best answer from the answer candidates. In order to account for multiple answers for a given question, we modify the prediction layer to apply the logistic function and optimize the cross entropy loss instead. For training, we use the parameter setting as in a publicly available MemN2N [1] except that we set the embedding size to 300 instead of 20. We train the model for 100 epochs and it takes about 2 hours for each domain on a Titan X GPU.

4.4 BiDAF-M

BiDAF (Bidirectional Attention Flow Networks) (Seo et al., 2017) is one of the top-performing models on the span-based question answering dataset SQuAD (Rajpurkar et al., 2016). We reimplement BiDAF with simplified parameterizations and change the prediction layer so that it can predict multiple answer spans.

Specifically, we encode the input story $\{x_1, ..., x_T\}$ and a given question $\{q_1, ..., q_J\}$ at the character level and the word level, where the character level uses CNNs and the word level uses pre-trained word vectors. The concatenation of the character and word embeddings are passed to a bidirectional LSTM to produce a contextual embedding for each word in the story context and in the question. Then, we apply the same bidirectional attention flow layer to model the interactions between the context and question embeddings, producing question-aware feature vectors for each word in the context, denoted as $\mathbf{G} \in \mathbb{R}^{d_g \times T}$. $\mathbf{G}$ is then fed into a bidirectional LSTM layer to obtain a feature matrix $\mathbf{M}_1 \in \mathbb{R}^{d_1 \times T}$ for predicting the start offset of the answer span, and $\mathbf{M}_1$ is then passed into

[1] https://github.com/domluna/memn2n

Within-World	MEETING	HOMEWORK	SOFTWARE	DEPARTMENT	SHOPPING	Avg. F1
Logistic Regression	50.1	55.7	60.9	55.9	61.1	56.7
Seq2Seq	22.5	32.6	16.7	39.1	31.5	28.5
MemN2N	55.4	46.6	69.5	67.3	46.3	57.0

another bidirectional LSTM layer to obtain a feature matrix $\mathbf{M}_2 \in \mathbb{R}^{d_2 \times T}$ for predicting the end offset of the answer span. We then compute two probability scores for each word i in the narrative: $\mathbf{p}^{start} = \text{sigmoid}(\mathbf{w}_1^T[\mathbf{G};\mathbf{M}_1])$ and $\mathbf{p}^{end} = \text{sigmoid}(\mathbf{w}_2^T[\mathbf{G};\mathbf{M}_1;\mathbf{M}_2])$, where $\mathbf{w}_1$ and $\mathbf{w}_2$ are trainable weights. The training objective is simply the sum of cross-entropy losses for predicting the start and end indices.

We use 50 1D filters for CNN character embedding, each with a width of 5. The word embedding size is 300 and the hidden dimension for LSTMs is 128. For optimization, we use Adam (Kingma and Ba, 2014) with an initial learning rate of 0.001, and use a minibatch size of 32 for 15 epochs. The training process takes roughly 20 hours for each domain on a Titan X GPU.

4.5 DrQA-M

DrQA (Chen et al., 2017) is an open-domain QA system that has demonstrated strong performance on multiple QA datasets. We modify the Document Reader component of DrQA and implement it in a similar framework as BiDAF-M for fair comparisons. First, we employ the same character-level and word-level encoding layers to both the input story and a given question. We then use the concatenation of the character and word embeddings as the final embeddings for words in the story and in the question. We compute the aligned question embedding (Chen et al., 2017) as a feature vector for each word in the story and concatenate it with the story word embedding and pass it into a bidirectional LSTM to obtain the contextual embeddings $\mathbf{E} \in \mathbb{R}^{d \times T}$ for words in the story. Another bidirectional LSTM is used to obtain the contextual embeddings for the question, and self-attention is used to compress them into one single vector $\mathbf{q} \in \mathbb{R}^{d}$. The final prediction layer uses a bilinear term to compute scores for predicting the start offset: $\mathbf{p}^{start} = \text{sigmoid}(\mathbf{q}^T\mathbf{W}_1\mathbf{E})$ and another bilinear term for predicting the end offset: $\mathbf{p}^{end} = \text{sigmoid}(\mathbf{q}^T\mathbf{W}_2\mathbf{E})$, where $\mathbf{W}_1$ and $\mathbf{W}_2$ are trainable weights. The training loss is the same as in BiDAF-M, and we use the same parameter setting. Training takes roughly 10 hours for each domain on a Titan X GPU.

5 Experiments

We use two evaluation settings for measuring performance at this task: *within-world* and *across-world*. In the *within-world* evaluation setting, we test on the same world that the model was trained on. We then compute the precision, recall and F_1 for each question and report the macro-average F1 score for questions in each world. In the *across-world* evaluation setting, the model is trained on four out of the five worlds, and tested on the remaining world. The *across-world* regime is obviously more challenging, as it requires the model to be able to learn to generalize to unseen relations and vocabulary. We consider the *across-world* evaluation setting to be the main evaluation criteria for any future models used on this dataset, as it mimics the practical requirement of any QA system used in personal assistants: it has to be able to answer questions on any new domain the user introduces to the system.

5.1 Results

We draw several important observations from our results. First, we observe that more compositional questions (i.e., those that integrate multiple relations) are more challenging for most models - as

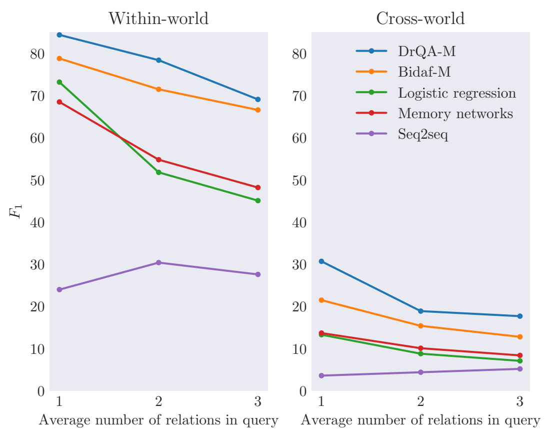

Figure 3: F_1 score breakdown based on the number of relations involved in the questions.

all models (except Seq2seq) decrease in performance with the number of relations composed in a question (Figure 5.1). This can be in part explained by the fact that more composition questions are typically longer, and also require the model to integrate more sources of information in the narrative in order to answer them. One surprising observation from our results is that the performance on questions that ask about a single relation and have only a single answer is lower than questions that ask about a single relation but that can have multiple answers (see detailed results in the Appendix). This is in part because questions that can have multiple answers typically have canonical entities as answers (e.g., person's name), and these entities generally repeat in the text, making it easier for the model to find the correct answer.

Table 3 reports the overall (macro-average) F1 scores for different baselines. We can see that BiDAF-M and DrQA-M perform surprisingly well in the *within-world* evaluation even though they do not use any entity span information. In particular, DrQA-M outperforms BiDAF-M which suggests that modeling question-context interactions using simple bilinear terms have advantages over using more complex bidirectional attention flows. The lower performance of MemN2N suggests that its effectiveness on the BABI dataset does not directly transfer to our dataset. Note that the original MemN2N architecture uses simple bag-of-words and position encoding for sentences. This may work well on dataset with a simple vocabulary, for example, MemN2N performs the best in the SOFTWARE world as the SOFTWARE world has a smaller vocabulary compared to other worlds. In general, we believe that better text representations for questions and narratives can lead to improved performance. Seq2Seq model also did not perform as well. This is due to the inherent difficulty of generation and encoding long sequences. We found that it performs better when training and testing on shorter stories (limited to 30 statements). Interestingly, the logistic regression baseline performs on a par with MemN2N, but there is still a large performance gap to BiDAF-M and DrQA-M, and the gap is greater for questions that compose multiple relations.

In the *across-world* setting, the performance of all methods dramatically decreases.[2] This suggests the limitations of these methods in generalizing to unseen relations and vocabulary. The span-based models BiDAF-M and DrQA-M have an advantage in this setting as they can learn to answer questions based on the alignment between the question and the narrative. However, the low performance still suggests their limitations in transferring question answering capabilities.

6 Conclusion

In this work, we have taken the first steps towards the task of multi-relational question answering expressed through personal narrative. Our hypothesis is that this task will become increasingly important as users begin to teach personal knowledge about their world to the personal assistants embedded in their devices. This task naturally synthesizes two main branches of question answering research: QA over KBs and QA over free text. One of our main contributions is a collection of diverse datasets that feature rich compositional questions over a dynamic knowledge graph expressed through simulated narrative. Another contribution of our work is a thorough set of experiments and analysis of different types of end-to-end architectures for QA at their ability to answer multi-relational questions of varying degrees of compositionality. Our long-term goal is that both the data and the simulation code we release will inspire and motivate the community to look towards the vision of letting end-users teach our personal assistants about the world around us.

[2]In order to allow generalization across different domains for the Seq2Seq model, we replace entities appearing in each story with an id that correlates to their appearance order. After the model outputs its prediction, the entity ids are converted back to the entity phrase.

Simple and Effective Multi-Paragraph Reading Comprehension

Christopher Clark[*]

mattg@allenai.org

Abstract

We introduce a method of adapting neural paragraph-level question answering models to the case where entire documents are given as input. Most current question answering models cannot scale to document or multi-document input, and naively applying these models to each paragraph independently often results in them being distracted by irrelevant text. We show that it is possible to significantly improve performance by using a modified training scheme that teaches the model to ignore non-answer containing paragraphs. Our method involves sampling multiple paragraphs from each document, and using an objective function that requires the model to produce globally correct output. We additionally identify and improve upon a number of other design decisions that arise when working with document-level data. Experiments on TriviaQA and SQuAD shows our method advances the state of the art, including a 10 point gain on TriviaQA.

1 Introduction

Teaching machines to answer arbitrary user-generated questions is a long-term goal of natural language processing. For a wide range of questions, existing information retrieval methods are capable of locating documents that are likely to contain the answer. However, automatically extracting the answer from those texts remains an open challenge. The recent success of neural models at answering questions given a related paragraph (Wang et al., 2017c; Tan et al., 2017) suggests they have the potential to be a key part of a solution to this problem. Most neural models are unable to scale beyond short paragraphs, so typically this requires adapting a paragraph-level model to process document-level input.

There are two basic approaches to this task. Pipelined approaches select a single paragraph from the input documents, which is then passed to the paragraph model to extract an answer (Joshi et al., 2017; Wang et al., 2017a). Confidence based methods apply the model to multiple paragraphs and return the answer with the highest confidence (Chen et al., 2017a). Confidence methods have the advantage of being robust to errors in the (usually less sophisticated) paragraph selection step, however they require a model that can produce accurate confidence scores for each paragraph. As we shall show, naively trained models often struggle to meet this requirement.

In this paper we start by proposing an improved pipelined method which achieves state-of-the-art results. Then we introduce a method for training models to produce accurate per-paragraph confidence scores, and we show how combining this method with multiple paragraph selection further increases performance.

Our pipelined method focuses on addressing the challenges that come with training on document-level data. We use a linear classifier to select which paragraphs to train and test on. Since annotating entire documents is expensive, data of this sort is typically distantly supervised, meaning only the answer text, not the answer spans, are known. To handle the noise this creates, we use a summed objective function that marginalizes the model's output over all locations the answer text occurs. We apply this approach with a model design that integrates some recent ideas in reading comprehension models, including self-attention (Cheng et al., 2016) and bi-directional attention (Seo et al., 2016).

[*]Work completed while interning at the Allen Institute for Artificial Intelligence

Our confidence method extends this approach to better handle the multi-paragraph setting. Previous approaches trained the model on questions paired with paragraphs that are known *a priori* to contain the answer. This has several downsides: the model is not trained to produce low confidence scores for paragraphs that do not contain an answer, and the training objective does not require confidence scores to be comparable between paragraphs. We resolve these problems by sampling paragraphs from the context documents, including paragraphs that do not contain an answer, to train on. We then use a shared-normalization objective where paragraphs are processed independently, but the probability of an answer candidate is marginalized over all paragraphs sampled from the same document. This requires the model to produce globally correct output even though each paragraph is processed independently.

We evaluate our work on TriviaQA (Joshi et al., 2017) in the wiki, web, and unfiltered setting. Our model achieves a nearly 10 point lead over published prior work. We additionally perform an ablation study on our pipelined method, and we show the effectiveness of our multi-paragraph methods on a modified version of SQuAD (Rajpurkar et al., 2016) where only the correct document, not the correct paragraph, is known. Finally, we combine our model with a web search backend to build a demonstration end-to-end QA system[1], and show it performs well on questions from the TREC question answering task (Voorhees et al., 1999). We release our code[2] to facilitate future work.

2 Pipelined Method

In this section we propose a pipelined QA system, where a single paragraph is selected and passed to a paragraph-level question answering model.

2.1 Paragraph Selection

If there is a single source document, we select the paragraph with the smallest TF-IDF cosine distance with the question. Document frequencies are computed using the individual paragraphs within the document. If there are multiple input documents, we found it beneficial to use a linear classifier that uses the same TF-IDF score, whether the paragraph was the first in its document, how many tokens preceded it, and the number of question words it includes as features. The classifier is trained on the distantly supervised objective of selecting paragraphs that contain at least one answer span. On TriviaQA web, relative to truncating the document as done by prior work, this improves the chance of the selected text containing the correct answer from 83.1% to 85.1%.

2.2 Handling Noisy Labels

Question: Which British general was killed at Khartoum in 1885?
Answer: Gordon
Context: In February 1885 Gordon returned to the Sudan to evacuate Egyptian forces. Khartoum came under siege the next month and rebels broke into the city, killing Gordon and the other defenders. The British public reacted to his death by acclaiming 'Gordon of Khartoum', a saint. However, historians have suggested that Gordon...

Figure 1: Noisy supervision can cause many spans of text that contain the answer, but are not situated in a context that relates to the question (red), to distract the model from learning from more relevant spans (green).

In a distantly supervised setup we label all text spans that match the answer text as being correct. This can lead to training the model to select unwanted answer spans. Figure 1 contains an example. To handle this difficulty, we use a summed objective function similar to the one from Kadlec et al. (2016), that optimizes the negative log-likelihood of selecting any correct answer span. The models we consider here work by independently predicting the start and end token of the answer span, so we take this approach for both predictions. For example, the objective for predicting the answer start token becomes $-\log\left(\sum_{a\in A} p_a\right)$ where A is the set of tokens that start an answer and p_i is the answer-start probability predicted by the model for token i. This objective has the advantage of being agnostic to how the model distributes probability mass across the possible answer spans, allowing the model to focus on only the most relevant spans.

2.3 Model

We use a model with the following layers (shown in Figure 2):

Embedding: We embed words using pretrained word vectors. We concatenate these with character-derived word embeddings, which are

[1]https://documentqa.allenai.org
[2]https://github.com/allenai/document-qa

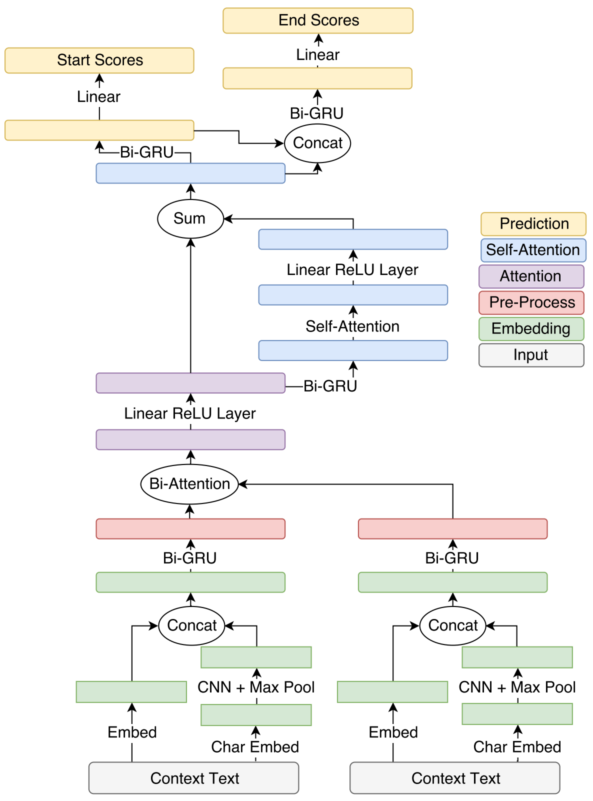

Figure 2: High level outline of our model.

produced by embedding characters using a learned embedding matrix and then applying a convolutional neural network and max-pooling.

Pre-Process: A shared bi-directional GRU (Cho et al., 2014) is used to process the question and passage embeddings.

Attention: The attention mechanism from the Bi-Directional Attention Flow (BiDAF) model (Seo et al., 2016) is used to build a query-aware context representation. Let $\mathbf{h_i}$ and $\mathbf{q_j}$ be the vector for context word i and question word j, and n_q and n_c be the lengths of the question and context respectively. We compute attention between context word i and question word j as:

$$a_{ij} = \mathbf{w_1} \cdot \mathbf{h_i} + \mathbf{w_2} \cdot \mathbf{q_j} + \mathbf{w_3} \cdot (\mathbf{h_i} \odot \mathbf{q_j})$$

where $\mathbf{w_1}$, $\mathbf{w_2}$, and $\mathbf{w_3}$ are learned vectors and $\odot$ is element-wise multiplication. We then compute an attended vector $\mathbf{c_i}$ for each context token as:

$$p_{ij} = \frac{e^{a_{ij}}}{\sum_{j=1}^{n_q} e^{a_{ij}}} \qquad \mathbf{c_i} = \sum_{j=1}^{n_q} \mathbf{q_j} p_{ij}$$

We also compute a query-to-context vector $\mathbf{q_c}$:

$$m_i = \max_{1 \leq j \leq n_q} a_{ij}$$

$$p_i = \frac{e^{m_i}}{\sum_{i=1}^{n_c} e^{m_i}} \qquad \mathbf{q_c} = \sum_{i=1}^{n_c} \mathbf{h_i} p_i$$

The final vector for each token is built by concatenating $\mathbf{h_i}$, $\mathbf{c_i}$, $\mathbf{h_i} \odot \mathbf{c_i}$, and $\mathbf{q_c} \odot \mathbf{c_i}$. In our model we subsequently pass the result through a linear layer with ReLU activations.

Self-Attention: Next we use a layer of residual self-attention. The input is passed through another bi-directional GRU. Then we apply the same attention mechanism, only now between the passage and itself. In this case we do not use query-to-context attention and we set $a_{ij} = -inf$ if $i = j$.

As before, we pass the concatenated output through a linear layer with ReLU activations. The result is then summed with the original input.

Prediction: In the last layer of our model a bi-directional GRU is applied, followed by a linear layer to compute answer start scores for each token. The hidden states are concatenated with the input and fed into a second bi-directional GRU and linear layer to predict answer end scores. The softmax function is applied to the start and end scores to produce answer start and end probabilities.

Dropout: We apply variational dropout (Gal and Ghahramani, 2016) to the input to all the GRUs and the input to the attention mechanisms at a rate of 0.2.

3 Confidence Method

We adapt this model to the multi-paragraph setting by using the un-normalized and un-exponentiated (i.e., before the softmax operator is applied) score given to each span as a measure of the model's confidence. For the boundary-based models we use here, a span's score is the sum of the start and end score given to its start and end token. At test time we run the model on each paragraph and select the answer span with the highest confidence. This is the approach taken by Chen et al. (2017a).

Our experiments in Section 5 show that these confidence scores can be very poor if the model is only trained on answer-containing paragraphs, as done by prior work. Table 1 contains some qualitative examples of the errors that occur.

We hypothesize that there are two key sources of error. First, for models trained with the softmax objective, the pre-softmax scores for all spans can be arbitrarily increased or decreased by a constant value without changing the resulting softmax probability distribution. As a result, nothing prevents models from producing scores that are arbitrarily all larger or all smaller for one paragraph

Question	Low Confidence Correct Extraction	High Confidence Incorrect Extraction
When is the Members Debate held?	**Immediately after Decision Time** a "Members Debate" is held, which lasts for 45 minutes...	...majority of the Scottish electorate voted for it in a referendum to be held on **1 March 1979** that represented at least...

Table 1: Examples from SQuAD where a model was less confident in a correct extraction from one paragraph (left) than in an incorrect extraction from another (right). Even if the passage has no correct answer and does not contain any question words, the model assigns high confidence to phrases that match the category the question is asking about. Because the confidence scores are not well-calibrated, this confidence is often higher than the confidence assigned to correct answer spans in different paragraphs, even when those correct spans have better contextual evidence.

than another. Second, if the model only sees paragraphs that contain answers, it might become too confident in heuristics or patterns that are only effective when it is known *a priori* that an answer exists. For example, the model might become too reliant on selecting answers that match semantic type the question is asking about, causing it be easily distracted by other entities of that type when they appear in irrelevant text. This kind of error has also been observed when distractor sentences are added to the context (Jia and Liang, 2017)

We experiment with four approaches to training models to produce comparable confidence scores, shown in the following subsections. In all cases we will sample paragraphs that do not contain an answer as additional training points.

3.1 Shared-Normalization

In this approach a modified objective function is used where span start and end scores are normalized across all paragraphs sampled from the same context. This means that paragraphs from the same context use a shared normalization factor in the final softmax operations. We train on this objective by including multiple paragraphs from the same context in each mini-batch. The key idea is that this will force the model to produce scores that are comparable between paragraphs, even though it does not have access to information about what other paragraphs are being considered.

3.2 Merge

As an alternative to the previous method, we experiment with concatenating all paragraphs sampled from the same context together during training. A paragraph separator token with a learned embedding is added before each paragraph.

3.3 No-Answer Option

We also experiment with allowing the model to select a special "no-answer" option for each paragraph. First we re-write our objective as:

$$-\log\left(\frac{e^{s_a}}{\sum_{i=1}^{n} e^{s_i}}\right) - \log\left(\frac{e^{g_b}}{\sum_{j=1}^{n} e^{g_j}}\right) =$$

$$-\log\left(\frac{e^{s_a+g_b}}{\sum_{i=1}^{n}\sum_{j=1}^{n} e^{s_i+g_j}}\right)$$

where s_j and g_j are the scores for the start and end bounds produced by the model for token j, and a and b are the correct start and end tokens. We have the model compute another score, z, to represent the weight given to a "no-answer" possibility. Our revised objective function becomes:

$$-\log\left(\frac{(1-\delta)e^{z} + \delta e^{s_a+g_b}}{e^{z} + \sum_{i=1}^{n}\sum_{j=1}^{n} e^{s_i+g_j}}\right)$$

where δ is 1 if an answer exists and 0 otherwise. If there are multiple answer spans we use the same objective, except the numerator includes the summation over all answer start and end tokens.

We compute z by adding an extra layer at the end of our model. We build input vectors by taking the summed hidden states of the RNNs used to predict the start/end token scores weighed by the start/end probabilities, and using a learned attention vector on the output of the self-attention layer.

These vectors are fed into a two layer network with an 80 dimensional hidden layer and ReLU activations that produces z as its only output.

3.4 Sigmoid

As a final baseline, we consider training models with the sigmoid loss objective function. That is, we compute a start/end probability for each token by applying the sigmoid function to the start/end scores of each token. A cross entropy loss is used on each individual probability. The intuition is that, since the scores are being evaluated independently of one another, they are more likely to be comparable between different paragraphs.

4 Experimental Setup

4.1 Datasets

We evaluate our approach on four datasets: TriviaQA unfiltered (Joshi et al., 2017), a dataset of questions from trivia databases paired with documents found by completing a web search of the questions; TriviaQA wiki, the same dataset but only including Wikipedia articles; TriviaQA web, a dataset derived from TriviaQA unfiltered by treating each question-document pair where the document contains the question answer as an individual training point; and SQuAD (Rajpurkar et al., 2016), a collection of Wikipedia articles and crowdsourced questions.

4.2 Preprocessing

We note that for TriviaQA web we do not subsample as was done by Joshi et al. (2017), instead training on the all 530k training examples. We also observe that TriviaQA documents often contain many small paragraphs, so we restructure the documents by merging consecutive paragraphs together up to a target size. We use a maximum paragraph size of 400 unless stated otherwise. Paragraph separator tokens with learned embeddings are added between merged paragraphs to preserve formatting information. We are also careful to mark all spans of text that would be considered an exact match by the official evaluation script, which includes some minor text pre-processing, as answer spans, not just spans that are an exact string match with the answer text.

4.3 Sampling

Our confidence-based approaches are trained by sampling paragraphs from the context during training. For SQuAD and TriviaQA web we take the top four paragraphs as judged by our paragraph ranking function (see Section 2.1). We sample two different paragraphs from those four each epoch to train on. Since we observe that the higher-ranked paragraphs are more likely to contain the context needed to answer the question, we sample the highest ranked paragraph that contains an answer twice as often as the others. For the merge and shared-norm approaches, we additionally require that at least one of the paragraphs contains an answer span, and both of those paragraphs are included in the same mini-batch. For TriviaQA wiki we repeat the process but use the top 8 paragraphs, and for TriviaQA unfiltered we use the top 16, because much more context is given in these settings.

Model	EM	F1
baseline (Joshi et al., 2017)	41.08	47.40
BiDAF	50.21	56.86
BiDAF + TF-IDF	53.41	59.18
BiDAF + sum	56.22	61.48
BiDAF + TF-IDF + sum	57.20	62.44
our model + TF-IDF + sum	61.10	66.04

Table 2: Results on TriviaQA web using our pipelined method.

4.4 Implementation

We train the model with the Adadelta optimizer (Zeiler, 2012) with a batch size 60 for TriviaQA and 45 for SQuAD. At test time we select the most probable answer span of length less than or equal to 8 for TriviaQA and 17 for SQuAD. The GloVe 300 dimensional word vectors released by Pennington et al. (2014) are used for word embeddings. On SQuAD, we use a dimensionality of size 100 for the GRUs and of size 200 for the linear layers employed after each attention mechanism. We found for TriviaQA, likely because there is more data, using a larger dimensionality of 140 for each GRU and 280 for the linear layers is beneficial. During training, we maintain an exponential moving average of the weights with a decay rate of 0.999. We use the weight averages at test time. We do not update the word vectors during training.

5 Results

5.1 TriviaQA Web and TriviaQA Wiki

First, we do an ablation study on TriviaQA web to show the effects of our proposed methods for our pipeline model. We start with a baseline following the one used by Joshi et al. (2017). This

Model	Web		Web Verified		Wiki		Wiki Verified	
	EM	F1	EM	F1	EM	F1	EM	F1
Baseline (Joshi et al., 2017)	40.74	47.06	49.54	55.80	40.32	45.91	44.86	50.71
Smarnet (Chen et al., 2017b)	40.87	47.09	51.11	55.98	42.41	48.84	50.51	55.90
Mnemonic Reader (Hu et al., 2017)	46.65	52.89	56.96	61.48	46.94	52.85	54.45	59.46
(Weissenborn et al., 2017a)	50.56	56.73	63.20	67.97	48.64	55.13	53.42	59.92
Neural Cascade (Swayamdipta et al., 2017)	53.75	58.57	63.20	66.88	51.59	55.95	58.90	62.53
S-Norm (ours)	66.37	71.32	79.97	83.70	63.99	68.93	67.98	72.88

Table 3: Published TriviaQA results. Our approach advances the state of the art by about 10 points on these datasets[4]

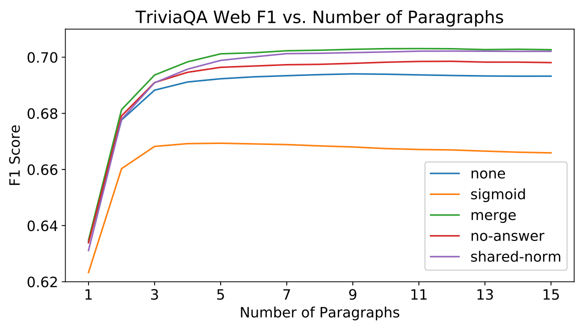

Figure 3: Results on TriviaQA web when applying our models to multiple paragraphs from each document. Most of our training methods improve the model's ability to utilize more text.

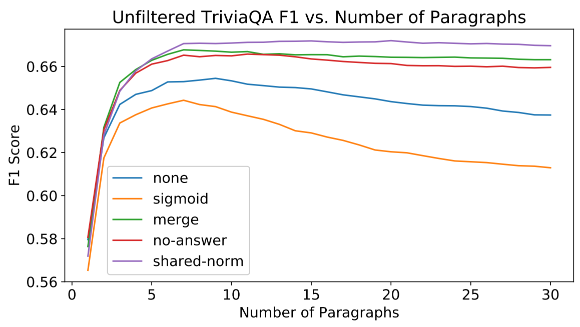

Figure 4: Results for our confidence methods on TriviaQA unfiltered. The shared-norm approach is the strongest, while the baseline model starts to lose performance as more paragraphs are used.

system uses BiDAF (Seo et al., 2016) as the paragraph model, and selects a random answer span from each paragraph each epoch to train on. The first 400 tokens of each document are used during training, and the first 800 during testing. When using the TF-IDF paragraph selection approach, we instead break the documents into paragraphs of size 400 when training and 800 when testing, and select the top-ranked paragraph to feed into the model. As shown in Table 2, our baseline outperforms the results reported by Joshi et al. (2017) significantly, likely because we are not subsampling the data. We find both TF-IDF ranking and the sum objective to be effective. Using our refined model increases the gain by another 4 points.

Next we show the results of our confidence-based approaches. For this comparison we split documents into paragraphs of at most 400 tokens, and rank them using TF-IDF cosine distance. Then we measure the performance of our proposed approaches as the model is used to independently process an increasing number of these paragraphs, and the highest confidence answer is selected as the final output. The results are shown in Figure 3.

On this dataset even the model trained without any of the proposed training methods ("none") improves as more paragraphs are used, showing it does a passable job at focusing on the correct paragraph. The no-answer option training approach lead to a significant improvement, and the shared-norm and merge approaches are even better.

We use the shared-norm approach for evaluation on the TriviaQA test sets. We found that increasing the paragraph size to 800 at test time, and to 600 during training, was slightly beneficial, allowing our model to reach 66.04 EM and 70.98 F1 on the dev set. As shown in Table 3, our model is firmly ahead of prior work on both the TriviaQA web and TriviaQA wiki test sets. Since our submission, a few additional entries have been added to the public leader for this dataset[5], although to the best of our knowledge these results have not yet been published.

5.2 TriviaQA Unfiltered

Next we apply our confidence methods to TriviaQA unfiltered. This dataset is of particular interest because the system is not told which document contains the answer, so it provides a plausible simulation of answering a question using a document

[4]Comparison made of 5/01/2018.
[5]https://competitions.codalab.org/competitions/17208

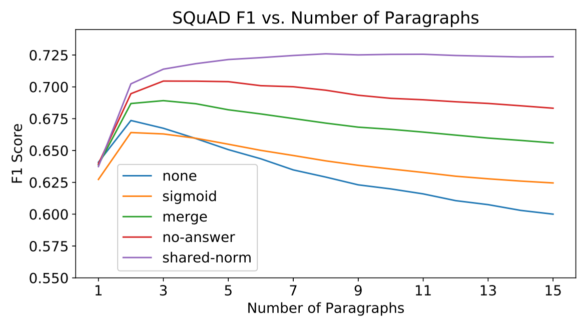

Figure 5: Results for our confidence methods on document-level SQuAD. The shared-norm model is the only model that does not lose performance when exposed to large numbers of paragraphs.

retrieval system. We show the same graph as before for this dataset in Figure 4. Our methods have an even larger impact on this dataset, probably because there are many more relevant and irrelevant paragraphs for each question, making paragraph selection more important.

Note the naively trained model starts to lose performance as more paragraphs are used, showing that errors are being caused by the model being overly confident in incorrect extractions. We achieve a score of 61.55 EM and 67.61 F1 on the dev set. This advances the only prior result reported for this dataset, 50.6 EM and 57.3 F1 from Wang et al. (2017b), by 10 points.

5.3 SQuAD

We additionally evaluate our model on SQuAD. SQuAD questions were not built to be answered independently of their context paragraph, which makes it unclear how effective of an evaluation tool they can be for document-level question answering. To assess this we manually label 500 random questions from the training set.

We categorize questions as:

1. Context-independent, meaning it can be understood independently of the paragraph.
2. Document-dependent, meaning it can be understood given the article's title. For example, "What individual is the school named after?" for the document "Harvard University".
3. Paragraph-dependent, meaning it can only be understood given its paragraph. For example, "What was the first step in the reforms?".

We find 67.4% of the questions to be context-independent, 22.6% to be document-dependent, and the remaining 10% to be paragraph-dependent. There are many document-dependent questions because questions are frequently about the subject of the document. Since a reasonably high fraction of the questions can be understood given the document they are from, and to isolate our analysis from the retrieval mechanism used, we choose to evaluate on the document-level. We build documents by concatenating all the paragraphs in SQuAD from the same article together into a single document.

Given the correct paragraph (i.e., in the standard SQuAD setting) our model reaches 72.14 EM and 81.05 F1 and can complete 26 epochs of training in less than five hours. Most of our variations to handle the multi-paragraph setting caused a minor (up to half a point) drop in performance, while the sigmoid version fell behind by a point and a half.

We graph the document-level performance in Figure 5. For SQuAD, we find it crucial to employ one of the suggested confidence training techniques. The base model starts to drop in performance once more than two paragraphs are used. However, the shared-norm approach is able to reach a peak performance of 72.37 F1 and 64.08 EM given 15 paragraphs. Given our estimate that 10% of the questions are ambiguous if the paragraph is unknown, our approach appears to have adapted to the document-level task very well.

Finally, we compare the shared-norm model with the document-level result reported by Chen et al. (2017a). We re-evaluate our model using the documents used by Chen et al. (2017a), which consist of the same Wikipedia articles SQuAD was built from, but downloaded at different dates. The advantage of this dataset is that it does not allow the model to know *a priori* which paragraphs were filtered out during the construction of SQuAD. The disadvantage is that some of the articles have been edited since the questions were written, so some questions may no longer be answerable. Our model achieves 59.14 EM and 67.34 F1 on this dataset, which significantly outperforms the 49.7 EM reported by Chen et al. (2017a).

5.4 Curated TREC

We perform one final experiment that tests our model as part of an end-to-end question answering system. For document retrieval, we re-implement the pipeline from Joshi et al. (2017). Given a question, we retrieve up to 10 web documents us-

Answer indirectly stated	20.2

Table 5: Error analysis on TriviaQA web.

ing a Bing web search of the question, and all Wikipedia articles about entities the entity linker TAGME (Ferragina and Scaiella, 2010) identifies in the question. We then use our linear paragraph ranker to select the 16 most relevant paragraphs from all these documents, which are passed to our model to locate the final answer span. We choose to use the shared-norm model trained on the TriviaQA unfiltered dataset since it is trained using multiple web documents as input. We use the same heuristics as Joshi et al. (2017) to filter out trivia or QA websites to ensure questions cannot be trivially answered using webpages that directly address the question. A demo of the system is publicly available[8].

We find accuracy on the TriviaQA unfiltered questions remains almost unchanged (within half a percent exact match score) when using our document retrieval method instead of the given documents, showing our pipeline does a good job of producing evidence documents that are similar to the ones in the training data.

We test the system on questions from the TREC QA tasks (Voorhees et al., 1999), in particular a curated set of questions from Baudiš (2015), the same dataset used in Chen et al. (2017a). We apply our system to the 694 test questions without retraining on the train questions.

We compare against DrQA (Chen et al., 2017a) and YodaQA (Baudiš, 2015). It is important to note that these systems use different document corpora (Wikipedia for DrQA, and Wikipedia, several knowledge bases, and optionally Bing web search for YodaQA) and different training data (SQuAD and the TREC training questions for DrQA, and TREC only for YodaQA), so we cannot make assertions about the relative performance of individual components. Nevertheless, it is instructive to show how the methods we experiment with in this work can advance an end-to-end QA system.

The results are listed in Table 4. Our method outperforms prior work, breaking the 50% accuracy mark. This is a strong proof-of-concept that neural paragraph reading combined with existing document retrieval methods can advance the state-of-the-art on general question answering. It also shows that, despite the noise, the data from TriviaQA is sufficient to train models that can be effective on out-of-domain QA tasks.

[8]https://documentqa.allenai.org/

5.5 Discussion

We found that models that have only been trained on answer-containing paragraphs can perform very poorly in the multi-paragraph setting. The results were particularly bad for SQuAD; we think this is partly because the paragraphs are shorter, so the model had less exposure to irrelevant text.

The shared-norm approach consistently outperformed the other methods, especially on SQuAD and TriviaQA unfiltered, where many paragraphs were needed to reach peak performance. Figures 3, 4, and 5 show this technique has a minimal effect on the performance when only one paragraph is used, suggesting the model's per-paragraph performance is preserved. Meanwhile, it can be seen the accuracy of the shared-norm model never drops as more paragraphs are added, showing it successfully resolves the problem of being distracted by irrelevant text.

The no-answer and merge approaches were moderately effective, we suspect because they at least expose the model to more irrelevant text. However, these methods do not address the fundamental issue of requiring confidence scores to be comparable between independent applications of the model to different paragraphs, which is why we think they lagged behind. The sigmoid objective function reduces the paragraph-level performance considerably, especially on the TriviaQA datasets. We suspect this is because it is vulnerable to label noise, as discussed in Section 2.2.

5.6 Error Analysis

We perform an error analysis by labeling 200 random TriviaQA web dev-set errors made by the shared-norm model. We found 40.5% of the errors were caused because the document did not contain sufficient evidence to answer the question, and 17% were caused by the correct answer not being contained in the answer key. The distribution of the remaining errors is shown in Table 5.

We found quite a few cases where a sentence contained the answer, but the model was unable to extract it due to complex syntactic structure or paraphrasing. Two kinds of multi-sentence reading errors were also common: cases that required connecting multiple statements made in a single paragraph, and long-range coreference cases where a sentence's subject was named in a previous paragraph. Finally, some questions required background knowledge, or required the model to extract answers that were only stated indirectly (e.g., examining a list to extract the nth element). Overall, these results suggest good avenues for improvement are to continue advancing the sentence and paragraph level reading comprehension abilities of the model, and adding a mechanism to handle document-level coreferences.

6 Related Work

Reading Comprehension Datasets. The state of the art in reading comprehension has been rapidly advanced by neural models, in no small part due to the introduction of many large datasets. The first large scale datasets for training neural reading comprehension models used a Cloze-style task, where systems must predict a held out word from a piece of text (Hermann et al., 2015; Hill et al., 2015). Additional datasets including SQuAD (Rajpurkar et al., 2016), WikiReading (Hewlett et al., 2016), MS Marco (Nguyen et al., 2016) and TriviaQA (Joshi et al., 2017) provided more realistic questions. Another dataset of trivia questions, Quasar-T (Dhingra et al., 2017), was introduced recently that uses ClueWeb09 (Callan et al., 2009) as its source for documents. In this work we choose to focus on SQuAD because it is well studied, and TriviaQA because it is more challenging and features documents and multi-document contexts (Quasar T is similar, but was released after we started work on this project).

Neural Reading Comprehension. Neural reading comprehension systems typically use some form of attention (Wang and Jiang, 2016), although alternative architectures exist (Chen et al., 2017a; Weissenborn et al., 2017b). Our model follows this approach, but includes some recent advances such as variational dropout (Gal and Ghahramani, 2016) and bi-directional attention (Seo et al., 2016). Self-attention has been used in several prior works (Cheng et al., 2016; Wang et al., 2017c; Pan et al., 2017). Our approach to allowing a reading comprehension model to produce a per-paragraph no-answer score is related to the approach used in the BiDAF-T (Min et al., 2017) model to produce per-sentence classification scores, although we use an attention-based method instead of max-pooling.

Open QA. Open question answering has been the subject of much research, especially spurred by the TREC question answering track (Voorhees et al., 1999). Knowledge bases can be used, such as in (Berant et al., 2013), although the resulting systems are limited by the quality of the knowledge base. Systems that try to answer questions using natural language resources such as YodaQA (Baudiš, 2015) typically use pipelined methods to retrieve related text, build answer candidates, and pick a final output.

Neural Open QA. Open question answering with neural models was considered by Chen et al. (2017a), where researchers trained a model on SQuAD and combined it with a retrieval engine for Wikipedia articles. Our work differs because we focus on explicitly addressing the problem of applying the model to multiple paragraphs. A pipelined approach to QA was recently proposed by Wang et al. (2017a), where a ranker model is used to select a paragraph for the reading comprehension model to process. More recent work has considered evidence aggregation techniques (Wang et al., 2017b; Swayamdipta et al., 2017). Our work shows paragraph-level models that produce well-calibrated confidence scores can effectively exploit large amounts of text without aggregation, although integrating aggregation techniques could further improve our results.

7 Conclusion

We have shown that, when using a paragraph-level QA model across multiple paragraphs, our training method of sampling non-answer-containing paragraphs while using a shared-norm objective function can be very beneficial. Combining this with our suggestions for paragraph selection, using the summed training objective, and our model design allows us to advance the state of the art on TriviaQA. As shown by our demo, this work can be directly applied to building deep-learning-powered open question answering systems.

Abstract

Complex machine learning models for NLP are often brittle, making different predictions for input instances that are extremely similar semantically. To automatically detect this behavior for individual instances, we present *semantically equivalent adversaries* (SEAs) – semantic-preserving perturbations that induce changes in the model's predictions. We generalize these adversaries into *semantically equivalent adversarial rules* (SEARs) – simple, universal replacement rules that induce adversaries on many instances. We demonstrate the usefulness and flexibility of SEAs and SEARs by detecting bugs in black-box state-of-the-art models for three domains: machine comprehension, visual question-answering, and sentiment analysis. Via user studies, we demonstrate that we generate high-quality local adversaries for more instances than humans, and that SEARs induce four times as many mistakes as the bugs discovered by human experts. SEARs are also actionable: retraining models using data augmentation significantly reduces bugs, while maintaining accuracy.

1 Introduction

With increasing complexity of models for tasks like classification (Joulin et al., 2016), machine comprehension (Rajpurkar et al., 2016; Seo et al., 2017), and visual question answering (Zhu et al., 2016), models are becoming increasingly challenging to debug, and to determine whether they are ready for deployment. In particular, these complex models are prone to brittleness: different ways of phrasing the same sentence can often cause the model to

In the United States especially, several high-profile cases such as Debra LaFave, Pamela Rogers, and Mary Kay Letourneau have caused increased scrutiny on teacher misconduct.

(d) **Semantically Equivalent Adversary**

Figure 1: Adversarial examples for question answering, where the model predicts the correct answer for the question and input paragraph (1a and 1b). It is possible to fool the model by adversarially changing a single character (1c), but at the cost of making the question nonsensical. A **Semantically Equivalent Adversary** (1d) results in an incorrect answer while preserving semantics.

output different predictions. While held-out accuracy is often useful, it is not sufficient: practitioners consistently overestimate their model's generalization (Patel et al., 2008) since test data is usually gathered in the same manner as training and validation. When deployed, these seemingly accurate models encounter sentences that are written very differently than the ones in the training data, thus making them prone to mistakes, and fragile with respect to distracting additions (Jia and Liang, 2017). These problems are exacerbated by the variability in language, and by cost and noise in annotations, making such bugs challenging to detect and fix.

A particularly challenging issue is *oversensitivity* (Jia and Liang, 2017): a class of bugs where models output different predictions for very similar inputs. These bugs are prevalent in image classifi-

Transformation Rules	#Flips
(`WP` *is*→`WP`*'s*)	70 (1%)
(*?*→*??*)	202(3%)

(a) Example Rules

Changed: What's the oncorhynchus also called? **A:** keta

(b) Example for (`WP` *is*→`WP`*'s*)

Original: How long is the Rhine? **A:** 1,230 km
Changed: How long is the Rhine?? **A:** more than 1,050,000

(c) Example for (*?*→*??*)

Figure 2: **Semantically Equivalent Adversarial Rules:** For the task of question answering, the proposed approach identifies transformation rules for questions in (a) that result in paraphrases of the queries, but lead to incorrect answers (#Flips is the number of times this happens in the validation data). We show examples of rephrased questions that result in incorrect answers for the two rules in (b) and (c).

cation (Szegedy et al., 2014), a domain where one can measure the magnitude of perturbations, and many small-magnitude changes are imperceptible to the human eye. For text, however, a single word addition can change semantics (e.g. adding "not"), or have no semantic impact for the task at hand.

Inspired by adversarial examples for images, we introduce *semantically equivalent adversaries* (**SEA**s) – text inputs that are perturbed in semantics-preserving ways, but induce changes in a black box model's predictions (example in Figure 1). Producing such adversarial examples systematically can significantly aid in debugging ML models, as it allows users to detect problems that happen in the real world, instead of oversensitivity only to malicious attacks such as intentionally scrambling, misspelling, or removing words (Bansal et al., 2014; Ebrahimi et al., 2018; Li et al., 2016).

While SEAs describe local brittleness (i.e. are specific to particular predictions), we are also interested in bugs that affect the model more globally. We represent these via simple replacement rules that induce SEAs on multiple predictions, such as in Figure 2, where a simple contraction of "is"after `Wh` pronouns (what, who, whom) (2b) makes 70 (1%) of the previously correct predictions of the model "flip" (i.e. become incorrect). Perhaps more surprisingly, adding a simple "?" induces mistakes in 3% of examples. We call such rules *semantically equivalent adversarial rules* (**SEAR**s).

In this paper, we present SEAs and SEARs, designed to unveil local and global oversensitivity bugs in NLP models. We first present an approach to generate semantically equivalent adversaries, based on paraphrase generation techniques (Lapata et al., 2017), that is model-agnostic (i.e. works for any black box model). Next, we generalize SEAs into semantically equivalent rules, and outline the properties for optimal rule sets: semantic equivalence, high adversary count, and non-redundancy. We frame the problem of finding such a set as a submodular optimization problem, leading to an accurate yet efficient algorithm.

Including the human into the loop, we demonstrate via user studies that SEARs help users uncover important bugs on a variety of state-of-the-art models for different tasks (sentiment classification, visual question answering). Our experiments indicate that SEAs and SEARs make humans significantly better at detecting impactful bugs – SEARs uncover bugs that cause 3 to 4 times more mistakes than human-generated rules, in much less time. Finally, we show that SEARs are actionable, enabling the human to close the loop by fixing the discovered bugs using a data augmentation procedure.

2 Semantically Equivalent Adversaries

Consider a black box model f that takes a sentence x and makes a prediction $f(x)$, which we want to debug. We identify adversaries by generating paraphrases of x, and getting predictions from f until the original prediction is changed.

Given an indicator function $\text{SemEq}(x, x')$ that is 1 if x is semantically equivalent to x' and 0 otherwise, we define a *semantically equivalent adversary* (SEA) as a semantically equivalent instance that changes the model prediction in Eq (1). Such adversaries are important in evaluating the robustness of f, as each is an undesirable bug.

$$\text{SEA}(x, x') = \mathbb{1}\left[\text{SemEq}(x, x') \wedge f(x) \neq f(x')\right] \quad (1)$$

While there are various ways of scoring semantic similarity between pairs of texts based on embeddings (Le and Mikolov, 2014; Wieting and Gimpel, 2017), they do not explicitly penalize unnatural sentences, and generating sentences requires surrounding context (Le and Mikolov, 2014) or training a separate model. We turn instead to paraphrasing based on neural machine translation (Lapata et al., 2017), where $P(x'|x)$ (the probability of a paraphrase x' given original sentence x) is proportional to translating x into multiple pivot languages and then taking the score of back-translating the translations into the original language. This approach scores semantics and "plausibility" simultaneously (as translation models have "built in" language models) and allows for easy paraphrase generation, by linearly combining the paths of each back-decoder when back-translating.

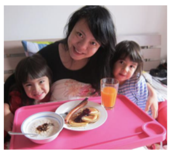
Unfortunately, given source sentences x and z, $P(x'|x)$ is not comparable to $P(z'|z)$, as each has a different normalization constant, and heavily depends on the shape of the distribution around x or z. If there are multiple perfect paraphrases near x, they will all share probability mass, while if there is a paraphrase much better than the rest near z, it will have a higher score than the ones near x, even if the paraphrase quality is the same. We thus define the semantic score $S(x, x')$ as a ratio between the probability of a paraphrase and the probability of the sentence itself:

$$S(x, x') = \min\left(1, \frac{P(x'|x)}{P(x|x)}\right) \tag{2}$$

We define $\text{SemEq}(x, x') = \mathbb{1}[S(x, x') \geq \tau]$, i.e. x' is semantically equivalent to x if the similarity score between x and x' is greater than some threshold τ (which we crowdsource in Section 5). In order to generate adversaries, we generate a set of paraphrases Π_x around x via beam search and get predictions on Π_x using the black box model until an adversary is found, or until $S(x, x') < \tau$. We may be interested in the best adversary for a particular instance, i.e. $\text{argmax}_{x' \in \Pi_x} S(x, x')\text{SEA}_x(x')$, or we may consider multiple SEAs for generalization purposes. We illustrate this process in Figure 3, where we generate SEAs for a VQA model by generating paraphrases around the question, and checking when the model prediction changes. The first two adversaries with highest $S(x, x')$ are semantically equivalent, the third maintains the semantics enough for it to be a useful adversary, and the fourth is ungrammatical and thus not useful.

3 Semantically Equivalent Adversarial Rules (SEARs)

While finding the best adversary for a particular instance is useful, humans may not have time or patience to examine too many SEAs, and may not be able to generalize well from them in order to understand and fix the most impactful bugs. In this section, we address the problem of generalizing local adversaries into Semantically Equivalent Adversarial Rules (SEARs), search and replace rules that produce semantic adversaries with little or no change in semantics, when applied to a corpus of sentences. Assuming that humans have limited time, and are thus willing to look at B rules, we propose a method for selecting such a set of rules given a reference dataset X.



What color is the tray?	**Pink**
What colour is the tray?	Green
Which color is the tray?	Green
What color is it?	Green
How color is tray?	Green

Figure 3: **Visual QA Adversaries:** Paraphrasing questions to find adversaries for the original question (top, in bold) asked of a given image. Adversaries are sorted by decreasing semantic similarity.

A rule takes the form $r = (a \rightarrow c)$, where the first instance of the antecedent a is replaced by the consequent c for every instance that includes a, as we previously illustrated in Figure 2a. The output after applying rule r on a sentence x is represented as the function call $r(x)$, e.g. if $r =$(*movie*$\rightarrow$*film*), r("Great movie!") = "Great film!".

Proposing a set of rules: In order to generalize a SEA x' into a candidate rule, we must represent the changes that took place from $x \rightarrow x'$. We will use x = "What color is it?" and x' = "Which color is it?" from Figure 4 as a running example.

One approach is exact matching: selecting the minimal contiguous sequence that turns x into x', (*What*$\rightarrow$*Which*) in the example. Such changes may not always be semantics preserving, so we also propose further rules by including the immediate context (previous and/or next word with respect to the sequence), e.g. (*What color*$\rightarrow$*Which color*). Adding such context, however, may make rules very specific, thus restricting their value. To allow for generalization, we also represent the antecedent of proposed rules by a product of their raw text with coarse and fine-grained Part-of-Speech tags, and allow these tags to happen in the consequent if they match the antecedent. In the running example, we would propose rules like (*What color*$\rightarrow$*Which color*), (*What* NOUN$\rightarrow$*Which* NOUN), (WP *color*$\rightarrow$*Which color*), etc.

We generate SEAs and propose rules for every $x \in X$, which gives us a set of candidate rules (second box in Figure 4, *for* loop in Algorithm 1).

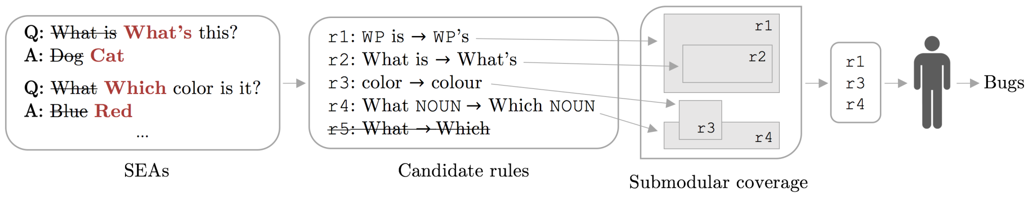


Figure 4: **SEAR process.** (1) SEAs are generalized into candidate rules, (2) rules that are not semantically equivalent are filtered out, e.g. `r5`: (*What→Which*), (3) rules are selected according to Eq (3), in order to maximize coverage and avoid redundancy (e.g. rejecting `r2`, valuing `r1` more highly than `r4`), and (4) a user vets selected rules and keeps the ones that they think are bugs.

Selecting a set of rules: Given a set of candidate rules, we want to select a set R such that $|R| \leq B$, and the following properties are met:

1. Semantic Equivalence: Application of the rules in the set should produce semantically equivalent instances. This is equivalent to considering rules that have a high probability of inducing semantically equivalent instances when applied, i.e. $E[\text{SemEq}(x, r(x))] \geq 1-\delta$. This is the *Filter* step in Algorithm 1. For example, consider the rule (*What→Which*) in Fig 4 which produces some semantically equivalent instances, but also produces many instances that are unnatural (e.g. "What is he doing?" → "Which is he doing?"), and is thus filtered out by this criterion.

2. High adversary count: The rules in the set should induce as many SEAs as possible in validation data. Furthermore, each of the induced SEAs should have as high of a semantic similarity score as possible, i.e. for each rule $r \in R$ we want to maximize $\sum_{x\in X} S(x, r(x))\text{SEA}(x, r(x))$. In Figure 4, `r1` induces more and more similar mistakes when compared to $r4$, and is thus superior to `r4`.

3. Non-redundancy: Different rules in the set may induce the same SEAs, or may induce different SEAs for the same instances. Ideally, rules in the set should cover as many instances in the validation as possible, rather than focus on a small set of fragile predictions. Furthermore, rules should not be repetitive to the user. In Figure 4 (mid), `r1` covers a superset of `r2`'s adversaries, making `r2` completely redundant and thus not included in R.

Properties 2 and 3 combined suggest a weighted coverage problem, where a rule r covers an instance x if $\text{SEA}(x, r(x))$, the weight of the connection being given by $S(x, r(x))$. We thus want to

Algorithm 1 Generating SEARs for a model

```
Require: Classifier $f$, Correct instances $X$
Require: Hyperparameters, $\delta$, $\tau$, Budget $B$
  $\mathcal{R} \leftarrow \{\}$ {Set of rules}
  for all $x \in X$ do
    $X' = \text{GenParaphrases}(X, \tau)$
    $\mathcal{A} \leftarrow \{x' \in X' \mid f(x) \neq f(x')\}$ {SEAs; §2}
    $\mathcal{R} \leftarrow \mathcal{R} \cup \text{Rules}(\mathcal{A})$
  end for
  $\mathcal{R} \leftarrow \text{Filter}(\mathcal{R}, \delta, \tau)$ {Remove low scoring SEARs}
  $\mathcal{R} \leftarrow \text{SubMod}(\mathcal{R}, B)$ {high count / score, diverse }
  return $\mathcal{R}$
```

find the set of semantically equivalent rules that:

$$\max_{R, |R|<B} \sum_{x\in X} \max_{r\in R} S(x, r(x))\text{SEA}(x, r(x)) \quad (3)$$

While Eq (3) is NP-hard, the objective is monotone submodular (Krause and Golovin, 2014), and thus a greedy algorithm that iteratively adds the rule with the highest marginal gain offers a constant-factor approximation guarantee of $1 - 1/e$ to the optimum. This is the *SubMod* procedure in Algorithm 1, represented pictorially in Figure 4, where the output is a set of rules given to a human, who judges if they are really bugs or not.

4 Illustrative Examples

Before evaluating the utility of SEAs and SEARs with user studies, we show examples in state-of-the-art models for different tasks. Note that we treat these models as black boxes, not using internals or gradients in any way when discovering these bugs.

Machine Comprehension: We take the AllenNLP (Gardner et al., 2017) implementation of BiDaF (Seo et al., 2017) for Machine Comprehension, and display some high coverage SEARs for it in Table 1 (also, Figures 1 and 2a). For each rule,

SEAR	Questions / SEAs	f(x)	Flips
What VBZ → What's	~~What is~~ What's the NASUWT?	~~Trade unions~~ Teachers in Wales	2%
	~~What is~~ What's a Hauptlied?	~~main hymn~~ Veni redemptor gentium	
What NOUN → Which NOUN	~~What resource~~ Which resource was mined in the Newcastle area?	~~coal~~ wool	1%
	~~What health~~ Which health problem did Tesla have in 1879?	~~nervous breakdown~~ relations	
What VERB → So what VERB	~~What was~~ So what was Ghandi's work called?	~~Satyagraha~~ Civil Disobedience	2%
	~~What is~~ So what is a new trend in teaching?	~~Co-teaching~~ educational institutions	
What VBD → And what VBD	~~What did~~ And what did Tesla develop in 1887?	~~an induction motor~~ laboratory	2%
	~~What was~~ And what was Kenneth Swezey's job?	~~journalist~~ sleep	

Table 1: SEARs for Machine Comprehension

SEAR	Questions / SEAs	f(x)	Flips
WP VBZ→ WP's	~~What has~~ What's been cut?	~~Cake~~ Pizza	3.3%
	~~Who is~~ Who's holding the baby	~~Woman~~ Man	
What NOUN→ Which NOUN	~~What~~ Which kind of floor is it?	~~Wood~~ Marble	3.9%
	~~What~~ Which color is the jet?	~~Gray~~ White	
color →colour	What ~~color~~ colour is the tray?	~~Pink~~ Green	2.2%
	What ~~color~~ colour is the jet?	~~Gray~~ Blue	
ADV is→ ADV's	~~Where is~~ Where's the jet?	~~Sky~~ Airport	2.1%
	~~How is~~ How's the desk?	~~Messy~~ Empty	

Table 2: SEARs for Visual QA

we display two example questions with the corresponding SEA, the prediction (with corresponding change) and the percentage of "flips" - instances previously predicted correctly on the validation data, but predicted incorrectly after the application of the rule. The rule (*What* VBZ→*What's*) generalizes the SEA on Figure 1, and shows that the model is fragile with respect to contractions (flips 2% of all correctly predicted instances on the validation data). The second rule uncovers a bug with respect to simple question rephrasing, while the third and fourth rules show that the model is not robust to a more conversational style of asking questions.

Visual QA: We show SEARs for a state-of-the-art visual question-answering model (Zhu et al., 2016) in Table 2. Even though the contexts are different (paragraphs for machine comprehension, images for VQA), it is interesting that both models display similar bugs. The fact that VQA is fragile to "Which" questions is because questions of this form are not in the training set, while (*color*→*colour*) probably stems from an American bias in data collection. Changes induced by these four rules flip more than 10% of the predictions in the validation data, which is of critical concern if the model is being evaluated for production.

SEAR	Reviews / SEAs	f(x)	Flips
movie → film	Yeah, the ~~movie~~ film pretty much sucked .	~~Neg~~ Pos	2%
	This is not ~~movie~~ film making .	~~Neg~~ Pos	
film → movie	Excellent ~~film~~ movie .	~~Pos~~ Neg	1%
	I'll give this ~~film~~ movie 10 out of 10 !	~~Pos~~ Neg	
is →was	Ray Charles ~~is~~ was legendary .	~~Pos~~ Neg	4%
	It ~~is~~ was a really good show to watch .	~~Pos~~ Neg	
this →that	Now ~~this~~ that is a movie I really dislike .	~~Neg~~ Pos	1%
	The camera really likes her in ~~this~~ that movie.	~~Pos~~ Neg	
DET NOUN is →it is	~~The movie is~~ It is terrible	~~Neg~~ Pos	1%
	~~The dialog is~~ It is atrocious	~~Neg~~ Pos	

Table 3: SEARs for Sentiment Analysis

Sentiment Analysis: Finally, in Table 3 we display SEARs for a fastText (Joulin et al., 2016) model for sentiment analysis trained on movie reviews. Surprisingly, many of its predictions change for perturbations that have no sentiment connotations, even in the presence of polarity-laden words.

5 User Studies

We compare automatically discovered SEAs and SEARs to user-generated adversaries and rules, and propose a way to fix the bugs induced by SEARs.

Our evaluation benchmark includes two tasks: visual question answering (VQA) and sentiment analysis on movie review sentences. We choose these tasks because a human can quickly look at a prediction and judge if it is correct or incorrect, can easily perturb instances, and judge if two instances in a pair are semantically equivalent or not. Since our focus is debugging, throughout the experiment we only considered SEAs and SEARs on examples that are originally predicted correctly (i.e. every adversary is also by construction a mistake). The user interfaces for all experiments in this section are included in the supplementary material.

5.1 Implementation Details

The paraphrasing model (Lapata et al., 2017) requires translation models to and from different languages. We train neural machine translation models using the default parameters of OpenNMT-py (Klein et al., 2017) for English↔Portuguese and English↔French models, on 2 million and 1 million parallel sentences (respectively) from EuroParl, news, and other sources (Tiedemann, 2012). We use the spacy library (`http://spacy.io`) for POS tagging. For SEAR generation, we set $\delta = 0.1$ (i.e. at least 90% equivalence). We generate a set of candidate adversaries as described in Section 2, and ask mechanical turkers to judge them

	Human vs SEA	Human vs HSEA
Neither	145 (48%)	127 (42%)
Only Human	47 (16%)	38 (13%)
Only SEA	**54 (18%)**	**72 (24%)**
Both	**54 (18%)**	**63 (21%)**

(a) Visual Question-Answering

	Human vs SEA	Human vs HSEA
Neither	177 (59%)	161 (54%)
Only Human	45 (15%)	40 (13%)
Only SEA	**47 (16%)**	**63 (21%)**
Both	**31 (10%)**	**36 (12%)**

(b) Sentiment Analysis

Table 4: **Finding Semantically Equivalent Adversaries:** we compare how often humans produce semantics-preserving adversaries, when compared to our automatically generated adversaries (SEA, left) and our adversaries filtered by humans (HSEA, right). There are four possible outcomes: neither produces a semantic equivalent adversary (i.e. they either do not produce an adversary or the adversary produced is not semantically equivalent), both do, or only one is able to do so.

for semantic equivalence. Using these evaluations, we identify $\tau = 0.0008$ as the value that minimizes the entropy in the induced splits, and use it for the remaining experiments. Source code and pretrained language models are available at `https://github.com/marcotcr/sears`.

For VQA, we use the multiple choice *telling* system and dataset of Zhu et al. (2016), using their implementation, with default parameters. The training data consists of questions that begin with "What", "Where", "When", "Who", "Why", and "How". The task is multiple choice, with four possible answers per instance. For sentiment analysis, we train a fastText (Joulin et al., 2016) model with unigrams and bigrams (embedding size of 50) on RottenTomato movie reviews (Pang and Lee, 2005), and evaluate it on IMDB sentence-sized reviews (Kotzias et al., 2015), simulating the common case where a model trained on a public dataset is applied to new data from a similar domain.

5.2 Can humans find good adversaries?

In this experiment, we compare our method for generating SEAs with user's ability to discover semantic-preserving adversaries. We take a random sample of 100 correctly-predicted instances for each task. In the first condition (**human**), we display each instance to 3 Amazon Mechanical Turk workers, and give them 10 attempts at creating semantically equivalent adversaries (with immediate feedback as to whether or not their attempts changed the prediction). Next, we ask them to choose the adversary that is semantically closest to the original instance, out of the candidates they generated. In the second condition (**SEA**), we generate adversaries for each of the instances, and pick the best adversary according to the semantic scorer. The third condition (**HSEA**) is a collaboration between our method and humans: we take the top 5 adversaries ranked by $S(x, x')$, and ask workers to pick the one closest to the original instance, rather than asking them to generate the adversaries.

To evaluate whether the proposed adversaries are semantically equivalent, we ask a separate set of workers to evaluate the similarity between each adversary and the original instance (with the image as context for VQA), on a scale of 1 (completely unrelated) to 5 (exactly the same meaning). Each adversary is evaluated by at least 10 workers, and considered equivalent if the median score ≥ 4. We thus obtain 300 comparisons between *human* and *SEA*, and 300 between *human* and *HSEA*.

The results in Table 4a and 4b are consistent across tasks: both models are susceptible to SEAs for a large fraction of predictions, and our fully automated method is able to produce SEAs as often as humans (left columns). On the other hand, asking humans to choose from generated SEAs (HSEA) yields much better results than asking humans to generate them (right columns), or using the highest scored SEA. The semantic scorer does make mistakes, so the top adversary is not always semantically equivalent, but a good quality SEA is often in the top 5, and is easily identified by users.

On both datasets, the automated method or humans were able to generate adversaries at the exclusion of the other roughly one third of the time, which indicates that they do not generate the same adversaries. Humans generate paraphrases differently than our method: the average character edit distance of our SEAs is 6.2 for VQA and 9.0 for Sentiment, while for humans it is 18.1 and 43.3, respectively. This is illustrated by examples in Table 5 - in Table 5a we see examples where very compact changes generate adversaries (humans were not able to find these changes though). The examples in Table 5b indicate that humans can generate adversaries that: (1) make use of the visual context in VQA, which our method does not, and (2) sig-

Dataset	Original	SEA
VQA	Where are the men? What kind of meat is on the boy's plate?	Where are the males? What sort of meat is on the boy's plate?
Sentiment	They are so easy to love, but even more easy to identify with. Today the graphics are crap.	They're so easy to love, but even more easy to identify with. Today, graphics are bullshit.

(a) Automatically generated adversaries, examples where humans failed to generate SEAs (**Only SEA**)

Dataset	Original	Human-generated SEA
VQA	How many suitcases? Where is the blue van?	How many suitcases are sitting on the shelf? What is the blue van's location?
Sentiment	(very serious spoilers) this movie was a huge disappointment. Also great directing and photography.	serious spoilers this movie did not deliver what I hoped Photography and directing were on point.

(b) Human generated adversaries, examples where our approach failed to generate SEAs (**Only Human**)

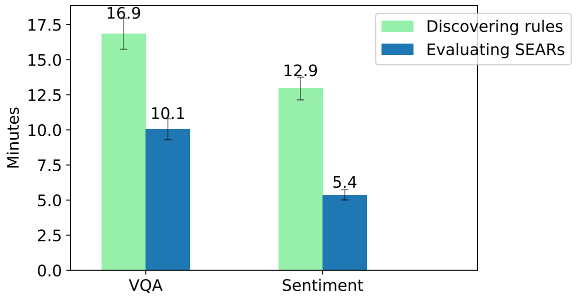

Figure 6: Time for users to create rules (green) and to evaluate SEARs (blue), with standard error bars

nificantly change the sentence structure, which the translation-based semantic scorer does not.

5.3 Can experts find high-impact bugs?

Here we investigate whether experts are able to detect high-impact global bugs, i.e. devise rules that flip many predictions, and compare them to generated SEARs. Instead of AMT workers, we have 26 expert subjects: students, graduates, or professors who have taken at least a graduate course in machine learning or NLP[1]. The experiment setup is as follows: for each task, subjects are given an interface where they see examples in the validation data, perturb those examples, and get predictions. The interface also allows them to create search and replace rules, with immediate feedback on how many mistakes are induced by their rules. They also see the list of examples where the rules apply, so they can verify semantic equivalence. Subjects are instructed to try to maximize the number of mistakes induced in the validation data (i.e. maximize "mistake coverage"), but only through semantically equivalent rules. They can try as many rules as they like, and are asked to select the best set of at most 10 rules at the end. This is quite a challenging task for humans (yet another reason to prefer algorithmic approaches), but we are not aware of any existing automated methods. Finally, we instruct subjects they could finish each task in about 15 minutes (some took longer, some ended earlier), in order to keep the total time reasonable.

After creating their rules for VQA and sentiment analysis, the subjects evaluate 20 SEARs (one rule at a time) for each task, and accept only semantically equivalent rules. When a subject rejects a rule, we recompute the remaining set according to Eq (3) in real time. If a subject accepts more than 10 rules, only the first 10 are considered, in order to ensure a fair comparison against the expert-generated rules.

We compare expert-generated rules with accepted SEARs (each subject's rules are compared to the SEARs they accepted) in terms of the percentage of the correct predictions that "flip" when the rules are applied. This is what we asked the subjects to maximize, and all the rules were ones deemed to be semantic equivalent by the subjects themselves. We also consider the union of expert-generated rules and accepted SEARs. The results in Figure 5 show that on both datasets, the filtered SEARs induce a much higher rate of mistakes than the rules the subjects themselves created, with a small increase when the union of both sets is taken. Furthermore, subjects spent less time evaluating

[1]We have an IRB/consent form, and personal information was only collected as needed to compensate subjects

	Error rate	
	Validation	Sensitivity
Visual QA		
Original Model	44.4.%	12.6%
SEAR Augmented	45.7 %	1.4%
Sentiment Analysis		
Original Model	22.1%	12.6%
SEAR Augmented	21.3%	3.4%

Table 6: **Fixing bugs using SEARs:** Effect of retraining models using SEARs, both on original validation and on sensitivity dataset. Retraining significantly reduces the number of bugs, with statistically insignificant changes to accuracy.

SEARs than trying to create their own rules (Figure 6). SEARs for sentiment analysis contain fewer POS tags, and are thus easier to evaluate for semantic equivalence than for VQA.

Discovering these bugs is hard for humans (even experts) without SEARs: not only do they need to imagine rules that maintain semantic equivalence, they must also discover the model's weak spots. Making good use of POS tags is also a challenge: only 50% of subjects attempt rules with POS tags for VQA, 36% for sentiment analysis.

Experts accepted 8.69 rules (on average) out of 20 for VQA as semantically equivalent, and 17.32 out of 20 for sentiment analysis. Similar to the previous experiment, errors made by the semantic scorer lead to rules that are not semantically equivalent (e.g. Table 7). With minimal human intervention, however, SEARs vastly outperform human experts in finding impactful bugs.

5.4 Fixing bugs using SEARs

Once such bugs are discovered, it is natural to want to fix them. The global and deterministic nature of SEARs make them actionable, as they represent bugs in a systematic manner. Once impactful bugs are identified, we use a simple data augmentation procedure: applying SEARs to the training data, and retraining the model on the original training augmented with the generated examples.

We take the rules that are accepted by ≥ 20 subjects as accepted bugs, a total of 4 rules (in Table 2) for VQA, and 16 rules for sentiment (including ones in Table 3). We then augment the training data by applying these rules to it, and retrain the models. To check if the bugs are still present, we create a sensitivity dataset by applying these SEARs to instances predicted correctly on the validation. A model not prone to the bugs described by these rules should not change any of its predictions, and should thus have error rate 0% on this sensitivity data. We also measure accuracy on the original validation data, to make sure that our bug-fixing procedure is not decreasing accuracy.

Table 6 shows that the incidence of these errors is greatly reduced after augmentation, with negligible changes to the validation accuracy (on both tasks, the changes are consistent with the effect of retraining with different seeds). These results show that SEARs are useful not only for discovering bugs, but are also actionable through a simple augmentation technique for any model.

6 Related Work

Previous work on debugging primarily focuses on *explaining* predictions in validation data in order to uncover bugs (Ribeiro et al., 2016, 2018; Kulesza et al., 2011), or find labeling errors (Zhang et al., 2018; Koh and Liang, 2017). Our work is complementary to these techniques, as they provide no mechanism to detect oversensitivity bugs. We are able to uncover these bugs even when they are not present in the data, since we generate sentences.

Adversarial examples for image recognition are typically indistinguishable to the human eye (Szegedy et al., 2014). These are more of a security concern than bugs per se, as images with adversarial noise are not "natural", and not expected to occur in the real world outside of targeted attacks. Adversaries are usually specific to predictions, and even universal adversarial perturbations (Moosavi-Dezfooli et al., 2017) are not natural, semantically meaningful to humans, or actionable. "Imperceptible" adversarial noise does not carry over from images to text, as adding or changing a single word in a sentence can drastically alter its meaning. Jia and Liang (2017) recognize that a true analog to detect oversensitivity would need semantic-preserving perturbations, but do not pursue an automated solution due to the difficulty of paraphrase generation. Their adversaries are whole sentence concatenations, generated by manually defined rules tailored to reading comprehension, and each adversary is specific to an individual instance. Zhao et al. (2018) generate natural text adversaries by projecting the input data to a latent space using a generative adversarial networks (GANs), and searching for adversaries close to the original instance in this latent space. Apart from the challenge of training GANs to generate high quality text, there is no guarantee that an example close in the latent space is semantically equivalent. Ebrahimi et al. (2018), along with proposing character-level changes that are not semantic-preserving, also propose a heuristic that replaces single words adversarially to preserve semantics. This approach not only depends on having white-box access to the model, but is also not able to generate many adversaries (only $\sim 1.6\%$ for sentiment analysis, compare to $\sim 33\%$ for SEAs in Table 4b). Developed concurrently with our work, Iyyer et al. (2018) proposes a neural paraphrase model based on back-translated data, which is able to produce paraphrases that have different sentence structures from the original. They use paraphrases to generate adversaries and try to post-process nonsensical outputs, but they do not explicitly reject non-semantics preserving ones, nor do they try to induce rules from individual adversaries. In any case, their adversaries are also useful for data augmentation, in experiments similar to ours.

In summary, previous work on text adversaries change semantics, only generate local (instance-specific) adversaries (Zhao et al., 2018; Iyyer et al., 2018), or are tailored for white-box models (Ebrahimi et al., 2018) or specific tasks (Jia and Liang, 2017). In contrast, SEAs expose oversensitivity for specific predictions of black-box models for a variety of tasks, while SEARs are intuitive and actionable global rules that induce a high number of high-quality adversaries. To our knowledge, we are also the first to evaluate human performance in adversarial generation (semantics-preserving or otherwise), and our extensive evaluation shows that SEAs and SEARs detect individual bugs and general patterns better than humans can.

7 Limitations and Future Work

Having demonstrated the usefulness of SEAs and SEARs in a variety of domains, we now describe their limitations and opportunities for future work.

Semantic scoring errors: Paraphrasing is still an active area of research, and thus our semantic scorer is sometimes incorrect in evaluating rules for semantic equivalence. We show examples of SEARs that are rejected by users in Table 7 – the semantic scorer does not sufficiently penalize preposition changes, and is biased towards common terms. The presence of such errors is why we still need humans in the loop to accept or reject SEARs.

SEAR	**Questions / SEAs**	**f(x)**
on →in	What is ~~on~~ in the background?	~~A building~~ Mountains
	What is ~~on~~? in	~~Lights~~ The television
VBP→is	Where ~~are~~ is the water bottles	~~Table~~ Vending Maching
	Where ~~are~~ is the people gathered	~~living room~~ kitchen
VERB on → VERB	What is ~~on~~ the background?	~~A building~~ Mountains
	What are the planes parked ~~on~~?	~~Concrete~~ landing strip

Table 7: SEARs for VQA that are rejected by users

Other paraphrase limitations: Paraphrase models based on neural machine translation are biased towards maintaining the sentence structure, and thus do not produce certain adversaries (e.g. Table 5b), which recent work on paraphrasing (Iyyer et al., 2018) or generation using GANs (Zhao et al., 2018) may address. More critically, existing models are inaccurate for long texts, restricting SEAs and SEARs to sentences.

Better bug fixing: Our data augmentation has the human users accept/reject rules based on whether or not they preserve semantics. Developing more effective ways of leveraging the expert's time to close the loop, and facilitating more interactive collaboration between humans and SEARs are exciting areas for future work.

8 Conclusion

We introduced SEAs and SEARs – adversarial examples and rules that preserve semantics, while causing models to make mistakes. We presented examples of such bugs discovered in state-of-the-art models for various tasks, and demonstrated via user studies that non-experts and experts alike are much better at detecting local and global bugs in NLP models by using our methods. We also *close the loop* by proposing a simple data augmentation solution that greatly reduced oversensitivity while maintaining accuracy. We demonstrated that SEAs and SEARs can be an invaluable tool for debugging NLP models, while indicating their current limitations and avenues for future work.

Style Transfer Through Back-Translation

Shrimai Prabhumoye, Yulia Tsvetkov, Ruslan Salakhutdinov, Alan W Black
Carnegie Mellon University, Pittsburgh, PA, USA
{sprabhum,ytsvetko,rsalakhu,awb}@cs.cmu.edu

Abstract

Style transfer is the task of rephrasing the text to contain specific stylistic properties without changing the intent or affect within the context. This paper introduces a new method for automatic style transfer. We first learn a latent representation of the input sentence which is grounded in a language translation model in order to better preserve the meaning of the sentence while reducing stylistic properties. Then adversarial generation techniques are used to make the output match the desired style. We evaluate this technique on three different style transformations: sentiment, gender and political slant. Compared to two state-of-the-art style transfer modeling techniques we show improvements both in automatic evaluation of style transfer and in manual evaluation of meaning preservation and fluency.

1 Introduction

Intelligent, situation-aware applications must produce naturalistic outputs, lexicalizing the same meaning differently, depending upon the environment. This is particularly relevant for language generation tasks such as machine translation (Sutskever et al., 2014; Bahdanau et al., 2015), caption generation (Karpathy and Fei-Fei, 2015; Xu et al., 2015), and natural language generation (Wen et al., 2017; Kiddon et al., 2016). In conversational agents (Ritter et al., 2011; Sordoni et al., 2015; Vinyals and Le, 2015; Li et al., 2016), for example, modulating the politeness style, to sound natural depending upon a situation: at a party with friends "Shut up! the video is starting!", or in a professional setting "Please be quiet, the video will begin shortly.".

These goals have motivated a considerable amount of recent research efforts focused at "controlled" language generation—aiming at separating the semantic content of *what* is said from the stylistic dimensions of *how* it is said. These include approaches relying on heuristic substitutions, deletions, and insertions to modulate demographic properties of a writer (Reddy and Knight, 2016), integrating stylistic and demographic speaker traits in statistical machine translation (Rabinovich et al., 2016; Niu et al., 2017), and deep generative models controlling for a particular stylistic aspect, e.g., politeness (Sennrich et al., 2016), sentiment, or tense (Hu et al., 2017; Shen et al., 2017). The latter approaches to style transfer, while more powerful and flexible than heuristic methods, have yet to show that in addition to transferring style they effectively preserve meaning of input sentences.

This paper introduces a novel approach to transferring style of a sentence while better preserving its meaning. We hypothesize—relying on the study of Rabinovich et al. (2016) who showed that author characteristics are significantly obfuscated by both manual and automatic machine translation—that grounding in back-translation is a plausible approach to rephrase a sentence while reducing its stylistic properties. We thus first use back-translation to rephrase the sentence and reduce the effect of the original style; then, we generate from the latent representation, using separate style-specific generators controlling for style (§2).

We focus on transferring author attributes: (1) gender and (2) political slant, and (3) on sentiment modification. The second task is novel: given a sentence by an author with a particular political leaning, rephrase the sentence to preserve its meaning but to confound classifiers of political slant (§3). The task of sentiment modification enables us to compare our approach with state-of-

the-art models (Hu et al., 2017; Shen et al., 2017).

Style transfer is evaluated using style classifiers trained on held-out data. Our back-translation style transfer model outperforms the state-of-the-art baselines (Shen et al., 2017; Hu et al., 2017) on the tasks of political slant and sentiment modification; 12% absolute improvement was attained for political slant transfer, and up to 7% absolute improvement in modification of sentiment (§5). Meaning preservation was evaluated manually, using A/B testing (§4). Our approach performs better than the baseline on the task of transferring gender and political slant. Finally, we evaluate the fluency of the generated sentences using human evaluation and our model outperforms the baseline in all experiments for fluency.

The main contribution of this work is a new approach to style transfer that outperforms state-of-the-art baselines in both the quality of input–output correspondence (meaning preservation and fluency), and the accuracy of style transfer. The secondary contribution is a new task that we propose to evaluate style transfer: transferring political slant.

2 Methodology

Given two datasets $\boldsymbol{X}_1 = \{\boldsymbol{x}_1^{(1)}, \ldots, \boldsymbol{x}_1^{(n)}\}$ and $\boldsymbol{X}_2 = \{\boldsymbol{x}_2^{(1)}, \ldots, \boldsymbol{x}_2^{(n)}\}$ which represent two different styles $\boldsymbol{s}_1$ and $\boldsymbol{s}_2$, respectively, our task is to generate sentences of the desired style while preserving the meaning of the input sentence. Specifically, we generate samples of dataset $\boldsymbol{X}_1$ such that they belong to style $\boldsymbol{s}_2$ and samples of $\boldsymbol{X}_2$ such that they belong to style $\boldsymbol{s}_1$. We denote the output of dataset $\boldsymbol{X}_1$ transfered to style $\boldsymbol{s}_2$ as $\hat{\boldsymbol{X}}_1 = \{\hat{\boldsymbol{x}}_2^{(1)}, \ldots, \hat{\boldsymbol{x}}_2^{(n)}\}$ and the output of dataset $\boldsymbol{X}_2$ transferred to style $\boldsymbol{s}_1$ as $\hat{\boldsymbol{X}}_2 = \{\hat{\boldsymbol{x}}_1^{(1)}, \ldots, \hat{\boldsymbol{x}}_1^{(n)}\}$.

Hu et al. (2017) and Shen et al. (2017) introduced state-of-the-art style transfer models that use variational auto-encoders (Kingma and Welling, 2014, VAEs) and cross-aligned auto-encoders, respectively, to model a latent content variable $\boldsymbol{z}$. The latent content variable $\boldsymbol{z}$ is a code which is not observed. The generative model conditions on this code during the generation process. Our aim is to design a latent code $\boldsymbol{z}$ which (1) represents the meaning of the input sentence grounded in back-translation and (2) weakens the style attributes of author's traits. To model the former, we use neural machine translation. Prior work has shown that the process of translating a sentence from a source language to a target language retains the meaning of the sentence but does not preserve the stylistic features related to the author's traits (Rabinovich et al., 2016). We hypothesize that a latent code $\boldsymbol{z}$ obtained through back-translation will normalize the sentence and devoid it from style attributes specific to author's traits.

Figure 1 shows the overview of the proposed method. In our framework, we first train a machine translation model from source language e to a target language f. We also train a back-translation model from f to e. Let us assume our styles $\boldsymbol{s}_1$ and $\boldsymbol{s}_2$ correspond to DEMOCRATIC and REPUBLICAN style, respectively. In Figure 1, the input sentence *i thank you, rep. visclosky.* is labeled as DEMOCRATIC. We translate the sentence using the $e \rightarrow f$ machine translation model and generate the parallel sentence in the target language f: *je vous remercie, rep. visclosky.* Using the fixed encoder of the $f \rightarrow e$ machine translation model, we encode this sentence in language f. The hidden representation created by this encoder of the back-translation model is used as $\boldsymbol{z}$. We condition our generative models on this $\boldsymbol{z}$. We then train two separate decoders for each style $\boldsymbol{s}_1$ and $\boldsymbol{s}_2$ to generate samples in these respective styles in source language e. Hence the sentence could be translated to the REPUBLICAN style using the decoder for $\boldsymbol{s}_2$. For example, the sentence *i'm praying for you sir.* is the REPUBLICAN ver-

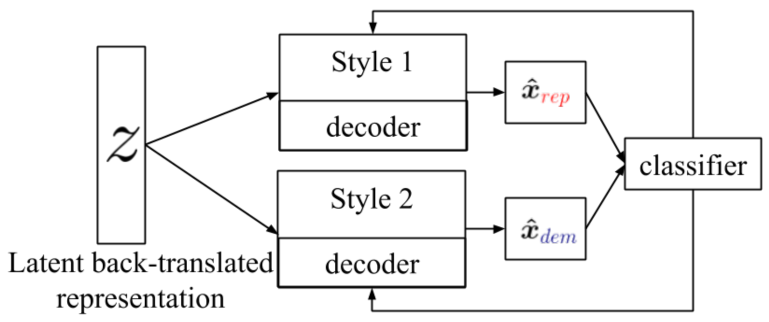

Figure 2: The latent representation from back-translation and the style classifier feedback are used to guide the style-specific generators.

sion of the input sentence and *i thank you, senator visclosky.* is the more DEMOCRATIC version of it.

Note that in this setting, the machine translation and the encoder of the back-translation model remain fixed. They are not dependent on the data we use across different tasks. This facilitates reusability and spares the need of learning separate models to generate $\boldsymbol{z}$ for a new style data.

2.1 Meaning-Grounded Representation

In this section we describe how we learn the latent content variable $\boldsymbol{z}$ using back-translation. The $e \rightarrow f$ machine translation and $f \rightarrow e$ back-translation models are trained using a sequence-to-sequence framework (Sutskever et al., 2014; Bahdanau et al., 2015) with style-agnostic corpus. The style-specific sentence *i thank you, rep. visclosky.* in source language e is translated to the target language f to get *je vous remercie, rep. visclosky.* The individual tokens of this sentence are then encoded using the encoder of the $f \rightarrow e$ back-translation model. The learned hidden representation is $\boldsymbol{z}$.

Formally, let $\boldsymbol{\theta}_E$ represent the parameters of the encoder of $f \rightarrow e$ translation system. Then $\boldsymbol{z}$ is given by:

$$\boldsymbol{z} = Encoder(\boldsymbol{x}_f; \boldsymbol{\theta}_E) \tag{1}$$

where, $\boldsymbol{x}_f$ is the sentence $\boldsymbol{x}$ in language f. Specifically, $\boldsymbol{x}_f$ is the output of $e \rightarrow f$ translation system when $\boldsymbol{x}_e$ is given as input. Since $\boldsymbol{z}$ is derived from a non-style specific process, this Encoder is not style specific.

2.2 Style-Specific Generation

Figure 2 shows the architecture of the generative model for generating different styles. Using the encoder embedding $\boldsymbol{z}$, we train multiple decoders for each style. The sentence generated by a decoder is passed through the classifier. The loss of the classifier for the generated sentence is used as feedback to guide the decoder for the generation process. The target attribute of the classifier is determined by the decoder from which the output is generated. For example, in the case of DEMOCRATIC decoder, the target attribute is DEMOCRATIC and for the REPUBLICAN decoder the target is REPUBLICAN.

2.2.1 Style Classifiers

We train a convolutional neural network (CNN) classifier to accurately predict the given style. We also use it to evaluate the error in the generated samples for the desired style. We train the classifier in a supervised manner. The classifier accepts either discrete or continuous tokens as inputs. This is done such that the generator output can be used as input to the classifier. We need labeled examples to train the classifier such that each instance in the dataset $\boldsymbol{X}$ should have a label in the set $\boldsymbol{s} = \{\boldsymbol{s}_1, \boldsymbol{s}_2\}$. Let $\boldsymbol{\theta}_C$ denote the parameters of the classifier. The objective to train the classifier is given by:

$$\mathcal{L}_{class}(\boldsymbol{\theta}_C) = \mathbb{E}_{\boldsymbol{X}}[\log q_C(\boldsymbol{s}|\boldsymbol{x})]. \tag{2}$$

To improve the accuracy of the classifier, we augment classifier's inputs with style-specific lexicons. We concatenate binary style indicators to each input word embedding in the classifier. The indicators are set to 1 if the input word is present in a style-specific lexicon; otherwise they are set to 0. Style lexicons are extracted using the log-odds ratio informative Dirichlet prior (Monroe et al., 2008), a method that identifies words that are statistically overrepresented in each of the categories.

2.2.2 Generator Learning

We use a bidirectional LSTM to build our decoders which generate the sequence of tokens $\hat{\boldsymbol{x}} = \{x_1, \cdots x_T\}$. The sequence $\hat{\boldsymbol{x}}$ is conditioned on the latent code $\boldsymbol{z}$ (in our case, on the machine translation model). In this work we use a corpus translated to French by the machine translation system as the input to the encoder of the back-translation model. The same encoder is used to encode sentences of both styles. The representation created by this encoder is given by Eq 1. Samples are generated as follows:

$$\begin{aligned} \hat{\boldsymbol{x}} \sim \boldsymbol{z} &= p(\hat{\boldsymbol{x}}|\boldsymbol{z}) && (3) \\ &= \prod_t p(\hat{x}_t|\hat{\boldsymbol{x}}^{<t}, \boldsymbol{z}) && (4) \end{aligned}$$

where, $\hat{\boldsymbol{x}}^{<t}$ are the tokens generated before $\hat{x}_t$.

Tokens are discrete and non-differentiable. This makes it difficult to use a classifier, as the generation process samples discrete tokens from the multinomial distribution parametrized using softmax function at each time step t. This non-differentiability, in turn, breaks down gradient propagation from the discriminators to the generator. Instead, following Hu et al. (2017) we use a continuous approximation based on softmax, along with the temperature parameter which anneals the softmax to the discrete case as training proceeds. To create a continuous representation of the output of the generative model which will be given as an input to the classifier, we use:

$$\hat{x}_t \sim \text{softmax}(\boldsymbol{o}_t/\tau),$$

where, $\boldsymbol{o}_t$ is the output of the generator and τ is the temperature which decreases as the training proceeds. Let $\boldsymbol{\theta}_G$ denote the parameters of the generators. Then the reconstruction loss is calculated using the cross entropy function, given by:

$$\mathcal{L}_{recon}(\boldsymbol{\theta}_G; \boldsymbol{x}) = \mathbb{E}_{q_E(\boldsymbol{z}|\boldsymbol{x})}[\log p_{gen}(\boldsymbol{x}|\boldsymbol{z})] \quad (5)$$

Here, the back-translation encoder E creates the latent code $\boldsymbol{z}$ by:

$$\boldsymbol{z} = E(\boldsymbol{x}) = q_E(\boldsymbol{z}|\boldsymbol{x}) \quad (6)$$

The generative loss $\mathcal{L}_{gen}$ is then given by:

$$\min_{\theta_{gen}} \mathcal{L}_{gen} = \mathcal{L}_{recon} + \lambda_c \mathcal{L}_{class} \quad (7)$$

where $\mathcal{L}_{recon}$ is given by Eq. (5), $\mathcal{L}_{class}$ is given by Eq (2) and λ_c is a balancing parameter.

We also use global attention of (Luong et al., 2015) to aid our generators. At each time step t of the generation process, we infer a variable length alignment vector $\boldsymbol{a}_t$:

$$\boldsymbol{a}_t = \frac{\exp(\text{score}(\boldsymbol{h}_t, \bar{\boldsymbol{h}}_s))}{\sum_{s'} \exp(\text{score}(\boldsymbol{h}_t, \bar{\boldsymbol{h}}_{s'}))} \quad (8)$$

$$\text{score}(\boldsymbol{h}_t, \bar{\boldsymbol{h}}_s) = \textbf{dot}(\boldsymbol{h}_t^T, \bar{\boldsymbol{h}}_s), \quad (9)$$

where $\boldsymbol{h}_t$ is the current target state and $\bar{\boldsymbol{h}}_s$ are all source states. While generating sentences, we use the attention vector to replace unknown characters (UNK) using the copy mechanism in (See et al., 2017).

3 Style Transfer Tasks

Much work in computational social science has shown that people's personal and demographic characteristics—either publicly observable (e.g., age, gender) or private (e.g., religion, political affiliation)—are revealed in their linguistic choices (Nguyen et al., 2016). There are practical scenarios, however, when these attributes need to be modulated or obfuscated. For example, some users may wish to preserve their anonymity online, for personal security concerns (Jardine, 2016), or to reduce stereotype threat (Spencer et al., 1999). Modulating authors' attributes while preserving meaning of sentences can also help generate demographically-balanced training data for a variety of downstream applications.

Moreover, prior work has shown that the quality of language identification and POS tagging degrades significantly on African American Vernacular English (Blodgett et al., 2016; Jørgensen et al., 2015); YouTube's automatic captions have higher error rates for women and speakers from Scotland (Rudinger et al., 2017). Synthesizing balanced training data—using style transfer techniques—is a plausible way to alleviate bias present in existing NLP technologies.

We thus focus on two tasks that have practical and social-good applications, and also accurate style classifiers. To position our method with respect to prior work, we employ a third task of sentiment transfer, which was used in two state-of-the-art approaches to style transfer (Hu et al., 2017; Shen et al., 2017). We describe the three tasks and associated dataset statistics below. The methodology that we advocate is general and can be applied to other styles, for transferring various social categories, types of bias, and in multi-class settings.

Gender. In sociolinguistics, gender is known to be one of the most important social categories driving language choice (Eckert and McConnell-Ginet, 2003; Lakoff and Bucholtz, 2004; Coates, 2015). Reddy and Knight (2016) proposed a heuristic-based method to obfuscate gender of a writer. This method uses statistical association measures to identify gender-salient words and substitute them with synonyms typically of the opposite gender. This simple approach produces highly fluent, meaning-preserving sentences, but does not allow for more general rephrasing of sentence beyond single-word substitutions. In our work, we adopt this task of transferring the author's gender and adapt it to our experimental settings.

We used Reddy and Knight's (2016) dataset of reviews from Yelp annotated for two genders corresponding to markers of sex.[1] We split the reviews to sentences, preserving the original gender labels. To keep only sentences that are strongly indicative of a gender, we then filtered out gender-neutral sentences (e.g., *thank you*) and sentences whose likelihood to be written by authors of one gender is lower than 0.7.[2]

Political slant. Our second dataset is comprised of top-level comments on Facebook posts from all 412 current members of the United States Senate and House who have public Facebook pages (Voigt et al., 2018).[3] Only top-level comments that directly respond to the post are included. Every comment to a Congressperson is labeled with the Congressperson's party affiliation: democratic or republican. Topic and sentiment in these comments reveal commenter's political slant. For example, *defund them all, especially when it comes to the illegal immigrants .* and *thank u james, praying for all the work u do .* are republican, whereas *on behalf of the hard-working nh public school teachers- thank you !* and *we need more strong voices like yours fighting for gun control .* represent examples of democratic sentences. Our task is to preserve intent of the commenter (e.g., to thank their representative), but to modify their observable political affiliation, as in the example in Figure 1. We preprocessed and filtered the comments similarly to the gender-annotated corpus above.

Style	*class*	*train*	*dev*	*test*
gender	2.57M	2.67M	4.5K	535K
political	80K	540K	4K	56K
sentiment	2M	444K	63.5K	127K

Table 1: Sentence count in style-specific corpora.

Sentiment. To compare our work with the state-of-the-art approaches of style transfer for non-parallel corpus we perform sentiment transfer, replicating the models and experimental setups of Hu et al. (2017) and Shen et al. (2017). Given a positive Yelp review, a style transfer model will generate a similar review but with an opposite sentiment. We used Shen et al.'s (2017) corpus of reviews from Yelp. They have followed the standard practice of labeling the reviews with rating of higher than three as positive and less than three as negative. They have also split the reviews to sentences and assumed that the sentence has the same sentiment as the review.

Dataset statistics. We summarize below corpora statistics for the three tasks: transferring gender, political slant, and sentiment. The dataset for sentiment modification task was used as described in (Shen et al., 2017). We split Yelp and Facebook corpora into four disjoint parts each: (1) a training corpus for training a style classifier (*class*); (2) a training corpus (*train*) used for training the style-specific generative model described in §2.2; (3) development and (4) test sets. We have removed from training corpora *class* and *train* all sentences that overlap with development and test corpora. Corpora sizes are shown in Table 1.

Table 2 shows the approximate vocabulary sizes used for each dataset. The vocabulary is the same for both the styles in each experiment.

Style	gender	political	sentiment
Vocabulary	20K	20K	10K

Table 2: Vocabulary sizes of the datasets.

Table 3 summarizes sentence statistics. All the

[1]We note that gender may be considered along a spectrum (Eckert and McConnell-Ginet, 2003), but use gender as a binary variable due to the absence of corpora with continuous-valued gender annotations.

[2]We did not experiment with other threshold values.

[3]The posts and comments are all public; however, to protect the identity of Facebook users in this dataset Voigt et al. (2018) have removed all identifying user information as well as Facebook-internal information such as User IDs and Post IDs, replacing these with randomized ID numbers.

sentences have maximum length of 50 tokens.

Style	Avg. Length	%data
male	18.08	50.00
female	18.21	50.00
republican	16.18	50.00
democratic	16.01	50.00
negative	9.66	39.81
positive	8.45	60.19

Table 3: Average sentence length and class distribution of style corpora.

4 Experimental Setup

In what follows, we describe our experimental settings, including baselines used, hyperparameter settings, datasets, and evaluation setups.

Baseline. We compare our model against the "cross-aligned" auto-encoder (Shen et al., 2017), which uses style-specific decoders to align the style of generated sentences to the actual distribution of the style. We used the off-the-shelf sentiment model released by Shen et al. (2017) for the sentiment experiments. We also separately train this model for the gender and political slant using hyper-parameters detailed below.[4]

Translation data. We trained an English–French neural machine translation system and a French–English back-translation system. We used data from Workshop in Statistical Machine Translation 2015 (WMT15) (Bojar et al., 2015) to train our translation models. We used the French–English data from the Europarl v7 corpus, the news commentary v10 corpus and the common crawl corpus from WMT15. Data were tokenized using the Moses tokenizer (Koehn et al., 2007). Approximately 5.4M English–French parallel sentences were used for training. A vocabulary size of 100K was used to train the translation systems.

Hyperparameter settings. In all the experiments, the generator and the encoders are a two-layer bidirectional LSTM with an input size of 300 and the hidden dimension of 500. The generator samples a sentence of maximum length 50. All the generators use global attention vectors of size 500. The CNN classifier is trained with 100 filters of size 5, with max-pooling. The input to CNN is of size 302: the 300-dimensional word embedding plus two bits for membership of the word in our style lexicons, as described in §2.2.1. Balancing parameter λ_c is set to 15. For sentiment task, we have used settings provided in (Shen et al., 2017).

5 Results

We evaluate our approach along three dimensions. (1) Style transfer accuracy, measuring the proportion of our models' outputs that generate sentences of the desired style. The style transfer accuracy is performed using classifiers trained on held-out train data that were not used in training the style transfer models. (2) Preservation of meaning. (3) Fluency, measuring the readability and the naturalness of the generated sentences. We conducted human evaluations for the latter two.

In what follows, we first present the quality of our neural machine translation systems, then we present the evaluation setups, and then present the results of our experiments.

Translation quality. The BLEU scores achieved for English–French MT system is 32.52 and for French–English MT system is 31.11; these are strong translation systems. We deliberately chose a European language close to English for which massive amounts of parallel data are available and translation quality is high, to concentrate on the style generation, rather than improving a translation system. [5]

5.1 Style Transfer Accuracy

We measure the accuracy of style transfer for the generated sentences using a pre-trained style classifier (§2.2.1). The classifier is trained on data that is not used for training our style transfer generative models (as described in §3). The classifier has an accuracy of 82% for the gender-annotated corpus, 92% accuracy for the political slant dataset and 93.23% accuracy for the sentiment dataset.

[4]In addition, we compared our model with the current state-of-the-art approach introduced by Hu et al. (2017); Shen et al. (2017) use this method as baseline, obtaining comparable results. We reproduced the results reported in (Hu et al., 2017) using their tasks and data. However, the same model trained on our political slant datasets (described in §3), obtained an almost random accuracy of 50.98% in style transfer. We thus omit these results.

[5]Alternatively, we could use a pivot language that is typologically more distant from English, e.g., Chinese. In this case we hypothesize that stylistic traits would be even less preserved in translation, but the quality of back-translated sentences would be worse. We have not yet investigated how the accuracy of the translation model, nor the language of translation affects our models.

We transfer the style of test sentences and then test the classification accuracy of the generated sentences for the opposite label. For example, if we want to transfer the style of male Yelp reviews to female, then we use the fixed common encoder of the back-translation model to encode the test male sentences and then we use the female generative model to generate the female-styled reviews. We then test these generated sentences for the *female* label using the gender classifier.

Experiment	CAE	BST
Gender	**60.40**	57.04
Political slant	75.82	**88.01**
Sentiment	80.43	**87.22**

Table 4: Accuracy of the style transfer in generated sentences.

In Table 4, we detail the accuracy of each classifier on generated style-transfered sentences.[6] We denote the Shen et al.'s (2017) **C**ross-aligned **A**uto-**E**ncoder model as CAE and our model as **B**ack-translation for **S**tyle **T**ransfer (BST).

On two out of three tasks our model substantially outperforms the baseline, by up to 12% in political slant transfer, and by up to 7% in sentiment modification.

5.2 Preservation of Meaning

Although we attempted to use automatics measures to evaluate how well meaning is preserved in our transformations; measures such as BLEU (Papineni et al., 2002) and Meteor (Denkowski and Lavie, 2011), or even cosine similarity between distributed representations of sentences do not capture this distance well.

Meaning preservation in style transfer is not trivial to define as literal meaning is likely to change when style transfer occurs. For example "My girlfriend loved the desserts" vs "My partner liked the desserts". Thus we must relax the condition of literal meaning to *intent* or *affect* of the utterance within the context of the discourse. Thus if the intent is to criticize a restaurant's service in a review, changing "salad" to "chicken" could still have the same effect but if the intent is to order food that substitution would not be acceptable. Ideally we wish to evaluate transfer within some downstream task and ensure that the task has the same outcome even after style transfer. This is a hard evaluation and hence we resort to a simpler evaluation of the "meaning" of the sentence.

[6]In each experiment, we report aggregated results across directions of style transfer; same results broke-down to style categories are listed in the Supplementary Material.

Experiment	CAE	No Pref.	BST
Gender	15.23	41.36	**43.41**
Political slant	14.55	**45.90**	39.55
Sentiment	35.91	**40.91**	23.18

Table 5: Human preference for meaning preservation in percentages.

We set up a manual pairwise comparison following Bennett (2005). The test presents the original sentence and then, in random order, its corresponding sentences produced by the baseline and our models. For the gender style transfer we asked "Which transferred sentence maintains the same sentiment of the source sentence in the same semantic context (i.e. you can ignore if food items are changed)". For the task of changing the political slant, we asked "Which transferred sentence maintains the same semantic intent of the source sentence while changing the political position". For the task of sentiment transfer we have followed the annotation instruction in (Shen et al., 2017) and asked "Which transferred sentence is semantically equivalent to the source sentence with an opposite sentiment"

We then count the preferences of the eleven participants, measuring the relative acceptance of the generated sentences.[7] A third option "=" was given to participants to mark no preference for either of the generated sentence. The "no preference" option includes choices both are equally bad and both are equally good. We conducted three tests one for each type of experiment - gender, political slant and sentiment. We also divided our annotation set into short (#tokens $\leq$ 15) and long ($15 <$ #tokens ≤ 30) sentences for the gender and the political slant experiment. In each set we had 20 random samples for each type of style transfer. In total we had 100 sentences to be annotated. Note that we did not ask about appropriateness of the style transfer in this test, or fluency of outputs, only about meaning preservation.

The results of human evaluation are presented in Table 5. Although a no-preference option was chosen often—showing that state-of-the-art systems are still not on par with hu-

[7]None of the human judges are authors of this paper

man expectations—the BST models outperform the baselines in the gender and the political slant transfer tasks.

Crucially, the BST models significantly outperform the CAE models when transferring style in longer and harder sentences. Annotators preferred the CAE model only for 12.5% of the long sentences, compared to 47.27% preference for the BST model.

5.3 Fluency

Finally, we evaluate the fluency of the generated sentences. Fluency was rated from 1 (unreadable) to 4 (perfect) as is described in (Shen et al., 2017). We randomly selected 60 sentences each generated by the baseline and the BST model.

The results shown in Table 6 are averaged scores for each model.

Experiment	CAE	BST
Gender	2.42	**2.81**
Political slant	2.79	**2.87**
Sentiment	3.09	**3.18**
Overall	2.70	**2.91**
Overall Short	3.05	**3.11**
Overall Long	2.18	**2.62**

Table 6: Fluency of the generated sentences.

BST outperforms the baseline overall. It is interesting to note that BST generates significantly more fluent longer sentences than the baseline model. Since the average length of sentences was higher for the gender experiment, BST notably outperformed the baseline in this task, relatively to the sentiment task where the sentences are shorter. Examples of the original and style-transfered sentences generated by the baseline and our model are shown in the Supplementary Material.

5.4 Discussion

The loss function of the generators given in Eq. 5 includes two competing terms, one to improve meaning preservation and the other to improve the style transfer accuracy. In the task of sentiment modification, the BST model preserved meaning worse than the baseline, on the expense of being better at style transfer. We note, however, that the sentiment modification task is not particularly well-suited for evaluating style transfer: it is particularly hard (if not impossible) to disentangle the sentiment of a sentence from its propositional content, and to modify sentiment while preserving meaning or intent. On the other hand, the style-transfer accuracy for gender is lower for BST model but the preservation of meaning is much better for the BST model, compared to CAE model and to "No preference" option. This means that the BST model does better job at closely representing the input sentence while taking a mild hit in the style transfer accuracy.

6 Related Work

Style transfer with non-parallel text corpus has become an active research area due to the recent advances in text generation tasks. Hu et al. (2017) use variational auto-encoders with a discriminator to generate sentences with controllable attributes. The method learns a disentangled latent representation and generates a sentence from it using a code. This paper mainly focuses on sentiment and tense for style transfer attributes. It evaluates the transfer strength of the generated sentences but does not evaluate the extent of preservation of meaning in the generated sentences. In our work, we show a qualitative evaluation of meaning preservation.

Shen et al. (2017) first present a theoretical analysis of style transfer in text using non-parallel corpus. The paper then proposes a novel cross-alignment auto-encoders with discriminators architecture to generate sentences. It mainly focuses on sentiment and word decipherment for style transfer experiments.

Fu et al. (2018) explore two models for style transfer. The first approach uses multiple decoders for each type of style. In the second approach, style embeddings are used to augment the encoded representations, so that only one decoder needs to be learned to generate outputs in different styles. Style transfer is evaluated on scientific paper titles and newspaper tiles, and sentiment in reviews. This method is different from ours in that we use machine translation to create a strong latent state from which multiple decoders can be trained for each style. We also propose a different human evaluation scheme.

Li et al. (2018) first extract words or phrases associated with the original style of the sentence, delete them from the original sentence and then replace them with new phrases associated with the target style. They then use a neural model to fluently combine these into a final output. Junbo et al. (2017) learn a representation which is style-agnostic, using adversarial training of the auto-encoder.

Our work is also closely-related to a problem of paraphrase generation (Madnani and Dorr, 2010; Dong et al., 2017), including methods relying on (phrase-based) back-translation (Ganitkevitch et al., 2011; Ganitkevitch and Callison-Burch, 2014). More recently, Mallinson et al. (2017) and Wieting et al. (2017) showed how neural back-translation can be used to generate paraphrases. An additional related line of research is machine translation with non-parallel data. Lample et al. (2018) and Artetxe et al. (2018) have proposed sophisticated methods for unsupervised machine translation. These methods could in principle be used for style transfer as well.

7 Conclusion

We propose a novel approach to the task of style transfer with non-parallel text.[8] We learn a latent content representation using machine translation techniques; this aids grounding the meaning of the sentences, as well as weakening the style attributes. We apply this technique to three different style transfer tasks. In transfer of political slant and sentiment we outperform an off-the-shelf state-of-the-art baseline using a cross-aligned autoencoder. The political slant task is a novel task that we introduce. Our model also outperforms the baseline in all the experiments of fluency, and in the experiments for meaning preservation in generated sentences of gender and political slant. Yet, we acknowledge that the generated sentences do not always adequately preserve meaning.

This technique is suitable not just for style transfer, but for enforcing style, and removing style too. In future work we intend to apply this technique to *debiasing* sentences and *anonymization* of author traits such as gender and age.

In the future work, we will also explore whether an enhanced back-translation by pivoting through several languages will learn better grounded latent meaning representations. In particular, it would be interesting to back-translate through multiple target languages with a single source language (Johnson et al., 2016).

Measuring the separation of style from content is hard, even for humans. It depends on the task and the context of the utterance within its discourse. Ultimately we must evaluate our style transfer within some down-stream task where our style transfer has its intended use but we achieve the same task completion criteria.

[8] All the code and data used in the experiments will be released to facilitate reproducibility at https://github.com/shrimai/Style-Transfer-Through-Back-Translation

Acknowledgments

This work was funded by a fellowship from Robert Bosch, and in part by the National Science Foundation through award IIS-1526745. We would like to thank Sravana Reddy for sharing the Yelp corpus used in gender transfer experiments, Zhiting Hu for providing an implementation of a VAE-based baseline, and the 11 CMU graduate students who helped with annotation and manual evaluations. We are also grateful to the anonymous reviewers for their constructive feedback, and to Dan Jurafsky, David Jurgens, Vinod Prabhakaran, and Rob Voigt for valuable discussions at earlier stages of this work.

Generating Fine-Grained Open Vocabulary Entity Type Descriptions

Rajarshi Bhowmik and **Gerard de Melo**

Abstract

While large-scale knowledge graphs provide vast amounts of structured facts about entities, a short textual description can often be useful to succinctly characterize an entity and its type. Unfortunately, many knowledge graph entities lack such textual descriptions. In this paper, we introduce a dynamic memory-based network that generates a short open vocabulary description of an entity by jointly leveraging induced fact embeddings as well as the dynamic context of the generated sequence of words. We demonstrate the ability of our architecture to discern relevant information for more accurate generation of type description by pitting the system against several strong baselines.

Figure 1: A motivating example question that demonstrates the importance of short textual descriptions.

1 Introduction

Broad-coverage knowledge graphs such as Freebase, Wikidata, and NELL are increasingly being used in many NLP and AI tasks. For instance, DBpedia and YAGO were vital for IBM's Watson! Jeopardy system (Welty et al., 2012). Google's Knowledge Graph is tightly integrated into its search engine, yielding improved responses for entity queries as well as for question answering. In a similar effort, Apple Inc. is building an in-house knowledge graph to power Siri and its next generation of intelligent products and services.

Despite being rich sources of factual knowledge, cross-domain knowledge graphs often lack a succinct textual description for many of the existing entities. Fig. 1 depicts an example of a concise entity description presented to a user. Descriptions of this sort can be beneficial both to humans and in downstream AI and natural language processing tasks, including question answering (e.g., *Who is Roger Federer?*), named entity disambiguation (e.g., *Philadelphia* as a city vs. the film or even the brand of cream cheese), and information retrieval, to name but a few.

Additionally, descriptions of this sort can also be useful to determine the ontological type of an entity – another challenging task that often needs to be addressed in cross-domain knowledge graphs. Many knowledge graphs already provide ontological type information, and there has been substantial previous research on how to predict such types automatically for entities in knowledge graphs (Neelakantan and Chang, 2015; Miao et al., 2016; Kejriwal and Szekely, 2017), in semi-structured resources such as Wikipedia (Ponzetto and Strube, 2007; de Melo and Weikum, 2010), or even in unstructured text (Snow et al., 2006; Bansal et al., 2014; Tandon et al., 2015). However, most such work has targeted a fixed inventory of types from a given target ontology, many of which are more abstract in nature (e.g., *human* or *artifact*). In this work, we consider the task of generating more detailed open vocabulary descriptions (e.g., *Swiss tennis player*) that can readily be presented to end users, generated from facts in the knowledge graph.

Apart from type descriptions, certain knowledge graphs, such as Freebase and DBpedia, also provide a paragraph-length textual abstract for every entity. In the latter case, these are sourced from Wikipedia. There has also been research on generating such abstracts automatically (Biran and McKeown, 2017). While abstracts of this sort provide considerably more detail than ontological types, they are not sufficiently concise to be grasped at a single glance, and thus the onus is put on the reader to comprehend and summarize them.

Typically, a short description of an entity will hence need to be synthesized just by drawing on certain most relevant facts about it. While in many circumstances, humans tend to categorize entities at a level of abstraction commonly referred to as basic level categories (Rosch et al., 1976), in an information seeking setting, however, such as in Fig. 1, humans naturally expect more detail from their interlocutor. For example, *occupation* and *nationality* are often the two most relevant properties used in describing a person in Wikidata, while terms such as *person* or *human being* are likely to be perceived as overly unspecific. However, choosing such most relevant and distinctive attributes from the set of available facts about the entity is non-trivial, especially given the diversity of different kinds of entities in broad-coverage knowledge graphs. Moreover, the generated text should be coherent, succinct, and non-redundant.

To address this problem, we propose a dynamic memory-based generative network that can generate short textual descriptions from the available factual information about the entities. To the best of our knowledge, we are the first to present neural methods to tackle this problem. Previous work has suggested generating short descriptions using predefined templates (cf. Section 4). However, this approach severely restricts the expressivity of the model and hence such templates are typically only applied to very narrow classes of entities. In contrast, our goal is to design a broad-coverage open domain description generation architecture.

In our experiments, we induce a new benchmark dataset for this task by relying on Wikidata, which has recently emerged as the most popular crowdsourced knowledge base, following Google's designation of Wikidata as the successor to Freebase (Tanon et al., 2016). With a broad base of 19,000 casual Web users as contributors, Wikidata is a crucial source of machine-readable knowledge in many applications. Unlike DBpedia and Freebase, Wikidata usually contains a very concise description for many of its entities. However, because Wikidata is based on user contributions, many new entries are created that still lack such descriptions. This can be a problem for downstream tools and applications using Wikidata for background knowledge. Hence, even for Wikidata, there is a need for tools to generate fine-grained type descriptions. Fortunately, we can rely on the entities for which users have already contributed short descriptions to induce a new benchmark dataset for the task of automatically inducing type descriptions from structured data.

2 A Dynamic Memory-based Generative Network Architecture

Our proposed dynamic memory-based generative network consists of three key components: an input module, a dynamic memory module, and an output module. A schematic diagram of these are given in Fig. 2.

2.1 Input Module

The input to the input module is a set of N facts $F = \{f_1, f_2, \ldots, f_N\}$ pertaining to an entity. Each of these input facts are essentially (s, p, o) triples, for subjects s, predicates p, and objects o. Upon being encoded into a distributed vector representation, we refer to them as *fact embeddings*.

Although many different encoding schemes can be adopted to obtain such fact embeddings, we opt for a positional encoding as described by Sukhbaatar et al. (2015), motivated in part by the considerations given by Xiong et al. (2016). For completeness, we describe the positional encoding scheme here.

We encode each fact f_i as a vector $\mathbf{f_i} = \sum_{j=1}^{J} \mathbf{l_j} \circ \mathbf{w_j^i}$, where $\circ$ is an element-wise multiplication, and $\mathbf{l_j}$ is a column vector with the structure $l_{kj} = (1 - \frac{j}{J}) - (k/d)(1 - 2\frac{j}{J})$, with J being the number of words in the factual phrase, $\mathbf{w_j^i}$ as the embedding of the j-th word, and d as the dimensionality of the embedding. Details about how these factual phrases are formed for our data are

given in Section 3.3.

Thus, the output of this module is a concatenation of N fact embeddings $\mathbf{F} = [\mathbf{f_1}; \mathbf{f_2}; \ldots; \mathbf{f_N}]$.

2.2 Dynamic Memory Module

The dynamic memory module is responsible for memorizing specific facts about an entity that will be useful for generating the next word in the output description sequence. Intuitively, such a memory should be able to update itself dynamically by accounting not only for the factual embeddings but also for the current context of the generated sequence of words.

To begin with, the memory is initialized as $\mathbf{m^{(0)}} = \max(\mathbf{0}, \mathbf{W_m F} + \mathbf{b_m})$. At each time step t, the memory module attempts to gather pertinent contextual information by attending to and summing over the fact embeddings in a weighted manner. These attention weights are scalar values informed by two factors: (1) how much information from a particular fact is used by the previous memory state $\mathbf{m}^{(t-1)}$, and (2) how much information of a particular fact is invoked in the current context of the output sequence $\mathbf{h}^{(t-1)}$. Formally,

$$\mathbf{x_i}^{(t)} = [|\mathbf{f_i} - \mathbf{h}^{(t-1)}|; |\mathbf{f_i} - \mathbf{m}^{(t-1)}|], \quad (1)$$

$$\mathbf{z_i}^{(t)} = \mathbf{W_2} \tanh(\mathbf{W_1 x_i}^{(t)} + \mathbf{b_1}) + \mathbf{b_2}, \quad (2)$$

$$a_i^{(t)} = \frac{\exp(\mathbf{z_i}^{(t)})}{\sum_{k=1}^{N} \exp(\mathbf{z_k}^{(t)})}, \quad (3)$$

where $|.|$ is the element-wise absolute difference and $[;]$ denotes the concatenation of vectors.

Having obtained the attention weights, we apply a soft attention mechanism to extract the current context vector at time t as

$$\mathbf{c}^{(t)} = \sum_{i=1}^{N} a_i^{(t)} \mathbf{f_i}. \quad (4)$$

This newly obtained context information is then used along with the previous memory state to update the memory state as follows:

$$\mathbf{C}^{(t)} = [\mathbf{m}^{(t-1)}; \mathbf{c}^{(t)}; \mathbf{h}^{(t-1)}] \quad (5)$$

$$\mathbf{m}^{(t)} = \max(\mathbf{0}, \mathbf{W_m C}^{(t)} + \mathbf{b_m}) \quad (6)$$

Such updated memory states serve as the input to the decoder sequence of the output module at each time step.

2.3 Output Module

The output module governs the process of repeatedly decoding the current memory state so as to emit the next word in an ordered sequence of output words. We rely on GRUs for this.

At each time step, the decoder GRU is presented as input a glimpse of the current memory state $\mathbf{m}^{(t)}$ as well as the previous context of the output sequence, i.e., the previous hidden state of the decoder $\mathbf{h}^{(t-1)}$. At each step, the resulting output of the GRU is concatenated with the context vector $\mathbf{c_i}^{(t)}$ and is passed through a fully connected layer and finally through a softmax layer. During training, we deploy *teacher forcing* at each step by providing the vector embedding of the previous correct word in the sequence as an additional input. During testing, when such a signal is not available, we use the embedding of the predicted word in the previous step as an additional input to the current step. Formally,

$$\mathbf{h}^{(t)} = \mathrm{GRU}([\mathbf{m}^{(t)}; \mathbf{w}^{(t-1)}], \mathbf{h}^{(t-1)}), \quad (7)$$

$$\tilde{\mathbf{h}}^{(t)} = \tanh(\mathbf{W_d}[\mathbf{h}^{(t)}; \mathbf{c}^{(t)}] + \mathbf{b_d}), \quad (8)$$

$$\hat{\mathbf{y}}^{(t)} = \mathrm{Softmax}(\mathbf{W_o}\tilde{\mathbf{h}}^{(t)} + \mathbf{b_o}), \quad (9)$$

where $[;]$ is the concatenation operator, $\mathbf{w}^{(t-1)}$ is vector embedding of the previous word in the sequence, and $\hat{\mathbf{y}}^{(t)}$ is the probability distribution for the predicted word over the vocabulary at the current step.

2.4 Loss Function and Training

Training this model amounts to picking suitable values for the model parameters θ, which include the matrices $\mathbf{W_1}$, $\mathbf{W_2}$, $\mathbf{W_m}$, $\mathbf{W_d}$, $\mathbf{W_o}$ and the corresponding bias terms $\mathbf{b_1}$, $\mathbf{b_2}$, $\mathbf{b_m}$, $\mathbf{b_d}$, and $\mathbf{b_o}$ as well as the various transition and output matrices of the GRU.

To this end, if each of the training instances has a description with a maximum of M words, we can rely on the categorical cross-entropy over the entire output sequence as the loss function:

$$\mathcal{L}(\theta) = -\sum_{t=1}^{M}\sum_{j=1}^{|\mathcal{V}|} y_j^{(t)} \log(\hat{y}_j^{(t)}). \quad (10)$$

where $y_j^{(t)} \in \{0, 1\}$ and $|\mathcal{V}|$ is the vocabulary size.

We train our model end-to-end using Adam as the optimization technique.

3 Evaluation

In this section, we describe the process of creating our benchmark dataset as well as the baseline methods and the experimental results.

3.1 Benchmark Dataset Creation

For the evaluation of our method, we introduce a novel benchmark dataset that we have extracted from Wikidata and transformed to a suitable format. We rely on the official RDF exports of Wikidata, which are generated regularly (Erxleben et al., 2014), specifically, the RDF dump dated 2016-08-01, which consists of 19,768,780 entities with 2,570 distinct properties. A pair of a property and its corresponding value represents a fact about an entity. In Wikidata parlance, such facts are called *statements*. We sample a dataset of 10K entities from Wikidata, and henceforth refer to the resulting dataset as WikiFacts10K. Our sampling method ensures that each entity in WikiFacts10K has an English description and at least 5 associated statements. We then transform each extracted statement into a phrasal form by concatenating the words of the property name and its value. For example, the (subject, predicate, object) triple (*Roger Federer*, *occupation*, *tennis player*) is transformed to *'occupation tennis player'*. We refer to these phrases as the *factual phrases*, which are embedded as described earlier. We randomly divide this dataset into training, validation, and test sets with a 8:1:1 ratio. We have made our code and data available[1] for reproducibility and to facilitate further research in this area.

3.2 Baselines

We compare our model against an array of baselines of varying complexity. We experiment with some variants of our model as well as several other state-of-the-art models that, although not specifically designed for this setting, can straightforwardly be applied to the task of generating descriptions from factual data.

1. **Facts-to-sequence Encoder-Decoder Model.** This model is a variant of the standard sequence-to-sequence encoder-decoder architecture described by Sutskever et al. (2014). However, instead of an input sequence, it here operates on a set of fact embeddings $\{\mathbf{f_1}, \mathbf{f_2}, \ldots, \mathbf{f_N}\}$, which are emitted by the positional encoder described in Section 2.1. We initialize the hidden state of the decoder with a linear transformation of the fact embeddings as $\mathbf{h}^{(0)} = \mathbf{WF} + \mathbf{b}$, where $\mathbf{F} = [\mathbf{f_1}; \mathbf{f_2}; \ldots; \mathbf{f_N}]$ is the concatenation of N fact embeddings.

   As an alternative, we also experimented with a sequence encoder that takes a separate fact embedding as input at each step and initializes the decoder hidden state with the final hidden state of the encoder. However, this approach did not yield us better results.

[1] https://github.com/kingsaint/Open-vocabulary-entity-type-description

Table 1: Automatic evaluation results of different models. For a detailed explanation of the baseline models, please refer to Section 3.2. The best performing model for each column is highlighted in boldface.

Model	B-1	B-2	B-3	B-4	ROUGE-L	METEOR	CIDEr
Facts-to-seq	0.404	0.324	0.274	0.242	0.433	0.214	1.627
Facts-to-seq w. Attention	0.491	0.414	0.366	0.335	0.512	0.257	2.207
Static Memory	0.374	0.298	0.255	0.223	0.383	0.185	1.328
DMN+	0.281	0.234	0.236	0.234	0.275	0.139	0.912
Our Model	**0.611**	**0.535**	**0.485**	**0.461**	**0.641**	**0.353**	**3.295**

2. **Facts-to-sequence Model with Attention Decoder.** The encoder of this model is identical to the one described above. The difference is in the decoder module that uses an attention mechanism.

   At each time step t, the decoder GRU receives a context vector $\mathbf{c}^{(t)}$ as input, which is an attention weighted sum of the fact embeddings. The attention weights and the context vectors are computed as follows:

$$\mathbf{x}^{(t)} = [\mathbf{w}^{(t-1)}; \mathbf{h}^{(t-1)}] \quad (11)$$

$$\mathbf{z}^{(t)} = \mathbf{W}\mathbf{x}^{(t)} + \mathbf{b} \quad (12)$$

$$\mathbf{a}^{(t)} = \mathrm{softmax}(\mathbf{z}^{(t)}) \quad (13)$$

$$\mathbf{c}^{(t)} = \max(\mathbf{0}, \sum_{i=1}^{N} a_i^{(t)} \mathbf{f}_\mathbf{i}) \quad (14)$$

   After obtaining the context vector, it is fed to the GRU as input:

$$\mathbf{h}^{(t)} = \mathrm{GRU}([\mathbf{w}^{(t-1)}; \mathbf{c}^{(t)}], \mathbf{h}^{(t-1)}) \quad (15)$$

3. **Static Memory Model.** This is a variant of our model in which we do not upgrade the memory dynamically at each time step. Rather, we use the initial memory state as the input to all of the decoder GRU steps.

4. **Dynamic Memory Network (DMN+).** We consider the approach proposed by Xiong et al. (2016), which supersedes Kumar et al. (2016). However, some minor modifications are needed to adapt it to our task. Unlike the bAbI dataset, our task does not involve any question. The presence of a question is imperative in DMN+, as it helps to determine the initial state of the episodic memory module. Thus, we prepend an interrogative phrase such as *"Who is"* or *"What is"* to every entity name. The question module of the DMN+ is hence presented with a question such as *"Who is Roger Federer?"* or *"What is Star Wars?"*. Another difference is in the output module. In DMN+, the final memory state is passed through a softmax layer to generate the answer. Since most answers in the bAbI dataset are unigrams, such an approach suffices. However, as our task is to generate a sequence of words as descriptions, we use a GRU-based decoder sequence model, which at each time step receives the final memory state $\mathbf{m}^{(T)}$ as input to the GRU. We restrict the number of memory update episodes to 3, which is also the preferred number of episodes in the original paper.

3.3 Experimental Setup

For each entity in the WikiFacts10K dataset, there is a corresponding set of facts expressed as factual phrases as defined earlier. Each factual phrase in turn is encoded as a vector by means of the positional encoding scheme described in Section 2.1. Although other variants could be considered, such as LSTMs and GRUs, we apply this standard fact encoding mechanism for our model as well as all our baselines for the sake of uniformity and fair comparison. Another factor that makes the use of a sequence encoder such as LSTMs or GRUs less suitable is that the set of input facts is essentially unordered without any temporal correlation between facts.

We fixed the dimensionality of the fact embeddings and all hidden states to be 100. The vocabulary size is 29K. Our models and all other baselines are trained for a maximum of 25 epochs with an early stopping criterion and a fixed learning rate of 0.001.

To evaluate the quality of the generated descriptions, we rely on the standard BLEU (B-1, B-2, B-3, B-4), ROUGE-L, METEOR and CIDEr metrics, as implemented by Sharma et al. (2017). Of course, we would be remiss not to point out that these metrics are imperfect. In general, they tend to be conservative in that they only reward generated descriptions that overlap substantially with the ground truth descriptions given in Wikidata. In reality, it may of course be the case that alternative descriptions are equally appropriate. In fact, inspecting the generated descriptions, we found that our method often indeed generates correct alternative descriptions. For instance, Darius Kaiser is described as a *cyclist*, but one could also describe him as a *German bicycle racer*. Despite their shortcomings, the aforementioned metrics have generally been found suitable for comparing supervised systems, in that systems with significantly higher scores tend to fare better at learning to reproduce ground truth captions.

3.4 Results

The results of the experiments are reported in Table 1. Across all metrics, we observe that our model obtains significantly better scores than the alternatives.

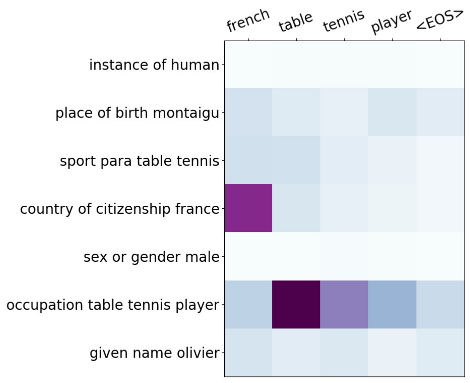
A facts-to-seq model exploiting our positional fact encoding performs adequately. With an additional attention mechanism (Facts-to-seq w. Attention), the results are even better. This is on account of the attention mechanism's ability to reconsider the attention distribution at each time step using the current context of the output sequence. The results suggest that this enables the model to more flexibly focus on the most pertinent parts of the input. In this regard, such a model thus resembles our approach. However, there are important differences between this baseline and our model. Our model not only uses the current context of the output sequence, but also memorizes how information of a particular fact has been used thus far, via the dynamic memory module. We conjecture that the dynamic memory module thereby facilitates generating longer description sequences more accurately by better tracking which parts have been attended to, as is empirically corroborated by the comparably higher BLEU scores for longer n-grams.

The analysis of the Static Memory approach amounts to an ablation study, as it only differs from our full model in lacking memory updates. The divergence of scores between the two variants suggests that the dynamic memory indeed is vital for more dynamically attending to the facts by taking into account the current context of the output sequence at each step. Our model needs to dynamically achieve different objectives at different time points. For instance, it may start off looking at several properties to infer a type of the appropriate granularity for the entity (e.g., *village*), while in the following steps it considers a salient property and emits the corresponding named entity for it as well as a suitable preposition (e.g., *in China*).

Finally, the poor results of the DMN+ approach show that a naïve application of a state-of-the-art dynamic memory architecture does not suffice to obtain strong results on this task. Indeed, the DMN+ is even outperformed by our Facts-to-seq baseline. This appears to stem from the inability of the model to properly memorize all pertinent facts in its encoder.

Analysis. In Figure 3, we visualize the attention distribution over facts. We observe how the model shifts its focus to different sorts of properties while generating successive words.

Table 2 provides a representative sample of the generated descriptions and their ground truth counterparts. A manual inspection reveals five distinct patterns. The first case is that of exact matches with the reference descriptions. The second involves examples on which there is a high overlap of words between the ground truth and generated descriptions, but the latter as a whole is incorrect because of semantic drift or other challenges. In some cases, the model may have never seen a word or named entity during training (e.g., *Hypocrisy*), or their frequency is very limited in the training set. While it has been shown that GRUs with an attention mechanism are capable of learning to copy random strings from the input (Gu et al., 2016), we conjecture that a dedicated copy mechanism may help to mitigate this problem, which we will explore in future research. In other cases, the model conflates semantically related concepts, as is evident from examples such as a *film* being described as a *filmmaker* and a *polo player* as a *water polo player*. Next, the third group involves generated descriptions that are more specific than the ground truth, but correct, while, in the fourth group, the generated outputs generalize the descriptions to a certain extent. For example, *American musician and pianist* is generalized as *American musician*, since *musician* is a hypernym of *pianist*. Finally, the last group consists of cases in which our model generated descriptions that are factually accurate and may be deemed appropriate despite diverging from the



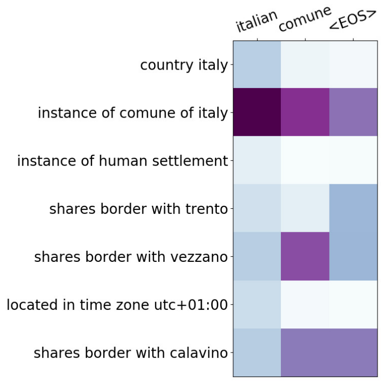


Figure 3: An example of attention distribution over the facts while emitting words. The *country of citizenship* property gets the most attention while generating the first word *French* of the left description. For generating the next three words, the fact *occupation* attracts the most attention. Similarly, *instance of* attracts the most attention when generating the sequence *Italian comune*.

reference descriptions to an extent that almost no overlapping words are shared with them. Note that such outputs are heavily penalized by the metrics considered in our evaluation.

4 Related Work

Type Prediction. There has been extensive work on predicting the ontological types of entities in large knowledge graphs (Neelakantan and Chang, 2015; Miao et al., 2016; Kejriwal and Szekely, 2017; Shimaoka et al., 2017), in semi-structured resources such as Wikipedia (Ponzetto and Strube, 2007; de Melo and Weikum, 2010), as well as in text (Del Corro et al., 2015; Yaghoobzadeh and Schütze, 2015; Ren et al., 2016). However, the major shortcoming of these sorts of methods, including those aiming at more fine-grained typing, is that they assume that the set of candidate types is given as input, and the main remaining challenge is to pick the correct one(s). In contrast, our work yields descriptions that often indicate the type of entity, but typically are more natural-sounding and descriptive (e.g. *French Impressionist artist*) than the oftentimes abstract ontological types (such as *human* or *artifact*) chosen by type prediction methods.

A separate, long-running series of work has obtained open vocabulary type predictions for named entities and concepts mentioned in text (Hearst, 1992; Snow et al., 2006), possibly also inducing taxonomies from them (Poon and Domingos, 2010; Velardi et al., 2013; Bansal et al., 2014). However, these methods typically just need to select existing spans of text from the input as the output description.

Text Generation from Structured Data. Research on methods to generate descriptions for entities has remained scant. Lebret et al. (2016) take Wikipedia infobox data as input and train a custom form of neural language model that, conditioned on occurrences of words in the input table, generates biographical sentences as output. However, their system is limited to a single kind of description (biographical sentences) that tend to share a common structure. Wang et al. (2016) focus on the problem of temporal ordering of extracted facts. Biran and McKeown (2017) introduced a template-based description generation framework for creating hybrid concept-to-text and text-to-text generation systems that produce descriptions of RDF entities. Their framework can be tuned for new domains, but does not yield a broad-coverage multi-domain model. Voskarides et al. (2017) first create sentence templates for specific entity relationships, and then, given a new relationship instance, generate a description by selecting the best template and filling the template slots with the appropriate entities from the knowledge graph. Kutlak et al. (2013) generates referring expressions by converting property-value pairs to text using a hand-crafted mapping scheme. Wiseman et al. (2017) considered the related task of mapping tables with numeric basketball statistics to natural language. They investigated an extensive array of current state-of-the-art neural pointer methods but found that template-based models outperform all neural models on this task by a significant margin. However, their method requires specific templates for each domain (for example, basketball games in their case). Applying template-based methods to cross-domain knowledge bases is highly challenging, as this would require too many different templates for different types of entities. Our dataset contains items of from a large number of diverse domains such as humans, books, films, paintings, music albums, genes, proteins, cities, scientific articles, etc., to name but a few.

Chen and Mooney (2008) studied the task of taking representations of observations from a sports simulation (Robocup simulator) as input, e.g. *pass(arg1=purple6, arg2=purple3)*, and generating game commentary. Liang et al. (2009) learned alignments between formal descriptions such as *rainChance(time=26-30,mode=Def)* and natural language weather reports. Mei et al. (2016) used LSTMs for these sorts of generation tasks, via a custom coarse-to-fine architecture that first determines which input parts to focus on.

Much of the aforementioned work essentially involves aligning small snippets in the input to the relevant parts in the training output and then learning to expand such input snippets into full sentences. In contrast, in our task, alignments between parts of the input and the output do not suffice. Instead, describing an entity often also involves considering all available evidence about that entity to infer information about it that is often not immediately given. Rather than verbalizing facts, our method needs a complex attention mechanism to predict an object's general type and consider the information that is most likely to appear salient to humans from across the entire input.

The WebNLG Challenge (Gardent et al., 2017) is another task for generating text from structured data. However, this task requires a textual verbalization of every triple. On the contrary, the task we consider in this work is quite complementary in that a verbalization of all facts one-by-one is not the sought result. Rather, our task requires synthesizing a short description by carefully selecting the most relevant and distinctive facts from the set of all available facts about the entity. Due to these differences, the WebNLG dataset was not suitable for the research question considered by our paper.

Neural Text Summarization. Generating entity descriptions is related to the task of text summarization. Most traditional work in this area was extractive in nature, i.e. it selects the most salient sentences from a given input text and concatenates them to form a shorter summary or presents them differently to the user (Yang et al., 2017). Abstractive summarization goes beyond this in generating new text not necessarily encountered in the input, as is typically necessary in our setting. The surge of sequence-to-sequence modeling of text via LSTMs naturally extends to the task of abstractive summarization by training a model to accept a longer sequence as input and learning to generate a shorter compressed sequence as a summary.

Rush et al. (2015) employed this idea to generate a short headline from the first sentence of a text. Subsequent work investigated the use of architectures such as pointer-generator networks to better cope with long input texts (See et al., 2017). Recently, Liu et al. (2018) presented a model that generates an entire Wikipedia article via a neural decoder component that performs abstractive summarization of multiple source documents. Our work differs from such previous work in that we do not consider a text sequence as input. Rather, our input are a series of entity relationships or properties, as reflected by our facts-to-sequence baselines in the experiments. Note that our task is in certain respects also more difficult than text summarization. While regular neural summarizers are often able to identify salient spans of text that can be copied to the output, our input is of a substantially different form than the desired output.

Additionally, our goal is to make our method applicable to any entity with factual information that may not have a corresponding Wikipedia-like article available. Indeed, Wikidata currently has 46 million items, whereas the English Wikipedia has only 5.6 million articles. Hence, for the vast majority of items in Wikidata, no corresponding Wikipedia article is available. In such cases, a summarization baseline will not be effective.

Episodic Memory Architectures. A number of neural models have been put forth that possess the ability to interact with a memory component. Recent advances in neural architectures that combine memory components with an attention mechanism exhibit the ability to extract and reason over factual information. A well-known example is the End-To-End Memory Network model by Sukhbaatar et al. (2015), which may make multiple passes over the memory input to facilitate multi-hop reasoning. These have been particularly successful on the bAbI test suite of artificial comprehension tests (Weston et al., 2015), due to their ability to extract and reason over the input.

At the core of the Dynamic Memory Networks (DMN) architecture (Kumar et al., 2016) is an episodic memory module, which is updated at each episode with new information that is required to answer a predefined question. Our approach shares several commonalities with DMNs, as it is also endowed with a dynamic memory of this sort. However, there are also a number of significant differences. First of all, DMN and its improved version DMN+ (Xiong et al., 2016) assume sequential correlations between the sentences and rely on them for reasoning purposes. To this end, DMN+ needs an additional layer of GRUs, which is used to capture sequential correlations among sentences. Our model does not need any such layer, as facts in a knowledge graph do not necessarily possess any sequential interconnections. Additionally, DMNs assume a predefined number of memory episodes, with the final memory state being passed to the answer module. Unlike DMNs, our model uses the dynamic context of the output sequence to update the memory state. The number of memory updates in our model flexibly depends on the length of the generated sequence. DMNs also have an additional question module as input, which guides the memory updates and also the output, while our model does not leverage any such guiding factor. Finally, in DMNs, the output is typically a unigram, whereas our model emits a sequence of words.

5 Conclusion

Short textual descriptions of entities facilitate instantaneous grasping of key information about entities and their types. Generating them from facts in a knowledge graph requires not only mapping the structured fact information to natural language, but also identifying the type of entity and then discerning the most crucial pieces of information for that particular type from the long list of input facts and compressing them down to a highly succinct form. This is very challenging in light of the very heterogeneous kinds of entities in our data.

To this end, we have introduced a novel dynamic memory-based neural architecture that updates its memory at each step to continually reassess the relevance of potential input signals. We have shown that our approach outperforms several competitive baselines. In future work, we hope to explore the potential of this architecture on further kinds of data, including multimodal data (Long et al., 2018), from which one can extract structured signals. Our code and data is freely available.[2]

Hierarchical Neural Story Generation

Angela Fan **Mike Lewis** **Yann Dauphin**

Abstract

We explore *story generation*: creative systems that can build coherent and fluent passages of text about a topic. We collect a large dataset of 300K human-written stories paired with writing prompts from an online forum. Our dataset enables hierarchical story generation, where the model first generates a premise, and then transforms it into a passage of text. We gain further improvements with a novel form of model fusion that improves the relevance of the story to the prompt, and adding a new gated multi-scale self-attention mechanism to model long-range context. Experiments show large improvements over strong baselines on both automated and human evaluations. Human judges prefer stories generated by our approach to those from a strong non-hierarchical model by a factor of two to one.

1 Introduction

Story-telling is on the frontier of current text generation technology: stories must remain thematically consistent across the complete document, requiring modeling very long range dependencies; stories require creativity; and stories need a high level plot, necessitating planning ahead rather than word-by-word generation (Wiseman et al., 2017).

We tackle the challenges of story-telling with a hierarchical model, which first generates a sentence called the *prompt* describing the topic for the story, and then conditions on this prompt when generating the story. Conditioning on the prompt or premise makes it easier to generate consistent stories because they provide grounding for the overall plot. It also reduces the tendency of standard sequence models to drift off topic.

Prompt: The Mage, the Warrior, and the Priest

Story: A light breeze swept the ground, and carried with it still the distant scents of dust and time-worn stone. The Warrior led the way, heaving her mass of armour and muscle over the uneven terrain. She soon crested the last of the low embankments, which still bore the unmistakable fingerprints of haste and fear. She lifted herself up onto the top the rise, and looked out at the scene before her. [...]

Figure 1: Example prompt and beginning of a story from our dataset. We train a hierarchical model that first generates a prompt, and then conditions on the prompt when generating a story.

We find that standard sequence-to-sequence (seq2seq) models (Sutskever et al., 2014) applied to hierarchical story generation are prone to degenerating into language models that pay little attention to the writing prompt (a problem that has been noted in other domains, such as dialogue response generation (Li et al., 2015a)). This failure is due to the complex and underspecified dependencies between the prompt and the story, which are much harder to model than the closer dependencies required for language modeling (for example, consider the subtle relationship between the first sentence and prompt in Figure 1).

To improve the relevance of the generated story to its prompt, we introduce a fusion mechanism (Sriram et al., 2017) where our model is trained on top of an pre-trained seq2seq model. To improve over the pre-trained model, the second model must focus on the link between the prompt and the story. For the first time, we show that fusion mechanisms can help seq2seq models build dependencies between their input and output.

Another major challenge in story generation is the inefficiency of modeling long documents with standard recurrent architectures—stories contain 734 words on average in our dataset. We improve efficiency using a convolutional architecture, al-

# Train Stories	272,600
# Test Stories	15,138
# Validation Stories	15,620
# Prompt Words	7.7M
# Story Words	200M
Average Length of Prompts	28.4
Average Length of Stories	734.5

Table 1: Statistics of WritingPrompts dataset

lowing whole stories to be encoded in parallel. Existing convolutional architectures only encode a bounded amount of context (Dauphin et al., 2017), so we introduce a novel gated self-attention mechanism that allows the model to condition on its previous outputs at different time-scales.

To train our models, we gathered a large dataset of 303,358 human generated stories paired with writing prompts from an online forum. Evaluating free form text is challenging, so we also introduce new evaluation metrics which isolate different aspects of story generation.

Experiments show that our fusion and self-attention mechanisms improve over existing techniques on both automated and human evaluation measures. Our new dataset and neural architectures allow for models which can creatively generate longer, more consistent and more fluent passages of text. Human judges prefer our hierarchical model's stories twice as often as those of a non-hierarchical baseline.

2 Writing Prompts Dataset

We collect a hierarchical story generation dataset[1] from Reddit's WritingPrompts forum.[2] WritingPrompts is a community where online users inspire each other to write by submitting story premises, or prompts, and other users freely respond. Each prompt can have multiple story responses. The prompts have a large diversity of topic, length, and detail. The stories must be at least 30 words, avoid general profanity and inappropriate content, and should be inspired by the prompt (but do not necessarily have to fulfill every requirement). Figure 1 shows an example.

We scraped three years of prompts and their associated stories using the official Reddit API. We clean the dataset by removing automated bot posts, deleted posts, special announcements, comments from moderators, and stories shorter than 30 words. We use NLTK for tokenization. The dataset models full text to generate immediately human-readable stories. We reserve 5% of the prompts for a validation set and 5% for a test set, and present additional statistics about the dataset in Table 1.

For our experiments, we limit the length of the stories to 1000 words maximum and limit the vocabulary size for the prompts and the stories to words appearing more than 10 times each. We model an unknown word token and an end of document token. This leads to a vocabulary size of 19,025 for the prompts and 104,960 for the stories. As the dataset is scraped from an online forum, the number of rare words and misspellings is quite large, so modeling the full vocabulary is challenging and computationally intensive.

3 Approach

The challenges of WritingPrompts are primarily in modeling long-range dependencies and conditioning on an abstract, high-level prompt. Recurrent and convolutional networks have successfully modeled sentences (Jozefowicz et al., 2016; Dauphin et al., 2017), but accurately modeling several paragraphs is an open problem. While seq2seq networks have strong performance on a variety of problems, we find that they are unable to build stories that accurately reflect the prompts. We will evaluate strategies to address these challenges in the following sections.

3.1 Hierarchical Story Generation

High-level structure is integral to good stories, but language models generate on a strictly-word-by-word basis and so cannot explicitly make high-level plans. We introduce the ability to plan by decomposing the generation process into two levels. First, we generate the premise or prompt of the story using the convolutional language model from Dauphin et al. (2017). The prompt gives a sketch of the structure of the story. Second, we use a seq2seq model to generate a story that follows the premise. Conditioning on the prompt makes it easier for the story to remain consistent and also have structure at a level beyond single phrases.

Figure 3: Multihead self-attention mechanism. The decoder layer depicted attends with itself to gate the input of the subsequent decoder layer.

3.2 Efficient Learning with Convolutional Sequence-to-Sequence Model

The length of stories in our dataset is a challenge for RNNs, which process tokens sequentially. To transform prompts into stories, we instead build on the convolutional seq2seq model of Gehring et al. (2017), which uses deep convolutional networks as the encoder and decoder. Convolutional models are ideally suited to modeling long sequences, because they allow parallelism of computation within the sequence. In the Conv seq2seq model, the encoder and decoder are connected with attention modules (Bahdanau et al., 2015) that perform a weighted sum of encoder outputs, using attention at each layer of the decoder.

3.3 Modeling Unbounded Context with Gated Multi-Scale Self-attention

CNNs can only model a bounded context window, preventing the modeling of long-range dependencies within the output story. To enable modeling of unbounded context, we supplement the decoder with a self-attention mechanism (Sukhbaatar et al., 2015; Vaswani et al., 2017), which allows the model to refer to any previously generated words. The self-attention mechanism improves the model's ability to extract long-range context with limited computational impact due to parallelism.

Gated Attention: Similar to Vaswani et al. (2017), we use multi-head attention to allow each head to attend to information at different positions. However, the queries, keys and values are not given by linear projections but by more expressive gated deep neural nets with Gated Linear Unit (Dauphin et al., 2017) activations. We show that gating lends the self-attention mechanism crucial capacity to make fine-grained selections.

Multi-Scale Attention: Further, we propose to have each head operating at a different time scale, depicted in Figure 2. Thus the input to each head is *downsampled* a different amount—the first head sees the full input, the second every other input timestep, the third every third input timestep, etc. The different scales encourage the heads to attend to different information. The downsampling operation limits the number of tokens in the attention maps, making them sharper.

The output of a single attention head is given by

$$h^{L+1}_{0:t} = \text{Linear}\Big(v(h^L_{0:t-1}) \odot \text{softmax}(q(h^L_{0:t})k(h^L_{0:t})^\top)\Big) \quad (1)$$

where $h^L_{0:t}$ contains the hidden states up to time t

at layer L, and q, k, v are gated downsampling networks as shown in Figure 2. Unlike Vaswani et al. (2017), we allow the model to optionally attend to a 0 vector at each timestep, if it chooses to ignore the information of past timesteps (see Figure 3). This mechanism allows the model to recover the non-self-attention architecture and avoid attending to the past if it provides only noise. Additionally, we do not allow the self-attention mechanism to attend to the current timestep, only the past.

3.4 Improving Relevance to Input Prompt with Model Fusion

Unlike tasks such as translation, where the semantics of the target are fully specified by the source, the generation of stories from prompts is far more open-ended. We find that seq2seq models ignore the prompt and focus solely on modeling the stories, because the local dependencies required for language modeling are easier to model than the subtle dependencies between prompt and story.

We propose a fusion-based approach to encourage conditioning on the prompt. We train a seq2seq model that has access to the hidden states of a pretrained seq2seq model. Doing so can be seen as a type of boosting or residual learning that allows the second model to focus on what the first model failed to learn—such as conditioning on the prompt. To our knowledge, this paper is the first to show that fusion reduces the problem of seq2seq models degenerating into language models that capture primarily syntactic and grammatical information.

The cold fusion mechanism of Sriram et al. (2017) pretrains a language model and subsequently trains a seq2seq model with a gating mechanism that learns to leverage the final hidden layer of the language model during seq2seq training. We modify this approach by combining two seq2seq models as follows (see Figure 4):

$$g_t = \sigma(W[h_t^{\text{Training}}; h_t^{\text{Pretrained}}] + b)$$
$$h_t = g_t \circ [h_t^{\text{Training}}; h_t^{\text{Pretrained}}]$$

where the hidden state of the pretrained seq2seq model and training seq2seq model (represented by h_t) are concatenated to learn gates g_t. The gates are computed using a linear projection with the weight matrix W. The gated hidden layers are combined by concatenation and followed by more fully connected layers with GLU activations (see

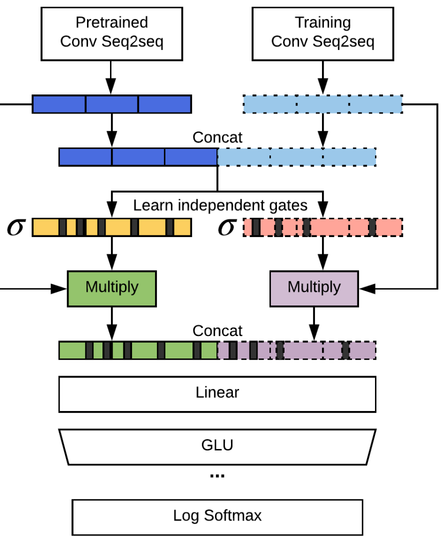

Figure 4: Diagram of our fusion model, which learns a second seq2seq model to improve a pretrained model. The separate hidden states are combined after gating through concatenation.

Appendix). We use layer normalization (Ba et al., 2016) after each fully connected layer.

4 Related Work

4.1 Story Generation

Sequence-to-sequence neural networks (Sutskever et al., 2014) have achieved state of the art performance on a variety of text generation tasks, such as machine translation (Sutskever et al., 2014) and summarization (Rush et al., 2015). Recent work has applied these models to more open-ended generation tasks, including writing Wikipedia articles (Liu et al., 2018) and poetry (Zhang and Lapata, 2014).

Previous work on story generation has explored seq2seq RNN architectures (Roemmele, 2016), but has focused largely on using various content to inspire the stories. For instance, Kiros et al. (2015) uses photos to inspire short paragraphs trained on romance novels, and Jain et al. (2017) chain a series of independent descriptions together into a short story. Martin et al. (2017) decompose story generation into two steps, first converting text into event representations, then modeling stories as sequences of events before translating back to natural language. Similarly, Harrison et al. (2017) generate summaries of movies as sequences of events using an RNN, then sample event representations using MCMC. They find this technique can generate text of the desired genre, but the movie plots are not interpretable (as the model outputs events, not raw text). However, we are not aware of previous work that has used hierarchical generation from a textual premise to improve the coherence and structure of stories.

4.2 Hierarchical Text Generation

Previous work has proposed decomposing the challenge of generating long sequences of text into a hierarchical generation task. For instance, Li et al. (2015b) use an LSTM to hierarchically learn word, then sentence, then paragraph embeddings, then transform the paragraph embeddings into text. Yarats and Lewis (2017) generate a discrete latent variable based on the context, then generates text conditioned upon it.

4.3 Fusion Models

Previous work has investigated the integration of language models with seq2seq models. The two models can be leveraged together without architectural modifications: Ramachandran et al. (2016) use language models to initialize the encoder and decoder side of the seq2seq model independently, and Chorowski and Jaitly (2016) combine the predictions of the language model and seq2seq model solely at inference time. Recent work has also proposed deeper integration. Gulcehre et al. (2015) combined a trained language model with a trained seq2seq model to learn a gating function that joins them. Sriram et al. (2017) propose training the seq2seq model given the fixed language model then learning a gate to filter the information from the language model.

5 Experimental Setup

5.1 Baselines

We evaluate a number of baselines:

(1) Language Models: Non-hierarchical models for story generation, which do not condition on the prompt. We use both the gated convolutional language (GCNN) model of Dauphin et al. (2017) and our additional self-attention mechanism.

(2) seq2seq: using LSTMs and convolutional seq2seq architectures, and Conv seq2seq with decoder self-attention.

(3) Ensemble: an ensemble of two Conv seq2seq with self-attention models.

(4) KNN: we also compare with a KNN model to find the closest prompt in the training set for each prompt in the test set. A TF-IDF vector for each prompt was created using FASTTEXT (Bojanowski et al., 2016) and FAISS (Johnson et al., 2017) was used for KNN search. The retrieved story from the training set is limited to 150 words to match the length of generated stories.

Model	**Valid Perplexity**	**Test Perplexity**
Conv seq2seq	45.27	45.54
+ self-attention	42.01	42.32
+ multihead	40.12	40.39
+ multiscale	38.76	38.91
+ gating	**37.37**	**37.94**

Table 2: Effect of new attention mechanism. Gated multi-scale attention significantly improves the perplexity on the WRITINGPROMPTS dataset.

5.2 Fusion Training

To train the fusion model, we first pretrain a Conv seq2seq with self-attention model on the WRITINGPROMPTS dataset. This pretrained model is fixed and provided to the second Conv seq2seq with self-attention model during training time. The two models are integrated with the fusion mechanism described in Section 3.4.

5.3 Training

We implement models with the fairseq-py library in PyTorch. Similar to Gehring et al. (2017), we train using the Nesterov accelerated gradient method (Sutskever et al., 2013) using gradient clipping (Pascanu et al., 2013). We perform hyperparameter optimization on each of our models by cross-validating with random search on a validation set. We provide model architectures in the appendix.

5.4 Generation

We generate stories from our models using a *top-k random sampling* scheme. At each timestep, the model generates the probability of each word in the vocabulary being the likely next word. We randomly sample from the $k = 10$ most likely candidates from this distribution. Then, subsequent timesteps generate words based on the previously selected words. We find this sampling strategy substantially more effective than beam search, which tends to produce common phrases and repetitive text from the training set (Vijayakumar et al., 2016; Shao et al., 2017). Sentences pro-

Model	# Parameters (mil)	Valid Perplexity	Test Perplexity
GCNN LM	123.4	54.50	54.79
GCNN + self-attention LM	126.4	51.84	51.18
LSTM seq2seq	110.3	46.83	46.79
Conv seq2seq	113.0	45.27	45.54
Conv seq2seq + self-attention	134.7	37.37	37.94
Ensemble: Conv seq2seq + self-attention	270.3	36.63	36.93
Fusion: Conv seq2seq + self-attention	255.4	**36.08**	**36.56**

Table 3: Perplexity on WRITINGPROMPTS. We dramatically improve over standard seq2seq models.

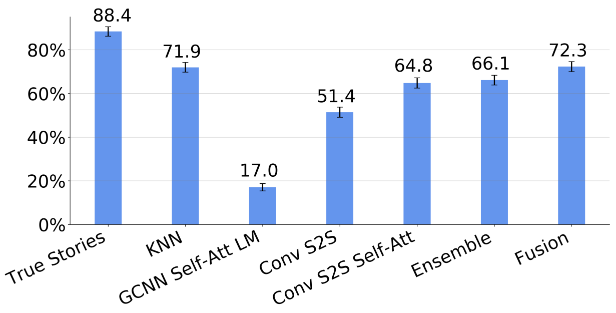

Figure 5: Human accuracy at pairing stories with the prompts used to generate them. People find that our fusion model significantly improves the link between the prompt and generated stories.

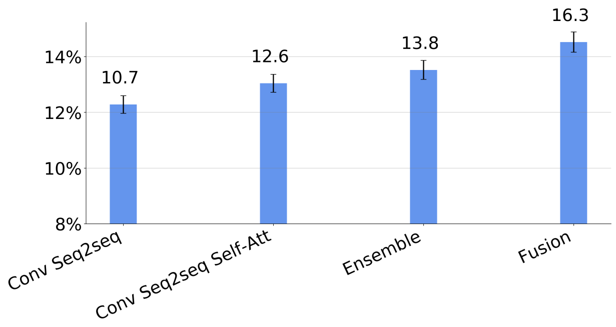

Figure 6: Accuracy of prompt ranking. The fusion model most accurately pairs prompt and stories.

duced by beam search tend to be short and generic. Completely random sampling can introduce very unlikely words, which can damage generation as the model has not seen such mistakes at training time. The restriction of sampling from the 10 most likely candidates reduces the risk of these low-probability samples.

For each model, we tune a temperature parameter for the softmax at generation time. To ease human evaluation, we generate stories of 150 words and do not generate unknown word tokens.

For prompt generation, we use a self-attentive GCNN language model trained with the same prompt-side vocabulary as the sequence-to-sequence story generation models. The language model to generate prompts has a validation perplexity of 63.06. Prompt generation is conducted using the top-k random sampling from the 10 most likely candidates, and the prompt is completed when the language model generates the end of prompt token.

5.5 Evaluation

We propose a number of evaluation metrics to quantify the performance of our models. Many commonly used metrics, such as BLEU for ma-

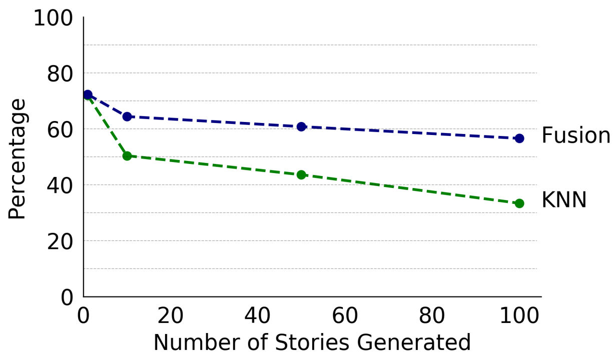

Figure 7: Accuracy on the prompt/story pairing task vs. number of generated stories. Our generative fusion model can produce many stories without degraded performance, while the KNN can only produce a limited number relevant stories.

Model	Human Preference
Language model	32.68%
Hierarchical Model	**67.32%**

Table 4: Effect of Hierarchical Generation. Human judges prefer stories that were generated hierarchically by first creating a premise and creating a full story based on it with a seq2seq model.

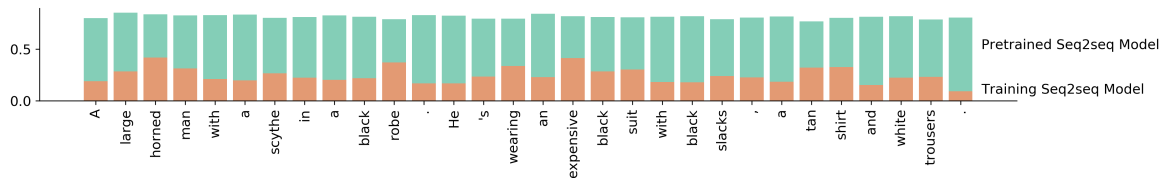

Figure 8: Average weighting of each model in our Fusion model for the beginning of the generated story for the prompt *Gates of Hell*. The fused model (orange) is primarily used for words which are closely related to the prompt, whereas generic words are generated by the pre-trained model (green).

chine translation or ROUGE for summarization, compute an n-gram overlap between the generated text and the human text—however, in our open-ended generation setting, these are not useful. We do not aim to generate a specific story; we want to generate viable and novel stories. We focus on measuring both the fluency of our models and their ability to adhere to the prompt.

For automatic evaluation, we measure *model perplexity* on the test set and *prompt ranking accuracy*. Perplexity is commonly used to evaluate the quality of language models, and it reflects how fluently the model can produce the correct next word given the preceding words. We use prompt ranking to assess how strongly a model's output depends on its input. Stories are decoded under 10 different prompts—9 randomly sampled prompts and 1 true corresponding prompt—and the likelihood of the story given the various prompts is recorded. We measure the percentage of cases where the true prompt is the most likely to generate the story. In our evaluation, we examined 1000 stories from the test set for each model.

For human evaluation, we use Amazon Mechanical Turk to conduct a *triple pairing task*. We use each model to generate stories based on held-out prompts from the test set. Then, groups of three stories are presented to the human judges. The stories and their corresponding prompts are shuffled, and human evaluators are asked to select the correct pairing for all three prompts. 105 stories per model are grouped into questions, and each question is evaluated by 15 judges.

Lastly, we conduct human evaluation to evaluate the importance of *hierarchical generation* for story writing. We use Amazon Mechanical Turk to compare the stories from hierarchical generation from a prompt with generation without a prompt. 400 pairs of stories were evaluated by 5 judges each in a blind test.

6 Results

We analyze the effect of our modeling improvements on the WRITINGPROMPTS dataset.

Effect of Hierarchical Generation: We explore leveraging our dataset to perform hierarchical story generation by first using a self-attentive GCNN language model to generate a prompt, and then using a fusion model to write a story given the generated prompt. We evaluate the effect of hierarchical generation using a human study in Table 4. 400 stories were generated from a self-attentive GCNN language model, and another 400 were generated from our hierarchical fusion model given generated prompts from a language model. In a blind comparison where raters were asked to choose the story they preferred reading, human raters preferred the hierarchical model 67% of the time.

Effect of new attention mechanism: Table 2 shows the effect of the proposed additions to the self-attention mechanism proposed by Vaswani et al. (2017). Table 3 shows that deep multi-scale self-attention and fusion each significantly improve the perplexity compared to the baselines. In combination these additions to the Conv seq2seq baseline reduce the perplexity by 9 points.

Effect of model fusion: Results in Table 3 show that adding our fusion mechanism substantially improves the likelihood of human-generated stories, and even outperforms an ensemble despite having fewer parameters. We observe in Figure 5 that fusion has a much more significant impact on the topicality of the stories. In comparison, ensembling has no effect on people's ability to associate stories with a prompt, but adding model fusion leads improves the pairing accuracy of the human judges by 7%. These results suggest that by training a second model on top of the first, we have encouraged that model to learn the challenging additional dependencies to relate to the source sequence. To our knowledge, these are the first results to show that fusion has such capabilities.

Comparison with Nearest Neighbours: Nearest Neighbour Search (KNN) provides a strong baseline for text generation. Figure 5 shows that the fusion model can match the performance of nearest neighbour search in terms of the connection between the story and prompt. The real value in our generative approach is that it can produce an unlimited number of stories, whereas KNN can never generalize from its training data. To quantify this improvement, Figure 7 plots the relevance of the *k*th best story to a given prompt; the performance of KNN degrades much more rapidly.

7 Discussion

7.1 Generation Quality

Our proposed fusion model is capable of generating unique text without copying directly from the training set. When analyzing 500 150-word generated stories from test-set prompts, the average longest common subsequence is 8.9. In contrast, the baseline Conv seq2seq model copies 10.2 words on average and the KNN baseline copies all 150 words from a story in the training set.

Figure 8 shows the values of the fusion gates for an example story, averaged at each timestep. The pretrained seq2seq model acts similarly to a language model producing common words and punctuation. The second seq2seq model learns to focus on rare words, such as *horned* and *robe*.

However, the fusion model has limitations. Using random sampling to generate can produce errors. For example, *can't* is tokenized to *ca n't*, and the model occasionally produces the first token but misses the second. A similar error is after one line of dialogue, the model may move to another line of dialogue without generating a newline token. A further obstacle is repetition. The model focuses frequently on what it has recently produced, which leads to the generation of similar text multiple times.

In the generation of prompts using the GCNN language model, we find that prompts are fairly generic compared to human prompts. Language models often struggle to model rare words accurately, as the probability distribution over the next word is dominated by more common words. This tends to produce similar prompts, particularly at the start — we see many prompts that start with *the man*. In contrast, many of the human prompts are very unique (e.g. prompting stories in fantasy worlds such as Harry Potter and Game of Thrones) and the language model rarely produces the specific vocabulary required by these settings.

7.2 Use of Attention

We analyze the encoder-decoder attention in the fusion model and find that unlike attention maps in machine translation, where each decoder timestep tends to attend to a different word on the encoder-side, the attention map for each decoder timestep looks similar and focuses mainly on salient words in the prompt. We further look at the usage of the self-attention layers within the decoder. While they could be leveraged to look at words generated very far in the past, at many timesteps the self-attention focuses on the recent past.

8 Conclusion

We have collected the first dataset for creative text generation based on short writing prompts. This new dataset pushes the boundaries of text generation by requiring longer range dependencies and conditioning on an abstract premise. Building on this dataset, we show through automatic and human evaluation that novel hierarchical models, self-attention mechanisms and model fusion significantly improves the fluency, topicality, and overall quality of the generated stories.

Generation with Fusion of Conv seq2seq + Self-Attention
Example Prompt 1: Aliens start abducting humans
It has been two weeks, and the last of my kind has gone. It is only a matter of time until there will be nothing left. I'm not sure what the hell is going on... I can't think. I can hear a distant scream. I think of a strange, alien sound. I try to speak, but am interrupted by something, something that feels like a drum, I ca not tell. I mean I'm just a little bit older than an average human. But I can, and I can feel the vibrations . I hear the sound of a ship approaching. The ground quakes at the force of the impact, and a loud explosion shatters the silence.
Example Prompt 2: The scientists have discovered something terrible .
The scientist stood there, a little dazed as he stared. "What is it?" He asked. "This...this...Thing...This is a virus. A chemical that can destroy entire planet and it is a very small, complex, chemical that could destroy any planet." The scientist replied. His lab assistant looked down at the tablet. "I've just discovered it. I can't believe it. It looks like it's made of some sort of chemical that's very dangerous." " Well, there's a virus on the ground. It's very effective..." " I can't believe what it is." he said, pointing to the scientist . " We don't know what this thing is. We haven't seen anything like it . We can't even see anything like this. " Dr. Jones stared at the scientist for a moment. "What do you mean what does it do ?" "It...It 's a monster."
Example Prompt 3: The silence before the storm comes
"I'm sorry," she said "I can't do this anymore." She sat in the grass, the grass blowing behind her as she sat staring at the sky. Her eyes were still closed but she was still staring at it. Her hand was still shaking, her eyes closed as she watched the rain roll in and out of view. She could see the world through her eyelids now. Her hands were still shaking like she hadn't eaten in days. Her fingers were still clenched tight and her fingers were now shaking. She wasn't even sure if she was going to cry or if she just wanted to cry. It wasn't until she was close enough to hear the words. "I ...I just...I need to...I ..." She was crying now and then, the rain was picking up. Her lips were shaking now and she could see that the storm was getting closer and closer. Her heart stopped when she heard the thunder. She knew it was coming. The storm was

Generation with Language Model + Self-Attention Baseline
Example 1:
I've always been the curious type. Growing up in the ghetto, I've been around for more than a year now. I still haven't heard it on my own. I'm not sure if I'm a good person. But I'm not the only one. I've been to the hospital, but it's not my first time. I've been to my psychiatrist's journals before. "Hey, are you ... are you okay?" I asked. "Yes" I said. "What's wrong?" she replied, "I was just ... Doing something." She said, "I've never been a bad person."
Example 2:
The man was an accountant. He had to be. He had to be the next president. I looked back over the top and saw that his wife was crying in the kitchen. I looked at the clock. It seemed to be coming slower, but I knew if I did it would not be long before I was in my own home. I wasn't sure. I had a hard time finding the right words to say. I was about to leave when he suddenly became angry and began talking to me. "Hello, sir, I'm John. What is your name?" "My name is Manuel and I'm a journalist." I said

Table 5: Example stories generated by the proposed hierarchical fusion approach compared to stories generated by a language model. Stories generated by the fusion model relate to the desired prompt and show increased coherence between sentences and ability to stay on one topic compared to the language modeling baseline.

No Metrics Are Perfect: Adversarial Reward Learning for Visual Storytelling

Xin Wang[*], **Wenhu Chen**[*], **Yuan-Fang Wang** , **William Yang Wang**
University of California, Santa Barbara
{xwang,wenhuchen,yfwang,william}@cs.ucsb.edu

Abstract

Though impressive results have been achieved in visual captioning, the task of generating abstract stories from photo streams is still a little-tapped problem. Different from captions, stories have more expressive language styles and contain many imaginary concepts that do not appear in the images. Thus it poses challenges to behavioral cloning algorithms. Furthermore, due to the limitations of automatic metrics on evaluating story quality, reinforcement learning methods with hand-crafted rewards also face difficulties in gaining an overall performance boost. Therefore, we propose an Adversarial REward Learning (AREL) framework to learn an implicit reward function from human demonstrations, and then optimize policy search with the learned reward function. Though automatic evaluation indicates slight performance boost over state-of-the-art (SOTA) methods in cloning expert behaviors, human evaluation shows that our approach achieves significant improvement in generating more human-like stories than SOTA systems. Code will be made available here[1].

1 Introduction

Recently, increasing attention has been focused on visual captioning (Chen et al., 2015; Xu et al., 2016; Wang et al., 2018c), which aims at describing the content of an image or a video. Though it has achieved impressive results, its capability of performing human-like understanding is still restrictive. To further investigate machine's capabilities in understanding more complicated visual scenarios and composing more structured expressions, visual storytelling (Huang et al., 2016) has been proposed. Visual captioning is aimed at depicting the concrete content of the images, and its expression style is rather simple. In contrast, visual storytelling goes one step further: it summarizes the idea of a photo stream and tells a story about it. Figure 1 shows an example of visual captioning and visual storytelling. We have observed that stories contain rich **emotions** (*excited, happy, not want*) and **imagination** (*siblings, parents, school, car*). It, therefore, requires the capability to associate with concepts that do not explicitly appear in the images. Moreover, stories are more **subjective**, so there barely exists standard

Captions:
(a) A small boy and a girl are sitting together.
(b) Two kids sitting on a porch with their backpacks on.
(c) Two young kids with backpacks sitting on the porch.
(d) Two young children that are very close to one another.
(e) A boy and a girl smiling at the camera together.

Story #1: The brother and sister were ready for the first day of school. They were excited to go to their first day and meet new friends. They told their mom how happy they were. They said they were going to make a lot of new friends . Then they got up and got ready to get in the car .

Story #2: The brother did not want to talk to his sister. The siblings made up. They started to talk and smile. Their parents showed up. They were happy to see them.

Figure 1: An example of visual storytelling and visual captioning. Both captions and stories are shown here: each image is captioned with one sentence, and we also demonstrate two diversified stories that match the same image sequence.

[*] Equal contribution
[1] https://github.com/littlekobe/AREL

templates for storytelling. As shown in Figure 1, the same photo stream can be paired with diverse stories, different from each other. This heavily increases the evaluation difficulty.

So far, prior work for visual storytelling (Huang et al., 2016; Yu et al., 2017b) is mainly inspired by the success of visual captioning. Nevertheless, because these methods are trained by maximizing the likelihood of the observed data pairs, they are restricted to generate simple and plain description with limited expressive patterns. In order to cope with the challenges and produce more human-like descriptions, Rennie et al. (2016) have proposed a reinforcement learning framework. However, in the scenario of visual storytelling, the common reinforced captioning methods are facing great challenges since the hand-crafted rewards based on string matches are either too biased or too sparse to drive the policy search. For instance, we used the METEOR (Banerjee and Lavie, 2005) score as the reward to reinforce our policy and found that though the METEOR score is significantly improved, the other scores are severely harmed. Here we showcase an adversarial example with an average METEOR score as high as 40.2:

> *We had a great time to have a lot of the. They were to be a of the. They were to be in the. The and it were to be the. The, and it were to be the.*

Apparently, the machine is gaming the metrics. Conversely, when using some other metrics (*e.g.* BLEU, CIDEr) to evaluate the stories, we observe an opposite behavior: many relevant and coherent stories are receiving a very low score (nearly zero).

In order to resolve the strong bias brought by the hand-coded evaluation metrics in RL training and produce more human-like stories, we propose an Adversarial REward Learning (AREL) framework for visual storytelling. We draw our inspiration from recent progress in inverse reinforcement learning (Ho and Ermon, 2016; Finn et al., 2016; Fu et al., 2017) and propose the AREL algorithm to learn a more intelligent reward function. Specifically, we first incorporate a Boltzmann distribution to associate reward learning with distribution approximation, then design the adversarial process with two models – a **policy model** and a **reward model**. The policy model performs the primitive actions and produces the story sequence, while the reward model is responsible for learning the implicit reward function from human demonstrations. The learned reward function would be employed to optimize the policy in return.

For evaluation, we conduct both automatic metrics and human evaluation but observe a poor correlation between them. Particularly, our method gains slight performance boost over the baseline systems on automatic metrics; human evaluation, however, indicates significant performance boost. Thus we further discuss the limitations of the metrics and validate the superiority of our AREL method in performing more intelligent understanding of the visual scenes and generating more human-like stories.

Our main contributions are four-fold:

- We propose an adversarial reward learning framework and apply it to boost visual story generation.
- We evaluate our approach on the Visual Storytelling (VIST) dataset and achieve the state-of-the-art results on automatic metrics.
- We empirically demonstrate that automatic metrics are not perfect for either training or evaluation.
- We design and perform a comprehensive human evaluation via Amazon Mechanical Turk, which demonstrates the superiority of the generated stories of our method on relevance, expressiveness, and concreteness.

2 Related Work

Visual Storytelling Visual storytelling is the task of generating a narrative story from a photo stream, which requires a deeper understanding of the event flow in the stream. Park and Kim (2015) has done some pioneering research on storytelling. Chen et al. (2017) proposed a multimodal approach for storyline generation to produce a stream of entities instead of human-like descriptions. Recently, a more sophisticated dataset for visual storytelling (VIST) has been released to explore a more human-like understanding of grounded stories (Huang et al., 2016). Yu et al. (2017b) proposes a multi-task learning algorithm for both album summarization and paragraph generation, achieving the best results on the VIST dataset. But these methods are still based on behavioral cloning and lack the ability to generate more structured stories.

Reinforcement Learning in Sequence Generation Recently, reinforcement learning (RL) has gained its popularity in many sequence generation tasks such as machine translation (Bahdanau et al., 2016), visual captioning (Ren et al., 2017; Wang et al., 2018b), summarization (Paulus et al., 2017; Chen et al., 2018), etc. The common wisdom of using RL is to view generating a word as an action and aim at maximizing the expected return by optimizing its policy. As pointed in (Ranzato et al., 2015), traditional maximum likelihood algorithm is prone to exposure bias and label bias, while the RL agent exposes the generative model to its own distribution and thus can perform better. But these works usually utilize hand-crafted metric scores as the reward to optimize the model, which fails to learn more implicit semantics due to the limitations of automatic metrics.

Rethinking Automatic Metrics Automatic metrics, including BLEU (Papineni et al., 2002), CIDEr (Vedantam et al., 2015), METEOR (Banerjee and Lavie, 2005), and ROUGE (Lin, 2004), have been widely applied to the sequence generation tasks. Using automatic metrics can ensure rapid prototyping and testing new models with fewer expensive human evaluation. However, they have been criticized to be biased and correlate poorly with human judgments, especially in many generative tasks like response generation (Lowe et al., 2017; Liu et al., 2016), dialogue system (Bruni and Fernández, 2017) and machine translation (Callison-Burch et al., 2006). The naive overlap-counting methods are not able to reflect many semantic properties in natural language, such as coherence, expressiveness, etc.

Generative Adversarial Network Generative adversarial network (GAN) (Goodfellow et al., 2014) is a very popular approach for estimating intractable probabilities, which sidestep the difficulty by alternately training two models to play a min-max two-player game:

$$\min_D \max_G \mathop{E}_{x \sim p_{data}} [\log D(x)] + \mathop{E}_{z \sim p_z} [\log D(G(z))] ,$$

where G is the generator and D is the discriminator, and z is the latent variable. Recently, GAN has quickly been adopted to tackle discrete problems (Yu et al., 2017a; Dai et al., 2017; Wang et al., 2018a). The basic idea is to use Monte Carlo policy gradient estimation (Williams, 1992) to update the parameters of the generator.

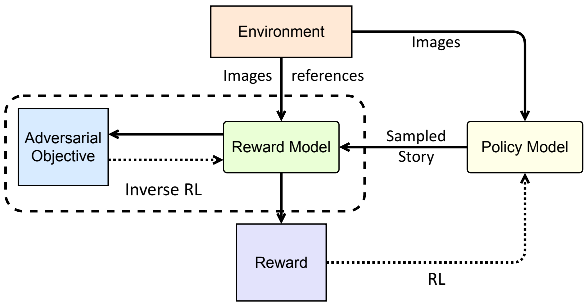

Figure 2: AREL framework for visual storytelling.

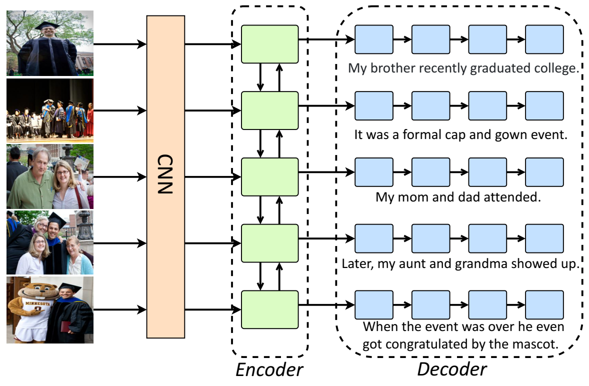
Inverse Reinforcement Learning Reinforcement learning is known to be hindered by the need for an extensive feature and reward engineering, especially under the unknown dynamics. Therefore, inverse reinforcement learning (IRL) has been proposed to infer expert's reward function. Previous IRL approaches include maximum margin approaches (Abbeel and Ng, 2004; Ratliff et al., 2006) and probabilistic approaches (Ziebart, 2010; Ziebart et al., 2008). Recently, adversarial inverse reinforcement learning methods provide an efficient and scalable promise for automatic reward acquisition (Ho and Ermon, 2016; Finn et al., 2016; Fu et al., 2017; Henderson et al., 2017). These approaches utilize the connection between IRL and energy-based model and associate every data with a scalar energy value by using Boltzmann distribution $p_\theta(x) \propto \exp(-E_\theta(x))$. Inspired by these methods, we propose a practical AREL approach for visual storytelling to uncover a robust reward function from human demonstrations and thus help produce human-like stories.

3 Our Approach

3.1 Problem Statement

Here we consider the task of visual storytelling, whose objective is to output a word sequence $W = (w_1, w_1, \cdots, w_T)$, $w_t \in \mathbb{V}$ given an input image stream of 5 ordered images $I = (I_1, I_2, \cdots, I_5)$, where $\mathbb{V}$ is the vocabulary of all output token. We formulate the generation as a markov decision process and design a reinforcement learning framework to tackle it. As described in Figure 2, our AREL framework is mainly composed of two modules: a **policy model** $\pi_\beta(W)$ and a **reward model** $R_\theta(W)$. The policy model takes an image sequence I as the input and performs sequential actions (choosing words w from the vocabulary $\mathbb{V}$) to form a narrative story W. The reward model



CNN
My brother recently graduated college.
It was a formal cap and gown event.
My mom and dad attended.
Later, my aunt and grandma showed up.
When the event was over he even got congratulated by the mascot.
Encoder
Decoder

Figure 3: Overview of the policy model. The visual encoder is a bidirectional GRU, which encodes the high-level visual features extracted from the input images. Its outputs are then fed into the RNN decoders to generate sentences in parallel. Finally, we concatenate all the generated sentences as a full story. Note that the five decoders share the same weights.

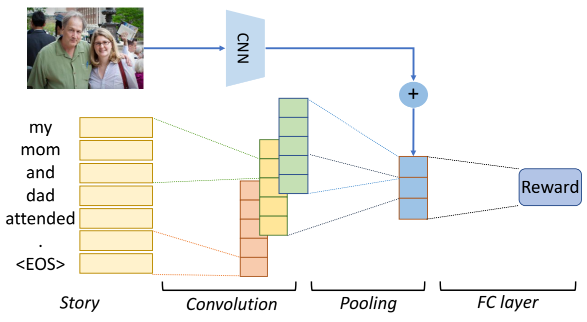


Figure 4: Overview of the reward model. Our reward model is a CNN-based architecture, which utilizes convolution kernels with size 2, 3 and 4 to extract bigram, trigram and 4-gram representations from the input sequence embeddings. Once the sentence representation is learned, it will be concatenated with the visual representation of the input image, and then be fed into the final FC layer to obtain the reward.

is optimized by the adversarial objective (see Section 3.3) and aims at deriving a human-like reward from both human-annotated stories and sampled predictions.

3.2 Model

Policy Model As is shown in Figure 3, the policy model is a CNN-RNN architecture. We fist feed the photo stream $I = (I_1, \cdots, I_5)$ into a pretrained CNN and extract their high-level image features. We then employ a visual encoder to further encode the image features as context vectors $h_i = [\overleftarrow{h_i}; \overrightarrow{h_i}]$. The visual encoder is a bidirectional gated recurrent units (GRU).

In the decoding stage, we feed each context vector h_i into a GRU-RNN decoder to generate a sub-story W_i. Formally, the generation process can be written as:

$$s_t^i = \text{GRU}(s_{t-1}^i, [w_{t-1}^i, h_i]) \,, \quad (1)$$

$$\pi_\beta(w_t^i | w_{1:t-1}^i) = softmax(W_s s_t^i + b_s) \,, \quad (2)$$

where s_t^i denotes the t-th hidden state of i-th decoder. We concatenate the previous token w_{t-1}^i and the context vector h_i as the input. W_s and b_s are the projection matrix and bias, which output a probability distribution over the whole vocabulary $\mathbb{V}$. Eventually, the final story W is the concatenation of the sub-stories W_i. β denotes all the parameters of the encoder, the decoder, and the output layer.

Reward Model The reward model $R_\theta(W)$ is a CNN-based architecture (see Figure 4). Instead of giving an overall score for the whole story, we apply the reward model to different story parts (sub-stories) W_i and compute partial rewards, where $i = 1, \cdots, 5$. We observe that the partial rewards are more fine-grained and can provide better guidance for the policy model.

We first query the word embeddings of the sub-story (one sentence in most cases). Next, multiple convolutional layers with different kernel sizes are used to extract the n-grams features, which are then projected into the sentence-level representation space by pooling layers (the design here is inspired by Kim (2014)). In addition to the textual features, evaluating the quality of a story should also consider the image features for relevance. Therefore, we then combine the sentence representation with the visual feature of the input image through concatenation and feed them into the final fully connected decision layer. In the end, the reward model outputs an estimated reward value $R_\theta(W)$. The process can be written in formula:

$$R_\theta(W) = W_r(f_{conv}(W) + W_i I_{CNN}) + b_r, \quad (3)$$

where W_r, b_r denotes the weights in the output layer, and f_{conv} denotes the operations in CNN. I_{CNN} is the high-level visual feature extracted from the image, and W_i projects it into the sentence representation space. θ includes all the parameters above.

3.3 Learning

Reward Boltzmann Distribution In order to associate story distribution with reward function, we apply EBM to define a Reward Boltzmann distribution:

$$p_\theta(W) = \frac{\exp(R_\theta(W))}{Z_\theta}\,, \tag{4}$$

Where W is the word sequence of the story and $p_\theta(W)$ is the approximate data distribution, and $Z_\theta = \sum_W \exp(R_\theta(W))$ denotes the partition function. According to the energy-based model (LeCun et al., 2006), the optimal reward function $R^*(W)$ is achieved when the Reward-Boltzmann distribution equals to the "real" data distribution $p_\theta(W) = p^*(W)$.

Adversarial Reward Learning We first introduce an empirical distribution $p_e(W) = \frac{\mathbb{1}(W \in D)}{|D|}$ to represent the empirical distribution of the training data, where D denotes the dataset with $|D|$ stories and $\mathbb{1}$ denotes an indicator function. We use this empirical distribution as the "good" examples, which provides the evidence for the reward function to learn from.

In order to approximate the Reward Boltzmann distribution towards the "real" data distribution $p^*(W)$, we design a min-max two-player game, where the Reward Boltzmann distribution p_θ aims at maximizing the its similarity with empirical distribution p_e while minimizing that with the "faked" data generated from policy model π_β. On the contrary, the policy distribution π_β tries to maximize its similarity with the Boltzmann distribution p_θ. Formally, the adversarial objective function is defined as

$$\max_\beta \min_\theta KL(p_e(W)||p_\theta(W)) - KL(\pi_\beta(W)||p_\theta(W))\,. \tag{5}$$

We further decompose it into two parts. First, because the objective J_β of the story generation policy is to minimize its similarity with the Boltzmann distribution p_θ, the optimal policy that minimizes KL-divergence is thus $\pi(W) \sim \exp(R_\theta(W))$, meaning if R_θ is optimal, the optimal $\pi_\beta = \pi^*$. In formula,

$$\begin{aligned} J_\beta =& -KL(\pi_\beta(W)||p_\theta(W)) \\ =& \mathop{E}_{W\sim\pi_\beta(W)}[R_\theta(W)] + H(\pi_\beta(W))\,, \end{aligned} \tag{6}$$

Algorithm 1 The AREL Algorithm.

```
1: for episode ← 1 to N do
2:     collect story $W$ by executing policy $\pi_\theta$
3:     if Train-Reward then
4:         $\theta \leftarrow \theta - \eta \times \frac{\partial J_\theta}{\partial \theta}$ (see Equation 9)
5:     else if Train-Policy then
6:         collect story $\tilde{W}$ from empirical $p_e$
7:         $\beta \leftarrow \beta - \eta \times \frac{\partial J_\beta}{\partial \beta}$ (see Equation 9)
8:     end if
9: end for
```

where H denotes the entropy of the policy model. On the other hand, the objective J_θ of the reward function is to distinguish between human-annotated stories and machine-generated stories. Hence it is trying to minimize the KL-divergence with the empirical distribution p_e and maximize the KL-divergence with the approximated policy distribution π_β:

$$\begin{aligned} J_\theta =& KL(p_e(W)||p_\theta(W)) - KL(\pi_\beta(W)||p_\theta(W)) \\ =& \sum_W [p_e(W)R_\theta(W) - \pi_\beta(W)R_\theta(W)] \\ & - H(p_e) + H(\pi_\beta)\,, \end{aligned} \tag{7}$$

Since $H(\pi_\beta)$ and $H(p_e)$ are irrelevant to θ, we denote them as constant C. Therefore, the objective J_θ can be further derived as

$$J_\theta = \mathop{E}_{W\sim p_e(W)}[R_\theta(W)] - \mathop{E}_{W\sim\pi_\beta(W)}[R_\theta(W)] + C\,. \tag{8}$$

Here we propose to use stochastic gradient descent to optimize these two models alternately. Formally, the gradients can be written as

$$\begin{aligned} \frac{\partial J_\theta}{\partial \theta} &= \mathop{E}_{W\sim p_e(W)} \frac{\partial R_\theta(W)}{\partial \theta} - \mathop{E}_{W\sim\pi_\beta(W)} \frac{\partial R_\theta(W)}{\partial \theta}\,, \\ \frac{\partial J_\beta}{\partial \beta} &= \mathop{E}_{W\sim\pi_\beta(W)} (R_\theta(W) + \log \pi_\theta(W) - b) \frac{\partial \log \pi_\beta(W)}{\partial \beta}\,, \end{aligned} \tag{9}$$

where b is the estimated baseline to reduce the variance.

Training & Testing As described in Algorithm 1, we introduce an alternating algorithm to train these two models using stochastic gradient descent. During testing, the policy model is used with beam search to produce the story.

4 Experiments and Analysis

4.1 Experimental Setup

VIST Dataset The VIST dataset (Huang et al., 2016) is the first dataset for sequential vision-to-language tasks including visual storytelling, which consists of 10,117 Flickr albums with 210,819 unique photos. In this paper, we mainly evaluate our AREL method on this dataset. After filtering the broken images[2], there are 40,098 training, 4,988 validation, and 5,050 testing samples. Each sample contains one story that describes 5 selected images from a photo album (mostly one sentence per image). And the same album is paired with 5 different stories as references. In our experiments, we used the same split settings as in (Huang et al., 2016; Yu et al., 2017b) for a fair comparison.

Evaluation Metrics In order to comprehensively evaluate our method on storytelling dataset, we adopted both the automatic metrics and human evaluation as our criterion. Four diverse automatic metrics were used in our experiments: BLEU, METEOR, ROUGE-L, and CIDEr. We utilized the open source evaluation code[3] used in (Yu et al., 2017b). For human evaluation, we employed the Amazon Mechanical Turk to perform two kinds of user studies (see Section 4.3 for more details).

Training Details We employ pretrained ResNet-152 model (He et al., 2016) to extract image features from the photo stream. We built a vocabulary of size 9,837 to include words appearing more than three times in the training set. More training details can be found at Appendix B.

4.2 Automatic Evaluation

In this section, we compare our AREL method with the state-of-the-art methods as well as standard reinforcement learning algorithms on automatic evaluation metrics. Then we further discuss the limitations of the hand-crafted metrics on evaluating human-like stories.

Comparison with SOTA on Automatic Metrics In Table 1, we compare our method with Huang et al. (2016) and Yu et al. (2017b), which report achieving best-known results on the VIST dataset. We first implement a strong baseline model (*XE-ss*), which share the same architecture with our policy model but is trained with cross-entropy loss and scheduled sampling. Besides, we adopt the traditional generative adversarial training for comparison (*GAN*). As shown in Table 1, our XE-ss model already outperforms the best-known results on the VIST dataset, and the GAN model can bring a performance boost. We then use the XE-ss model to initialize our policy model and further train it with *AREL*. Evidently, our AREL model performs the best and achieves the new state-of-the-art results across all metrics.

Method	B-1	B-2	B-3	B-4	M	R	C
Huang et al.	-	-	-	-	31.4	-	-
Yu et al.	-	-	21.0	-	34.1	29.5	7.5
XE-ss	62.3	38.2	22.5	13.7	34.8	**29.7**	8.7
GAN	62.8	38.8	23.0	14.0	35.0	29.5	9.0
AREL-s-50	63.8	38.9	22.9	13.8	34.9	29.4	9.5
AREL-t-50	63.4	39.0	23.1	**14.1**	**35.2**	29.6	9.5
AREL-s-100	**63.9**	**39.1**	23.0	13.9	35.0	**29.7**	**9.6**
AREL-t-100	63.8	**39.1**	**23.2**	**14.1**	35.0	29.5	9.4

Table 1: Automatic evaluation on the VIST dataset. We report BLEU (B), METEOR (M), ROUGH-L (R), and CIDEr (C) scores of the SOTA systems and the models we implemented, including XE-ss, GAN and AREL. AREL-s-N denotes AREL models with sigmoid as output activation and alternate frequency as N, while AREL-t-N denoting AREL models with tahn as the output activation (N = 50 or 100).

But, compared with the XE-ss model, the performance gain is minor, especially on METEOR and ROUGE-L scores. However, in Sec. 4.3, the extensive human evaluation has indicated that our AREL framework brings a significant improvement on generating human-like stories over the XE-ss model. The inconsistency of automatic evaluation and human evaluation lead to a suspect that these hand-crafted metrics lack the ability to fully evaluate stories' quality due to the complicated characteristics of the stories. Therefore, we conduct experiments to analyze and discuss the defects of the automatic metrics in section 4.2.

Limitations of Automatic Metrics As we claimed in the introduction, string-match-based automatic metrics are not perfect and fail to evaluate some semantic characteristics of the stories, like the expressiveness and coherence of the stories. In order to confirm our conjecture, we utilize automatic metrics as rewards to reinforce the visual storytelling model by adopting policy gradient with baseline to train the policy model. The quantitative results are demonstrated in Table 1.

Apparently, METEOR-RL and ROUGE-RL are severely ill-posed: they obtain the highest scores on their own metrics but damage the other met-

[2]There are only 3 (out of 21,075) broken images in the test set, which basically has no influence on the final results. Moreover, Yu et al. (2017b) also removed the 3 pictures, so it is a fair comparison.

[3]`https://github.com/lichengunc/vist_eval`

Method	B-1	B-2	B-3	B-4	M	R	C
XE-ss	62.3	38.2	22.5	13.7	34.8	**29.7**	8.7
BLEU-RL	62.1	38.0	22.6	13.9	34.6	29.0	8.9
METEOR-RL	**68.1**	35.0	15.4	6.8	**40.2**	30.0	1.2
ROUGE-RL	58.1	18.5	1.6	0	27.0	**33.8**	0
CIDEr-RL	61.9	37.8	22.5	13.8	34.9	29.7	8.1
AREL (avg)	**63.7**	**39.0**	**23.1**	**14.0**	**35.0**	29.6	**9.5**

Table 2: Comparison with different RL models with different metric scores as the rewards. We report the average scores of the AREL models as AREL (avg). Although METEOR-RL and ROUGE-RL models achieve very high scores on their own metrics, the underlined scores are severely damaged. Actually, they are gaming their own metrics with nonsense sentences.

Method	Win	Lose	Unsure
XE-ss	22.4%	71.7%	5.9%
BLEU-RL	23.4%	67.9%	8.7%
CIDEr-RL	13.8%	80.3%	5.9%
GAN	34.3%	60.5%	5.2%
AREL	**38.4%**	**54.2%**	**7.4%**

Table 3: Turing test results.

rics severely. We observe that these models are actually overfitting to a given metric while losing the overall coherence and semantical correctness. Same as METEOR score, there is also an adversarial example for ROUGE-L[4], which is nonsense but achieves an average ROUGE-L score of 33.8.

Besides, as can be seen in Table 1, after reinforced training, BLEU-RL and CIDEr-RL do not bring a consistent improvement over the XE-ss model. We plot the histogram distributions of both BLEU-3 and CIDEr scores on the test set in Figure 5. An interesting fact is that there are a large number of samples with nearly zero score on both metrics. However, we observed those "zero-score" samples are not pointless results; instead, lots of them make sense and deserve a better score than zero. Here is a "zero-score" example on BLEU-3:

I had a great time at the restaurant today. The food was delicious. I had a lot of food. The food was delicious. T had a great time.

The corresponding reference is

The table of food was a pleasure to see! Our food is both nutritious and beautiful! Our chicken was especially tasty! We love greens as they taste great and are healthy! The fruit was a colorful display that tantalized our palette..

Although the prediction is not as good as the reference, it is actually coherent and relevant to the theme "food and eating", which showcases the defeats of using BLEU and CIDEr scores as a reward for RL training.

Moreover, we compare the human evaluation scores with these two metric scores in Figure 5. Noticeably, both BLEU-3 and CIDEr have a poor correlation with the human evaluation scores. Their distributions are more biased and thus cannot fully reflect the quality of the generated stories. In terms of BLEU, it is extremely hard for machines to produce the exact 3-gram or 4-gram matching, so the scores are too low to provide useful guidance. CIDEr measures the similarity of a sentence to the majority of the references. However, the references to the same image sequence are photostream different from each other, so the score is very low and not suitable for this task. In contrast, our AREL framework can lean a more robust reward function from human-annotated stories, which is able to provide better guidance to the policy and thus improves its performances over different metrics.

Comparison with GAN We here compare our method with traditional GAN (Goodfellow et al., 2014), the update rule for generator can be generally classified into two categories. We demonstrate their corresponding objectives and ours as follows:

$$\begin{aligned} GAN1: \quad & J_\beta = \underset{W\sim p_\beta}{E}\left[-\log R_\theta(W)\right], \\ GAN2: \quad & J_\beta = \underset{W\sim p_\beta}{E}\left[\log(1-R_\theta(W))\right], \\ ours: \quad & J_\beta = \underset{W\sim p_\beta}{E}\left[-R_\theta(W)\right]. \end{aligned}$$

As discussed in Arjovsky et al. (2017), $GAN1$ is prone to the unstable gradient issue and $GAN2$ is prone to the vanishing gradient issue. Analytically, our method does not suffer from these two common issues and thus is able converge to optimum solutions more easily. From Table 1, we can observe slight gains of using AREL over GAN

[4]An adversarial example for ROUGE-L: *we the was a . and to the . we the was a . and to the . we the was a . and to the . we the was a . and to the . we the was a . and to the .*

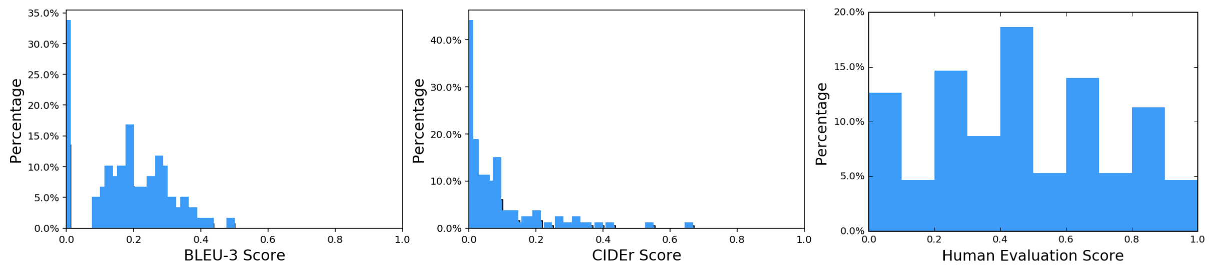

Figure 5: Metric score distributions. We plot the histogram distributions of BLEU-3 and CIDEr scores on the test set, as well as the human evaluation score distribution on the test samples. For a fair comparison, we use the Turing test results to calculate the human evaluation scores (see Section 4.3). Basically, 0.2 score is given if the generated story wins the Turing test, 0.1 for tie, and 0 if losing. Each sample has 5 scores from 5 judges, and we use the sum as the human evaluation score, so it is in the range [0, 1].

	AREL *vs* XE-ss			AREL *vs* BLEU-RL			AREL *vs* CIDEr-RL			AREL *vs* GAN		
Choice (%)	AREL	XE-ss	Tie	AREL	BLEU-RL	Tie	AREL	CIDEr-RL	Tie	AREL	GAN	Tie
Relevance	**61.7**	25.1	13.2	**55.8**	27.9	16.3	**56.1**	28.2	15.7	**52.9**	35.8	11.3
Expressiveness	**66.1**	18.8	15.1	**59.1**	26.4	14.5	**59.1**	26.6	14.3	**48.5**	32.2	19.3
Concreteness	**63.9**	20.3	15.8	**60.1**	26.3	13.6	**59.5**	24.6	15.9	**49.8**	35.8	14.4

Table 4: Pairwise human comparisons. The results indicate the consistent superiority of our AREL model in generating more human-like stories than the SOTA methods.

with automatic metrics, therefore we further deploy human evaluation for a better comparison.

4.3 Human Evaluation

Automatic metrics cannot fully evaluate the capability of our AREL method. Therefore, we perform two different kinds of human evaluation studies on Amazon Mechanical Turk: Turing test and pairwise human evaluation. For both tasks, we use 150 stories (750 images) sampled from the test set, each assigned to 5 workers to eliminate human variance. We batch six items as one assignment and insert an additional assignment as a sanity check. Besides, the order of the options within each item is shuffled to make a fair comparison.

Turing Test We first conduct five independent Turing tests for XE-ss, BLEU-RL, CIDEr-RL, GAN, and AREL models, during which the worker is given one human-annotated sample and one machine-generated sample, and needs to decide which is human-annotated. As shown in Table 3, our AREL model significantly outperforms all the other baseline models in the Turing test: it has much more chances to fool AMT worker (the ratio is AREL:XE-ss:BLEU-RL:CIDEr-RL:GAN = 45.8%:28.3%:32.1%:19.7%:39.5%), which confirms the superiority of our AREL framework in generating human-like stories. Unlike automatic metric evaluation, the Turing test has indicated a much larger margin between AREL and other competing algorithms. Thus, we empirically confirm that metrics are not perfect in evaluating many implicit semantic properties of natural language. Besides, the Turing test of our AREL model reveals that nearly half of the workers are fooled by our machine generation, indicating a preliminary success toward generating human-like stories.

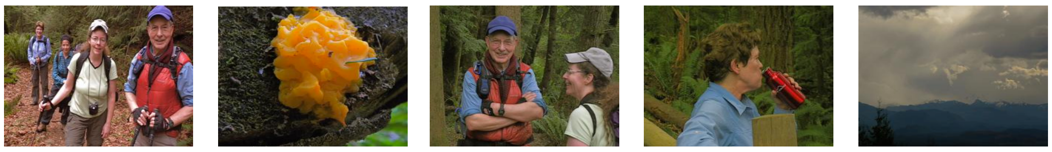
Pairwise Comparison In order to have a clear comparison with competing algorithms with respect to different semantic features of the stories, we further perform four pairwise comparison tests: AREL *vs* XE-ss/BLEU-RL/CIDEr-RL/GAN. For each photo stream, the worker is presented with two generated stories and asked to make decisions from the three aspects: relevance[5], expressiveness[6] and concreteness[7]. This head-to-head compete is designed to help us understand in what aspect our model outperforms the competing algorithms, which is displayed in Table 4.

Consistently on all the three comparisons, a large majority of the AREL stories trumps the competing systems with respect to their relevance,

[5]Relevance: the story accurately describes what is happening in the image sequence and covers the main objects.

[6]Expressiveness: coherence, grammatically and semantically correct, no repetition, expressive language style.

[7]Concreteness: the story should narrate concretely what is in the image rather than giving very general descriptions.



XE-ss	We took a trip to the mountains.	There were many different kinds of different kinds.	We had a great time.	He was a great time.	It was a beautiful day.
AREL	The family decided to take a trip to the countryside.	There were so many different kinds of things to see.	The family decided to go on a hike.	I had a great time.	At the end of the day, we were able to take a picture of the beautiful scenery.
Human-created Story	We went on a hike yesterday.	There were a lot of strange plants there.	I had a great time.	We drank a lot of water while we were hiking.	The view was spectacular.

Figure 6: Qualitative comparison example with XE-ss. The direct comparison votes (AREL:XE-ss:Tie) were 5:0:0 on Relevance, 4:0:1 on Expressiveness, and 5:0:0 on Concreteness.

expressiveness, and concreteness. Therefore, it empirically confirms that our generated stories are more relevant to the image sequences, more coherent and concrete than the other algorithms, which however is not explicitly reflected by the automatic metric evaluation.

4.4 Qualitative Analysis

Figure 6 gives a qualitative comparison example between AREL and XE-ss models. Looking at the individual sentences, it is obvious that our results are more grammatically and semantically correct. Then connecting the sentences together, we observe that the AREL story is more coherent and describes the photo stream more accurately. Thus, our AREL model significantly surpasses the XE-ss model on all the three aspects of the qualitative example. Besides, it won the Turing test (3 out 5 AMT workers think the AREL story is created by a human). In the appendix, we also show a negative case that fails the Turing test.

5 Conclusion

In this paper, we not only introduce a novel adversarial reward learning algorithm to generate more human-like stories given image sequences, but also empirically analyze the limitations of the automatic metrics for story evaluation. We believe there are still lots of improvement space in the narrative paragraph generation tasks, like how to better simulate human imagination to create more vivid and diversified stories.

Abstract

We present a deep neural network that leverages images to improve bilingual text embeddings. Relying on bilingual image tags and descriptions, our approach conditions text embedding induction on the shared visual information for both languages, producing highly correlated bilingual embeddings. In particular, we propose a novel model based on Partial Canonical Correlation Analysis (PCCA). While the original PCCA finds linear projections of two views in order to maximize their canonical correlation conditioned on a shared third variable, we introduce a non-linear Deep PCCA (DPCCA) model, and develop a new stochastic iterative algorithm for its optimization. We evaluate PCCA and DPCCA on multilingual word similarity and cross-lingual image description retrieval. Our models outperform a large variety of previous methods, despite not having access to any visual signal during test time inference.[1]

1 Introduction

Research in multi-modal semantics deals with the *grounding problem* (Harnad, 1990), motivated by evidence that many semantic concepts, irrespective of the actual language, are grounded in the perceptual system (Barsalou and Wiemer-Hastings, 2005). In particular, recent studies have shown that performance on NLP tasks can be improved by joint modeling of text and vision, with multi-modal and perceptually enhanced representation learning outperforming purely textual representations (Feng and Lapata, 2010; Kiela and Bottou, 2014; Lazaridou et al., 2015).

These findings are not surprising, and can be explained by the fact that humans understand language not only by its words, but also by their visual/perceptual context. The ability to connect vision and language has also enabled new tasks which require both visual *and* language understanding, such as visual question answering (Antol et al., 2015; Fukui et al., 2016; Xu and Saenko, 2016), image-to-text retrieval and text-to-image retrieval (Kiros et al., 2014; Mao et al., 2014), image caption generation (Farhadi et al., 2010; Mao et al., 2015; Vinyals et al., 2015; Xu et al., 2015), and visual sense disambiguation (Gella et al., 2016).

While the main focus is still on monolingual settings, the fact that visual data can serve as a natural bridge between languages has sparked additional interest towards *multilingual multi-modal modeling*. Such models induce bilingual multi-modal spaces based on multi-view learning (Calixto et al., 2017; Gella et al., 2017; Rajendran et al., 2016).

In this work, we propose a novel effective approach for learning bilingual *text* embeddings *conditioned on shared visual information*. This additional perceptual modality bridges the gap between languages and reveals latent connections between concepts in the multilingual setup. The shared visual information in our work takes the form of images with word-level tags or sentence-level descriptions assigned in more than one language.

We propose a *deep* neural architecture termed Deep Partial Canonical Correlation Analysis (DPCCA) based on the Partial CCA (PCCA) method (Rao, 1969). To the best of our knowledge, PCCA has not been used in multilingual settings before. In short, PCCA is a variant of CCA which learns maximally correlated linear projections of two views (e.g., two language-specific "text-based views") conditioned on a shared third view (e.g.,

[1] Our code and data are available at: https://github.com/rotmanguy/DPCCA.

the "visual view"). We discuss the PCCA and DPCCA methods in §3 and show how they can be applied without having access to the shared images at test time inference.

PCCA inherits one disadvantageous property from CCA: both methods compute estimates for covariance matrices based on all training data. This would prevent feasible training of their deep non-linear variants, since deep neural nets (DNNs) are predominantly optimized via stochastic optimization algorithms. To resolve this major hindrance, we propose an effective optimization algorithm for DPCCA, inspired by the work of Wang et al. (2015b) on Deep CCA (DCCA) optimization.

We evaluate our DPCCA architecture on two semantic tasks: **1)** multilingual word similarity and **2)** cross-lingual image description retrieval. For the former, we construct and provide to the community a new Word-Image-Word (WIW) dataset containing bilingual lexicons for three languages with shared images for 5K+ concepts. WIW is used as training data for word similarity experiments, while evaluation is conducted on the standard multilingual SimLex-999 dataset (Hill et al., 2015; Leviant and Reichart, 2015).

The results reveal stable improvements over a large space of non-deep and deep CCA-style baselines in both tasks. Most importantly, **1)** PCCA is overall better than other methods which do not use the additional perceptual view; **2)** DPCCA outperforms PCCA, indicating the importance of non-linear transformations modeled through DNNs; **3)** DPCCA outscores DCCA, again verifying the importance of conditioning multilingual text embedding induction on the shared visual view; and **4)** DPCCA outperforms two recent multi-modal bilingual models which also leverage visual information (Gella et al., 2017; Rajendran et al., 2016).

2 Related Work

This work is related to two research threads: **1)** multi-modal models that combine vision and language, with a focus on multilingual settings; **2)** correlational multi-view models based on CCA which learn a shared vector space for multiple views.

Multi-Modal Modeling in Multilingual Settings Research in cognitive science suggests that human meaning representations are grounded in our perceptual system and sensori-motor experience (Harnad, 1990; Lakoff and Johnson, 1999; Louwerse, 2011). Visual context serves as a useful cross-lingual grounding signal (Bruni et al., 2014; Glavaš et al., 2017) due to its language invariance, even enabling the induction of word-level bilingual semantic spaces solely through tagged images obtained from the Web (Bergsma and Van Durme, 2011; Kiela et al., 2015). Vulić et al. (2016) combine text embeddings with visual features via simple techniques of concatenation and averaging to obtain bilingual multi-modal representations, with noted improvements over text-only embeddings on word similarity and bilingual lexicon extraction. However, similar to the monolingual model of Kiela and Bottou (2014), their models lack the training phase, and require the visual signal at test time.

Recent work from Gella et al. (2017) exploits visual content as a bridge between multiple languages by optimizing a contrastive loss function. Furthermore, Rajendran et al. (2016) extend the work of Chandar et al. (2016) and propose to use a pivot representation in multimodal multilingual setups, with English representations serving as the pivot. While these works learn shared multimodal multilingual vector spaces, we demonstrate improved performance with our models (see §7).

Finally, although not directly comparable, recent work in neural machine translation has constructed models that can translate image descriptions by additionally relying on visual features of the image provided (Calixto and Liu, 2017; Elliott et al., 2015; Hitschler et al., 2016; Huang et al., 2016; Nakayama and Nishida, 2017, *inter alia*).

Correlational Models CCA-based techniques support multiple views on related data: e.g., when coupled with a bilingual dictionary, input monolingual word embeddings for two different languages can be seen as two views of the same latent semantic signal. Recently, CCA-based models for bilingual text embedding induction were proposed. These models rely on the basic CCA model (Chandar et al., 2016; Faruqui and Dyer, 2014), its deep variant (Lu et al., 2015), and a CCA extension which supports more than two views (Funaki and Nakayama, 2015; Rastogi et al., 2015). In this work, we propose to use (D)PCCA, which organically supports our setup: it conditions the two (textual) views on a shared (visual) view.

CCA-based methods (including PCCA) require the estimation of covariance matrices over *all* training data (Kessy et al., 2017). This hinders the use of DNNs with these models, as DNNs are typically trained via stochastic optimization over mini-batches on very large training sets. To address this limitation, various optimization methods for Deep CCA were proposed. Andrew et al. (2013) use L-BFGS (Byrd et al., 1995) over all training samples, while Arora and Livescu (2013) and Yan and Mikolajczyk (2015) train with large batches. However, these methods suffer from high memory complexity with unstable numerical computations.

Wang et al. (2015b) have recently proposed a stochastic approach for CCA and DCCA which copes well with small and large batch sizes while preserving high model performance. They use orthogonal iterations to estimate a moving average of the covariance matrices, which improves memory consumption. Therefore, we base our novel optimization algorithm for DPCCA on this approach.

3 Methodology: Deep Partial CCA

Given two image descriptions $\boldsymbol{x}$ and $\boldsymbol{y}$ in two languages and an image $\boldsymbol{z}$ that they refer to, the task is to learn a shared bilingual space such that similar descriptions obtain similar representations in the induced space. The image $\boldsymbol{z}$ serves as a shared third view on the textual data during training. The representation model is then utilized in cross-lingual and monolingual tasks. In this paper we focus on the more realistic scenario where no relevant visual content is available at test time. For this goal we propose a novel Deep Partial CCA (DPCCA) framework.

In what follows, we first review the CCA model and its deep variant: DCCA. We then introduce our DPCCA architecture, and describe our new stochastic optimization algorithm for DPCCA.

3.1 CCA and Deep CCA

DCCA (Andrew et al., 2013) extends CCA by learning non-linear (instead of linear) transformations of features contained in the input matrices $\boldsymbol{X} \in \mathbb{R}^{D_x \times N}$ and $\boldsymbol{Y} \in \mathbb{R}^{D_y \times N}$, where D_x and D_y are input vector dimensionalities, and N is the number of input items. Since CCA is a special case of the non-linear DCCA (see below), we here briefly outline the more general DCCA model.

The DCCA architecture is illustrated in Figure 1a. Non-linear transformations are achieved through two DNNs $\boldsymbol{f} : \mathbb{R}^{D_x \times N} \rightarrow \mathbb{R}^{D'_x \times N}$ and $\boldsymbol{g} : \mathbb{R}^{D_y \times N} \rightarrow \mathbb{R}^{D'_y \times N}$ for $\boldsymbol{X}$ and $\boldsymbol{Y}$. D'_x and D'_y are the output dimensionalities. A final linear layer is added to resemble the linear CCA projection.

The goal is to project the features of $\boldsymbol{X}$ and $\boldsymbol{Y}$ into a shared L-dimensional ($1 \leq L \leq min(D'_x, D'_y)$) space such that the canonical correlation of the final outputs $\boldsymbol{F}(\boldsymbol{X}) = \boldsymbol{W}^{\boldsymbol{T}}\boldsymbol{f}(\boldsymbol{X})$ and $\boldsymbol{G}(\boldsymbol{Y}) = \boldsymbol{V}^{\boldsymbol{T}}\boldsymbol{g}(\boldsymbol{Y})$ is maximized. $\boldsymbol{W} \in \mathbb{R}^{D'_x \times L}$ and $\boldsymbol{V} \in \mathbb{R}^{D'_y \times L}$ are projection matrices: they project the final outputs of the DNNs to the shared space. $\boldsymbol{W_f}$ and $\boldsymbol{V_g}$ (the parameters of $\boldsymbol{f}$ and $\boldsymbol{g}$) and the projection matrices are the model parameters: $\boldsymbol{W_F} = \{\boldsymbol{W_f}, \boldsymbol{W}\}$; $\boldsymbol{V_G} = \{\boldsymbol{V_g}, \boldsymbol{V}\}$.[2] Formally, the DCCA objective can be written as:

$$\max_{\boldsymbol{W_F},\boldsymbol{V_G}} Tr(\hat{\boldsymbol{\Sigma}}_{\boldsymbol{FG}}) \quad \text{so that } \hat{\boldsymbol{\Sigma}}_{\boldsymbol{FF}} = \hat{\boldsymbol{\Sigma}}_{\boldsymbol{GG}} = \boldsymbol{I}. \tag{1}$$

$\hat{\boldsymbol{\Sigma}}_{\boldsymbol{FG}} \equiv \frac{1}{N-1}\boldsymbol{F}(\boldsymbol{X})\boldsymbol{G}(\boldsymbol{Y})^{\boldsymbol{T}}$ is the estimation of the cross-covariance matrix of the outputs, and $\hat{\boldsymbol{\Sigma}}_{\boldsymbol{FF}} \equiv \frac{1}{N-1}\boldsymbol{F}(\boldsymbol{X})\boldsymbol{F}(\boldsymbol{X})^{\boldsymbol{T}}$, $\hat{\boldsymbol{\Sigma}}_{\boldsymbol{GG}} \equiv \frac{1}{N-1}\boldsymbol{G}(\boldsymbol{Y})\boldsymbol{G}(\boldsymbol{Y})^{\boldsymbol{T}}$ are the estimations of the auto-covariance matrices of the outputs.[3] Further, following Wang et al. (2015b), the optimal solution of Eq. (1) is equivalent to the optimal solution of the following:

$$\min_{\boldsymbol{W_F},\boldsymbol{V_G}} \frac{1}{N-1}\|\boldsymbol{F}(\boldsymbol{X}) - \boldsymbol{G}(\boldsymbol{Y})\|_F^2 \quad s.t.\ \hat{\boldsymbol{\Sigma}}_{\boldsymbol{FF}} = \hat{\boldsymbol{\Sigma}}_{\boldsymbol{GG}} = \boldsymbol{I}. \tag{2}$$

The main disadvantage of DCCA is its inability to support more than two views, and to learn conditioned on an additional shared view, which is why we introduce Deep Partial CCA.

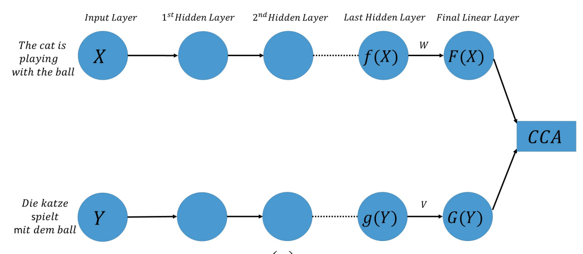
3.2 New Model: Deep Partial CCA

Figure 1b illustrates the architecture of DPCCA. The training data now consists of triplets $(\boldsymbol{x_i}, \boldsymbol{y_i}, \boldsymbol{z_i})_{1=1}^{N}$ from three views, forming the columns of $\boldsymbol{X}$, $\boldsymbol{Y}$ and $\boldsymbol{Z}$, where $\boldsymbol{x_i} \in \mathbb{R}^{D_x}, \boldsymbol{y_i} \in \mathbb{R}^{D_y}, \boldsymbol{z_i} \in \mathbb{R}^{D_z}$ for $i = 1, \ldots, N$. The objective is to maximize the canonical correlation of the first two views $\boldsymbol{X}$ and $\boldsymbol{Y}$ conditioned on the shared third variable $\boldsymbol{Z}$. Following Rao (1969)'s work on Partial CCA, we first consider two multivariate linear multiple regression models:

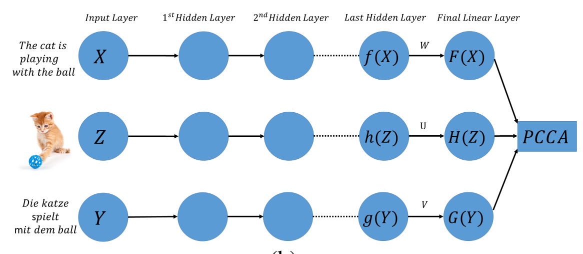
$$\boldsymbol{F}(\boldsymbol{X}) = \boldsymbol{AZ} + \boldsymbol{F}(\boldsymbol{X}|\boldsymbol{Z}), \tag{3}$$
$$\boldsymbol{G}(\boldsymbol{Y}) = \boldsymbol{BZ} + \boldsymbol{G}(\boldsymbol{Y}|\boldsymbol{Z}). \tag{4}$$

[2]For notational simplicity, we assume $\boldsymbol{f}(\boldsymbol{X})$ and $\boldsymbol{g}(\boldsymbol{Y})$ to have zero-means, otherwise it is possible to centralize them at the final layer of each network to the same effect.

[3]The CCA model can be seen as a special (linear) case of the more general DCCA model. The basic CCA objective can be recovered from the DCCA objective by simply setting $D'_x = D_x$, $D'_y = D_y$ and $\boldsymbol{f}(\boldsymbol{X}) = id_X$, $\boldsymbol{g}(\boldsymbol{Y}) = id_Y$; id is the identity mapping.



(a)



(b)

Figure 1: DCCA and DPCCA architectures. **(a)**: DCCA. $\boldsymbol{X}$ and $\boldsymbol{Y}$ (English and German image descriptions) are fed through two identical deep feed-forward neural networks followed by a final linear layer. The final nodes of the networks $\boldsymbol{F}(\boldsymbol{X})$ and $\boldsymbol{G}(\boldsymbol{Y})$ are then maximally correlated via the CCA objective. **(b)**: DPCCA. In addition, a third (shared) variable $\boldsymbol{Z}$ (an image) is either optimized via an identical architecture of the two main views (DPCCA Variant B, illustrated here) or kept fixed (DPCCA Variant A). The final nodes of the networks $\boldsymbol{F}(\boldsymbol{X})$ and $\boldsymbol{G}(\boldsymbol{Y})$ are maximally correlated conditioned on the final node in the middle network $\boldsymbol{H}(\boldsymbol{Z})$ (or directly on the input node $\boldsymbol{Z}$ in DPCCA Variant A).

$\boldsymbol{A}, \boldsymbol{B} \in \mathbb{R}^{L \times D_z}$ are matrices of coefficients, and $\boldsymbol{F}(\boldsymbol{X}|\boldsymbol{Z}), \boldsymbol{G}(\boldsymbol{Y}|\boldsymbol{Z}) \in \mathbb{R}^{L \times N}$ are normal random error matrices: residuals. We then minimize the mean-squared error regression criterion:

$$\min_{\boldsymbol{A}} \frac{1}{N-1} \|\boldsymbol{F}(\boldsymbol{X}) - \boldsymbol{A}\boldsymbol{Z}\|_F^2, \tag{5}$$

$$\min_{\boldsymbol{B}} \frac{1}{N-1} \|\boldsymbol{G}(\boldsymbol{Y}) - \boldsymbol{B}\boldsymbol{Z}\|_F^2. \tag{6}$$

After obtaining the optimal solutions for the coefficients, $\hat{\boldsymbol{A}}$ and $\hat{\boldsymbol{B}}$, the residuals are as follows:

$$\begin{aligned}\boldsymbol{F}(\boldsymbol{X}|\boldsymbol{Z}) &= \boldsymbol{F}(\boldsymbol{X}) - \hat{\boldsymbol{A}}\boldsymbol{Z} \\ &= \boldsymbol{F}(\boldsymbol{X}) - \hat{\boldsymbol{\Sigma}}_{\boldsymbol{FZ}} \hat{\boldsymbol{\Sigma}}_{\boldsymbol{ZZ}}^{-1} \boldsymbol{Z}.\end{aligned} \tag{7}$$

$\boldsymbol{G}(\boldsymbol{Y}|\boldsymbol{Z})$ is computed in the analogous manner, now relying on $\boldsymbol{G}(\boldsymbol{Y})$ and $\hat{\boldsymbol{B}}\boldsymbol{Z}$. $\hat{\boldsymbol{\Sigma}}_{\boldsymbol{S'Z}} \equiv \frac{1}{N-1}\boldsymbol{S}\boldsymbol{Z}^{\boldsymbol{T}}$ refers to the covariance matrix estimator of $\boldsymbol{S'}$ and $\boldsymbol{Z}$, where $(\boldsymbol{S'}, \boldsymbol{S}) \in \{(\boldsymbol{F}, \boldsymbol{F}(\boldsymbol{X})), (\boldsymbol{G}, \boldsymbol{G}(\boldsymbol{Y})), (\boldsymbol{Z}, \boldsymbol{Z})\}$.[4]

The canonical correlation between the residual matrices $\boldsymbol{F}(\boldsymbol{X}|\boldsymbol{Z})$ and $\boldsymbol{G}(\boldsymbol{Y}|\boldsymbol{Z})$ is referred to as the *partial canonical correlation*. The Deep PCCA objective can be obtained by replacing $\boldsymbol{F}(\boldsymbol{X})$ and $\boldsymbol{G}(\boldsymbol{Y})$ with their residuals in Eq. (2):

$$\begin{aligned}&\min_{\boldsymbol{W_F}, \boldsymbol{V_G}} \frac{1}{N-1} \|\boldsymbol{F}(\boldsymbol{X}|\boldsymbol{Z}) - \boldsymbol{G}(\boldsymbol{Y}|\boldsymbol{Z})\|_F^2 \\ &s.t.\ \hat{\boldsymbol{\Sigma}}_{\boldsymbol{FF}|\boldsymbol{Z}} = \hat{\boldsymbol{\Sigma}}_{\boldsymbol{GG}|\boldsymbol{Z}} = \boldsymbol{I}.\end{aligned} \tag{8}$$

The computation of the conditional covariance matrix $\hat{\boldsymbol{\Sigma}}_{\boldsymbol{FF}|\boldsymbol{Z}}$ can be formulated as follows:

$$\begin{aligned}\hat{\boldsymbol{\Sigma}}_{\boldsymbol{FF}|\boldsymbol{Z}} &\equiv \frac{1}{N-1} \boldsymbol{F}(\boldsymbol{X}|\boldsymbol{Z}) \boldsymbol{F}(\boldsymbol{X}|\boldsymbol{Z})^{\boldsymbol{T}} \\ &= \hat{\boldsymbol{\Sigma}}_{\boldsymbol{FF}} - \hat{\boldsymbol{\Sigma}}_{\boldsymbol{FZ}} \hat{\boldsymbol{\Sigma}}_{\boldsymbol{ZZ}}^{-1} \hat{\boldsymbol{\Sigma}}_{\boldsymbol{FZ}}^{\boldsymbol{T}}.\end{aligned} \tag{9}$$

[4] A small value $\epsilon > 0$ is added to the main diagonal of the covariance estimators for numerical stability.

The other conditional covariance matrix $\hat{\boldsymbol{\Sigma}}_{\boldsymbol{GG}|\boldsymbol{Z}}$ is again computed in the analogous manner, replacing $\boldsymbol{F}$ with $\boldsymbol{G}$ and $\boldsymbol{X}$ with $\boldsymbol{Y}$.[5]

While the (D)PCCA objective is computed over the residuals, after the network is trained (using multilingual texts and corresponding images) we can compute the representations of $\boldsymbol{F}(\boldsymbol{X})$ and $\boldsymbol{G}(\boldsymbol{Y})$ at test time without having access to images (see the network structure in Figure 1b). This heuristic enables the use of DPCCA in a real-life scenario in which images are unavailable at test time, and its encouraging results are demonstrated in §7.

Model Variants We consider two DPCCA variants : **1)** in DPCCA Variant A, the shared view $\boldsymbol{Z}$ is kept fixed; **2)** DPCCA Variant B also optimizes over $\boldsymbol{Z}$, as illustrated in Figure 1b. Variant A may be seen as a special case of Variant B.[6]

Variant B learns a non-linear function of the shared variable, $\boldsymbol{H}(\boldsymbol{Z}) = \boldsymbol{U}^{\boldsymbol{T}}\boldsymbol{h}(\boldsymbol{Z})$, during training, where $\boldsymbol{h} : \mathbb{R}^{D_z \times N} \to \mathbb{R}^{D_{z'} \times N}$ is a DNN having the same architecture as $\boldsymbol{f}$ and $\boldsymbol{g}$. $\boldsymbol{U} \in \mathbb{R}^{D_{z'} \times L}$ is the final linear layer of $\boldsymbol{H}$, such that overall, the additional parameters of the model are $\boldsymbol{U_H} = \{\boldsymbol{U_h}, \boldsymbol{U}\}$. Instead of assuming a linear connection between $\boldsymbol{F}(\boldsymbol{X})$ and $\boldsymbol{G}(\boldsymbol{Y})$ to $\boldsymbol{Z}$, as in Variant A, we now assume that the linear connection takes place with $\boldsymbol{H}(\boldsymbol{Z})$. This assumption

[5] The original PCCA objective can be recovered by setting $D'_x = D_x$, $D'_y = D_y$ and $\boldsymbol{f}(\boldsymbol{X}) = id_X, \boldsymbol{g}(\boldsymbol{Y}) = id_Y$.

[6] For Variant A, in order for $\boldsymbol{Z}$ to be on the same range of values as in $\boldsymbol{F}$ and $\boldsymbol{G}$, we pass it through the activation function of the network, $\boldsymbol{Z} = \sigma(\boldsymbol{Z})$. Due to space constraints we discuss DPCCA Variant A in the supplementary material only.

changes Eq. (3) and Eq. (4) to:[7]

$$F(X) = A' \cdot H(Z) + F(X|H(Z)), \quad (10)$$
$$G(Y) = B' \cdot H(Z) + G(Y|H(Z)). \quad (11)$$

4 DPCCA: Optimization Algorithm

Training deep variants of CCA-style multi-view models is non-trivial due to estimation on the entire training set related to whitening constraints (i.e., the orthogonality of covariance matrices). To overcome this issue, Wang et al. (2015b) proposed a stochastic optimization algorithm for DCCA via non-linear orthogonal iterations (DCCA_NOI). Relying on the solution for DCCA (§4.1), we develop a new optimization algorithm for DPCCA in §4.2.

4.1 Optimization of DCCA

The DCCA optimization from Wang et al. (2015b), fully provided in Algorithm 1, relies on three key steps. First, the estimation of the covariance matrices in the form of $\hat{\Sigma}_{FF_t}$ at time t is calculated by a moving average over the minibatches:

$$\hat{\Sigma}_{FF_t} \leftarrow \rho\hat{\Sigma}_{FF_{t-1}} + (1-\rho)\left(\frac{|b_t|}{N-1}\right)^{-1} F(X_{b_t})F(X_{b_t})^T. \quad (12)$$

b_t is the minibatch at time t, X_{b_t} is the current input matrix at time t, and $\rho \in [0, 1]$ controls the ratio between the overall covariance estimation and the covariance estimation of the current minibatch.[8] This step eliminates the need of estimating the covariances over all training data, as well as the inherent bias when the estimate relies only on the current minibatch.

Second, the DCCA_NOI algorithm forces the whitening constraints to hold by performing an explicit matrix transformation in the form of:

$$\widetilde{F(X_{b_t})} = \hat{\Sigma}_{FF_t}^{-\frac{1}{2}} F(X_{b_t}). \quad (13)$$

According to Horn et al. (1988), if $\rho = 0$:

$$\left(\frac{|b_t|}{N-1}\right)^{-1} \widetilde{F(X_{b_t})}\widetilde{F(X_{b_t})}^T = I. \quad (14)$$

Finally, in order to optimize the DCCA objective (see Eq. (2)), the weights of the two DNNs are decoupled: i.e., the objective is disassembled into two separate mean-squared error objectives. Instead of trying to bring $F(X_{b_t})$ and $G(Y_{b_t})$ closer in one gradient descent step, two steps are performed: one of the views is fixed, and a gradient step over the other is performed, and so on, iteratively. The final objective functions at each time step are:

$$\min_{W_F} \frac{1}{|b_t|} \|F(X_{b_t}) - \widetilde{G(Y_{b_t})}\|_F^2, \quad (15)$$

$$\min_{V_G} \frac{1}{|b_t|} \|G(Y_{b_t}) - \widetilde{F(X_{b_t})}\|_F^2. \quad (16)$$

Wang et al. (2015b) show that the projection matrices W and V converge to the exact solutions of CCA as t$\rightarrow \infty$ when considering linear CCA.

Algorithm 1 The non-linear orthogonal iterations (NOI) algorithm for DCCA (DCCA_NOI)

```
Input: Data matrices $X \in \mathbb{R}^{D_x \times N}$, $Y \in \mathbb{R}^{D_y \times N}$, time constant $\rho$, learning rate $\eta$.

initialization: Initialize weights ($W_F$, $V_G$).
Randomly choose a minibatch ($X_{b_0}$, $Y_{b_0}$).
Initialize covariances:
$\hat{\Sigma}_{FF} \leftarrow \frac{N-1}{|b_0|} F(X_{b_0})F(X_{b_0})^T$
$\hat{\Sigma}_{GG} \leftarrow \frac{N-1}{|b_0|} G(Y_{b_0})G(Y_{b_0})^T$

  for $t = 1, 2, \ldots, n$ do
  Randomly choose a minibatch ($X_{b_t}$, $Y_{b_t}$).

  Update covariances:
  $\hat{\Sigma}_{FF} \leftarrow \rho\hat{\Sigma}_{FF} + (1-\rho)\frac{N-1}{|b_t|} F(X_{b_t})F(X_{b_t})^T$
  $\hat{\Sigma}_{GG} \leftarrow \rho\hat{\Sigma}_{GG} + (1-\rho)\frac{N-1}{|b_t|} G(Y_{b_t})G(Y_{b_t})^T$
  Fix $\widetilde{G(Y_{b_t})} = \hat{\Sigma}_{GG}^{-\frac{1}{2}} G(Y_{b_t})$, and compute $\nabla W_F$ with respect to:
  $\min_{W_F} \frac{1}{|b_t|} \|F(X_{b_t}) - \widetilde{G(Y_{b_t})}\|_F^2$
  Update parameters:
  $W_F \leftarrow W_F - \eta\nabla W_F$
  Fix $\widetilde{F(X_{b_t})} = \hat{\Sigma}_{FF}^{-\frac{1}{2}} F(X_{b_t})$, and compute $\nabla V_G$ with respect to:
  $\min_{V_G} \frac{1}{|b_t|} \|G(Y_{b_t}) - \widetilde{F(X_{b_t})}\|_F^2$
  Update parameters:
  $V_G \leftarrow V_G - \eta\nabla V_G$
  end for
Output: ($W_F$, $V_G$)
```

4.2 Optimization of DPCCA

Our DPCCA optimization is based on the DCCA_NOI algorithm with several adjustments. Besides the requirement to obtain the sample covariances $\hat{\Sigma}_{FF}$ and $\hat{\Sigma}_{GG}$, when calculating the conditional variables $F(X|Z)$, $G(Y|Z)$, $\hat{\Sigma}_{FF|Z}$ and $\hat{\Sigma}_{GG|Z}$, we additionally have to obtain the stochastic estimators $\hat{\Sigma}_{FZ}$, $\hat{\Sigma}_{GZ}$ and $\hat{\Sigma}_{ZZ}$. To this end, we use the moving average estimation from Eq. (12). Next, we define the whitening transformation on the residuals:

[7]Note that the matrices of coefficients A', $B' \in \mathbb{R}^{L \times L}$.

[8]Setting ρ to a high value indicates slow updates of the estimator; setting it low mostly erases the overall estimation and relies more on the current minibatch estimation.

$$\boldsymbol{F}(\widetilde{\boldsymbol{X}_{\boldsymbol{b_t}}|\boldsymbol{Z}}_{\boldsymbol{b_t}}) = \hat{\boldsymbol{\Sigma}}^{-\frac{1}{2}}_{\boldsymbol{FF_t|Z}}\boldsymbol{F}(\boldsymbol{X}_{\boldsymbol{b_t}}|\boldsymbol{Z}_{\boldsymbol{b_t}}), \tag{17}$$

$$\boldsymbol{G}(\widetilde{\boldsymbol{Y}_{\boldsymbol{b_t}}|\boldsymbol{Z}}_{\boldsymbol{b_t}}) = \boldsymbol{\Sigma}^{-\frac{1}{2}}_{\boldsymbol{GG_t|Z}}\boldsymbol{G}(\boldsymbol{Y}_{\boldsymbol{b_t}}|\boldsymbol{Z}_{\boldsymbol{b_t}}). \tag{18}$$

As before, the whitening constraints hold when ρ = 0. From here, we derive our two final objective functions over the residuals at time t:

$$\min_{\boldsymbol{W_F}} \frac{1}{|b_t|}\|\boldsymbol{F}(\boldsymbol{X}_{\boldsymbol{b_t}}|\boldsymbol{Z}_{\boldsymbol{b_t}}) - \boldsymbol{G}(\widetilde{\boldsymbol{Y}_{\boldsymbol{b_t}}|\boldsymbol{Z}}_{\boldsymbol{b_t}})\|^2_F, \tag{19}$$

$$\min_{\boldsymbol{V_G}} \frac{1}{|b_t|}\|\boldsymbol{G}(\boldsymbol{Y}_{\boldsymbol{b_t}}|\boldsymbol{Z}_{\boldsymbol{b_t}}) - \boldsymbol{F}(\widetilde{\boldsymbol{X}_{\boldsymbol{b_t}}|\boldsymbol{Z}}_{\boldsymbol{b_t}})\|^2_F. \tag{20}$$

Equivalently to Eq. (15)-(16) that replace Eq. (2), Eq. (19)-(20) replace Eq. (8) by performing stochastic, decoupled and unconstrained steps. As our algorithm performs CCA over the residuals, we gain the same guarantees as Wang et al. (2015b), now for the projection matrices of the residuals.

Algorithm 2 shows the full optimization procedure for the more complex DPCCA Variant B. The full algorithm for Variant A is provided in the supplementary material. The main difference is that with Variant B we replace $\boldsymbol{Z}$ with $\boldsymbol{H}(\boldsymbol{Z})$ in all equations where it appears, and we optimize over $\boldsymbol{U_H}$ along with $\boldsymbol{W_F}$ and $\boldsymbol{V_G}$ in Eq. (19) and Eq. (20), respectively.

Algorithm 2 The non-linear orthogonal iterations (NOI) algorithm for DPCCA Variant B

```
Input: Data matrices $\boldsymbol{X} \in \mathbb{R}^{D_x \times N}$, $\boldsymbol{Y} \in \mathbb{R}^{D_y \times N}$, $\boldsymbol{Z} \in \mathbb{R}^{D_z \times N}$, time constant $\rho$, learning rate $\eta$.

initialization: Initialize weights $(\boldsymbol{W_F}, \boldsymbol{V_G}, \boldsymbol{U_H})$.
Randomly choose a minibatch $(\boldsymbol{X_{b_0}}, \boldsymbol{Y_{b_0}}, \boldsymbol{Z_{b_0}})$.
Initialize covariances:
$\hat{\boldsymbol{\Sigma}}_{\boldsymbol{FF}} \leftarrow \frac{N-1}{|b_0|}\boldsymbol{F}(\boldsymbol{X_{b_0}})\boldsymbol{F}(\boldsymbol{X_{b_0}})^{\boldsymbol{T}}$
$\hat{\boldsymbol{\Sigma}}_{\boldsymbol{GG}} \leftarrow \frac{N-1}{|b_0|}\boldsymbol{G}(\boldsymbol{Y_{b_0}})\boldsymbol{G}(\boldsymbol{Y_{b_0}})^{\boldsymbol{T}}$
$\hat{\boldsymbol{\Sigma}}_{\boldsymbol{HH}} \leftarrow \frac{N-1}{|b_0|}\boldsymbol{H}(\boldsymbol{Z_{b_0}})\boldsymbol{H}(\boldsymbol{Z_{b_0}})^{\boldsymbol{T}}$
$\hat{\boldsymbol{\Sigma}}_{\boldsymbol{FH}} \leftarrow \frac{N-1}{|b_0|}\boldsymbol{F}(\boldsymbol{X_{b_0}})\boldsymbol{H}(\boldsymbol{Z_{b_0}})^{\boldsymbol{T}}$
$\hat{\boldsymbol{\Sigma}}_{\boldsymbol{GH}} \leftarrow \frac{N-1}{|b_0|}\boldsymbol{G}(\boldsymbol{Y_{b_0}})\boldsymbol{H}(\boldsymbol{Z_{b_0}})^{\boldsymbol{T}}$

  for $t = 1, 2, \ldots, n$ do
  Randomly choose a minibatch $(\boldsymbol{X_{b_t}}, \boldsymbol{Y_{b_t}}, \boldsymbol{Z_{b_t}})$.
  Update covariances:
  $\hat{\boldsymbol{\Sigma}}_{\boldsymbol{FF}} \leftarrow \rho\hat{\boldsymbol{\Sigma}}_{\boldsymbol{FF}} + (1-\rho)\frac{N-1}{|b_t|}\boldsymbol{F}(\boldsymbol{X_{b_t}})\boldsymbol{F}(\boldsymbol{X_{b_t}})^{\boldsymbol{T}}$
  $\hat{\boldsymbol{\Sigma}}_{\boldsymbol{GG}} \leftarrow \rho\hat{\boldsymbol{\Sigma}}_{\boldsymbol{GG}} + (1-\rho)\frac{N-1}{|b_t|}\boldsymbol{G}(\boldsymbol{Y_{b_t}})\boldsymbol{G}(\boldsymbol{Y_{b_t}})^{\boldsymbol{T}}$
  $\hat{\boldsymbol{\Sigma}}_{\boldsymbol{HH}} \leftarrow \rho\hat{\boldsymbol{\Sigma}}_{\boldsymbol{HH}} + (1-\rho)\frac{N-1}{|b_t|}\boldsymbol{H}(\boldsymbol{Z_{b_t}})\boldsymbol{H}(\boldsymbol{Z_{b_t}})^{\boldsymbol{T}}$
  $\hat{\boldsymbol{\Sigma}}_{\boldsymbol{FH}} \leftarrow \rho\hat{\boldsymbol{\Sigma}}_{\boldsymbol{FH}} + (1-\rho)\frac{N-1}{|b_t|}\boldsymbol{F}(\boldsymbol{X_{b_t}})\boldsymbol{H}(\boldsymbol{Z_{b_t}})^{\boldsymbol{T}}$
  $\hat{\boldsymbol{\Sigma}}_{\boldsymbol{GH}} \leftarrow \rho\hat{\boldsymbol{\Sigma}}_{\boldsymbol{GH}} + (1-\rho)\frac{N-1}{|b_t|}\boldsymbol{G}(\boldsymbol{Y_{b_t}})\boldsymbol{H}(\boldsymbol{Z_{b_t}})^{\boldsymbol{T}}$

  Update conditional variables:
  $\boldsymbol{F|H} \leftarrow \boldsymbol{F}(\boldsymbol{X_{b_t}}) - \hat{\boldsymbol{\Sigma}}_{\boldsymbol{FH}}\hat{\boldsymbol{\Sigma}}^{-1}_{\boldsymbol{HH}}\boldsymbol{H}(\boldsymbol{Z_{b_t}})$
  $\boldsymbol{G|H} \leftarrow \boldsymbol{G}(\boldsymbol{Y_{b_t}}) - \hat{\boldsymbol{\Sigma}}_{\boldsymbol{GH}}\hat{\boldsymbol{\Sigma}}^{-1}_{\boldsymbol{HH}}\boldsymbol{H}(\boldsymbol{Z_{b_t}})$
  $\hat{\boldsymbol{\Sigma}}_{\boldsymbol{FF|H}} \leftarrow \hat{\boldsymbol{\Sigma}}_{\boldsymbol{FF}} - \hat{\boldsymbol{\Sigma}}_{\boldsymbol{FH}}\hat{\boldsymbol{\Sigma}}^{-1}_{\boldsymbol{HH}}\hat{\boldsymbol{\Sigma}}^{\boldsymbol{T}}_{\boldsymbol{FH}}$
  $\hat{\boldsymbol{\Sigma}}_{\boldsymbol{GG|H}} \leftarrow \hat{\boldsymbol{\Sigma}}_{\boldsymbol{GG}} - \hat{\boldsymbol{\Sigma}}_{\boldsymbol{GH}}\hat{\boldsymbol{\Sigma}}^{-1}_{\boldsymbol{HH}}\hat{\boldsymbol{\Sigma}}^{\boldsymbol{T}}_{\boldsymbol{GH}}$

  Fix $\widetilde{\boldsymbol{G|H}} = \hat{\boldsymbol{\Sigma}}^{-\frac{1}{2}}_{\boldsymbol{GG|H}}\boldsymbol{G|H}$, and compute $\nabla\boldsymbol{W_F}$, $\nabla\boldsymbol{U_H}$ with respect to:
  $\min_{\boldsymbol{W_F},\boldsymbol{U_H}} \frac{1}{|b_t|}\|\boldsymbol{F|H} - \widetilde{\boldsymbol{G|H}}\|^2_F$
  Update parameters:
  $\boldsymbol{W_F} \leftarrow \boldsymbol{W_F} - \eta\nabla\boldsymbol{W_F}, \boldsymbol{U_H} \leftarrow \boldsymbol{U_H} - \eta\nabla\boldsymbol{U_H}$
  Fix $\widetilde{\boldsymbol{F|H}} = \hat{\boldsymbol{\Sigma}}^{-\frac{1}{2}}_{\boldsymbol{FF|H}}\boldsymbol{F|H}$, and compute $\nabla\boldsymbol{V_G}$, $\nabla\boldsymbol{U_H}$ with respect to:
  $\min_{\boldsymbol{V_G},\boldsymbol{U_H}} \frac{1}{|b_t|}\|\boldsymbol{G|H} - \widetilde{\boldsymbol{F|H}}\|^2_F$
  Update parameters:
  $\boldsymbol{V_G} \leftarrow \boldsymbol{V_G} - \eta\nabla\boldsymbol{V_G}, \boldsymbol{U_H} \leftarrow \boldsymbol{U_H} - \eta\nabla\boldsymbol{U_H}$
  end for
Output: $(\boldsymbol{W_F}, \boldsymbol{V_G}, \boldsymbol{U_H})$
```

5 Tasks and Data

Cross-lingual Image Description Retrieval The cross-lingual image description retrieval task is formulated as follows: taking an image description as a *query* in the source language, the system has to retrieve a set of *relevant descriptions* in the target language which describe the same image. Our evaluation assumes a *single-best* scenario, where only a single target description is relevant for each query. In addition, in our setup, images are not available during inference: retrieval is performed based solely on text queries. This enables a fair comparison between our model and many baseline models that cannot represent images and text in a shared space. Moreover, it allows us to test our model in the realistic setup where images are not available at test time. To avoid the use of images at retrieval time with DPCCA, we perform the retrieval on $\boldsymbol{F}(\boldsymbol{X})$ and $\boldsymbol{G}(\boldsymbol{Y})$, rather than on $\boldsymbol{F}(\boldsymbol{X}|\boldsymbol{Z})$ and $\boldsymbol{G}(\boldsymbol{Y}|\boldsymbol{Z})$ (see §3.2).

We use the Multi30K dataset (Elliott et al., 2016), originated from Flickr30K (Young et al., 2014) that is comprised of Flicker images described with 1-5 English descriptions per image. Multi30K adds German descriptions to a total of 30,014 images: most were written independently of the English descriptions, while some are direct translations. Each image is associated with one English and one German description. We rely on the original Multi30K splits with 29,000, 1,014, and 1,000 triplets for training, validation, and test, respectively.

Multilingual Word Similarity The word similarity task tests the correlation between automatic and human generated word similarity scores. We evaluate with the Multilingual SimLex-999 dataset (Leviant and Reichart, 2015): the 999 English (EN)

	EN-DE	EN-IT	EN-RU
Nouns	4606	4735	4106
Adjectives	405	416	348
Verbs	392	400	227
Adverbs	167	161	142
Prepositions	12	12	9
Total	**5598**	**5740**	**4838**

Table 1: WIW statistics: the number of WIW entries across POS classes in each language pair. The numbers of words per POS class are not summed to the total number of words as other (less frequent) POS tags are also represented.

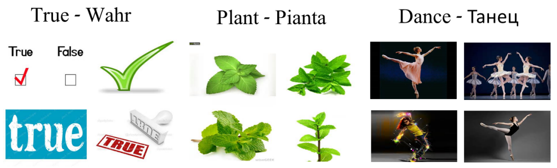


Figure 2: WIW examples from each of the three bilingual lexicons. Note that the designated words can be either abstract (*true*), express an action (*dance*) or be more concrete (*plant*).

word pairs from SimLex-999 (Hill et al., 2015) were translated to German (DE), Italian (IT), and Russian (RU), and similarity scores were crowdsourced from native speakers.

We introduce a new dataset termed *Word-Image-Word* (WIW), which we use to train word-level models for the multilingual word similarity task. WIW contains three bilingual lexicons (EN-DE, EN-IT, EN-RU) with images shared between words in a lexicon entry. Each WIW entry is a triplet: an English word, its translation in DE/IT/RU, and a set of images relevant to the pair.

English words were taken from the January 2017 Wikipedia dump. After removing stop words and punctuation, we extract the 6,000 most frequent words from the cleaned corpus not present in SimLex. DE/IT/RU words were obtained semi-automatically from the EN words using Google Translate. The images are crawled from the Bing search engine using MMFeat[9] (Kiela, 2016) by querying the EN words only. Following the suggestions from the study of Kiela et al. (2016), we save the top 20 images as relevant images.[10]

Table 1 provides a summary of the WIW dataset. The dataset contains both concrete and abstract words, and words of different POS tags.[11] This property has an influence on the image collection: similar to Kiela et al. (2014), we have noticed that images of more concrete concepts are less dispersed (see also examples from Figure 2).

6 Experimental Setup

Data Preprocessing and Embeddings For the sentence-level task, all descriptions were lowercased and tokenized. Each sentence is represented with one vector: the average of its word embeddings. For English, we rely on 500-dimensional English skip-gram word embeddings (Mikolov et al., 2013) trained on the January 2017 Wikipedia dump with bag-of-words contexts (window size of 5). For German we use the deWaC 1.7B corpus (Baroni et al., 2009) to obtain 500-dimensional German embeddings using the same word embedding model. For word similarity, to be directly comparable to previous work, we rely on 300-dim word vectors in EN, DE, IT, and RU from Mrkšić et al. (2017).

Visual features are extracted from the penultimate layer (FC7) of the VGG-19 network (Simonyan and Zisserman, 2015), and compressed to the dimensionality of the textual inputs by a Principal Component Analysis (PCA) step. For the word similarity task, we average the visual vectors across all images of each word pair as done in, e.g., (Vulić et al., 2016), before the PCA step.

Baseline Models We consider a wide variety of multi-view CCA-based baselines. First, we compare against the original (linear) **CCA** model (Hotelling, 1936), and its deep non-linear extension **DCCA** (Andrew et al., 2013). For DCCA: 1) we rely on its improved optimization algorithm from Wang et al. (2015a) which uses a stochastic approach with large minibatches; 2) we compare against the **DCCA_NOI** variant (Wang et al., 2015b) described by Algorithm 1, and another recent DCCA variant with the optimization algorithm based on a stochastic decorrelational loss (Chang et al., 2017) (**DCCA_SDL**); and 3) we also test the DCCA Autoencoder model (**DCCAE**) (Wang et al., 2015a), which offers a trade-off between maximizing the canonical correlation of two sets of variables and finding informative features for their reconstruction.

Another baseline is Generalized CCA (**GCCA**) (Funaki and Nakayama, 2015; Horst, 1961; Rastogi et al., 2015): a linear model which extends CCA to

[9]https://github.com/douwekiela/mmfeat.
[10]Offensive words and images are manually cleaned.
[11]POS tag information is taken from the NLTK toolkit for the English words.

three or more views. Unlike PCCA, GCCA does not condition two variables on the third shared one, but rather seeks to maximize the canonical correlations of all pairs of views. We also compare to Nonparametric CCA (**NCCA**) (Michaeli et al., 2016), and to a probabilistic variant of PCCA (**PPCCA**, Mukuta and Harada (2014)).

Finally, we compare with the two recent models which operate in the setup most similar to ours: 1) Bridge Correlational Networks (**BCN**) (Rajendran et al., 2016); and 2) Image Pivoting (**IMG_PIVOT**) from Gella et al. (2017). For both models, we report results only with the strongest variant based on the findings from the original papers, also verified by additional experimentation in our work.[12]

Hyperparameter Tuning The hyperparameters of the different models are tuned with a grid search over the following values: {2,3,4,5} for number of layers, {*tanh, sigmoid, ReLU*} as the activation functions (we use the same activation function in all the layers of the same network), {64,128,256} for minibatch size, {0.001,0.0001} for learning rate, and {128,256} for L (the size of the output vectors). The dimensions of all mid-layers are set to the input size. We use the Adam optimizer (Kingma and Ba, 2015), with the number of epochs set to 300.

For all participating models, we report test performance of the best hyperparameter on the validation set. For word similarity, following a standard practice (Levy et al., 2015; Vulić et al., 2017) we tune all models on one half of the SimLex data and evaluate on the other half, and vice versa. The reported score is the average of the two halves. Similarity scores for all tasks were computed using the *cosine similarity* measure.

7 Results and Discussion

Cross-lingual Image Description Retrieval We report two standard evaluation metrics: 1) *Recall at 1* (R@1) scores, and 2) the sentence-level *BLEU+1* metric (Lin and Och, 2004), a variant of BLEU which smooths terms for higher-order n-grams, making it more suitable for evaluating short sentences. The scores for the retrieval task with all models are summarized in Table 2.

[12] More details about preprocessing and baselines (including all *links to their code*), are in the the supplementary material. We use original readily available implementations of all baselines whenever this is possible, and our in-house implementations for baselines for which no code is provided by the original authors.

	R@1		**BLEU+1**	
Model	EN→DE	DE→EN	EN→DE	DE→EN
DPCCA (Variant A)	0.795	0.779	0.836	0.827
DPCCA (Variant B)	0.809	**0.794**	0.848	**0.839**
DPCCA(B)+DCCA_NOI (concat)	**0.826**	0.791	**0.863**	0.837
DCCA_NOI (Wang et al., 2015b)	0.812	0.788	0.849	0.830
DCCA_SDL (Chang et al., 2017)	0.507	0.487	0.552	0.533
DCCA (Wang et al., 2015a)	0.619	0.621	0.664	0.673
DCCAE (Wang et al., 2015a)	0.564	0.542	0.607	0.598
IMG_PIVOT (Gella et al., 2017)	0.772	0.763	0.789	0.781
BCN (Rajendran et al., 2016)	0.579	0.570	0.628	0.629
PCCA (Rao, 1969)	<u>0.785</u>	<u>0.737</u>	<u>0.825</u>	<u>0.787</u>
CCA (Hotelling, 1936)	0.764	0.704	0.803	0.754
GCCA (Funaki and Nakayama, 2015)	0.699	0.690	0.742	0.743
NCCA (Michaeli et al., 2016)	0.157	0.165	0.205	0.213
PPCCA (Mukuta and Harada, 2014)	0.035	0.050	0.063	0.086

Table 2: Results on cross-lingual image description retrieval. NN-based models are above the dashed line. Best overall results are in bold. Best results with non-deep models are underlined.

The results clearly demonstrate the superiority of DPCCA (with a slight advantage to the more complex Variant B) and of the concatenation of their representation with that of the DCCA_NOI (strongest) baseline. Furthermore, the non-deep, linear PCCA achieves strong results: it outscores all non-deep models, as well as all deep models except from DCCA_NOI, IMG_PIVOT in one case, and its deep version: DPCCA. This emphasizes our contribution in proposing PCCA for multilingual processing with images as a cross-lingual bridge.

The results suggest that: 1) the inclusion of visual information in the training process helps the retrieval task even without such information during inference. DPCCA outscores all DCCA variants (either alone or through a concatenation with the DCCA_NOI representation), and PCCA outscores the original two-view CCA model; and 2) deep, non-linear architectures are useful: our DPCCA outperforms the linear PCCA model.

We also note clear improvements over the two recent models which also rely on visual information: IMG_PIVOT and BCN. The gain over IMG_PIVOT is observed despite the fact that IMG_PIVOT is a more complex multi-modal model which relies on RNNs, and is tailored to sentence-level tasks. Finally, the scores from Table 2 suggest that improved performance can be achieved by an ensemble model, that is, a simple concatenation of DPCCA (B) and DCCA_NOI.

Multilingual Word Similarity The results, presented as standard Spearman's rank correlation scores, are summarized in Table 3: we present fine-grained results over different POS classes for EN and DE, and compare them to the results from

Model	English-German					
	EN-Adj	EN-Verbs	EN-Nouns	DE-Adj	DE-Verbs	DE-Nouns
DPCCA (Variant A)	**0.640**	0.311	0.369	0.430	**0.321**	**0.404**
DPCCA (Variant B)	0.626	**0.316**	**0.382**	**0.462**	0.319	0.399
DCCA_NOI (Wang et al., 2015b)	0.611	0.308	0.361	0.441	0.297	0.398
DCCA (Wang et al., 2015a)	0.618	0.261	0.327	0.404	0.290	0.362
PCCA (Rao, 1969)	0.614	0.296	0.340	0.305	0.143	0.340
CCA (Hotelling, 1936)	0.557	0.297	0.321	0.284	0.157	0.346
GCCA (Funaki and Nakayama, 2015)	0.636	0.280	0.378	0.446	0.277	0.398
INIT_EMB	0.582	0.160	0.306	0.407	0.164	0.285

Table 3: Results on EN and DE SimLex-999 (POS-based evaluation). All scores are Spearman's rank correlations. INIT_EMB refers to initial pre-trained monolingual word embeddings (see §6).

Model	EN-DE WIW		EN-IT WIW		EN-RU WIW	
	EN	DE	EN	IT	EN	RU
DPCCA (A)	0.398	**0.400**	0.412	**0.429**	0.404	**0.407**
DPCCA (B)	**0.405**	**0.400**	0.413	0.427	**0.413**	0.402
PCCA	0.374	0.301	0.370	0.386	0.374	0.374
DCCA_NOI	0.390	0.398	0.413	0.422	0.407	0.398
GCCA	0.395	0.386	**0.414**	0.407	0.412	0.396
INIT_EMB	0.321	0.278	0.321	0.361	0.321	0.385

Table 4: Results (Spearman rank correlation) of our models and the strongest baselines on Multilingual SimLex-999 (all data).

a selection of strongest baselines. Further, Table 4 presents results on all SimLex word pairs. The POS class result patterns for EN-IT and EN-RU are very similar to the patterns in Table 3 and are provided in the supplementary material. First, the results over the initial monolingual embeddings before training (INIT_EMB) clearly indicate that multilingual information is beneficial for the word similarity task. We observe improvements with all models (the only exception being extremely low-scoring PPCCA and NCCA, not shown). Moreover, by additionally grounding concepts from two languages in the visual modality it is possible to further boost word similarity scores. This result is in line with prior work in monolingual settings (Chrupała et al., 2015; Kiela and Bottou, 2014; Lazaridou et al., 2015), which have shown to profit from multi-modal features.

The results on the POS classes represented in SimLex-999 (nouns, verbs, adjectives, Table 3) form our main finding: conditioning the multilingual representations on a shared image leads to improvements in verb and adjective representations. While for nouns one of the DPCCA variants is the best performing model for both languages, the gaps from the best performing baselines are much smaller. This is interesting since, e.g., verbs are more abstract than nouns (Hartmann and Søgaard, 2017; Hill et al., 2014). Considering the fact that SimLex-999 consists of 666 noun pairs, 222 verb pairs and 111 adjective pairs, this is the reason that the gains of DPCCA over the strongest baselines across the entire evaluation set are more modest (Table 4). We note again that the same patterns presented in Table 3 for EN-DE – more prominent verb and adjective gains and a smaller gain on nouns – also hold for EN-IT and EN-RU (see the supplementary material).

8 Conclusion and Future Work

We addressed the problem of utilizing images as a bridge between languages to learn improved bilingual text representations. Our main contribution is two-fold. First, we proposed to use the Partial CCA (PCCA) method. In addition, we proposed a stochastic optimization algorithm for the deep version of PCCA that overcomes the challenges posed by the covariance estimation required by the method. Our experiments reveal the effectiveness of these methods for both sentence-level and word-level tasks. Crucially, our proposed solution does not require access to images at inference/test time, in line with the realistic scenario where images that describe sentential queries are not readily available.

In future work we plan to improve our methods by exploiting the internal structure of images and sentences as well as by effectively integrating signals from more than two languages.

Illustrative Language Understanding: Large-Scale Visual Grounding with Image Search

Jamie Ryan Kiros* **William Chan*** **Geoffrey E. Hinton**

Google Brain Toronto

Abstract

We introduce Picturebook, a large-scale lookup operation to ground language via 'snapshots' of our physical world accessed through image search. For each word in a vocabulary, we extract the top-k images from Google image search and feed the images through a convolutional network to extract a word embedding. We introduce a multimodal gating function to fuse our Picturebook embeddings with other word representations. We also introduce Inverse Picturebook, a mechanism to map a Picturebook embedding back into words. We experiment and report results across a wide range of tasks: word similarity, natural language inference, semantic relatedness, sentiment/topic classification, image-sentence ranking and machine translation. We also show that gate activations corresponding to Picturebook embeddings are highly correlated to human judgments of concreteness ratings.

1 Introduction

Constructing grounded representations of natural language is a promising step towards achieving human-like language learning. In recent years, a large amount of research has focused on integrating vision and language to obtain visually grounded word and sentence representations. One source of grounding, which has been utilized in existing work, is image search engines. Search engines allow us to obtain correspondences between language and images that are far less restricted than existing multimodal datasets which typically have restricted vocabularies. While true natural language understanding may require fully embodied cognition, search engines allow us to get a form of quasi-grounding from high-coverage 'snapshots' of our physical world provided by the interaction of millions of users.

One place to incorporate grounding is in the lookup table that maps tokens to vectors. The dominant approach to learning distributed word representations is through indexing a learned matrix. While immensely successful, this lookup operation is typically learned through co-occurrence objectives or a task-dependent reward signal. A very different way to obtain word embeddings is to aggregate features obtained by using the word as a query for an image search engine. This involves retrieving the top-k images from a search engine, running those through a convolutional network and aggregating the results. These word embeddings are grounded via the retrieved images. While several authors have considered this approach, it has been largely limited to a few thousand queries and only a small number of tasks.

In this paper we introduce Picturebook embeddings produced by image search using words as queries. Picturebook embeddings are obtained through a convolutional network trained with a semantic ranking objective on a proprietary image dataset with over 100+ million images (Wang et al., 2014). Using Google image search, a Picturebook embedding for a word is obtained by concatenating the k-feature vectors of our convolutional network on the top-k retrieved search results. The main contributions of our work are as follows:

- We obtain Picturebook embeddings for the 2.2 million words that occur in the Glove vocabulary (Pennington et al., 2014) [1], allowing each word to have a Glove embedding and a parallel grounded word representation. This collection of word representations that we visually

*Both authors contributed equally to this work.

[1]Common Crawl, 840B tokens

ground via image search is 2-3 orders of magnitude larger than prior work.

- We introduce a multimodal gating mechanism to selectively choose between Glove and Picturebook embeddings in a task-dependent way. We apply our approach to over a dozen datasets and several different tasks: word similarity, sentence relatedness, natural language inference, topic/sentiment classification, image sentence ranking and Machine Translation (MT).
- We introduce Inverse Picturebook to perform the inverse lookup operation. Given a Picturebook embedding, we find the closest words which would generate the embedding. This is useful for generative modelling tasks.
- We perform an extensive analysis of our gating mechanism, showing that the gate activations for Picturebook embeddings are highly correlated with human judgments of concreteness. We also show that Picturebook gate activations are negatively correlated with image dispersion (Kiela et al., 2014), indicating that our model selectively chooses between word embeddings based on their abstraction level.
- We highlight the importance of the convolutional network used to extract embeddings. In particular, networks trained with semantic labels result in better embeddings than those trained with visual labels, even when evaluating similarity on concrete words.

2 Related Work

The use of image search for obtaining word representations is not new. Table 1 illustrates existing methods that utilize image search and the tasks considered in their work. There has also been other work using other image sources such as ImageNet (Kiela and Bottou, 2014; Collell and Moens, 2016) over the WordNet synset vocabulary, and using Flickr photos and captions (Joulin et al., 2016). Our approach differs from the above methods in three main ways: a) we obtain search-grounded representations for over 2 million words as opposed to a few thousand, b) we apply our representations to a higher diversity of tasks than previously considered, and c) we introduce a multimodal gating mechanism that allows for a more flexible integration of features than mere concatenation.

Our work also relates to existing multimodal models combining different representations of the data (Hill and Korhonen, 2014). Various work has also fused text-based representations with image-based representations (Bruni et al., 2014; Lazaridou et al., 2015; Chrupala et al., 2015; Mao et al., 2016; Silberer et al., 2017; Kiela et al., 2017; Collell et al., 2017; Zablocki et al., 2018) and representations derived from a knowledge-graph (Thoma et al., 2017). More recently, gating-based approaches have been developed for fusing traditional word embeddings with visual representations. Arevalo et al. (2017) introduce a gating mechanism inspired by the LSTM while Kiela et al. (2018) describe an asymmetric gate that allows one modality to 'attend' to the other. The work that most closely matches ours is that of Wang et al. (2018) who also consider fusing Glove embeddings with visual features. However, their analysis is restricted to word similarity tasks and they require text-to-image regression to obtain visual embeddings for unseen words, due to the use of ImageNet. The use of image search allows us to obtain visual embeddings for a virtually unlimited vocabulary without needing a mapping function.

3 Picturebook Embeddings

Our Picturebook embeddings ground language using the 'snapshots' returned by an image search engine. Given a word (or phrase), we image search for the top-k images and extract the images. We then pass each image through a CNN trained with a semantic ranking objective to extract its embedding. Our Picturebook embeddings reflect the search rankings by concatenating the individual embeddings in the order of the search results. We can perform all of these operations offline to construct a matrix E_p representing the Picturebook embeddings over a vocabulary.

3.1 Inducing Picturebook Embeddings

The convolutional network used to obtain Picturebook embeddings is based off of Wang et al. (2014). Let p_i, p_i^+, p_i^- denote a triplet of query, positive and negative images, respectively. We define the following hinge loss for a given triplet as follows:

$$l(p_i, p_i^+, p_i^-) = \max\{0, g + D(f(p_i), f(p_i^+)) - D(f(p_i), f(p_i^-))\} \tag{1}$$

where $f(p_i)$ represents the embedding of image p_i, $D(\cdot,\cdot)$ is the Euclidean distance and g is a margin (gap) hyperparameter. Suppose we have available pairwise relevance scores $r_{i,j} = r(p_i, p_j)$ indicating the similarity of images p_i and p_j. The objective function that is optimized is given by:

$$\begin{aligned}&\min \sum_i \xi_i + \lambda \|W\|_2^2 \\ &s.t. : l(p_i, p_i^+, p_i^-) \le \xi_i \\ &\quad \forall p_i, p_i^+, p_i^- \text{ such that } r(p_i, p_i^+) > r(p_i, p_i^-)\end{aligned} \tag{2}$$

where ξ_i are slack variables and W is a vector of the network's model parameters. The model is trained end-to-end using a proprietary dataset with 100+ million images. We refer the reader to Wang et al. (2014) for additional details of training, including the specifics of the architecture used.

After the model is trained, we can use the convolutional network as a feature extractor for images by computing an embedding vector $f(p)$ for an image p. Suppose we would like to obtain a Picturebook embedding for a given word w. We first perform an image search with query w to obtain a ranked list of images $p_1^w, \dots, p_k^w$. The Picturebook embedding for a word w is then represented as:

$$e_p(w) = [f(p_1^w); f(p_2^w); \dots; f(p_k^w)] \tag{3}$$

namely, the concatenation of the feature vectors in ranked order. In our model, each embedding results in a 64-dimensional vector with the final Picturebook embedding being $64 * k$ dimensions. Most of our experiments use $k = 10$ images resulting in a word embedding size of 640. To obtain the full collection of embeddings, we run the full Glove vocabulary (2.2M words) through image search to obtain a corresponding Picturebook embedding to each word in the Glove vocabulary.

3.2 Visual vs Semantic Similarity

The training procedure is heavily influenced by the choice of similarity function $r_{i,j}$. We consider two types of image similarity: visual and semantic. As an example, an image of a blue car would have high visual similarity to other blue cars but would have higher semantic similarity to cars of the same make, independent of color. In our experiments we consider two types of Picturebook embedding: one trained through optimizing for visual similarity and another for semantic similarity. As we will show in our experiments, the semantic Picturebook embeddings result in representations that are more useful for natural language processing tasks than the visual embeddings.

3.3 Multimodal Fusion Gating

Picturebook embeddings on their own are likely to be useful for representing concrete words but it is not clear whether they will be of benefit for abstract words. Consequently, we would like to fuse our Picturebook embeddings with other sources of information, for example Glove embeddings (Pennington et al., 2014) or randomly initialized embeddings that will be trained. Let $e_g = e_g(w)$ be our other embedding (i.e., Glove) for a word w and $e_p = e_p(w)$ be our Picturebook embedding. We fuse our embeddings using a multimodal gating mechanism:

$$g = \sigma(e_g, e_p) \tag{4}$$

$$e = g \odot \phi(e_g) + (1 - g) \odot \psi(e_p) \tag{5}$$

where σ is a 1 hidden layer DNN with ReLU activations and $\mathrm{sigmoid}$ outputs, ϕ and ψ are 1 hidden layer DNNs with ReLU activations and $\tanh$ outputs. The gating DNN σ allows the model to learn how visual a word is as a function of its input e_p and e_g. Similar gating mechanisms can be found in LSTMs (Hochreiter and Schmidhuber, 1997) and other multimodal models (Arevalo et al., 2017; Wang et al., 2018; Kiela et al., 2018). On some experiments we found it beneficial to include a skip connection from the hidden layer of σ. We chose this form of fusion over other approaches, such as CCA variants and metric learning methods, to allow for easier interpretability and analysis. We leave comparison of alternative fusion strategies for future work.

3.4 Contextual Gating

The gating described above is non-contextual, in the sense that each embedding computes a gate value independent of the context the words occur in. In some cases it may be beneficial to use contextual gates that are aware of the sentence that words appear in to decide how to weight Glove and Picturebook embeddings. For contextual gates, we use the same approach as above except we replace the controller $\sigma(e_g, e_p)$ with inputs that have been fed through a bidirectional-LSTM, e.g. $\sigma(\text{BiLSTM}(e_g),\text{BiLSTM}(e_p))$. We experiment with contextual gating for all experiments that use a bidirectional-LSTM encoder.

3.5 Inverse Picturebook

Picturebook embeddings can be seen as a form of implicit image search: given a word (or phrase), image search the word query and concatenate the embeddings of the images produced by a CNN. Up until now, we have only discussed scenarios where we have a word and we want to perform this implicit search operation. In generative modelling problems (i.e., MT), we want to perform the opposite operation. Given a Picturebook embedding, we want to find the closest word or phrase aligned to the representation. For example, given the word 'bicycle' in English and its Picturebook embedding, we want to find the closest French word that would generate this representation (i.e., 'vélo'). We want to perform this inverse image search operation given its Picturebook embedding.

We introduce a differentiable mechanism which allows us to align words across source and target languages in the Picturebook embedding domain. Let h be our internal representation of our model (i.e., seq2seq decoder state), and e_i be the i-th word embedding from our Picturebook embedding matrix E_p:

$$p(y_i|h) = \frac{\exp(\langle h, e_i \rangle)}{\sum_j \exp(\langle h, e_j \rangle)} \tag{6}$$

Given a representation h, Equation 6 simply finds the most similar word in the embedding space. This can be easily implemented by setting the output softmax matrix as the transpose of the Picturebook embedding matrix E_p. In practice, we find adding additional parameters helps with learning:

$$p(y_i|h) = \frac{\exp(\langle h, e_i + e'_i \rangle + b_i)}{\sum_j \exp(\langle h, e_j + e'_j \rangle + b_j)} \tag{7}$$

where e'_i is a trainable weight vector per word and b_i is a trainable bias per word. A similar technique to tie the softmax matrix as the transpose of the embedding matrix can be found in language modelling (Press and Wolf, 2017; Inan et al., 2017).

4 Experiments

To evaluate the effectiveness of our embeddings, we perform both quantitative and qualitative evaluation across a wide range of natural language processing tasks. Hyperparameter details of each experiment are included in the appendix. Since the use of Picturebook embeddings adds extra parameters to our models, we include a baseline for each experiment (either based on Glove or learned embeddings) that we extensively tune. In most experiments, we end up with baselines that are stronger than what has previously been reported.

4.1 Nearest neighbours

In order to get a sense of the representations our model learns, we first compute nearest neighbour results of several words, shown in Table 2. These results can be interpreted as follows: the words that appear as neighbours are those which have semantically similar images to that of the query. Often this captures visual similarity as well. Some words capture multimodality, such as 'deep' referring both to deep sea as well as to AI. Searching for cities returns cities which have visually similar characteristics. Words like 'sun' also return the corresponding word in different languages, such as 'Sol' in Spanish and 'Soleil' in French. Finally, it's worth highlighting that the most frequent association of a word may not be what is represented in image search results. For example, the word 'is' returns words related to terrorists and ISIS and 'it' returns words related to scary and clowns due to the 2017 film of the same name. We also report nearest neighbour examples across languages in Appendix A.1.

4.2 Word similarity

Our first quantitative experiment aims to determine how well Picturebook embeddings capture word similarity. We use the SimLex-999 dataset (Hill et al., 2015) and report results across 9 categories: all (the whole evaluation), adjectives, nouns, verbs, concreteness quartiles and the hardest 333 pairs. For the concreteness quartiles, the first quartile corresponds to the most abstract words, while the last corresponds to the most concrete words. The hardest pairs are those for which similarity is difficult to distinguish from relatedness. This is an interesting category since image-based word embeddings are perhaps less likely to confuse similarity with relatedness than distributional-based methods. For Glove, scores

Picturebook (10)	37.3	11.7	48.2	17.3	14.4	27.5	46.2	60.7	28.8

Table 3: SimLex-999 results (Spearman's ρ). Best results overall are bolded. Best results per section are underlined. Bracketed numbers signify the number of images used. Some rows are copied across sections for ease of reading.

are computed via cosine similarity. For computing a score between 2 word pairs with Picturebook, we set $s(w^{(1)}, w^{(2)}) = -min_{i,j}\ d(e_i^{(1)}, e_j^{(2)})$. [2] That is, the score is minus the smallest cosine distance between all pairs of images of the two words. Note that this reduces to negative cosine distance when using only 1 image per word. We also report results combining Glove and Picturebook by summing their two independent similarity scores. By default, we use 10 images for each embedding using the semantic convolutional network.

Table 3 displays our results, from which several observations can be made. First, we observe that combining Glove and Picturebook leads to improved similarity across most categories. For adjectives and the most abstract category, Glove performs significantly better, while for the most concrete category Picturebook is significantly better. This result confirms that Glove and Picturebook capture very different properties of words. Next we observe that the performance of Picturebook gets progressively better across each concreteness quartile rating, with a 20 point improvement over Glove for the most concrete category. For the hardest subset of words, Picturebook performs slightly better than Glove while Glove performs better across all pairs. We also compare to a convolutional network trained with visual similarity. We observe a performance difference between our visual and semantic embeddings: on all categories except verbs, the semantic embeddings outperform visual ones, even on the most concrete categories. This indicates the importance of the type of similarity used for training the model. Finally we note that adding more images nearly consistently improves similarity scores across categories. Kiela et al. (2016) showed that after 10-20 images, performance tends to saturate. All subsequent experiments use 10 images with semantic Picturebook.

4.3 Sentential Inference and Relatedness

We next consider experiments on 3 pairwise prediction datasets: SNLI (Bowman et al., 2015), MultiNLI (Williams et al., 2017) and SICK (Marelli et al., 2014). The first two are natural language inference tasks and the third is a sentence semantic relatedness task. We explore the use of two types of sentential encoders: Bag-of-Words (BoW) and BiLSTM-Max (Conneau et al., 2017a).

[2] We found scoring all pairs of images to outperform scoring only the corresponding equally ranked image.

Model	SNLI		MultiNLI		SICK Relatedness		
	dev	test	dev-mat	dev-mis	test-p	test-s	test-mse
Glove (bow)	85.2	84.2	70.5	69.9	86.8	79.8	25.2
Picturebook (bow)	84.0	83.8	67.9	67.1	85.8	79.3	27.0
Glove + Picturebook (bow)	86.2	85.2	71.3	70.9	**87.2**	**80.9**	**24.4**
BiLSTM-Max (Conneau et al., 2017a)	85.0	84.5					
Glove	86.8	86.3	74.1	**74.5**			
Picturebook	85.2	85.1	70.7	70.3			
Glove + Picturebook	86.7	86.1	73.7	73.7			
Glove + Picturebook + Contextual Gating	**86.9**	**86.5**	**74.2**	74.4			

Table 4: Classification accuracies are reported for SNLI and MulitNLI. For SICK we report Pearson, Spearman and MSE. Higher is better for all metrics except MSE. Best results overall per column are bolded. Best results per section are underlined.

Three sets of features are used: Glove only, Picturebook only and Glove + Picturebook. For the latter, we use multimodal gating for all encoders and contextual gating in the BiLSTM-Max model. For SICK, we follow previous work and report average results across 5 runs (Tai et al., 2015). Due to the small size of the dataset, we only experiment with BoW on SICK. The full details of hyperparameters are discussed in Appendix B.

Table 4 displays our results. For BoW models, adding Picturebook embeddings to Glove results in significant gains across all three tasks. For BiLSTM-Max, our contextual gating sets a new state-of-the-art on SNLI sentence encoding methods (methods without interaction layers), outperforming the recently proposed methods of Im and Cho (2017); Shen et al. (2018). It is worth noting the effect that different encoders have when using our embeddings. While non-contextual gating is sufficient to improve bag-of-words methods, with BiLSTM-Max it slightly hurts performance over the Glove baseline. Adding contextual gating was necessary to improve over the Glove baseline on SNLI. Finally we note the strength of our own Glove baseline over the reported results of Conneau et al. (2017a), from which we improve on their accuracy from 85.0 to 86.8 on the development set. [3]

4.4 Sentiment and Topic Classification

Our next set of experiments aims to determine how well Picturebook embeddings do on tasks that are primarily non-visual, such as topic and sentiment classification. We experiment with 7 datasets provided by Zhang et al. (2015) and compare bag-of-words models against n-gram baselines provided by the authors as well as fastText (Joulin et al., 2017). Hyperparameter details are reported in Appendix B.

Our experimental results are provided in Table 5. Perhaps unsurprisingly, adding Picturebook to Glove matches or only slightly improves on 5 out of 7 tasks and obtains a lower result on AG News and Yahoo. Our results show that Picturebook embeddings, while minimally aiding in performance, can perform reasonably well on their own - outperforming the n-gram baselines of (Zhang et al., 2015) on 5 out of 7 tasks and the unigram fastText baseline on all 7 tasks. This result shows that our embeddings are able to work as a general text embedding, though they typically lag behind Glove. We note that the best performing methods on these tasks are based on convolutional neural networks (Conneau et al., 2017b).

4.5 Image-Sentence Ranking

We next consider experiments that map images and sentences into a common vector space for retrieval. Here, we utilize VSE++ (Faghri et al., 2017) as our base model and evaluate on the COCO dataset (Lin et al., 2014). VSE++ improves over the original CNN-LSTM embedding method of Kiros et al. (2015a) by using hard negatives instead of summing over contrastive examples. We re-implement their model with 2 modifications: 1) we replace the unidirectional LSTM encoder with a BiLSTM-Max sentence encoder and 2) we use Inception-V3 (Szegedy et al., 2016) as our CNN instead of ResNet 152 (He et al., 2016). As in previous work, we report the mean Recall@K (R@K) and the median rank over 1000 images and 5000 sentences. Full details of the hyperparameters are in Appendix B.

Table 6 displays our results on this task.

[3]All reported results on SNLI are available at `https://nlp.stanford.edu/projects/snli/`

Model	AG	DBP	Yelp P.	Yelp F.	Yah. A.	Amz. F.	Amz. P.
BoW (Zhang et al., 2015)	88.8	96.6	92.2	58.0	68.9	54.6	90.4
ngrams (Zhang et al., 2015)	92.0	98.6	95.6	56.3	68.5	54.3	92.0
ngrams TFIDF (Zhang et al., 2015)	92.4	**98.7**	95.4	54.8	68.5	52.4	91.5
fastText (Joulin et al., 2017)	91.5	98.1	93.8	60.4	72.0	55.8	91.2
fastText-bigram (Joulin et al., 2017)	92.5	98.6	**95.7**	**63.9**	72.3	**60.2**	**94.6**
Glove (bow)	**94.0**	98.6	94.4	61.7	**74.1**	58.5	93.2
Picturebook (bow)	92.8	98.5	94.4	61.6	73.3	57.8	92.9
Glove + Picturebook (bow)	93.9	98.6	94.5	61.9	73.8	58.7	93.2

Table 5: Test accuracy [%] on topic and sentiment classification datasets. Best results per dataset are bolded, best results per section are underlined. We compare directly against other bag of ngram baselines.

	Image Annotation				Image Search			
Model	R@1	R@5	R@10	Med *r*	R@1	R@5	R@10	Med *r*
VSE++ (Faghri et al., 2017)	**64.6**		95.7	1	52.0		92.0	1
Glove	**64.6**	88.9	95.5	1	53.7	86.5	94.4	1
Picturebook	62.4	90.2	95.3	1	54.2	86.4	94.3	1
Glove + Picturebook	61.8	89.2	95.0	1	54.1	86.7	**94.7**	1
Glove + Picturebook + Contextual Gating	63.4	**90.3**	**96.5**	1	**55.2**	**87.2**	94.4	1

Table 6: COCO test-set results for image-sentence retrieval experiments. Our models use VSE++. R@K is Recall@K (high is good). Med *r* is the median rank (low is good).

Our Glove baseline was able to match or outperform the reported results in Faghri et al. (2017) with the exception of Recall@10 for image annotation, where it performs slightly worse. Glove+Picturebook improves over the Glove baseline for image search but falls short on image annotation. However, using contextual gating results in improvements over the baseline on all metrics except R@1 for image annotation. Our reported results have been recently outperformed by Gu et al. (2018); Huang et al. (2018b); Lee et al. (2018), which are more sophisticated methods that incorporate generative modelling, reinforcement learning and attention.

4.6 Machine Translation

We experiment with the Multi30k (Elliott et al., 2016, 2017) dataset for MT. We compare our Picturebook models with other text-only non-ensembled models on the Flickr Test2016, Flickr Test2017 and MSCOCO test sets from Caglayan et al. (2017), the winner of the WMT 17 Multimodal Machine Translation competition (Elliott et al., 2017). We use the standard seq2seq (Sutskever et al., 2015) with content-based attention (Bahdanau et al., 2015) model and we describe our hyperparmeters in Appendix B.

Table 7 summarizes our English → German results and Table 8 summarizes our English → French results. We find our models to perform better in BLEU than METEOR relatively compared to (Caglayan et al., 2017). We believe this is due to the fact we did not use Byte Pair Encoding (BPE) (Sennrich et al., 2016), and METEOR captures word stemming (Denkowski and Lavie, 2014). This is also highlighted where our French models perform better than our German models relatively, due to the compounding nature of German words. Since seq2seq MT models are typically trained without Glove embeddings, we also did not use Glove embeddings for this task, but rather we combine randomly initialized learnable embeddings with the fixed Picturebook embeddings. We find the gating mechanism not to help much with the MT task since the trainable embeddings are free to change their norm magnitudes. We did not experiment with regularizing the norm of the embeddings. On the English → German tasks, we find our Picturebook model to perform on average 0.8 BLEU or 0.7 METEOR over our baseline. On the German task, compared to the previously best published results (Caglayan et al., 2017) we do better in BLEU but slightly worse in METEOR. We suspect this is due to the fact that we did not use BPE. On the English → French task, the Picturebook models do on average 1.2 BLEU better or 1.0 METEOR over our baseline.

We also report results for the IWSLT 2014 German-English task (Cettolo et al., 2014) in Table 9. Compared to our baseline, we report a gain of 0.3 and 1.1 BLEU for German → English and English → German respectively. We

Model	Test2016		Test2017		MSCOCO	
	BLEU	METEOR	BLEU	METEOR	BLEU	METEOR
BPE (Caglayan et al., 2017)	38.1	**57.3**	30.8	**51.6**	26.4	**46.8**
Baseline	38.9	56.5	32.6	50.7	26.8	45.4
Picturebook	39.6	56.9	31.8	50.1	27.7	45.8
Picturebook + Inverse Picturebook	**40.2**	57.2	32.3	50.7	27.8	46.3
Picturebook + Inverse Picturebook + Gating	40.0	**57.3**	**33.0**	51.1	**27.9**	46.5

Table 7: Machine Translation results on the Multi30k English → German task. We note that our models do not use BPE, and we perform better in BLEU relative to METEOR.

Model	Test2016		Test2017		MSCOCO	
	BLEU	METEOR	BLEU	METEOR	BLEU	METEOR
BPE (Caglayan et al., 2017)	52.5	69.6	50.4	67.5	41.2	61.3
Baseline	60.7	74.1	52.3	67.4	42.8	60.6
Picturebook	61.0	74.2	52.4	67.5	43.1	61.0
Picturebook + Inverse Picturebook	61.8	75.0	52.6	67.7	42.8	61.2
Picturebook + Inverse Picturebook + Gating	**62.1**	**75.2**	**53.6**	**68.4**	**43.8**	**61.6**

Table 8: Machine Translation results on the Multi30k English → French task.

report new state-of-the-art results for the English → German task at 25.4 BLEU, while our German → English model achieves 29.6 BLEU which is slightly behind the recently proposed Neural Phrase-based Machine Translation (NPMT) model at 29.9 (Huang et al., 2018a). We note that the NPMT is not a seq2seq model and can be augmented with our Picturebook embeddings. We also note that our models may not be directly comparable to previously published seq2seq models from (Wiseman and Rush, 2016; Bahdanau et al., 2017) since we used a deeper encoder and decoder.

4.7 Limitations

We explored the use of Picturebook for larger machine translation tasks, including the popular WMT14 benchmarks. For these tasks, we found that models that incorporate Picturebook led to faster convergence. However, we were not able to improve upon BLEU scores from equivalent models that do not use Picturebook. This indicates that while our embeddings are useful for smaller MT experiments, further research is needed on how to best incorporate grounded representations in larger translation tasks.

4.8 Gate Analysis

In this section we perform an extensive analysis of the gating mechanism for models trained across datasets used in our experiments. In our first experiment, we aim to determine how well gate activations correlate to a) human judgments of concreteness and b) image dispersion (Kiela et al., 2014). For concreteness ratings, we use the dataset of Brysbaert et al. (2013) which provides ratings for 40,000 English lemmas. Image dispersion is the average distance between all pairs of images returned from a search query. It was shown in Kiela et al. (2014) that abstract words tend to have higher dispersion ratings, due to having much higher variety in the types of images returned from a query. On the other hand, low dispersion ratings were more associated with concrete words. For each word, we compute the mean gate activation value for Picturebook embeddings. [4] For concreteness ratings, we take the intersection of words that have ratings with the dataset vocabulary. We then compute the Spearman correlation of mean gate activations with a) concreteness ratings and b) image dispersion scores.

Table 10 illustrates the result of this analysis. We observe that gates have high correlations with concreteness ratings and strong negative correlations with image dispersion scores. Moreover, this result holds true across all datasets, even those that are not inherently visual. These results provide evidence that our gating mechanism actively prefers Glove embeddings for abstract words and Picturebook embeddings for concrete words. Appendix A contains examples of words that most strongly activate Glove and Picturebook gates.

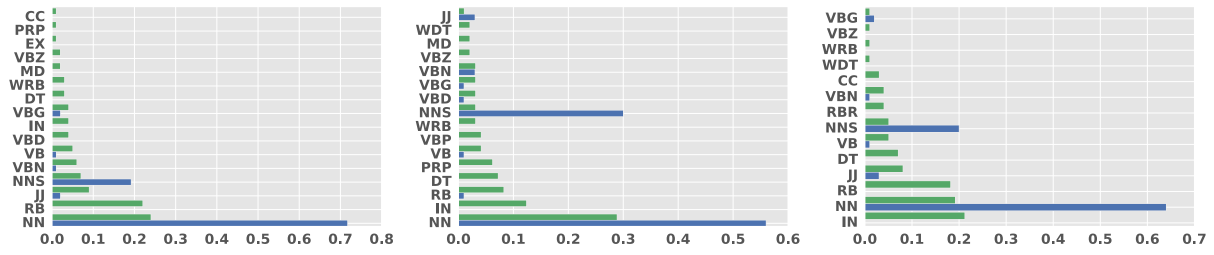
[4]We only consider non-contextualized gates.

Model	DE → EN BLEU	EN → DE BLEU
MIXER (Ranzato et al., 2016)	21.8	
Beam Search Optimization (Wiseman and Rush, 2016)	25.5	
Actor-Critic + Log Likelihood (Bahdanau et al., 2017)	28.5	
Neural Phrase-based Machine Translation (Huang et al., 2018a)	**29.9**	25.1
Baseline	29.3	24.3
Picturebook	29.6	**25.4**

Table 9: Machine Translation results on the IWSLT 2014 German-English task.

Rank	SNLI		MultiNLI		COCO		AG-News		DBpedia		Yelp		Amazon	
	ccorr	disp	ccorr	disp	ccorr	disp	ccorr	disp	ccorr	disp	ccorr	disp	ccorr	disp
top-1%	73	-41	39	-27	53	-22	60	-16	56	-30	47	-28	32	-17
top-10%	54	-39	48	-34	34	-23	52	-24	54	-32	49	-26	50	-30
all	35	-30	30	-27	21	-16	36	-17	39	-30	24	-20	33	-31

Table 10: Correlations (rounded, x100) of mean Picturebook gate activations to human judgements of concreteness ratings (ccorr) and image dispersion (disp) within the specified most frequent words.



(a) SNLI (b) MultiNLI (c) AG-News

Figure 1: POS analysis. Top bar for each tag is Glove, bottom is Picturebook. Tags are sorted by Glove frequencies. Results taken over the top 100 mean activation values within the 10K most frequent words.

Finally we analyze the parts-of-speech (POS) of the highest activated words. These results are shown in Figure 1. The highest scoring Picturebook words are almost all singular and plural nouns (NN / NNS). We also observe tags which are exclusively Glove oriented, namely adverbs (RB), prepositions (IN) and determiners (DT).

5 Conclusion

Traditionally, word representations have been built on co-occurrences of neighbouring words; and such representations only make use of the statistics of the text distribution. Picturebook embeddings offer an alternative approach to constructing word representations grounded in image search engines. In this work we demonstrated that Picturebook complements traditional embeddings on a wide variety of tasks. Through the use of multimodal gating, our models lead to interpretable weightings of abstract vs concrete words. In future work, we would like to explore other aspects of search engines for language grounding as well as the effect these embeddings may have on learning generic sentence representations (Kiros et al., 2015b; Hill et al., 2016; Conneau et al., 2017a; Logeswaran and Lee, 2018). Recently, contextualized word representations have shown promising improvements when combined with existing embeddings (Melamud et al., 2016; Peters et al., 2017; McCann et al., 2017; Peters et al., 2018). We expect that integrating Picturebook with these embeddings to lead to further performance improvements as well.

What Action Causes This? Towards Naive Physical Action-Effect Prediction

Abstract

Despite recent advances in knowledge representation, automated reasoning, and machine learning, artificial agents still lack the ability to understand basic action-effect relations regarding the physical world, for example, the action of cutting a cucumber most likely leads to the state where the cucumber is broken apart into smaller pieces. If artificial agents (e.g., robots) ever become our partners in joint tasks, it is critical to empower them with such action-effect understanding so that they can reason about the state of the world and plan for actions. Towards this goal, this paper introduces a new task on naive physical action-effect prediction, which addresses the relations between concrete actions (expressed in the form of verb-noun pairs) and their effects on the state of the physical world as depicted by images. We collected a dataset for this task and developed an approach that harnesses web image data through distant supervision to facilitate learning for action-effect prediction. Our empirical results have shown that web data can be used to complement a small number of seed examples (e.g., three examples for each action) for model learning. This opens up possibilities for agents to learn physical action-effect relations for tasks at hand through communication with humans with a few examples.

1 Introduction

Causation in the physical world has long been a central discussion to philosophers who study casual reasoning and explanation (Ducasse, 1926; Gopnik et al., 2007), to mathematicians or computer scientists who apply computational approaches to model cause-effect prediction (Pearl et al., 2009), and to domain experts (e.g., medical doctors) who attempt to understand the underlying cause-effect relations (e.g., disease and symptoms) for their particular inquires. Apart from this wide range of topics, this paper investigates a specific kind of causation, the very basic causal relations between a concrete action (expressed in the form of a verb-noun pair such as "cut-cucumber") and the change of the physical state caused by this action. We call such relations *naive* physical action-effect relations.

For example, given an image as shown in Figure 1, we would have no problem predicting what actions can cause the state of the world depicted in the image, e.g., slicing an apple will likely lead to the state. On the other hand, given a statement "slice an apple", it would not be hard for us to imagine what state change may happen to the apple. We can make such action-effect prediction because we have developed an understanding of this kind of basic action-effect relations at a very young age (Baillargeon, 2004). What happens to machines? Will artificial agents be able to make the same kind of predictions? The answer is not yet.

Despite tremendous progress in knowledge representation, automated reasoning, and machine learning, artificial agents still lack the understanding of naive causal relations regarding the physical world. This is one of the bottlenecks in machine intelligence. If artificial agents ever become capable of working with humans as partners, they will need to have this kind of physical action-effect understanding to help them reason, learn, and perform actions.

To address this problem, this paper introduces a new task on naive physical action-effect prediction. This task supports both *cause predic-*

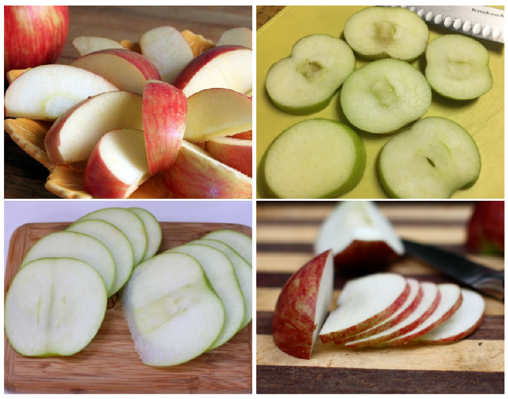

Figure 1: Images showing the effects of "slice an apple".

tion: given an image which describes a state of the world, identify the most likely action (in the form of a verb-noun pair, from a set of candidates) that can result in that state; and *effect prediction*: given an action in the form of a verb-noun pair, identify images (from a set of candidates) that depicts the most likely effects on the state of the world caused by that action. Note that there could be different ways to formulate this problem, for example, both causes and effects are in the form of language or in the form of images/videos. Here we intentionally frame the action as a language expression (i.e., a verb-noun pair) and the effect as depicted in an image in order to make a connection between language and perception. This connection is important for physical agents that not only can perceive and act, but also can communicate with humans in language.

As a first step, we collected a dataset of 140 verb-noun pairs. Each verb-noun pair is annotated with possible effects described in language and depicted in images (where language descriptions and image descriptions are collected separately). We have developed an approach that applies distant supervision to harness web data for bootstrapping action-effect prediction models. Our empirical results have shown that, using a simple bootstrapping strategy, our approach can combine the noisy web data with a small number of seed examples to improve action-effect prediction. In addition, for a new verb-noun pair, our approach can infer its effect descriptions and predict action-effect relations only based on 3 image examples.

The contributions of this paper are three folds. First, it introduces a new task on physical action-effect prediction, a first step towards an understanding of causal relations between physical actions and the state of the physical world. Such ability is central to robots which not only perceive from the environment, but also act to the environment through planning. To our knowledge, there is no prior work that attempts to connect actions (in language) and effects (in images) in this nature. Second, our approach harnesses the large amount of image data available on the web with minimum supervision. It has shown that physical action-effect models can be learned through a combination of a few annotated examples and a large amount of un-annotated web data. This opens up the possibility for humans to teach robots new tasks through language communication with a small number of examples. Third, we have created a dataset for this task, which is available to the community [1]. Our bootstrapping approach can serve as a baseline for future work on this topic.

In the following sections, we first describe our data collection effort, then introduce the bootstrapping approach for action-effect prediction, and finally present results from our experiments.

2 Related Work

In the NLP community, there has been extensive work that models cause-effect relations from text (Cole et al., 2005; Do et al., 2011; Yang and Mao, 2014). Most of these previous studies address high-level causal relations between events, for example, "the collapse of the housing bubble" causes the effect of "stock prices to fall" (Sharp et al., 2016). They do not concern the kind of naive physical action-effect relations in this paper. There is also an increasing amount of effort on capturing commonsense knowledge, for example, through knowledge base population. Except for few (Yatskar et al., 2016) that acquires knowledge from images, most of the previous effort apply information extraction techniques to extract facts from a large amount of web data (Dredze et al., 2010; Rajani and Mooney, 2016). DBPedia (Lehmann et al., 2015), Freebase (Bollacker et al., 2008), and YAGO (Suchanek et al., 2007) knowledge bases contain millions of facts about the world such as people and places. However, they do not contain basic cause-effect knowledge related to concrete actions and their effects to the world. Recent work started looking into phys-

[1]This dataset is available at `http://lair.cse.msu.edu/lair/projects/actioneffect.html`

ical causality of action verbs (Gao et al., 2016) and other physical properties of verbs (Forbes and Choi, 2017; Zellers and Choi, 2017; Chao et al., 2015). But they do not address action-effect prediction.

The idea of modeling object physical state change has also been studied in the computer vision community (Fire and Zhu, 2016). Computational models have been developed to infer object states from observations and to further predict future state changes (Zhou and Berg, 2016; Wu et al., 2016, 2017). The action recognition task can be treated as detecting the transformation on object states (Fathi and Rehg, 2013; Yang et al., 2013; Wang et al., 2016). However these previous works only focus on the visual presentation of motion effects. Recent years have seen an increasing amount of work integrating language and vision, for example, visual question answering (Antol et al., 2015; Fukui et al., 2016; Lu et al., 2016), image description generation (Xu et al., 2015; Vinyals et al., 2015), and grounding language to perception (Yang et al., 2016; Roy, 2005; Tellex et al., 2011; Misra et al., 2017). While many approaches require a large amount of training data, recent works have developed zero/few shot learning for language and vision (Mukherjee and Hospedales, 2016; Xu et al., 2016, 2017a,b; Tsai and Salakhutdinov, 2017). Different from these previous works, this paper introduces a new task that connects language with vision for physical action-effect prediction.

In the robotics community, an important task is to enable robots to follow human natural language instructions. Previous works (She et al., 2014; Misra et al., 2015; She and Chai, 2016, 2017) explicitly model verb semantics as desired goal states and thus linking natural language commands with underlying planning systems for action planning and execution. However, these studies were carried out either in a simulated world or in a carefully curated simple environment within the limitation of the robot's manipulation system. And they only focus on a very limited set of domain specific actions which often only involve the change of locations. In this work, we study a set of open-domain physical actions and a variety of effects perceived from the environment (i.e., from images).

3 Action-Effect Data Collection

We collected a dataset to support the investigation on physical action-effect prediction. This dataset consists of actions expressed in the form of verb-noun pairs, effects of actions described in language, and effects of actions depicted in images. Note that, as we would like to have a wide range of possible effects, language data and image data are collected separately.

Actions (verb-noun pairs). We selected 40 nouns that represent everyday life objects, most of them are from the COCO dataset (Lin et al., 2014), with a combination of food, kitchen ware, furniture, indoor objects, and outdoor objects. We also identified top 3000 most frequently used verbs from Google Syntactic N-gram dataset (Goldberg and Orwant, 2013) (Verbargs set). And we extracted top frequent verb-noun pairs containing a verb from the top 3000 verbs and a noun in the 40 nouns which hold a *dobj* (i.e., direct object) dependency relation. This resulted in 6573 candidate verb-noun pairs. As changes to an object can occur at various dimensions (e.g., size, color, location, attachment, etc.), we manually selected a subset of verb-noun pairs based on the following criteria: (1) changes to the objects are visible (as opposed to other types such as temperature change, etc.); and (2) changes reflect one particular dimension as opposed to multiple dimensions (as entailed by high-level actions such as "cook a meal", which correspond to multiple dimensions of change and can be further decomposed into basic actions). As a result, we created a subset of 140 verb-noun pairs (containing 62 unique verbs and 39 unique nouns) for our investigation.

Effects Described in Language. The basic knowledge about physical action-effect is so fundamental and shared among humans. It is often presupposed in our communication and not explicitly stated. Thus, it is difficult to extract naive action-effect relations from the existing textual data (e.g., web). This kind of knowledge is also not readily available in commonsense knowledge bases such as ConceptNet (Speer and Havasi, 2012). To overcome this problem, we applied crowd-sourcing (Amazon Mechanical Turk) and collected a dataset of language descriptions describing effects for each of the 140 verb-noun pairs. The workers were shown a verb-noun pair, and were asked to use their own words and imag-

Action	Effect Text

stain shirt	There is a visible mark on the shirt.

Table 1: Example action and effect text from our collected data.

inations to describe what changes might occur to the corresponding object as a result of the action. Each verb-noun pair was annotated by 10 different annotators, which has led to a total of 1400 effect descriptions. Table 1 shows some examples of collected effect descriptions. These effect language descriptions allow us to derive *seed effect knowledge* in a symbolic form.

Effects Depicted in Images. For each action, three students searched the web and collected a set of images depicting potential effects. Specifically, given a verb-noun pair, each of the three students was asked to collect at least 5 positive images and 5 negative images. Positive images are those deemed to capture the resulting world state of the action. And negative images are those deemed to capture some state of the related object (i.e., the nouns in the verb-noun pairs), but are not the resulting state of the corresponding action. Then, each student was also asked to provide positive or negative labels for the images collected by the other two students. As a result each image has three positive/negative labels. We only keep the images whose labels are agreed by all three students. In total, the dataset contains 4163 images. On average, each action has 15 positive images, and 15 negative images. Figure 2 shows several examples of positive images and negative images of the action *peel-orange*. The positive images show an orange in a *peeled* state, while the negative images show oranges in different states (orange as a whole, orange slices, orange juice, etc.).

4 Action-Effect Prediction

Action-effect prediction is to connect actions (as causes) to the effects of actions. Specifically, given an image which depicts a state of the world, our task is to predict what concrete actions could cause the state of the world. This task is different from traditional action recognition as the underlying actions (e.g., human body posture/movement) are not captured by the images. In this regard, it is also different from image description generation.

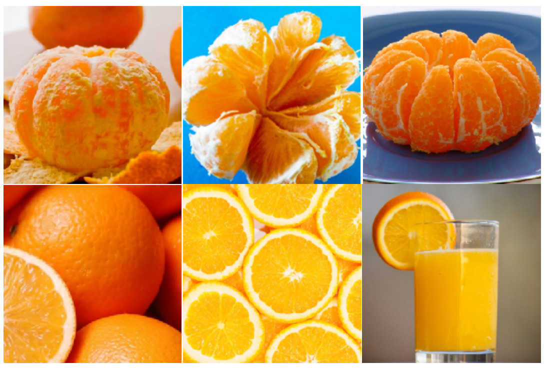

Figure 2: Positive images (top row) and negative images (bottom row) of the action *peel-orange*.

We frame the problem as a few-shot learning task, by only providing a few human-labelled images for each action at the training stage. Given the very limited training data, we attempt to make use of web-search images. Web search has been adopted by previous computer vision studies to acquire training data (Fergus et al., 2005; Kennedy et al., 2006; Berg et al., 2010; Otani et al., 2016). Compared with human annotations, web-search comes at a much lower cost, but with a trade-off of poor data quality. To address this issue, we apply a bootstrapping approach that aims to handle data with noisy labels.

The first question is what search terms should be used for image search. There are two options. The first option is to directly use the action terms (i.e., verb-noun pairs) to search images and the downloaded web images are referred to as *action web images*. As desired images should be depicting effects of an action, terms describing effects become a natural choice. The second option is to use the key phrases extracted from language effect descriptions to search the web. The downloaded web images are referred to as *effect web images*.

4.1 Extracting Effect Phrases from Language Data

We first apply chunking (shallow parsing) using the SENNA software (Collobert et al., 2011) to break an effect description into phrases such as noun phrases (NP), verb phrases (VP), prepositional phrases (PP), adjectives (ADJP), adverbs (ADVP), etc. After some examination, we found that most of the effect descriptions follow simple syntactic patterns. For a *verb-noun* pair, around 80% of its effect descriptions start with the same noun as the subject. In an effect description, the

Example patterns	Example *Effect Phrases* (bold) extracted from effect descriptions
VP with a verb $\in$ {be, become, turn, get}	The ship **is destroyed**.
VP + PRT	The wall is **knocked off**.
VP + ADVP	The door **swings forward**.
ADJP	The window would begin to get **clean**.
PP + NP	The eggs are divided **into whites and yolks**.

Table 2: Example patterns that are used to extract effect phrases (bold) from sample sentences.

change of state associated with the noun is mainly captured by some key phrases. For example, an adjective phrase usually describes a physical state; verbs like *be*, *become*, *turn*, *get* often indicate a description of change of the state. Based on these observations, we defined a set of patterns to identify phrases that describe physical states of an object. In total 1997 *effect phrases* were extracted from the language data. Table 2 shows some example patterns and example effect phrases that are extracted.

4.2 Downloading Web Images

The purpose of querying search engine is to retrieve images of objects in certain effect states. To form image searching keywords, the effect phrases are concatenated with the corresponding noun phrases, for example, "apple + into thin pieces". The image search results are downloaded and used as supplementary training data for the action-effect prediction models. However, web images can be noisy. First of all, not all of the automatically extracted effect phrases describe visible state of objects. Even if a phrase represents visible object states, the retrieved results may not be relevant. Figure 3 shows some example image search results using queries describing the object name "book", and describing the object state such as "book is on fire", "book is set aflame". These state phrases were used by human annotators to describe the effect of the action "burn a book". We can see that the images returned from the query "book is set aflame" are not depicting the physical effect state of "burn a book". Therefore, it's important to identify images with relevant effect states to train the model. To do that, we applied a bootstrapping method to handle the noisy web images as described in Section 4.3. For an action (i.e., a verb-noun pair), it has multiple corresponding effect phrases, and all of their image search results are treated as training images for this action.

Since both the human annotated image data (Section 3) and the web-search image data were obtained from Internet search engines, they may

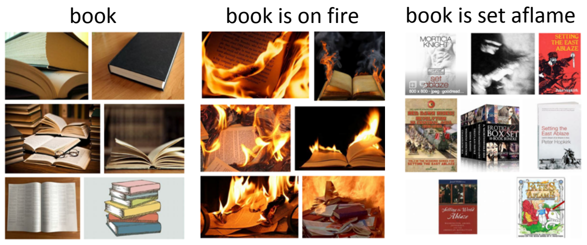

Figure 3: Examples of image search results.

have duplicates. As part of the annotated images are used as test data to evaluate the models, it is important to remove duplicates. We designed a simple method to remove any images from the web-search image set that has a duplicate in the human annotated set. We first embed all images into feature vectors using pre-trained CNNs. For each web-search image, we calculate its cosine similarity score with each of the annotated images. And we simply remove the web images that have a score larger than 0.95.

4.3 Models

We formulate the action-effect prediction task as a multi-class classification problem. Given an image, the model will output a probability distribution $\mathbf{q}$ over the candidate actions (i.e., verb-noun pairs) that can potentially cause the effect depicted in the image.

Specifically for model training, we are given a set of human annotated seeding image data $\{\mathbf{x}, \mathbf{t}\}$ and a set of web-search image data $\{\mathbf{x}', \mathbf{t}'\}$. Here $\mathbf{x}$ and $\mathbf{x}'$ are the images (depicting effect states), and $\mathbf{t}$ and $\mathbf{t}'$ are their classification targets (i.e., actions that cause the effects). Each target vector is the observed image label, $\mathbf{t} \in \{0, 1\}^C$, $\sum_i t_i = 1$, and C is the number of classes (i.e., actions). The human annotated targets $\mathbf{t}$ can be trusted. But the targets of web-search images $\mathbf{t}'$ are usually very noisy. Bootstrapping method has been shown to be an effective method to handle noisy labelled data (Rosenberg et al., 2005; Whitney and Sarkar, 2012; Reed et al., 2014). The objective of the

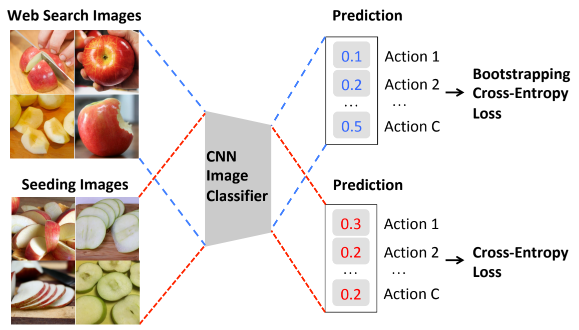

Figure 4: Architecture for the action-effect prediction model with bootstrapping.

cross-entropy loss is defined as follows:

$$\mathcal{L}(\mathbf{t}, \mathbf{q}) = \sum_{i=1}^{C} t_i \log(q_i), \quad (1)$$

where $\mathbf{q}$ are the predicted class probabilities, and C is the number of classes. To handle the noisy labels in the web-search data $\{\mathbf{x}', \mathbf{t}'\}$, we adopt a bootstrapping objective following Reed's work (Reed et al., 2014):

$$\mathcal{L}(\mathbf{t}', \mathbf{q}) = \sum_{i=1}^{C} [\beta t'_i + (1-\beta) z_i] \log(q_i), \quad (2)$$

where $\beta \in [0, 1]$ is a model parameter to be assigned, $\mathbf{z}$ is the one-hot vector of the prediction $\mathbf{q}$, $z_i = 1$, if $i = \text{argmax } q_k, k = 1 \ldots C$.

The model architecture is shown in Figure 4. After each training batch, the current model will be used to make predictions $\mathbf{q}$ on images in the next batch. And the target probabilities is calculated as a linear combination of the current predictions $\mathbf{q}$ and the observed noisy labels $\mathbf{t}'$. The idea behind this bootstrapping strategy is to ensure the consistency of the model's predictions. By first initializing the model on the seeding image data, the bootstrapping approach allows the model to trust more on the web images that are consistent with the seeding data.

4.4 Evaluation

We evaluate the models on the action-effect prediction task. Given an image that illustrates a state of the world, the goal is to predict what action could cause that state. Given an action in the form of a verb-noun pair, the goal is to identify images that depict the most likely effects on the state of the world caused by that action.

For each of the 140 verb-noun pairs, we use 10% of the human annotated images as the seeding image data for training, and use 30% for development and the rest 60% for test. The seeding image data set contains 408 images. On average, each verb-noun pair has less than 3 seeding images (including positive images and negative images). The development set contains 1252 images. The test set contains 2503 images. The model parameters were selected based on the performance on the development set.

As a given image may not be relevant to any effect, we add a background class to refer to images where effects are not caused by any action in the space of actions. So the total of classes for our evaluation model is 141. For each verb-noun pair and each of the effect phrases, around 40 images were downloaded from the Bing image search engine and used as candidate training examples. In total we have 6653 action web images and 59575 effect web images.

Methods for Comparison

All the methods compared are based on one neural network structure. We use ResNet (He et al., 2016) pre-trained on ImageNet (Deng et al., 2009) to extract image features. The extracted image features are fed to a fully connected layer with rectified linear units and then to a softmax layer to make predictions. More specifically, we compare the following configurations:

(1) *BS+Seed+Act+Eff*. The bootstrapping approach trained on the seeding images, the action web images, and the effect web images. During the training stage, the model was first trained on the seeding image data using vanilla cross-entropy objective (Equation 1). Then it was further trained on a combination of the seeding image data and web-search data using the bootstrapping objective (Equation 2). In the experiments we set $\beta = 0.3$.

(2) *BS+Seed+Act*. The bootstrapping approach trained in the same fashion as (1). The only difference is that this method does not use the effect web images.

(3) *Seed+Act+Eff*. A baseline method trained on a combination of the seeding images, the web action images, and the web effect images, using the vanilla cross-entropy objective.

(4) *Seed+Act*. A baseline method trained on a combination of the seeding images and the action web images, using the vanilla cross-entropy objective.

	Top Action Predictions	Top Effect Descriptions		Top Action Predictions	Top Effect Descriptions
	bake potato	potato crispy		wrap book	book is ripped
	peel potato	potato is crushed		**tear book**	paper become creased
	boil potato	eggs get beaten		fold paper	book into smaller pieces
