(5) *Seed*. A baseline method that was only trained on the seeding image data, using the vanilla cross-entropy objective.

Evaluation Results

We apply the trained classification model to all of the test images. Based on the matrix of prediction scores, we can evaluate action-effect prediction from two angles: (1) given an action class, rank all the candidate images; (2) given an image, rank all the candidate action classes. Table 3 and 4 show the results for these two angels respectively. We report both mean average precision (MAP) and top prediction accuracy.

Overall, *BS+Seed+Act+Eff* gives the best performance. By comparing the bootstrap approach with baseline approaches (i.e., *BS+Seed+Act+Eff* vs. *Seed+Act+Eff*, and *BS+Seed+Act* vs. *Seed+Act*), the bootstrapping approaches clearly outperforms their counterparts, demonstrating its ability in handling noisy web data. Comparing *BS+Seed+Act+Eff* with *BS+Seed+Act*, we can see that *BS+Seed+Act+Eff* performs better. This indicates the use of effect descriptions can bring more relevant images to train better models for action-effect prediction.

In Table 4, the poor performance of *Seed+Act+Eff* and *Seed+Act* shows that it is risky to fully rely on the noisy web search results. These two methods had trouble in distinguishing the background class from the rest.

We further trained another multi-class classifier with web effect images, using their corresponding effect phrases as class labels. Given a test image, we apply this new classifier to predict the effect descriptions of this image. Figure 5 shows some example images, their predicted actions based on our bootstrapping approach and their predicted effect phrases based on the new classifier. These examples also demonstrate another advantage of incorporating seed effect knowledge from language data: it provides state descriptions that can be used to better explain the perceived state. Such explanation can be crucial in human-agent communication for action planning and reasoning.

5 Generalizing Effect Knowledge to New Verb-Noun Pairs

In real applications, it is very likely that we do not have the effect knowledge (i.e., language effect descriptions) for every verb-noun pair. And annotat-

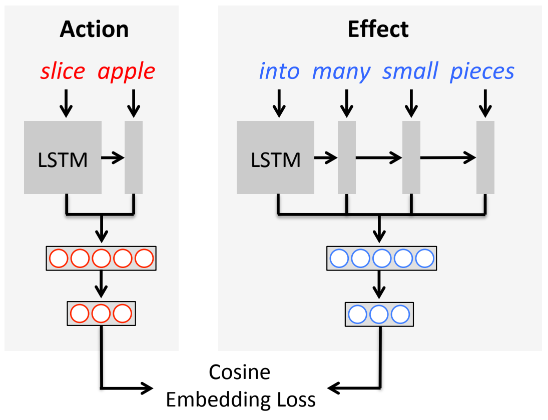

Figure 6: Architecture of the action-effect embedding model.

ing effect knowledge using language (as shown in Section 3) can be very expensive. In this section, we describe how to potentially generalize seed effect knowledge to new verb-noun pairs through an embedding model.

5.1 Action-Effect Embedding Model

The structure of our model is shown in Figure 6. It is composed of two sub-networks: one for verb-noun pairs (i.e., *action*) and the other one for effect phrases (i.e, *effect*). The *action* or *effect* is fed into an LSTM encoder and then to two fully-connected layers. The output is an action embedding $\mathbf{v}_c$ and effect embedding $\mathbf{v}_e$. The networks are trained by minimizing the following cosine embedding loss function:

$$\mathcal{L}(\mathbf{v}_c, \mathbf{v}_e) = \begin{cases} 1 - \mathrm{s}(\mathbf{v}_c, \mathbf{v}_e), & \text{if } (c, e) \in T \\ \max(0, \mathrm{s}(\mathbf{v_c}, \mathbf{v_e})), & \text{if } (c, e) \notin T \end{cases}$$

$\mathrm{s}(\cdot, \cdot)$ is the cosine similarity between vectors. T is a collection of action-effect pairs. Suppose c is an input for *action* and e is an input for *effect*, this loss function will learn an action and effect semantic space that maximizes the similarities between c and e if they have an action-effect relation (i.e., $(c, e) \in T$). During training, the negative action-effect pairs (i.e., $(c, e) \notin T$) are randomly sampled from data. In the experiments, the negative sampling ratio is set to 25. That is, for each positive action-effect pair, 25 negative pairs are created through random sampling.

At the inference step, given an unseen verb-noun pair, we embed it into the action and effect semantic space. Its embedding vector will be used to calculate similarities with all the embedding vectors of the candidate effect phrases.

5.2 Evaluation

We divided the 140 verb-noun pairs into 70% training set (98 verb-noun pairs), 10% development set (14) and 20% test set (28). For the action-effect embedding model, we use pre-trained GloVe word embeddings (Pennington et al., 2014) as input to the LSTM. The embedding model was trained using the language effect data corresponding to the training verb-noun pairs, and then it was applied to predict effect phrases for the unseen verb-noun pairs in the test set. For each unseen verb-noun pair, we collected its top five predicted effect phrases. Each predicted effect phrase was then used as query keywords to download web effect images. This set of web images are referred to as *pEff* and will be used in training the action-effect prediction model.

For each of the 28 test (i.e., new) verb-noun pairs, we use the same ratio 10% (about 3 examples) of the human annotated images as the seeding images, which were combined with downloaded web images to train the prediction model. The remaining 30% and 60% are used as the development set, and the test set. We compare the following different configurations:

(1) *BS+Seed+Act+pEff*. The bootstrapping approach trained on the seeding images, the action web images, and the web images downloaded using the predicted effect phrases.

(2) *BS+Seed+Act+Eff*. The bootstrapping approach trained on the seeding images, the action web images, and the effect web images (downloaded using ground-truth effect phrases).

(3) *BS+Seed+Act*. The bootstrapping approach trained on the seeding images and the action web

Action Text	Predicted Effect Text

ignite paper	paper is being charred , paper is being burned, paper is set, paper is being destroyed, paper is lit
mash potato	potato into chunks, potato into sandwiches, potato into slices, potato is chewed, potato into smaller pieces

Table 7: Example predicted effect phrases for new verb-noun pairs. Unseen verbs and nouns are shown in bold.

images.

(4) *Seed*. A baseline only trained on the seeding images.

Table 5 and 6 show the results for the action-effect prediction task for unseen verb-noun pairs. From the results we can see that *BS+Seed+Act+pEff* achieves close performance compared with *BS+Seed+Act+Eff*, which uses human annotated effect phrases. Although in most cases, *BS+Seed+Act+pEff* outperforms the baseline, which seems to point to the possibility that semantic embedding space can be employed to extend effect knowledge to new verb-noun pairs. However, the current results are not conclusive partly due to the small testing set. More in-depth evaluation is needed in the future.

Table 7 shows top predicted effect phrases for several new verb-noun pairs. After analyzing the action-effect prediction results we notice that generalizing the effect knowledge to a verb-noun pair that contains an unseen verb tends to be more difficult than generalizing to a verb-noun pair that contains an unseen noun. Among the 28 test verb-noun pairs, 12 of them contain unseen verbs and known nouns, 7 of them contain unseen nouns and known verbs. For the task of ranking images given an action, the mean average precision is 0.447 for the unseen verb cases and 0.584 for the unseen noun cases. Although not conclusive, this might indicate that, verbs tend to capture more information about the effect states of the world than nouns.

6 Discussion and Conclusion

When robots operate in the physical world, they not only need to perceive the world, but also need to act to the world. They need to understand the current state, to map their goals to the world state, and to plan for actions that can lead to the goals. All of these point to the importance of the ability to understand causal relations between actions and the state of the world. To address this issue, this paper introduces a new task on action-effect prediction.

Particularly, we focus on modeling the connection between an action (a verb-noun pair) and its effect as illustrated in an image and treat natural language effect descriptions as side knowledge to help acquiring web image data and bootstrap training. Our current model is very simple and performance is yet to be improved. We plan to apply more advanced approaches in the future, for example, attention models that jointly capture actions, image states, and effect descriptions. We also plan to incorporate action-effect prediction to human-robot collaboration, for example, to bridge the gap of commonsense knowledge about the physical world between humans and robots.

This paper presents an initial investigation on action-effect prediction. There are many challenges and unknowns, from problem formulation to knowledge representation; from learning and inference algorithms to methods and metrics for evaluations. Nevertheless, we hope this work can motivate more research in this area, enabling physical action-effect reasoning, towards agents which can perceive, act, and communicate with humans in the physical world.

Abstract

Target-oriented sentiment classification aims at classifying sentiment polarities over individual opinion targets in a sentence. RNN with attention seems a good fit for the characteristics of this task, and indeed it achieves the state-of-the-art performance. After re-examining the drawbacks of attention mechanism and the obstacles that block CNN to perform well in this classification task, we propose a new model to overcome these issues. Instead of attention, our model employs a CNN layer to extract salient features from the transformed word representations originated from a bi-directional RNN layer. Between the two layers, we propose a component to generate target-specific representations of words in the sentence, meanwhile incorporate a mechanism for preserving the original contextual information from the RNN layer. Experiments show that our model achieves a new state-of-the-art performance on a few benchmarks.[1]

1 Introduction

Target-oriented (also mentioned as "target-level" or "aspect-level" in some works) sentiment classification aims to determine sentiment polarities over "opinion targets" that explicitly appear in the sentences (Liu, 2012). For example, in the sentence *"I am pleased with the fast **log on**, and the long **battery life**"*, the user mentions two targets "***log on***" and "***better life***", and expresses positive sentiments over them. The task is usually formulated as predicting a sentiment category for a (target, sentence) pair.

Recurrent Neural Networks (RNNs) with attention mechanism, firstly proposed in machine translation (Bahdanau et al., 2014), is the most commonly-used technique for this task. For example, Wang et al. (2016); Tang et al. (2016b); Yang et al. (2017); Liu and Zhang (2017); Ma et al. (2017) and Chen et al. (2017) employ attention to measure the semantic relatedness between each context word and the target, and then use the induced attention scores to aggregate contextual features for prediction. In these works, the attention weight based combination of word-level features for classification may introduce noise and downgrade the prediction accuracy. For example, in "*This **dish** is my favorite and I always get it and never get tired of it.*", these approaches tend to involve irrelevant words such as "never" and "tired" when they highlight the opinion modifier "favorite". To some extent, this drawback is rooted in the attention mechanism, as also observed in machine translation (Luong et al., 2015) and image captioning (Xu et al., 2015).

Another observation is that the sentiment of a target is usually determined by key phrases such as "is my favorite". By this token, Convolutional Neural Networks (CNNs)—whose capability for extracting the informative n-gram features (also called "active local features") as sentence representations has been verified in (Kim, 2014; Johnson and Zhang, 2015)— should be a suitable model for this classification problem. However, CNN likely fails in cases where a sentence expresses different sentiments over multiple targets, such as *"great **food** but the **service** was dreadful!"*. One reason is that CNN cannot fully explore the target information as done by RNN-based meth-

*The work was done when Xin Li was an intern at Tencent AI Lab. This project is substantially supported by a grant from the Research Grant Council of the Hong Kong Special Administrative Region, China (Project Code: 14203414).

[1]Our code is open-source and available at https://github.com/lixin4ever/TNet

ods (Tang et al., 2016a).[2] Moreover, it is hard for vanilla CNN to differentiate opinion words of multiple targets. Precisely, multiple active local features holding different sentiments (e.g., "great food" and "service was dreadful") may be captured for a single target, thus it will hinder the prediction.

We propose a new architecture, named Target-Specific **T**ransformation **Net**works (TNet), to solve the above issues in the task of target sentiment classification. TNet firstly encodes the context information into word embeddings and generates the contextualized word representations with LSTMs. To integrate the target information into the word representations, TNet introduces a novel Target-Specific Transformation (TST) component for generating the target-specific word representations. Contrary to the previous attention-based approaches which apply the same target representation to determine the attention scores of individual context words, TST firstly generates different representations of the target conditioned on individual context words, then it consolidates each context word with its tailor-made target representation to obtain the transformed word representation. Considering the context word *"long"* and the target "*battery life*" in the above example, TST firstly measures the associations between "long" and individual target words. Then it uses the association scores to generate the target representation conditioned on "long". After that, TST transforms the representation of "long" into its target-specific version with the new target representation. Note that "long" could also indicate a negative sentiment (say for "startup time"), and the above TST is able to differentiate them.

As the context information carried by the representations from the LSTM layer will be lost after the non-linear TST, we design a context-preserving mechanism to contextualize the generated target-specific word representations. Such mechanism also allows deep transformation structure to learn abstract features[3]. To help the CNN feature extractor locate sentiment indicators more accurately, we adopt a proximity strategy to scale the input of convolutional layer with positional relevance between a word and the target.

[2]One method could be concatenating the target representation with each word representation, but the effect as shown in (Wang et al., 2016) is limited.

[3]Abstract features usually refer to the features ultimately useful for the task (Bengio et al., 2013; LeCun et al., 2015).

In summary, our contributions are as follows:

• TNet adapts CNN to handle target-level sentiment classification, and its performance dominates the state-of-the-art models on benchmark datasets.

• A novel Target-Specific Transformation component is proposed to better integrate target information into the word representations.

• A context-preserving mechanism is designed to forward the context information into a deep transformation architecture, thus, the model can learn more abstract contextualized word features from deeper networks.

2 Model Description

Given a target-sentence pair $(\mathbf{w}^\tau, \mathbf{w})$, where $\mathbf{w}^\tau = \{w_1^\tau, w_2^\tau, ..., w_m^\tau\}$ is a sub-sequence of $\mathbf{w} = \{w_1, w_2, ..., w_n\}$, and the corresponding word embeddings $\mathbf{x}^\tau = \{x_1^\tau, x_2^\tau, ..., x_m^\tau\}$ and $\mathbf{x} = \{x_1, x_2, ..., x_n\}$, the aim of target sentiment classification is to predict the sentiment polarity $y \in \{P, N, O\}$ of the sentence $\mathbf{w}$ over the target $\mathbf{w}^\tau$, where P, N and O denote "positive", "negative" and "neutral" sentiments respectively.

The architecture of the proposed Target-Specific Transformation Networks (TNet) is shown in Fig. 1. The bottom layer is a BiLSTM which transforms the input $\mathbf{x} = \{x_1, x_2, ..., x_n\} \in \mathbb{R}^{n\times \dim_w}$ into the contextualized word representations $\mathbf{h}^{(0)} = \{h_1^{(0)}, h_2^{(0)}, ..., h_n^{(0)}\} \in \mathbb{R}^{n\times 2\dim_h}$ (i.e. hidden states of BiLSTM), where $\dim_w$ and $\dim_h$ denote the dimensions of the word embeddings and the hidden representations respectively. The middle part, the core part of our TNet, consists of L Context-Preserving Transformation (CPT) layers. The CPT layer incorporates the target information into the word representations via a novel Target-Specific Transformation (TST) component. CPT also contains a context-preserving mechanism, resembling identity mapping (He et al., 2016a,b) and highway connection (Srivastava et al., 2015a,b), allows preserving the context information and learning more abstract word-level features using a deep network. The top most part is a position-aware convolutional layer which first encodes positional relevance between a word and a target, and then extracts informative features for classification.

2.1 Bi-directional LSTM Layer

As observed in Lai et al. (2015), combining contextual information with word embeddings is an

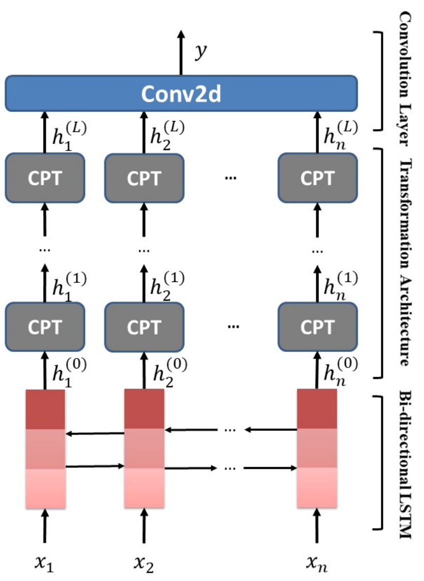

Figure 1: Architecture of TNet.

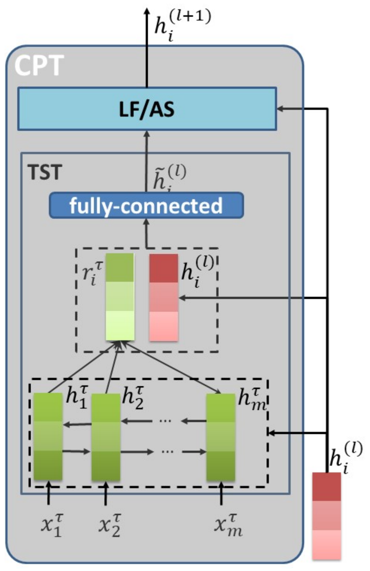

Figure 2: Details of a CPT module.

effective way to represent a word in convolution-based architectures. TNet also employs a BiLSTM to accumulate the context information for each word of the input sentence, i.e., the bottom part in Fig. 1. For simplicity and space issue, we denote the operation of an LSTM unit on x_i as $\mathrm{LSTM}(x_i)$. Thus, the contextualized word representation $h_i^{(0)} \in \mathbb{R}^{2\dim_h}$ is obtained as follows:

$$h_i^{(0)} = [\overrightarrow{\mathrm{LSTM}}(x_i); \overleftarrow{\mathrm{LSTM}}(x_i)], i \in [1, n]. \quad (1)$$

2.2 Context-Preserving Transformation

The above word-level representation has not considered the target information yet. Traditional attention-based approaches keep the word-level features static and aggregate them with weights as the final sentence representation. In contrast, as shown in the middle part in Fig. 1, we introduce multiple CPT layers and the detail of a single CPT is shown in Fig. 2. In each CPT layer, a tailor-made TST component that aims at better consolidating word representation and target representation is proposed. Moreover, we design a context-preserving mechanism enabling the learning of target-specific word representations in a deep neural architecture.

2.2.1 Target-Specific Transformation

TST component is depicted with the TST block in Fig. 2. The first task of TST is to generate the representation of the target. Previous methods (Chen et al., 2017; Liu and Zhang, 2017) average the embeddings of the target words as the target representation. This strategy may be inappropriate in some cases because different target words usually do not contribute equally. For example, in the target "*amd turin processor*", the word "processor" is more important than "amd" and "turin", because the sentiment is usually conveyed over the phrase head, i.e.,"processor", but seldom over modifiers (such as brand name "amd"). Ma et al. (2017) attempted to overcome this issue by measuring the importance score between each target word representation and the averaged sentence vector. However, it may be ineffective for sentences expressing multiple sentiments (e.g., *"Air has higher resolution but the fonts are small."*), because taking the average tends to neutralize different sentiments.

We propose to dynamically compute the importance of target words based on each sentence word rather than the whole sentence. We first employ another BiLSTM to obtain the target word representations $\mathbf{h}^\tau \in \mathbb{R}^{m \times 2\dim_h}$:

$$h_j^\tau = [\overrightarrow{\mathrm{LSTM}}(x_j^\tau); \overleftarrow{\mathrm{LSTM}}(x_j^\tau)], j \in [1, m]. \quad (2)$$

Then, we dynamically associate them with each word w_i in the sentence to tailor-make target representation r_i^τ at the time step i:

$$r_i^\tau = \sum_{j=1}^{m} h_j^\tau * \mathcal{F}(h_i^{(l)}, h_j^\tau), \quad (3)$$

where the function $\mathcal{F}$ measures the relatedness between the j-th target word representation h_j^τ and the i-th word-level representation $h_i^{(l)}$:

$$\mathcal{F}(h_i^{(l)}, h_j^\tau) = \frac{\exp{(h_i^{(l)\top} h_j^\tau)}}{\sum_{k=1}^m \exp{(h_i^{(l)\top} h_k^\tau)}}. \quad (4)$$

Finally, the concatenation of r_i^τ and $h_i^{(l)}$ is fed into a fully-connected layer to obtain the i-th target-specific word representation $\tilde{h}_i^{(l)}$:

$$\tilde{h}_i^{(l)} = g(W^\tau[h_i^{(l)} : r_i^\tau] + b^\tau), \quad (5)$$

where $g(*)$ is a non-linear activation function and ":" denotes vector concatenation. W^τ and b^τ are the weights of the layer.

2.2.2 Context-Preserving Mechanism

After the non-linear TST (see Eq. 5), the context information captured with contextualized representations from the BiLSTM layer will be lost since the mean and the variance of the features within the feature vector will be changed. To take advantage of the context information, which has been proved to be useful in (Lai et al., 2015), we investigate two strategies: Lossless Forwarding (LF) and Adaptive Scaling (AS), to pass the context information to each following layer, as depicted by the block "**LF/AS**" in Fig. 2. Accordingly, the model variants are named **TNet-LF** and **TNet-AS**.

Lossless Forwarding. This strategy preserves context information by directly feeding the features before the transformation to the next layer. Specifically, the input $h_i^{(l+1)}$ of the $(l+1)$-th CPT layer is formulated as:

$$h_i^{(l+1)} = h_i^{(l)} + \tilde{h}_i^{(l)}, i \in [1, n], l \in [0, L], \quad (6)$$

where $h_i^{(l)}$ is the input of the l-th layer and $\tilde{h}_i^{(l)}$ is the output of TST in this layer. We unfold the recursive form of Eq. 6 as follows:

$$h_i^{(l+1)} = h_i^{(0)} + \text{TST}(h_i^{(0)}) + \cdots + \text{TST}(h_i^{(l)}). \quad (7)$$

Here, we denote $\tilde{h}_i^{(l)}$ as $\text{TST}(h_i^{(l)})$. From Eq. 7, we can see that the output of each layer will contain the contextualized word representations (i.e., $h_i^{(0)}$), thus, the context information is encoded into the transformed features. We call this strategy "Lossless Forwarding" because the contextualized representations and the transformed representations (i.e., $\text{TST}(h_i^{(l)})$) are kept unchanged during the feature combination.

Adaptive Scaling. Lossless Forwarding introduces the context information by directly adding back the contextualized features to the transformed features, which raises a question: Can the weights of the input and the transformed features be adjusted dynamically? With this motivation, we propose another strategy, named "Adaptive Scaling". Similar to the gate mechanism in RNN variants (Jozefowicz et al., 2015), Adaptive Scaling introduces a gating function to control the passed proportions of the transformed features and the input features. The gate $\mathbf{t}^{(l)}$ as follows:

$$t_i^{(l)} = \sigma(W_{trans} h_i^{(l)} + b_{trans}), \quad (8)$$

where $t_i^{(l)}$ is the gate for the i-th input of the l-th CPT layer, and σ is the *sigmoid* activation function. Then we perform convex combination of $h_i^{(l)}$ and $\tilde{h}_i^{(l)}$ based on the gate:

$$h_i^{(l+1)} = t_i^{(l)} \odot \tilde{h}_i^{(l)} + (1 - t_i^{(l)}) \odot h_i^{(l)}. \quad (9)$$

Here, $\odot$ denotes element-wise multiplication. The non-recursive form of this equation is as follows (for clarity, we ignore the subscripts):

$$h^{(l+1)} = [\prod_{k=0}^{l}(1 - t^{(k)})] \odot h^{(0)}$$
$$+[t^{(0)} \prod_{k=1}^{l}(1 - t^{(k)})] \odot \text{TST}(h^{(0)}) + \cdots$$
$$+t^{(l-1)}(1 - t^{(l)}) \odot \text{TST}(h^{(l-1)}) + t^{(l)} \odot \text{TST}(h^{(l)}).$$

Thus, the context information is integrated in each upper layer and the proportions of the contextualized representations and the transformed representations are controlled by the computed gates in different transformation layers.

2.3 Convolutional Feature Extractor

Recall that the second issue that blocks CNN to perform well is that vanilla CNN may associate a target with unrelated general opinion words which are frequently used as modifiers for different targets across domains. For example, "***service***" in *"Great food but the service is dreadful"* may be associated with both "great" and "dreadful". To solve it, we adopt a proximity strategy, which is observed effective in (Chen et al., 2017; Li and Lam, 2017). The idea is a closer opinion word is more likely to be the actual modifier of the target.

		# Positive	# Negative	# Neutral
LAPTOP	Train	980	858	454
	Test	340	128	171
REST	Train	2159	800	632
	Test	730	195	196
TWITTER	Train	1567	1563	3127
	Test	174	174	346

Table 1: Statistics of datasets.

Specifically, we first calculate the position relevance v_i between the i-th word and the target[4]:

$$v_i = \begin{cases} 1 - \frac{(k+m-i)}{C} & i < k+m \\ 1 - \frac{i-k}{C} & k+m \le i \le n \\ 0 & i > n \end{cases} \quad (10)$$

where k is the index of the first target word, C is a pre-specified constant, and m is the length of the target $\mathbf{w}^\tau$. Then, we use v to help CNN locate the correct opinion w.r.t. the given target:

$$\hat{h}_i^{(l)} = h_i^{(l)} * v_i, i \in [1, n], l \in [1, L]. \quad (11)$$

Based on Eq. 10 and Eq. 11, the words close to the target will be highlighted and those far away will be downgraded. v is also applied on the intermediate output to introduce the position information into each CPT layer. Then we feed the weighted $\mathbf{h}^{(L)}$ to the convolutional layer, i.e., the top-most layer in Fig. 1, to generate the feature map $\mathbf{c} \in \mathbb{R}^{n-s+1}$ as follows:

$$c_i = \text{ReLU}(\boldsymbol{w}_{conv}^\top \mathbf{h}_{i:i+s-1}^{(L)} + b_{conv}), \quad (12)$$

where $\mathbf{h}_{i:i+s-1}^{(L)} \in \mathbb{R}^{s \cdot \dim_h}$ is the concatenated vector of $\hat{h}_i^{(L)}, \cdots, \hat{h}_{i+s-1}^{(L)}$, and s is the kernel size. $\boldsymbol{w}_{conv} \in \mathbb{R}^{s \cdot \dim_h}$ and $b_{conv} \in \mathbb{R}$ are learnable weights of the convolutional kernel. To capture the most informative features, we apply max pooling (Kim, 2014) and obtain the sentence representation $z \in \mathbb{R}^{n_k}$ by employing n_k kernels:

$$z = [\max(\mathbf{c}_1), \cdots, \max(\mathbf{c}_{n_k})]^\top. \quad (13)$$

Finally, we pass z to a fully connected layer for sentiment prediction:

$$p(y|\mathbf{w}^\tau, \mathbf{w}) = \text{Softmax}(W_f z + b_f). \quad (14)$$

where W_f and b_f are learnable parameters.

[4]As we perform sentence padding, it is possible that the index i is larger than the actual length n of the sentence.

3 Experiments

3.1 Experimental Setup

As shown in Table 1, we evaluate the proposed TNet on three benchmark datasets: LAPTOP and REST are from SemEval ABSA challenge (Pontiki et al., 2014), containing user reviews in laptop domain and restaurant domain respectively. We also remove a few examples having the "conflict label" as done in (Chen et al., 2017); TWITTER is built by Dong et al. (2014), containing twitter posts. All tokens are lowercased without removal of stop words, symbols or digits, and sentences are zero-padded to the length of the longest sentence in the dataset. Evaluation metrics are Accuracy and Macro-Averaged F1 where the latter is more appropriate for datasets with unbalanced classes. We also conduct pairwise t-test on both Accuracy and Macro-Averaged F1 to verify if the improvements over the compared models are reliable.

TNet is compared with the following methods.

- **SVM** (Kiritchenko et al., 2014): It is a traditional support vector machine based model with extensive feature engineering;
- **AdaRNN** (Dong et al., 2014): It learns the sentence representation toward target for sentiment prediction via semantic composition over dependency tree;
- **AE-LSTM**, and **ATAE-LSTM** (Wang et al., 2016): AE-LSTM is a simple LSTM model incorporating the target embedding as input, while ATAE-LSTM extends AE-LSTM with attention;
- **IAN** (Ma et al., 2017): IAN employs two LSTMs to learn the representations of the context and the target phrase interactively;
- **CNN-ASP**: It is a CNN-based model implemented by us which directly concatenates target representation to each word embedding;
- **TD-LSTM** (Tang et al., 2016a): It employs two LSTMs to model the left and right contexts of the target separately, then performs predictions based on concatenated context representations;
- **MemNet** (Tang et al., 2016b): It applies attention mechanism over the word embeddings multiple times and predicts sentiments

Table 2: Settings of hyper-parameters.

based on the top-most sentence representations;

- **BILSTM-ATT-G** (Liu and Zhang, 2017): It models left and right contexts using two attention-based LSTMs and introduces gates to measure the importance of left context, right context, and the entire sentence for the prediction;

- **RAM** (Chen et al., 2017): RAM is a multilayer architecture where each layer consists of attention-based aggregation of word features and a GRU cell to learn the sentence representation.

We run the released codes of TD-LSTM and BILSTM-ATT-G to generate results, since their papers only reported results on TWITTER. We also rerun MemNet on our datasets and evaluate it with both accuracy and Macro-Averaged F1.[5]

We use pre-trained GloVe vectors (Pennington et al., 2014) to initialize the word embeddings and the dimension is 300 (i.e., $\text{dim}_w = 300$). For out-of-vocabulary words, we randomly sample their embeddings from the uniform distribution $\mathcal{U}(-0.25, 0.25)$, as done in (Kim, 2014). We only use one convolutional kernel size because it was observed that CNN with single optimal kernel size is comparable with CNN having multiple kernel sizes on small datasets (Zhang and Wallace, 2017). To alleviate overfitting, we apply dropout on the input word embeddings of the LSTM and the ultimate sentence representation z. All weight matrices are initialized with the uniform distribution $\mathcal{U}(-0.01, 0.01)$ and the biases are initialized as zeros. The training objective is cross-entropy, and Adam (Kingma and Ba, 2015) is adopted as the optimizer by following the learning rate and the decay rates in the original paper.

The hyper-parameters of TNet-LF and TNet-AS are listed in Table 2. Specifically, all hyper-parameters are tuned on 20% randomly held-out training data and the hyper-parameter collection producing the highest accuracy score is used for testing. Our model has comparable number of parameters compared to traditional LSTM-based models as we reuse parameters in the transformation layers and BiLSTM.[6]

3.2 Main Results

As shown in Table 3, both TNet-LF and TNet-AS consistently achieve the best performance on all datasets, which verifies the efficacy of our whole TNet model. Moreover, TNet can perform well for different kinds of user generated content, such as product reviews with relatively formal sentences in LAPTOP and REST, and tweets with more ungrammatical sentences in TWITTER. The reason is the CNN-based feature extractor arms TNet with more power to extract accurate features from ungrammatical sentences. Indeed, we can also observe that another CNN-based baseline, i.e., CNN-ASP implemented by us, also obtains good results on TWITTER.

On the other hand, the performance of those comparison methods is mostly unstable. For the tweet in TWITTER, the competitive BILSTM-ATT-G and RAM cannot perform as effective as they do for the reviews in LAPTOP and REST, due to the fact that they are heavily rooted in LSTMs and the ungrammatical sentences hinder their ca-

[5]The codes of TD-LSTM/MemNet and BILSTM-ATT-G are available at: `http://ir.hit.edu.cn/~dytang` and `http://leoncrashcode.github.io`. Note that MemNet was only evaluated with accuracy.

[6]All experiments are conducted on a single NVIDIA GTX 1080. The prediction cost of a sentence is about 2 ms.

Table 3: Experimental results (%). The results with symbol"$\natural$" are retrieved from the original papers, and those starred ($*$) one are from Dong et al. (2014). The marker † refers to p-value < 0.01 when comparing with BILSTM-ATT-G, while the marker ‡ refers to p-value < 0.01 when comparing with RAM.

pability in capturing the context features. Another difficulty caused by the ungrammatical sentences is that the dependency parsing might be error-prone, which will affect those methods such as AdaRNN using dependency information.

From the above observations and analysis, some takeaway message for the task of target sentiment classification could be:

- LSTM-based models relying on sequential information can perform well for formal sentences by capturing more useful context features;
- For ungrammatical text, CNN-based models may have some advantages because CNN aims to extract the most informative n-gram features and is thus less sensitive to informal texts without strong sequential patterns.

3.3 Performance of Ablated TNet

To investigate the impact of each component such as deep transformation, context-preserving mechanism, and positional relevance, we perform comparison between the full TNet models and its ablations (the third group in Table 3). After removing the deep transformation (i.e., the techniques introduced in Section 2.2), both TNet-LF and TNet-AS are reduced to TNet w/o transformation (where position relevance is kept), and their results in both accuracy and F1 measure are incomparable with those of TNet. It shows that the integration of target information into the word-level representations is crucial for good performance.

Comparing the results of TNet and TNet w/o context (where TST and position relevance are kept), we observe that the performance of TNet w/o context drops significantly on LAPTOP and REST[7], while on TWITTER, TNet w/o context performs very competitive (p-values with TNet-LF and TNet-AS are 0.066 and 0.053 respectively for Accuracy). Again, we could attribute this phenomenon to the ungrammatical user generated content of twitter, because the context-preserving component becomes less important for such data. TNet w/o context performs consistently better than TNet w/o transformation, which verifies the efficacy of the target specific transformation (TST), before applying context-preserving.

As for the position information, we conduct statistical t-test between TNet-LF/AS and TNet-LF/AS w/o position together with performance comparison. All of the produced p-values are less than 0.05, suggesting that the improvements brought in by position information are significant.

[7]Without specification, the significance level is set to 0.05.

3.4 CPT versus Alternatives

The next interesting question is what if we replace the transformation module (i.e., the CPT layers in Fig.1) of TNet with other commonly-used components? We investigate two alternatives: attention mechanism and fully-connected (FC) layer, resulting in three pipelines as shown in the second group of Table 3 (position relevance is kept for them).

LSTM-ATT-CNN applies attention as the alternative[8], and it does not need the context-preserving mechanism. It performs unexceptionally worse than the TNet variants. We are surprised that LSTM-ATT-CNN is even worse than TNet w/o transformation (a pipeline simply removing the transformation module) on TWITTER. More concretely, applying attention results in negative effect on TWITTER, which is consistent with the observation that all those attention-based state-of-the-art methods (i.e., TD-LSTM, MemNet, BILSTM-ATT-G, and RAM) cannot perform well on TWITTER.

LSTM-FC-CNN-LF and LSTM-FC-CNN-AS are built by applying FC layer to replace TST and keeping the context-preserving mechanism (i.e., LF and AS). Specifically, the concatenation of word representation and the averaged target vector is fed to the FC layer to obtain target-specific features. Note that LSTM-FC-CNN-LF/AS are equivalent to TNet-LF/AS when processing single-word targets (see Eq. 3). They obtain competitive results on all datasets: comparable with or better than the state-of-the-art methods. The TNet variants can still outperform LSTM-FC-CNN-LF/AS with significant gaps, e.g., on LAPTOP and REST, the accuracy gaps between TNet-LF and LSTM-FC-CNN-LF are 0.42% ($p < 0.03$) and 0.38% ($p < 0.04$) respectively.

3.5 Impact of CPT Layer Number

As our TNet involves multiple CPT layers, we investigate the effect of the layer number L. Specifically, we conduct experiments on the held-out training data of LAPTOP and vary L from 2 to 10, increased by 2. The cases L=1 and L=15 are also included. The results are illustrated in Figure 3. We can see that both TNet-LF and TNet-AS achieve the best results when L=2. While increasing L, the performance is basically becoming worse. For large L, the performance of TNet-AS

[8]We tried different attention mechanisms and report the best one here, namely, *dot* attention (Luong et al., 2015).

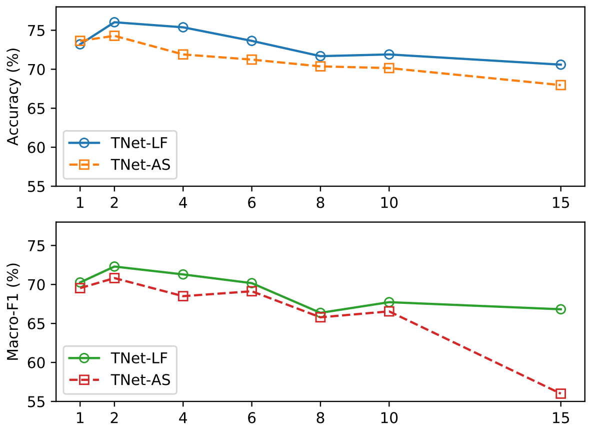

Figure 3: Effect of L.

generally becomes more sensitive, it is probably because AS involves extra parameters (see Eq 9) that increase the training difficulty.

3.6 Case Study

Table 4 shows some sample cases. The input targets are wrapped in the brackets with true labels given as subscripts. The notations P, N and O in the table represent positive, negative and neutral respectively. For each sentence, we underline the target with a particular color, and the text of its corresponding most informative n-gram feature[9] captured by TNet-AS (TNet-LF captures very similar features) is in the same color (so color printing is preferred). For example, for the target "resolution" in the first sentence, the captured feature is "Air has higher". Note that as discussed above, the CNN layer of TNet captures such features with the size-three kernels, so that the features are trigrams. Each of the last features of the second and seventh sentences contains a padding token, which is not shown.

Our TNet variants can predict target sentiment more accurately than RAM and BILSTM-ATT-G in the transitional sentences such as the first sentence by capturing correct trigram features. For the third sentence, its second and third most informative trigrams are "100% . PAD" and "' s not", being used together with "features make up", our models can make correct predictions. Moreover, TNet can still make correct prediction when the explicit opinion is target-specific. For example,

[9]For each convolutional filter, only one n-gram feature in the feature map will be kept after the max pooling. Among those from different filters, the n-gram with the highest frequency will be regarded as the most informative n-gram w.r.t. the given target.

Sentence	BILSTM-ATT-G	RAM	TNet-LF	TNet-AS
1. Air has higher **[resolution]**$_P$ but the **[fonts]**$_N$ are small .	(N$^{✗}$, N)	(N$^{✗}$, N)	(P, N)	(P, N)
2. Great **[food]**$_P$ but the **[service]**$_N$ is dreadful .	(P, N)	(P, N)	(P, N)	(P, N)
3. Sure it ' s not light and slim but the **[features]**$_P$ make up for it 100% .	N$^{✗}$	N$^{✗}$	P	P
4. Not only did they have amazing , **[sandwiches]**$_P$, **[soup]**$_P$, **[pizza]**$_P$ etc , but their **[homemade sorbets]**$_P$ are out of this world !	(P, O$^{✗}$, O$^{✗}$, P)	(P, P, O$^{✗}$, P)	(P, P, P, P)	(P, P, P, P)
5. **[startup times]**$_N$ are incredibly long : over two minutes .	P$^{✗}$	P$^{✗}$	N	N
6. I am pleased with the fast **[log on]**$_P$, speedy **[wifi connection]**$_P$ and the long **[battery life]**$_P$ (> 6 hrs) .	(P, P, P)	(P, P, P)	(P, P, P)	(P, P, P)
7. The **[staff]**$_N$ should be a bit more friendly .	P$^{✗}$	P$^{✗}$	P$^{✗}$	P$^{✗}$

Table 4: Example predictions, color printing is preferred. The input targets are wrapped in brackets with the true labels given as subscripts. ✗ indicates incorrect prediction.

"long" in the fifth sentence is negative for "startup time", while it could be positive for other targets such as "battery life" in the sixth sentence. The sentiment of target-specific opinion word is conditioned on the given target. Our TNet variants, armed with the word-level feature transformation w.r.t. the target, is capable of handling such case.

We also find that all these models cannot give correct prediction for the last sentence, a commonly used subjunctive style. In this case, the difficulty of prediction does not come from the detection of explicit opinion words but the inference based on implicit semantics, which is still quite challenging for neural network models.

4 Related Work

Apart from sentence level sentiment classification (Kim, 2014; Shi et al., 2018), aspect/target level sentiment classification is also an important research topic in the field of sentiment analysis. The early methods mostly adopted supervised learning approach with extensive hand-coded features (Blair-Goldensohn et al., 2008; Titov and McDonald, 2008; Yu et al., 2011; Jiang et al., 2011; Kiritchenko et al., 2014; Wagner et al., 2014; Vo and Zhang, 2015), and they fail to model the semantic relatedness between a target and its context which is critical for target sentiment analysis. Dong et al. (2014) incorporate the target information into the feature learning using dependency trees. As observed in previous works, the performance heavily relies on the quality of dependency parsing. Tang et al. (2016a) propose to split the context into two parts and associate target with contextual features separately. Similar to (Tang et al., 2016a), Zhang et al. (2016) develop a three-way gated neural network to model the interaction between the target and its surrounding contexts. Despite the advantages of jointly modeling target and context, they are not capable of capturing long-range information when some critical context information is far from the target. To overcome this limitation, researchers bring in the attention mechanism to model target-context association (Tang et al., 2016a,b; Wang et al., 2016; Yang et al., 2017; Liu and Zhang, 2017; Ma et al., 2017; Chen et al., 2017; Zhang et al., 2017; Tay et al., 2017). Compared with these methods, our TNet avoids using attention for feature extraction so as to alleviate the attended noise.

5 Conclusions

We re-examine the drawbacks of attention mechanism for target sentiment classification, and also investigate the obstacles that hinder CNN-based models to perform well for this task. Our TNet model is carefully designed to solve these issues. Specifically, we propose target specific transformation component to better integrate target information into the word representation. Moreover, we employ CNN as the feature extractor for this classification problem, and rely on the context-preserving and position relevance mechanisms to maintain the advantages of previous LSTM-based models. The performance of TNet consistently dominates previous state-of-the-art methods on different types of data. The ablation studies show the efficacy of its different modules, and thus verify the rationality of TNet's architecture.

Abstract

Aspect sentiment classification (ASC) is a fundamental task in sentiment analysis. Given an aspect/target and a sentence, the task classifies the sentiment polarity expressed on the target in the sentence. Memory networks (MNs) have been used for this task recently and have achieved state-of-the-art results. In MNs, attention mechanism plays a crucial role in detecting the sentiment context for the given target. However, we found an important problem with the current MNs in performing the ASC task. Simply improving the attention mechanism will not solve it. The problem is referred to as *target-sensitive sentiment*, which means that the sentiment polarity of the (detected) context is dependent on the given target and it cannot be inferred from the context alone. To tackle this problem, we propose the *target-sensitive memory networks* (TMNs). Several alternative techniques are designed for the implementation of TMNs and their effectiveness is experimentally evaluated.

1 Introduction

Aspect sentiment classification (ASC) is a core problem of sentiment analysis (Liu, 2012). Given an aspect and a sentence containing the aspect, ASC classifies the sentiment polarity expressed in the sentence about the aspect, namely, positive, neutral, or negative. Aspects are also called *opinion targets* (or simply *targets*), which are usually product/service features in customer reviews. In this paper, we use aspect and target interchangeably. In practice, aspects can be specified by the user or extracted automatically using an aspect extraction technique (Liu, 2012). In this work, we assume the aspect terms are given and only focus on the classification task.

Due to their impressive results in many NLP tasks (Deng et al., 2014), neural networks have been applied to ASC (see the survey (Zhang et al., 2018)). Memory networks (MNs), a type of neural networks which were first proposed for question answering (Weston et al., 2015; Sukhbaatar et al., 2015), have achieved the state-of-the-art results in ASC (Tang et al., 2016). A key factor for their success is the attention mechanism. However, we found that using existing MNs to deal with ASC has an important problem and simply relying on attention modeling cannot solve it. That is, their performance degrades when the sentiment of a context word is sensitive to the given target.

Let us consider the following sentences:

(1) *The screen resolution is **excellent** but the price is **ridiculous**.*
(2) *The screen resolution is **excellent** but the price is **high**.*
(3) *The price is **high**.*
(4) *The screen resolution is **high**.*

In sentence (1), the sentiment expressed on aspect *screen resolution* (or *resolution* for short) is positive, whereas the sentiment on aspect *price* is negative. For the sake of predicting correct sentiment, a crucial step is to first detect the sentiment context about the given aspect/target. We call this step *targeted-context detection*. Memory networks (MNs) can deal with this step quite well because the sentiment context of a given aspect can be captured by the internal attention mechanism in MNs. Concretely, in sentence (1) the word "excellent" can be identified as the sentiment context when *resolution* is specified. Likewise, the context word "ridiculous" will be placed with a high attention when *price* is the target. With the correct targeted-context detected, a trained MN, which recognizes "excellent" as positive sentiment and "ridiculous" as negative sentiment, will infer correct sentiment polarity for the given target. This is relatively easy as "excellent" and "ridiculous" are both target-independent sentiment words, i.e., the words themselves already indicate clear sentiments.

As illustrated above, the attention mechanism addressing the targeted-context detection problem is very useful for ASC, and it helps classify many sentences like sentence (1) accurately. This also led to existing and potential research in improving attention modeling (discussed in Section 5). However, we observed that simply focusing on tackling the target-context detection problem and learning better attention are not sufficient to solve the problem found in sentences (2), (3) and (4).

Sentence (2) is similar to sentence (1) except that the (sentiment) context modifying aspect/target *price* is "high". In this case, when "high" is assigned the correct attention for the aspect *price*, the model also needs to capture the sentiment interaction between "high" and *price* in order to identify the correct sentiment polarity. This is not as easy as sentence (1) because "high" itself indicates no clear sentiment. Instead, its sentiment polarity is dependent on the given target.

Looking at sentences (3) and (4), we further see the importance of this problem and also why relying on attention mechanism alone is insufficient. In these two sentences, sentiment contexts are both "high" (i.e., same attention), but sentence (3) is negative and sentence (4) is positive simply because their target aspects are different. Therefore, focusing on improving attention will not help in these cases. We will give a theoretical insight about this problem with MNs in Section 3.

In this work, we aim to solve this problem. To distinguish it from the aforementioned targeted-context detection problem as shown by sentence (1), we refer to the problem in (2), (3) and (4) as the *target-sensitive sentiment* (or target-dependent sentiment) problem, which means that the sentiment polarity of a detected/attended context word is conditioned on the target and cannot be directly inferred from the context word alone, unlike "excellent" and "ridiculous". To address this problem, we propose *target-sensitive memory networks* (TMNs), which can capture the sentiment interaction between targets and contexts. We present several approaches to implementing TMNs and experimentally evaluate their effectiveness.

2 Memory Network for ASC

This section describes our basic memory network for ASC, also as a background knowledge. It does not include the proposed target-sensitive sentiment solutions, which are introduced in Section 4. The model design follows previous studies (Sukhbaatar et al., 2015; Tang et al., 2016) except that a different attention alignment function is used (shown in Eq. 1). Their original models will be compared in our experiments as well. The definitions of related notations are given in Table 1.

t	a target word, $t \in \mathbb{R}^{V \times 1}$
v_t	target embedding of t, $v_t \in \mathbb{R}^{d \times 1}$
x_i	a context word in a sentence, $x_i \in \mathbb{R}^{V \times 1}$
m_i, c_i	input, output context embedding of word x_i, and $m_i, c_i \in \mathbb{R}^{d \times 1}$
V	number of words in vocabulary
d	vector/embedding dimension
A	input embedding matrix $A \in \mathbb{R}^{d \times V}$
C	output embedding matrix $C \in \mathbb{R}^{d \times V}$
α	attention distribution in a sentence
α_i	attention of context word i, $\alpha_i \in (0, 1)$
o	output representation, $o \in \mathbb{R}^{d \times 1}$
K	number of sentiment classes
s	sentiment score, $s \in \mathbb{R}^{K \times 1}$
y	sentiment probability

Table 1: Definition of Notations

Input Representation: Given a target aspect t, an embedding matrix A is used to convert t into a vector representation, v_t ($v_t = At$). Similarly, each context word (non-aspect word in a sentence) $x_i \in \{x_1, x_2, ...x_n\}$ is also projected to the continuous space stored in memory, denoted by m_i ($m_i = Ax_i$) $\in \{m_1, m_2, ...m_n\}$. Here n is the number of words in a sentence and i is the word position/index. Both t and x_i are one-hot vectors. For an aspect expression with multiple words, its aspect representation v_t is the averaged vector of those words (Tang et al., 2016).

Attention: Attention can be obtained based on the above input representation. Specifically, an attention weight α_i for the context word x_i is computed based on the alignment function:

$$\alpha_i = softmax(v_t^T M m_i) \tag{1}$$

where $M \in \mathbb{R}^{d \times d}$ is the general learning matrix suggested by Luong et al. (2015). In this manner, attention $\alpha = \{\alpha_1, \alpha_2, ..\alpha_n\}$ is represented as a vector of probabilities, indicating the weight/importance of context words towards a given target. Note that $\alpha_i \in (0, 1)$ and $\sum_i \alpha_i = 1$.

Output Representation: Another embedding matrix C is used for generating the individual (output) continuous vector c_i ($c_i = Cx_i$) for each context word x_i. A final response/output vector o is produced by summing over these vectors weighted with the attention α, i.e., $o = \sum_i \alpha_i c_i$.

Sentiment Score (or Logit): The aspect sentiment scores (also called logits) for positive, neutral, and negative classes are then calculated, where a sentiment-specific weight matrix $W \in \mathbb{R}^{K\times d}$ is used. The sentiment scores are represented in a vector $s \in \mathbb{R}^{K\times 1}$, where K is the number of (sentiment) classes, which is 3 in ASC.

$$s = W(o + v_t) \tag{2}$$

The final sentiment probability y is produced with a $softmax$ operation, i.e., $y = softmax(s)$.

3 Problem of the above Model for Target-Sensitive Sentiment

This section analyzes the problem of target-sensitive sentiment in the above model. The analysis can be generalized to many existing MNs as long as their improvements are on attention α only. We first expand the sentiment score calculation from Eq. 2 to its individual terms:

$$\begin{aligned} s = W(o + v_t) &= W(\sum_i \alpha_i c_i + v_t) \\ &= \alpha_1 W c_1 + \alpha_2 W c_2 + ...\alpha_n W c_n + W v_t \end{aligned} \tag{3}$$

where "+" denotes element-wise summation. In Eq. 3, $\alpha_i W c_i$ can be viewed as the individual sentiment logit for a context word and Wv_t is the sentiment logit of an aspect. They are linearly combined to determine the final sentiment score s. This can be problematic in ASC. First, an aspect word often expresses no sentiment, for example, "screen". However, if the aspect term v_t is simply removed from Eq. 3, it also causes the problem that the model cannot handle target-dependent sentiment. For instance, the sentences (3) and (4) in Section 1 will then be treated as identical if their aspect words are not considered. Second, if an aspect word is considered and it directly bears some positive or negative sentiment, then when an aspect word occurs with different context words for expressing opposite sentiments, a contradiction can be resulted from them, especially in the case that the context word is a target-sensitive sentiment word. We explain it as follows.

Let us say we have two target words *price* and *resolution* (denoted as p and r). We also have two possible context words "high" and "low" (denoted as h and l). As these two sentiment words can modify both aspects, we can construct four snippets "high price", "low price", "high resolution" and "low resolution". Their sentiments are negative, positive, positive, and negative respectively. Let us set W to $\mathbb{R}^{1\times d}$ so that s becomes a 1-dimensional sentiment score indicator. $s > 0$ indicates a positive sentiment and $s < 0$ indicates a negative sentiment. Based on the above example snippets or phrases we have four corresponding inequalities: (a) $W(\alpha_h c_h + v_p) < 0$, (b) $W(\alpha_l c_l + v_p) > 0$, (c) $W(\alpha_h c_h + v_r) > 0$ and (d) $W(\alpha_l c_l + v_r) < 0$. We can drop all α terms here as they all equal to 1, i.e., they are the only context word in the snippets to attend to (the target words are not contexts). From (a) and (b) we can infer (e) $Wc_h < -Wv_p < Wc_l$. From (c) and (d) we can infer (f) $Wc_l < -Wv_r < Wc_h$. From (e) and (f) we have (g) $Wc_h < Wc_l < Wc_h$, which is a contradiction.

This contradiction means that MNs cannot learn a set of parameters W and C to correctly classify the above four snippets/sentences at the same time. This contradiction also generalizes to real-world sentences. That is, although real-world review sentences are usually longer and contain more words, since the attention mechanism makes MNs focus on the most important sentiment context (the context with high α_i scores), the problem is essentially the same. For example, in sentences (2) and (3) in Section 1, when *price* is targeted, the main attention will be placed on "high". For MNs, these situations are nearly the same as that for classifying the snippet "high price". We will also show real examples in the experiment section.

One may then ask whether improving attention can help address the problem, as α_i can affect the final results by adjusting the sentiment effect of the context word via $\alpha_i W c_i$. This is unlikely, if not impossible. First, notice that α_i is a scalar ranging in (0,1), which means it essentially assigns higher or lower weight to increase or decrease the sentiment effect of a context word. It cannot change the intrinsic sentiment orientation/polarity of the context, which is determined by Wc_i. For example, if Wc_i assigns the context word "high" a positive sentiment ($Wc_i > 0$), α_i will not make it negative (i.e., $\alpha_i W c_i < 0$ cannot be achieved by changing α_i). Second, other irrelevant/unimportant context words often carry no or little sentiment information, so increasing or decreasing their weights does not help. For example, in the sentence "the price is high", adjusting the weights of context words "the" and "is" will neither help solve the problem nor be intuitive to do so.

4 The Proposed Approaches

This section introduces six (6) alternative target-sensitive memory networks (TMNs), which all can deal with the target-sensitive sentiment problem. Each of them has its characteristics.

Non-linear Projection (NP): This is the first approach that utilizes a non-linear projection to capture the interplay between an aspect and its context. Instead of directly following the common linear combination as shown in Eq. 3, we use a non-linear projection (*tanh*) as the replacement to calculate the aspect-specific sentiment score.

$$s = W \cdot tanh(\sum_i \alpha_i c_i + v_t) \tag{4}$$

As shown in Eq. 4, by applying a non-linear projection over attention-weighted c_i and v_t, the context and aspect information are coupled in a way that the final sentiment score cannot be obtained by simply summing their individual contributions (compared with Eq. 3). This technique is also intuitive in neural networks. However, notice that by using the non-linear projection (or adding more sophisticated hidden layers) over them in this way, we sacrifice some interpretability. For example, we may have difficulty in tracking how each individual context word (c_i) affects the final sentiment score s, as all context and target representations are coupled. To avoid this, we can use the following five alternative techniques.

Contextual Non-linear Projection (CNP): Despite the fact that it also uses the non-linear projection, this approach incorporates the interplay between a context word and the given target into its (output) context representation. We thus name it Contextual Non-linear Projection (CNP).

$$s = W \sum_i \alpha_i \cdot tanh(c_i + v_t) \tag{5}$$

From Eq. 5, we can see that this approach can keep the linearity of attention-weighted context aggregation while taking into account the aspect information with non-linear projection, which works in a different way compared to NP. If we define $\tilde{c}_i = tanh(c_i + v_t)$, $\tilde{c}_i$ can be viewed as the target-aware context representation of context x_i and the final sentiment score is calculated based on the aggregation of such $\tilde{c}_i$. This could be a more reasonable way to carry the aspect information rather than simply summing the aspect representation (Eq. 3).

However, one potential disadvantage is that this setting uses the same set of vector representations (learned by embeddings C) for multiple purposes, i.e., to learn output (context) representations and to capture the interplay between contexts and aspects. This may degenerate its model performance when the computational layers in memory networks (called "hops") are deep, because too much information is required to be encoded in such cases and a sole set of vectors may fail to capture all of it.

To overcome this, we suggest the involvement of an additional new set of embeddings/vectors, which is exclusively designed for modeling the sentiment interaction between an aspect and its context. The key idea is to decouple different functioning components with different representations, but still make them work jointly. The following four techniques are based on this idea.

Interaction Term (IT): The third approach is to formulate explicit target-context sentiment interaction terms. Different from the targeted-context detection problem which is captured by attention (discussed in Section 1), here the ***target-context sentiment (TCS) interaction*** measures the sentiment-oriented interaction effect between targets and contexts, which we refer to as *TCS interaction* (or *sentiment interaction*) for short in the rest of this paper. Such sentiment interaction is captured by a new set of vectors, and we thus also call such vectors *TCS vectors*.

$$s = \sum_i \alpha_i (W_s c_i + w_I \langle d_i, d_t \rangle) \tag{6}$$

In Eq. 6, $W_s \in \mathbb{R}^{K \times d}$ and $w_I \in \mathbb{R}^{K \times 1}$ are used instead of W in Eq. 3. W_s models the direct sentiment effect from c_i while w_I works with d_i and d_t together for learning the TCS interaction. d_i and d_t are TCS vector representations of context x_i and aspect t, produced from a new embedding matrix D, i.e., $d_i = Dx_i, d_t = Dt$ ($D \in \mathbb{R}^{d \times V}$ and $d_i, d_t \in \mathbb{R}^{d \times 1}$).

Unlike input and output embeddings A and C, D is designed to capture the sentiment interaction. The vectors from D affect the final sentiment score through $w_I \langle d_i, d_t \rangle$, where w_I is a sentiment-specific vector and $\langle d_i, d_t \rangle \in \mathbb{R}$ denotes the dot product of the two TCS vectors d_i and d_t. Compared to the basic MNs, this model can better capture target-sensitive sentiment because the interactions between a context word h and different aspect words (say, p and r) can be different, i.e., $\langle d_h, d_p \rangle \neq \langle d_h, d_r \rangle$.

The key advantage is that now the sentiment effect is explicitly dependent on its target and context. For example, $\langle d_h, d_p \rangle$ can help shift the final sentiment to negative and $\langle d_h, d_r \rangle$ can help shift it to positive. Note that α is still needed to control the importance of different contexts. In this manner, targeted-context detection (attention) and TCS interaction are jointly modeled and work together for sentiment inference. The proposed techniques introduced below also follow this core idea but with different implementations or properties. We thus will not repeat similar discussions.

Coupled Interaction (CI): This proposed technique associates the TCS interaction with an additional set of context representation. This representation is for capturing the global correlation between context and different sentiment classes.

$$s = \sum_i \alpha_i (W_s c_i + W_I \langle d_i, d_t \rangle e_i) \qquad (7)$$

Specifically, e_i is another output representation for x_i, which is coupled with the sentiment interaction factor $\langle d_i, d_t \rangle$. For each context word x_i, e_i is generated as $e_i = E x_i$ where $E \in \mathbb{R}^{d \times V}$ is an embedding matrix. $\langle d_i, d_t \rangle$ and e_i function together as a target-sensitive context vector and are used to produce sentiment scores with W_I ($W_I \in \mathbb{R}^{K \times d}$).

Joint Coupled Interaction (JCI): A natural variant of the above model is to replace e_i with c_i, which means to learn a joint output representation. This can also reduce the number of learning parameters and simplify the CI model.

$$s = \sum_i \alpha_i (W_s c_i + W_I \langle d_i, d_t \rangle c_i) \qquad (8)$$

Joint Projected Interaction (JPI): This model also employs a unified output representation like JCI, but a context output vector c_i will be projected to two different continuous spaces before sentiment score calculation. To achieve the goal, two projection matrices W_1, W_2 and the non-linear projection function $tanh$ are used. The intuition is that, when we want to reduce the (embedding) parameters and still learn a joint representation, two different sentiment effects need to be separated in different vector spaces. The two sentiment effects are modeled as two terms:

$$\begin{aligned} s = & \sum_i \alpha_i W_J \tanh(W_1 c_i) \\ & + \sum_i \alpha_i W_J \langle d_i, d_t \rangle \tanh(W_2 c_i) \end{aligned} \qquad (9)$$

where the first term can be viewed as learning target-independent sentiment effect while the second term captures the TCS interaction. A joint sentiment-specific weight matrix $W_J (W_J \in \mathbb{R}^{K \times d})$ is used to control/balance the interplay between these two effects.

Discussions: (a) In IT, CI, JCI, and JPI, their first-order terms are still needed, because not in all cases sentiment inference needs TCS interaction. For some simple examples like "the battery is good", the context word "good" simply indicates clear sentiment, which can be captured by their first-order term. However, notice that the modeling of second-order terms offers additional help in both general and target-sensitive scenarios. (b) TCS interaction can be calculated by other modeling functions. We have tried several methods and found that using the dot product $\langle d_i, d_t \rangle$ or $d_i^T W d_t$ (with a projection matrix W) generally produces good results. (c) One may ask whether we can use fewer embeddings or just use one universal embedding to replace A, C and D (the definition of D can be found in the introduction of IT). We have investigated them as well. We found that merging A and C is basically workable. But merging D and A/C produces poor results because they essentially function with different purposes. While A and C handle targeted-context detection (attention), D captures the TCS interaction. (d) Except NP, we do not apply non-linear projection to the sentiment score layer. Although adding non-linear transformation to it may further improve model performance, the individual sentiment effect from each context will become untraceable, i.e., losing some interpretability. In order to show the effectiveness of learning TCS interaction and for analysis purpose, we do not use it in this work. But it can be flexibly added for specific tasks/analyses that do not require strong interpretability.

Loss function: The proposed models are all trained in an end-to-end manner by minimizing the cross entropy loss. Let us denote a sentence and a target aspect as x and t respectively. They appear together in a pair format (x, t) as input and all such pairs construct the dataset H. $g_{(x,t)}$ is a one-hot vector and $g^k_{(x,t)} \in \{0, 1\}$ denotes a gold sentiment label, i.e., whether (x, t) shows sentiment k. $y_{x,t}$ is the model-predicted sentiment distribution for (x, t). $y^k_{x,t}$ denotes its probability in class k. Based on them, the training loss is constructed as:

$$loss = - \sum_{(x,t) \in H} \sum_{k \in K} g^k_{(x,t)} \log y^k_{(x,t)} \tag{10}$$

5 Related Work

Aspect sentiment classification (ASC) (Hu and Liu, 2004), which is different from document or sentence level sentiment classification (Pang et al., 2002; Kim, 2014; Yang et al., 2016), has recently been tackled by neural networks with promising results (Dong et al., 2014; Nguyen and Shirai, 2015) (also see the survey (Zhang et al., 2018)). Later on, the seminal work of using attention mechanism for neural machine translation (Bahdanau et al., 2015) popularized the application of the attention mechanism in many NLP tasks (Hermann et al., 2015; Cho et al., 2015; Luong et al., 2015), including ASC.

Memory networks (MNs) (Weston et al., 2015; Sukhbaatar et al., 2015) are a type of neural models that involve such attention mechanisms (Bahdanau et al., 2015), and they can be applied to ASC. Tang et al. (2016) proposed an MN variant to ASC and achieved the state-of-the-art performance. Another common neural model using attention mechanism is the RNN/LSTM (Wang et al., 2016).

As discussed in Section 1, the attention mechanism is suitable for ASC because it effectively addresses the targeted-context detection problem. Along this direction, researchers have studied more sophisticated attentions to further help the ASC task (Chen et al., 2017; Ma et al., 2017; Liu and Zhang, 2017). Chen et al. (2017) proposed to use a recurrent attention mechanism. Ma et al. (2017) used multiple sets of attentions, one for modeling the attention of aspect words and one for modeling the attention of context words. Liu and Zhang (2017) also used multiple sets of attentions, one obtained from the left context and one obtained from the right context of a given target. Notice that our work does not lie in this direction. Our goal is to solve the target-sensitive sentiment and to capture the TCS interaction, which is a different problem. This direction is also finer-grained, and none of the above works addresses this problem. Certainly, both directions can improve the ASC task. We will also show in our experiments that our work can be integrated with an improved attention mechanism.

To the best of our knowledge, none of the existing studies addresses the target-sensitive sentiment problem in ASC under the purely data-driven and supervised learning setting. Other concepts like sentiment shifter (Polanyi and Zaenen, 2006) and sentiment composition (Moilanen and Pulman, 2007; Choi and Cardie, 2008; Socher et al., 2013) are also related, but they are not learned automatically and require rule/patterns or external resources (Liu, 2012). Note that our approaches do not rely on handcrafted patterns (Ding et al., 2008; Wu and Wen, 2010), manually compiled sentiment constraints and review ratings (Lu et al., 2011), or parse trees (Socher et al., 2013).

6 Experiments

We perform experiments on the datasets of SemEval Task 2014 (Pontiki et al., 2014), which contain online reviews from domain *Laptop* and *Restaurant*. In these datasets, aspect sentiment polarities are labeled. The training and test sets have also been provided. Full statistics of the datasets are given in Table 2.

Dataset	Positive		Neutral		Negative	
	Train	Test	Train	Test	Train	Test
Restaurant	2164	728	637	196	807	196
Laptop	994	341	464	169	870	128

Table 2: Statistics of Datasets

6.1 Candidate Models for Comparison

MN: The classic end-to-end memory network (Sukhbaatar et al., 2015).

AMN: A state-of-the-art memory network used for ASC (Tang et al., 2016). The main difference from MN is in its attention alignment function, which concatenates the distributed representations of the context and aspect, and uses an additional weight matrix for attention calculation, following the method introduced in (Bahdanau et al., 2015).

BL-MN: Our basic memory network presented in Section 2, which does not use the proposed techniques for capturing target-sensitive sentiments.

AE-LSTM: RNN/LSTM is another popular attention based neural model. Here we compare with a state-of-the-art attention-based LSTM for ASC, AE-LSTM (Wang et al., 2016).

ATAE-LSTM: Another attention-based LSTM for ASC reported in (Wang et al., 2016).

Target-sensitive Memory Networks (TMNs): The six proposed techniques, NP, CNP, IT, CI, JCI, and JPI give six target-sensitive memory networks.

Note that other non-neural network based models like SVM and neural models without attention mechanism like traditional LSTMs have been compared and reported with inferior performance in the ASC task (Dong et al., 2014; Tang et al., 2016; Wang et al., 2016), so they are excluded from comparisons here. Also, note that non-neural models like SVMs require feature engineering to manually encode aspect information, while this work aims to improve the aspect representation learning based approaches.

6.2 Evaluation Measure

Since we have a three-class classification task (positive, negative and neutral) and the classes are imbalanced as shown in Table 2, we use F1-score as our evaluation measure. We report both F1-Macro over all classes and all individual class-based F1 scores. As our problem requires fine-grained sentiment interaction, the class-based F1 provides more indicative information. In addition, we report the accuracy (same as F1-Micro), as it is used in previous studies. However, we suggest using F1-score because accuracy biases towards the majority class.

6.3 Training Details

We use the open-domain word embeddings[1] for the initialization of word vectors. We initialize other model parameters from a uniform distribution U(-0.05, 0.05). The dimension of the word embedding and the size of the hidden layers are 300. The learning rate is set to 0.01 and the dropout rate is set to 0.1. Stochastic gradient descent is used as our optimizer. The position encoding is also used (Tang et al., 2016). We also compare the memory networks in their multiple computational layers version (i.e., multiple hops) and the number of hops is set to 3 as used in the mentioned previous studies. We implemented all models in the TensorFlow environment using same input, embedding size, dropout rate, optimizer, etc. so as to test our hypotheses, i.e., to make sure the achieved improvements do not come from elsewhere. Meanwhile, we can also report all evaluation measures discussed above[2]. 10% of the training data is used as the development set. We report the best results for all models based on their F-1 Macro scores.

6.3.1 Result Analysis

The classification results are shown in Table 3. Note that the candidate models are all based on classic/standard attention mechanism, i.e., without sophisticated or multiple attentions involved. We compare the 1-hop and 3-hop memory networks as two different settings. The top three F1-Macro scores are marked in bold. Based on them, we have the following observations:

1. Comparing the 1-hop memory networks (first nine rows), we see significant performance gains achieved by CNP, CI, JCI, and JPI on both datasets, where each of them has $p < 0.01$ over the strongest baseline (BL-MN) from paired t-test using F1-Macro. IT also outperforms the other baselines while NP has similar performance to BL-MN. This indicates that TCS interaction is very useful, as BL-MN and NP do not model it.
2. In the 3-hop setting, TMNs achieve much better results on Restaurant. JCI, IT, and CI achieve the best scores, outperforming the strongest baseline AMN by 2.38%, 2.18%, and 2.03%. On Laptop, BL-MN and most TMNs (except CNP and JPI) perform similarly. However, BL-MN performs poorly on Restaurant (only better than two models) while TMNs show more stable performance.
3. Comparing all TMNs, we see that JCI works the best as it always obtains the top-three scores on two datasets and in two settings. CI and JPI also perform well in most cases. IT, NP, and CNP can achieve very good scores in some cases but are less stable. We also analyzed their potential issues in Section 4.
4. It is important to note that these improvements are quite large because in many cases sentiment interactions may not be necessary (like sentence (1) in Section 1). The overall good results obtained by TMNs demonstrate their capability of handling both general and target-sensitive sentiments, i.e., the proposed

techniques do not bring harm while capturing additional target-sensitive signals.

5. Micro-F1/accuracy is greatly affected by the majority class, as we can see the scores from Pos. and Micro are very consistent. TMNs, in fact, effectively improve the minority classes, which are reflected in Neg. and Neu., for example, JCI improves BL-MN by 3.78% in Neg. on Restaurant. This indicates their usefulness of capturing fine-grained sentiment signals. We will give qualitative examples in next section to show their modeling superiority for identifying target-sensitive sentiments.

RMN	67.17	62.65	55.31	83.55	72.07

Table 4: Results with Recurrent Attention

Integration with Improved Attention: As discussed, the goal of this work is not for learning better attention but addressing the target-sensitive sentiment. In fact, solely improving attention does not solve our problem (see Sections 1 and 3). However, better attention can certainly help achieve an overall better performance for the ASC task, as it makes the targeted-context detection more accurate. Here we integrate our proposed technique JCI with a state-of-the-art sophisticated attention mechanism, namely, the recurrent attention framework, which involves multiple attentions learned iteratively (Kumar et al., 2016; Chen et al., 2017). We name our model with this integration as Target-sensitive Recurrent-attention Memory Network (TRMN) and the basic memory network with the recurrent attention as Recurrent-attention Memory Network (RMN). Their results are given in Table 4. TRMN achieves significant performance gain with $p < 0.05$ in paired t-test.

6.4 Effect of TCS Interaction for Identifying Target-Sensitive Sentiment

We now give some real examples to show the effectiveness of modeling TCS interaction for identifying target-sensitive sentiments, by comparing a regular MN and a TMN. Specifically, BL-MN and JPI are used. Other MNs/TMNs have similar performances to BL-MN/JPI qualitatively, so we do not list all of them here. For BL-MN and JPI, their sentiment scores of a single context word i are calculated by $\alpha_i W c_i$ (from Eq. 3) and $\alpha_i W_J tanh(W_1 c_i) + \alpha_i W_J \langle d_i, d_t \rangle tanh(W_2 c_i)$ (from Eq. 9), each of which results in a 3-dimensional vector.

Illustrative Examples: Table 5 shows two records in Laptop. In record 1, to identify the sentiment of target *price* in the presented sentence, the sentiment interaction between the context word "higher" and the target word *price* is the key. The

Record 1				Record 2			
Sentence	Price was higher when purchased on MAC..			**Sentence**	(MacBook) Air has higher resolution..		
Target	*Price*	**Sentiment**	*Negative*	**Target**	*Resolution*	**Sentiment**	*Positive*
Result	**Sentiment Logits on context "higher"**			**Result**	**Sentiment Logits on context "higher"**		
TMN	Negative	Neutral	Positive	**TMN**	Negative	Neutral	Positive
	0.2663 (Correct)	-0.2604	-0.0282		-0.4729	-0.3949	**0.9041 (Correct)**
MN	Negative	Neutral	Positive	**MN**	Negative	Neutral	Positive
	0.3641 (Correct)	-0.3275	-0.0750		**0.2562 (Wrong)**	-0.2305	- 0.0528

Table 5: Sample Records and Model Comparison between MN and TMN

specific sentiment scores of the word "higher" towards negative, neutral and positive classes in both models are reported. We can see both models accurately assign the highest sentiment scores to the negative class. We also observe that in MN the negative score (0.3641) in the 3-dimension vector $\{0.3641, -0.3275, -0.0750\}$ calculated by $\alpha_i W c_i$ is greater than neutral (-0.3275) and positive (-0.0750) scores. Notice that α_i is always positive (ranging in $(0, 1)$), so it can be inferred that the first value in vector Wc_i is greater than the other two values. Here c_i denotes the vector representation of "higher" so we use c_{higher} to highlight it and we have $\{Wc_{higher}\}^{Negative} > \{Wc_{higher}\}^{Neutral/Positive}$ as an inference.

In record 2, the target is *resolution* and its sentiment is positive in the presented sentence. Although we have the same context word "higher", different from record 1, it requires a positive sentiment interaction with the current target. Looking at the results, we see TMN assigns the highest sentiment score of word "higher" to positive class correctly, whereas MN assigns it to negative class. This error is expected if we consider the above inference $\{Wc_{higher}\}^{Negative} > \{Wc_{higher}\}^{Neutral/Positive}$ in MN. The cause of this unavoidable error is that Wc_i is not conditioned on the target. In contrast, $W_J\langle d_i, \cdot d_t\rangle tanh(W_2 c_i)$ can change the sentiment polarity with the aspect vector d_t encoded. Other TMNs also achieve it (like $W_I\langle d_i, d_t\rangle c_i$ in JCI).

One may notice that the aspect information (v_t) is actually also considered in the form of $\alpha_i W c_i + W v_t$ in MNs and wonder whether Wv_t may help address the problem given different v_t. Let us assume it helps, which means in the above example an MN makes $Wv_{resolution}$ favor the positive class and Wv_{price} favor the negative class. But then we will have trouble when the context word is "lower", where it requires $Wv_{resolution}$ to favor the negative class and Wv_{price} to favor the positive class. This contradiction reflects the theoretical problem discussed in Section 3.

Other Examples: We also found other interesting target-sensitive sentiment expressions like "*large bill*" and "*large portion*", "*small tip*" and "*small portion*" from Restaurant. Notice that TMNs can also improve the neutral sentiment (see Table 3). For instance, TMN generates a sentiment score vector of the context "over" for target aspect *price*: {**0.1373**, 0.0066, -0.1433} (negative) and for target aspect *dinner*: {0.0496, **0.0591**, -0.1128} (neutral) accurately. But MN produces both negative scores {**0.0069**, 0.0025, -0.0090} (negative) and {**0.0078**, 0.0028, -0.0102} (negative) for the two different targets. The latter one in MN is incorrect.

7 Conclusion and Future Work

In this paper, we first introduced the target-sensitive sentiment problem in ASC. After that, we discussed the basic memory network for ASC and analyzed the reason why it is incapable of capturing such sentiment from a theoretical perspective. We then presented six techniques to construct target-sensitive memory networks. Finally, we reported the experimental results quantitatively and qualitatively to show their effectiveness.

Since ASC is a fine-grained and complex task, there are many other directions that can be further explored, like handling sentiment negation, better embedding for multi-word phrase, analyzing sentiment composition, and learning better attention. We believe all these can help improve the ASC task. The work presented in this paper lies in the direction of addressing target-sensitive sentiment, and we have demonstrated the usefulness of capturing this signal. We believe that there will be more effective solutions coming in the near future.

Identifying Transferable Information Across Domains for Cross-domain Sentiment Classification

Raksha Sharma[1], Pushpak Bhattacharyya[1], Sandipan Dandapat[2] and Himanshu Sharad Bhatt[3]

Abstract

Getting manually labeled data in each domain is always an expensive and a time consuming task. Cross-domain sentiment analysis has emerged as a demanding concept where a labeled source domain facilitates a sentiment classifier for an unlabeled target domain. However, polarity orientation (positive or negative) and the significance of a word to express an opinion often differ from one domain to another domain. Owing to these differences, cross-domain sentiment classification is still a challenging task. In this paper, we propose that words that do not change their polarity and significance represent the transferable (usable) information across domains for cross-domain sentiment classification. We present a novel approach based on χ^2 test and cosine-similarity between context vector of words to identify polarity preserving significant words across domains. Furthermore, we show that a weighted ensemble of the classifiers enhances the cross-domain classification performance.

1 Introduction

The choice of the words to express an opinion depends on the domain as users often use domain-specific words (Qiu et al., 2009; Sharma and Bhattacharyya, 2015). For example, *entertaining* and *boring* are frequently used in the movie domain to express an opinion; however, finding these words in the electronics domain is rare. Moreover, there are words which are likely to be used across domains in the same proportion, but may change their polarity orientation from one domain to another (Choi et al., 2009). For example, a word like *unpredictable* is positive in the movie domain (*unpredictable plot*), but negative in the automobile domain (*unpredictable steering*). Such a *polarity changing* word should be assigned positive orientation in the movie domain and negative orientation in the automobile domain.[1] Due to these differences across domains, a supervised algorithm trained on a labeled source domain, does not generalize well on an unlabeled target domain and the cross-domain performance degrades.

Generally, supervised learning algorithms have to be re-trained from scratch on every new domain using the manually annotated review corpus (Pang et al., 2002; Kanayama and Nasukawa, 2006; Pang and Lee, 2008; Esuli and Sebastiani, 2005; Breck et al., 2007; Li et al., 2009; Prabowo and Thelwall, 2009; Taboada et al., 2011; Cambria et al., 2013; Rosenthal et al., 2014). This is not practical as there are numerous domains and getting manually annotated data for every new domain is an expensive and time consuming task (Bhattacharyya, 2015). On the other hand, domain adaptation techniques work in contrast to traditional supervised techniques on the principle of transferring learned knowledge across domains (Blitzer et al., 2007; Pan et al., 2010; Bhatt et al., 2015). The existing transfer learning based domain adaptation algorithms for cross-domain classification have generally been proven useful in reducing the labeled data requirement, but they do not consider words like *unpredictable* that change polarity orientation across domains. Transfer (reuse) of changing polarity words affects the cross-domain performance negatively. Therefore, one cannot use transfer learning as the proverbial hammer, rather one needs to gauge what to transfer from the source domain to the target domain.

In this paper, we propose that the words which

[1]The word 'unpredictable' is a classic example of changing (inconsistent) polarity across domains (Turney, 2002; Fahrni and Klenner, 2008).

are equally significant with a consistent polarity across domains represent the usable information for cross-domain sentiment analysis. χ^2 is a popularly used and reliable statistical test to identify significance and polarity of a word in an annotated corpus (Oakes et al., 2001; Al-Harbi et al., 2008; Cheng and Zhulyn, 2012; Sharma and Bhattacharyya, 2013). However, for an unlabeled corpus no such statistical technique is applicable. Therefore, identification of words which are significant with a consistent polarity across domains is a non-trivial task. In this paper, we present a novel technique based on χ^2 test and cosine-similarity between context vector of words to identify Significant Consistent Polarity (SCP) words across domains.[2] The major contribution of this research is as follows.

1. *Extracting significant consistent polarity words across domains*: A technique which exploits cosine-similarity between context vector of words and χ^2 test is used to identify SCP words across labeled source and unlabeled target domains.

2. *An ensemble-based adaptation algorithm*: A classifier (C_s) trained on SCP words in the labeled source domain acts as a seed to initiate a classifier (C_t) on the target specific features. These classifiers are then combined in a weighted ensemble to further enhance the cross-domain classification performance.

Our results show that our approach gives a statistically significant improvement over Structured Correspondence Learning (SCL) (Bhatt et al., 2015) and common unigrams in identification of transferable words, which eventually facilitates a more accurate sentiment classifier in the target domain. The road-map for rest of the paper is as follows. Section 2 describes the related work. Section 3 describes the extraction of the SCP and the ensemble-based adaptation algorithm. Section 4 elaborates the dataset and the experimental protocol. Section 5 presents the results and section 6 reports the error analysis. Section 7 concludes the paper.[3]

[2]SCP words are words which are significant in both the domains with consistent polarity orientation.

[3]Majority of this work is done at Conduent Labs India till February 2016.

2 Related Work

The most significant efforts in the learning of transferable knowledge for cross-domain text classification are Structured Correspondence Learning (SCL) (Blitzer et al., 2007) and Structured Feature Alignment (SFA) (Pan et al., 2010). SCL aims to learn the co-occurrence between features from the two domains. It starts with learning pivot features that occur frequently in both the domains. It models correlation between pivots and all other features by training linear predictors to predict presence of pivot features in the unlabeled target domain data. SCL has shown significant improvement over a baseline (shift-unaware) model. SFA uses some domain-independent words as a bridge to construct a bipartite graph to model the co-occurrence relationship between domain-specific words and domain-independent words. Our approach also exploits the concept of co-occurrence (Pan et al., 2010), but we measure the co-occurrence in terms of similarity between context vector of words, unlike SCL and SFA, which literally look for the co-occurrence of words in the corpus. The use of context vector of words in place of words helps to overcome the data sparsity problem (Sharma et al., 2015).

Domain adaptation for sentiment classification has been explored by many researchers (Jiang and Zhai, 2007; Ji et al., 2011; Saha et al., 2011; Glorot et al., 2011; Xia et al., 2013; Zhou et al., 2014; Bhatt et al., 2015). Most of the works have focused on learning a shared low dimensional representation of features that can be generalized across different domains. However, none of the approaches explicitly analyses significance and polarity of words across domains. On the other hand, Glorot et al., (2011) proposed a deep learning approach which learns to extract a meaningful representation for each review in an unsupervised fashion. Zhou et al., (2014) also proposed a deep learning approach to learn a feature mapping between cross-domain heterogeneous features as well as a better feature representation for mapped data to reduce the bias issue caused by the cross-domain correspondences. Though deep learning based approaches perform reasonably good, they don't perform explicit identification and visualization of transferable features across domains unlike SFA and SCL, which output a set of words as transferable (reusable) features. Our approach explicitly determines the words which are equally significant with a consistent polarity across source and target domains. Our results show that the use of SCP words as features identified by our approach leads to a more accurate cross-domain sentiment classifier in the unlabeled target domain.

3 Approach: Cross-domain Sentiment Classification

The proposed approach identifies words which are equally significant for sentiment classification with a consistent polarity across source and target domains. These Significant Consistent Polarity (SCP) words make a set of transferable knowledge from the labeled source domain to the unlabeled target domain for cross-domain sentiment analysis. The algorithm further adapts to the unlabeled target domain by learning target domain specific features. The following sections elaborate SCP features extraction (3.1) and the ensemble-based cross-domain adaptation algorithm (3.2).

3.1 Extracting SCP Features

The words which are not significant for classification in the labeled source domain, do not transfer useful knowledge to the target domain through a supervised classifier trained in the source domain. Moreover, words that are significant in both the domains, but have different polarity orientation transfer the wrong information to the target domain through a supervised classifier trained in the labeled source domain, which also downgrade the cross-domain performance.

Our algorithm identifies the significance and the polarity of all the words individually in their respective domains. Then the words which are significant in both the domains with the consistent polarity orientation are used to initiate the cross-domain adaptation algorithm. The following sections elaborate how the significance and the polarity of the words are obtained in the labeled source and the unlabeled target domains.

3.1.1 Extracting Significant Words with the Polarity Orientation from the Labeled Source Domain

Since we have a polarity annotated dataset in the source domain, a statistical test like χ^2 test can be applied to find the significance of a word in the corpus for sentiment classification (Cheng and Zhulyn, 2012; Zheng et al., 2004). We have used *goodness of fit chi*^{2} *test* with equal number of reviews in positive and negative corpora. This test is generally used to determine whether sample data is consistent with a null hypothesis.[4] Here, the null hypothesis is that the word is equally used in the positive and the negative corpora. The χ^2 test is formulated as follows:

$$\chi^2(w) = ((c_p^w - \mu^w)^2 + (c_n^w - \mu^w)^2)/\mu^w \quad (1)$$

Where, c_p^w is the observed count of a word w in the positive documents and c_n^w is the observed count in the negative documents. μ^w represents an average of the word's count in the positive and the negative documents. Here, μ^w is the expected count or the value of the null-hypothesis. There is an inverse relation between χ^2 value and the p-value which is probability of the data given null hypothesis is true. In such a case where a word results in a p-value smaller than the critical p-value (0.05), we reject the null-hypothesis. Consequently, we assume that the word w belongs to a particular class (positive or negative) in the data, hence it is a significant word for classification (Sharma and Bhattacharyya, 2013).

Polarity of Words in the Labeled Source Domain: Chi-square test substantiates the statistically significant association of a word with a class label. Based on this association we assign a polarity orientation to a word in the domain. In other words, if a word is found significant by χ^2 test, then the exact class of the word is determined by comparing c_p^w and c_n^w. For instance, if c_p^w is higher than c_n^w, then the word is *positive*, else *negative*.

3.1.2 Extracting Significant Words with the Polarity Orientation from the Unlabeled Target Domain

Target domain data is unlabeled and hence, χ^2 test cannot be used to find significance of the words. However, to obtain SCP words across domains, we take advantage of the fact that we have to identify significance of only those words in the target domain which are already proven to be significant in the source domain. We presume that a word which is significant in the source domain as per χ^2 test and occurs with a frequency greater than a certain threshold (θ) in the target domain is significant in the target domain also.

$$count_t(significant_s(\mathrm{w})) > \theta \Rightarrow significant_t(\mathrm{w}) \quad (2)$$

[4]http://stattrek.com/chi-square-test/goodness-of-fit.aspx?Tutorial=AP.

Equation (2) formulates the significance test in the unlabeled target (t) domain. Here, function $significant_s$ assures the significance of the word w in the labeled source (s) domain and $count_t$ gives the normalized count of the w in t.[5] χ^2 test has one key assumption that the expected value of an observed variable should not be less than 5 to be significant. Considering this assumption as a base, we fix the value of θ as 10.[6]

Polarity of Words in the Unlabeled Target Domain: Generally, in a polar corpus, a positive word occurs more frequently in context of other positive words, while a negative word occurs in context of other negative words (Sharma et al., 2015).[7] Based on this hypothesis, we explore the contextual information of a word that is captured well by its context vector to assign polarity to words in the target domain (Rill et al., 2012; Rong, 2014). Mikolov et al., (2013) showed that similarity between context vector of words in vicinity such as 'go' and 'to' is higher compared to distant words or words that are not in the neighborhood of each other. Here, the observed concept is that if a word is positive, then its context vector learned from the polar review corpus will give higher cosine-similarity with a known positive polarity word in comparison to a known negative polarity word or vice versa. Therefore, based on the cosine-similarity scores we can assign the label of the known polarity word to the unknown polarity word. We term known polarity words as *Positive-pivot* and *Negative-pivot*.

Context Vector Generation: To compute context vector ($conVec$) of a word (w), we have used publicly available word2vec toolkit with the skip-gram model (Mikolov et al., 2013).[8] In this model, each word's Huffman code is used as an input to a log-linear classifier with a continuous projection layer and words within a given window are predicted (Faruqui et al., 2014). We construct a 100 dimensional vector for each candidate word from the unlabeled target domain data. The decision method given in Equation 3 defines the polarity assignment to the unknown polarity words of the target domain. If a word w gives a higher cosine-similarity with the PosPivot (Positive-pivot) than the NegPivot (Negative-pivot), the decision method assigns the positive polarity to the word w, else negative polarity to the word w.

$$\begin{aligned} &\text{If}(cosine(conVec(\text{w}), conVec(\text{PosPivot})) > \\ &\quad cosine(conVec(\text{w}), conVec(\text{NegPivot}))) \\ &\quad \Rightarrow \text{Positive} \\ &\text{If}(cosine(conVec(\text{w}), conVec(\text{PosPivot})) \\ &\quad < cosine(conVec(\text{w}), conVec(\text{NegPivot}))) \\ &\quad \Rightarrow \text{Negative} \end{aligned} \tag{3}$$

Pivot Selection Method: We empirically observed that a polar word which has the highest frequency in the corpus gives more coverage to estimate the polarity orientation of other words while using context vector. Essentially, the frequent occurrence of the word in the corpus allows it to be in context of other words frequently. Therefore a polar word having the *highest frequency* in the target domain is observed to be more accurate as *pivot* for identification of polarity of input words.[9] Table 1 shows the examples of a few words in the electronics domain whose polarity orientation is derived based on the similarity scores obtained with PosPivot and NegPivot words in the electronics domain.

Transferable Knowledge: The proposed algorithm uses the above mentioned techniques to identify the significance and the polarity of words in the labeled source data (cf. Section 3.1.1) and the unlabeled target data (cf. Section 3.1.2). The words which are found significant in both the domains with the same polarity orientation form a set of SCP features for cross-domain sentiment classification. The weights learned for the SCP features in the labeled source domain by the classification algorithm can be reused for sentiment classification in the unlabeled target domain as SCP features have consistent impacts in both the domains.

[5] Normalized count of w in t shows the proportion of occurrences of w in t.

[6] We tried with smaller values of $theta$ also, but they were not found as effective as $theta$ value of 10 for significant words identification.

[7] For example, 'excellent' will be used more often in positive reviews in comparison to negative reviews, hence, it would have more positive words in its context. Likewise, 'terrible' will be used more frequently in negative reviews in comparison to positive reviews, hence, it would have more negative words in its context.

[8] Available at: `https://radimrehurek.com/gensim/models/word2vec.html`

[9] To obtain the highest frequency based pivots, words in the target corpus (unlabeled) were ordered based on their frequency in the corpus, then a few top words were manually observed (by three human annotators) to pick out a positive word and a negative word. The positive and negative polarity of pivots were confirmed manually to get rid of random high frequency words (for example, *function words*). These highest frequency polar words were set as Positive-pivot and Negative-pivot.

Word	Great	Poor	Polarity
Noisy	0.03	**0.24**	Neg
Crap	0.04	**0.28**	Neg
Weak	0.05	**0.21**	Neg
Defective	0.21	**0.70**	Neg
Sturdy	**0.43**	0.04	Pos
Durable	**0.44**	0.00	Pos
Perfect	**0.48**	0.20	Pos
Handy	**0.60**	0.21	Pos

Table 1: Cosine-similarity scores with PosPivot (great) and NegPivot (poor), and inferred polarity orientation of the words.

Symbol	Description
s, t	Represent Source (s) and Target (t) respectively
l, u	Represent labeled and unlabeled respectively
D_s^l, D_t^u	Represent Dataset in s and t domains respectively
V_s, V_t	Vocabularies of words in the s and t respectively
r_s^i,r_t^i	i^{th} review in D_s^l and D_t^u respectively
$sigPol()$	Identifies significant words with their polarity
f	Set of features
SVM	Implemented classification algorithm
C_s	Classifier C_s is trained on D_s^l with SCP as features
R_t^n	Top-n reviews in t as per classification score by C_s
C_t	Classifier C_t is trained on R_n^t
$unigrams()$	Gives bag-of-words
W_s, W_t	Weights for C_s and C_t respectively
WSM	Weighted Sum Model

Table 2: Notations used in the paper

3.2 Ensemble-based Cross-domain Adaptation Algorithm

Apart from the transferable SCP words (Obtained in Section 3.1), each domain has specific discriminating words which can be discovered only from that domain data. The proposed cross-domain adaptation approach (Algorithm 1) attempts to learn such domain specific features from the target domain using a classifier trained on SCP words in the source domain. An ensemble of the classifiers trained on the SCP features (transferred from the source) and domain specific features (learned within the target) further enhances the cross-domain performance. Table 2 lists the notations used in the algorithm. The working of the cross-domain adaptation algorithm is as follows:

1. Identify SCP features from the labeled source and the unlabeled target domain data.

2. A SVM based classifier is trained on SCP words as features using labeled source domain data, named as C_s.

3. The classifier C_s is used to predict the labels for the unlabeled target domain instances D_t^u, and the confidently predicted instances of D_t^u form a set of pseudo labeled instances R_t^n.

4. A SVM based classifier is trained on the pseudo labeled target domain instances R_t^n, using unigrams in R_t^n as features to include the target specific words, this classifier is named as C_t .

5. Finally, a Weighted Sum Model (WSM) of C_s and C_t gives a classifier in the target domain.

The confidence in the prediction of D_t^u is measured in terms of the classification-score of the document, *i.e.*, the distance of the input document from the separating hyper-plane given by the SVM classifier (Hsu et al., 2003). The top n confidently predicted pseudo labeled instances (R_t^n) are used to train classifier C_t, where n depends on a threshold that is empirically set to $|\pm 0.2|$.[10] The classifier C_s trained on the SCP features (transferred knowledge) from the source domain and the classifier C_t trained on self-discovered target specific features from the pseudo labeled target domain instances bring in complementary information from the two domains. Therefore, combining C_s and C_t in a weighted ensemble (WSM) further enhances the cross-domain performance. Algorithm 1 gives the pseudo code of the proposed adaptation approach.

```
Input: $D_s^l = \{r_s^1, r_s^2, r_s^3, ....r_s^j\}$,
       $D_t^u = \{r_t^1, r_t^2, r_t^3, ....r_t^k\}$,
       $V_s = \{w_s^1, w_s^2, w_s^3, ....w_s^p\}$,
       $V_t = \{w_t^1, w_t^2, w_t^3, ....w_t^q\}$
Output: Sentiment Classifier in the Target Domain
1: SCP $= sigPol(D_s^l) \cap sigPol(D_t^u)$
2: $C_s =$ Train-SVM$(D_s^l)$, where $f =$ SCP
3: Predict Label: $C_s(D_t^u) \rightarrow D_t^l$
4: Select: $R_t^n \mid \forall r_t^i \in D_t^u$ , $C_s(r_t^i) > \phi$, where $i \in$
   $\{1, 2....k\}$ and $n <= k$
5: $C_t =$ Train-SVM$(R_t^n)$, where $f = \{unigrams(R_t^n)\}$
6: WSM $= (C_s * W_s + C_t * W_t)/(W_s + W_t)$
7: Sentiment Classifier in the Target Domain $=$ WSM
```

ALGORITHM 1: Building of target domain classifier from the source domain

Weighted Sum Model (WSM): The weighted ensemble of classifiers helps to overcome the er-

[10]Balamurali et al., (2013) have shown that 350 to 400 labeled documents are required to get a high accuracy classifier in a domain using supervised classification techniques, but beyond 400 labeled documents there is not much improvement in the classification accuracy. Hence, threshold on classification score is set such that it can give a sufficient number of documents for supervised classification. Threshold $|\pm 0.2|$ gives documents between 350 to 400.

rors produced by the individual classifier. The formulation of WSM is given in step-6 of the Algorithm 1. If C_s has wrongly predicted a document at boundary point and C_t has predicted the same document confidently, then weighted sum of C_s and C_t predicts the document correctly or vice versa. For example, a document is classified by C_s as negative (wrong prediction) with a classification-score of -0.07, while the same document is classified by C_t as positive (correct prediction) with a classification-score of 0.33, the WSM of C_s and C_t will classify the document as *positive* with a classification-score of 0.12 (Equation 4).

$$WSM = \frac{(-0.07 * 0.765 + 0.33 * 0.712)}{(0.765 + 0.712)} = 0.12 \tag{4}$$

Here 0.765 and 0.712 are the weights W_s and W_t to the classifiers C_s and C_t respectively.

Weights to the Classifiers in WSM: The weights W_s and W_t are the classification accuracies obtained by C_s and C_t respectively on the cross-validation data from the target domain. The weights W_s and W_t allow C_s and C_t to participate in the WSM in proportion of their accuracy on the cross-validation data. This restriction facilitates the domination of the classifier which is more accurate.

4 Dataset & Experimental Protocol

In this paper, we show comparison between SCP-based domain adaptation (our approach) and SCL-based domain adaptation approach proposed by Bhatt el al. (2015) using four domains, *viz.,* Electronics (E), Kitchen (K), Books (B), and DVD.[11] We use SVM algorithm with linear kernel (Tong and Koller, 2002) to train a classifier in all the mentioned classification systems in the paper. To implement SVM algorithm, we have used the publicly available Python based Scikit-learn package (Pedregosa et al., 2011).[12] Data in each domain is divided into three parts, *viz.,* train (60%), validation (20%) and test (20%). The SCP words are extracted from the training data. The weights W_S and W_t for the source and target classifiers are essentially accuracies obtained by C_s and C_t respectively on validation dataset from the *target domain*. We report the accuracy for all the systems on the test data. Table 3 shows the statistics of the dataset.

Domain	No. of Reviews	Avg. Length
Electronic (E)	2000	110 words
Kitchen (K)	2000	93 words
Books (B)	2000	173 words
DVD (D)	2000	197 words

Table 3: Dataset statistics

5 Results

In this paper, we compare our approach with Structured Correspondence Learning (SCL) and common unigrams. SCL is used by Bhatt et al., (2015) for identification of transferable information from the labeled source domain to the unlabeled target domain for cross-domain sentiment analysis. They showed that transferable features extracted by SCL provide a better cross-domain sentiment analysis system than the transferable features extracted by Structured Feature Alignment (Pan et al., 2010). The SCL-based sentiment classifier in the target domain proposed by Bhatt et. al., (2015) is state-of-the-art for cross-domain sentiment analysis. On the other hand, common unigrams of the source and target are the most visible transferable information.[13]

Gold standard SCP words: Chi-square test gives us significance and polarity of the word in the corpus by taking into account the polarity labels of the reviews. Application of chi-square test in both the domains, considering that the target domain is also labeled, gives us gold standard SCP words. There is no manual annotation involved.

F-score for SCP Words Identification Task: The set of SCP words represent the usable information across domains for cross-domain classification, hence we compare the F-score for the SCP words identification task obtained with our approach, SCL and common-unigrams in Figure 1. It demonstrates that our approach gives a huge improvement in the F-score over SCL and common unigrams for all the 12 pairs of the source and target domains. To measure the statistical significance of this improvement, we applied t-test on the F-score distribution obtained with our approach, SCL and common unigrams. t-test is a

[11]The same multi-domain dataset is used by Bhatt et al. (2015), available at: `http://www.cs.jhu.edu/~mdredze/datasets/sentiment/index2.html`.

[12]Available at: `http://scikit-learn.org/stable/modules/svm.html`.

[13]Common unigrams is a set of unique words which appear in both the domains.

statistical significance test. It is used to determine whether two sets of data are significantly different or not.[14] Our approach performs significantly better than SCL and common unigrams, while SCL performs better than common unigrams as per t-test.

Comparison among C_s, C_t and WSM: Table 4 shows the comparison among classifiers obtained in the target domain using SCP given by our approach, SCL, common-unigrams, and gold standard SCP for electronics as the source and movie as the target domains. Since electronics and movie are two very dissimilar domains in terms of domain specific words, unlike, books and movie, getting a high accuracy classifier in the movie domain from the electronics domain is a challenging task (Pang et al., 2002). Therefore, in Table 4 results are reported with electronics as the source domain and movie as the target domain.[15] In all four cases, there is difference in the transferred information from the source to the target, but the ensemble-based classification algorithm (Section 3.2) is the same. Table 4 depicts sentiment classification accuracy obtained with C_s, C_t and WSM. The weights W_s and W_t in WSM are normalized accuracies by C_s and C_t respectively on the validation set from the target domain. The fourth column (size) represents the feature set size. We observed that WSM gives the highest accuracy, which validates our assumption that a weighted sum of two classifiers is better than the performance of individual classifiers. The WSM accuracy obtained with SCP words given by our approach is comparable to the accuracy obtained with gold standard SCP words.

The motivation of this research is to learn shared representation cognizant of significant and polarity changing words across domains. Hence, we report cross-domain classification accuracy obtained with three different types of shared representations (transferable knowledge), *viz.*, common-unigrams, SCL and our approach.[16] System-1, system-2 and system-3 in Table 5 show the final cross-domain sentiment classification accuracy obtained with WSM in the target domain for 12 pairs of source and target using common-unigrams, SCL and our approach respectively.

	W_s & W_t	**Features**	**Size**	**Acc**
C_s		SCP (Our approach)	296	75.0
C_t		Unigrams	4751	74.3
WSM	0.72 & 0.69	-	-	**77.5**
C_s		SCL	1000	66.8
C_t		Unigrams	4615	68.0
WSM	0.63 & 0.61	-	-	**69.3**
C_s		Common-Unigrams	2236	64.0
C_t		Unigrams	4236	64.0
WSM	0.62 & 0.58	-	-	**65**
C_s		SCP (Gold standard)	163	77.0
C_t		Unigrams	1183	78.5
WSM	0.73 & 0.75	-	-	**80.0**

Table 4: Classification accuracy in % given by C_s, C_t and WSM with different feature sets for electronics as source and movie as target.

System-1: This system considers common-unigrams of both the domains as shared representation. **System-2:** It differs from system-1 in the shared representation, which is learned using Structured Correspondence Learning (SCL) (Bhatt et al., 2015) to initiate the process. **System-3:** This system implements the proposed domain adaptation algorithm. Here, the shared representation is the *SCP words* and the ensemble-based domain adaptation algorithm (Section 3.2) gives the final classifier in the target domain. Table 5 depicts that the system-3 is better than system-1 and system-2 for all pairs, except K to B and B to D. For these two pairs, system-2 performs better than system-3, though the difference in accuracy is very low (below 1%).

To enhance the final accuracy in the target domain, Bhatt et al., (2015) performed iterations over the pseudo labeled target domain instances (R_t^n). In each iteration, they obtained a new C_t trained on increased number of pseudo labeled documents. This process is repeated till all the training instances of the target domain are considered. The C_t obtained in the last iteration makes WSM with C_s which is trained on the transferable features given by SCL. Bhatt et al., (2015) have shown that iteration-based domain adaptation technique is more effective than one-shot

[14] The detail about the test is available at: `http://www.socialresearchmethods.net/kb/stat_t.php`.

[15] The movie review dataset is a balanced corpus of 2000 reviews. Available at: `http://www.cs.cornell.edu/people/pabo/movie-review-data/`

[16] The reported accuracy is the ratio of correctly predicted documents to that of the total number of documents in the test dataset.

adaptation approaches. **System-4, system-5**, and **system-6** in Table 5 incorporate the iterative process into **system-1, system-2,** and **system-3** respectively. We observed the same trend after the inclusion of the iterative process also, as the SCP-based system-6 performed the best in all 12 cases. On the other hand, SCL-based system-5 performs better than the common-unigrams based system-4. Table 7 shows the results of significance test (t-test) performed on the accuracy distributions produced by the six different systems. The noticeable point is that the iterations over SCL (system-5) and our approach (system-6) narrow down the difference in the accuracy between system-2 and system-3 as system-2 and system-3 have a statistically significant difference in accuracy with the p-value of 0.039 (Row-4 of Table 7), but the difference between system-5 and system-6 is not statistically significant. Essentially, system-3 does not give much improvement with iterations, unlike system-2. In other words, addition of the iterative process with the shared representation given by SCL overcomes the errors introduced by SCL. On the other hand, SCP given by our approach were able to produce a less erroneous system in one-shot. Table 6 shows the in-domain sentiment classification accuracy obtained with unigrams and significant words as features considering labeled data in the domain. System-6 tries to equalize the in-domain accuracy obtained with unigrams.

	P-value	Significant?
sys1 *vs* sys2	0.719	No
sys1 *vs* sys3	0.011	**Yes**
sys2 *vs* sys3	0.039	**Yes**
sys1 *vs* sys4	0.219	No
sys2 *vs* sys4	0.467	No
sys3 *vs* sys4	0.090	No
sys1 *vs* sys5	0	**Yes**
sys2 *vs* sys5	0	**Yes**
sys3 *vs* sys5	0.101	No
sys4 *vs* sys5	0	**Yes**
sys1 *vs* sys6	0	**Yes**
sys2 *vs* sys6	0	**Yes**
sys3 *vs* sys6	0.0130	**Yes**
sys4 *vs* sys6	0	**Yes**
sys5 *vs* sys6	0.231	No

Table 7: t-test (α = 0.05) results on the difference in accuracy produced by various systems (cf. Table 5).

To validate our assertion that polarity preserving significant words (SCP) across source and target domains make a less erroneous set of transferable knowledge from the source domain to the target domain, we computed Pearson product-moment correlation between F-score obtained for our approach (cf. Figure 1) and cross-domain accuracy obtained with SCP (System-3, cf. Table 5). We observed a *strong positive correlation* (r) of 0.78 between F-score and cross-domain accuracy. Essentially, an accurate set of SCP words positively stimulates an improved classifier in the unlabeled target domain.

6 Error Analysis

The pairs of domains which share a greater number of domain-specific words, result in a higher accuracy cross-domain classifier. For example, Electronics (E) and Kitchen (K) domains share many domain-specific words, hence pairing of such similar domains as the source and the target results into a higher accuracy classifier in the target domain. Table 5 shows that K→E outperforms B→E and D→E, and E→K outperforms B→K and D→K. On the other hand, DVD (D) and electronics are two very different domains unlike electronics and Kitchen, or DVD and books. The DVD dataset contains reviews about the music albums. This difference in types of reviews makes them to share less number of words. Table 8 shows the percent (%) of common words among the 4 domains. The percent of common unique words are common unique words divided by the summation of unique words in the domains individually.

E - D	E - K	E - B	D - K	D - B	K - B
15	22	17	14	22	17

Table 8: Common unique words between the domains in percent (%).

7 Conclusion

In this paper, we proposed that the Significant Consistent Polarity (SCP) words represent the transferable information from the labeled source domain to the unlabeled target domain for cross-domain sentiment classification. We showed a strong *positive correlation of* 0.78 *between the SCP words identified by our approach and the sentiment classification accuracy achieved in the unlabeled target domain*. Essentially, a set of less erroneous transferable features leads to a more accurate classification system in the unlabeled target domain. We have presented a technique based on χ^2 test and cosine-similarity between context vector of words to identify SCP words. Results show that the SCP words given by our approach represent more accurate transferable information in comparison to the Structured Correspondence Learning (SCL) algorithm and common-unigrams. Furthermore, we show that an ensemble of the classifiers trained on the SCP features and target specific features overcomes the errors of the individual classifiers.

Abstract

The goal of sentiment-to-sentiment "translation" is to change the underlying sentiment of a sentence while keeping its content. The main challenge is the lack of parallel data. To solve this problem, we propose a cycled reinforcement learning method that enables training on unpaired data by collaboration between a neutralization module and an emotionalization module. We evaluate our approach on two review datasets, Yelp and Amazon. Experimental results show that our approach significantly outperforms the state-of-the-art systems. Especially, the proposed method substantially improves the content preservation performance. The BLEU score is improved from 1.64 to 22.46 and from 0.56 to 14.06 on the two datasets, respectively.[1]

1 Introduction

Sentiment-to-sentiment "translation" requires the system to change the underlying sentiment of a sentence while preserving its non-emotional semantic content as much as possible. It can be regarded as a special style transfer task that is important in Natural Language Processing (NLP) (Hu et al., 2017; Shen et al., 2017; Fu et al., 2018). It has broad applications, including review sentiment transformation, news rewriting, etc. Yet the lack of parallel training data poses a great obstacle to a satisfactory performance.

Recently, several related studies for language style transfer (Hu et al., 2017; Shen et al., 2017) have been proposed. However, when applied to the sentiment-to-sentiment "translation" task, most existing studies only change the underlying sentiment and fail in keeping the semantic content. For example, given "The food is delicious" as the source input, the model generates "What a bad movie" as the output. Although the sentiment is successfully transformed from positive to negative, the output text focuses on a different topic. The reason is that these methods attempt to implicitly separate the emotional information from the semantic information in the same dense hidden vector, where all information is mixed together in an uninterpretable way. Due to the lack of supervised parallel data, it is hard to only modify the underlying sentiment without any loss of the non-emotional semantic information.

To tackle the problem of lacking parallel data, we propose a cycled reinforcement learning approach that contains two parts: a neutralization module and an emotionalization module. The neutralization module is responsible for extracting non-emotional semantic information by explicitly filtering out emotional words. The advantage is that only emotional words are removed, which does not affect the preservation of non-emotional words. The emotionalization module is responsible for adding sentiment to the neutralized semantic content for sentiment-to-sentiment translation.

In cycled training, given an emotional sentence with sentiment s, we first neutralize it to the non-emotional semantic content, and then force the emotionalization module to reconstruct the original sentence by adding the sentiment s. Therefore, the emotionalization module is taught to add sentiment to the semantic context in a supervised way. By adding opposite sentiment, we can achieve the goal of sentiment-to-sentiment translation. Because of the discrete choice of neutral words, the gradient is no longer differentiable over the neutralization module. Thus, we use policy gradient,

*Equal Contribution.

[1]The released code can be found in https://github.com/lancopku/unpaired-sentiment-translation

one of the reinforcement learning methods, to reward the output of the neutralization module based on the feedback from the emotionalization module. We add different sentiment to the semantic content and use the quality of the generated text as reward. The quality is evaluated by two useful metrics: one for identifying whether the generated text matches the target sentiment; one for evaluating the content preservation performance. The reward guides the neutralization module to better identify non-emotional words. In return, the improved neutralization module further enhances the emotionalization module.

Our contributions are concluded as follows:

- For sentiment-to-sentiment translation, we propose a cycled reinforcement learning approach. It enables training with unpaired data, in which only reviews and sentiment labels are available.
- Our approach tackles the bottleneck of keeping semantic information by explicitly separating sentiment information from semantic content.
- Experimental results show that our approach significantly outperforms the state-of-the-art systems, especially in content preservation.

2 Related Work

Style transfer in computer vision has been studied (Johnson et al., 2016; Gatys et al., 2016; Liao et al., 2017; Li et al., 2017; Zhu et al., 2017). The main idea is to learn the mapping between two image domains by capturing shared representations or correspondences of higher-level structures.

There have been some studies on unpaired language style transfer recently. Hu et al. (2017) propose a new neural generative model that combines variational auto-encoders (VAEs) and holistic attribute discriminators for effective imposition of style semantic structures. Fu et al. (2018) propose to use an adversarial network to make sure that the input content does not have style information. Shen et al. (2017) focus on separating the underlying content from style information. They learn an encoder that maps the original sentence to style-independent content and a style-dependent decoder for rendering. However, their evaluations only consider the transferred style accuracy. We argue that content preservation is also an indispensable evaluation metric. However, when applied to the sentiment-to-sentiment translation task, the previously mentioned models share the same problem. They have the poor preservation of non-emotional semantic content.

In this paper, we propose a cycled reinforcement learning method to improve sentiment-to-sentiment translation in the absence of parallel data. The key idea is to build supervised training pairs by reconstructing the original sentence. A related study is "back reconstruction" in machine translation (He et al., 2016; Tu et al., 2017). They couple two inverse tasks: one is for translating a sentence in language A to a sentence in language B; the other is for translating a sentence in language B to a sentence in language A. Different from the previous work, we do not introduce the inverse task, but use collaboration between the neutralization module and the emotionalization module.

Sentiment analysis is also related to our work (Socher et al., 2011; Pontiki et al., 2015; Rosenthal et al., 2017; Chen et al., 2017; Ma et al., 2017, 2018b). The task usually involves detecting whether a piece of text expresses positive, negative, or neutral sentiment. The sentiment can be general or about a specific topic.

3 Cycled Reinforcement Learning for Unpaired Sentiment-to-Sentiment Translation

In this section, we introduce our proposed method. An overview is presented in Section 3.1. The details of the neutralization module and the emotionalization module are shown in Section 3.2 and Section 3.3. The cycled reinforcement learning mechanism is introduced in Section 3.4.

3.1 Overview

The proposed approach contains two modules: a neutralization module and an emotionalization module, as shown in Figure 1. The neutralization module first extracts non-emotional semantic content, and then the emotionalization module attaches sentiment to the semantic content. Two modules are trained by the proposed cycled reinforcement learning method. The proposed method requires the two modules to have initial learning ability. Therefore, we propose a novel pre-training method, which uses a self-attention based sentiment classifier (SASC). A sketch of cycled reinforcement learning is shown in Algorithm 1. The

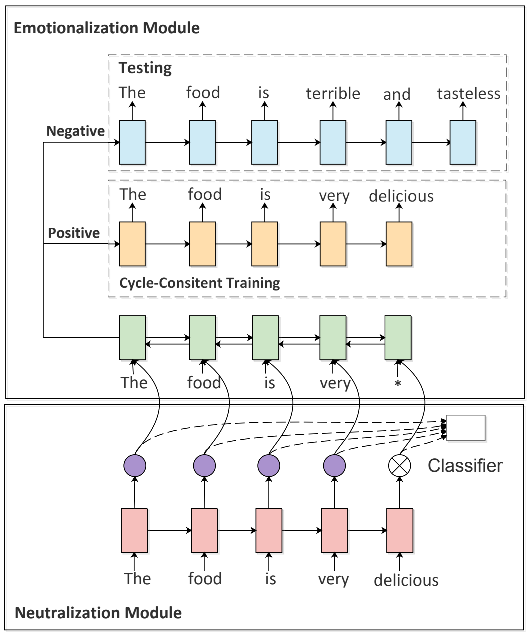

Figure 1: An illustration of the two modules. Lower: The neutralization module removes emotional words and extracts non-emotional semantic information. Upper: The emotionalization module adds sentiment to the semantic content. The proposed self-attention based sentiment classifier is used to guide the pre-training.

details are introduced as follows.

3.2 Neutralization Module

The neutralization module N_θ is used for explicitly filtering out emotional information. In this paper, we consider this process as an extraction problem. The neutralization module first identifies non-emotional words and then feeds them into the emotionalization module. We use a single Long-short Term Memory Network (LSTM) to generate the probability of being neutral or being polar for every word in a sentence. Given an emotional input sequence $\boldsymbol{x} = (x_1, x_2, \ldots, x_T)$ of T words from Γ, the vocabulary of words, this module is responsible for producing a neutralized sequence.

Since cycled reinforcement learning requires the modules with initial learning ability, we propose a novel pre-training method to teach the neutralization module to identify non-emotional words. We construct a self-attention based sentiment classifier and use the learned attention weight as the supervisory signal. The motivation comes from the fact that, in a well-trained sentiment classification model, the attention weight reflects the sentiment contribution of each word to

Algorithm 1 The cycled reinforcement learning method for training the neutralization module N_θ and the emotionalization module E_ϕ.

```
 1: Initialize the neutralization module $N_\theta$, the emotionalization module $E_\phi$ with random weights $\theta$, $\phi$
 2: Pre-train $N_\theta$ using MLE based on Eq. 6
 3: Pre-train $E_\phi$ using MLE based on Eq. 7
 4: for each iteration $i = 1, 2, ..., M$ do
 5:     Sample a sequence $\boldsymbol{x}$ with sentiment $s$ from $X$
 6:     Generate a neutralized sequence $\hat{\boldsymbol{x}}$ based on $N_\theta$
 7:     Given $\hat{\boldsymbol{x}}$ and $s$, generate an output based on $E_\phi$
 8:     Compute the gradient of $E_\phi$ based on Eq. 8
 9:     Compute the reward $R_1$ based on Eq. 11
10:     $\bar{s}$ = the opposite sentiment
11:     Given $\hat{\boldsymbol{x}}$ and $\bar{s}$, generate an output based on $E_\phi$
12:     Compute the reward $R_2$ based on Eq. 11
13:     Compute the combined reward $R_c$ based on Eq. 10
14:     Compute the gradient of $N_\theta$ based on Eq. 9
15:     Update model parameters $\theta$, $\phi$
16: end for
```

some extent. Emotional words tend to get higher attention weights while neutral words usually get lower weights. The details of sentiment classifier are described as follows.

Given an input sequence $\boldsymbol{x}$, a sentiment label y is produced as

$$y = softmax(W \cdot \boldsymbol{c}) \tag{1}$$

where W is a parameter. The term $\boldsymbol{c}$ is computed as a weighted sum of hidden vectors:

$$\boldsymbol{c} = \sum_{i=0}^{T} \alpha_i \boldsymbol{h}_i \tag{2}$$

where α_i is the weight of h_i. The term $\boldsymbol{h}_i$ is the output of LSTM at the i-th word. The term α_i is computed as

$$\alpha_i = \frac{\exp(e_i)}{\sum_{i=0}^{T} \exp(e_i)} \tag{3}$$

where $e_i = f(\boldsymbol{h}_i, \boldsymbol{h}_T)$ is an alignment model. We consider the last hidden state $\boldsymbol{h}_T$ as the context vector, which contains all information of an input sequence. The term e_i evaluates the contribution of each word for sentiment classification.

Our experimental results show that the proposed sentiment classifier achieves the accuracy of 89% and 90% on two datasets. With high classification accuracy, the attention weight produced by the classifier is considered to adequately capture the sentiment information of each word.

To extract non-emotional words based on continuous attention weights, we map attention weights to discrete values, 0 and 1. Since the discrete method is not the key part is this paper, we only use the following method for simplification.

We first calculate the averaged attention value in a sentence as

$$\bar{\alpha} = \frac{1}{T}\sum_{i=0}^{T}\alpha_i \tag{4}$$

where $\bar{\alpha}$ is used as the threshold to distinguish non-emotional words from emotional words. The discrete attention weight is calculated as

$$\hat{\alpha_i} = \begin{cases} 1, & \text{if } \alpha_i \leq \bar{\alpha} \\ 0, & \text{if } \alpha_i > \bar{\alpha} \end{cases} \tag{5}$$

where $\hat{\alpha_i}$ is treated as the identifier.

For pre-training the neutralization module, we build the training pair of input text $\boldsymbol{x}$ and a discrete attention weight sequence $\hat{\boldsymbol{\alpha}}$. The cross entropy loss is computed as

$$L_\theta = -\sum_{i=1}^{T} P_{N_\theta}(\hat{\alpha_i}|x_i) \tag{6}$$

3.3 Emotionalization Module

The emotionalization module E_ϕ is responsible for adding sentiment to the neutralized semantic content. In our work, we use a bi-decoder based encoder-decoder framework, which contains one encoder and two decoders. One decoder adds the positive sentiment and the other adds the negative sentiment. The input sentiment signal determines which decoder to use. Specifically, we use the seq2seq model (Sutskever et al., 2014) for implementation. Both the encoder and decoder are LSTM networks. The encoder learns to compress the semantic content into a dense vector. The decoder learns to add sentiment based on the dense vector. Given the neutralized semantic content and the target sentiment, this module is responsible for producing an emotional sequence.

For pre-training the emotionalization module, we first generate a neutralized input sequence $\hat{\boldsymbol{x}}$ by removing emotional words identified by the proposed sentiment classifier. Given the training pair of a neutralized sequence $\hat{\boldsymbol{x}}$ and an original sentence $\boldsymbol{x}$ with sentiment s, the cross entropy loss is computed as

$$L_\phi = -\sum_{i=1}^{T} P_{E_\phi}(x_i|\hat{x}_i, s) \tag{7}$$

where a positive example goes through the positive decoder and a negative example goes through the negative decoder.

We also explore a simpler method for pre-training the emotionalization module, which uses the product between a continuous vector $1 - \boldsymbol{\alpha}$ and a word embedding sequence as the neutralized content where $\boldsymbol{\alpha}$ represents an attention weight sequence. Experimental results show that this method achieves much lower results than explicitly removing emotional words based on discrete attention weights. Thus, we do not choose this method in our work.

3.4 Cycled Reinforcement Learning

Two modules are trained by the proposed cycled method. The neutralization module first neutralizes an emotional input to semantic content and then the emotionalization module is forced to reconstruct the original sentence based on the source sentiment and the semantic content. Therefore, the emotionalization module is taught to add sentiment to the semantic content in a supervised way. Because of the discrete choice of neutral words, the loss is no longer differentiable over the neutralization module. Therefore, we formulate it as a reinforcement learning problem and use policy gradient to train the neutralization module. The detailed training process is shown as follows.

We refer the neutralization module N_θ as the first agent and the emotionalization module E_ϕ as the second one. Given a sentence $\boldsymbol{x}$ associated with sentiment s, the term $\hat{\boldsymbol{x}}$ represents the middle neutralized context extracted by $\hat{\boldsymbol{\alpha}}$, which is generated by $P_{N_\theta}(\hat{\boldsymbol{\alpha}}|\boldsymbol{x})$.

In cycled training, the original sentence can be viewed as the supervision for training the second agent. Thus, the gradient for the second agent is

$$\nabla_\phi J(\phi) = \nabla_\phi \log(P_{E_\phi}(\boldsymbol{x}|\hat{\boldsymbol{x}}, s)) \tag{8}$$

We denote $\bar{\boldsymbol{x}}$ as the output generated by $P_{E_\phi}(\bar{\boldsymbol{x}}|\hat{\boldsymbol{x}}, s)$. We also denote $\boldsymbol{y}$ as the output generated by $P_{E_\phi}(\boldsymbol{y}|\hat{\boldsymbol{x}}, \bar{s})$ where $\bar{s}$ represents the opposite sentiment. Given $\bar{\boldsymbol{x}}$ and $\boldsymbol{y}$, we first calculate rewards for training the neutralized module, R_1 and R_2. The details of calculation process will be introduced in Section 3.4.1. Then, we optimize parameters through policy gradient by maximizing the expected reward to train the neutralization module. It guides the neutralization module to identify non-emotional words better. In return, the improved neutralization module further enhances the emotionalization module.

According to the policy gradient theorem (Williams, 1992), the gradient for the first agent is

$$\nabla_\theta J(\theta) = \mathbb{E}[R_c \cdot \nabla_\theta \log(P_{N_\theta}(\hat{\boldsymbol{\alpha}}|\boldsymbol{x}))] \quad (9)$$

where R_c is calculated as

$$R_c = R_1 + R_2 \quad (10)$$

Based on Eq. 8 and Eq. 9, we use the sampling approach to estimate the expected reward. This cycled process is repeated until converge.

3.4.1 Reward

The reward consists of two parts, sentiment confidence and BLEU. Sentiment confidence evaluates whether the generated text matches the target sentiment. We use a pre-trained classifier to make the judgment. Specially, we use the proposed self-attention based sentiment classifier for implementation. The BLEU (Papineni et al., 2002) score is used to measure the content preservation performance. Considering that the reward should encourage the model to improve both metrics, we use the harmonic mean of sentiment confidence and BLEU as reward, which is formulated as

$$R = (1 + \beta^2)\frac{2 \cdot BLEU \cdot Confid}{(\beta^2 \cdot BLEU) + Confid} \quad (11)$$

where β is a harmonic weight.

4 Experiment

In this section, we evaluate our method on two review datasets. We first introduce the datasets, the training details, the baselines, and the evaluation metrics. Then, we compare our approach with the state-of-the-art systems. Finally, we show the experimental results and provide the detailed analysis of the key components.

4.1 Unpaired Datasets

We conduct experiments on two review datasets that contain user ratings associated with each review. Following previous work (Shen et al., 2017), we consider reviews with rating above three as positive reviews and reviews below three as negative reviews. The positive and negative reviews are not paired. Since our approach focuses on sentence-level sentiment-to-sentiment translation where sentiment annotations are provided at the document level, we process the two datasets with the following steps. First, following previous work (Shen et al., 2017), we filter out the reviews that exceed 20 words. Second, we construct text-sentiment pairs by extracting the first sentence in a review associated with its sentiment label, because the first sentence usually expresses the core idea. Finally, we train a sentiment classifier and filter out the text-sentiment pairs with the classifier confidence below 0.8. Specially, we use the proposed self-attention based sentiment classifier for implementation. The details of the processed datasets are introduced as follows.

Yelp Review Dataset (Yelp): This dataset is provided by Yelp Dataset Challenge.[2] The processed Yelp dataset contains 400K, 10K, and 3K pairs for training, validation, and testing, respectively.

Amazon Food Review Dataset (Amazon): This dataset is provided by McAuley and Leskovec (2013). It consists of amounts of food reviews from Amazon.[3] The processed Amazon dataset contains 230K, 10K, and 3K pairs for training, validation, and testing, respectively.

4.2 Training Details

We tune hyper-parameters based on the performance on the validation sets. The self-attention based sentiment classifier is trained for 10 epochs on two datasets. We set β for calculating reward to 0.5, hidden size to 256, embedding size to 128, vocabulary size to 50K, learning rate to 0.6, and batch size to 64. We use the Adagrad (Duchi et al., 2011) optimizer. All of the gradients are clipped when the norm exceeds 2. Before cycled training, the neutralization module and the emotionalization module are pre-trained for 1 and 4 epochs on the yelp dataset, for 3 and 5 epochs on the Amazon dataset.

4.3 Baselines

We compare our proposed method with the following state-of-the-art systems.

Cross-Alignment Auto-Encoder (CAAE): This method is proposed by Shen et al. (2017). They propose a method that uses refined alignment of latent representations in hidden layers to

[2]`https://www.yelp.com/dataset/challenge`

[3]`http://amazon.com`

perform style transfer. We treat this model as a baseline and adapt it by using the released code.

Multi-Decoder with Adversarial Learning (MDAL): This method is proposed by Fu et al. (2018). They use a multi-decoder model with adversarial learning to separate style representations and content representations in hidden layers. We adapt this model by using the released code.

4.4 Evaluation Metrics

We conduct two evaluations in this work, including an automatic evaluation and a human evaluation. The details of evaluation metrics are shown as follows.

4.4.1 Automatic Evaluation

We quantitatively measure sentiment transformation by evaluating the accuracy of generating designated sentiment. For a fair comparison, we do not use the proposed sentiment classification model. Following previous work (Shen et al., 2017; Hu et al., 2017), we instead use a state-of-the-art sentiment classifier (Vieira and Moura, 2017), called TextCNN, to automatically evaluate the transferred sentiment accuracy. TextCNN achieves the accuracy of 89% and 88% on two datasets. Specifically, we generate sentences given sentiment s, and use the pre-trained sentiment classifier to assign sentiment labels to the generated sentences. The accuracy is calculated as the percentage of the predictions that match the sentiment s.

To evaluate the content preservation performance, we use the BLEU score (Papineni et al., 2002) between the transferred sentence and the source sentence as an evaluation metric. BLEU is a widely used metric for text generation tasks, such as machine translation, summarization, etc. The metric compares the automatically produced text with the reference text by computing overlapping lexical n-gram units.

To evaluate the overall performance, we use the geometric mean of ACC and BLEU as an evaluation metric. The G-score is one of the most commonly used “single number” measures in Information Retrieval, Natural Language Processing, and Machine Learning.

4.4.2 Human Evaluation

While the quantitative evaluation provides indication of sentiment transfer quality, it can not evaluate the quality of transferred text accurately. Therefore, we also perform a human evaluation on the test set. We randomly choose 200 items for the human evaluation. Each item contains the transformed sentences generated by different systems given the same source sentence. The items are distributed to annotators who have no knowledge about which system the sentence is from. They are asked to score the transformed text in terms of sentiment and semantic similarity. Sentiment represents whether the sentiment of the source text is transferred correctly. Semantic similarity evaluates the context preservation performance. The score ranges from 1 to 10 (1 is very bad and 10 is very good).

Yelp	ACC	BLEU	G-score
CAAE (Shen et al., 2017)	93.22	1.17	10.44
MDAL (Fu et al., 2018)	85.65	1.64	11.85
Proposed Method	80.00	22.46	**42.38**
Amazon	**ACC**	**BLEU**	**G-score**
CAAE (Shen et al., 2017)	84.19	0.56	6.87
MDAL (Fu et al., 2018)	70.50	0.27	4.36
Proposed Method	70.37	14.06	**31.45**

Table 1: Automatic evaluations of the proposed method and baselines. ACC evaluates sentiment transformation. BLEU evaluates content preservation. G-score is the geometric mean of ACC and BLEU.

4.5 Experimental Results

Automatic evaluation results are shown in Table 1. ACC evaluates sentiment transformation. BLEU evaluates semantic content preservation. G-score represents the geometric mean of ACC and BLEU. CAAE and MDAL achieve much lower BLEU scores, 1.17 and 1.64 on the Yelp dataset, 0.56 and 0.27 on the Amazon dataset. The low BLEU scores indicate the worrying content preservation performance to some extent. Even with the desired sentiment, the irrelevant generated text leads to worse overall performance. In general, these two systems work more like sentiment-aware language models that generate text only based on the target sentiment and neglect the source input. The main reason is that these two systems attempt to separate emotional information from non-emotional content in a hidden layer, where all information is complicatedly mixed together. It is difficult to only modify emotional information without any loss of non-emotional semantic content.

In comparison, our proposed method achieves the best overall performance on the two datasets,

Yelp	Sentiment	Semantic	G-score
CAAE (Shen et al., 2017)	7.67	3.87	5.45
MDAL (Fu et al., 2018)	7.12	3.68	5.12
Proposed Method	6.99	5.08	**5.96**
Amazon	**Sentiment**	**Semantic**	**G-score**
CAAE (Shen et al., 2017)	8.61	3.15	5.21
MDAL (Fu et al., 2018)	7.93	3.22	5.05
Proposed Method	7.92	4.67	**6.08**

Table 2: Human evaluations of the proposed method and baselines. *Sentiment* evaluates sentiment transformation. *Semantic* evaluates content preservation.

demonstrating the ability of learning knowledge from unpaired data. This result is attributed to the improved BLEU score. The BLEU score is largely improved from 1.64 to 22.46 and from 0.56 to 14.06 on the two datasets. The score improvements mainly come from the fact that we separate emotional information from semantic content by explicitly filtering out emotional words. The extracted content is preserved and fed into the emotionalization module. Given the overall quality of transferred text as the reward, the neutralization module is taught to extract non-emotional semantic content better.

Table 2 shows the human evaluation results. It can be clearly seen that the proposed method obviously improves semantic preservation. The semantic score is increased from 3.87 to 5.08 on the Yelp dataset, and from 3.22 to 4.67 on the Amazon dataset. In general, our proposed model achieves the best overall performance. Furthermore, it also needs to be noticed that with the large improvement in content preservation, the sentiment accuracy of the proposed method is lower than that of CAAE on the two datasets. It shows that simultaneously promoting sentiment transformation and content preservation remains to be studied further.

By comparing two evaluation results, we find that there is an agreement between the human evaluation and the automatic evaluation. It indicates the usefulness of automatic evaluation metrics. However, we also notice that the human evaluation has a smaller performance gap between the baselines and the proposed method than the automatic evaluation. It shows the limitation of automatic metrics for giving accurate results. For evaluating sentiment transformation, even with a high accuracy, the sentiment classifier sometimes generates noisy results, especially for those neutral sentences (e.g., "I ate a cheese sandwich"). For evaluating content preservation, the BLEU score is computed based on the percentage of overlapping n-grams between the generated text and the reference text. However, the overlapping n-grams contain not only content words but also function words, bringing the noisy results. In general, accurate automatic evaluation metrics are expected in future work.

Input: *I would strongly advise against using this company.* **CAAE**: *I love this place for a great experience here.* **MDAL**: *I have been a great place was great.* **Proposed Method**: *I would love using this company.*
Input: *The service was nearly non-existent and extremely rude.* **CAAE**: *The best place in the best area in vegas.* **MDAL**: *The food is very friendly and very good.* **Proposed Method**: *The service was served and completely fresh.*
Input: *Asked for the roast beef and mushroom sub, only received roast beef.* **CAAE**: *We had a great experience with.* **MDAL**: *This place for a great place for a great food and best.* **Proposed Method**: *Thanks for the beef and spring bbq.*
Input: *Worst cleaning job ever!* **CAAE**: *Great food and great service!* **MDAL**: *Great food, food!* **Proposed Method**: *Excellent outstanding job ever!*
Input: *Most boring show I've ever been.* **CAAE**: *Great place is the best place in town.* **MDAL**: *Great place I've ever ever had.* **Proposed Method**: *Most amazing show I've ever been.*
Input: *Place is very clean and the food is delicious.* **CAAE**: *Don't go to this place.* **MDAL**: *This place wasn't worth the worst place is horrible.* **Proposed Method**: *Place is very small and the food is terrible.*
Input: *Really satisfied with experience buying clothes.* **CAAE**: *Don't go to this place.* **MDAL**: *Do not impressed with this place.* **Proposed Method**: *Really bad experience.*

Table 3: Examples generated by the proposed approach and baselines on the Yelp dataset. The two baselines change not only the polarity of examples, but also the semantic content. In comparison, our approach changes the sentiment of sentences with higher semantic similarity.

Table 3 presents the examples generated by different systems on the Yelp dataset. The two baselines change not only the polarity of examples, but also the semantic content. In comparison, our method precisely changes the sentiment of sentences (and paraphrases slightly to ensure fluency), while keeping the semantic content unchanged.

Yelp	ACC	BLEU	G-score
Emotionalization Module	41.84	25.66	32.77
+ NM + Cycled RL	85.71	1.08	9.62
+ NM + Pre-training	70.61	17.02	34.66
+ NM + Cycled RL + Pre-training	80.00	22.46	**42.38**
Amazon	ACC	BLEU	G-score
Emotionalization Module	57.28	12.22	26.46
+ NM + Cycled RL	64.16	8.03	22.69
+ NM + Pre-training	69.61	11.16	27.87
+ NM + Cycled RL + Pre-training	70.37	14.06	**31.45**

Table 4: Performance of key components in the proposed approach. "NM" denotes the neutralization module. "Cycled RL" represents cycled reinforcement learning.

4.6 Incremental Analysis

In this section, we conduct a series of experiments to evaluate the contributions of our key components. The results are shown in Table 4.

We treat the emotionalization module as a baseline where the input is the original emotional sentence. The emotionalization module achieves the highest BLEU score but with much lower sentiment transformation accuracy. The encoding of the original sentiment leads to the emotional hidden vector that influences the decoding process and results in worse sentiment transformation performance.

It can be seen that the method with all components achieves the best performance. First, we find that the method that only uses cycled reinforcement learning performs badly because it is hard to guide two randomly initialized modules to teach each other. Second, the pre-training method brings a slight improvement in overall performance. The G-score is improved from 32.77 to 34.66 and from 26.46 to 27.87 on the two datasets. The bottleneck of this method is the noisy attention weight because of the limited sentiment classification accuracy. Third, the method that combines cycled reinforcement learning and pre-training achieves the better performance than using one of them. Pre-training gives the two modules initial learning ability. Cycled training teaches the two modules to improve each other based on the feedback signals. Specially, the G-score is improved from 34.66 to 42.38 and from 27.87 to 31.45 on the two datasets. Finally, by comparing the methods with and without the neutralization module, we find that the neutralization mechanism improves a lot in sentiment transformation with a slight reduction on content preservation. It proves the effectiveness of explicitly separating sentiment information from semantic content.

Michael is absolutely wonderful.
I would strongly advise against using this company.
Horrible experience!
Worst cleaning job ever!
Most boring show i 've ever been.
Hainan chicken was really good.
I really don't understand all the negative reviews for this dentist.
Smells so weird in there.
The service was nearly non-existent and extremely rude.

Table 5: Analysis of the neutralization module. Words in red are removed by the neutralization module.

Furthermore, to analyze the neutralization ability in the proposed method, we randomly sample several examples, as shown in Table 5. It can be clearly seen that emotional words are removed accurately almost without loss of non-emotional information.

4.7 Error Analysis

Although the proposed method outperforms the state-of-the-art systems, we also observe several failure cases, such as sentiment-conflicted sentences (e.g., "Outstanding and bad service"), neutral sentences (e.g., "Our first time here"). Sentiment-conflicted sentences indicate that the original sentiment is not removed completely. This problem occurs when the input contains emotional words that are unseen in the training data, or the sentiment is implicitly expressed. Handling complex sentiment expressions is an important problem for future work. Neutral sentences demonstrate that the decoder sometimes fails in adding the target sentiment and only generates text based on the semantic content. A better sentiment-aware decoder is expected to be explored in future work.

5 Conclusions and Future Work

In this paper, we focus on unpaired sentiment-to-sentiment translation and propose a cycled reinforcement learning approach that enables training in the absence of parallel training data. We conduct experiments on two review datasets. Experimental results show that our method substantially outperforms the state-of-the-art systems, especially in terms of semantic preservation. For future work, we would like to explore a fine-grained version of sentiment-to-sentiment translation that not only reverses sentiment, but also changes the strength of sentiment.

Abstract

Natural Language Inference (NLI), also known as Recognizing Textual Entailment (RTE), is one of the most important problems in natural language processing. It requires to infer the logical relationship between two given sentences. While current approaches mostly focus on the interaction architectures of the sentences, in this paper, we propose to transfer knowledge from some important discourse markers to augment the quality of the NLI model. We observe that people usually use some discourse markers such as "so" or "but" to represent the logical relationship between two sentences. These words potentially have deep connections with the meanings of the sentences, thus can be utilized to help improve the representations of them. Moreover, we use reinforcement learning to optimize a new objective function with a reward defined by the property of the NLI datasets to make full use of the labels information. Experiments show that our method achieves the state-of-the-art performance on several large-scale datasets.

1 Introduction

In this paper, we focus on the task of Natural Language Inference (NLI), which is known as a significant yet challenging task for natural language understanding. In this task, we are given two sentences which are respectively called **premise** and **hypothesis**. The goal is to determine whether the logical relationship between them is *entailment*, *neutral*, or *contradiction*.

Recently, performance on NLI(Chen et al., 2017b; Gong et al., 2018; Chen et al., 2017c) has been significantly boosted since the release of some high quality large-scale benchmark datasets such as SNLI(Bowman et al., 2015) and MultiNLI(Williams et al., 2017). Table 1 shows some examples in SNLI. Most state-of-the-art works focus on the interaction architectures between the premise and the hypothesis, while they rarely concerned the discourse relations of the sentences, which is a core issue in natural language understanding.

Premise: A soccer game with multiple males playing. **Hypothesis**: Some men are playing a sport. **Label**: *Entailment*
Premise: An older and younger man smiling. **Hypothesis**: Two men are smiling and laughing at the cats playing on the floor. **Label**: *Neutral*
Premise: A black race car starts up in front of a crowd of people **Hypothesis**: A man is driving down a lonely road. **Label**: *Contradiction*

Table 1: Three examples in SNLI dataset.

People usually use some certain set of words to express the discourse relation between two sentences[1]. These words, such as "but" or "and", are denoted as *discourse markers*. These discourse markers have deep connections with the intrinsic relations of two sentences and intuitively correspond to the intent of NLI, such as "but" to "contradiction", "so" to "entailment", *etc.*

Very few NLI works utilize this information revealed by discourse markers. Nie et al. (2017) proposed to use discourse markers to help rep-

[*]corresponding author

[1]Here sentences mean either the whole sentences or the main clauses of a compound sentence.

resent the meanings of the sentences. However, they represent each sentence by a single vector and directly concatenate them to predict the answer, which is too simple and not ideal for the large-scale datasets.

In this paper, we propose a *Discourse Marker Augmented Network* for natural language inference, where we transfer the knowledge from the existing supervised task: Discourse Marker Prediction (DMP)(Nie et al., 2017), to an integrated NLI model. We first propose a sentence encoder model that learns the representations of the sentences from the DMP task and then inject the encoder to the NLI network. Moreover, because our NLI datasets are manually annotated, each example from the datasets might get several different labels from the annotators although they will finally come to a consensus and also provide a certain label. In consideration of that different confidence level of the final labels should be discriminated, we employ reinforcement learning with a reward defined by the uniformity extent of the original labels to train the model. The contributions of this paper can be summarized as follows.

- Unlike previous studies, we solve the task of the natural language inference via transferring knowledge from another supervised task. We propose the Discourse Marker Augmented Network to combine the learned encoder of the sentences with the integrated NLI model.
- According to the property of the datasets, we incorporate reinforcement learning to optimize a new objective function to make full use of the labels' information.
- We conduct extensive experiments on two large-scale datasets to show that our method achieves better performance than other state-of-the-art solutions to the problem.

2 Task Description

2.1 Natural Language Inference (NLI)

In the natural language inference tasks, we are given a pair of sentences (P, H), which respectively means the premise and hypothesis. Our goal is to judge whether their logical relationship between their meanings by picking a label from a small set: *entailment* (The hypothesis is definitely a true description of the premise), *neutral* (The hypothesis might be a true description of the premise), and *contradiction* (The hypothesis is definitely a false description of the premise).

2.2 Discourse Marker Prediction (DMP)

For DMP, we are given a pair of sentences (S_1, S_2), which is originally the first half and second half of a complete sentence. The model must predict which discourse marker was used by the author to link the two ideas from a set of candidates.

3 Sentence Encoder Model

Following (Nie et al., 2017; Kiros et al., 2015), we use BookCorpus(Zhu et al., 2015) as our training data for discourse marker prediction, which is a dataset of text from unpublished novels, and it is large enough to avoid bias towards any particular domain or application. After preprocessing, we obtain a dataset with the form (S_1, S_2, m), which means the first half sentence, the last half sentence, and the discourse marker that connected them in the original text. Our goal is to predict the m given S_1 and S_2.

We first use *Glove*(Pennington et al., 2014) to transform $\{S_t\}_{t=1}^{2}$ into vectors word by word and subsequently input them to a bi-directional LSTM:

$$\begin{aligned} \overrightarrow{\mathbf{h}_t^i} &= \overrightarrow{\text{LSTM}}(Glove(S_t^i)), i = 1, ..., |S_t| \\ \overleftarrow{\mathbf{h}_t^i} &= \overleftarrow{\text{LSTM}}(Glove(S_t^i)), i = |S_t|, ..., 1 \end{aligned} \tag{1}$$

where $Glove(w)$ is the embedding vector of the word w from the *Glove* lookup table, $|S_t|$ is the length of the sentence S_t. We apply max pooling on the concatenation of the hidden states from both directions, which provides regularization and shorter back-propagation paths(Collobert and Weston, 2008), to extract the features of the whole sequences of vectors:

$$\begin{aligned} \overrightarrow{\mathbf{r}_t} &= \text{Max}_{dim}([\overrightarrow{\mathbf{h}_t^1}; \overrightarrow{\mathbf{h}_t^2}; ...; \overrightarrow{\mathbf{h}_t^{|S_t|}}]) \\ \overleftarrow{\mathbf{r}_t} &= \text{Max}_{dim}([\overleftarrow{\mathbf{h}_t^1}; \overleftarrow{\mathbf{h}_t^2}; ...; \overleftarrow{\mathbf{h}_t^{|S_t|}}]) \end{aligned} \tag{2}$$

where Max_{dim} means that the max pooling is performed across each dimension of the concatenated vectors, $[;]$ denotes concatenation. Moreover, we combine the last hidden state from both directions and the results of max pooling to represent our sentences:

$$\mathbf{r}_t = [\overrightarrow{\mathbf{r}_t}; \overleftarrow{\mathbf{r}_t}; \overrightarrow{\mathbf{h}_t^{|S_t|}}; \overleftarrow{\mathbf{h}_t^1}] \tag{3}$$

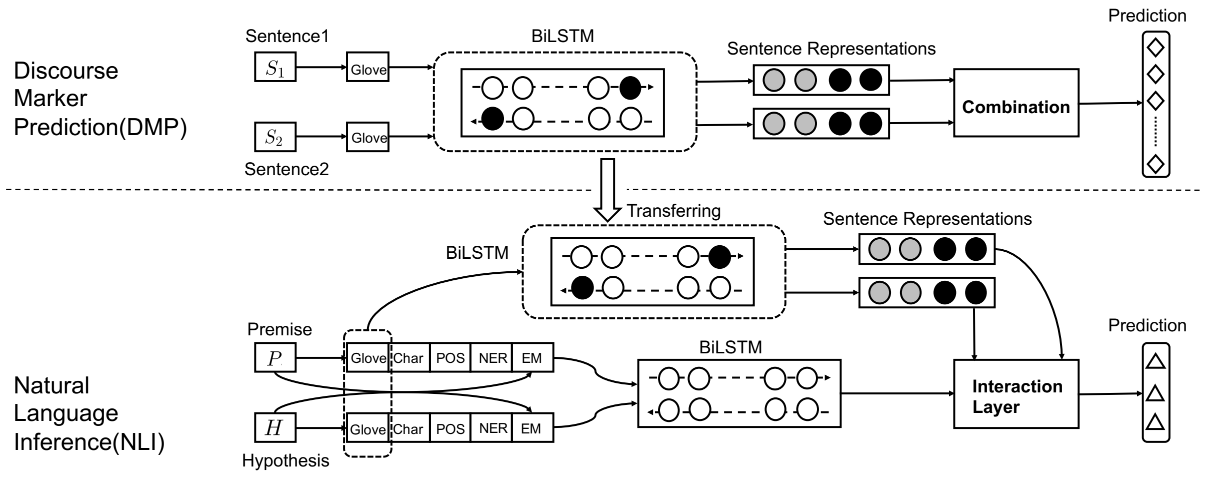

Figure 1: Overview of our Discource Marker Augmented Network, comprising the part of Discourse Marker Prediction (upper) for pre-training and Natural Language Inferance (bottom) to which the learned knowledge will be transferred.

where $\mathbf{r}_t$ is the representation vector of the sentence S_t. To predict the discourse marker between S_1 and S_2, we combine the representations of them with some linear operation:

$$\mathbf{r} = [\mathbf{r}_1; \mathbf{r}_2; \mathbf{r}_1 + \mathbf{r}_2; \mathbf{r}_1 \odot \mathbf{r}_2] \tag{4}$$

where $\odot$ is elementwise product. Finally we project $\mathbf{r}$ to a vector of label size (the total number of discourse markers in the dataset) and use softmax function to normalize the probability distribution.

4 Discourse Marker Augmented Network

As presented in Figure 1, we show how our Discourse Marker Augmented Network incorporates the learned encoder into the NLI model.

4.1 Encoding Layer

We denote the premise as P and the hypothesis as H. To encode the words, we use the concatenation of following parts:

Word Embedding: Similar to the previous section, we map each word to a vector space by using pre-trained word vectors *GloVe*.

Character Embedding: We apply Convolutional Neural Networks (CNN) over the characters of each word. This approach is proved to be helpful in handling out-of-vocab (OOV) words(Yang et al., 2017).

POS and NER tags: We use the part-of-speech (POS) tags and named-entity recognition (NER) tags to get syntactic information and entity label of the words. Following (Pan et al., 2017b), we apply the skip-gram model(Mikolov et al., 2013) to train two new lookup tables of POS tags and NER tags respectively. Each word can get its own POS embedding and NER embedding by these lookup tables. This approach represents much better geometrical features than common used one-hot vectors.

Exact Match: Inspired by the machine comprehension tasks(Chen et al., 2017a), we want to know whether every word in P is in H (and H in P). We use three binary features to indicate whether the word can be exactly matched to any question word, which respectively means original form, lowercase and lemma form.

For encoding, we pass all sequences of vectors into a bi-directional LSTM and obtain:

$$\begin{aligned} \mathbf{p}_i &= \text{BiLSTM}(f_{rep}(P_i), \mathbf{p}_{i-1}), i = 1, ..., n \\ \mathbf{u}_j &= \text{BiLSTM}(f_{rep}(H_j), \mathbf{u}_{j-1}), j = 1, ..., m \end{aligned} \tag{5}$$

where $f_{rep}(\mathbf{x}) = [\text{Glove}(\mathbf{x}); \text{Char}(\mathbf{x}); \text{POS}(\mathbf{x}); \text{NER}(\mathbf{x}); \text{EM}(\mathbf{x})]$ is the concatenation of the embedding vectors and the feature vectors of the word $\mathbf{x}$, $n = |P|$, $m = |H|$.

4.2 Interaction Layer

In this section, we feed the results of the encoding layer and the learned sentence encoder into the attention mechanism, which is responsible for linking and fusing information from the premise and the hypothesis words.

We first obtain a similarity matrix $\mathbf{A} \in R^{n \times m}$ between the premise and hypothesis by

$$\mathbf{A}_{ij} = \mathbf{v}_1^\top [\mathbf{p}_i; \mathbf{u}_j; \mathbf{p}_i \circ \mathbf{u}_j; \mathbf{r}_p; \mathbf{r}_h] \tag{6}$$

where $\mathbf{v}_1$ is the trainable parameter, $\mathbf{r}_p$ and $\mathbf{r}_h$ are sentences representations from the equation (3) learned in the Section 3, which denote the premise and hypothesis respectively. In addition to previous popular similarity matrix, we incorporate the relevance of each word of $P(H)$ to the whole sentence of $H(P)$. Now we use $\mathbf{A}$ to obtain the attentions and the attended vectors in both directions.

To signify the attention of the i-th word of P to every word of H, we use the weighted sum of $\mathbf{u}_j$ by $\mathbf{A}_{i:}$:

$$\tilde{\mathbf{u}}_i = \sum_j \mathbf{A}_{ij} \cdot \mathbf{u}_j \tag{7}$$

where $\tilde{\mathbf{u}}_i$ is the attention vector of the i-th word of P for the entire H. In the same way, the $\tilde{\mathbf{p}}_j$ is obtained via:

$$\tilde{\mathbf{p}}_j = \sum_i \mathbf{A}_{ij} \cdot \mathbf{p}_i \tag{8}$$

To model the local inference between aligned word pairs, we integrate the attention vectors with the representation vectors via:

$$\begin{aligned} \hat{\mathbf{p}}_i &= f([\mathbf{p}_i; \tilde{\mathbf{u}}_i; \mathbf{p}_i - \tilde{\mathbf{u}}_i; \mathbf{p}_i \odot \tilde{\mathbf{u}}_i]) \\ \hat{\mathbf{u}}_j &= f([\mathbf{u}_j; \tilde{\mathbf{p}}_j; \mathbf{u}_j - \tilde{\mathbf{p}}_j; \mathbf{u}_j \odot \tilde{\mathbf{p}}_j]) \end{aligned} \tag{9}$$

where f is a 1-layer feed-forward neural network with the ReLU activation function, $\hat{\mathbf{p}}_i$ and $\hat{\mathbf{u}}_j$ are local inference vectors. Inspired by (Seo et al., 2016) and (Chen et al., 2017b), we use a modeling layer to capture the interaction between the premise and the hypothesis. Specifically, we use bi-directional LSTMs as building blocks:

$$\begin{aligned} \mathbf{p}_i^M &= \mathrm{BiLSTM}(\hat{\mathbf{p}}_i, \mathbf{p}_{i-1}^M) \\ \mathbf{u}_j^M &= \mathrm{BiLSTM}(\hat{\mathbf{u}}_j, \mathbf{u}_{j-1}^M) \end{aligned} \tag{10}$$

Here, $\mathbf{p}_i^M$ and $\mathbf{u}_j^M$ are the modeling vectors which contain the crucial information and relationship among the sentences.

We compute the representation of the whole sentence by the weighted average of each word:

$$\begin{aligned} \mathbf{p}^M &= \sum_i \frac{\exp(\mathbf{v}_2^\top \mathbf{p}_i^M)}{\sum_{i'} \exp(\mathbf{v}_2^\top \mathbf{p}_{i'}^M)} \mathbf{p}_i^M \\ \mathbf{u}^M &= \sum_j \frac{\exp(\mathbf{v}_3^\top \mathbf{u}_j^M)}{\sum_{j'} \exp(\mathbf{v}_3^\top \mathbf{u}_{j'}^M)} \mathbf{u}_j^M \end{aligned} \tag{11}$$

Label Number	SNLI		MultiNLI	
	Correct	Total	Correct	Total
1	510711	510711	392702	392702
2	0	0	0	0
3	8748	0	3045	0
4	16395	2199	4859	0
5	33179	56123	11743	19647

Table 2: Statistics of the labels of SNLI and MuliNLI. **Total** means the number of examples whose number of annotators is in the left column. **Correct** means the number of examples whose number of correct labels from the annotators is in the left column.

where $\mathbf{v}_2, \mathbf{v}_3$ are trainable vectors. We don't share these parameter vectors in this seemingly parallel strucuture because there is some subtle difference between the premise and hypothesis, which will be discussed later in Section 5.

4.3 Output Layer

The NLI task requires the model to predict the logical relation from the given set: *entailment*, *neutral* or *contradiction*. We obtain the probability distribution by a linear function with softmax function:

$$\mathbf{d} = \mathrm{softmax}(\mathbf{W}[\mathbf{p}^M; \mathbf{u}^M; \mathbf{p}^M \odot \mathbf{u}^M; \mathbf{r}_p \odot \mathbf{r}_h]) \tag{12}$$

where $\mathbf{W}$ is a trainable parameter. We combine the representations of the sentences computed above with the representations learned from DMP to obtain the final prediction.

4.4 Training

As shown in Table 2, many examples from our datasets are labeled by several people, and the choices of the annotators are not always consistent. For instance, when the label number is 3 in SNLI, "total=0" means that no examples have 3 annotators (maybe more or less); "correct=8748" means that there are 8748 examples whose number of correct labels is 3 (the number of annotators maybe 4 or 5, but some provided wrong labels). Although all the labels for each example will be unified to a final (correct) label, diversity of the labels for a single example indicates the low confidence of the result, which is not ideal to only use the final label to optimize the model.

We propose a new objective function that combines both the log probabilities of the ground-truth label and a reward defined by the property of the datasets for the reinforcement learning. The most widely used objective function for the natural language inference is to minimize the negative log cross-entropy loss:

$$J_{CE}(\Theta) = -\frac{1}{N}\sum_{k}^{N} log(\mathbf{d}_l^k) \tag{13}$$

where Θ are all the parameters to optimize, N is the number of examples in the dataset, $\mathbf{d}_l$ is the probability of the ground-truth label l.

However, directly using the final label to train the model might be difficult in some situations, where the example is confusing and the labels from the annotators are different. For instance, consider an example from the SNLI dataset:

- P: "A smiling costumed woman is holding an umbrella."
- H: "A happy woman in a fairy costume holds an umbrella."

The final label is *neutral*, but the original labels from the five annotators are *neural*, *neural*, *entailment*, *contradiction*, *neural*, in which case the relation between "smiling" and "happy" might be under different comprehension. The final label's confidence of this example is obviously lower than an example that all of its labels are the same. To simulate the thought of human being more closely, in this paper, we tackle this problem by using the REINFORCE algorithm(Williams, 1992) to minimize the negative expected reward, which is defined as:

$$J_{RL}(\Theta) = -\mathbb{E}_{l\sim\pi(l|P,H)}[R(l, \{l^*\})] \tag{14}$$

where $\pi(l|P, H)$ is the previous action policy that predicts the label given P and H, $\{l^*\}$ is the set of annotated labels, and

$$R(l, \{l^*\}) = \frac{\text{number of } l \text{ in } \{l^*\}}{|\{l^*\}|} \tag{15}$$

is the reward function defined to measure the distance to all the ideas of the annotators.

To avoid of overwriting its earlier results and further stabilize training, we use a linear function to integrate the above two objective functions:

$$J(\Theta) = \lambda J_{CE}(\Theta) + (1 - \lambda)J_{RL}(\Theta) \tag{16}$$

where λ is a tunable hyperparameter.

Table 3: Statistics of discouse markers in our dataset from BookCorpus.

5 Experiments

5.1 Datasets

BookCorpus: We use the dataset from BookCorpus(Zhu et al., 2015) to pre-train our sentence encoder model. We preprocessed and collected discourse markers from BookCorpus as (Nie et al., 2017). We finally curated a dataset of 6527128 pairs of sentences for 8 discourse markers, whose statistics are shown in Table 3.

SNLI: Stanford Natural Language Inference(Bowman et al., 2015) is a collection of more than 570k human annotated sentence pairs labeled for entailment, contradiction, and semantic independence. SNLI is two orders of magnitude larger than all other resources of its type. The premise data is extracted from the captions of the Flickr30k corpus(Young et al., 2014), the hypothesis data and the labels are manually annotated. The original SNLI corpus contains also the other category, which includes the sentence pairs lacking consensus among multiple human annotators. We remove this category and use the same split as in (Bowman et al., 2015) and other previous work.

MultiNLI: Multi-Genre Natural Language Inference(Williams et al., 2017) is another large-scale corpus for the task of NLI. MultiNLI has 433k sentences pairs and is in the same format as SNLI, but it includes a more diverse range of text, as well as an auxiliary test set for cross-genre transfer evaluation. Half of these selected genres appear in training set while the rest are not, creating in-domain (matched) and cross-domain (mismatched) development/test sets.

Table 4: Performance on the SNLI dataset and the MultiNLI dataset. In the top part, we show sentence encoding-based models; In the medium part, we present the performance of integrated neural network models; In the bottom part, we show the results of ensemble models.

5.2 Implementation Details

We use the Stanford CoreNLP toolkit(Manning et al., 2014) to tokenize the words and generate POS and NER tags. The word embeddings are initialized by 300d *Glove*(Pennington et al., 2014), the dimensions of POS and NER embeddings are 30 and 10. The dataset we use to train the embeddings of POS tags and NER tags are the training set given by SNLI. We apply Tensorflow r1.3 as our neural network framework. We set the hidden size as 300 for all the LSTM layers and apply dropout(Srivastava et al., 2014) between layers with an initial ratio of 0.9, the decay rate as 0.97 for every 5000 step. We use the AdaDelta for optimization as described in (Zeiler, 2012) with ρ as 0.95 and ϵ as 1e-8. We set our batch size as 36 and the initial learning rate as 0.6. The parameter λ in the objective function is set to be 0.2. For DMP task, we use stochastic gradient descent with initial learning rate as 0.1, and we anneal by half each time the validation accuracy is lower than the previous epoch. The number of epochs is set to be 10, and the feedforward dropout rate is 0.2. The learned encoder in subsequent NLI task is trainable.

5.3 Results

In table 4, we compare our model to other competitive published models on SNLI and MultiNLI. As we can see, our method Discourse Marker Augmented Network (DMAN) clearly outperforms all the baselines and achieves the state-of-the-art results on both datasets.

The methods in the top part of the table are sentence encoding based models. Bowman et al. (2016) proposed a simple baseline that uses LSTM to encode the whole sentences and feed them into a MLP classifier to predict the final inference relationship, they achieve an accuracy of 80.6% on SNLI. Nie and Bansal (2017) test their model on both SNLI and MiltiNLI, and achieves competitive results.

In the medium part, we show the results of other neural network models. Obviously, the performance of most of the integrated methods are better than the sentence encoding based models above. Both DIIN(Gong et al., 2018) and

Ablation Model	Accuracy
Only Sentence Encoder Model	83.37
No Sentence Encoder Model	87.24
No Char Embedding	87.95
No POS Embedding	88.76
No NER Embedding	88.71
No Exact Match	88.26
No REINFORCE	88.41
DMAN	88.83

Table 5: Ablations on the SNLI development dataset.

CAFE(Tay et al., 2017) exceed other methods by more than 4% on MultiNLI dataset. However, our DMAN achieves 88.8% on SNLI, 78.9% on matched MultiNLI and 78.2% on mismatched MultiNLI, which are all best results among the baselines.

We present the ensemble results on both datasets in the bottom part of the table 4. We build an ensemble model which consists of 10 single models with the same architecture but initialized with different parameters. The performance of our model achieves 89.6% on SNLI, 80.3% on matched MultiNLI and 79.4% on mismatched MultiNLI, which are all state-of-the-art results.

5.4 Ablation Analysis

As shown in Table 5, we conduct an ablation experiment on SNLI development dataset to evaluate the individual contribution of each component of our model. Firstly we only use the results of the sentence encoder model to predict the answer, in other words, we represent each sentence by a single vector and use dot product with a linear function to do the classification. The result is obviously not satisfactory, which indicates that only using sentence embedding from discourse markers to predict the answer is not ideal in large-scale datasets. We then remove the sentence encoder model, which means we don't use the knowledge transferred from the DMP task and thus the representations $\mathbf{r}_p$ and $\mathbf{r}_h$ are set to be zero vectors in the equation (6) and the equation (12). We observe that the performance drops significantly to 87.24%, which is nearly 1.5% to our DMAN model, which indicates that the discourse markers have deep connections with the logical relations between two sentences they links. When

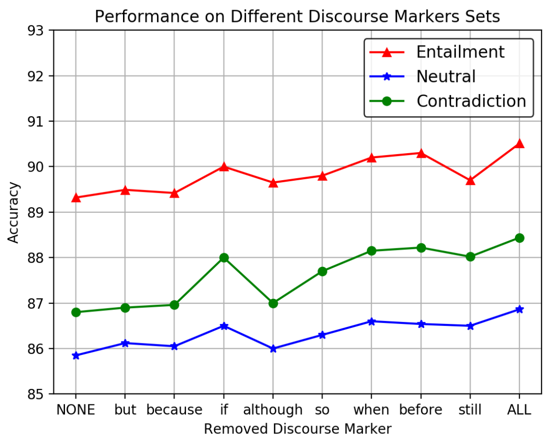

Figure 2: Performance when the sentence encoder is pretrained on different discourse markers sets. "NONE" means the model doesn't use any discourse markers; "ALL" means the model use all the discourse markers.

we remove the character-level embedding and the POS and NER features, the performance drops a lot. We conjecture that those feature tags help the model represent the words as a whole while the char-level embedding can better handle the out-of-vocab (OOV) or rare words. The exact match feature also demonstrates its effectiveness in the ablation result. Finally, we ablate the reinforcement learning part, in other words, we only use the original loss function to optimize the model (set $\lambda = 1$). The result drops about 0.5%, which proves that it is helpful to utilize all the information from the annotators.

5.5 Semantic Analysis

In Figure 2, we show the performance on the three relation labels when the model is pre-trained on different discourse markers sets. In other words, we removed discourse marker from the original set each time and use the rest 7 discourse markers to pre-train the sentence encoder in the DMP task and then train the DMAN. As we can see, there is a sharp decline of accuracy when removing "but", "because" and "although". We can intuitively speculate that "but" and "although" have direct connections with the contradiction label (which drops most significantly) while "because" has some links with the entailment label. We observe that some discourse markers such as "if" or "before" contribute much less than other words which have strong logical hints, although they

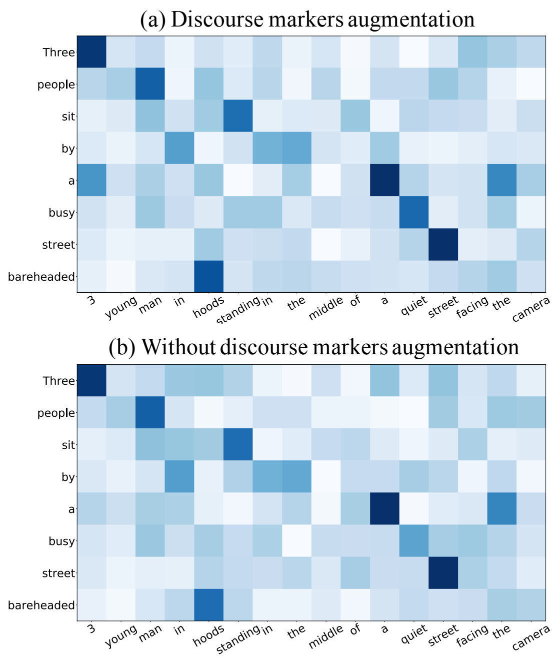

Figure 3: Comparison of the visualized similarity relations.

actually improve the performance of the model. Compared to the other two categories, the "contradiction" label examples seem to benefit the most from the pre-trained sentence encoder.

5.6 Visualization

In Figure 3, we also provide a visualized analysis of the hidden representation from similarity matrix $\mathbf{A}$ (computed in the equation (6)) in the situations that whether we use the discourse markers or not. We pick a sentence pair whose premise is "*3 young man in hoods standing in the middle of a quiet street facing the camera.*" and hypothesis is "*Three people sit by a busy street bareheaded.*" We observe that the values are highly correlated among the synonyms like "people" with "man", "three" with "3" in both situations. However, words that might have contradictory meanings like "hoods" with "bareheaded", "quiet" with "busy" perform worse without the discourse markers augmentation, which conforms to the conclusion that the "contradiction" label examples benefit a lot which is observed in the Section 5.5.

6 Related Work

6.1 Discourse Marker Applications

This work is inspired most directly by the DisSent model and Discourse Prediction Task of Nie et al. (2017), which introduce the use of the discourse markers information for the pretraining of sentence encoders. They follow (Kiros et al., 2015) to collect a large sentence pairs corpus from BookCorpus(Zhu et al., 2015) and propose a sentence representation based on that. They also apply their pre-trained sentence encoder to a series of natural language understanding tasks such as sentiment analysis, question-type, entailment, and relatedness. However, all those datasets are provided by Conneau et al. (2017) for evaluating sentence embeddings and are almost all small-scale and are not able to support more complex neural network. Moreover, they represent each sentence by a single vector and directly combine them to predict the answer, which is not able to interact among the words level.

In closely related work, Jernite et al. (2017) propose a model that also leverage discourse relations. However, they manually group the discourse markers into several categories based on human knowledge and predict the category instead of the explicit discourse marker phrase. However, the size of their dataset is much smaller than that in (Nie et al., 2017), and sometimes there has been disagreement among annotators about what exactly is the correct categorization of discourse relations(Hobbs, 1990).

Unlike previous works, we insert the sentence encoder into an integrated network to augment the semantic representation for NLI tasks rather than directly combining the sentence embeddings to predict the relations.

6.2 Natural Language Inference

Earlier research on the natural language inference was based on small-scale datasets(Marelli et al., 2014), which relied on traditional methods such as shallow methods(Glickman et al., 2005), natural logic methods(MacCartney and Manning, 2007), *etc.* These datasets are either not large enough to support complex deep neural network models or too easy to challenge natural language.

Large and complicated networks have been successful in many natural language processing tasks(Zhu et al., 2017; Chen et al., 2017e; Pan et al., 2017a). Recently, Bowman et al. (2015) released Stanford Natural language Inference (SNLI) dataset, which is a high-quality and large-scale benchmark, thus inspired many significant works(Bowman et al., 2016; Mou et al., 2016; Vendrov et al., 2016; Conneau et al., 2017; Wang et al., 2017; Gong et al., 2018; McCann et al., 2017; Chen et al., 2017b; Choi et al., 2017; Tay et al., 2017). Most of them focus on the improvement of the interaction architectures and obtain competitive results, while transfer learning from external knowledge is popular as well. Vendrov et al. (2016) incorpated Skipthought(Kiros et al., 2015), which is an unsupervised sequence model that has been proven to generate useful sentence embedding. McCann et al. (2017) proposed to transfer the pre-trained encoder from the neural machine translation (NMT) to the NLI tasks.

Our method combines a pre-trained sentence encoder from the DMP task with an integrated NLI model to compose a novel framework. Furthermore, unlike previous studies, we make full use of the labels provided by the annotators and employ policy gradient to optimize a new objective function in order to simulate the thought of human being.

7 Conclusion

In this paper, we propose *Discourse Marker Augmented Network* for the task of the natural language inference. We transfer the knowledge learned from the discourse marker prediction task to the NLI task to augment the semantic representation of the model. Moreover, we take the various views of the annotators into consideration and employ reinforcement learning to help optimize the model. The experimental evaluation shows that our model achieves the state-of-the-art results on SNLI and MultiNLI datasets. Future works involve the choice of discourse markers and some other transfer learning sources.

Abstract

During the last years, there has been a lot of interest in achieving some kind of complex reasoning using deep neural networks. To do that, models like Memory Networks (MemNNs) have combined external memory storages and attention mechanisms. These architectures, however, lack of more complex reasoning mechanisms that could allow, for instance, relational reasoning. Relation Networks (RNs), on the other hand, have shown outstanding results in relational reasoning tasks. Unfortunately, their computational cost grows quadratically with the number of memories, something prohibitive for larger problems. To solve these issues, we introduce the Working Memory Network, a MemNN architecture with a novel working memory storage and reasoning module. Our model retains the relational reasoning abilities of the RN while reducing its computational complexity from quadratic to linear. We tested our model on the text QA dataset bAbI and the visual QA dataset NLVR. In the jointly trained bAbI-10k, we set a new state-of-the-art, achieving a mean error of less than 0.5%. Moreover, a simple ensemble of two of our models solves all 20 tasks in the joint version of the benchmark.

1 Introduction

A central ability needed to solve daily tasks is complex reasoning. It involves the capacity to comprehend and represent the environment, retain information from past experiences, and solve problems based on the stored information. Our ability to solve those problems is supported by multiple specialized components, including short-term memory storage, long-term semantic and procedural memory, and an executive controller that, among others, controls the attention over memories (Baddeley, 1992).

Many promising advances for achieving complex reasoning with neural networks have been obtained during the last years. Unlike symbolic approaches to complex reasoning, deep neural networks can learn representations from perceptual information. Because of that, they do not suffer from the symbol grounding problem (Harnad, 1999), and can generalize better than classical symbolic approaches. Most of these neural network models make use of an explicit memory storage and an attention mechanism. For instance, Memory Networks (MemNN), Dynamic Memory Networks (DMN) or Neural Turing Machines (NTM) (Weston et al., 2014; Kumar et al., 2016; Graves et al., 2014) build explicit memories from the perceptual inputs and access these memories using learned attention mechanisms. After that some memories have been attended, using a multi-step procedure, the attended memories are combined and passed through a simple output layer that produces a final answer. While this allows some multi-step inferential process, these networks lack a more complex reasoning mechanism, needed for more elaborated tasks such as inferring relations among entities (relational reasoning). On the contrary, Relation Networks (RNs), proposed in Santoro et al. (2017), have shown outstanding performance in relational reasoning tasks. Nonetheless, a major drawback of RNs is that they consider each of the input objects in pairs, having to process a quadratic number of relations. That limits the usability of the model on large problems and makes forward and backward computations quite expensive. To solve these problems we propose a novel Memory Network

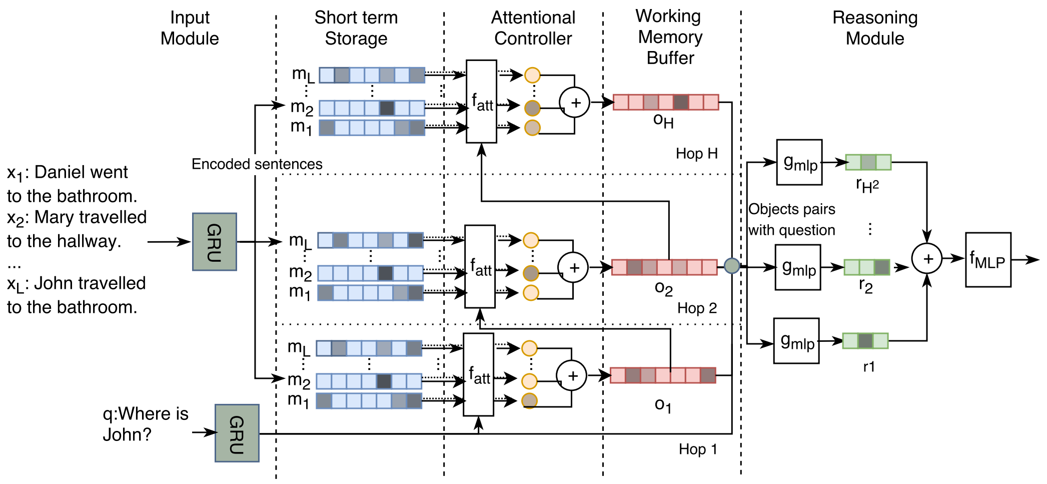

Figure 1: The W-MemNN model applied to textual question answering. Each input fact is processed using a GRU, and the output representation is stored in the short-term memory storage. Then, the attentional controller computes an output vector that summarizes relevant parts of the memories. This process is repeated H hops (a dotted line delimits each hop), and each output is stored in the working memory buffer. Finally, the output of each hop is passed to the reasoning module that produces the final output.

architecture called the Working Memory Network (W-MemNN). Our model augments the original MemNN with a relational reasoning module and a new working memory buffer.

The attention mechanism of the Memory Network allows the filtering of irrelevant inputs, reducing a lot of the computational complexity while keeping the relational reasoning capabilities of the RN. Three main components compose the W-MemNN: An input module that converts the perceptual inputs into an internal vector representation and save these representations into a short-term storage, an attentional controller that attend to these internal representations and update a working memory buffer, and a reasoning module that operates on the set of objects stored in the working memory buffer in order to produce a final answer. This component-based architecture is inspired by the well-known model from cognitive sciences called the multi-component working memory model, proposed in Baddeley and Hitch (1974).

We studied the proposed model on the text-based QA benchmark bAbI (Weston et al., 2015) which consists of 20 different toy tasks that measure different reasoning skills. While models such as EntNet (Henaff et al., 2016) have focused on the per-task training version of the benchmark (where a different model is trained for each task), we decided to focus on the jointly trained version of the task, where the model is trained on all tasks simultaneously. In the jointly trained bAbI-10k benchmark we achieved state-of-the-art performance, improving the previous state-of-the-art on more than 2%. Moreover, a simple ensemble of two of our models can solve all 20 tasks simultaneously. Also, we tested our model on the visual QA dataset NLVR. In that dataset, we obtained performance at the level of the Module Neural Networks (Andreas et al., 2016). Our model, however, achieves these results using the raw input statements, without the extra text processing used in the Module Networks.

Finally, qualitative and quantitative analysis shows that the inclusion of the Relational Reasoning module is crucial to improving the performance of the MemNN on tasks that involve relational reasoning. We can achieve this performance by also reducing the computation times of the RN considerably. Consequently, we hope that this contribution may allow applying RNs to larger problems.

2 Model

Our model is based on the Memory Network architecture. Unlike MemNN we have included a reasoning module that helps the network to solve more complex tasks. The proposed model consists of three main modules: An input module, an attentional controller, and a reasoning module. The model processes the input information in multiple passes or hops. At each pass the output of the previous hop can condition the current pass, allowing some incremental refinement.

Input module: The input module converts the perceptual information into an internal feature representation. The input information can be processed in chunks, and each chunk is saved into a short-term storage. The definition of what is a chunk of information depends on each task. For instance, for textual question answering, we define each chunk as a sentence. Other options might be n-grams or full documents. This short-term storage can only be accessed during the hop.

Attentional Controller: The attentional controller decides in which parts of the short-term storage the model should focus. The attended memories are kept during all the hops in a working memory buffer. The attentional controller is conditioned by the task at hand, for instance, in question answering the question can condition the attention. Also, it may be conditioned by the output of previous hops, allowing the model to change its focus to new portions of the memory over time. Many models compute the attention for each memory using a compatibility function between the memory and the question. Then, the output is calculated as the weighted sum of the memory values, using the attention as weight. A simple way to compute the attention for each memory is to use dot-product attention. This kind of mechanism is used in the original Memory Network and computes the attention value as the dot product between each memory and the question. Although this kind of attention is simple, it may not be enough for more complex tasks. Also, since there are no learned weights in the attention mechanism, the attention relies entirely on the learned embeddings. That is something that we want to avoid in order to separate the learning of the input and attention module. One way to allow learning in the dot-product attention is to project the memories and query vectors linearly. That is done by multiplying each vector by a learned projection matrix (or equivalently a feed-forward neural network). In this way, we can set apart the attention and input embeddings learning, and also allow more complex patterns of attention.

Reasoning Module: The memories stored in the working memory buffer are passed to the reasoning module. The choice of reasoning mechanism is left open and may depend on the task at hand. In this work, we use a Relation Network as the reasoning module. The RN takes the attended memories in pairs to infer relations among the memories. That can be useful, for example, in tasks that include comparisons.

A detailed description of the full model is shown in Figure 1.

2.1 W-MemN2N for Textual Question Answering

We proceed to describe an implementation of the model for textual question answering. In textual question answering the input consists of a set of sentences or facts, a question, and an answer. The goal is to answer the question correctly based on the given facts.

Let (s, q, a) represents an input sample, consisting of a set of sentences $s = \{x_i\}_{i=1}^{L}$, a query q and an answer a. Each sentence contains M words, $\{w_i\}_{i=1}^{M}$, where each word is represented as a one-hot vector of length $|V|$, being $|V|$ the vocabulary size. The question contains Q words, represented as in the input sentences.

Input Module

Each word in each sentence is encoded into a vector representation v_i using an embedding matrix $W \in \mathbb{R}^{|V|\times d}$, where d is the embedding size. Then, the sentence is converted into a memory vector m_i using the final output of a gated recurrent neural network (GRU) (Chung et al., 2014):

$$m_i = \text{GRU}([v_1, v_2, ..., v_M])$$

Each memory $\{m_i\}_{i=1}^{L}$, where $m_i \in \mathbb{R}^d$, is stored into the short-term memory storage. The question is encoded into a vector u in a similar way, using the output of a gated recurrent network.

Attentional Controller

Our attention module is based on the Multi-Head attention mechanism proposed in Vaswani et al. (2017). First, the memories are projected using a projection matrix $W_m \in \mathbb{R}^{d\times d}$, as $m'_i = W_m m_i$. Then, the similarity between the projected memory and the question is computed using the Scaled Dot-Product attention:

$$\alpha_i = \text{Softmax}\left(\frac{u^T m'_i}{\sqrt{d}}\right) \quad (1)$$

$$= \frac{\exp((u^T m'_i)/\sqrt{d})}{\sum_j \exp((u^T m'_j)/\sqrt{d})}. \quad (2)$$

Next, the memories are combined using the attention weights α_i, obtaining an output vector $h = \sum_j \alpha_j m_j$.
In the Multi-Head mechanism, the memories are projected S times using different projection matrices $\{W_m^s\}_{s=1}^S$. For each group of projected memories, an output vector $\{h_i\}_{i=1}^S$ is obtained using the Scaled Dot-Product attention (eq. 2). Finally, all vector outputs are concatenated and projected again using a different matrix:

$$o_k = [h_1; h_2; ...; h_S]W_o,$$

where ; is the concatenation operator and $W_o \in \mathbb{R}^{Sd \times d}$. The o_k vector is the final response vector for the hop k. This vector is stored in the working memory buffer. The attention procedure can be repeated many times (or hops). At each hop, the attention can be conditioned on the previous hop by replacing the question vector u by the output of the previous hop. To do that we pass the output through a simple neural network f_t. Then, we use the output of the network as the new conditioner:

$$o_k^n = f_t(o_k). \tag{3}$$

This network allows some learning in the transition patterns between hops.
We found Multi-Head attention to be very useful in the joint bAbI task. This can be a product of the intrinsic multi-task nature of the bAbI dataset. A possibility is that each attention head is being adapted for different groups of related tasks. However, we did not investigate this further.
Also, note that while in this section we use the same set of memories at each hop, this is not necessary. For larger sequences each hop can operate in different parts of the input sequence, allowing the processing of the input in various steps.

Reasoning Module

The outputs stored in the working memory buffer are passed to the reasoning module. The reasoning module used in this work is a Relation Network (RN). In the RN the output vectors are concatenated in pairs together with the question vector. Each pair is passed through a neural network g_θ and all the outputs of the network are added to produce a single vector. Then, the sum is passed to a final neural network f_ϕ:

$$r = f_\phi\left(\sum_{i,j} g_\theta([o_i; o_j; u])\right), \tag{4}$$

The output of the Relation Network is then passed through a final weight matrix and a softmax to produce the predicted answer:

$$\hat{a} = \text{Softmax}(Vr), \tag{5}$$

where $V \in \mathbb{R}^{|A| \times d_\phi}$, $|A|$ is the number of possible answers and d_ϕ is the dimension of the output of f_ϕ. The full network is trained end-to-end using standard cross-entropy between $\hat{a}$ and the true label a.

3 Related Work

3.1 Memory Augmented Neural Networks

During the last years, there has been plenty of work on achieving complex reasoning with deep neural networks. An important part of these developments has used some kind of explicit memory and attention mechanisms. One of the earliest recent work is that of Memory Networks (Weston et al., 2014). Memory Networks work by building an addressable memory from the inputs and then accessing those memories in a series of reading operations. Another, similar, line of work is the one of Neural Turing Machines. They were proposed in Graves et al. (2014) and are the basis for recent neural architectures including the Differentiable Neural Computer (DNC) and the Sparse Access Memory (SAM) (Graves et al., 2016; Rae et al., 2016). The NTM model also uses a content addressable memory, as in the Memory Network, but adds a write operation that allows updating the memory over time. The management of the memory, however, is different from the one of the MemNN. While the MemNN model pre-load the memories using all the inputs, the NTM writes and read the memory one input at a time.

An additional model that makes use of explicit external memory is the Dynamic Memory Network (DMN) (Kumar et al., 2016; Xiong et al., 2016). The model shares some similarities with the Memory Network model. However, unlike the MemNN model, it operates in the input sequentially (as in the NTM model). The model defines an Episodic Memory module that makes use of a Gated Recurrent Neural Network (GRU) to store and update an internal state that represents the episodic storage.

3.2 Memory Networks

Since our model is based on the MemNN architecture, we proceed to describe it in more detail. The

Memory Network model was introduced in Weston et al. (2014). In that work, the authors proposed a model composed of four components: The input feature map that converts the input into an internal vector representation, the generalization module that updates the memories given the input, the output feature map that produces a new output using the stored memories, and the response module that produces the final answer. The model, as initially proposed, needed some strong supervision that explicitly tells the model which memories to attend. In order to solve that limitation, the End-To-End Memory Network (MemN2N) was proposed in Sukhbaatar et al. (2015).

The model replaced the hard-attention mechanism used in the original MemNN by a soft-attention mechanism that allowed to train it end-to-end without strong supervision. In our model, we use a component-based approach, as in the original MemNN architecture. However, there are some differences: First, our model makes use of two external storages: a short-term storage, and a working memory buffer. The first is equivalent to the one updated by the input and generalization module of the MemNN. The working memory buffer, on the other hand, does not have a counterpart in the original model. Second, our model replaces the response module by a reasoning module. Unlike the original MemNN, our reasoning module is intended to make more complex work than the response module, that was only designed to produce a final answer.

3.3 Relation Networks

The ability to infer and learn relations between entities is fundamental to solve many complex reasoning problems. Recently, a number of neural network models have been proposed for this task. These include Interaction Networks, Graph Neural Networks, and Relation Networks (Battaglia et al., 2016; Scarselli et al., 2009; Santoro et al., 2017). In specific, Relation Networks (RNs) have shown excellent results in solving textual and visual question answering tasks requiring relational reasoning. The model is relatively simple: First, all the inputs are grouped in pairs and each pair is passed through a neural network. Then, the outputs of the first network are added, and another neural network processes the final vector. The role of the first network is to infer relations among each pair of objects. In Palm et al. (2017) the authors propose a recurrent extension to the RN. By allowing multiple steps of relational reasoning, the model can learn to solve more complex tasks. The main issue with the RN architecture is that its scale very poorly for larger problems. That is because it operates on $O(n^2)$ pairs, where n is the number of input objects (for instance, sentences in the case of textual question answering). This becomes quickly prohibitive for tasks involving many input objects.

3.4 Cognitive Science

The concept of working memory has been extensively developed in cognitive psychology. It consists of a limited capacity system that allows temporary storage and manipulation of information and is crucial to any reasoning task. One of the most influential models of working memory is the multi-component model of working memory proposed by Baddeley and Hitch (1974). This model is composed both of a supervisory attentional controller (the central executive) and two short-term storage systems: The phonological loop, capable of holding speech-based information, and the visuospatial sketchpad, concerned with visual storage. The central executive plays various functions, including the capacity to focus attention, to divide attention and to control access to long-term memory. Later modifications to the model (Baddeley, 2000) include an episodic buffer that is capable of integrating and holding information from different sources. Connections of the working memory model to memory augmented neural networks have been already studied in Graves et al. (2014). We follow this effort and subdivide our model into components that resemble (in a basic way) the multi-component model of working memory. Note, however, that we use the term working memory buffer instead of episodic buffer. That is because the episodic buffer has an integration function that our model does not cover. However, that can be an interesting source of inspiration for next versions of the model that integrate both visual and textual information for question answering.

4 Experiments

4.1 Textual Question Answering

To evaluate our model on textual question answering we used the Facebook bAbI-10k dataset (Weston et al., 2015). The bAbI dataset is a textual

QA benchmark composed of 20 different tasks. Each task is designed to test a different reasoning skill, such as deduction, induction, and coreference resolution. Some of the tasks need relational reasoning, for instance, to compare the size of different entities. Each sample is composed of a question, an answer, and a set of facts. There are two versions of the dataset, referring to different dataset sizes: bAbI-1k and bAbI-10k. In this work, we focus on the bAbI-10k version of the dataset which consists of $10,000$ training samples per task. A task is considered solved if a model achieves greater than 95% accuracy. Note that training can be done per-task or joint (by training the model on all tasks at the same time). Some models (Liu and Perez, 2017) have focused in the per-task training performance, including the EntNet model (Henaff et al., 2016) that solves all the tasks in the per-task training version. We choose to focus on the joint training version since we think is more indicative of the generalization properties of the model. A detailed analysis of the dataset can be found in Lee et al. (2015).

Model Details

To encode the input facts we used a word embedding that projected each word in a sentence into a real vector of size d. We defined $d = 30$ and used a GRU with 30 units to process each sentence. We used the 30 sentences in the support set that were immediately prior to the question. The question was processed using the same configuration but with a different GRU. We used 8 heads in the Multi-Head attention mechanism. For the transition networks f_t, which operates in the output of each hop, we used a two-layer MLP consisting of 15 and 30 hidden units (so the output preserves the memory dimension). We used $H = 4$ hops (or equivalently, a working memory buffer of size 4). In the reasoning module, we used a 3-layer MLP consisting of 128 units in each layer and with ReLU non-linearities for g_θ. We omitted the f_ϕ network since we did not observe improvements when using it. The final layer was a linear layer that produced logits for a softmax over the answer vocabulary.

Training Details

We trained our model end-to-end with a cross-entropy loss function and using the Adam optimizer (Kingma and Ba, 2014). We used a learning rate of $\nu = 1e^{-3}$. We trained the model during 400 epochs. For training, we used a batch size of 32. As in Sukhbaatar et al. (2015) we did not average the loss over a batch. Also, we clipped gradients with norm larger than 40 (Pascanu et al., 2013). For all the dense layers we used ℓ_2 regularization with value $1e^{-3}$. All weights were initialized using Glorot normal initialization (Glorot and Bengio, 2010). 10% of the training set was held-out to form a validation set that we used to select the architecture and for hyperparameter tunning. In some cases, we found useful to restart training after the 400 epochs with a smaller learning rate of $1e^{-5}$ and anneals every 5 epochs by $\nu/2$ until 20 epochs were reached.

bAbI-10k Results

On the jointly trained bAbI-10k dataset our best model (out of 10 runs) achieves an accuracy of **99.58%**. That is a **2.38%** improvement over the previous state-of-the-art that was obtained by the Sparse Differential Neural Computer (SDNC) (Rae et al., 2016). The best model of the 10 runs solves almost all tasks of the bAbI-10k dataset (by a 0.3% margin). However, a simple ensemble of the best two models solves all 20 tasks and achieves an almost perfect accuracy of **99.7%**. We list the results for each task in Table 1. Other authors have reported high variance in the results, for instance, the authors of the SDNC report a mean accuracy and standard deviation over 15 runs of 93.6 ± 2.5 (with 15.9 ± 1.6 passed tasks). In contrast, our model achieves a mean accuracy of 98.3 ± 1.2 (with 18.6 ± 0.4 passed tasks), which is better and more stable than the average results obtained by the SDNC.
The Relation Network solves 18/20 tasks. We achieve even better performance, and with considerably fewer computations, as is explained in Section 4.3. We think that by including the attention mechanism, the relation reasoning module can focus on learning the relation among relevant objects, instead of learning spurious relations among irrelevant objects. For that, the Multi-Head attention mechanism was very helpful.

The Effect of the Relational Reasoning Module

When compared to the original Memory Network, our model substantially improves the accuracy of tasks 17 (positional reasoning) and 19 (path finding). Both tasks require the analysis of multiple relations (Lee et al., 2015). For instance, the task 19 needs that the model reasons about the relation of different positions of the entities, and in that way find a path to arrive from one to another. The accuracy improves in **75.1%** for task 19 and in **41.5%** for task 17 when compared with the MemN2N model. Since both tasks require reasoning about relations, we hypothesize that the relational reasoning module of the W-MemNN was of great help to improve the performance on both tasks.
The Relation Network, on the other hand, fails in the tasks 2 (2 supporting facts) and 3 (3 supporting facts). Both tasks require handling a significant number of facts, especially in task 3. In those cases, the attention mechanism is crucial to filter out irrelevant facts.

4.2 Visual Question Answering

To further study our model we evaluated its performance on a visual question answering dataset. For that, we used the recently proposed NLVR dataset (Suhr et al., 2017). Each sample in the NLVR dataset is composed of an image with three sub-images and a statement. The task consists in judging if the statement is true or false for that image. Evaluating the statement requires reasoning about the sets of objects in the image, comparing objects properties, and reasoning about spatial relations. The dataset is interesting for us for two reasons. First, the statements evaluation requires complex relational reasoning about the objects in the image. Second, unlike the bAbI dataset, the statements are written in natural language. Because of that, each statement displays a range of syntactic and semantic phenomena that are not present in the bAbI dataset.

Model details

Our model can be easily adapted to deal with visual information. Following the idea from Santoro et al. (2017), instead of processing each input using a recurrent neural network, we use a Convolutional Neural Network (CNN). The CNN takes as input each sub-image and convolved them through convolutional layers. The output of the CNN consists of k feature maps (where k is the number

Question: What color is greg? Answer: white, Pred: white					

Table 2: Examples of visualizations of attention for textual and visual QA. Top: Visualization of attention values for the NLVR dataset. To get more aesthetic figures we applied a gaussian blur to the attention matrix. Bottom: Attention values for the bAbI dataset. In each cell, the sum of the attention for all heads is shown.

of kernels in the final convolutional layer) of size $d \times d$. Then, each memory is built from the vector composed by the concatenation of the cells in the same position of each feature map. Consequently, $d \times d$ memories of size k are stored in the short-term storage. The statement is processed using a GRU neural network as in the textual reasoning task. Then, we can proceed using the same architecture for the reasoning and attention module that the one used in the textual QA model. However, for the visual QA task, we used an additive attention mechanism. The additive attention computes the attention weight using a feed-forward neural network applied to the concatenation of the memory vector and statement vector.

Results

Our model achieves a validation / test accuracy of $65.6\%/65.8\%$. Notably, we achieved a performance comparable to the results of the Module Neural Networks (Andreas et al., 2016) that make use of standard NLP tools to process the statements into structured representations. Unlike the Module Neural Networks, we achieved our results using only raw input statements, allowing the model to learn how to process the textual input by itself. Note that given the more complex nature of the language used in the NLVR dataset we needed to use a larger embedding size and GRU hidden layer than in the bAbI dataset (100 and 128 respectively). That, however, is a nice feature of separating the input from the reasoning and attention component: One way to process more complex language statements is increasing the capacity of the input module.

4.3 From $O(n^2)$ to $O(n)$

One of the major limitations of RNs is that they need to process each one of the memories in pairs. To do that, the RN must perform $O(n^2)$ forward and backward passes (where n is the number of memories). That becomes quickly prohibitive for a larger number of memories. In contrast, the dependence of the W-MemNN run times on the number of memories is linear. Note, however, that computation times in the W-MemNN depend quadratically on the size of the working memory buffer. Nonetheless, this number is expected to be much smaller than the number of memories. To compare both models we measured the wall-clock time for a forward and backward pass for a single batch of size 32. We performed these experiments on a GPU NVIDIA K80. Figure 2 shows the results.

4.4 Memory Visualizations

One nice feature from Memory Networks is that they allow some interpretability of the reasoning procedure by looking at the attention weights. At each hop, the attention weights show which parts of the memory the model found relevant to produce the output. RNs, on the contrary, lack of this feature. Table 2 shows the attention values for visual and textual question answering.

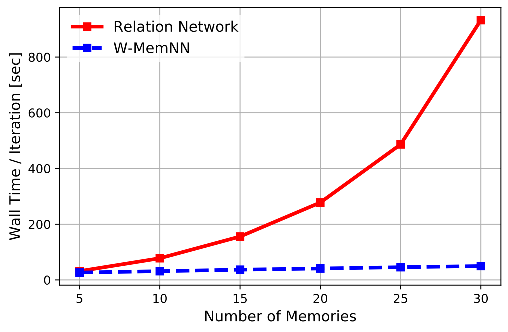

Figure 2: Wall-clock times for a forward and backward pass for a single batch. The batch size used is 32. While for 5 memories the times are comparable, for 30 memories the W-MemNN takes around 50s while the RN takes 930s, a speedup of almost 20×.

5 Conclusion

We have proposed a novel Working Memory Network architecture that introduces improved reasoning abilities to the original MemNN model. We demonstrated that by augmenting the MemNN architecture with a Relation Network, the computational complexity of the RN can be reduced, without loss of performance. That opens the opportunity for using RNs in larger problems, something that may be very useful, given the many tasks requiring a significant amount of memories.

Although we have used RN as the reasoning module in this work, other options can be tested. It might be interesting to analyze how other reasoning modules can improve different weaknesses of the model.

We presented results on the jointly trained bAbI-10k dataset, where we achieve a new state-of-the-art, with an average error of less than 0.5%. Also, we showed that our model can be easily adapted for visual question answering.

Our architecture combines perceptual input processing, short-term memory storage, an attention mechanism, and a reasoning module. While other models have focused on different parts of these components, we think that is important to find ways to combine these different mechanisms if we want to build models capable of complex reasoning. Evidence from cognitive sciences seems to show that all these abilities are needed in order to achieve human-level complex reasoning.

Abstract

Sarcasm is a sophisticated speech act which commonly manifests on social communities such as Twitter and Reddit. The prevalence of sarcasm on the social web is highly disruptive to opinion mining systems due to not only its tendency of polarity flipping but also usage of figurative language. Sarcasm commonly manifests with a contrastive theme either between positive-negative sentiments or between literal-figurative scenarios. In this paper, we revisit the notion of modeling *contrast* in order to reason with sarcasm. More specifically, we propose an attention-based neural model that looks *in-between* instead of *across*, enabling it to explicitly model contrast and incongruity. We conduct extensive experiments on six benchmark datasets from Twitter, Reddit and the Internet Argument Corpus. Our proposed model not only achieves state-of-the-art performance on all datasets but also enjoys improved interpretability.

1 Introduction

Sarcasm, commonly defined as *'An ironical taunt used to express contempt'*, is a challenging NLP problem due to its highly figurative nature. The usage of sarcasm on the social web is prevalent and can be frequently observed in reviews, microblogs (*tweets*) and online forums. As such, the battle against sarcasm is also regularly cited as one of the key challenges in sentiment analysis and opinion mining applications (Pang et al., 2008). Hence, it is both imperative and intuitive that effective sarcasm detectors can bring about numerous benefits to opinion mining applications.

Sarcasm is often associated to several linguistic phenomena such as (1) an explicit contrast between sentiments or (2) disparity between the conveyed emotion and the author's situation (context). Prior work has considered sarcasm to be a contrast between a positive and negative sentiment (Riloff et al., 2013). Consider the following examples:

1. I absolutely *love* to be *ignored*!
2. Yay!!! The best thing to wake up to is my neighbor's drilling.
3. Perfect movie for people who can't fall asleep.

Given the examples, we make a crucial observation - Sarcasm relies a lot on the semantic relationships (and contrast) between individual words and phrases in a sentence. For instance, the relationships between phrases {*love*, *ignored*}, {*best*, *drilling*} and {*movie*, *asleep*} (in the examples above) richly characterize the nature of sarcasm conveyed, i.e., word pairs tend to be contradictory and more often than not, express a juxtaposition of positive and negative terms. This concept is also explored in (Joshi et al., 2015) in which the authors refer to this phenomena as *'incongruity'*. Hence, it would be useful to capture the relationships between selected word pairs in a sentence, i.e., *looking in-between*.

State-of-the-art sarcasm detection systems mainly rely on deep and *sequential* neural networks (Ghosh and Veale, 2016; Zhang et al., 2016). In these works, compositional encoders such as gated recurrent units (GRU) (Cho et al., 2014) or long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) are often employed, with the input document being parsed one word at a time. This has several shortcomings for the sarcasm detection task. Firstly, there is no explicit interaction between word pairs, which hampers its ability to explicitly model contrast, incongruity or juxtaposition of situations. Secondly, it is difficult to capture long-range dependencies. In this case, contrastive situations (or sentiments) which are commonplace in sarcastic language may be hard to detect with simple sequential models.

To overcome the weaknesses of standard sequential models such as recurrent neural networks, our work is based on the intuition that modeling intra-sentence relationships can not only improve classification performance but also pave the way for more explainable neural sarcasm detection methods. In other words, our key intuition manifests itself in the form of an attention-based neural network. While the key idea of most neural attention mechanisms is to focus on relevant words and sub-phrases, it merely looks *across* and does not explicitly capture word-word relationships. Hence, it suffers from the same shortcomings as sequential models.

In this paper, our aim is to combine the effectiveness of state-of-the-art recurrent models while harnessing the intuition of *looking in-between*. We propose a multi-dimensional intra-attention recurrent network that models intricate similarities between each word pair in the sentence. In other words, our novel deep learning model aims to capture *'contrast'* (Riloff et al., 2013) and *'incongruity'* (Joshi et al., 2015) within end-to-end neural networks. Our model can be thought of self-targeted co-attention (Xiong et al., 2016), which allows our model to not only capture word-word relationships but also long-range dependencies. Finally, we show that our model produces interpretable attention maps which aid in the explainability of model outputs. To the best of our knowledge, our model is the first attention model that can produce explainable results in the sarcasm detection task.

Briefly, the prime contributions of this work can be summarized as follows:

- We propose a new state-of-the-art method for sarcasm detection. Our proposed model, the Multi-dimensional Intra-Attention Recurrent Network (MIARN) is strongly based on the intuition of compositional learning by leveraging intra-sentence relationships. To the best of our knowledge, none of the existing state-of-the-art models considered exploiting intra-sentence relationships, solely relying on sequential composition.
- We conduct extensive experiments on multiple benchmarks from Twitter, Reddit and the Internet Argument Corpus. Our proposed MIARN achieves highly competitive performance on all benchmarks, outperforming existing state-of-the-art models such as GRNN (Zhang et al., 2016) and CNN-LSTM-DNN (Ghosh and Veale, 2016).

2 Related Work

Sarcasm is a complex linguistic phenomena that have long fascinated both linguists and NLP researchers. After all, a better computational understanding of this complicated speech act could potentially bring about numerous benefits to existing opinion mining applications. Across the rich history of research on sarcasm, several theories such as the Situational Disparity Theory (Wilson, 2006) and the Negation Theory (Giora, 1995) have emerged. In these theories, a common theme is a motif that is strongly grounded in contrast, whether in sentiment, intention, situation or context. (Riloff et al., 2013) propagates this premise forward, presenting an algorithm strongly based on the intuition that sarcasm arises from a juxtaposition of positive and negative situations.

2.1 Sarcasm Detection

Naturally, many works in this area have treated the sarcasm detection task as a standard text classification problem. An extremely comprehensive overview can be found at (Joshi et al., 2017). Feature engineering approaches were highly popular, exploiting a wide diverse range of features such as syntactic patterns (Tsur et al., 2010), sentiment lexicons (González-Ibánez et al., 2011), n-gram (Reyes et al., 2013), word frequency (Barbieri et al., 2014), word shape and pointedness features (Ptáček et al., 2014), readability and flips (Rajadesingan et al., 2015), etc. Notably, there have been quite a reasonable number of works that propose features based on similarity and contrast. (Hernández-Farías et al., 2015) measured the Wordnet based semantic similarity between words. (Joshi et al., 2015) proposed a framework based on explicit and implicit incongruity, utilizing features based on positive-negative patterns. (Joshi et al., 2016) proposed similarity features based on word embeddings.

2.2 Deep Learning for Sarcasm Detection

Deep learning based methods have recently garnered considerable interest in many areas of NLP research. In our problem domain, (Zhang et al., 2016) proposed a recurrent-based model with a gated pooling mechanism for sarcasm detection on Twitter. (Ghosh and Veale, 2016) proposed a convolutional long-short-term memory network (CNN-LSTM-DNN) that achieves state-of-the-art performance.

While our work focuses on document-only sarcasm detection, several notable works have proposed models that exploit personality information (Ghosh and Veale, 2017) and user context (Amir et al., 2016). Novel methods for sarcasm detection such as gaze / cognitive features (Mishra et al., 2016, 2017) have also been explored. (Peled and Reichart, 2017) proposed a novel framework based on neural machine translation to convert a sequence from sarcastic to non-sarcastic. (Felbo et al., 2017) proposed a layer-wise training scheme that utilizes emoji-based distant supervision for sentiment analysis and sarcasm detection tasks.

2.3 Attention Models for NLP

In the context of NLP, the key idea of neural attention is to soft select a sequence of words based on their relative importance to the task at hand. Early innovations in attentional paradigms mainly involve neural machine translation (Luong et al., 2015; Bahdanau et al., 2014) for aligning sequence pairs. Attention is also commonplace in many NLP applications such as sentiment classification (Chen et al., 2016; Yang et al., 2016), aspect-level sentiment analysis (Tay et al., 2018s, 2017b; Chen et al., 2017) and entailment classification (Rocktäschel et al., 2015). Co-attention / Bi-Attention (Xiong et al., 2016; Seo et al., 2016) is a form of pairwise attention mechanism that was proposed to model query-document pairs. Intra-attention can be interpreted as a self-targetted co-attention and is seeing a lot promising results in many recent works (Vaswani et al., 2017; Parikh et al., 2016; Tay et al., 2017a; Shen et al., 2017). The key idea is to model a sequence against itself, learning to attend while capturing long term dependencies and word-word level interactions. To the best of our knowledge, our work is not only the first work that only applies intra-attention to sarcasm detection but also the first attention model for sarcasm detection.

3 Our Proposed Approach

In this section, we describe our proposed model. Figure 1 illustrates our overall model architecture.

3.1 Input Encoding Layer

Our model accepts a sequence of one-hot encoded vectors as an input. Each one-hot encoded vector corresponds to a single word in the vocabulary. In the input encoding layer, each one-hot vector is converted into a low-dimensional vector representation (word embedding). The word embeddings are parameterized by an embedding layer $\mathbf{W} \in \mathbb{R}^{n \times |V|}$. As such, the output of this layer is a sequence of word embeddings, i.e., $\{w_1, w_2, \cdots w_\ell\}$ where ℓ is a predefined maximum sequence length.

3.2 Multi-dimensional Intra-Attention

In this section, we describe our multi-dimensional intra-attention mechanism for sarcasm detection. We first begin by describing the standard single-dimensional intra-attention. The multi-dimensional adaptation will be introduced later in this section. The key idea behind this layer is to *look in-between*, i.e., modeling the semantics between each word in the input sequence. We first begin by modeling the relationship of each word pair in the input sequence. A simple way to achieve this is to use a linear[1] transformation layer to project the concatenation of each word embedding **pair** into a scalar score as follows:

$$s_{ij} = W_a([w_i; w_j]) + b_a \tag{1}$$

where $W_a \in \mathbb{R}^{2n \times 1}, b_a \in \mathbb{R}$ are the parameters of this layer. $[.;.]$ is the vector concatenation operator and s_{ij} is a scalar representing the affinity score between word pairs (w_i, w_j). We can easily observe that s is a symmetrical matrix of $\ell \times \ell$ dimensions. In order to learn attention vector a, we apply a row-wise max-pooling operator on matrix s.

$$a = softmax(\max_{row} s) \tag{2}$$

where $a \in \mathbb{R}^\ell$ is a vector representing the learned intra-attention weights. Then, the vector a is employed to learn weighted representation of $\{w_1, w_2 \cdots w_\ell\}$ as follows:

$$v_a = \sum_{i=1}^{\ell} w_i a_i \tag{3}$$

[1]Early experiments found that adding nonlinearity here may degrade performance.

where $v \in \mathbb{R}^n$ is the intra-attentive representation of the input sequence. While other choices of pooling operators may be also employed (e.g., mean-pooling over max-pooling), the choice of max-pooling is empirically motivated. Intuitively, this attention layer learns to pay attention based on a word's *largest* contribution to all words in the sequence. Since our objective is to highlight words that might contribute to the contrastive theories of sarcasm, a more discriminative pooling operator is desirable. Notably, we also mask values of s where $i = j$ such that we do not allow the relationship scores of a word with respect to itself to influence the overall attention weights.

Furthermore, our network can be considered as an *'inner'* adaptation of neural attention, modeling intra-sentence relationships between the raw word representations instead of representations that have been compositionally manipulated. This allows word-to-word similarity to be modeled *'as it is'* and not be influenced by composition. For example, when using the outputs of a compositional encoder (e.g., LSTM), matching words n and $n + 1$ might not be meaningful since they would be relatively similar in terms of semantic composition. For relatively short documents (such as tweets), it is also intuitive that attention typically focuses on the last hidden representation.

Intuitively, the relationships between two words is often not straightforward. Words are complex and often hold more than one meanings (or word senses). As such, it might be beneficial to model *multiple views* between two words. This can be modeled by representing the word pair interaction with a vector instead of a scalar. As such, we propose a multi-dimensional adaptation of the intra-attention mechanism. The key idea here is that each word pair is projected down to a low-dimensional vector before we compute the affinity score, which allows it to not only capture one view (one scalar) but also multiple views. A modification to Equation (1) constitutes our Multi-Dimensional Intra-Attention variant.

$$s_{ij} = W_p(ReLU(W_q([w_i; w_j]) + b_q)) + b_p \quad (4)$$

where $W_q \in \mathbb{R}^{n \times k}, W_p \in \mathbb{R}^{k \times 1}, b_q \in \mathbb{R}^k, b_p \in \mathbb{R}$ are the parameters of this layer. The final intra-attentive representation is then learned with Equation (2) and Equation (3) which we do not repeat here for the sake of brevity.

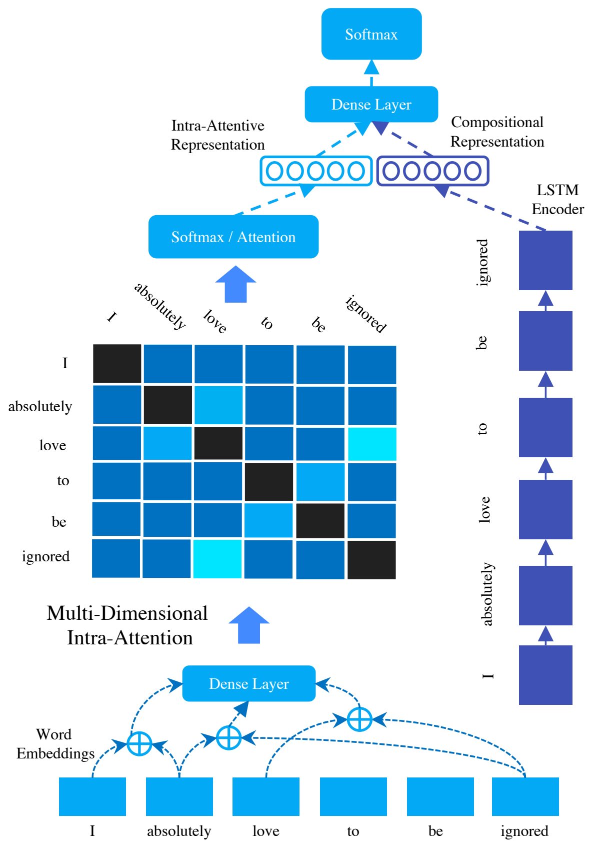

Figure 1: High level overview of our proposed MIARN architecture. MIARN learns two representations, one based on intra-sentence relationships (intra-attentive) and another based on sequential composition (LSTM). Both views are used for prediction.

3.3 Long Short-Term Memory Encoder

While we are able to simply use the learned representation v for prediction, it is clear that v does not encode compositional information and may miss out on important compositional phrases such as *'not happy'*. Clearly, our intra-attention mechanism simply considers a word-by-word interaction and does not model the input document sequentially. As such, it is beneficial to use a separate compositional encoder for this purpose, i.e., learning compositional representations. To this end, we employ the standard Long Short-Term Memory (LSTM) encoder. The output of an LSTM encoder at each time-step can be briefly defined as:

$$h_i = \text{LSTM}(w, i), \quad \forall i \in [1, \dots \ell] \quad (5)$$

where ℓ represents the maximum length of the sequence and $h_i \in \mathbb{R}^d$ is the hidden output of the LSTM encoder at time-step i. d is the size of the hidden units of the LSTM encoder. LSTM encoders are parameterized by gating mechanisms learned via nonlinear transformations. Since

LSTMs are commonplace in standard NLP applications, we omit the technical details for the sake of brevity. Finally, to obtain a compositional representation of the input document, we use $v_c = h_\ell$ which is the last hidden output of the LSTM encoder. Note that the inputs to the LSTM encoder are the word embeddings right after the input encoding layer and not the output of the intra-attention layer. We found that applying an LSTM on the intra-attentively scaled representations do not yield any benefits.

3.4 Prediction Layer

The inputs to the final prediction layer are two representations, namely (1) the intra-attentive representation ($v_a \in \mathbb{R}^n$) and (2) the compositional representation ($v_c \in \mathbb{R}^d$). This layer learns a joint representation of these two views using a nonlinear projection layer.

$$v = ReLU(W_z([v_a; v_c]) + b_z) \tag{6}$$

where $W_z \in \mathbb{R}^{(d+n)\times d}$ and $b_z \in \mathbb{R}^d$. Finally, we pass v into a Softmax classification layer.

$$\hat{y} = Softmax(W_f\, v + b_f) \tag{7}$$

where $W_f \in \mathbb{R}^{d\times 2}, b_f \in \mathbb{R}^2$ are the parameters of this layer. $\hat{y} \in \mathbb{R}^2$ is the output layer of our proposed model.

3.5 Optimization and Learning

Our network is trained end-to-end, optimizing the standard binary cross-entropy loss function.

$$J = -\sum_{i=1}^{N} [y_i \log \hat{y}_i + (1 - y_i)\log(1 - \hat{y}_i)] + R \tag{8}$$

where J is the cost function, $\hat{y}$ is the output of the network, $R = ||\theta||_{L2}$ is the L2 regularization and λ is the weight of the regularizer.

4 Empirical Evaluation

In this section, we describe our experimental setup and results. Our experiments were designed to answer the following research questions (**RQ**s).

- **RQ1** - Does our proposed approach outperform existing state-of-the-art models?
- **RQ2** - What are the impacts of some of the architectural choices of our model? How much does intra-attention contribute to the model performance? Is the Multi-Dimensional adaptation better than the Single-Dimensional adaptation?
- **RQ3** - What can we interpret from the intra-attention layers? Does this align with our hypothesis about *looking in-between* and modeling contrast?

4.1 Datasets

We conduct our experiments on six publicly available benchmark datasets which span across three well-known sources.

- **Tweets** - Twitter[2] is a microblogging platform which allows users to post statuses of less than 140 characters. We use two collections for sarcasm detection on tweets. More specifically, we use the dataset obtained from (1) (Ptáček et al., 2014) in which tweets are trained via hashtag based semi-supervised learning, i.e., hashtags such as #not, #sarcasm and #irony are marked as sarcastic tweets and (2) (Riloff et al., 2013) in which Tweets are hand annotated and manually checked for sarcasm. For both datasets, we retrieve. Tweets using the Twitter API using the provided tweet IDs.
- **Reddit** - Reddit[3] is a highly popular social forum and community. Similar to Tweets, sarcastic posts are obtained via the tag '/s' which are marked by the authors themselves. We use two Reddit datasets which are obtained from the subreddits */r/movies* and */r/technology* respectively. Datasets are subsets from (Khodak et al., 2017).
- **Debates** - We use two datasets[4] from the Internet Argument Corpus (IAC) (Lukin and Walker, 2017) which have been hand annotated for sarcasm. This dataset, unlike the first two, is mainly concerned with long text and provides a diverse comparison from the other datasets. The IAC corpus was designed for research on political debates on online forums. We use the V1 and V2 versions of the sarcasm corpus which are denoted as IAC-V1 and IAC-V2 respectively.

The statistics of the datasets used in our experiments is reported in Table 1.

Table 1: Statistics of datasets used in our experiments.

4.2 Compared Methods

We compare our proposed model with the following algorithms.

- **NBOW** is a simple neural bag-of-words baseline that sums all the word embeddings and passes the summed vector into a simple logistic regression layer.
- **CNN** is a vanilla Convolutional Neural Network with max-pooling. CNNs are considered as compositional encoders that capture n-gram features by parameterized sliding windows. The filter width is 3 and number of filters $f = 100$.
- **LSTM** is a vanilla Long Short-Term Memory Network. The size of the LSTM cell is set to $d = 100$.
- **ATT-LSTM (Attention-based LSTM)** is a LSTM model with a neural attention mechanism applied to all the LSTM hidden outputs. We use a similar adaptation to (Yang et al., 2016), albeit only at the document-level.
- **GRNN (Gated Recurrent Neural Network)** is a Bidirectional Gated Recurrent Unit (GRU) model that was proposed for sarcasm detection by (Zhang et al., 2016). GRNN uses a gated pooling mechanism to aggregate the hidden representations from a standard BiGRU model. Since we only compare on document-level sarcasm detection, we do not use the variant of GRNN that exploits user context.
- **CNN-LSTM-DNN (Convolutional LSTM + Deep Neural Network)**, proposed by (Ghosh and Veale, 2016), is the state-of-the-art model for sarcasm detection. This model is a combination of a CNN, LSTM and Deep Neural Network via stacking. It stacks two layers of 1D convolution with 2 LSTM layers. The output passes through a deep neural network (DNN) for prediction.

Both CNN-LSTM-DNN (Ghosh and Veale, 2016) and GRNN (Zhang et al., 2016) are state-of-the-art models for document-level sarcasm detection and have outperformed numerous neural and non-neural baselines. In particular, both works have well surpassed feature-based models (Support Vector Machines, etc.), as such we omit comparisons for the sake of brevity and focus comparisons with recent neural models instead. Moreover, since our work focuses only on document-level sarcasm detection, we do not compare against models that use external information such as user profiles, context, personality information (Ghosh and Veale, 2017) or emoji-based distant supervision (Felbo et al., 2017).

For our model, we report results on both multi-dimensional and single-dimensional intra-attention. The two models are named as MIARN and SIARN respectively.

4.3 Implementation Details and Metrics

We adopt standard the evaluation metrics for the sarcasm detection task, i.e., macro-averaged F1 and accuracy score. Additionally, we also report precision and recall scores. All deep learning models are implemented using TensorFlow (Abadi et al., 2015) and optimized on a NVIDIA GTX1070 GPU. Text is preprocessed with NLTK[5]'s Tweet tokenizer. Words that only appear once in the entire corpus are removed and marked with the UNK token. Document lengths are truncated at $40, 20, 80$ tokens for Twitter, Reddit and Debates dataset respectively. Mentions of other users on the Twitter dataset are replaced by '@USER'. Documents with URLs (i.e., containing 'http') are removed from the corpus. Documents with less than 5 tokens are also removed. The learning optimizer used is the RMSProp with an initial learning rate of 0.001. The L2 regularization is set to 10^{-8}. We initialize the word embedding layer with GloVe (Pennington et al., 2014). We use the GloVe model trained on 2B Tweets for the Tweets and Reddit dataset. The Glove model trained on Common Crawl is used for the Debates corpus. The size of the word embeddings is fixed at $d = 100$ and are fine-tuned during training. In all experiments, we use a development set to select the best hyperparameters. Each model is trained for a total of 30 epochs and the model is saved each time the performance

on the development set is topped. The batch size is tuned amongst $\{128, 256, 512\}$ for all datasets. The only exception is the Tweets dataset from (Riloff et al., 2013), in which a batch size of 16 is used in lieu of the much smaller dataset size. For fair comparison, all models have the same hidden representation size and are set to 100 for both recurrent and convolutional based models (i.e., number of filters). For MIARN, the size of intra-attention hidden representation is tuned amongst $\{4, 8, 10, 20\}$.

4.4 Experimental Results

Table 2, Table 3 and Table 4 reports a performance comparison of all benchmarked models on the Tweets, Reddit and Debates datasets respectively. We observe that our proposed SIARN and MIARN models achieve the best results across all six datasets. The relative improvement differs across domain and datasets. On the Tweets dataset from (Ptáček et al., 2014), MIARN achieves about $\approx 2\% - 2.2\%$ improvement in terms of F1 and accuracy score when compared against the best baseline. On the other Tweets dataset from (Riloff et al., 2013), the performance gain of our proposed model is larger, i.e., $3\% - 5\%$ improvement on average over most baselines. Our proposed SIARN and MIARN models achieve very competitive performance on the Reddit datasets, with an average of $\approx 2\%$ margin improvement over the best baselines. Notably, the baselines we compare against are extremely competitive state-of-the-art neural network models. This further reinforces the effectiveness of our proposed approach. Additionally, the performance improvement on Debates (long text) is significantly larger than short text (i.e., Twitter and Reddit). For example, MIARN outperforms GRNN and CNN-LSTM-DNN by $\approx 8\% - 10\%$ on both IAC-V1 and IAC-V2. At this note, we can safely put **RQ1** to rest.

Overall, the performance of MIARN is often marginally better than SIARN (with some exceptions, e.g., *Tweets* dataset from (Riloff et al., 2013)). We believe that this is attributed to the fact that more complex word-word relationships can be learned by using multi-dimensional values instead of single-dimensional scalars. The performance brought by our additional intra-attentive representations can be further observed by comparing against the vanilla LSTM model. Clearly, removing the intra-attention network reverts our model to the standard LSTM. The performance improvements are encouraging, leading to almost 10% improvement in terms of F1 and accuracy. On datasets with short text, the performance improvement is often a modest $\approx 2\% - 3\%$ (**RQ2**). Notably, our proposed models also perform much better on long text, which can be attributed to the intra-attentive representations explicitly modeling long range dependencies. Intuitively, this is problematic for models that only capture sequential dependencies (e.g., word by word).

Finally, the relative performance of competitor methods are as expected. NBOW performs the worse, since it is just a naive bag-of-words model without any compositional or sequential information. On short text, LSTMs are overall better than CNNs. However, this trend is reversed on long text (i.e., Debates) since the LSTM model may be overburdened by overly long sequences. On short text, we also found that attention (or the gated pooling mechanism from GRNN) did not really help make any significant improvements over the vanilla LSTM model and a qualitative explanation to why this is so is deferred to the next section. However, attention helps for long text (such as debates), resulting in Attention LSTMs becoming the strongest baseline on the Debates datasets. However, our proposed intra-attentive model is both effective on short text and long text, outperforming Attention LSTMs consistently on all datasets.

4.5 In-depth Model Analysis

In this section, we present an in-depth analysis of our proposed model. More specifically, we not only aim to showcase the interpretability of our model but also explain how representations are formed. More specifically, we test our model (trained on Tweets dataset by (Ptáček et al., 2014)) on two examples. We extract the attention maps of three models, namely MIARN, Attention LSTM (ATT-LSTM) and applying Attention mechanism directly on the word embeddings without using a LSTM encoder (ATT-RAW). Table 5 shows the visualization of the attention maps.

Label	Model	Sentence
True	MIARN	I totally love being ignored !!
	ATT-LSTM	I totally love being ignored !!
	ATT-RAW	I totally love being ignored !!
False	MIARN	Being ignored sucks big time
	ATT-LSTM	Being ignored sucks big time
	ATT-RAW	Being ignored sucks big time

Table 5: Visualization of normalized attention weights on three different attention models (*Best viewed in color*). The intensity denotes the strength of the attention weight on the word.

In the first example (*true* label), we notice that the attention maps of MIARN are focusing on the words *'love'* and *'ignored'*. This is in concert with our intuition about modeling contrast and incongruity. On the other hand, both ATT-LSTM and ATT-RAW learn very different attention maps. As for ATT-LSTM, the attention weight is focused completely on the last representation - the token *'!!'*. Additionally, we also observed that this is true for many examples in the Tweets and Reddit dataset. We believe that this is the reason why standard neural attention does not help as what the attention mechanism is learning is to select the last representation (i.e., vanilla LSTM). Without the LSTM encoder, the attention weights focus on *'love'* but not *'ignored'*. This fails to capture any concept of contrast or incongruity.

Next, we consider the *false* labeled example. This time, the attention maps of MIARN are not as distinct as before. However, they focus on sentiment-bearing words, composing the words *'ignored sucks'* to form the majority of the intra-attentive representation. This time, passing the vector made up of *'ignored sucks'* allows the subsequent layers to recognize that there is no contrasting situation or sentiment. Similarly, ATT-LSTM focuses on the last word *time* which is totally non-interpretable. On the other hand, ATT-RAW focuses on relatively non-meaningful words such as *'big'*.

Overall, we analyzed two cases (positive and negative labels) and found that MIARN produces very explainable attention maps. In general, we found that MIARN is able to identify contrast and incongruity in sentences, allowing our model to better detect sarcasm. This is facilitated by modeling intra-sentence relationships. Notably, the standard vanilla attention is not explainable or interpretable.

5 Conclusion

Based on the intuition of intra-sentence similarity (i.e., *looking in-between*), we proposed a new neural network architecture for sarcasm detection. Our network incorporates a multi-dimensional intra-attention component that learns an intra-attentive representation of the sentence, enabling it to detect contrastive sentiment, situations and incongruity. Extensive experiments over six public benchmarks confirm the empirical effectiveness of our proposed model. Our proposed MIARN model outperforms strong state-of-the-art baselines such as GRNN and CNN-LSTM-DNN. Analysis of the intra-attention scores shows that our model learns highly interpretable attention weights, paving the way for more explainable neural sarcasm detection methods.

Abstract

Learning by contrasting positive and negative samples is a general strategy adopted by many methods. Noise contrastive estimation (NCE) for word embeddings and translating embeddings for knowledge graphs are examples in NLP employing this approach. In this work, we view contrastive learning as an abstraction of all such methods and augment the negative sampler into a mixture distribution containing an adversarially learned sampler. The resulting adaptive sampler finds harder negative examples, which forces the main model to learn a better representation of the data. We evaluate our proposal on learning word embeddings, order embeddings and knowledge graph embeddings and observe both faster convergence and improved results on multiple metrics.

1 Introduction

Many models learn by contrasting losses on observed positive examples with those on some fictitious negative examples, trying to decrease some score on positive ones while increasing it on negative ones. There are multiple reasons why such contrastive learning approach is needed. Computational tractability is one. For instance, instead of using softmax to predict a word for learning word embeddings, noise contrastive estimation (NCE) (Dyer, 2014; Mnih and Teh, 2012) can be used in skip-gram or CBOW word embedding models (Gutmann and Hyvärinen, 2012; Mikolov et al., 2013; Mnih and Kavukcuoglu, 2013; Vaswani et al., 2013). Another reason is modeling need, as certain assumptions are best expressed as some score or energy in margin based or un-normalized probability models (Smith and Eisner, 2005). For example, modeling entity relations as translations or variants thereof in a vector space naturally leads to a distance-based score to be minimized for observed entity-relation-entity triplets (Bordes et al., 2013).

Given a scoring function, the gradient of the model's parameters on observed positive examples can be readily computed, but the negative phase requires a design decision on how to sample data. In noise contrastive estimation for word embeddings, a negative example is formed by replacing a component of a positive pair by randomly selecting a sampled word from the vocabulary, resulting in a fictitious word-context pair which would be unlikely to actually exist in the dataset. This negative sampling by corruption approach is also used in learning knowledge graph embeddings (Bordes et al., 2013; Lin et al., 2015; Ji et al., 2015; Wang et al., 2014; Trouillon et al., 2016; Yang et al., 2014; Dettmers et al., 2017), order embeddings (Vendrov et al., 2016), caption generation (Dai and Lin, 2017), etc.

Typically the corruption distribution is the same for all inputs like in skip-gram or CBOW NCE, rather than being a conditional distribution that takes into account information about the input sample under consideration. Furthermore, the corruption process usually only encodes a human prior as to what constitutes a hard negative sample, rather than being learned from data. For these two reasons, the simple fixed corruption process often yields only easy negative examples. Easy negatives are sub-optimal for learning discriminative representation as they do not force the model to find critical characteristics of observed positive data, which has been independently discovered in applications outside NLP previously (Shrivastava

[*] authors contributed equally
[†] Work done while author was an intern at Borealis AI

et al., 2016). Even if hard negatives are occasionally reached, the infrequency means slow convergence. Designing a more sophisticated corruption process could be fruitful, but requires costly trial-and-error by a human expert.

In this work, we propose to augment the simple corruption noise process in various embedding models with an adversarially learned conditional distribution, forming a mixture negative sampler that adapts to the underlying data and the embedding model training progress. The resulting method is referred to as adversarial contrastive estimation (ACE). The adaptive conditional model engages in a minimax game with the primary embedding model, much like in Generative Adversarial Networks (GANs) (Goodfellow et al., 2014a), where a discriminator net (D), tries to distinguish samples produced by a generator (G) from real data (Goodfellow et al., 2014b). In ACE, the main model learns to distinguish between a real positive example and a negative sample selected by the mixture of a fixed NCE sampler and an adversarial generator. The main model and the generator takes alternating turns to update their parameters. In fact, our method can be viewed as a conditional GAN (Mirza and Osindero, 2014) on discrete inputs, with a mixture generator consisting of a learned and a fixed distribution, with additional techniques introduced to achieve stable and convergent training of embedding models.

In our proposed ACE approach, the conditional sampler finds harder negatives than NCE, while being able to gracefully fall back to NCE whenever the generator cannot find hard negatives. We demonstrate the efficacy and generality of the proposed method on three different learning tasks, word embeddings (Mikolov et al., 2013), order embeddings (Vendrov et al., 2016) and knowledge graph embeddings (Ji et al., 2015).

2 Method

2.1 Background: contrastive learning

In the most general form, our method applies to supervised learning problems with a contrastive objective of the following form:

$$L(\omega) = \mathbb{E}_{p(x^+,y^+,y^-)}\, l_\omega(x^+, y^+, y^-) \qquad (1)$$

where $l_\omega(x^+, y^+, y^-)$ captures both the model with parameters ω and the loss that scores a positive tuple (x^+, y^+) against a negative one (x^+, y^-). $\mathbb{E}_{p(x^+,y^+,y^-)}(.)$ denotes expectation with respect to some joint distribution over positive and negative samples. Furthermore, by the law of total expectation, and the fact that given x^+, the negative sampling is not dependent on the positive label, i.e. $p(y^+, y^-|x^+) = p(y^+|x^+)p(y^-|x^+)$, Eq. 1 can be re-written as

$$\mathbb{E}_{p(x^+)}[\mathbb{E}_{p(y^+|x^+)p(y^-|x^+)}\, l_\omega(x^+, y^+, y^-)] \qquad (2)$$

Separable loss

In the case where the loss decomposes into a sum of scores on positive and negative tuples such as $l_\omega(x^+, y^+, y^-) = s_\omega\,(x^+, y^+) - \tilde{s}_\omega\,(x^+, y^-)$, then Expression. 2 becomes

$$\mathbb{E}_{p^+(x)}[\mathbb{E}_{p^+(y|x)}\, s_\omega\,(x, y) - \mathbb{E}_{p^-(y|x)}\, \tilde{s}_\omega\,(x, y)] \qquad (3)$$

where we moved the $+$ and $-$ to p for notational brevity. Learning by stochastic gradient descent aims to adjust ω to pushing down $s_\omega\,(x, y)$ on samples from p^+ while pushing up $\tilde{s}_\omega\,(x, y)$ on samples from p^-. Note that for generality, the scoring function for negative samples, denoted by $\tilde{s}_\omega$, could be slightly different from s_ω. For instance, $\tilde{s}$ could contain a margin as in the case of Order Embeddings in Sec. 4.2.

Non separable loss

Eq. 1 is the general form that we would like to consider because for certain problems, the loss function cannot be separated into sums of terms containing only positive (x^+, y^+) and terms with negatives (x^+, y^-). An example of such a non-separable loss is the triplet ranking loss (Schroff et al., 2015): $l_\omega = \max(0, \eta + s_\omega\,(x^+, y^+) - s_\omega\,(x^+, y^-))$, which does not decompose due to the rectification.

Noise contrastive estimation

The typical NCE approach in tasks such as word embeddings (Mikolov et al., 2013), order embeddings (Vendrov et al., 2016), and knowledge graph embeddings can be viewed as a special case of Eq. 2 by taking $p(y^-|x^+)$ to be some unconditional $p_{nce}(y)$.

This leads to efficient computation during training, however, $p_{nce}(y)$ sacrifices the sampling efficiency of learning as the negatives produced using a fixed distribution are not tailored toward x^+, and as a result are not necessarily hard negative examples. Thus, the model is not forced to discover discriminative representation of observed positive data. As training progresses, more and more negative examples are correctly learned, the probability of drawing a hard negative example diminishes further, causing slow convergence.

2.2 Adversarial mixture noise

To remedy the above mentioned problem of a fixed unconditional negative sampler, we propose to augment it into a mixture one, $\lambda p_{nce}(y) + (1 - \lambda) g_\theta(y|x)$, where g_θ is a conditional distribution with a learnable parameter θ and λ is a hyperparameter. The objective in Expression. 2 can then be written as (conditioned on x for notational brevity):

$$L(\omega, \theta; x) = \lambda\, \mathbb{E}_{p(y^+|x) p_{nce}(y^-)}\, l_\omega(x, y^+, y^-) \\ + (1 - \lambda)\, \mathbb{E}_{p(y^+|x) g_\theta(y^-|x)}\, l_\omega(x, y^+, y^-) \quad (4)$$

We learn (ω, θ) in a GAN-style minimax game:

$$\min_\omega \max_\theta V(\omega, \theta) = \min_\omega \max_\theta \mathbb{E}_{p^+(x)}\, L(\omega, \theta; x) \quad (5)$$

The embedding model behind $l_\omega(x, y^+, y^-)$ is similar to the discriminator in (conditional) GAN (or critic in Wasserstein (Arjovsky et al., 2017) or Energy-based GAN (Zhao et al., 2016), while $g_\theta(y|x)$ acts as the generator. Henceforth, we will use the term discriminator (D) and embedding model interchangeably, and refer to g_θ as the generator.

2.3 Learning the generator

There is one important distinction to typical GAN: $g_\theta(y|x)$ defines a categorical distribution over possible y values, and samples are drawn accordingly; in contrast to typical GAN over continuous data space such as images, where samples are generated by an implicit generative model that warps noise vectors into data points. Due to the discrete sampling step, g_θ cannot learn by receiving gradient through the discriminator. One possible solution is to use the Gumbel-softmax reparametrization trick (Jang et al., 2016; Maddison et al., 2016), which gives a differentiable approximation. However, this differentiability comes at the cost of drawing N Gumbel samples per each categorical sample, where N is the number of categories. For word embeddings, N is the vocabulary size, and for knowledge graph embeddings, N is the number of entities, both leading to infeasible computational requirements.

Instead, we use the REINFORCE (Williams, 1992) gradient estimator for $\nabla_\theta L(\theta, x)$:

$$(1-\lambda)\, \mathbb{E}\left[-l_\omega(x, y^+, y^-) \nabla_\theta \log(g_\theta(y^-|x))\right] \quad (6)$$

where the expectation $\mathbb{E}$ is with respect to $p(y^+, y^-|x) = p(y^+|x) g_\theta(y^-|x)$, and the discriminator loss $l_\omega(x, y^+, y^-)$ acts as the reward.

With a separable loss, the (conditional) value function of the minimax game is:

$$L(\omega, \theta; x) = \mathbb{E}_{p^+(y|x)}\, s_\omega(x, y) \\ - \mathbb{E}_{p_{nce}(y)}\, \tilde{s}_\omega(x, y) - \mathbb{E}_{g_\theta(y|x)}\, \tilde{s}_\omega(x, y) \quad (7)$$

and only the last term depends on the generator parameter ω. Hence, with a separable loss, the reward is $-\tilde{s}(x^+, y^-)$. This reduction does not happen with a non-separable loss, and we have to use $l_\omega(x, y^+, y^-)$.

2.4 Entropy and training stability

GAN training can suffer from instability and degeneracy where the generator probability mass collapses to a few modes or points. Much work has been done to stabilize GAN training in the continuous case (Arjovsky et al., 2017; Gulrajani et al., 2017; Cao et al., 2018). In ACE, if the generator g_θ probability mass collapses to a few candidates, then after the discriminator successfully learns about these negatives, g_θ cannot adapt to select new hard negatives, because the REINFORCE gradient estimator Eq. 6 relies on g_θ being able to explore other candidates during sampling. Therefore, if the g_θ probability mass collapses, instead of leading to oscillation as in typical GAN, the min-max game in ACE reaches an equilibrium where the discriminator wins and g_θ can no longer adapt, then ACE falls back to NCE since the negative sampler has another mixture component from NCE.

This behavior of gracefully falling back to NCE is more desirable than the alternative of stalled training if $p^-(y|x)$ does not have a simple p_{nce} mixture component. However, we would still like to avoid such collapse, as the adversarial samples provide greater learning signals than NCE samples. To this end, we propose to use a regularizer to encourage the categorical distribution $g_\theta(y|x)$ to have high entropy. In order to make the the regularizer interpretable and its hyperparameters easy to tune, we design the following form:

$$R_{ent}(x) = min(0, c - H(g_\theta(y|x))) \quad (8)$$

where $H(g_\theta(y|x))$ is the entropy of the categorical distribution $g_\theta(y|x)$, and $c = \log(k)$ is the entropy of a uniform distribution over k choices, and k is a hyper-parameter. Intuitively, R_{ent} expresses the prior that the generator should spread its mass over more than k choices for each x.

2.5 Handling false negatives

During negative sampling, $p^-(y|x)$ could actually produce y that forms a positive pair that exists in the training set, i.e., a false negative. This possibility exists in NCE already, but since p_{nce} is not adaptive, the probability of sampling a false negative is low. Hence in NCE, the score on this false negative (true observation) pair is pushed up less in the negative term than in the positive term.

However, with the adaptive sampler, $g_\omega(y|x)$, false negatives become a much more severe issue. $g_\omega(y|x)$ can learn to concentrate its mass on a few false negatives, significantly canceling the learning of those observations in the positive phase. The entropy regularization reduces this problem as it forces the generator to spread its mass, hence reducing the chance of a false negative.

To further alleviate this problem, whenever computationally feasible, we apply an additional two-step technique. First, we maintain a hash map of the training data in memory, and use it to efficiently detect if a negative sample (x^+, y^-) is an actual observation. If so, its contribution to the loss is given a zero weight in ω learning step. Second, to upate θ in the generator learning step, the reward for false negative samples are replaced by a large penalty, so that the REINFORCE gradient update would steer g_θ away from those samples. The second step is needed to prevent null computation where g_θ learns to sample false negatives which are subsequently ignored by the discriminator update for ω.

2.6 Variance Reduction

The basic REINFORCE gradient estimator is poised with high variance, so in practice one often needs to apply variance reduction techniques. The most basic form of variance reduction is to subtract a baseline from the reward. As long as the baseline is not a function of actions (i.e., samples y^- being drawn), the REINFORCE gradient estimator remains unbiased. More advanced gradient estimators exist that also reduce variance (Grathwohl et al., 2017; Tucker et al., 2017; Liu et al., 2018), but for simplicity we use the self-critical baseline method (Rennie et al., 2016), where the baseline is $b(x) = l_\omega(y^+, y^\star, x)$, or $b(x) = -\tilde{s}_\omega(y^\star, x)$ in the separable loss case, and $y^\star = \text{argmax}_i g_\theta(y_i|x)$. In other words, the baseline is the reward of the most likely sample according to the generator.

2.7 Improving exploration in g_θ by leveraging NCE samples

In Sec. 2.4 we touched on the need for sufficient exploration in g_θ. It is possible to also leverage negative samples from NCE to help the generator learn. This is essentially off-policy exploration in reinforcement learning since NCE samples are not drawn according to $g_\theta(y|x)$. The generator learning can use importance re-weighting to leverage those samples. The resulting REINFORCE gradient estimator is basically the same as Eq. 6 except that the rewards are reweighted by $g_\theta(y^-|x)/p_{nce}(y^-)$, and the expectation is with respect to $p(y^+|x)p_{nce}(y^-)$. This additional off-policy learning term provides gradient information for generator learning if $g_\theta(y^-|x)$ is not zero, meaning that for it to be effective in helping exploration, the generator cannot be collapsed at the first place. Hence, in practice, this term is only used to further help on top of the entropy regularization, but it does not replace it.

3 Related Work

Smith and Eisner (2005) proposed contrastive estimation as a way for unsupervised learning of log-linear models by taking implicit evidence from user-defined neighborhoods around observed datapoints. Gutmann and Hyvärinen (2010) introduced NCE as an alternative to the hierarchical softmax. In the works of Mnih and Teh (2012) and Mnih and Kavukcuoglu (2013), NCE is applied to log-bilinear models and Vaswani et al. (2013) applied NCE to neural probabilistic language models (Yoshua et al., 2003). Compared to these previous NCE methods that rely on simple fixed sampling heuristics, ACE uses an adaptive sampler that produces harder negatives.

In the domain of max-margin estimation for structured prediction (Taskar et al., 2005), loss augmented MAP inference plays the role of finding hard negatives (the hardest). However, this inference is only tractable in a limited class of models such structured SVM (Tsochantaridis et al., 2005). Compared to those models that use exact maximization to find the hardest negative configuration each time, the generator in ACE can be viewed as learning an approximate amortized inference network. Concurrently to this work, Tu and Gimpel (2018) proposes a very similar framework, using a learned inference network for Structured prediction energy networks (SPEN) (Belanger and McCallum, 2016).

Concurrent with our work, there have been other interests in applying the GAN to NLP problems (Fedus et al., 2018; Wang et al., 2018; Cai and Wang, 2017). Knowledge graph models naturally lend to a GAN setup, and has been the subject of study in Wang et al. (2018) and Cai and Wang (2017). These two concurrent works are most closely related to one of the three tasks on which we study ACE in this work. Besides a more general formulation that applies to problems beyond those considered in Wang et al. (2018) and Cai and Wang (2017), the techniques introduced in our work on handling false negatives and entropy regularization lead to improved experimental results as shown in Sec. 5.4.

4 Application of ACE on three tasks

4.1 Word Embeddings

Word embeddings learn a vector representation of words from co-occurrences in a text corpus. NCE casts this learning problem as a binary classification where the model tries to distinguish positive word and context pairs, from negative noise samples composed of word and false context pairs. The NCE objective in Skip-gram (Mikolov et al., 2013) for word embeddings is a separable loss of the form:

$$\begin{aligned} L = -\sum_{w_t \in V} [\log p(y=1|w_t, w_c^+) \\ + \sum_{c=1}^{K} \log p(y=0|w_t, w_c^-)] \end{aligned} \tag{9}$$

Here, w_c^+ is sampled from the set of true contexts and $w_c^- \sim Q$ is sampled k times from a fixed noise distribution. Mikolov et al. (2013) introduced a further simplification of NCE, called "Negative Sampling" (Dyer, 2014). With respect to our ACE framework, the difference between NCE and Negative Sampling is inconsequential, so we continue the discussion using NCE. A drawback of this sampling scheme is that it favors more common words as context. Another issue is that the negative context words are sampled in the same way, rather than tailored toward the actual target word. To apply ACE to this problem we first define the value function for the minimax game, $V(D, G)$, as follows:

$$\begin{aligned} V(D,G) &= \mathbb{E}_{p^+(w_c)}[\log D(w_c, w_t)] \\ &- \mathbb{E}_{p_{nce}(w_c)}[-\log(1 - D(w_c, w_t))] \\ &- \mathbb{E}_{g_\theta(w_c|w_t)}[-\log(1 - D(w_c, w_t))] \end{aligned} \tag{10}$$

with $D = p(y = 1|w_t, w_c)$ and $G = g_\theta(w_c|w_t)$.

Implementation details

For our experiments, we train all our models on a single pass of the May 2017 dump of the English Wikipedia with lowercased unigrams. The vocabulary size is restricted to the top $150k$ most frequent words when training from scratch while for finetuning we use the same vocabulary as Pennington et al. (2014), which is $400k$ of the most frequent words. We use 5 NCE samples for each positive sample and 1 adversarial sample in a window size of 10 and the same positive subsampling scheme proposed by Mikolov et al. (2013). Learning for both G and D uses Adam (Kingma and Ba, 2014) optimizer with its default parameters. Our conditional discriminator is modeled using the Skip-Gram architecture, which is a two layer neural network with a linear mapping between the layers. The generator network consists of an embedding layer followed by two small hidden layers, followed by an output softmax layer. The first layer of the generator shares its weights with the second embedding layer in the discriminator network, which we find really speeds up convergence as the generator does not have to relearn its own set of embeddings. The difference between the discriminator and generator is that a sigmoid nonlinearity is used after the second layer in the discriminator, while in the generator, a softmax layer is used to define a categorical distribution over negative word candidates. We find that controlling the generator entropy is critical for finetuning experiments as otherwise the generator collapses to its favorite negative sample. The word embeddings are taken to be the first dense matrix in the discriminator.

4.2 Order Embeddings Hypernym Prediction

As introduced in Vendrov et al. (2016), ordered representations over hierarchy can be learned by order embeddings. An example task for such ordered representation is hypernym prediction. A hypernym pair is a pair of concepts where the first concept is a specialization or an instance of the second.

For completeness, we briefly describe order embeddings, then analyze ACE on the hypernym prediction task. In order embeddings, each entity is represented by a vector in $\mathbb{R}^N$, the score for a positive ordered pair of entities (x, y) is defined by $s_\omega(x, y) = ||max(0, y - x)||^2$ and, score for a negative ordered pair (x^+, y^-) is defined by $\tilde{s}_\omega(x^+, y^-) = \max\{0, \eta - s(x^+, y^-)\}$, where is η is the margin. Let $f(u)$ be the embedding function which takes an entity as input and outputs en embedding vector. We define P as a set of positive pairs and N as negative pairs, the separable loss function for order embedding task is defined by:

$$L = \sum_{(u,v)\in P} s_\omega(f(u), f(v))) + \sum_{(u,v)\in N} \tilde{s}(f(u), f(v)) \tag{11}$$

Implementation details

Our generator for this task is just a linear fully connected softmax layer, taking an embedding vector from discriminator as input and outputting a categorical distribution over the entity set. For the discriminator, we inherit all model setting from Vendrov et al. (2016): we use 50 dimensions hidden state and bash size 1000, a learning rate of 0.01 and the Adam optimizer. For the generator, we use a batch size of 1000, a learning rate 0.01 and the Adam optimizer. We apply weight decay with rate 0.1 and entropy loss regularization as described in Sec. 2.4. We handle false negative as described in Sec. 2.5. After cross validation, variance reduction and leveraging NCE samples does not greatly affect the order embedding task.

4.3 Knowledge Graph Embeddings

Knowledge graphs contain entity and relation data of the form *(head entity, relation, tail entity)*, and the goal is to learn from observed positive entity relations and predict missing links (a.k.a. link prediction). There have been many works on knowledge graph embeddings, e.g. TransE (Bordes et al., 2013), TransR (Lin et al., 2015), TransH (Wang et al., 2014), TransD (Ji et al., 2015), Complex (Trouillon et al., 2016), DistMult (Yang et al., 2014) and ConvE (Dettmers et al., 2017). Many of them use a contrastive learning objective. Here we take TransD as an example, and modify its noise contrastive learning to ACE, and demonstrate significant improvement in sample efficiency and link prediction results.

Implementation details

Let a positive entity-relation-entity triplet be denoted by $\xi^+ = (h^+, r^+, t^+)$, and a negative triplet could either have its head or tail be a negative sample, i.e. $\xi^- = (h^-, r^+, t^+)$ or $\xi^- = (h^+, r^+, t^-)$. In either case, the general formulation in Sec. 2.1 still applies. The non-separable loss function takes on the form:

$$l = \max(0, \eta + s_\omega(\xi^+) - s_\omega(\xi^-)) \tag{12}$$

The scoring rule is:

$$s = \|\mathbf{h}_\perp + \mathbf{r} - \mathbf{t}_\perp\| \tag{13}$$

where $\mathbf{r}$ is the embedding vector for r, and $\mathbf{h}_\perp$ is projection of the embedding of h onto the space of $\mathbf{r}$ by $\mathbf{h}_\perp = \mathbf{h} + \mathbf{r}_p\mathbf{h}_p^\top\mathbf{h}$, where $\mathbf{r}_p$ and $\mathbf{h}_p$ are projection parameters of the model. $\mathbf{t}_\perp$ is defined in a similar way through parameters $\mathbf{t}$, $\mathbf{t}_p$ and $\mathbf{r}_p$.

The form of the generator $g_\theta(t^-|r^+, h^+)$ is chosen to be $f_\theta(\mathbf{h}_\perp, \mathbf{h}_\perp + \mathbf{r})$, where f_θ is a feedforward neural net that concatenates its two input arguments, then propagates through two hidden layers, followed by a final softmax output layer. As a function of (r^+, h^+), g_θ shares parameter with the discriminator, as the inputs to f_θ are the embedding vectors. During generator learning, only θ is updated and the TransD model embedding parameters are frozen.

5 Experiments

We evaluate ACE with experiments on word embeddings, order embeddings, and knowledge graph embeddings tasks. In short, whenever the original learning objective is contrastive (all tasks except Glove fine-tuning) our results consistently show that ACE improves over NCE. In some cases, we include additional comparisons to the state-of-art results on the task to put the significance of such improvements in context: the generic ACE can often make a reasonable baseline competitive with SOTA methods that are optimized for the task.

For word embeddings, we evaluate models trained from scratch as well as fine-tuned Glove models (Pennington et al., 2014) on word similarity tasks that consist of computing the similarity

between word pairs where the ground truth is an average of human scores. We choose the Rare word dataset (Luong et al., 2013) and WordSim-353 (Finkelstein et al., 2001) by virtue of our hypothesis that ACE learns better representations for both rare and frequent words. We also qualitatively evaluate ACE word embeddings by inspecting the nearest neighbors of selected words.

For the hypernym prediction task, following Vendrov et al. (2016), hypernym pairs are created from the WordNet hierarchy's transitive closure. We use the released random development split and test split from Vendrov et al. (2016), which both contain 4000 edges.

For knowledge graph embeddings, we use TransD (Ji et al., 2015) as our base model, and perform ablation study to analyze the behavior of ACE with various add-on features, and confirm that entropy regularization is crucial for good performance in ACE. We also obtain link prediction results that are competitive or superior to the state-of-arts on the WN18 dataset (Bordes et al., 2014).

5.1 Training Word Embeddings from scratch

In this experiment, we empirically observe that training word embeddings using ACE converges significantly faster than NCE after one epoch. As shown in Fig. 3 both ACE (a mixture of p_{nce} and g_θ) and just g_θ (denoted by ADV) significantly outperforms the NCE baseline, with an absolute improvement of 73.1% and 58.5% respectively on RW score. We note similar results on WordSim-353 dataset where ACE and ADV outperforms NCE by 40.4% and 45.7%. We also evaluate our model qualitatively by inspecting the nearest neighbors of selected words in Table. 1. We first present the five nearest neighbors to each word to show that both NCE and ACE models learn sensible embeddings. We then show that ACE embeddings have much better semantic relevance in a larger neighborhood (nearest neighbor 45-50).

5.2 Finetuning Word Embeddings

We take off-the-shelf pre-trained Glove embeddings which were trained using 6 billion tokens (Pennington et al., 2014) and fine-tune them using our algorithm. It is interesting to note that the original Glove objective does not fit into the contrastive learning framework, but nonetheless we find that they benefit from ACE. In fact, we observe that training such that 75% of the words appear as positive contexts is sufficient to beat the largest dimensionality pre-trained Glove model on word similarity tasks. We evaluate our performance on the Rare Word and WordSim353 data. As can be seen from our results in Table 2, ACE on RW is not always better and for the 100d and 300d Glove embeddings is marginally worse. However, on WordSim353 ACE does considerably better across the board to the point where 50d Glove embeddings outperform the 300d baseline Glove model.

5.3 Hypernym Prediction

As shown in Table 3, with ACE training, our method achieves a 1.5% improvement on accu-

order-embeddings + Our ACE	**92.0**

Table 3: Order Embedding Performance

racy over Vendrov et al. (2016) without tunning any of the discriminator's hyperparameters. We further report training curve in Fig. 1, we report loss curve on randomly sampled pairs. We stress that in the ACE model, we train random pairs and generator generated pairs jointly, as shown in Fig. 2, hard negatives help the order embedding model converges faster.

5.4 Ablation Study and Improving TransD

To analyze different aspects of ACE, we perform an ablation study on the knowledge graph embedding task. As described in Sec. 4.3, the base model (discriminator) we apply ACE to is TransD (Ji et al., 2015). Fig. 5 shows validation performance as training progresses. All variants of ACE converges to better results than base NCE. Among ACE variants, all methods that include entropy regularization significantly outperform without entropy regularization. Without the self critical baseline variance reduction, learning could progress faster at the beginning but the final performance suffers slightly. The best performance is obtained without the additional off-policy learning of the generator.

Table. 4 shows the final test results on WN18 link prediction task. It is interesting to note that ACE improves MRR score more significantly than hit@10. As MRR is a lot more sensitive to the top rankings, i.e., how the correct configuration ranks among the competitive alternatives, this is consistent with the fact that ACE samples hard negatives and forces the base model to learn a more discriminative representation of the positive examples.

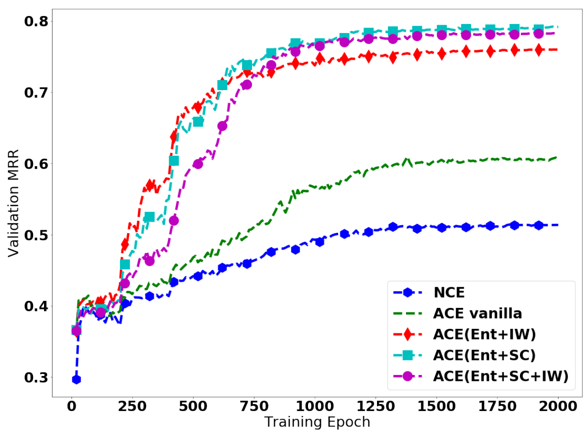

Figure 5: Ablation study: measuring validation Mean Reciprocal Rank (MRR) on WN18 dataset as training progresses.

	MRR	hit@10
ACE(Ent+SC)	0.792	0.945
ACE(Ent+SC+IW)	0.768	**0.949**
NCE TransD (ours)	0.527	0.947
NCE TransD ((Ji et al., 2015))	-	0.925
KBGAN(DISTMULT) ((Cai and Wang, 2017))	0.772	0.948
KBGAN(COMPLEX) ((Cai and Wang, 2017))	0.779	0.948
Wang et al. ((Wang et al., 2018))	-	0.93
COMPLEX ((Trouillon et al., 2016))	**0.941**	0.947

Table 4: WN18 experiments: the first portion of the table contains results where the base model is TransD, the last separated line is the COMPLEX embedding model (Trouillon et al., 2016), which achieves the SOTA on this dataset. Among all TransD based models (the best results in this group is underlined), ACE improves over basic NCE and another GAN based approach KBGAN. The gap on MRR is likely due to the difference between TransD and COMPLEX models.

5.5 Hard Negative Analysis

To better understand the effect of the adversarial samples proposed by the generator we plot the discriminator loss on both p_{nce} and g_θ samples. In this context, a harder sample means a higher loss assigned by the discriminator. Fig. 4 shows that discriminator loss for the word embedding task on g_θ samples are always higher than on p_{nce} samples, confirming that the generator is indeed sampling harder negatives.
For Hypernym Prediction task, Fig.2 shows discriminator loss on negative pairs sampled from NCE and ACE respectively. The higher the loss the harder the negative pair is. As indicated in the left plot, loss on the ACE negative terms collapses faster than on the NCE negatives. After adding entropy regularization and weight decay, the generator works as expected.

6 Limitations

When the generator softmax is large, the current implementation of ACE training is computationally expensive. Although ACE converges faster per iteration, it may converge more slowly on wall-clock time depending on the cost of the softmax. However, embeddings are typically used as pre-trained building blocks for subsequent tasks. Thus, their learning is usually the pre-computation step for the more complex downstream models and spending more time is justified, especially with GPU acceleration. We believe that the computational cost could potentially be reduced via some existing techniques such as the "augment and reduce" variational inference of (Ruiz et al., 2018), adaptive softmax (Grave et al., 2016), or the "sparsely-gated" softmax of Shazeer et al. (2017), but leave that to future work.

Another limitation is on the theoretical front. As noted in Goodfellow (2014), GAN learning does not implement maximum likelihood estimation (MLE), while NCE has MLE as an asymptotic limit. To the best of our knowledge, more distant connections between GAN and MLE training are not known, and tools for analyzing the equilibrium of a min-max game where players are parametrized by deep neural nets are currently not available to the best of our knowledge.

7 Conclusion

In this paper, we propose Adversarial Contrastive Estimation as a general technique for improving supervised learning problems that learn by contrasting observed and fictitious samples. Specifically, we use a generator network in a conditional GAN like setting to propose hard negative examples for our discriminator model. We find that a mixture distribution of randomly sampling negative examples along with an adaptive negative sampler leads to improved performances on a variety of embedding tasks. We validate our hypothesis that hard negative examples are critical to optimal learning and can be proposed via our ACE framework. Finally, we find that controlling the entropy of the generator through a regularization term and properly handling false negatives is crucial for successful training.

Abstract

This paper focuses on detection tasks in information extraction, where positive instances are sparsely distributed and models are usually evaluated using F-measure on positive classes. These characteristics often result in deficient performance of neural network based detection models. In this paper, we propose *adaptive scaling*, an algorithm which can handle the positive sparsity problem and directly optimize over F-measure via dynamic cost-sensitive learning. To this end, we borrow the idea of marginal utility from economics and propose a theoretical framework for instance importance measuring without introducing any additional hyper-parameters. Experiments show that our algorithm leads to a more effective and stable training of neural network based detection models.

1 Introduction

Detection problems, aiming to identify occurrences of specific kinds of information (e.g., events, relations, or entities) in documents, are fundamental and widespread in information extraction (IE). For instance, an event detection (Walker et al., 2006) system may want to detect triggers for "*Attack*" events, such as "*shot*" in sentence "*He was shot*". In relation detection (Hendrickx et al., 2009), we may want to identify all instances of a specific relation, such as "*Jane joined Google*" for "*Employment*" relation.

Recently, a number of researches have employed neural network models to solve detection problems, and have achieved significant improvement in many tasks, such as event detection (Chen et al., 2015; Nguyen and Grishman, 2015), relation detection (Zeng et al., 2014; Santos et al., 2015) and named entity recognition (Huang et al., 2015; Chiu and Nichols, 2015; Lample et al., 2016). These methods usually regard detection problems as standard classification tasks, with several positive classes for targets to detect and one negative class for irrelevant (background) instances. For example, an event detection model will identify event triggers in sentence "*He was shot*" by classifying word "*shot*" into positive class "*Attack*", and classifying all other words into the negative class "*NIL*". To optimize classifiers, cross-entropy loss function is commonly used in this paradigm.

	Classification	**Detection**
Target Instances	All instances	Sparse positive instances
Evaluation	Accuracy or F-measure **on all classes**	F-measure **on only positive classes**
Typical Tasks	Text Classification, Sentiment Classification	Event Detection, Relation Detection

Table 1: Comparison between standard classification tasks and detection problems.

However, different from standard classification tasks, detection tasks have unique *class inequality* characteristic, which stems from both data distribution and applied evaluation metric. Table 1 shows their differences. First, positive instances are commonly sparsely distributed in detection tasks. For example, in event detection, less than 2% of words are a trigger of an event in RichERE dataset (Song et al., 2015). Furthermore, detection tasks are commonly evaluated using F-measure on positive classes, rather than accuracy or F-measure on all classes. Therefore positive and negative classes play different roles in the evaluation: the performance is evaluated by only considering how well we can detect positive instances, while correct predictions of negative instances are ignored.

Due to the class inequality characteristic, reported results indicate that simply applying standard classification paradigm to detection tasks will result in deficient performance (Anand et al., 1993; Carvajal et al., 2004; Lin et al., 2017). This is because minimizing cross-entropy loss function corresponds to maximize the accuracy of neural networks on all training instances, rather than F-measure on positive classes. Furthermore, due to the positive sparsity problem, training procedure will easily achieve a high accuracy on negative class, but is difficult to converge on positive classes and often leads to a low recall rate. Although simple sampling heuristics can alleviate this problem to some extent, they either suffer from losing inner class information or over-fitting positive instances (He and Garcia, 2009; Fernández-Navarro et al., 2011), which often result in instability during the training procedure.

Some previous approaches (Joachims, 2005; Jansche, 2005, 2007; Dembczynski et al., 2011; Chinta et al., 2013; Narasimhan et al., 2014; Natarajan et al., 2016) tried to solve this problem by directly optimizing F-measure. Parambath et al. (2014) proved that it is sufficient to solve F-measure optimization problem via cost-sensitive learning, where class-specific cost factors are applied to indicate the importance of different classes to F-measure. However, optimal factors are not known a priori so ε-search needs to be applied, which is too time consuming for the optimization of neural networks.

To solve the class inequality problem for sparse detection model optimization, this paper proposes a theoretical framework to quantify the importance of positive/negative instances during training. We borrow the idea of marginal utility from Economics (Stigler, 1950), and regard the evaluation metric (i.e., F-measure commonly) as the utility to optimize. Based on the above idea, the importance of an instance is measured using the marginal utility of correctly predicting it. For standard classification tasks evaluated using accuracy, our framework proves that correct predictions of positive and negative instances will have equal and unchanged marginal utility, i.e., all instances are with the same importance. For detection problems evaluated using F-measure, our framework proves that the utility of correctly predicting one more positive instance (*marginal positive utility*) and that of correctly predicting one more negative instance (*marginal negative utility*) are different and dynamically changed during model training. That is, the importance of instances of each class is not only determined by their data distribution, but also affected by how well the current model can converge on different classes.

Based on the above framework, we propose *adaptive scaling*, a dynamic cost-sensitive learning algorithm which adaptively scales costs of instances of different classes with above quantified importance during the training procedure, and thus can make the optimization criteria consistent with the evaluation metric. Furthermore, a batch-wise version of our adaptive scaling algorithm is proposed to make it directly applicable as a plug-in of conventional neural network training algorithms. Compared with previous methods, adaptive scaling is designed based on marginal utility framework and doesn't introduce any additional hyper-parameter, and therefore is more efficient and stable to transfer among datasets and models.

Generally, the main contributions of this paper are:

- We propose a marginal utility based framework for detection model optimization, which can dynamically quantify instance importance to different evaluation metrics.
- Based on the above framework, we present adaptive scaling, a plug-in algorithm which can effectively resolve the class inequality problem in neural detection model optimization via dynamic cost-sensitive learning.

We conducted experimental studies[1] on event detection, a typical sparse detection task in IE. We thoroughly compared various methods for adapting classical neural network models into detection problems. Experiment results show that our adaptive scaling algorithm not only achieves a better performance, but also is more stable and more adaptive for training neural networks on various models and datasets.

2 Background

Relation between Accuracy Metric and Cross-Entropy Loss. Recent neural network methods usually regard detection problems as standard classification tasks, with several positive classes to detect, and one negative class for other irrelevant

[1]Our source code is openly available at `github.com/sanmusunrise/AdaScaling`.

instances. Formally, given P positive training instances $\mathcal{P} = \{(x_i, y_i)_{i=1}^{P}\}$, and N negative instances $\mathcal{N} = \{(x_i, y_i)_{i=1}^{N}\}$ (due to positive sparsity, $P \ll N$), the training of neural network classifiers usually involves in minimizing the softmax cross-entropy loss function regarding to model parameters θ:

$$\mathcal{L}_{CE}(\theta) = -\frac{1}{P+N} \sum_{(x_i,y_i)\in\mathcal{P}\bigcup\mathcal{N}} \log p(y_i|x_i;\theta) \quad (1)$$

and if $P, N \to \infty$, we have

$$\lim_{P,N\to\infty} \mathcal{L}_{CE}(\theta) = -\mathbb{E}[\log p(y|x;\theta)] = -\log(\text{Accuracy}) \quad (2)$$

which reveals that minimizing cross-entropy loss corresponds to maximize the expected accuracy of the classifier on training data.

Divergence between F-Measure and Cross-Entropy Loss. However, detection tasks are mostly evaluated using F-measure computed on positive classes, which makes it unsuitable to optimize classifiers using cross-entropy loss. For instance, due to the positive sparsity, simply classifying all instances into negative class will achieve a high accuracy but zero F-measure.

To show where this divergence comes from, let $c_1, c_2, ..., c_{k-1}$ denote $k-1$ positive classes and c_k is the negative class, we define $TP = \sum_{i=1}^{k-1} TP_i$, where TP_i is the population of correctly predicted instances of positive class c_i. TN denotes the number of correctly predicted negative instances. PE represents positive-positive error, where an instance is classified into one positive class c_i but its golden label is another positive class c_j. Then we have following metrics[2]:

$$\text{Accuracy} = \frac{TP+TN}{P+N} \quad (3)$$

$$\text{Precision} = \frac{TP}{N-TN+PE+TP} \quad (4)$$

$$\text{Recall} = \frac{TP}{P} \quad (5)$$

$$\begin{aligned} F_\beta &= (1+\beta^2)\frac{\text{Precision}\cdot\text{Recall}}{\beta^2\cdot\text{Precision}+\text{Recall}} \\ &= (1+\beta^2)\frac{TP}{\beta^2 P + N - TN + PE + TP} \end{aligned} \quad (6)$$

where β in F_β is a factor indicating the metric attaches β times as much importance to recall as precision. We can easily see that for accuracy metric, correct predictions of positive and negative instances are equally regarded (i.e., TP and TN are symmetric), which is consistent with cross-entropy loss function. However, when measuring using F-measure, this condition is no longer holding. The importance varies from different classes (i.e., TP and TN are asymmetric). Therefore, to make the training procedure consistent with F-measure, it is critical to take this importance difference into consideration.

F-measure Optimization via Cost-sensitive Learning. Parambath et al. (2014) have shown that F-measure can be optimized via cost-sensitive learning, where a cost (importance) is set for each class for adjusting their impact on model learning. However, most previous studies set such costs manually (Anand et al., 1993; Domingos, 1999; Krawczyk et al., 2014) or search them on large scale dataset (Nan et al., 2012; Parambath et al., 2014), whose best settings are not transferable and very time-consuming to find for neural network models. This motivates us to develop a theoretical framework for measuring such importance.

3 Adaptive Scaling for Sparse Detection

This section describes how to effectively optimize neural network detection models via dynamic cost-sensitive learning. Specifically, we first propose a marginal utility based theoretical framework for measuring the importance of positive/negative instances. Then we present our adaptive scaling algorithm, which can leverage the importance of each class for effective and robust training of neural network detection models. Finally, a batch-wise version of our algorithm is proposed to make it can be applied as a plug-in of batch-based neural network training algorithms.

3.1 Marginal Utility based Importance Measuring

Conventional methods commonly deal with the class inequality problem in sparse detection by deemphasizing the importance of negative instances during training. This raises two questions: 1) How to quantify the importance of instances of each class? As mentioned by Parambath et al. (2014), that importance is related to the convergence ability of models, which means that this problem cannot be solved by only considering the distribution of training data. 2) Is the im-

[2]This paper considers micro-averaged metrics. But our conclusions can be easily extended to macro-averaged metrics by scaling above-mentioned coefficients with sample sizes of each class.

portance of positive/negative instances remaining unchanged during the entire training process? If not, how it changes according to the convergence of the model?

To this end, we borrow the idea of *marginal utility* from economics, which means the change of utility from consuming one more unit of product. In detection tasks, we regard its evaluation metric (F-measure) as the utility function. The increment of utility from correctly predicting one more positive instance (marginal positive utility) can be regarded as the relative importance of positive classes, and that from correctly predicting one more negative instance (marginal negative utility) is look upon as the relative importance of the negative class. If marginal positive utility overweighs marginal negative utility, positive instances should be considered more important during optimization because it can lead to more improvement on the evaluation metric. In contrast, if marginal negative utility is higher, training procedure should incline to negative instances since it is more effective for optimizing the evaluation metric.

Formally, we derive marginal positive utility $MU(TP)$ and marginal negative utility $MU(TN)$ by computing the partial derivative of the evaluation metric with respect to TP and TN respectively. For instance, the marginal positive utility $MU_{acc}(TP)$ and the marginal negative utility $MU_{acc}(TN)$ regarding to accuracy metric are:

$$MU_{acc}(TP) = \frac{\partial(\text{Accuracy})}{\partial(TP)} = \frac{1}{P+N} \tag{7}$$

$$MU_{acc}(TN) = \frac{\partial(\text{Accuracy})}{\partial(TN)} = \frac{1}{P+N} \tag{8}$$

We can see that $MU_{acc}(TP)$ and $MU_{acc}(TN)$ are equal and constant regardless of the values of TP and TN. This indicates that, to optimize accuracy, we can simply treat positive and negative instances equally during the training phase, and this is what we exactly do when optimizing cross-entropy loss in Equation 1. For detection problems evaluated using F-measure, we can obtain the marginal utilities from Equation 6 as:

$$MU_{F_\beta}(TP) = \frac{(1+\beta^2)(\beta^2 P + N - TN + PE)}{(\beta^2 P + N - TN + PE + TP)^2} \tag{9}$$

$$MU_{F_\beta}(TN) = \frac{(1+\beta^2)\cdot TP}{(\beta^2 P + N - TN + PE + TP)^2} \tag{10}$$

This result is different from that of accuracy metric. First, $MU_{F_\beta}(TP)$ and $MU_{F_\beta}(TN)$ is no longer equal, indicating that the importance of positive/negative instances to F-measure are different. Besides, it is notable that $MU_{F_\beta}(TP)$ and $MU_{F_\beta}(TN)$ are dynamically changed during the training phase and are highly related to how well current model can fit positive instances and negative instances, i.e., TP and TN.

3.2 Adaptive Scaling Algorithm

In this section, we describe how to incorporate the above importance measures into the training procedure of neural networks, so that it can dynamically adjust weights of positive and negative instances regarding to F-measure.

Specifically, given the current model of neural networks parameterized by θ, let $w_\beta(\theta)$ denote the relative importance of negative instances to positive instances for F_β-measure. Then $w_\beta(\theta)$ can be computed as the ratio of marginal negative utility $MU_{F_\beta}(TN(\theta))$ to the marginal positive utility $MU_{F_\beta}(TP(\theta))$, where $TP(\theta)$ and $TN(\theta)$ are TP and TN on training data with respect to θ-parameterized model:

$$w_\beta(\theta) = \frac{MU_{F_\beta}(TN(\theta))}{MU_{F_\beta}(TP(\theta))} = \frac{TP(\theta)}{\beta^2 P + N - TN(\theta) + PE} \tag{11}$$

Then at each iteration of the model optimization (i.e., each step of gradient descending), we want the model to take next update step proportional to the gradient of the w_β-scaled cross-entropy loss function $\mathcal{L}_{AS}(\theta)$ at the current point:

$$\begin{aligned} \mathcal{L}_{AS}(\theta) = &- \sum_{(x_i,y_i)\in\mathcal{P}} \log p(y_i|x_i;\theta) \\ &- \sum_{(x_i,y_i)\in\mathcal{N}} w_\beta(\theta)\cdot \log p(y_i|x_i;\theta) \end{aligned} \tag{12}$$

Consequently, based on the contributions that correctly predicting one more instances of each class bringing to F-measure, the training procedure dynamically adjusts its attention between positive and negative instances. Thus our adaptive scaling algorithm can take the class inequality characteristic of detection problems into consideration without introducing any additional hyper-parameter[3].

3.3 Properties and Relations to Previous Empirical Conclusions

In this section, we investigate the properties of our adaptive scaling algorithm. By investigating the

[3]Note that β is set according to the applied F_β evaluation metric and therefore is not a hyper-parameter.

change of scaling coefficient $w_\beta(\theta)$ during training, we find that our method has a tight relation to previous empirical conclusions on solving the class inequality problem.

Property 1. *The relative importance of positive/negative instances is related to the ratio of the instance number of each class, as well as how well current model can fit each class.* It is easy to derive that if we fix the accuracies of each classes, $w_\beta(\theta)$ will be smaller if the ratio of the size of negative instances to that of the positive instances (i.e., $\frac{N}{P}$) increases. This indicates that the training procedure should pay more attention to positive instances if the empirical distribution inclines more severely towards negative class, which is identical to conventional practice that we should deemphasize more on negative instances if the positive sparsity problem is more severe (Japkowicz and Stephen, 2002). Besides, $w_\beta(\theta)$ highly depends on TP and TN, which is identical to previous conclusion that the best cost factors are related to the convergence ability of models (Parambath et al., 2014).

Property 2. *For micro-averaged F-measure, all positive instances are equally weighted regardless of the sample size of its class.* Let $MU(TP_i)$ be the marginal utility of positive class c_i, we have:

$$MU_{F_\beta}(TP_i) = \frac{\partial(F_\beta)}{\partial(TP)} \cdot \frac{\partial(TP)}{\partial(TP_i)} = MU_{F_\beta}(TP) \tag{13}$$

This corresponds to the applied micro-averaged F-measure, in which all positive instances are equally considered regardless of the sample size of its class. Thus correctly predicting one more positive instance of any class will result in the same increment of micro-averaged F-measure.

Property 3. *The importance of negative instances increases with the rise of accuracy on positive classes.* This is a straightforward consequence because if the model has higher accuracy on positive instances then it should shift more of its attention to negative ones. Besides, if the accuracy of positive class is close to zero, F-measure will also be close to zero no matter how high the accuracy on negative class is, i.e., correctly predicting negative instances can result in little F-measure increment. Therefore negative instances are inconsequential when the accuracy on positive class is low. And with the increment of positive accuracy, the importance of negative class also increases.

Property 4. *The importance of negative instances increased with the rise of accuracy on the negative class.* This can make the training procedure incline to hard negative instances, which is similar to Focal Loss (Lin et al., 2017). During model convergence, easy negative instances can be correctly classified at the very beginning of training and its loss (negative log probability) will reduce very quickly. This is analogical to removing easy negative instances out of the training procedure and the hard negative instances remaining become more balanced proportional to positive instances. Therefore the importance w_β of remaining hard negative instances are increased to make the model fit them better.

Property 5. *The importance of negative instances increases when more attention is paid to precision than recall.* We can see that w_β decreases with the rise of β, which indicates we focus more on recall than precision. This is identical to practice in sampling heuristics that models should attach more attention to negative instances and sub-sample more of them if evaluation metrics incline more to precision than recall.

3.4 Batch-wise Adaptive Scaling

In large-scale machine learning, batch-wise gradient based algorithm is more popular and efficient for neural network training. This section presents a batch-wise version of our adaptive scaling algorithm, which uses batch-based estimator $\hat{w_\beta}(\theta)$ to replace $w_\beta(\theta)$ in Equation 12.

First, because the main challenge of detection tasks is to identify positive instances from background ones, rather than distinguish between positive classes, we ignore the positive-positive error PE in our experiments. In fact, we found that compared with P and $N - TN$, PE is much smaller and has very limited impact on the final result. Besides, for TP and TN, we approximate them using their expectation on the current batch, which can produce a robust estimation even when the batch size is not large enough. Specifically, let $\mathcal{P}^\mathcal{B} = \{(x_i, y_i)_{i=1}^{P^B}\}$ denotes P^B positive instances and $\mathcal{N}^\mathcal{B} = \{(x_i, y_i)_{i=1}^{N^B}\}$ is N^B negative instances in the batch, we estimate $TP(\theta)$ and $TN(\theta)$ as:

$$TP^B(\theta) = \sum_{(x_i,y_i)\in\mathcal{P}^\mathcal{B}} p(y_i|x_i;\theta) \tag{14}$$

$$TN^B(\theta) = \sum_{(x_i,y_i)\in\mathcal{N}^\mathcal{B}} p(y_i|x_i;\theta) \tag{15}$$

Then we can compute the estimator $\hat{w_\beta}(\theta)$ for $w_\beta(\theta)$ as:

$$\hat{w_\beta}(\theta) = \frac{TP^B(\theta)}{\beta^2 P^B + N^B - TN^B(\theta)} \tag{16}$$

where $\hat{w_\beta}(\theta)$ is computed using only the instances in a batch, which makes it can be directly applied as a plug-in of conventional batch-based neural network optimization algorithm where the loss of negative instances in batch are scaled by $\hat{w_\beta}(\theta)$.

4 Experiments

4.1 Data Preparation

To assess the effectiveness of our method, we conducted experiments on event detection, which is a typical detection task in IE. We used the official evaluation datasets of TAC KBP 2017 Event Nugget Detection Evaluation (LDC2017E55) as test sets, which contains 167 English documents and 167 Chinese documents annotated with Rich ERE annotation standard. For English, we used previously annotated RichERE datasets, including LDC2015E29, LDC2015E68, LDC2016E31 and TAC KBP 2015-2016 Evaluation datasets in LDC2017E02 as the training set. For Chinese, the training set includes LDC2015E105, LDC2015E112, LDC2015E78 and the Chinese part of LDC2017E02. For both Chinese and English, we sampled 20 documents from the evaluation dataset of 2016 year as the development set. Finally, there are 866/20/167 documents in English train/development/test set and 506/20/167 documents in Chinese train/development/test set respectively. We used Stanford CoreNLP toolkit (Manning et al., 2014) for sentence splitting and word segmentation in Chinese.

4.2 Baselines

To verify the effectiveness of our adaptive scaling algorithm, we conducted experiments on two state-of-the-art neural network event detection models. The first one is Dynamic Multipooling Convolutional Neural network (DMCNN) proposed by Chen et al. (2015), a one-layer CNN model with a dynamic multi-pooling operation over convolutional feature maps. The second one is BiLSTM used by Feng et al. (2016) and Yang and Mitchell (2017), where a bidirectional LSTM layer is firstly applied to the input sentence and then word-wise classification is directly conducted on the output of the BiLSTM layer of each word.

We compared our method with following baselines upon above-mentioned two models:

1) **Vanilla models (Vanilla)**, which used the original cross-entropy loss function without any additional treatment for class inequality problem.

2) **Under-sampling (Sampling)**, which samples only part of negative instances as the training data. This is the most widely used solution in event detection (Chen et al., 2015).

3) **Static scaling (Scaling)**, which scales loss of negative instances with a constant. This is a simple but effective cost-sensitive learning method.

4) **Focal Loss (Focal)** (Lin et al., 2017), which scales loss of an instance with a factor proportional to the probability of incorrectly predicting it. This method proves to be effective in some detection problems such as Object Detection.

5) **Softmax-Margin Loss (CLUZH)** (Makarov and Clematide, 2017), which sets additional costs for false-negative error and positive-positive error. This method was used in the 5-model ensembling CLUZH system in TAC KBP 2017 Evaluation. Besides, it also introduced several strong handcraft features, which makes it achieve the best performance on Chinese and very competitive performance on English in the evaluation.

We evaluated all systems with micro-F1 metric computed using the official evaluation toolkit[4]. We reported the average performance of 10 runs (Mean) of each system on the official *type classification* task.[5] We also reported the variance (Var) of the performance to evaluate the stabilities of different methods. As TAC KBP2017 allowed each team to submit 3 different runs, to make our results comparable with evaluation results, we selected 3 best runs of each system on the development set and reported the best test set performance among them, which is referred as *Best3* in this paper. We applied grid search (Hsu et al., 2003) to find best hyper-parameters for all methods.

4.3 Overall results

Table 2 shows the overall results on both English and Chinese. From this table, we can see that:

1) **The class inequality problem is crucial for sparse detection tasks and requires special consideration.** Compared with vanilla models, all

[4]`github.com/hunterhector/EvmEval/tarball/master`

[5]Realis classification, another task in the evaluation, can be regarded as a standard classification task without background class, so we didn't include it here.

Model	English			Chinese		
	Mean	Var	Best3	Mean	Var	Best3
CLUZH*	-	-	**48.60**	-	-	50.14
BiLSTM						
Vanilla	41.91	1.40	43.27	44.23	1.88	47.13
Focal	43.23	0.52	44.65	44.37	4.45	46.90
Sampling	46.66	0.27	47.70	48.97	0.97	50.24
Scaling	46.61	0.35	47.71	48.87	0.83	49.99
A-Scaling	47.48	0.20	48.11	49.19	0.46	50.40
DMCNN						
Vanilla	44.41	2.21	47.12	44.85	5.63	48.16
Focal	45.24	1.38	47.33	44.61	7.59	49.74
Sampling	46.83	0.23	47.65	50.77	2.34	52.50
Scaling	47.06	1.92	48.07	51.38	0.74	52.49
A-Scaling	**47.60**	**0.16**	48.31	**51.87**	**0.39**	**52.99**

Table 2: Experiment results on TAC KBP 2017 evaluation datasets. * indicates the best (ensembling) results reported in the original paper. "A-Scaling" is batch-wise adaptive scaling algorithm.

other methods trying to tackle this problem have shown significant improvements on both models and both languages, especially on Chinese dataset where the positive sparsity problem is more severe (Makarov and Clematide, 2017).

2) **It is critical to take the different roles of classes into consideration for F-measure optimization.** Even down-weighting the loss assigned to well-classified examples can alleviate the positive sparsity problem by deemphasizing easy negative instances during optimization, Focal Loss cannot achieve competitive performance because it does not distinguish between different classes.

3) **Marginal Utility based framework provides a solid foundation for measuring instance importance, thus makes our adaptive scaling algorithm steadily outperform all heuristic baselines.** No matter on mean or Best3 metric, adaptive scaling steadily outperforms other baselines on both BiLSTM and DMCNN model. Furthermore, we can see that simple models with adaptive scaling outperform the state-of-the-art CLUZH system on Chinese (which has more severe positive sparsity problem) and achieve comparable results with it on English. Please note that CLUZH is an ensemble of five models and uses extra hand-crafted features. This verified the effectiveness of our adaptive scaling algorithm.

4) **Our adaptive scaling algorithm doesn't need additional hyper-parameters and the importance of instances is dynamically estimated. This leads to a more stable and transferable solution for detection model optimization.** First, we can see that adaptive scaling has the lowest

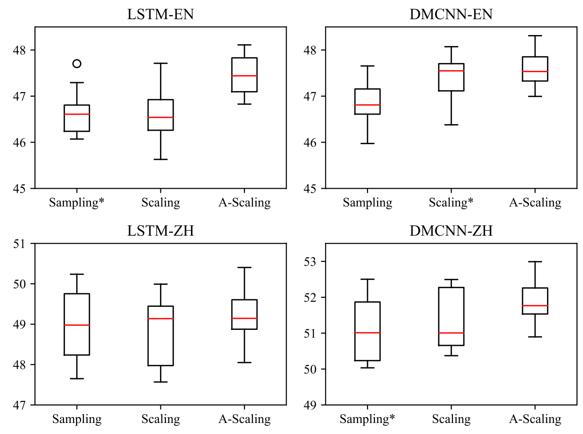

Figure 1: Box plots of three different methods. * indicates outliers not shown in the figure exist.

variance among all methods, which means that it is more stable than other methods. Besides, adaptive scaling doesn't introduce any additional hyper-parameters. In contrast, in experiment we found that the best hyper-parameters for undersampling (the ratio of sampled negative instances to positive instances) and static scaling (the prior cost for negative instances) remarkably varied from models and datasets.

4.4 Stability Analysis

This section investigated the stability of different methods. Table 2 have shown that adaptive scaling has a much smaller variance than other baselines. To investigate its reason, Figure 1 shows the box plots of adaptive scaling and other heuristic methods on both models and both languages.

We can see that interquartile ranges (i.e., the difference between 75th and 25th percentiles of data) of the performances of adaptive scaling are smaller than other methods. In all groups of experiments, the performances of our adaptive scaling algorithm are with a smaller fluctuation. This demonstrates the stability of adaptive scaling algorithm. Furthermore, we found that conventional methods are more instable on Chinese dataset where the data distribution is more skewed. We believe that this is because:

1) Under-Sampling might undermine the inner sub-concept structure of negative class by simply dropping negative instances, and its performance depends on the quality of sampled data, which can result in the instability.

2) Static scaling sets the importance of negative instances statically in the entire training procedure. However, as shown in Section 3, the rel-

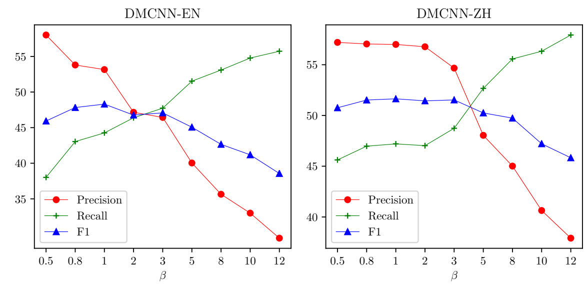

Figure 2: Change of Precision, Recall and F1 regarding to β using adaptive scaling on DMCNN.

ative importance between different classes is dynamically changed during the training procedure, which makes static scaling incapable of achieving stable performance in different phases of training.

3) Adaptive scaling achieves more stable performance during the entire training procedure. First, it doesn't drop any instances, so it can maintain the inner structure of negative class without any information loss. Besides, our algorithm can dynamically adjust the scaling factor during training, therefore can automatically shift attention between positive and negative classes according to the convergence state of the model.

4.5 Adaptability on Different β

Figure 2 shows the change of Precision, Recall and F1 measures regarding to different β. We can see that when β increases, the precision decreased and the recall increased by contrast. This is identical to the nature of F_β where β represents the relative importance of precision and recall. Furthermore, adaptive scaling with $\beta = 1$ achieved the best performance on F_1 measure. This further demonstrates that w_β derived from our marginal utility framework is a good and adaptive estimator for the relative importance of the negative class to positive classes of F_β measure.

5 Related Work

This paper proposes adaptive scaling algorithm for sparse detection problem. Related work to this paper mainly includes:

Classification on Imbalanced Data. Conventional approaches addressed data imbalance from either data-level or algorithm-level. Data-level approaches resample the training data to maintain the balance between different classes (Japkowicz and Stephen, 2002; Drummond et al., 2003). Further improvements on this direction involve how to better sampling data with minimum information loss (Carvajal et al., 2004; Estabrooks et al., 2004; Han et al., 2005; Fernández-Navarro et al., 2011). Algorithm-level approaches attempt to choose an appropriate inductive bias on models or algorithms to make them more suitable on data imbalance condition, including instance weighting (Ting, 2002; Lin et al., 2017), cost-sensitive learning (Anand et al., 1993; Domingos, 1999; Sun et al., 2007; Krawczyk et al., 2014) and active learning approaches (Ertekin et al., 2007a,b; Zhu and Hovy, 2007).

F-Measure Optimization. Previous research on F-measure optimization mainly fell into two paradigms (Nan et al., 2012): 1) Decision-theoretic approaches (DTA), which first estimate a probability model and find the optimal predictions according to that model (Joachims, 2005; Jansche, 2005, 2007; Dembczynski et al., 2011; Busa-Fekete et al., 2015; Natarajan et al., 2016). The main drawback of these methods is that they need to estimate the joint probability with exponentially many combinations, thus make them hard to use in practice; 2) Empirical utility maximization (EUM) approaches, which adapt approximate methods to find a best classifier in hypothesises (Musicant et al., 2003; Chinta et al., 2013; Parambath et al., 2014; Narasimhan et al., 2014). However, EUM methods depend on thresholds or costs that are not known a priori so time-consuming searching on large development set is required. Our adaptive scaling algorithm is partially inspired by EUM approaches, but is based on the marginal utility framework, which doesn't introduce any additional hyper-parameter or searching procedure.

Neural Network based Event Detection. Event detection is a typical task of detection problems. Recently neural network based methods have achieved significant progress in Event Detection. CNNs (Chen et al., 2015; Nguyen and Grishman, 2015) and Bi-LSTMs (Zeng et al., 2016; Yang and Mitchell, 2017) are two effective and widely used models. Some improvements have been made by jointly predicting triggers and arguments (Nguyen et al., 2016) or introducing more complicated architectures to capture larger scale of contexts (Feng et al., 2016; Nguyen and Grishman, 2016; Ghaeini et al., 2016).

6 Conclusions

This paper proposes adaptive scaling algorithm for detection tasks, which can deal with its positive sparsity problem and directly optimize F-measure by adaptively scaling the influence of negative instances in loss function. Based on the marginal utility theory framework, our method leads to more effective, stable and transferable optimization of neural networks without introducing additional hyper-parameters. Experiments on event detection verified the effectiveness and stability of our adaptive scaling algorithm.

The divergence between loss functions and evaluation metrics is common in NLP and machine learning. In the future we want to apply our marginal utility based framework to other metrics, such as Mean Average Precision (MAP).

Abstract

Novel neural models have been proposed in recent years for learning under domain shift. Most models, however, only evaluate on a single task, on proprietary datasets, or compare to weak baselines, which makes comparison of models difficult. In this paper, we re-evaluate classic general-purpose bootstrapping approaches in the context of neural networks under domain shifts vs. recent neural approaches and propose a novel *multi-task tri-training* method that reduces the time and space complexity of classic tri-training. Extensive experiments on two benchmarks are negative: while our novel method establishes a new state-of-the-art for sentiment analysis, it does not fare consistently the best. More importantly, we arrive at the somewhat surprising conclusion that classic tri-training, with some additions, outperforms the state of the art. We conclude that classic approaches constitute an important and strong baseline.

1 Introduction

Deep neural networks (DNNs) excel at learning from labeled data and have achieved state of the art in a wide array of supervised NLP tasks such as dependency parsing (Dozat and Manning, 2017), named entity recognition (Lample et al., 2016), and semantic role labeling (He et al., 2017).

In contrast, learning from unlabeled data, especially under domain shift, remains a challenge. This is common in many real-world applications where the distribution of the training and test data differs. Many state-of-the-art domain adaptation approaches leverage task-specific characteristics such as sentiment words (Blitzer et al., 2006; Wu and Huang, 2016) or distributional features (Schnabel and Schütze, 2014; Yin et al., 2015) which do not generalize to other tasks. Other approaches that are in theory more general only evaluate on proprietary datasets (Kim et al., 2017) or on a single benchmark (Zhou et al., 2016), which carries the risk of overfitting to the task. In addition, most models only compare against weak baselines and, strikingly, almost none considers evaluating against approaches from the extensive semi-supervised learning (SSL) literature (Chapelle et al., 2006).

In this work, we make the argument that such algorithms make strong baselines for any task in line with recent efforts highlighting the usefulness of classic approaches (Melis et al., 2017; Denkowski and Neubig, 2017). We re-evaluate bootstrapping algorithms in the context of DNNs. These are general-purpose semi-supervised algorithms that treat the model as a black box and can thus be used easily—with a few additions—with the current generation of NLP models. Many of these methods, though, were originally developed with in-domain performance in mind, so their effectiveness in a domain adaptation setting remains unexplored.

In particular, we re-evaluate three traditional bootstrapping methods, self-training (Yarowsky, 1995), tri-training (Zhou and Li, 2005), and tri-training with disagreement (Søgaard, 2010) for neural network-based approaches on *two* NLP tasks with different characteristics, namely, a sequence prediction and a classification task (POS tagging and sentiment analysis). We evaluate the methods across multiple domains on two well-established benchmarks, without taking any further task-specific measures, and compare to the best results published in the literature.

We make the somewhat surprising observation that classic tri-training outperforms task-agnostic state-of-the-art semi-supervised learning (Laine and Aila, 2017) and recent neural adaptation approaches (Ganin et al., 2016; Saito et al., 2017).

In addition, we propose *multi-task tri-training*, which reduces the main deficiency of tri-training, namely its time and space complexity. It establishes a new state of the art on unsupervised domain adaptation for sentiment analysis but it is outperformed by classic tri-training for POS tagging.

Contributions Our contributions are: a) We propose a novel multi-task tri-training method. b) We show that tri-training can serve as a strong and robust semi-supervised learning baseline for the current generation of NLP models. c) We perform an extensive evaluation of bootstrapping[1] algorithms compared to state-of-the-art approaches on two benchmark datasets. d) We shed light on the task and data characteristics that yield the best performance for each model.

2 Neural bootstrapping methods

We first introduce three classic bootstrapping methods, self-training, tri-training, and tri-training with disagreement and detail how they can be used with neural networks. For in-depth details we refer the reader to (Abney, 2007; Chapelle et al., 2006; Zhu and Goldberg, 2009). We introduce our novel multi-task tri-training method in §2.3.

2.1 Self-training

Self-training (Yarowsky, 1995; McClosky et al., 2006b) is one of the earliest and simplest bootstrapping approaches. In essence, it leverages the model's own predictions on unlabeled data to obtain additional information that can be used during training. Typically the most confident predictions are taken at face value, as detailed next.

Self-training trains a model m on a labeled training set L and an unlabeled data set U. At each iteration, the model provides predictions $m(x)$ in the form of a probability distribution over classes for all unlabeled examples x in U. If the probability assigned to the most likely class is higher than a predetermined threshold τ, x is added to the labeled examples with $p(x) = \arg\max m(x)$ as pseudo-label. This instantiation is the most widely used and shown in Algorithm 1.

Calibration It is well-known that output probabilities in neural networks are poorly calibrated (Guo et al., 2017). Using a fixed threshold τ is thus not the best choice. While the *absolute* confidence value is inaccurate, we can expect that the *relative* order of confidences is more robust.

For this reason, we select the top n unlabeled examples that have been predicted with the highest confidence after every epoch and add them to the labeled data. This is one of the many variants for self-training, called *throttling* (Abney, 2007). We empirically confirm that this outperforms the classic selection in our experiments.

Algorithm 1 Self-training (Abney, 2007)

```
1: repeat
2:     $m \leftarrow train\_model(L)$
3:     for $x \in U$ do
4:         if $\max m(x) > \tau$ then
5:             $L \leftarrow L \cup \{(x, p(x))\}$
6: until no more predictions are confident
```

Online learning In contrast to many classic algorithms, DNNs are trained online by default. We compare training setups and find that training until convergence on labeled data and then training until convergence using self-training performs best.

Classic self-training has shown mixed success. In parsing it proved successful only with small datasets (Reichart and Rappoport, 2007) or when a generative component is used together with a reranker in high-data conditions (McClosky et al., 2006b; Suzuki and Isozaki, 2008). Some success was achieved with careful task-specific data selection (Petrov and McDonald, 2012), while others report limited success on a variety of NLP tasks (Plank, 2011; Van Asch and Daelemans, 2016; van der Goot et al., 2017). Its main downside is that the model is not able to correct its own mistakes and errors are amplified, an effect that is increased under domain shift.

2.2 Tri-training

Tri-training (Zhou and Li, 2005) is a classic method that reduces the bias of predictions on unlabeled data by utilizing the agreement of three independently trained models. Tri-training (cf. Algorithm 2) first trains three models m_1, m_2, and m_3 on bootstrap samples of the labeled data L. An unlabeled data point is added to the training set of a model m_i if the other two models m_j and m_k agree on its label. Training stops when the classifiers do not change anymore.

Tri-training *with disagreement* (Søgaard, 2010)

[1]We use the term bootstrapping as used in the semi-supervised learning literature (Zhu, 2005), which should not be confused with the statistical procedure of the same name (Efron and Tibshirani, 1994).

Algorithm 2 Tri-training (Zhou and Li, 2005)

```
1:  for $i \in \{1..3\}$ do
2:      $S_i \leftarrow bootstrap\_sample(L)$
3:      $m_i \leftarrow train\_model(S_i)$
4:  repeat
5:      for $i \in \{1..3\}$ do
6:          $L_i \leftarrow \emptyset$
7:          for $x \in U$ do
8:              if $p_j(x) = p_k(x)(j, k \neq i)$ then
9:                  $L_i \leftarrow L_i \cup \{(x, p_j(x))\}$
            $m_i \leftarrow train\_model(L \cup L_i)$
10: until none of $m_i$ changes
11: apply majority vote over $m_i$
```

is based on the intuition that a model should only be strengthened in its weak points and that the labeled data should not be skewed by easy data points. In order to achieve this, it adds a simple modification to the original algorithm (altering line 8 in Algorithm 2), requiring that for an unlabeled data point on which m_j and m_k *agree*, the other model m_i *disagrees* on the prediction. Tri-training with disagreement is more data-efficient than tri-training and has achieved competitive results on part-of-speech tagging (Søgaard, 2010).

Sampling unlabeled data Both tri-training and tri-training with disagreement can be very expensive in their original formulation as they require to produce predictions for each of the three models on all unlabeled data samples, which can be in the millions in realistic applications. We thus propose to sample a number of unlabeled examples at every epoch. For all traditional bootstrapping approaches we sample 10k candidate instances in each epoch. For the neural approaches we use a linearly growing candidate sampling scheme proposed by (Saito et al., 2017), increasing the candidate pool size as the models become more accurate.

Confidence thresholding Similar to self-training, we can introduce an additional requirement that pseudo-labeled examples are only added if the probability of the prediction of at least one model is higher than some threshold τ. We did not find this to outperform prediction without threshold for traditional tri-training, but thresholding proved essential for our method (§2.3).

The most important condition for tri-training and tri-training with disagreement is that the models are diverse. Typically, bootstrap samples are used to create this diversity (Zhou and Li, 2005; Søgaard, 2010). However, training separate models on bootstrap samples of a potentially large amount of training data is expensive and takes a lot of time. This drawback motivates our approach.

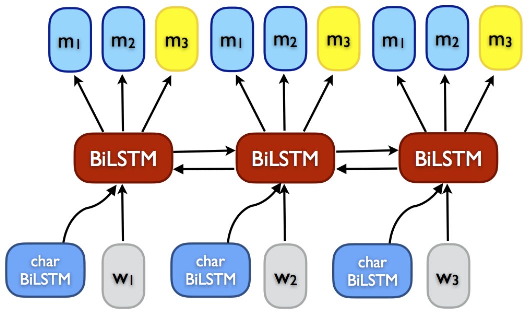

Figure 1: Multi-task tri-training (MT-Tri).

2.3 Multi-task tri-training

In order to reduce both the time and space complexity of tri-training, we propose Multi-task Tri-training (MT-Tri). MT-Tri leverages insights from multi-task learning (MTL) (Caruana, 1993) to share knowledge across models and accelerate training. Rather than storing and training each model separately, we propose to share the parameters of the models and train them jointly using MTL.[2] All models thus collaborate on learning a joint representation, which improves convergence.

The output softmax layers are model-specific and are only updated for the input of the respective model. We show the model in Figure 1 (as instantiated for POS tagging). As the models leverage a joint representation, we need to ensure that the features used for prediction in the softmax layers of the different models are as diverse as possible, so that the models can still learn from each other's predictions. In contrast, if the parameters in all output softmax layers were the same, the method would degenerate to self-training.

To guarantee diversity, we introduce an orthogonality constraint (Bousmalis et al., 2016) as an additional loss term, which we define as follows:

$$\mathcal{L}_{orth} = \|W_{m_1}^{\top} W_{m_2}\|_F^2 \tag{1}$$

where $|\cdot\|_F^2$ is the squared Frobenius norm and W_{m_1} and W_{m_2} are the softmax output parameters

[2]Note: we use the term multi-task learning here albeit all tasks are of the same kind, similar to work on multi-lingual modeling treating each language (but same label space) as separate task e.g., (Fang and Cohn, 2017). It is interesting to point out that our model is further doing implicit multi-view learning by way of the orthogonality constraint.

of the two source and pseudo-labeled output layers m_1 and m_2, respectively. The orthogonality constraint encourages the models not to rely on the same features for prediction. As enforcing pair-wise orthogonality between three matrices is not possible, we only enforce orthogonality between the softmax output layers of m_1 and m_2,[3] while m_3 is gradually trained to be more target-specific. We parameterize $\mathcal{L}_{orth}$ by γ=0.01 following (Liu et al., 2017). We do not further tune γ.

More formally, let us illustrate the model by taking the sequence prediction task (Figure 1) as illustration. Given an utterance with labels $y_1, .., y_n$, our Multi-task Tri-training loss consists of three task-specific (m_1, m_2, m_3) tagging loss functions (where $\vec{h}$ is the uppermost Bi-LSTM encoding):

$$\mathcal{L}(\boldsymbol{\theta}) = -\sum_{i}\sum_{1,..,n} \log P_{m_i}(y|\vec{h}) + \gamma\mathcal{L}_{orth} \quad (2)$$

In contrast to classic tri-training, we can train the multi-task model with its three model-specific outputs jointly and *without* bootstrap sampling on the labeled source domain data until convergence, as the orthogonality constraint enforces different representations between models m_1 and m_2. From this point, we can leverage the pair-wise agreement of two output layers to add pseudo-labeled examples as training data to the third model. We train the third output layer m_3 only on pseudo-labeled target instances in order to make tri-training more robust to a domain shift. For the final prediction, majority voting of all three output layers is used, which resulted in the best instantiation, together with confidence thresholding ($\tau = 0.9$, except for high-resource POS where $\tau = 0.8$ performed slightly better). We also experimented with using a domain-adversarial loss (Ganin et al., 2016) on the jointly learned representation, but found this not to help. The full pseudo-code is given in Algorithm 3.

Computational complexity The motivation for MT-Tri was to reduce the space and time complexity of tri-training. We thus give an estimate of its efficiency gains. MT-Tri is ~3× more space-efficient than regular tri-training; tri-training stores one set of parameters for each of the three models, while MT-Tri only stores one set of parameters (we use three output layers, but these make up a comparatively small part of the total parameter budget). In terms of time efficiency, tri-training first requires to train each of the models from scratch. The actual tri-training takes about the same time as training from scratch and requires a separate forward pass for each model, effectively training three independent models simultaneously. In contrast, MT-Tri only necessitates one forward pass as well as the evaluation of the two additional output layers (which takes a negligible amount of time) and requires about as many epochs as tri-training until convergence (see Table 3, second column) while adding fewer unlabeled examples per epoch (see Section 3.4). In our experiments, MT-Tri trained about 5-6× faster than traditional tri-training.

Algorithm 3 Multi-task Tri-training

```
1:  $m \leftarrow train\_model(L)$
2:  **repeat**
3:      **for** $i \in \{1..3\}$ **do**
4:          $L_i \leftarrow \emptyset$
5:          **for** $x \in U$ **do**
6:              **if** $p_j(x) = p_k(x)(j, k \neq i)$ **then**
7:                  $L_i \leftarrow L_i \cup \{(x, p_j(x))\}$
8:          **if** $i = 3$ **then** $m_i = train\_model(L_i)$
9:          **else** $m_i \leftarrow train\_model(L \cup L_i)$
10: **until** end condition is met
11: apply majority vote over $m_i$
```

MT-Tri can be seen as a self-ensembling technique, where different variations of a model are used to create a stronger ensemble prediction. Recent approaches in this line are *snapshot ensembling* (Huang et al., 2017) that ensembles models converged to different minima during a training run, *asymmetric tri-training* (Saito et al., 2017) (ASYM) that leverages agreement on two models as information for the third, and *temporal ensembling* (Laine and Aila, 2017), which ensembles predictions of a model at different epochs. We tried to compare to temporal ensembling in our experiments, but were not able to obtain consistent results.[4] We compare to the closest most recent method, asymmetric tri-training (Saito et al., 2017). It differs from ours in two aspects: a) ASYM leverages only pseudo-labels from data points on which m_1 and m_2 agree, and b) it uses only one task (m_3) as final predictor. In essence, our formulation of MT-Tri is closer to the original tri-training formulation (agreements on two provide pseudo-labels to the third) thereby incorporating more diversity.

[3]We also tried enforcing orthogonality on a hidden layer rather than the output layer, but this did not help.

[4]We suspect that the sparse features in NLP and the domain shift might be detrimental to its unsupervised consistency loss.

Table 1: Number of labeled and unlabeled sentences for each domain in the SANCL 2012 dataset (Petrov and McDonald, 2012) for POS tagging (above) and the Amazon Reviews dataset (Blitzer et al., 2006) for sentiment analysis (below).

3 Experiments

In order to ascertain which methods are robust across different domains, we evaluate on two widely used unsupervised domain adaptation datasets for two tasks, a sequence labeling and a classification task, cf. Table 1 for data statistics.

3.1 POS tagging

For POS tagging we use the SANCL 2012 shared task dataset (Petrov and McDonald, 2012) and compare to the top results in both low and high-data conditions (Schnabel and Schütze, 2014; Yin et al., 2015). Both are strong baselines, as the FLORS tagger has been developed for this challenging dataset and it is based on contextual distributional features (excluding the word's identity), and hand-crafted suffix and shape features (including some language-specific morphological features). We want to gauge to what extent we can adopt a nowadays fairly standard (but more lexicalized) general neural tagger.

Our POS tagging model is a state-of-the-art Bi-LSTM tagger (Plank et al., 2016) with word and 100-dim character embeddings. Word embeddings are initialized with the 100-dim Glove embeddings (Pennington et al., 2014). The BiLSTM has one hidden layer with 100 dimensions. The base POS model is trained on WSJ with early stopping on the WSJ development set, using patience 2, Gaussian noise with $\sigma = 0.2$ and word dropout with $p = 0.25$ (Kiperwasser and Goldberg, 2016).

Regarding data, the source domain is the Ontonotes 4.0 release of the Penn treebank Wall Street Journal (WSJ) annotated for 48 fine-grained POS tags. This amounts to 30,060 labeled sentences. We use 100,000 WSJ sentences from 1988 as unlabeled data, following Schnabel and Schütze (2014).[5] As target data, we use the five SANCL domains (answers, emails, newsgroups, reviews, weblogs). We restrict the amount of unlabeled data for each SANCL domain to the first 100k sentences, and do not do any pre-processing. We consider the development set of ANSWERS as our only target dev set to set hyperparameters. This may result in suboptimal per-domain settings but better resembles an unsupervised adaptation scenario.

3.2 Sentiment analysis

For sentiment analysis, we evaluate on the Amazon reviews dataset (Blitzer et al., 2006). Reviews with 1 to 3 stars are ranked as negative, while reviews with 4 or 5 stars are ranked as positive. The dataset consists of four domains, yielding 12 adaptation scenarios. We use the same pre-processing and architecture as used in (Ganin et al., 2016; Saito et al., 2017): 5,000-dimensional tf-idf weighted unigram and bigram features as input; 2k labeled source samples and 2k unlabeled target samples for training, 200 labeled target samples for validation, and between 3k-6k samples for testing. The model is an MLP with one hidden layer with 50 dimensions, sigmoid activations, and a softmax output. We compare against the Variational Fair Autoencoder (VFAE) (Louizos et al., 2015) model and domain-adversarial neural networks (DANN) (Ganin et al., 2016).

3.3 Baselines

Besides comparing to the top results published on both datasets, we include the following baselines:

a) the task model trained on the source domain;
b) self-training (Self);
c) tri-training (Tri);
d) tri-training with disagreement (Tri-D); and
e) asymmetric tri-training (Saito et al., 2017).

Our proposed model is multi-task tri-training (MT-Tri). We implement our models in DyNet (Neubig et al., 2017). Reporting single evaluation scores might result in biased results (Reimers and Gurevych, 2017). Throughout the paper, we report mean accuracy and standard deviation over five runs for POS tagging and over ten runs for

[5]Note that our unlabeled data might slightly differ from theirs. We took the first 100k sentences from the 1988 WSJ dataset from the BLLIP 1987-89 WSJ Corpus Release 1.

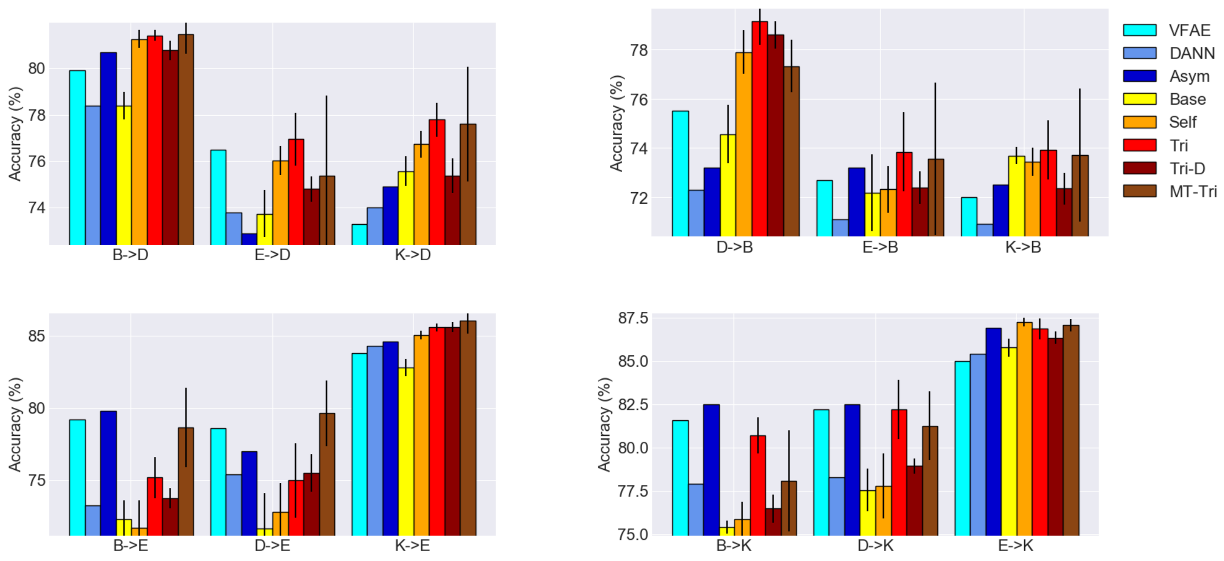

Figure 2: Average results for unsupervised domain adaptation on the Amazon dataset. Domains: B (Book), D (DVD), E (Electronics), K (Kitchen). Results for VFAE, DANN, and Asym are from Saito et al. (2017).

sentiment analysis. Significance is computed using bootstrap test. The code for all experiments is released at: `https://github.com/bplank/semi-supervised-baselines`.

3.4 Results

Sentiment analysis We show results for sentiment analysis for all 12 domain adaptation scenarios in Figure 2. For clarity, we also show the accuracy scores averaged across each target domain as well as a global macro average in Table 2.

Table 2: Average accuracy scores for each SA target domain. *: result from Saito et al. (2017).

Self-training achieves surprisingly good results but is not able to compete with tri-training. Tri-training with disagreement is only slightly better than self-training, showing that the disagreement component might not be useful when there is a strong domain shift. Tri-training achieves the best average results on two target domains and clearly outperforms the state of the art on average.

MT-Tri finally outperforms the state of the art on 3/4 domains, and even slightly traditional tri-training, resulting in the overall best method. This improvement is mainly due to the B->E and D->E scenarios, on which tri-training struggles. These domain pairs are among those with the highest $\mathcal{A}$-distance (Blitzer et al., 2007), which highlights that tri-training has difficulty dealing with a strong shift in domain. Our method is able to mitigate this deficiency by training one of the three output layers only on pseudo-labeled target domain examples.

In addition, MT-Tri is more efficient as it adds a smaller number of pseudo-labeled examples than tri-training at every epoch. For sentiment analysis, tri-training adds around 1800-1950/2000 unlabeled examples at every epoch, while MT-Tri only adds around 100-300 in early epochs. This shows that the orthogonality constraint is useful for inducing diversity. In addition, adding fewer examples poses a smaller risk of swamping the learned representations with useless signals and is more akin to fine-tuning, the standard method for supervised domain adaptation (Howard and Ruder, 2018).

We observe an asymmetry in the results between some of the domain pairs, e.g. B->D and D->B. We hypothesize that the asymmetry may be due to properties of the data and that the domains are relatively far apart e.g., in terms of $\mathcal{A}$-distance. In fact, asymmetry in these domains is already reflected

in the results of Blitzer et al. (2007) and is corroborated in the results for asymmetric tri-training (Saito et al., 2017) and our method.

We note a weakness of this dataset is high variance. Existing approaches only report the mean, which makes an objective comparison difficult. For this reason, we believe it is essential to evaluate proposed approaches also on other tasks.

POS tagging Results for tagging in the low-data regime (10% of WSJ) are given in Table 3.

Self-training does not work for the sequence prediction task. We report only the best instantiation (throttling with n=800). Our results contribute to negative findings regarding self-training (Plank, 2011; Van Asch and Daelemans, 2016).

In the low-data setup, tri-training *with disagreement* works best, reaching an overall average accuracy of 89.70, closely followed by classic tri-training, and significantly outperforming the baseline on 4/5 domains. The exception is newsgroups, a difficult domain with high OOV rate where none of the approches beats the baseline (see §3.4). Our proposed MT-Tri is better than asymmetric tri-training, but falls below classic tri-training. It beats

the baseline significantly on only 2/5 domains (answers and emails). The FLORS tagger (Yin et al., 2015) fares better. Its contextual distributional features are particularly helpful on unknown word-tag combinations (see § 3.4), which is a limitation of the lexicalized generic bi-LSTM tagger.

For the high-data setup (Table 4) results are similar. Disagreement, however, is only favorable in the low-data setups; the effect of avoiding easy points no longer holds in the full data setup. Classic tri-training is the best method. In particular, traditional tri-training is complementary to word embedding initialization, pushing the non-pre-trained baseline to the level of SRC with Glove initalization. Tri-training pushes performance even further and results in the best model, significantly outperforming the baseline again in 4/5 cases, and reaching FLORS performance on weblogs. Multi-task tri-training is often slightly more effective than asymmetric tri-training (Saito et al., 2017); however, improvements for both are not robust across domains, sometimes performance even drops. The model likely is too simplistic for such a high-data POS setup, and exploring shared-private models might prove more fruitful (Liu et al., 2017). On the test sets, tri-training performs consistently the best.

POS analysis We analyze POS tagging accuracy with respect to word frequency[6] and unseen word-tag combinations (UWT) on the dev sets. Table 5 (top rows) provides percentage of unknown tags, OOVs and unknown word-tag (UWT) rate. The SANCL dataset is overall very challenging: OOV rates are high (6.8-11% compared to 2.3% in WSJ), so is the unknown word-tag (UWT) rate (answers and emails contain 2.91% and 3.47% UWT compared to 0.61% on WSJ) and almost all target domains even contain unknown tags (Schnabel and Schütze, 2014) (unknown tags: ADD,GW,NFP,XX), except for weblogs. Email is the domain with the highest OOV rate and highest unknown-tag-for-known-words rate. We plot accuracy with respect to word frequency on email in Figure 3, analyzing how the three methods fare in comparison to the baseline on this difficult domain.

Regarding OOVs, the results in Table 5 (second part) show that classic tri-training outperforms the source model (trained on only source data) on 3/5 domains in terms of OOV accuracy, except on two domains with high OOV rate (newsgroups and weblogs). In general, we note that tri-training works best on OOVs and on low-frequency tokens, which is also shown in Figure 3 (leftmost bins). Both other methods fall typically below the baseline in terms of OOV accuracy, but MT-Tri still outperforms Asym in 4/5 cases. Table 5 (last part) also shows that no bootstrapping method works well on unknown word-tag combinations. UWT tokens are very difficult to predict correctly using an unsupervised approach; the less lexicalized and more context-driven approach taken by FLORS is clearly superior for these cases, resulting in higher UWT accuracies for 4/5 domains.

4 Related work

Learning under Domain Shift There is a large body of work on domain adaptation. Studies on unsupervised domain adaptation include early work on *bootstrapping* (Steedman et al., 2003; McClosky et al., 2006a), *shared feature representations* (Blitzer et al., 2006, 2007) and *instance weighting* (Jiang and Zhai, 2007). Recent ap-

[6]The binned log frequency was calculated with base 2 (bin 0 are OOVs, bin 1 are singletons and rare words etc).

proaches include *adversarial learning* (Ganin et al., 2016) and *fine-tuning* (Sennrich et al., 2016). There is almost no work on bootstrapping approaches for recent neural NLP, in particular under domain shift. Tri-training is less studied, and only recently re-emerged in the vision community (Saito et al., 2017), albeit is not compared to classic tri-training.

Neural network ensembling Related work on self-ensembling approaches includes snapshot ensembling (Huang et al., 2017) or temporal ensembling (Laine and Aila, 2017). In general, the line between "explicit" and "implicit" ensembling (Huang et al., 2017), like dropout (Srivastava et al., 2014) or temporal ensembling (Saito et al., 2017), is more fuzzy. As we noted earlier our multi-task learning setup can be seen as a form of self-ensembling.

Multi-task learning in NLP Neural networks are particularly well-suited for MTL allowing for parameter sharing (Caruana, 1993). Recent NLP conferences witnessed a "tsunami" of deep learning papers (Manning, 2015), followed by what we call a multi-task learning "wave": MTL has been successfully applied to a wide range of NLP tasks (Cohn and Specia, 2013; Cheng et al., 2015; Luong et al., 2015; Plank et al., 2016; Fang and Cohn, 2016; Søgaard and Goldberg, 2016; Ruder et al., 2017; Augenstein et al., 2018). Related to it is the pioneering work on adversarial learning (DANN) (Ganin et al., 2016). For sentiment analysis we found tri-training and our MT-Tri model to outperform DANN. Our MT-Tri model lends itself well to shared-private models such as those proposed recently (Liu et al., 2017; Kim et al., 2017), which extend upon (Ganin et al., 2016) by having separate source and target-specific encoders.

5 Conclusions

We re-evaluate a range of traditional general-purpose bootstrapping algorithms in the context of neural network approaches to semi-supervised learning under domain shift. For the two examined NLP tasks classic tri-training works the best and even outperforms a recent state-of-the-art method. The drawback of tri-training it its time and space complexity. We therefore propose a more efficient multi-task tri-training model, which outperforms both traditional tri-training and recent alternatives in the case of sentiment analysis. For POS tagging, classic tri-training is superior, performing especially well on OOVs and low frequency tokens, which suggests it is less affected by error propagation. Overall we emphasize the importance of comparing neural approaches to strong baselines and reporting results across several runs.

Fluency Boost Learning and Inference for Neural Grammatical Error Correction

Tao Ge **Furu Wei** **Ming Zhou**
Microsoft Research Asia, Beijing, China
{tage, fuwei, mingzhou}@microsoft.com

Abstract

Most of the neural sequence-to-sequence (seq2seq) models for grammatical error correction (GEC) have two limitations: (1) a seq2seq model may not be well generalized with only limited error-corrected data; (2) a seq2seq model may fail to completely correct a sentence with multiple errors through normal seq2seq inference. We attempt to address these limitations by proposing a fluency boost learning and inference mechanism. Fluency boosting learning generates fluency-boost sentence pairs during training, enabling the error correction model to learn how to improve a sentence's fluency from more instances, while fluency boosting inference allows the model to correct a sentence incrementally through multi-round seq2seq inference until the sentence's fluency stops increasing. Experiments show our approaches improve the performance of seq2seq models for GEC, achieving state-of-the-art results on both CoNLL-2014 and JFLEG benchmark datasets.

1 Introduction

Sequence-to-sequence (seq2seq) models (Cho et al., 2014; Sutskever et al., 2014) for grammatical error correction (GEC) have drawn growing attention (Yuan and Briscoe, 2016; Xie et al., 2016; Ji et al., 2017; Schmaltz et al., 2017; Sakaguchi et al., 2017; Chollampatt and Ng, 2018) in recent years. However, most of the seq2seq models for GEC have two flaws. **First**, the seq2seq models are trained with only limited error-corrected sentence pairs like Figure 1(a). Limited by the size of training data, the models with millions of parameters may not be well generalized. Thus, it is common that the models fail to correct a sentence perfectly even if the sentence is slightly different from the training instance, as illustrated by Figure 1(b). **Second**, the seq2seq models usually cannot perfectly correct a sentence with many grammatical errors through single-round seq2seq inference, as shown in Figure 1(b) and 1(c), because some errors in a sentence may make the context strange, which confuses the models to correct other errors.

Figure 1: **(a)** an error-corrected sentence pair; **(b)** if the sentence becomes slightly different, the model fails to correct it perfectly; **(c)** single-round seq2seq inference cannot perfectly correct the sentence, but multi-round inference can.

To address the above-mentioned limitations in model learning and inference, this paper proposes a novel fluency boost learning and inference mechanism, illustrated in Figure 2.

For fluency boosting learning, not only is a seq2seq model trained with original error-corrected sentence pairs, but also it generates less fluent sentences (e.g., from its n-best outputs) to establish new error-corrected sentence pairs by pairing them with their correct sentences during training, as long as the sentences' fluency[1] is be-

[1]A sentence's fluency score is defined to be inversely proportional to the sentence's cross entropy, as is in Eq (3).

Figure 2: Fluency boost learning and inference: **(a)** given a training instance (i.e., an error-corrected sentence pair), fluency boost learning establishes multiple fluency boost sentence pairs from the seq2seq's n-best outputs during training. The fluency boost sentence pairs will be used as training instances in subsequent training epochs, which helps expand the training set and accordingly benefits model learning; **(b)** fluency boost inference allows an error correction model to correct a sentence incrementally through multi-round seq2seq inference until its fluency score stops increasing.

low that of their correct sentences, as Figure 2(a) shows. Specifically, we call the generated error-corrected sentence pairs **fluency boost sentence pairs** because the sentence in the target side always improves fluency over that in the source side. The generated fluency boost sentence pairs during training will be used as additional training instances during subsequent training epochs, allowing the error correction model to see more grammatically incorrect sentences during training and accordingly improving its generalization ability.

For model inference, fluency boost inference mechanism allows the model to correct a sentence incrementally with multi-round inference as long as the proposed edits can boost the sentence's fluency, as Figure 2(b) shows. For a sentence with multiple grammatical errors, some of the errors will be corrected first. The corrected parts will make the context clearer, which may benefit the model to correct the remaining errors.

Experiments demonstrate fluency boost learning and inference enable neural seq2seq models to perform better for GEC and achieve state-of-the-art results on multiple GEC benchmarks.

Our contributions are summarized as follows:

- We present a novel learning and inference mechanism to address the limitations in previous seq2seq models for GEC.
- We propose and compare multiple novel fluency boost learning strategies, exploring the learning methodology for neural GEC.
- Our approaches are proven to be effective to improve neural seq2seq GEC models to achieve state-of-the-art results on CoNLL-2014 and JFLEG benchmark datasets.

2 Background: Neural grammatical error correction

As neural machine translation (NMT), a typical neural GEC approach uses a Recurrent Neural Network (RNN) based encoder-decoder seq2seq model (Sutskever et al., 2014; Cho et al., 2014) with attention mechanism (Bahdanau et al., 2014) to edit a raw sentence into the grammatically correct sentence it should be, as Figure 1(a) shows.

Given a raw sentence $\boldsymbol{x^r} = (x_1^r, \cdots, x_M^r)$ and its corrected sentence $\boldsymbol{x^c} = (x_1^c, \cdots, x_N^c)$ in which x_M^r and x_N^c are the M-th and N-th words of sentence $\boldsymbol{x^r}$ and $\boldsymbol{x^c}$ respectively, the error correction seq2seq model learns a probabilistic mapping $P(\boldsymbol{x^c}|\boldsymbol{x^r})$ from error-corrected sentence pairs through maximum likelihood estimation (MLE), which learns model parameters $\boldsymbol{\Theta_{crt}}$ to maximize the following equation:

$$\boldsymbol{\Theta}^*_{\boldsymbol{crt}} = \arg\max_{\boldsymbol{\Theta_{crt}}} \sum_{(\boldsymbol{x^r},\boldsymbol{x^c})\in\mathcal{S}^*} \log P(\boldsymbol{x^c}|\boldsymbol{x^r};\boldsymbol{\Theta_{crt}}) \qquad (1)$$

where $\mathcal{S}^*$ denotes the set of error-corrected sentence pairs.

For model inference, an output sequence $\boldsymbol{x^o} = (x_1^o, \cdots, x_i^o, \cdots, x_L^o)$ is selected through beam search, which maximizes the following equation:

$$P(\boldsymbol{x^o}|\boldsymbol{x^r}) = \prod_{i=1}^{L} P(x_i^o|\boldsymbol{x^r}, \boldsymbol{x^o}_{<i};\boldsymbol{\Theta_{crt}}) \qquad (2)$$

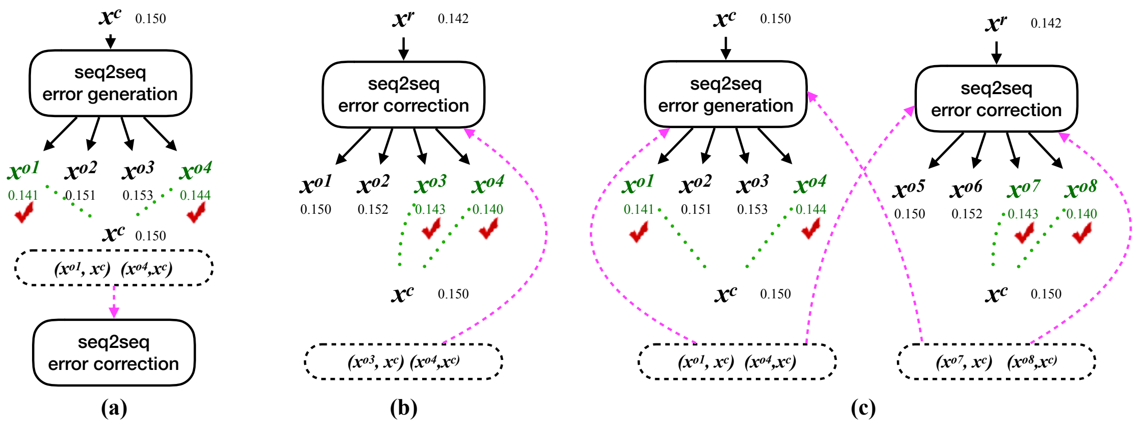

Figure 3: Three fluency boost learning strategies: **(a)** back-boost, **(b)** self-boost, **(c)** dual-boost; all of them generate fluency boost sentence pairs (the pairs in the dashed boxes) to help model learning during training. The numbers in this figure are fluency scores of their corresponding sentences.

3 Fluency boost learning

Conventional seq2seq models for GEC learns model parameters only from original error-corrected sentence pairs. However, such error-corrected sentence pairs are not sufficiently available. As a result, many neural GEC models are not very well generalized.

Fortunately, neural GEC is different from NMT. For neural GEC, its goal is improving a sentence's fluency[2] without changing its original meaning; thus, any sentence pair that satisfies this condition (we call it **fluency boost condition**) can be used as a training instance.

In this paper, we define $f(\boldsymbol{x})$ as the fluency score of a sentence $\boldsymbol{x}$:

$$f(\boldsymbol{x}) = \frac{1}{1 + H(\boldsymbol{x})} \tag{3}$$

$$H(\boldsymbol{x}) = -\frac{\sum_{i=1}^{|\boldsymbol{x}|} \log P(x_i|\boldsymbol{x}_{<i})}{|\boldsymbol{x}|} \tag{4}$$

where $P(x_i|\boldsymbol{x}_{<i})$ is the probability of x_i given context $\boldsymbol{x}_{<i}$, computed by a language model, and $|\boldsymbol{x}|$ is the length of sentence $\boldsymbol{x}$. $H(\boldsymbol{x})$ is actually the cross entropy of the sentence $\boldsymbol{x}$, whose range is $[0, +\infty)$. Accordingly, the range of $f(\boldsymbol{x})$ is $(0, 1]$.

The core idea of fluency boost learning is to generate fluency boost sentence pairs that satisfy the fluency boost condition during training, as Figure 2(a) illustrates, so that these pairs can further help model learning.

In this section, we present three fluency boost learning strategies: back-boost, self-boost, and dual-boost that generate fluency boost sentence pairs in different ways, as illustrated in Figure 3.

[2]Fluency of a sentence in this paper refers to how likely the sentence is written by a native speaker. In other words, if a sentence is very likely to be written by a native speaker, it should be regarded highly fluent.

3.1 Back-boost learning

Back-boost learning borrows the idea from back translation (Sennrich et al., 2016) in NMT, referring to training a backward model (we call it error generation model, as opposed to error correction model) that is used to convert a fluent sentence to a less fluent sentence with errors. Since the less fluent sentences are generated by the error generation seq2seq model trained with error-corrected data, they usually do not change the original sentence's meaning; thus, they can be paired with their correct sentences, establishing fluency boost sentence pairs that can be used as training instances for error correction models, as Figure 3(a) shows.

Specifically, we first train a seq2seq error generation model $\boldsymbol{\Theta_{gen}}$ with $\widetilde{\mathcal{S}^*}$ which is identical to $\mathcal{S}^*$ except that the source sentence and the target sentence are interchanged. Then, we use the model $\boldsymbol{\Theta_{gen}}$ to predict n-best outputs $\boldsymbol{x^{o_1}}, \cdots, \boldsymbol{x^{o_n}}$ given a correct sentence $\boldsymbol{x^c}$. Given the fluency boost condition, we compare the fluency of each output $\boldsymbol{x^{o_k}}$ (where $1 \leq k \leq n$) to that of its correct sentence $\boldsymbol{x^c}$. If an output sentence's fluency score is much lower than its correct sentence, we call it **a disfluency candidate** of $\boldsymbol{x^c}$.

To formalize this process, we first define $\mathcal{Y}_n(\boldsymbol{x}; \boldsymbol{\Theta})$ to denote the n-best outputs predicted by model $\boldsymbol{\Theta}$ given the input $\boldsymbol{x}$. Then, disfluency candidates of a correct sentence $\boldsymbol{x^c}$ can be derived:

$$\mathcal{D}_{back}(\boldsymbol{x^c}) = \{\boldsymbol{x^{o_k}} | \boldsymbol{x^{o_k}} \in \mathcal{Y}_n(\boldsymbol{x_c}; \boldsymbol{\Theta}_{gen}) \wedge \frac{f(\boldsymbol{x^c})}{f(\boldsymbol{x^{o_k}})} \geq \sigma\} \tag{5}$$

Algorithm 1 Back-boost learning

```
1: Train error generation model $\boldsymbol{\Theta_{gen}}$ with $\widetilde{\mathcal{S}^*}$;
2: for each sentence pair $(\boldsymbol{x^r}, \boldsymbol{x^c}) \in \mathcal{S}$ do
3:     Compute $\mathcal{D}_{back}(\boldsymbol{x^c})$ according to Eq (5);
4: end for
5: for each training epoch $t$ do
6:     $\mathcal{S}' \leftarrow \emptyset$;
7:     Derive a subset $\mathcal{S}_t$ by randomly sampling $|\mathcal{S}^*|$ elements from $\mathcal{S}$;
8:     for each $(\boldsymbol{x^r}, \boldsymbol{x^c}) \in \mathcal{S}_t$ do
9:         Establish a fluency boost pair $(\boldsymbol{x'}, \boldsymbol{x^c})$ by randomly sampling $\boldsymbol{x'} \in \mathcal{D}_{back}(\boldsymbol{x^c})$;
10:        $\mathcal{S}' \leftarrow \mathcal{S}' \cup \{(\boldsymbol{x'}, \boldsymbol{x^c})\}$;
11:    end for
12:    Update error correction model $\boldsymbol{\Theta_{crt}}$ with $\mathcal{S}^* \cup \mathcal{S}'$;
13: end for
```

Algorithm 2 Self-boost learning

```
1: for each sentence pair $(\boldsymbol{x^r}, \boldsymbol{x^c}) \in \mathcal{S}$ do
2:     $\mathcal{D}_{self}(\boldsymbol{x^c}) \leftarrow \emptyset$;
3: end for
4: $\mathcal{S}' \leftarrow \emptyset$
5: for each training epoch $t$ do
6:     Update error correction model $\boldsymbol{\Theta_{crt}}$ with $\mathcal{S}^* \cup \mathcal{S}'$;
7:     $\mathcal{S}' \leftarrow \emptyset$
8:     Derive a subset $\mathcal{S}_t$ by randomly sampling $|\mathcal{S}^*|$ elements from $\mathcal{S}$;
9:     for each $(\boldsymbol{x^r}, \boldsymbol{x^c}) \in \mathcal{S}_t$ do
10:        Update $\mathcal{D}_{self}(\boldsymbol{x^c})$ according to Eq (6);
11:        Establish a fluency boost pair $(\boldsymbol{x'}, \boldsymbol{x^c})$ by randomly sampling $\boldsymbol{x'} \in \mathcal{D}_{self}(\boldsymbol{x^c})$;
12:        $\mathcal{S}' \leftarrow \mathcal{S}' \cup \{(\boldsymbol{x'}, \boldsymbol{x^c})\}$;
13:    end for
14: end for
```

where $\mathcal{D}_{back}(\boldsymbol{x^c})$ denotes the disfluency candidate set for $\boldsymbol{x^c}$ in back-boost learning. σ is a threshold to determine if $\boldsymbol{x^{o_k}}$ is less fluent than $\boldsymbol{x^c}$ and it should be slightly larger[3] than 1.0, which helps filter out sentence pairs with unnecessary edits (e.g., I like this book. → I like the book.).

In the subsequent training epochs, the error correction model will not only learn from the original error-corrected sentence pairs ($\boldsymbol{x^r}$,$\boldsymbol{x^c}$), but also learn from fluency boost sentence pairs ($\boldsymbol{x^{o_k}}$,$\boldsymbol{x^c}$) where $\boldsymbol{x^{o_k}}$ is a sample of $\mathcal{D}_{back}(\boldsymbol{x^c})$.

We summarize this process in Algorithm 1 where $\mathcal{S}^*$ is the set of original error-corrected sentence pairs, and $\mathcal{S}$ can be tentatively considered identical to $\mathcal{S}^*$ when there is no additional native data to help model training (see Section 3.4). Note that we constrain the size of $\mathcal{S}_t$ not to exceed $|\mathcal{S}^*|$ (the 7th line in Algorithm 1) to avoid that too many fluency boost pairs overwhelm the effects of the original error-corrected pairs on model learning.

3.2 Self-boost learning

In contrast to back-boost learning whose core idea is originally from NMT, self-boost learning is original, which is specially devised for neural GEC. The idea of self-boost learning is illustrated by Figure 3(b) and was already briefly introduced in Section 1 and Figure 2(a). Unlike back-boost learning in which an error generation seq2seq model is trained to generate disfluency candidates, self-boost learning allows the error correction model to generate the candidates by itself. Since the disfluency candidates generated by the error correction seq2seq model trained with error-corrected data rarely change the input sentence's meaning; thus, they can be used to establish fluency boost sentence pairs.

For self-boost learning, given an error corrected pair $(\boldsymbol{x^r}, \boldsymbol{x^c})$, an error correction model $\boldsymbol{\Theta_{crt}}$ first predicts n-best outputs $\boldsymbol{x^{o_1}}, \cdots, \boldsymbol{x^{o_n}}$ for the raw sentence $\boldsymbol{x^r}$. Among the n-best outputs, any output that is not identical to $\boldsymbol{x^c}$ can be considered as an error prediction. Instead of treating the error predictions useless, self-boost learning fully exploits them. Specifically, if an error prediction $\boldsymbol{x^{o_k}}$ is much less fluent than that of its correct sentence $\boldsymbol{x^c}$, it will be added to $\boldsymbol{x^c}$'s disfluency candidate set $\mathcal{D}_{self}(\boldsymbol{x^c})$, as Eq (6) shows:

$$\begin{aligned}&\mathcal{D}_{self}(\boldsymbol{x^c}) = \mathcal{D}_{self}(\boldsymbol{x^c}) \cup \\ &\{\boldsymbol{x^{o_k}} | \boldsymbol{x^{o_k}} \in \mathcal{Y}_n(\boldsymbol{x_r}; \boldsymbol{\Theta}_{crt}) \wedge \frac{f(\boldsymbol{x^c})}{f(\boldsymbol{x^{o_k}})} \geq \sigma\}\end{aligned} \quad (6)$$

In contrast to back-boost learning, self-boost generates disfluency candidates from a different perspective – by editing the raw sentence $\boldsymbol{x^r}$ rather than the correct sentence $\boldsymbol{x^c}$. It is also noteworthy that $\mathcal{D}_{self}(\boldsymbol{x^c})$ is incrementally expanded because the error correction model $\boldsymbol{\Theta_{crt}}$ is dynamically updated, as shown in Algorithm 2.

3.3 Dual-boost learning

As introduced above, back- and self-boost learning generate disfluency candidates from different perspectives to create more fluency boost sentence pairs to benefit training the error correction model. Intuitively, the more diverse disfluency candidates generated, the more helpful for training an error correction model. Inspired by He et al. (2016) and Zhang et al. (2018), we propose a dual-boost learning strategy, combining both back- and self-boost's perspectives to generate disfluency candidates.

[3]In this paper, we set $\sigma = 1.05$ since the corrected sentence in our training data improves its corresponding raw sentence about 5% fluency on average.

Algorithm 3 Dual-boost learning

```
1: for each $(\boldsymbol{x}^r, \boldsymbol{x}^c) \in \mathcal{S}$ do
2:     $\mathcal{D}_{dual}(\boldsymbol{x}^c) \leftarrow \emptyset$;
3: end for
4: $\mathcal{S}' \leftarrow \emptyset$; $\mathcal{S}'' \leftarrow \emptyset$;
5: for each training epoch $t$ do
6:     Update error correction model $\boldsymbol{\Theta_{crt}}$ with $\mathcal{S}^* \cup \mathcal{S}'$;
7:     Update error generation model $\boldsymbol{\Theta_{gen}}$ with $\widetilde{\mathcal{S}^*} \cup \mathcal{S}''$;
8:     $\mathcal{S}' \leftarrow \emptyset$; $\mathcal{S}'' \leftarrow \emptyset$;
9:     Derive a subset $\mathcal{S}_t$ by randomly sampling $|\mathcal{S}^*|$ elements from $\mathcal{S}$;
10:    for each $(\boldsymbol{x}^r, \boldsymbol{x}^c) \in \mathcal{S}_t$ do
11:        Update $D_{dual}(\boldsymbol{x}^c)$ according to Eq (7);
12:        Establish a fluency boost pair $(\boldsymbol{x}', \boldsymbol{x}^c)$ by randomly sampling $\boldsymbol{x}' \in \mathcal{D}_{dual}(\boldsymbol{x}^c)$;
13:        $\mathcal{S}' \leftarrow \mathcal{S}' \cup \{(\boldsymbol{x}', \boldsymbol{x}^c)\}$;
14:        Establish a reversed fluency boost pair $(\boldsymbol{x}^c, \boldsymbol{x}'')$ by randomly sampling $\boldsymbol{x}'' \in \mathcal{D}_{dual}(\boldsymbol{x}^c)$;
15:        $\mathcal{S}'' \leftarrow \mathcal{S}'' \cup \{(\boldsymbol{x}^c, \boldsymbol{x}'')\}$;
16:    end for
17: end for
```

As Figure 3(c) shows, disfluency candidates in dual-boost learning are from both the error generation model and the error correction model :

$$\mathcal{D}_{dual}(\boldsymbol{x}^c) = \mathcal{D}_{dual}(\boldsymbol{x}^c) \cup$$
$$\{\boldsymbol{x}^{o_k} | \boldsymbol{x}^{o_k} \in \mathcal{Y}_n(\boldsymbol{x}_r; \boldsymbol{\Theta}_{crt}) \cup \mathcal{Y}_n(\boldsymbol{x}_c; \boldsymbol{\Theta}_{gen}) \wedge \frac{f(\boldsymbol{x}^c)}{f(\boldsymbol{x}^{o_k})} \geq \sigma\} \tag{7}$$

Moreover, the error correction model and the error generation model are dual and both of them are dynamically updated, which improves each other: the disfluency candidates produced by error generation model can benefit training the error correction model, while the disfluency candidates created by error correction model can be used as training data for the error generation model. We summarize this learning approach in Algorithm 3.

3.4 Fluency boost learning with large-scale native data

Our proposed fluency boost learning strategies can be easily extended to utilize the huge volume of native data which is proven to be useful for GEC.

As discussed in Section 3.1, when there is no additional native data, $\mathcal{S}$ in Algorithm 1–3 is identical to $\mathcal{S}^*$. In the case where additional native data is available to help model learning, $\mathcal{S}$ becomes:

$$\mathcal{S} = \mathcal{S}^* \cup \mathcal{C}$$

where $\mathcal{C} = \{(\boldsymbol{x}^c, \boldsymbol{x}^c)\}$ denotes the set of self-copied sentence pairs from native data.

4 Fluency boost inference

As we discuss in Section 1, some sentences with multiple grammatical errors usually cannot be perfectly corrected through normal seq2seq inference which does only single-round inference. Fortunately, neural GEC is different from NMT: its source and target language are the same. The characteristic allows us to edit a sentence more than once through multi-round model inference, which motivates our fluency boost inference. As Figure 2(b) shows, fluency boost inference allows a sentence to be incrementally edited through multi-round seq2seq inference as long as the sentence's fluency can be improved. Specifically, an error correction seq2seq model first takes a raw sentence $\boldsymbol{x}^r$ as an input and outputs a hypothesis $\boldsymbol{x}^{o_1}$. Instead of regarding $\boldsymbol{x}^{o_1}$ as the final prediction, fluency boost inference will then take $\boldsymbol{x}^{o_1}$ as the input to generate the next output $\boldsymbol{x}^{o_2}$. The process will not terminate unless $\boldsymbol{x}^{o_t}$ does not improve $\boldsymbol{x}^{o_{t-1}}$ in terms of fluency.

5 Experiments

5.1 Dataset and evaluation

Corpus	**#sent pair**
Lang-8	1,114,139
CLC	1,366,075
NUCLE	57,119
Total	2,537,333

Table 1: Error-corrected training data.

As previous studies (Ji et al., 2017), we use the public Lang-8 Corpus (Mizumoto et al., 2011; Tajiri et al., 2012), Cambridge Learner Corpus (CLC) (Nicholls, 2003) and NUS Corpus of Learner English (NUCLE) (Dahlmeier et al., 2013) as our original error-corrected training data. Table 1 shows the stats of the datasets. In addition, we also collect 2,865,639 non-public error-corrected sentence pairs from Lang-8.com. The native data we use for fluency boost learning is English Wikipedia that contains 61,677,453 sentences.

We use CoNLL-2014 shared task dataset with original annotations (Ng et al., 2014), which contains 1,312 sentences, as our main test set for evaluation. We use MaxMatch (M^2) precision, recall and $F_{0.5}$ (Dahlmeier and Ng, 2012b) as our evaluation metrics. As previous studies, we use CoNLL-2013 test data as our development set.

5.2 Experimental setting

We set up experiments in order to answer the following questions:

Model	seq2seq			fluency boost			seq2seq (+LM)			fluency boost (+LM)		
	P	R	$F_{0.5}$	P	R	$F_{0.5}$	P	R	$F_{0.5}$	P	R	$F_{0.5}$
normal seq2seq	61.06	18.49	41.81	61.56	18.85	42.37	61.75	23.30	46.42	61.94	23.70	46.83
back-boost	61.66	19.54	43.09	61.43	19.61	43.07	61.47	24.74	47.40	61.24	25.01	47.48
self-boost	61.64	19.83	43.35	61.50	19.90	43.36	62.13	24.45	47.49	61.67	24.76	47.51
dual-boost	62.03	20.82	44.44	61.64	21.19	44.61	62.22	25.49	48.30	61.64	26.45	48.69
back-boost (+native)	63.93	22.03	46.31	63.95	22.12	46.40	62.04	27.43	49.54	61.98	27.70	49.68
self-boost (+native)	64.33	22.10	46.54	64.14	22.19	46.54	62.18	27.59	49.71	61.64	**28.37**	49.93
dual-boost (+native)	65.77	21.92	46.98	**65.82**	22.14	47.19	62.64	27.40	49.83	62.70	27.69	**50.04**
back-boost (+native)$\star$	**67.37**	24.31	49.75	67.25	24.35	49.73	64.61	28.44	51.51	64.46	28.78	51.66
self-boost (+native)$\star$	66.52	25.13	50.03	66.78	25.33	50.31	63.82	30.15	52.17	63.34	**31.63**	52.21
dual-boost (+native)$\star$	66.34	25.39	50.16	66.45	25.51	50.30	64.72	30.06	52.59	64.47	30.48	**52.72**

Table 2: Performance of seq2seq for GEC with different learning (row) and inference (column) methods on CoNLL-2014 dataset. (+LM) denotes decoding with the RNN language model through shallow fusion. The last 3 systems (with $\star$) use the additional non-public Lang-8 data for training.

- Whether is fluency boost learning mechanism helpful for training the error correction model, and which of the strategies (back-boost, self-boost, dual-boost) is the most effective?
- Whether does our fluency boost inference improve normal seq2seq inference for GEC?
- Whether can our approach improve neural GEC to achieve state-of-the-art results?

The training details for our seq2seq error correction model and error generation model are as follows: the encoder of the seq2seq models is a 2-layer bidirectional GRU RNN and the decoder is a 2-layer GRU RNN with the general attention mechanism (Luong et al., 2015). Both the dimensionality of word embeddings and the hidden size of GRU cells are 500. The vocabulary sizes of the encoder and decoder are 100,000 and 50,000 respectively. The models' parameters are uniformly initialized in [-0.1,0.1]. We train the models with an Adam optimizer with a learning rate of 0.0001 up to 40 epochs with batch size $= 128$. Dropout is applied to non-recurrent connections at a ratio of 0.15. For fluency boost learning, we generate disfluency candidates from 10-best outputs. During model inference, we set beam size to 5 and decode 1-best result with a 2-layer GRU RNN language model (Mikolov et al., 2010) through shallow fusion (Gülçehre et al., 2015) with weight $\beta = 0.15$. The RNN language model is trained from the native data mentioned in Section 5.1, which is also used for computing fluency score in Eq (3). UNK tokens are replaced with the source token with the highest attention weight.

We resolve spelling errors with a public spell checker[4] as preprocessing, as Xie et al. (2016) and Sakaguchi et al. (2017) do.

[4]https://azure.microsoft.com/en-us/services/cognitive-services/spell-check/

5.3 Experimental results

5.3.1 Effectiveness of fluency boost learning

Table 2 compares the performance of seq2seq error correction models with different learning and inference methods. By comparing by row, one can observe that our fluency boost learning approaches improve the performance over normal seq2seq learning, especially on the recall metric, since the fluency boost learning approaches generate a variety of grammatically incorrect sentences, allowing the error correction model to learn to correct much more sentences than the conventional learning strategy. Among the proposed three fluency boost learning strategies, dual-boost achieves the best result in most cases because it produces more diverse incorrect sentences (average $|\mathcal{D}_{dual}| \approx 9.43$) than either back-boost (avg $|\mathcal{D}_{back}| \approx 1.90$) or self-boost learning (avg $|\mathcal{D}_{self}| \approx 8.10$). With introducing large amounts of native text data, the performance of all the fluency boost learning approaches gets improved. One reason is that our learning approaches produce more error-corrected sentence pairs to let the model be better generalized. In addition, the huge volume of native data benefits the decoder to learn better to generate a fluent and error-free sentence.

We test the effect of hyper-parameter σ in Eq (5–7) on fluency boost learning and show the result in Table 3. When σ is slightly larger than 1.0 (e.g., $\sigma = 1.05$), the model achieves the best performance because it effectively avoids generating sentence pairs with unnecessary or undesirable edits that affect the performance, as we discussed in Section 3.1. When σ continues increasing, the disfluency candidate set $|\mathcal{D}_{dual}|$ drastically decreases, making the dual-boost learning gradually degrade to normal seq2seq learning.

Table 4 shows some examples of disfluency

σ	0	0.95	1.0	1.05	1.1	2.0
$\lvert\mathcal{D}_{dual}\rvert$	41.18	39.21	29.40	9.43	3.87	0.01
$F_{0.5}$	43.20	43.30	43.39	**44.44**	43.30	41.78

Table 3: The effect of σ on dual-boost learning with normal seq2seq inference. $\lvert\mathcal{D}_{dual}\rvert$ is the average size of dual-boost disfluency candidate sets.

Correct sentence	How autism occurs is not well understood.
Disfluency candidates	How autism occurs is not good understood.
	How autism occur is not well understood.
	What autism occurs is not well understood.
	How autism occurs is not well understand.
	How autism occurs does not well understood.

Table 4: Examples of disfluency candidates for a correct sentence in dual-boost learning.

candidates[5] generated in dual-boost learning given a correct sentence in the native data. It is clear that our approach can generate less fluent sentences with various grammatical errors and most of them are typical mistakes that a human learner tends to make. Therefore, they can be used to establish high-quality training data with their correct sentence, which will be helpful for increasing the size of training data to numbers of times, accounting for the improvement by fluency boost learning.

5.3.2 Effectiveness of fluency boost inference

The effectiveness of various inference approaches can be observed by comparing the results in Table 2 by column. Compared to the normal seq2seq inference and seq2seq (+LM) baselines, fluency boost inference brings about on average 0.14 and 0.18 gain on $F_{0.5}$ respectively, which is a significant[6] improvement, demonstrating multi-round edits by fluency boost inference is effective.

Take our best system (the last row in Table 2) as an example, among 1,312 sentences in the CoNLL-2014 dataset, seq2seq inference with shallow fusion LM edits 566 sentences. In contrast, fluency boost inference additionally edits 23 sentences during the second round inference, improving $F_{0.5}$ from 52.59 to 52.72.

5.3.3 Towards the state-of-the-art for GEC

Now, we answer the last question raised in Section 5.2 by testing if our approaches achieve the state-of-the-art result.

We first compare our best models – dual-boost learning (+native) with fluency boost inference and shallow fusion LM – to top-performing GEC systems evaluated on CoNLL-2014 dataset:

[5]We give more details about disfluency candidates, including error type proportion, in the supplementary notes.

[6]$p < 0.0005$ according to Wilcoxon Signed-Rank Test.

Table 5: Performance of systems on CoNLL-2014 dataset. The system with bold fonts are based on seq2seq models. $\star$ denotes the system uses the non-public error-corrected data from Lang-8.com.

- CAMB14, CAMB16$_{\text{SMT}}$, CAMB16$_{\text{NMT}}$ and CAMB17: GEC systems (Felice et al., 2014; Yuan et al., 2016; Yuan and Briscoe, 2016; Yannakoudakis et al., 2017) developed by Cambridge University.
- AMU14 and AMU16: SMT-based GEC systems (Junczys-Dowmunt and Grundkiewicz, 2014, 2016) developed by AMU.
- CUUI and VT16: the former system (Rozovskaya et al., 2014) uses a classifier-based approach, which is improved by the latter system (Rozovskaya and Roth, 2016) through combining with an SMT-based approach.
- NUS14, NUS16 and NUS17: GEC systems (Susanto et al., 2014; Chollampatt et al., 2016a; Chollampatt and Ng, 2017) that combine SMT with other techniques (e.g., classifiers).
- Char-seq2seq: a character-level seq2seq model (Xie et al., 2016). It uses a rule-based method to synthesize errors for data augmentation.
- Nested-seq2seq: a nested attention neural hybrid seq2seq model (Ji et al., 2017).
- Adapt-seq2seq: a seq2seq model adapted to incorporate edit operations (Schmaltz et al., 2017).

Table 5 shows the evaluation results on the CoNLL-2014 dataset. Without using the non-public training data from Lang-8.com, our single model obtains 50.04 $F_{0.5}$, larlgely outperforming the other seq2seq models and only inferior to CAMB17 (AMU16 based) and NUS17. It should be noted, however, that the CAMB17 and NUS17 are actually re-rankers built on top of an SMT-based GEC system (AMU16's framework); thus, they are ensemble models. When we build our approach on top of AMU16 (i.e., we take AMU16's outputs as the input to our GEC system to edit on top of its outputs), we achieve 53.30 $F_{0.5}$ score. With introducing the non-public training data, our single and ensemble system obtain 52.72 and 54.51 $F_{0.5}$ score respectively, which is a state-of-the-art result[7] on CoNLL-2014 dataset.

Moreover, we evaluate our approach on JFLEG corpus (Napoles et al., 2017). JFLEG is the latest released dataset for GEC evaluation and it contains 1,501 sentences (754 in dev set and 747 in test set). To test our approach's generalization ability, we evaluate our single models used for CoNLL evaluation (in Table 5) on JFLEG without re-tuning.

Table 6 shows the JFLEG leaderboard. Instead of M^2 score, JFLEG uses GLEU (Napoles et al., 2015) as its evaluation metric, which is a fluency-oriented GEC metric based on a variant of BLEU (Papineni et al., 2002) and has several advantages over M^2 for GEC evaluation. It is observed that our single models consistently perform well on JFLEG, outperforming most of the CoNLL-2014 top-performing systems and yielding a state-of-the-art result[8] on this benchmark, demonstrating that our models are well generalized and perform stably on multiple datasets.

6 Related work

Most of advanced GEC systems are classifier-based (Chodorow et al., 2007; De Felice and Pulman, 2008; Han et al., 2010; Leacock et al., 2010; Tetreault et al., 2010a; Dale and Kilgarriff, 2011) or MT-based (Brockett et al., 2006; Dahlmeier and Ng, 2011, 2012a; Yoshimoto et al., 2013; Yuan and Felice, 2013; Behera and Bhattacharyya, 2013). For example, top-performing systems (Felice et al., 2014; Rozovskaya et al., 2014; Junczys-Dowmunt and Grundkiewicz, 2014) in CoNLL-2014 shared task (Ng et al., 2014) use either of the methods. Recently, many novel approaches (Susanto et al., 2014; Chollampatt et al., 2016b,a; Rozovskaya and Roth, 2016; Junczys-Dowmunt and Grundkiewicz, 2016; Mizumoto and Matsumoto, 2016; Yuan et al., 2016; Hoang et al., 2016; Yannakoudakis et al., 2017) have been proposed for GEC. Among them, seq2seq models (Yuan and Briscoe, 2016; Xie et al., 2016; Ji et al., 2017; Sakaguchi et al., 2017; Schmaltz et al., 2017; Chollampatt and Ng, 2018) have caught much attention. Unlike the models trained only with original error-corrected data, we propose a novel fluency boost learning mechanism for dynamic data augmentation along with training for GEC, despite some previous studies that explore artificial error generation for GEC (Brockett et al., 2006; Foster and Andersen, 2009; Rozovskaya and Roth, 2010, 2011; Rozovskaya et al., 2012; Felice and Yuan, 2014; Xie et al., 2016; Rei et al., 2017). Moreover, we propose fluency boost inference which allows the model to repeatedly edit a sentence as long as the sentence's fluency can be improved. To the best of our knowledge, it is the first to conduct multi-round seq2seq inference for GEC, while similar ideas have been proposed for NMT (Xia et al., 2017).

In addition to the studies on GEC, there is also much research on grammatical error detection

System	JFLEG Dev GLEU	JFLEG Test GLEU

Table 6: JFLEG Leaderboard. Ours denote the single dual-boost models in Table 5. The systems with bold fonts are based on seq2seq models. * denotes the system is tuned on JFLEG.

[7]The state-of-the-art result on CoNLL-2014 dataset has been recently advanced by Chollampatt and Ng (2018) ($F_{0.5}$=54.79) and Grundkiewicz and Junczys-Dowmunt (2018) ($F_{0.5}$=56.25), which are contemporaneous to this paper. In contrast to the basic seq2seq model in this paper, they used advanced approaches for modeling (e.g., convolutional seq2seq with pre-trained word embedding, using edit operation features, ensemble decoding and advanced model combinations). It should be noted that their approaches are orthogonal to ours, making it possible to apply our fluency boost learning and inference mechanism to their models.

[8]The recently proposed SMT-NMT hybrid system (Grundkiewicz and Junczys-Dowmunt, 2018), which is tuned towards GLEU on JFLEG Dev set, reports a higher result (GLEU=61.50 on JFLEG test set).

(Leacock et al., 2010; Rei and Yannakoudakis, 2016; Kaneko et al., 2017) and GEC evaluation (Tetreault et al., 2010b; Madnani et al., 2011; Dahlmeier and Ng, 2012c; Napoles et al., 2015; Sakaguchi et al., 2016; Napoles et al., 2016; Bryant et al., 2017; Asano et al., 2017). We do not introduce them in detail because they are not much related to this paper's contributions.

7 Conclusion

We propose a novel fluency boost learning and inference mechanism to overcome the limitations of previous neural GEC models. Our proposed fluency boost learning fully exploits both error-corrected data and native data, largely improving the performance over normal seq2seq learning, while fluency boost inference utilizes the characteristic of GEC to incrementally improve a sentence's fluency through multi-round inference. The powerful learning and inference mechanism enables the seq2seq models to achieve state-of-the-art results on both CoNLL-2014 and JFLEG benchmark datasets.

Abstract

The International Classification of Diseases (ICD) provides a hierarchy of diagnostic codes for classifying diseases. Medical coding – which assigns a subset of ICD codes to a patient visit – is a mandatory process that is crucial for patient care and billing. Manual coding is time-consuming, expensive, and error-prone. In this paper, we build a neural architecture for automated coding. It takes the diagnosis descriptions (DDs) of a patient as inputs and selects the most relevant ICD codes. This architecture contains four major ingredients: (1) tree-of-sequences LSTM encoding of code descriptions (CDs), (2) adversarial learning for reconciling the different writing styles of DDs and CDs, (3) isotonic constraints for incorporating the importance order among the assigned codes, and (4) attentional matching for performing many-to-one and one-to-many mappings from DDs to CDs. We demonstrate the effectiveness of the proposed methods on a clinical datasets with 59K patient visits.

1 Introduction

The International Classification of Diseases (ICD) is a healthcare classification system maintained by the World Health Organization (Organization et al., 1978). It provides a hierarchy of diagnostic codes of diseases, disorders, injuries, signs, symptoms, etc. It is widely used for reporting diseases and health conditions, assisting in medical reimbursement decisions, collecting morbidity and mortality statistics, to name a few.

While ICD codes are important for making clinical and financial decisions, medical coding – which assigns proper ICD codes to a patient visit – is time-consuming, error-prone, and expensive. Medical coders review the diagnosis descriptions written by physicians in the form of textual phrases and sentences, and (if necessary) other information in the electronic health record of a clinical episode, then manually attribute the appropriate ICD codes by following the coding guidelines (O'malley et al., 2005). Several types of errors frequently occur. First, the ICD codes are organized in a hierarchical structure. For a node representing a disease C, the children of this node represent the subtypes of C. In many cases, the difference between disease subtypes is very subtle. It is common that human coders select incorrect subtypes. Second, when writing diagnosis descriptions, physicians often utilize abbreviations and synonyms, which causes ambiguity and imprecision when the coders are matching ICD codes to those descriptions (Sheppard et al., 2008). Third, in many cases, several diagnosis descriptions are closely related and should be mapped to a single ICD code. However, unexperienced coders may code each disease separately. Such errors are called *unbundling*. The cost incurred by coding errors and the financial investment spent on improving coding quality are estimated to be \$25 billion per year in the US (Lang, 2007; Farkas and Szarvas, 2008).

To reduce coding errors and cost, we aim at building an ICD coding model which automatically and accurately translates the free-text diagnosis descriptions into ICD codes. To achieve this goal, several technical challenges need to be addressed. First, there exists a hierarchical structure among the ICD codes. This hierarchy can be leveraged to improve coding accuracy. On one hand, if code A and B are both children of C, then it is unlikely to simultaneously assign A and B to a patient. On the other hand, if the distance between A and B in the code tree is smaller than that between A and C and we know A is the correct code, then B is more likely to be a correct code than C, since codes with smaller distance are more clinically relevant. How to explore this hierarchical structure for better coding is technically demanding. Second, the diagnosis descriptions and the textual descriptions of ICD codes are written in quite different styles even if they refer to the same disease. In particular, the textual description of an ICD code is formally and precisely worded, while diagnosis descriptions are usually written by physicians in an informal and ungrammatical way, with telegraphic phrases, abbreviations, and typos. Third, it is required that the assigned ICD codes are ranked according to their relevance to the patient. How to correctly determine this order is technically nontrivial. Fourth, as stated earlier, there does not necessarily exist an one-to-one mapping between diagnosis descriptions and ICD codes, and human coders should consider the overall health condition when assigning codes. In many cases, two closely related diagnosis descriptions need to be mapped onto a single combination ICD code. On the other hand, physicians may write two health conditions into one diagnosis description which should be mapped onto two ICD codes under such circumstances.

Contributions In this paper, we design a neural architecture to automatically perform ICD coding given the diagnosis descriptions. Specifically, we make the following contributions:

- We propose a tree-of-sequences LSTM architecture to simultaneously capture the hierarchical relationship among codes and the semantics of each code.
- We use an adversarial learning approach to reconcile the heterogeneous writing styles of diagnosis descriptions and ICD code descriptions.
- We use isotonic constraints to preserve the importance order among codes and develop an algorithm based on ADMM and isotonic projection to solve the constrained problem.
- We use an attentional matching mechanism to perform many-to-one and one-to-many mappings between diagnosis descriptions and codes.
- On a clinical datasets with 59K patient visits, we demonstrate the effectiveness of the proposed methods.

The rest of the paper is organized as follows. Section 2 introduces related works. Section 3 and 4 present the dataset and methods. Section 5 gives experimental results. Section 6 presents conclusions and discussions.

2 Related Works

Larkey and Croft (1996) studied the automatic assignment of ICD-9 codes to dictated inpatient discharge summaries, using a combination of three classifiers: k-nearest neighbors, relevance feedback, and Bayesian independence classifiers. This method assigns a single code to each patient visit. However, in clinical practice, each patient is usually assigned with multiple codes. Franz et al. (2000) investigated the automated coding of German-language free-text diagnosis phrases. This approach performs one-to-one mapping between diagnosis descriptions and ICD codes. This is not in accordance with the coding practice where one-to-many and many-to-one mappings widely exist (O'malley et al., 2005). Pestian et al. (2007) studied the assignment of ICD-9 codes to radiology reports. Kavuluru et al. (2013) proposed an unsupervised ensemble approach to automatically perform ICD-9 coding based on textual narratives in electronic health records (EHRs) Kavuluru et al. (2015) developed multi-label classification, feature selection, and learning to rank approaches for ICD-9 code assignment of in-patient visits based on EHRs. Koopman et al. (2015) explored the automatic ICD-10 classification of cancers from free-text death certificates. These methods did not consider the hierarchical relationship or importance order among codes.

The tree LSTM network was first proposed by (Tai et al., 2015) to model the constituent or dependency parse trees of sentences. Teng and Zhang (2016) extended the unidirectional tree LSTM to a bidirectional one. Xie and Xing (2017) proposed a sequence-of-trees LSTM network to model a passage. In this network, a sequential LSTM is used to compose a sequence of tree LSTMs. The tree LSTMs are built on the constituent parse trees of individual sentences and the sequential LSTM is built on the sequence of sentences. Our proposed tree-of-sequences LSTM network differs from the previous works in two-fold. First, it is applied to a code tree to capture the hierarchical relationship among codes. Second, it uses a tree LSTM to compose a hierarchy

Diagnosis Descriptions
1. Prematurity at 35 4/7 weeks gestation
2. Twin number two of twin gestation
3. Respiratory distress secondary to transient tachypnea of the newborn
4. Suspicion for sepsis ruled out
Assigned ICD Codes
1. V31.00 (Twin birth, mate liveborn, born in hospital, delivered without mention of cesarean section)
2. 765.18 (Other preterm infants, 2,000-2,499 grams)
3. 775.6 (Neonatal hypoglycemia)
4. 770.6 (Transitory tachypnea of newborn)
5. V29.0 (Observation for suspected infectious condition)
6. V05.3 (Need for prophylactic vaccination and inoculation against viral hepatitis)

Table 1: The diagnosis descriptions of a patient visit and the assigned ICD codes. Inside the parentheses are the descriptions of the codes. The codes are ranked according to descending importance.

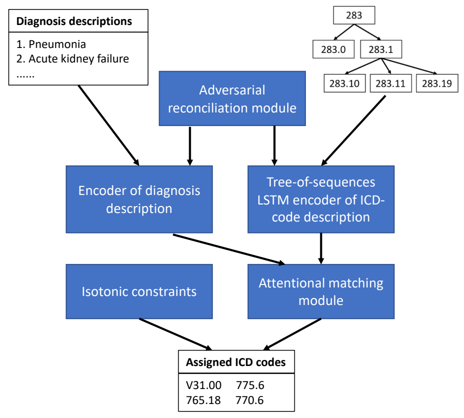

Figure 1: Architecture of the ICD Coding Model

of sequential LSTMs.

Adversarial learning (Goodfellow et al., 2014) has been widely applied to image generation (Goodfellow et al., 2014), domain adaption (Ganin and Lempitsky, 2015), feature learning (Donahue et al., 2016), text generation (Yu et al., 2017), to name a few. In this paper, we use adversarial learning for mitigating the discrepancy among the writing styles of a pair of sentences.

The attention mechanism was widely used in machine translation (Bahdanau et al., 2014), image captioning (Xu et al., 2015), reading comprehension (Seo et al., 2016), text classification (Yang et al., 2016), etc. In this work, we compute attention between sentences to perform many-to-one and one-to-many mappings.

3 Dataset and Preprocessing

We performed the study on the publicly available MIMIC-III dataset (Johnson et al., 2016), which contains de-identified electronic health records (EHRs) of 58,976 patient visits in the Beth Israel Deaconess Medical Center from 2001 to 2012. Each EHR has a clinical note called discharge summary, which contains multiple sections of information, such as 'discharge diagnosis', 'past medical history', etc. From the 'discharge diagnosis' and 'final diagnosis' sections, we extracted the diagnosis descriptions (DDs) written by physicians. Each DD is a short phrase or a sentence, articulating a certain disease or condition. Medical coders perform ICD coding mainly based on DDs. Following such a practice, in this paper, we set the inputs of the automated coding model to be the DDs while acknowledging that other information in the EHRs is also valuable and is referred to by coders for code assignment. For simplicity, we leave the incorporation of non-DD information to future study.

Each patient visit is assigned with a list of ICD codes, ranked in descending order of importance and relevance. For each visit, the number of codes is usually not equal to the number of diagnosis descriptions. These ground-truth codes serve as the labels to train our coding model. The entire dataset contains 6,984 unique codes, each of which has a textual description, describing a disease, symptom, or condition. The codes are organized into a hierarchy where the top-level codes correspond to general diseases while the bottom-level ones represent specific diseases. In the code tree, children of a node represent subtypes of a disease. Table 1 shows the DDs and codes of an exemplar patient.

4 Methods

In this section, we present a neural architecture for ICD coding.

4.1 Overview

Figure 1 shows the overview of our approach. The proposed ICD coding model consists of five modules. The model takes the ICD-code tree and diagnosis descriptions (DDs) of a patient as inputs and assigns a set of ICD codes to the patient. The encoder of DDs generates a latent representation vector for a DD. The encoder of ICD codes is a tree-of-sequences long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) network. It takes the textual descriptions of the ICD codes and their hierarchical structure as in-

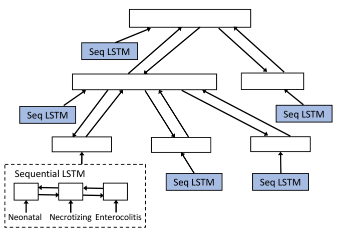

Figure 2: Tree-of-Sequences LSTM

puts and produces a latent representation for each code. The representation aims at simultaneously capturing the semantics of each code and the hierarchical relationship among codes. By incorporating the code hierarchy, the model can avoid selecting codes that are subtypes of the same disease and promote the selection of codes that are clinically correlated. The writing styles of DDs and code descriptions (CDs) are largely different, which makes the matching between a DD and a CD error-prone. To address this issue, we develop an adversarial learning approach to reconcile the writing styles. On top of the latent representation vectors of the descriptions, we build a discriminative network to distinguish which ones are DDs and which are CDs. The encoders of DDs and CDs try to make such a discrimination impossible. By doing this, the learned representations are independent of the writing styles and facilitate more accurate matching. The representations of DDs and CDs are fed into an attentional matching module to perform code assignment. This attentional mechanism allows multiple DDs to be matched to a single code and allows a single DD to be matched to multiple codes. During training, we incorporate the order of importance among codes as isotonic constraints. These constraints regulate the model's weight parameters so that codes with higher importance are given larger prediction scores.

4.2 Tree-of-Sequences LSTM Encoder

This section introduces the encoder of ICD codes. Each code has a description (a sequence of words) that tells the semantics of this code. We use a sequential LSTM (SLSTM) (Hochreiter and Schmidhuber, 1997) to encode this description. To capture the hierarchical relationship among codes, we build a tree LSTM (TLSTM) (Tai et al., 2015) along the code tree. At each TLSTM node, the input vector is the latent representation generated by the SLSTM. Combining these two types of LSTMs together, we obtain a tree-of-sequences LSTM network (Figure 2).

Sequential LSTM A sequential LSTM (SLSTM) (Hochreiter and Schmidhuber, 1997) network is a special type of recurrent neural network that (1) learns the latent representation (which usually reflects certain semantic information) of words, and (2) models the sequential structure among words. In the word sequence, each word t is allocated with an SLSTM unit, which consists of the following components: an input gate $\mathbf{i}_t$, a forget gate $\mathbf{f}_t$, an output gate $\mathbf{o}_t$, a memory cell $\mathbf{c}_t$, and a hidden state $\mathbf{s}_t$. These components (vectors) are computed as follows:

$$\begin{aligned}
&\mathbf{i}_t = \sigma(\mathbf{W}^{(i)}\mathbf{s}_{t-1} + \mathbf{U}^{(i)}\mathbf{x}_t + \mathbf{b}^{(i)})\\
&\mathbf{f}_t = \sigma(\mathbf{W}^{(f)}\mathbf{s}_{t-1} + \mathbf{U}^{(f)}\mathbf{x}_t + \mathbf{b}^{(f)})\\
&\mathbf{o}_t = \sigma(\mathbf{W}^{(o)}\mathbf{s}_{t-1} + \mathbf{U}^{(o)}\mathbf{x}_t + \mathbf{b}^{(o)})\\
&\mathbf{c}_t = \mathbf{i}_t \odot \tanh(\mathbf{W}^{(c)}\mathbf{s}_{t-1} + \mathbf{U}^{(c)}\mathbf{x}_t + \mathbf{b}^{(c)})\\
&\qquad + \mathbf{f}_t \odot \mathbf{c}_{t-1}\\
&\mathbf{s}_t = \mathbf{o}_t \odot \tanh(\mathbf{c}_t)
\end{aligned} \tag{1}$$

where $\mathbf{x}_t$ is the embedding vector of word t. $\mathbf{W}$, $\mathbf{U}$ are component-specific weight matrices and $\mathbf{b}$ are bias vectors.

Tree-of-sequences LSTM We use a bidirectional tree LSTM (TLSTM) (Tai et al., 2015; Xie and Xing, 2017) to capture the hierarchical relationships among codes. The inputs of this LSTM include the code hierarchy and hidden states of individual codes produced by the SLSTMs. It consists of a bottom-up TLSTM and a top-down TLSTM, which produce two hidden states $\mathbf{h}_\uparrow$ and $\mathbf{h}_\downarrow$ at each node in the tree.

In the bottom-up TLSTM, an internal node (representing a code C, having M children) is comprised of these components: an input gate $\mathbf{i}_\uparrow$, an output gate $\mathbf{o}_\uparrow$, a memory cell $\mathbf{c}_\uparrow$, a hidden state $\mathbf{h}_\uparrow$ and M child-specific forget gates $\{\mathbf{f}_\uparrow^{(m)}\}_{m=1}^{M}$ where $\mathbf{f}_\uparrow^{(m)}$ corresponds to the m-th child. The transition equations among components are:

$$\begin{aligned}
&\mathbf{i}_\uparrow = \sigma(\textstyle\sum_{m=1}^{M} \mathbf{W}_\uparrow^{(i,m)}\mathbf{h}_\uparrow^{(m)} + \mathbf{U}^{(i)}\mathbf{s} + \mathbf{b}_\uparrow^{(i)})\\
&\forall m, \mathbf{f}_\uparrow^{(m)} = \sigma(\mathbf{W}_\uparrow^{(f,m)}\mathbf{h}_\uparrow^{(m)} + \mathbf{U}^{(f,m)}\mathbf{s} + \mathbf{b}_\uparrow^{(f,m)})\\
&\mathbf{o}_\uparrow = \sigma(\textstyle\sum_{m=1}^{M} \mathbf{W}_\uparrow^{(o,m)}\mathbf{h}_\uparrow^{(m)} + \mathbf{U}^{(o)}\mathbf{s} + \mathbf{b}_\uparrow^{(o)})\\
&\mathbf{u}_\uparrow = \tanh(\textstyle\sum_{m=1}^{M} \mathbf{W}_\uparrow^{(u,m)}\mathbf{h}_\uparrow^{(m)} + \mathbf{U}^{(u)}\mathbf{s} + \mathbf{b}_\uparrow^{(u)})\\
&\mathbf{c}_\uparrow = \mathbf{i}_\uparrow \odot \mathbf{u}_\uparrow + \textstyle\sum_{m=1}^{M} \mathbf{f}_\uparrow^{(m)} \odot \mathbf{c}_\uparrow^{(m)}\\
&\mathbf{h}_\uparrow = \mathbf{o}_\uparrow \odot \tanh(\mathbf{c}_\uparrow)
\end{aligned} \tag{2}$$

where $\mathbf{s}$ is the SLSTM hidden state that encodes the description of code C; $\{\mathbf{h}_{\uparrow}^{(m)}\}_{m=1}^{M}$ and $\{\mathbf{c}_{\uparrow}^{(m)}\}_{m=1}^{M}$ are the bottom-up TLSTM hidden states and memory cells of the children. $\mathbf{W}$, $\mathbf{U}$, $\mathbf{b}$ are component-specific weight matrices and bias vectors. For a leaf node having no children, its only input is the SLSTM hidden state $\mathbf{s}$ and no forget gates are needed.

In the top-down TLSTM, for a non-root node, it has such components: an input gate $\mathbf{i}_{\downarrow}$, a forget gate $\mathbf{f}_{\downarrow}$, an output gate $\mathbf{o}_{\downarrow}$, a memory cell $\mathbf{c}_{\downarrow}$ and a hidden state $\mathbf{h}_{\downarrow}$. The transition equations are:

$$\begin{aligned}
\mathbf{i}_{\downarrow} &= \sigma(\mathbf{W}_{\downarrow}^{(i)}\mathbf{h}_{\downarrow}^{(p)} + \mathbf{b}_{\downarrow}^{(i)})\\
\mathbf{f}_{\downarrow} &= \sigma(\mathbf{W}_{\downarrow}^{(f)}\mathbf{h}_{\downarrow}^{(p)} + \mathbf{b}_{\downarrow}^{(f)})\\
\mathbf{o}_{\downarrow} &= \sigma(\mathbf{W}_{\downarrow}^{(o)}\mathbf{h}_{\downarrow}^{(p)} + \mathbf{b}_{\downarrow}^{(o)})\\
\mathbf{u}_{\downarrow} &= \tanh(\mathbf{W}_{\downarrow}^{(u)}\mathbf{h}_{\downarrow}^{(p)} + \mathbf{b}_{\downarrow}^{(u)})\\
\mathbf{c}_{\downarrow} &= \mathbf{i}_{\downarrow} \odot \mathbf{u}_{\downarrow} + \mathbf{f}_{\downarrow} \odot \mathbf{c}_{\downarrow}^{(p)}\\
\mathbf{h}_{\downarrow} &= \mathbf{o}_{\downarrow} \odot \tanh(\mathbf{c}_{\downarrow})
\end{aligned} \tag{3}$$

where $\mathbf{h}_{\downarrow}^{(p)}$ and $\mathbf{c}_{\downarrow}^{(p)}$ are the top-down TLSTM hidden state and memory cell of the parent of this node. For the root node which has no parent, $\mathbf{h}_{\downarrow}$ cannot be computed using the above equations. Instead, we set $\mathbf{h}_{\downarrow}$ to $\mathbf{h}_{\uparrow}$ (the bottom-up TLSTM hidden state generated at the root node). $\mathbf{h}_{\uparrow}$ captures the semantics of all codes in this hierarchy, which is then propagated downwards to each individual code via the top-down TLSTM dynamics.

We concatenate the hidden states of the two directions to obtain the bidirectional TLSTM encoding of each code $\mathbf{h} = [\mathbf{h}_{\uparrow}; \mathbf{h}_{\downarrow}]$. The bottom-up TLSTM composes the semantics of children (representing sub-diseases) and merge them into the current node, which hence captures child-to-parent relationship. The top-down TLSTM makes each node inherit the semantics of its parent, which captures parent-to-child relation. As a result, the hierarchical relationship among codes are encoded in the hidden states.

For the diagnosis descriptions of a patient, we use an SLSTM network to encode each description individually. The weight parameters of this SLSTM are tied with those of the SLSTM used for encoding code descriptions.

4.3 Attentional Matching

Next, we introduce how to map the DDs to codes. We denote the hidden representations of DDs and codes as $\{\mathbf{h}_m\}_{m=1}^{M}$ and $\{\mathbf{u}_n\}_{n=1}^{N}$ respectively, where M is the number of DDs of one patient and N is the total number of codes in the dataset. The mapping from DDs to codes is not one-to-one. In many cases, a code is assigned only when a certain combination of K ($1 < K \leq M$) diseases simultaneously appear within the M DDs and the value of K depends on this code. Among the K diseases, their importance of determining the assignment of this code is different. For the rest $M - K$ DDs, we can consider their importance score to be zero. We use a soft-attention mechanism (Bahdanau et al., 2014) to calculate these importance scores. For a code $\mathbf{u}_n$, the importance of a DD $\mathbf{h}_m$ to $\mathbf{u}_n$ is calculated as $a_{nm} = \mathbf{u}_n^{\top}\mathbf{h}_m$. We normalize the scores $\{a_{nm}\}_{m=1}^{M}$ of all DDs into a probabilistic simplex using the softmax operation: $\tilde{a}_{nm} = \exp(a_{nm})/\sum_{l=1}^{M}\exp(a_{nl})$. Given these normalized importance scores $\{\tilde{a}_{nm}\}_{m=1}^{M}$, we use them to weight the representations of DDs and get a single attentional vector of the M DDs: $\widehat{\mathbf{h}}_n = \sum_{m=1}^{M}\tilde{a}_{nm}\mathbf{h}_m$. Then we concatenate $\widehat{\mathbf{h}}_n$ and $\mathbf{u}_n$, and use a linear classifier to predict the probability that code n should be assigned: $p_n = \mathrm{sigmoid}(\mathbf{w}_n^{\top}[\widehat{\mathbf{h}}_n; \mathbf{u}_n] + b_n)$, where the coefficients $\mathbf{w}_n$ and bias b_n are specific to code n.

We train the weight parameters Θ of the proposed model using the data of L patient visits. Θ includes the sequential LSTM weights $\mathbf{W}_s$, tree LSTM weights $\mathbf{W}_t$ and weights $\mathbf{W}_p$ in the final prediction layer. Let $c^{(l)} \in \mathbb{R}^N$ be a binary vector where $c_n^{(l)} = 1$ if the n-th code is assigned to this patient and $c_n^{(l)} = 0$ if otherwise. Θ can be learned by minimizing the following prediction loss:

$$\min_{\Theta} \quad \mathcal{L}_{\text{pred}}(\Theta) = \sum_{l=1}^{L}\sum_{n=1}^{N}\mathrm{CE}(p_n^{(l)}, c_n^{(l)}) \tag{4}$$

where $p_n^{(l)}$ is the predicted probability that code n is assigned to patient visit l and $p_n^{(l)}$ is a function of Θ. $\mathrm{CE}(\cdot,\cdot)$ is the cross-entropy loss.

4.4 Adversarial Reconciliation of Writing Styles

We use an adversarial learning (Goodfellow et al., 2014) approach to reconcile the different writing styles of diagnosis descriptions (DDs) and code descriptions (CDs). The basic idea is: after encoded, if a description cannot be discerned to be a DD or a CD, then the difference in their writing styles is eliminated. We build a discriminative network which takes the encoding vector of a description as input and tries to identify it as a DD or CD. The encoders of DDs and CDs adjust their weight parameters so that such a discrimination is difficult to be achieved by the discriminative network. Consider all the descriptions $\{t_r, y_r\}_{r=1}^{R}$ where t_r is a description and y_r is a binary label. $y_r = 1$ if t_r is a DD and $y_r = 0$ if otherwise. Let $f(t_r; \mathbf{W}_s)$ denote the sequential LSTM (SLSTM) encoder parameterized by $\mathbf{W}_s$. This encoder is shared by the DDs and CDs. Note that for CDs, a tree LSTM is further applied on top of the encodings produced by the SLSTM. We use the SLSTM encoding vectors of CDs as the input of the discriminative network rather than using the TLSTM encodings since the latter are irrelevant to writing styles. Let $g(f(t_r; \mathbf{W}_s); \mathbf{W}_d)$ denote the discriminative network parameterized by $\mathbf{W}_d$. It takes the encoding vector $f(t_r; \mathbf{W}_s)$ as input and produces the probability that t_r is a DD. Adversarial learning is performed by solving this problem:

$$\max_{\mathbf{W}_s} \min_{\mathbf{W}_d} \mathcal{L}_{\text{adv}} = \sum_{r=1}^{R} \text{CE}(g(f(t_r; \mathbf{W}_s); \mathbf{W}_d), y_r) \tag{5}$$

The discriminative network tries to differentiate DDs from CDs by minimizing this classification loss while the encoder maximizes this loss so that DDs and CDs are not distinguishable.

4.5 Isotonic Constraints

Next, we incorporate the importance order among ICD codes. For the $D^{(l)}$ codes assigned to patient l, without loss of generality, we assume the order is $1 \succ 2 \cdots \succ D^{(l)}$ (the order is given by human coders as ground-truth in the MIMIC-III dataset). We use the predicted probability p_i $(1 \leq i \leq D^{(l)})$ defined in Section 4.3 to characterize the importance of code i. To incorporate the order, we impose an isotonic constraint on the probabilities: $p_1^{(l)} \succ p_2^{(l)} \cdots \succ p_{D^{(l)}}^{(l)}$, and solve the following problem:

$$\begin{array}{ll} \min_\Theta & \mathcal{L}_{\text{pred}}(\Theta) + \max_{\mathbf{W}_d}(-\lambda \mathcal{L}_{\text{adv}}(\mathbf{W}_s, \mathbf{W}_d)) \\ s.t. & p_1^{(l)} \succ p_2^{(l)} \cdots \succ p_{D^{(l)}}^{(l)} \\ & \forall l = 1, \cdots, L \end{array} \tag{6}$$

where the probabilities $p_i^{(l)}$ are functions of Θ and λ is a tradeoff parameter.

We develop an algorithm based on the alternating direction method of multiplier (ADMM) (Boyd et al., 2011) to solve the problem defined in Eq.(6). Let $\mathbf{p}^{(l)}$ be a $|D^{(l)}|$-dimensional vector where the i-th element is $p_i^{(l)}$. We first write the problem into an equivalent form

$$\begin{array}{ll} \min_\Theta & \mathcal{L}_{\text{pred}}(\Theta) + \max_{\mathbf{W}_d}(-\lambda \mathcal{L}_{\text{adv}}(\mathbf{W}_s, \mathbf{W}_d)) \\ s.t. & \mathbf{p}^{(l)} = \mathbf{q}^{(l)} \\ & q_1^{(l)} \succ q_2^{(l)} \cdots \succ q_{|D^{(l)}|}^{(l)} \\ & \forall l = 1, \cdots, L \end{array} \tag{7}$$

Then we write down the augmented Lagrangian

$$\begin{array}{ll} \min\limits_{\Theta, \mathbf{q}, \mathbf{v}} & \mathcal{L}_{\text{pred}}(\Theta) + \max_{\mathbf{W}_d}(-\lambda \mathcal{L}_{\text{adv}}(\mathbf{W}_s, \mathbf{W}_d)) \\ & + \langle \mathbf{p}^{(l)} - \mathbf{q}^{(l)}, \mathbf{v}^{(l)} \rangle + \frac{\rho}{2} \|\mathbf{p}^{(l)} - \mathbf{q}^{(l)}\|_2^2 \\ s.t. & q_1^{(l)} \succ q_2^{(l)} \cdots \succ q_{|D^{(l)}|}^{(l)} \\ & \forall l = 1, \cdots, L \end{array} \tag{8}$$

We solve this problem by alternating between $\{\mathbf{p}^{(l)}\}_{l=1}^{L}$, $\{\mathbf{q}^{(l)}\}_{l=1}^{L}$ and $\{\mathbf{v}^{(l)}\}_{l=1}^{L}$ The sub-problem defined over $\mathbf{q}^{(l)}$ is

$$\begin{array}{ll} \min_{\mathbf{q}^{(l)}} & -\langle \mathbf{q}^{(l)}, \mathbf{v}^{(l)} \rangle + \frac{\rho}{2} \|\mathbf{p}^{(l)} - \mathbf{q}^{(l)}\|_2^2 \\ s.t. & q_1^{(l)} \succ q_2^{(l)} \cdots \succ q_{|D^{(l)}|}^{(l)} \end{array} \tag{9}$$

which is an isotonic projection problem and can be solved via the algorithm proposed in (Yu and Xing, 2016). With $\{\mathbf{q}^{(l)}\}_{l=1}^{L}$ and $\{\mathbf{v}^{(l)}\}_{l=1}^{L}$ fixed, the sub-problem is $\min_\Theta$ $\mathcal{L}_{\text{pred}}(\Theta) + \max_{\mathbf{W}_d}(-\lambda \mathcal{L}_{\text{adv}}(\mathbf{W}_s, \mathbf{W}_d))$ which can be solved using stochastic gradient descent (SGD). The update of $\mathbf{v}^{(l)}$ is simple: $\mathbf{v}^{(l)} = \mathbf{v}^{(l)} + \rho(\mathbf{p}^{(l)} - \mathbf{q}^{(l)})$.

5 Experiments

In this section, we present experiment results.

5.1 Experimental Settings

Out of the 6,984 unique codes, we selected 2,833 codes that have the top frequencies to perform the study. We split the data into a train/validation/test dataset with 40k/7k/12k patient visits respectively. The hyperparameters were tuned on the validation set. The SLSTMs were bidirectional and dropout with 0.5 probability (Srivastava et al., 2014) was used. The size of hidden states in all LSTMs was set to 100. The word embeddings were trained on the fly and their dimension was set to 200. The tradeoff parameter λ was set to 0.1. The parameter ρ in the ADMM algorithm was set to 1. In the SGD algorithm for solving $\min_\Theta \mathcal{L}_{\text{pred}}(\Theta) + \max_{\mathbf{W}_d}(-\lambda \mathcal{L}_{\text{adv}}(\mathbf{W}_s, \mathbf{W}_d))$, we used the ADAM (Kingma and Ba, 2014) optimizer with an initial learning rate 0.001 and a mini-batch size 20. Sensitivity (true positive rate) and specificity (true negative rate) were used to evaluate the code assignment performance. We calculated these two scores for each individual code on the test set, then took a weighted (proportional to codes' frequencies) average across all codes. To evaluate the ranking performance of codes, we used normalized discounted cumulative gain (NDCG) (Järvelin and Kekäläinen, 2002).

5.2 Ablation Study

We perform ablation study to verify the effectiveness of each module in our model. To evaluate module X, we remove it from the model without changing other modules and denote such a baseline by No-X. The comparisons of No-X with the full model are given in Table 2.

	Sensitivity	Specificity
(Larkey and Croft, 1996)	0.15	0.17
(Franz et al., 2000)	0.19	0.21
(Pestian et al., 2007)	0.12	0.21
(Kavuluru et al., 2013)	0.09	0.11
(Kavuluru et al., 2015)	0.21	0.25
(Koopman et al., 2015)	0.18	0.20
LET	0.23	0.29
HierNet	0.26	0.30
HybridNet	0.25	0.31
BranchNet	0.25	0.29
No-TLSTM	0.23	0.28
Bottom-up TLSTM	0.27	0.31
No-AL	0.26	0.31
No-IC	0.24	0.29
No-AM	0.27	0.29
Our full model	**0.29**	**0.33**

Table 2: Sensitivity and Specificity on the Test Set

Tree-of-sequences LSTM To evaluate this module, we compared with the two configurations: (1) *No-TLSTM*, which removes the tree LSTM and directly uses the hidden states produced by the sequential LSTM as final representations of codes; (2) *Bottom-up TLSTM*, which removes the hidden states generated by the top-down TLSTM. In addition, we compared with four hierarchical classification baselines including (1) hierarchical network (HierNet) (Yan et al., 2015), (2) HybridNet (Hou et al., 2017), (3) branch network (BranchNet) (Zhu and Bain, 2017), (4) label embedding tree (LET) (Bengio et al., 2010), by using them to replace the bidirectional tree LSTM while keeping other modules untouched. Table 2 shows the average sensitivity and specificity scores achieved by these methods on the test set. We make the following observations. First, removing tree LSTM largely degrades performance: the sensitivity and specificity of No-TLSTM is 0.23 and 0.28 respectively while our full model (which uses bidirectional TLSTM) achieves 0.29 and 0.33 respectively. The reason is No-TLSTM ignores the hierarchical relationship among codes. Second, bottom-up tree LSTM alone performs less well than bidirectional tree LSTM. This demonstrates the necessity of the top-down TLSTM, which ensures every two codes are connected by directed paths and can more expressively capture code-relations in the hierarchy. Third, our method outperforms the four baselines. The possible reason is our method directly builds codes' hierarchical relationship into their representations while the baselines perform representation-learning and relationship-capturing separately.

Next, we present some qualitative results. For a patient (admission ID 147798) having a DD 'E Coli urinary tract infection', without using tree LSTM, two sibling codes 585.2 (chronic kidney disease, stage II (mild)) – which is the ground-truth – and 585.4 (chronic kidney disease, stage IV (severe)) are simultaneously assigned possibly because their textual descriptions are very similar (only differ in the level of severity). This is incorrect because 585.2 and 585.4 are the children of 585 (chronic kidney disease) and the severity level of this disease cannot simultaneously be mild and severe. After tree LSTM is added, the false prediction of 585.4 is eliminated, which demonstrates the effectiveness of tree LSTM in incorporating one constraint induced by the code hierarchy: among the nodes sharing the same parent, only one should be selected.

For patient 197205, No-TLSTM assigns the following codes: 462 (subacute sclerosing panencephalitis), 790.29 (other abnormal glucose), 799.9 (unspecified viral infection), and 285.21 (anemia in chronic kidney disease). Among these codes, the first three are ground-truth and the fourth one is incorrect (the ground-truth is 401.9 (unspecified essential hypertension)). Adding tree LSTM fixes this error. The average distance between 401.9 and the rest of ground-truth codes is 6.2. For the incorrectly assigned code 285.21, such a distance is 7.9. This demonstrates that tree LSTM is able to capture another constraint imposed by the hierarchy: codes with smaller tree-distance are more likely to be assigned together.

Position	2	4	6	8
No-IC	0.27	0.26	0.23	0.20
IC	0.32	0.29	0.27	0.23

Table 3: Comparison of NDCG Scores in the Ablation Study of Isotonic Constraints.

Adversarial learning To evaluate the efficacy of adversarial learning (AL), we remove it from the full model and refer to this baseline as No-AL. Specifically, in Eq.(6), the loss term $\max_{\mathbf{W}_d}(-\mathcal{L}_{\text{adv}}(\mathbf{W}_s, \mathbf{W}_d))$ is taken away. Table 2 shows the results, from which we observe that after AL is removed, the sensitivity and specificity are dropped from 0.29 and 0.33 to 0.26 and 0.31 respectively. No-AL does not reconcile different writing styles of diagnosis descriptions (DDs) and code descriptions (CDs). As a result, a DD and a CD that have similar semantics may be mismatched because their writing styles are different. For example, a patient (admission ID 147583) has a DD 'h/o DVT on anticoagulation', which contains abbreviation DVT (deep vein thrombosis). Due to the presence of this abbreviation, it is difficult to assign a proper code to this DD since the textual descriptions of codes do not contain abbreviations. With adversarial learning, our model can correctly map this DD to a ground-truth code: 443.9 (peripheral vascular disease, unspecified). Without AL, this code is not selected. As another example, a DD 'coronary artery disease, STEMI, s/p 2 stents placed in RCA' was given to patient 148532. This DD is written informally and ungrammatically, and contains too much detailed information, e.g., 's/p 2 stents placed in RCA'. Such a writing style is quite different from that of CDs. With AL, our model successfully matches this DD to a ground-truth code: 414.01 (coronary atherosclerosis of native coronary artery). On the contrary, No-AL fails to achieve this.

Isotonic constraint (IC) To evaluate this ingredient, we remove the ICs from Eq.(6) during training and denote this baseline as No-IC. We use NDCG to measure the ranking performance, which is calculated in the following way. Consider a testing patient-visit l where the ground-truth ICD codes are $\mathcal{M}^{(l)}$. For any code c, we define the relevance score of c to l as 0 if $c \notin \mathcal{M}^{(l)}$ and as $|\mathcal{M}^{(l)}| - r(c)$ if otherwise, where $r(c)$ is the ground-truth rank of c in $\mathcal{M}^{(l)}$. We rank codes in descending order of their corresponding prediction probabilities and obtain the predicted rank for each code. We calculate the NDCG scores at position 2, 4, 6, 8 based on the relevance scores and predicted ranks, which are shown in Table 3. As can be seen, using IC achieves much higher NDCG than No-IC, which demonstrates the effectiveness of IC in capturing the importance order among codes.

We also evaluate how IC affects the sensitivity and specificity of code assignment. As can be seen from Table 2, No-IC degrades the two scores from 0.29 and 0.33 to 0.24 and 0.29 respectively, which indicates that IC is helpful in training a model that can more correctly assign codes. This is because IC encourages codes that are highly relevant to the patients to be ranked at top positions, which prevents the selection of irrelevant codes.

Attentional matching (AM) In the evaluation of this module, we compare with a baseline – No-AM, which performs an unweighted average of the M DDs: $\widehat{\mathbf{h}}_n = \frac{1}{M}\sum_{m=1}^{M}\mathbf{h}_m$, concatenates $\widehat{\mathbf{h}}_n$ with $\mathbf{u}_n$ and feeds the concatenated vector into the final prediction layer. From Table 2, we can see our full model (with AM) outperforms No-AM, which demonstrates the effectiveness of attentional matching. In determining whether a code should be assigned, different DDs have different importance weights. No-AM ignores such weights, therefore performing less well.

AM can correctly perform many-to-one mapping from multiple DDs to a CD. For example, patient 190236 was given two DDs: 'renal insufficiency' and 'acute renal failure'. AM maps them to a combined ICD code: 403.91 (hypertensive chronic kidney disease, unspecified, with chronic kidney disease stage V or end stage renal disease), which is in the ground-truth provided by medical coders. On the contrary, No-AM fails to assign this code. On the other hand, AM is able to correctly map a DD to multiple CDs. For example, a DD 'congestive heart failure, diastolic' was given to patient 140851. AM successfully maps this DD to two codes: (1) 428.0 (congestive heart failure, unspecified); (2) 428.30 (diastolic heart failure, unspecified). Without AM, this DD is mapped only to 428.0.

5.3 Holistic Comparison with Other Baselines

In addition to evaluating the four modules individually, we also compared our full model with four other baselines proposed by (Larkey and Croft, 1996; Franz et al., 2000; Pestian et al., 2007; Kavuluru et al., 2013, 2015; Koopman et al., 2015) for ICD coding. Table 2 shows the results. As can be seen, our approach achieves much better sensitivity and specificity scores. The reason that our model works better is two-fold. First, our model is based on deep neural network, which has arguably better modeling power than linear methods used in the baselines. Second, our model is able to capture the hierarchical relationship and importance order among codes, can alleviate the discrepancy in writing styles and allows flexible many-to-one and one-to-many mappings from DDs to CDs. These merits are not possessed by the baselines.

6 Conclusions and Discussions

In this paper, we build a neural network model for automated ICD coding. Evaluations on the MIMIC-III dataset demonstrate the following. First, the tree-of-sequences LSTM network effectively discourages the co-selection of sibling codes and promotes the co-assignment of clinically-relevant codes. Adversarial learning improves the matching accuracy by alleviating the discrepancy among the writing styles of DDs and CDs. Third, isotonic constraints promote the correct ranking of codes. Fourth, the attentional matching mechanism is able to perform many-to-one and one-to-many mappings.

In the coding practice of human coders, in addition to the diagnosis descriptions, other information contained in nursing notes, lab values, and medical procedures are also leveraged for code assignment. We have initiated preliminary investigation along this line and added two new input sources: (1) the rest of discharge summary and (2) lab values. The sensitivity is improved from 0.29 to 0.32 and the specificity is improved from 0.33 to 0.35. A full study is ongoing.

At present, the major limitations of this work include: (1) it does not perform well on infrequent codes; (2) it is less capable of dealing with abbreviations. We will address these two issues in future by investigating diversity-promoting regularization (Xie et al., 2017) and leveraging an external knowledge base that maps medical abbreviations into their full names.

The proposed methods can be applied to other tasks in NLP. The tree-of-sequences model can be applied for ontology annotation. It takes the textual descriptions of concepts in the ontology and their hierarchical structure as inputs and produces a latent representation for each concept. The representations can simultaneously capture the semantics of codes and their relationships. The proposed adversarial reconciliation of writing styles and attentional matching can be applied for knowledge mapping or entity linking. For example, in tweets, we can use the method to map an informally written mention 'nbcbightlynews' to a canonical entity 'NBC Nightly News' in the knowledge base.

Abstract

The success of deep neural networks (DNNs) is heavily dependent on the availability of labeled data. However, obtaining labeled data is a big challenge in many real-world problems. In such scenarios, a DNN model can leverage labeled and unlabeled data from a related domain, but it has to deal with the shift in data distributions between the source and the target domains. In this paper, we study the problem of classifying social media posts during a crisis event (e.g., Earthquake). For that, we use labeled and unlabeled data from past similar events (e.g., Flood) and unlabeled data for the current event. We propose a novel model that performs adversarial learning based domain adaptation to deal with distribution drifts and graph based semi-supervised learning to leverage unlabeled data within a single unified deep learning framework. Our experiments with two real-world crisis datasets collected from Twitter demonstrate significant improvements over several baselines.

1 Introduction

The application that motivates our work is the time-critical analysis of social media (Twitter) data at the sudden-onset of an event like natural or man-made disasters (Imran et al., 2015). In such events, affected people post timely and useful information of various types such as reports of injured or dead people, infrastructure damage, urgent needs (e.g., food, shelter, medical assistance) on these social networks. Humanitarian organizations believe timely access to this important information from social networks can help significantly and reduce both human loss and economic damage (Varga et al., 2013; Vieweg et al., 2014; Power et al., 2013).

In this paper, we consider the basic task of classifying each incoming tweet during a crisis event (e.g., Earthquake) into one of the predefined classes of interest (e.g., *relevant* vs. *non-relevant*) in real-time. Recently, deep neural networks (DNNs) have shown great performance in classification tasks in NLP and data mining. However the success of DNNs on a task depends heavily on the availability of a large labeled dataset, which is not a feasible option in our setting (i.e., classifying tweets at the onset of an Earthquake). On the other hand, in most cases, we can have access to a good amount of labeled and abundant unlabeled data from past similar events (e.g., Floods) and possibly some unlabeled data for the current event. In such situations, we need methods that can leverage the labeled and unlabeled data in a past event (we refer to this as a *source* domain), and that can adapt to a new event (we refer to this as a *target* domain) without requiring any labeled data in the new event. In other words, we need models that can do *domain adaptation* to deal with the distribution drift between the domains and *semi-supervised* learning to leverage the unlabeled data in both domains.

Most recent approaches to semi-supervised learning (Yang et al., 2016) and domain adaptation (Ganin et al., 2016) use the automatic feature learning capability of DNN models. In this paper, we extend these methods by proposing a novel model that performs domain adaptation and semi-supervised learning within a single unified deep learning framework. In this framework, the basic task-solving network (a convolutional neural network in our case) is put together with two other networks – one for semi-supervised learning and the other for domain adaptation. The semi-supervised component learns internal representations (features) by predicting contextual nodes in a graph that encodes *similarity* between labeled and unlabeled training instances. The domain adaptation is achieved by training the feature extractor (or encoder) in *adversary* with respect to a domain discriminator, a binary classifier that tries to distinguish the domains. The overall idea is to learn high-level abstract representation that is discriminative for the main classification task, but is invariant across the domains. We propose a stochastic gradient descent (SGD) algorithm to train the components of our model simultaneously.

The evaluation of our proposed model is conducted using two Twitter datasets on scenarios where there is only unlabeled data in the target domain. Our results demonstrate the following.

1. When the network combines the semi-supervised component with the supervised component, depending on the amount of labeled data used, it gives 5% to 26% absolute gains in F1 compared to when it uses only the supervised component.
2. Domain adaptation with adversarial training improves over the adaptation baseline (i.e., a transfer model) by 1.8% to 4.1% absolute F1.
3. When the network combines domain adversarial training with semi-supervised learning, we get further gains ranging from 5% to 7% absolute in F1 across events.

Our source code is available on Github[1] and the data is available on CrisisNLP[2].

The rest of the paper is organized as follows. In Section 2, we present the proposed method, i.e., domain adaptation and semi-supervised graph embedding learning. In Section 3, we present the experimental setup and baselines. The results and analysis are presented in Section 4. In Section 5, we present the works relevant to this study. Finally, conclusions appear in Section 6.

2 The Model

We demonstrate our approach for domain adaptation with adversarial training and graph embedding on a tweet classification task to support crisis response efforts. Let $\mathcal{D}_S^l = \{\mathbf{t}_i, y_i\}_{i=1}^{L_s}$ and $\mathcal{D}_S^u = \{\mathbf{t}_i\}_{i=1}^{U_s}$ be the set of labeled and unlabeled tweets for a source crisis event S (e.g., Nepal earthquake), where $y_i \in \{1, \ldots, K\}$ is the class label for tweet $\mathbf{t}_i$, L_s and U_s are the number of labeled and unlabeled tweets for the source event, respectively. In addition, we have unlabeled tweets $\mathcal{D}_T^u = \{\mathbf{t}_i\}_{i=1}^{U_t}$ for a target event T (e.g., Queensland flood) with U_t being the number of unlabeled tweets in the target domain. Our ultimate goal is to train a cross-domain model $p(y|\mathbf{t}, \theta)$ with parameters θ that can classify any tweet in the target event T without having any information about class labels in T.

Figure 1 shows the overall architecture of our neural model. The input to the network is a tweet $\mathbf{t} = (w_1, \ldots, w_n)$ containing words that come from a finite vocabulary $\mathcal{V}$ defined from the training set. The first layer of the network maps each of these words into a distributed representation $\mathbb{R}^d$ by looking up a shared embedding matrix $E \in \mathbb{R}^{|\mathcal{V}| \times d}$. We initialize the embedding matrix E in our network with word embeddings that are pretrained on a large crisis dataset (Subsection 2.5). However, embedding matrix E can also be initialize randomly. The output of the look-up layer is a matrix $X \in \mathbb{R}^{n \times d}$, which is passed through a number of convolution and pooling layers to learn higher-level feature representations. A *convolution* operation applies a *filter* $\mathbf{u} \in \mathbb{R}^{k.d}$ to a window of k vectors to produce a new feature h_t as

$$h_t = f(\mathbf{u}.X_{t:t+k-1}) \tag{1}$$

where $X_{t:t+k-1}$ is the concatenation of k look-up vectors, and f is a nonlinear activation; we use rectified linear units or ReLU. We apply this filter to each possible k-length windows in X with stride size of 1 to generate a *feature map* $\mathbf{h}^j$ as:

$$\mathbf{h}^j = [h_1, \ldots, h_{n+k-1}] \tag{2}$$

We repeat this process N times with N different filters to get N different feature maps. We use a *wide* convolution (Kalchbrenner et al., 2014), which ensures that the filters reach the entire tweet, including the boundary words. This is done by performing *zero-padding*, where out-of-range (i.e., $t<1$ or $t>n$) vectors are assumed to be zero. With wide convolution, o zero-padding size and 1 stride size, each feature map contains $(n + 2o - k + 1)$ convoluted features. After the convolution, we apply a *max-pooling* operation to each of the feature maps,

$$\mathbf{m} = [\mu_p(\mathbf{h}^1), \cdots, \mu_p(\mathbf{h}^N)] \tag{3}$$

[1]https://github.com/firojalam/domain-adaptation
[2]http://crisisnlp.qcri.org

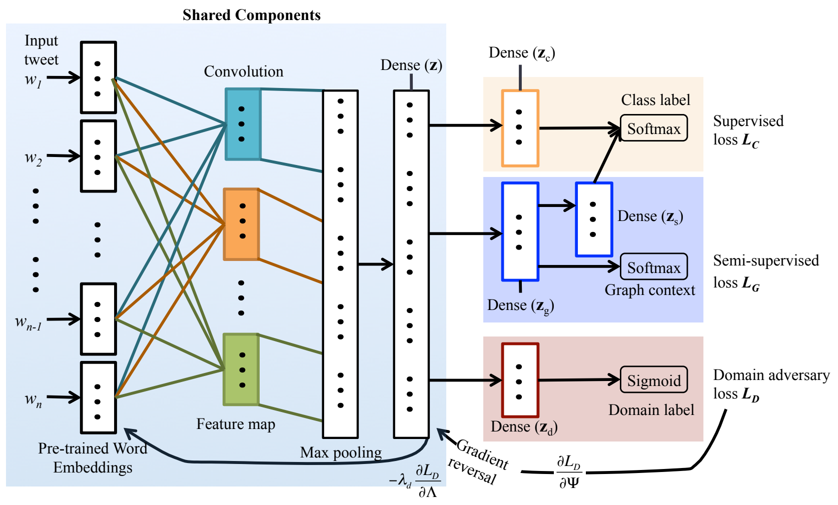

Figure 1: The system architecture of the domain adversarial network with graph-based semi-supervised learning. The shared components part is shared by supervised, semi-supervised and domain classifier.

where $\mu_p(\mathbf{h}^j)$ refers to the $\max$ operation applied to each window of p features with stride size of 1 in the feature map $\mathbf{h}^i$. Intuitively, the convolution operation composes local features into higher-level representations in the feature maps, and max-pooling extracts the most important aspects of each feature map while reducing the output dimensionality. Since each convolution-pooling operation is performed independently, the features extracted become invariant in order (i.e., where they occur in the tweet). To incorporate order information between the pooled features, we include a fully-connected (dense) layer

$$\mathbf{z} = f(V\mathbf{m}) \tag{4}$$

where V is the weight matrix. We choose a convolutional architecture for feature composition because it has shown impressive results on similar tasks in a supervised setting (Nguyen et al., 2017).

The network at this point splits into three branches (shaded with three different colors in Figure 1) each of which serves a different purpose and contributes a separate loss to the overall loss of the model as defined below:

$$\mathcal{L}(\Lambda, \Phi, \Omega, \Psi) = \mathcal{L}_C(\Lambda, \Phi) + \lambda_g \mathcal{L}_G(\Lambda, \Omega) + \lambda_d \mathcal{L}_D(\Lambda, \Psi) \tag{5}$$

where $\Lambda = \{U, V\}$ are the convolutional filters and dense layer weights that are shared across the three branches. The first component $\mathcal{L}_C(\Lambda, \Phi)$ is a supervised classification loss based on the labeled data in the source event. The second component $\mathcal{L}_G(\Lambda, \Omega)$ is a graph-based semi-supervised loss that utilizes both labeled and unlabeled data in the source and target events to induce structural similarity between training instances. The third component $\mathcal{L}_D(\Lambda, \Omega)$ is an adversary loss that again uses all available data in the source and target domains to induce domain invariance in the learned features. The tunable hyperparameters λ_g and λ_d control the relative strength of the components.

2.1 Supervised Component

The supervised component induces label information (e.g., *relevant* vs. *non-relevant*) directly in the network through the classification loss $\mathcal{L}_C(\Lambda, \Phi)$, which is computed on the labeled instances in the source event, $\mathcal{D}_S^l$. Specifically, this branch of the network, as shown at the top in Figure 1, takes the shared representations $\mathbf{z}$ as input and pass it through a task-specific dense layer

$$\mathbf{z}_c = f(V_c \mathbf{z}) \tag{6}$$

where V_c is the corresponding weight matrix. The activations $\mathbf{z}_c$ along with the activations from the semi-supervised branch $\mathbf{z}_s$ are used for classification. More formally, the classification layer defines a Softmax

$$p(y = k|\mathbf{t}, \theta) = \frac{\exp\left(W_k^T [\mathbf{z}_c; \mathbf{z}_s]\right)}{\sum_{k'} \exp\left(W_{k'}^T [\mathbf{z}_c; \mathbf{z}_s]\right)} \tag{7}$$

where $[.;.]$ denotes concatenation of two column vectors, W_k are the class weights, and $\theta = \{U, V, V_c, W\}$ defines the relevant parameters for this branch of the network with $\Lambda = \{U, V\}$ being the shared parameters and $\Phi = \{V_c, W\}$ being the parameters specific to this branch. Once learned, we use θ for prediction on test tweets. The classification loss $\mathcal{L}_C(\Lambda, \Phi)$ (or $\mathcal{L}_C(\theta)$) is defined as

$$\mathcal{L}_C(\Lambda, \Phi) = -\frac{1}{L_s}\sum_{i=1}^{L_s} \mathbb{I}(y_i = k) \log p(y_i = k|\mathbf{t}_i, \Lambda, \Phi) \quad (8)$$

where $\mathbb{I}(.)$ is an indicator function that returns 1 when the argument is true, otherwise it returns 0.

2.2 Semi-supervised Component

The semi-supervised branch (shown at the middle in Figure 1) induces structural similarity between training instances (labeled or unlabeled) in the source and target events. We adopt the recently proposed graph-based semi-supervised deep learning framework (Yang et al., 2016), which shows impressive gains over existing semi-supervised methods on multiple datasets. In this framework, a "similarity" graph G first encodes relations between training instances, which is then used by the network to learn internal representations (i.e., embeddings).

2.2.1 Learning Graph Embeddings

The semi-supervised branch takes the shared representation $\mathbf{z}$ as input and learns internal representations by predicting a node in the graph context of the input tweet. Following (Yang et al., 2016), we use *negative sampling* to compute the loss for predicting the context node, and we sample two types of contextual nodes: (*i*) one is based on the graph G to encode structural information, and (*ii*) the second is based on the labels in $\mathcal{D}_S^l$ to incorporate label information through this branch of the network. The ratio of positive and negative samples is controlled by a random variable $\rho_1 \in (0, 1)$, and the proportion of the two context types is controlled by another random variable $\rho_2 \in (0, 1)$; see Algorithm 1 of (Yang et al., 2016) for details on the sampling procedure.

Let (j, γ) is a tuple sampled from the distribution $p(j, \gamma|i, \mathcal{D}_S^l, G)$, where j is a context node of an input node i and $\gamma \in \{+1, -1\}$ denotes whether it is a positive or a negative sample; $\gamma = +1$ if $\mathbf{t}_i$ and $\mathbf{t}_j$ are neighbors in the graph (for graph-based context) or they both have same labels (for label-based context), otherwise $\gamma = -1$. The negative log loss for context prediction $\mathcal{L}_G(\Lambda, \Omega)$ can be written as

$$\mathcal{L}_G(\Lambda, \Omega) = -\frac{1}{L_s + U_s}\sum_{i=1}^{L_s+U_s} \mathbb{E}_{(j,\gamma)} \log \sigma\left(\gamma C_j^T \mathbf{z}_g(i)\right) \quad (9)$$

where $\mathbf{z}_g(i) = f(V_g\mathbf{z}(i))$ defines another dense layer (marked as *Dense* ($\mathbf{z}_g$) in Figure 1) having weights V_g, and C_j is the weight vector associated with the context node $\mathbf{t}_j$. Note that here $\Lambda = \{U, V\}$ defines the shared parameters and $\Omega = \{V_g, C\}$ defines the parameters specific to the semi-supervised branch of the network.

2.2.2 Graph Construction

Typically graphs are constructed based on a relational knowledge source, e.g., citation links in (Lu and Getoor, 2003), or distance between instances (Zhu, 2005). However, we do not have access to such a relational knowledge in our setting. On the other hand, computing distance between $n(n-1)/2$ pairs of instances to construct the graph is also very expensive (Muja and Lowe, 2014). Therefore, we choose to use k-nearest neighbor-based approach as it has been successfully used in other study (Steinbach et al., 2000).

The nearest neighbor graph consists of n vertices and for each vertex, there is an edge set consisting of a subset of n instances, i.e., tweets in our training set. The edge is defined by the distance measure $d(i, j)$ between tweets $\mathbf{t}_i$ and $\mathbf{t}_j$, where the value of d represents how similar the two tweets are. We used k-d tree data structure (Bentley, 1975) to efficiently find the nearest instances. To construct the graph, we first represent each tweet by averaging the word2vec vectors of its words, and then we measure $d(i, j)$ by computing the *Euclidean* distance between the vectors. The number of nearest neighbor k was set to 10. The reason of averaging the word vectors is that it is computationally simpler and it captures the relevant semantic information for our task in hand. Likewise, we choose to use Euclidean distance instead of cosine for computational efficiency.

2.3 Domain Adversarial Component

The network described so far can learn abstract features through convolutional and dense layers that are discriminative for the classification task (*relevant* vs. *non-relevant*). The supervised branch of the network uses labels in the source event to induce label information directly, whereas the semi-supervised branch induces similarity information between labeled and unlabeled instances. However, our goal is also to make these learned features invariant across domains or events (e.g., *Nepal Earthquake* vs. *Queensland Flood*). We achieve this by domain *adversarial* training of neural networks (Ganin et al., 2016).

We put a domain discriminator, another branch in the network (shown at the bottom in Figure 1) that takes the shared internal representation $\mathbf{z}$ as input, and tries to discriminate between the domains of the input — in our case, whether the input tweet is from $\mathcal{D}_S$ or from $\mathcal{D}_T$. The domain discriminator is defined by a sigmoid function:

$$\hat{\delta} = p(d = 1|\mathbf{t}, \Lambda, \Psi) = \text{sigm}(\mathbf{w}_d^T \mathbf{z}_d) \quad (10)$$

where $d \in \{0, 1\}$ denotes the domain of the input tweet $\mathbf{t}$, $\mathbf{w}_d$ are the final layer weights of the discriminator, and $\mathbf{z}_d = f(V_d \mathbf{z})$ defines the hidden layer of the discriminator with layer weights V_d. Here $\Lambda = \{U, V\}$ defines the shared parameters, and $\Psi = \{V_d, \mathbf{w}_d\}$ defines the parameters specific to the domain discriminator. We use the negative log-probability as the discrimination loss:

$$\mathcal{J}_i(\Lambda, \Psi) = -d_i \log \hat{\delta} - (1 - d_i) \log \left(1 - \hat{\delta}\right) \quad (11)$$

We can write the overall domain adversary loss over the source and target domains as

$$\mathcal{L}_D(\Lambda, \Psi) = -\frac{1}{L_s + U_s} \sum_{i=1}^{L_s+U_s} \mathcal{J}_i(\Lambda, \Psi) - \frac{1}{U_t} \sum_{i=1}^{U_t} \mathcal{J}_i(\Lambda, \Psi) \quad (12)$$

where $L_s + U_s$ and U_t are the number of training instances in the source and target domains, respectively. In adversarial training, we seek parameters (saddle point) such that

$$\theta^* = \underset{\Lambda, \Phi, \Omega}{\text{argmin}} \max_{\Psi} \mathcal{L}(\Lambda, \Phi, \Omega, \Psi) \quad (13)$$

which involves a maximization with respect to Ψ and a minimization with respect to $\{\Lambda, \Phi, \Omega\}$. In other words, the updates of the shared parameters $\Lambda = \{U, V\}$ for the discriminator work adversarially to the rest of the network, and vice versa. This is achieved by reversing the gradients of the discrimination loss $\mathcal{L}_D(\Lambda, \Psi)$, when they are back-propagated to the shared layers (see Figure 1).

2.4 Model Training

Algorithm 1 illustrates the training algorithm based on stochastic gradient descent (SGD). We first initialize the model parameters. The word embedding matrix E is initialized with pre-trained word2vec vectors (see Subsection 2.5) and is kept fixed during training.[3] Other parameters are initialized with small random numbers sampled from a uniform distribution (Bengio and Glorot, 2010). We use AdaDelta (Zeiler, 2012) adaptive update to update the parameters.

[3]Tuning E on our task by backpropagation increased the training time immensely (3 days compared to 5 hours on a Tesla GPU) without any significant performance gain.

Algorithm 1: Model Training with SGD

```
Input  : data $\mathcal{D}_S^l$, $\mathcal{D}_S^u$, $\mathcal{D}_T^u$; graph $G$
Output: learned parameters $\theta = \{\Lambda, \Phi\}$
1. Initialize model parameters $\{E, \Lambda, \Phi, \Omega, \Psi\}$;
2. repeat
      // Semi-supervised
      for each batch sampled from $p(j, \gamma|i, \mathcal{D}_S^l, G)$ do
          a) Compute loss $\mathcal{L}_G(\Lambda, \Omega)$
          b) Take a gradient step for $\mathcal{L}_G(\Lambda, \Omega)$;
      end
      // Supervised & domain adversary
      for each batch sampled from $\mathcal{D}_S^l$ do
          a) Compute $\mathcal{L}_C(\Lambda, \Phi)$ and $\mathcal{L}_D(\Lambda, \Psi)$
          b) Take gradient steps for $\mathcal{L}_C(\Lambda, \Phi)$ and
          $\mathcal{L}_D(\Lambda, \Psi)$;
      end
      // Domain adversary
      for each batch sampled from $\mathcal{D}_S^u$ and $\mathcal{D}_T^u$ do
          a) Compute $\mathcal{L}_D(\Lambda, \Psi)$
          b) Take a gradient step for $\mathcal{L}_D(\Lambda, \Psi)$;
      end
   until convergence;
```

In each iteration, we do three kinds of gradient updates to account for the three different loss components. First, we do an epoch over all the training instances updating the parameters for the semi-supervised loss, then we do an epoch over the labeled instances in the source domain, each time updating the parameters for the supervised and the domain adversary losses. Finally, we do an epoch over the unlabeled instances in the two domains to account for the domain adversary loss.

The main challenge in adversarial training is to balance the competing components of the network. If one component becomes smarter than the other, its loss to the shared layer becomes useless, and the training fails to converge (Arjovsky et al., 2017). Equivalently, if one component becomes weaker, its loss overwhelms that of the other, causing the training to fail. In our experiments, we observed the domain discriminator is weaker than the rest of the network. This could be due to the noisy nature of tweets, which makes the job for the domain discriminator harder. To balance the components, we would want the error signals from the discriminator to be fairly weak, also we would want the supervised loss to have more impact than the semi-supervised loss. In our experiments, the weight of the domain adversary loss λ_d was fixed to $1e - 8$, and the weight of the semi-supervised loss λ_g was fixed to $1e - 2$. Other sophisticated weighting schemes have been proposed recently

(Ganin et al., 2016; Arjovsky et al., 2017; Metz et al., 2016). It would be interesting to see how our model performs using these advanced tuning methods, which we leave as a future work.

2.5 Crisis Word Embedding

As mentioned, we used word embeddings that are pre-trained on a crisis dataset. To train the word-embedding model, we first pre-processed tweets collected using the AIDR system (Imran et al., 2014) during different events occurred between 2014 and 2016. In the preprocessing step, we lowercased the tweets and removed URLs, digit, time patterns, special characters, single character, username started with the @ symbol. After pre-processing, the resulting dataset contains about 364 million tweets and about 3 billion words.

There are several approaches to train word embeddings such as continuous bag-of-words (CBOW) and skip-gram models of wrod2vec (Mikolov et al., 2013), and Glove (Pennington et al., 2014). For our work, we trained the CBOW model from word2vec. While training CBOW, we filtered out words with a frequency less than or equal to 5, and we used a context window size of 5 and $k = 5$ negative samples. The resulting embedding model contains about 2 million words with vector dimensions of 300.

3 Experimental Settings

In this section, we describe our experimental settings – datasets used, settings of our models, compared baselines, and evaluation metrics.

3.1 Datasets

To conduct the experiment and evaluate our system, we used two real-world Twitter datasets collected during the *2015 Nepal earthquake* (NEQ) and the *2013 Queensland floods* (QFL). These datasets are comprised of millions of tweets collected through the Twitter streaming API[4] using event-specific keywords/hashtags.

To obtain the labeled examples for our task we employed paid workers from the Crowdflower[5] – a crowdsourcing platform. The annotation consists of two classes *relevant* and *non-relevant*. For the annotation, we randomly sampled 11,670 and 10,033 tweets from the Nepal earthquake and the Queensland floods datasets, respectively. Given a

Dataset	Relevant	Non-relevant	Train	Dev	Test
NEQ	5,527	6,141	7,000	1,167	3,503
QFL	5,414	4,619	6,019	1,003	3,011

Table 1: Distribution of labeled datasets for Nepal earthquake (NEQ) and Queensland flood (QFL).

tweet, we asked crowdsourcing workers to assign the *"relevant"* label if the tweet conveys/reports information useful for crisis response such as a report of injured or dead people, some kind of infrastructure damage, urgent needs of affected people, donations requests or offers, otherwise assign the *"non-relevant"* label. We split the labeled data into 60% as training, 30% as test and 10% as development. Table 1 shows the resulting datasets with class-wise distributions. Data preprocessing was performed by following the same steps used to train the word2vec model (Subsection 2.5). In all the experiments, the classification task consists of two classes: *relevant* and *non-relevant*.

3.2 Model Settings and Baselines

In order to demonstrate the effectiveness of our joint learning approach, we performed a series of experiments. To understand the contribution of different network components, we performed an ablation study showing how the model performs as a semi-supervised model alone and as a domain adaptation model alone, and then we compare them with the combined model that incorporates all the components.

3.2.1 Settings for Semi-supervised Learning

As a baseline for the semi-supervised experiments, we used the self-training approach (Scudder, 1965). For this purpose, we first trained a supervised model using the CNN architecture (i.e., shared components followed by the supervised part in Figure 1). The trained model was then used to automatically label the unlabeled data. Instances with a classifier confidence score ≥ 0.75 were then used to retrain a new model.

Next, we run experiments using our graph-based semi-supervised approach (i.e., shared components followed by the supervised and semi-supervised parts in Figure 1), which exploits unlabeled data. For reducing the computational cost, we randomly selected $50K$ unlabeled instances from the same domain. For our semi-supervised setting, one of the main goals was to understand how much labeled data is sufficient to obtain a

[4]https://dev.twitter.com/streaming/overview
[5]http://crowdflower.com

reasonable result. Therefore, we experimented our system by incrementally adding batches of instances, such as 100, 500, 2000, 5000, and all instances from the training set. Such an understanding can help us design the model at the onset of a crisis event with sufficient amount of labeled data. To demonstrate that the semi-supervised approach outperforms the supervised baseline, we run supervised experiments using the same number of labeled instances. In the supervised setting, only $\mathbf{z}_c$ activations in Figure 1 are used for classification.

3.2.2 Settings for Domain Adaptation

To set a baseline for the domain adaptation experiments, we train a CNN model (i.e., shared components followed by the supervised part in Figure 1) on one event (source) and test it on another event (target). We call this as *transfer baseline*.

To assess the performance of our domain adaptation technique alone, we exclude the semi-supervised component from the network. We train and evaluate models with this network configuration using different source and target domains.

Finally, we integrate all the components of the network as shown in Figure 1 and run domain adaptation experiments using different source and target domains. In all our domain adaptation experiments, we only use unlabeled instances from the target domain. In domain adaption literature, this is known as *unsupervised* adaptation.

3.2.3 Training Settings

We use 100, 150, and 200 filters each having the window size of 2, 3, and 4, respectively, and pooling length of 2, 3, and 4, respectively. We do not tune these hyperparameters in any experimental setting since the goal was to have an end-to-end comparison with the same hyperparameter setting and understand whether our approach can outperform the baselines or not. Furthermore, we do not filter out any vocabulary item in any settings.

As mentioned before in Subsection 2.4, we used AdaDelta (Zeiler, 2012) to update the model parameters in each SGD step. The learning rate was set to 0.1 when optimizing on the classification loss and to 0.001 when optimizing on the semi-supervised loss. The learning rate for domain adversarial training was set to 1.0. The maximum number of epochs was set to 200, and dropout rate of 0.02 was used to avoid overfitting (Srivastava et al., 2014). We used validation-based *early stopping* using the F-measure with a patience of 25,

Experiments	AUC	P	R	F1
NEPAL EARTHQUAKE				
Supervised	61.22	62.42	62.31	60.89
Semi-supervised (Self-training)	61.15	61.53	61.53	61.26
Semi-supervised (Graph-based)	64.81	64.58	64.63	65.11
QUEENSLAND FLOODS				
Supervised	80.14	80.08	80.16	80.16
Semi-supervised (Self-training)	81.04	80.78	80.84	81.08
Semi-supervised (Graph-based)	92.20	92.60	94.49	93.54

Table 2: Results using supervised, self-training, and graph-based semi-supervised approaches in terms of Weighted average AUC, precision (P), recall (R) and F-measure (F1).

i.e., we stop training if the score does not increase for 25 consecutive epochs.

3.2.4 Evaluation Metrics

To measure the performance of the trained models using different approaches described above, we use weighted average precision, recall, F-measure, and Area Under ROC-Curve (AUC), which are standard evaluation measures in the NLP and machine learning communities. The rationale behind choosing the weighted metric is that it takes into account the class imbalance problem.

4 Results and Discussion

In this section, we present the experimental results and discuss our main findings.

4.1 Semi-supervised Learning

In Table 2, we present the results obtained from the supervised, self-training based semi-supervised, and our graph-based semi-supervised experiments for the both datasets. It can be clearly observed that the graph-based semi-supervised approach outperforms the two baselines – supervised and self-training based semi-supervised. Specifically, the graph-based approach shows 4% to 13% absolute improvements in terms of F1 scores for the Nepal and Queensland datasets, respectively.

To determine how the semi-supervised approach performs in the early hours of an event when only fewer labeled instances are available, we mimic a batch-wise (not to be confused with minibatch in SGD) learning setting. In Table 3, we present the results using different batch sizes – 100, 500, 1,000, 2,000, and all labels.

From the results, we observe that models' performance improve as we include more labeled data

Exp.	100	500	1000	2000	All L
		NEPAL EARTHQUAKE			
L	43.63	52.89	56.37	60.11	60.89
L+50kU	52.32	59.95	61.89	64.05	65.11
		QUEENSLAND FLOOD			
L	48.97	76.62	80.62	79.16	80.16
L+∼21kU	75.08	85.54	89.08	91.54	93.54

Table 3: Weighted average F-measure for the graph-based semi-supervised settings using different batch sizes. *L* refers to labeled data, *U* refers to unlabeled data, *All L* refers to all labeled instances for that particular dataset.

— from 43.63 to 60.89 for NEQ and from 48.97 to 80.16 for QFL in the case of labeled only (***L***). When we compare supervised vs. semi-supervised (***L*** vs. ***L+U***), we observe significant improvements in F1 scores for the semi-supervised model for all batches over the two datasets. As we include unlabeled instances with labeled instances from the same event, performance significantly improves in each experimental setting giving 5% to 26% absolute improvements over the supervised models. These improvements demonstrate the effectiveness of our approach. We also notice that our semi-supervised approach can perform above 90% depending on the event. Specifically, major improvements are observed from batch size 100 to 1,000, however, after that the performance improvements are comparatively minor. The results obtained using batch sizes 500 and 1,000 are reasonably in the acceptable range when labeled and unlabeled instances are combined (i.e., *L+50kU* for Nepal and *L+∼21kU* for Queensland), which is also a reasonable number of training examples to obtain at the onset of an event.

4.2 Domain Adaptation

In Table 4, we present domain adaptation results. The first block shows event-specific (i.e., train and test on the same event) results for the supervised CNN model. These results set the upper bound for our domain adaptation methods. The *transfer* baselines are shown in the next block, where we train a CNN model in one domain and test it on a different domain. Then, the third block shows the results for the domain adversarial approach without the semi-supervised loss. These results show the importance of domain adversarial component. After that, the fourth block presents the performance of the model trained with graph embedding without domain adaptation to show the importance of semi-supervised learning. The final block present the results for the complete model that includes all the loss components.

Source	Target	AUC	P	R	F1
	IN-DOMAIN SUPERVISED MODEL				
Nepal	**Nepal**	61.22	62.42	62.31	60.89
Queensland	**Queensland**	80.14	80.08	80.16	80.16
	TRANSFER BASELINES

Queensland	**Nepal**	54.60	54.58	55.00	54.79
	GRAPH EMBEDDING WITH DOMAIN ADVERSARIAL				
Nepal	**Queensland**	66.49	67.48	65.90	65.92
Queensland	**Nepal**	58.81	58.63	59.00	59.05

Table 4: Domain adaptation experimental results. Weighted average AUC, precision (P), recall (R) and F-measure (F1).

The results with domain adversarial training show improvements across both events – from 1.8% to 4.1% absolute gains in F1. These results attest that adversarial training is an effective approach to induce domain invariant features in the internal representation as shown previously by Ganin et al. (2016).

Finally, when we do both semi-supervised learning and unsupervised domain adaptation, we get further improvements in F1 scores ranging from 5% to 7% absolute gains. From these improvements, we can conclude that domain adaptation with adversarial training along with graph-based semi-supervised learning is an effective method to leverage unlabeled and labeled data from a different domain.

Note that for our domain adaptation methods, we only use unlabeled data from the target domain. Hence, we foresee future improvements of this approach by utilizing a small amount of target domain labeled data.

5 Related Work

Two lines of research are directly related to our work: (*i*) semi-supervised learning and (*ii*) domain adaptation. Several models have been proposed for semi-supervised learning. The earliest approach is self-training (Scudder, 1965), in which a trained model is first used to label unlabeled data instances followed by the model retraining with the most confident predicted labeled instances. The co-training (Mitchell, 1999) approach assumes that features can be split into two sets and each subset is then used to train a classifier with an assumption that the two sets are conditionally independent. Then each classifier classifies the unlabeled data, and then most confident data instances are used to re-train the other classifier, this process repeats multiple times.

In the graph-based semi-supervised approach, nodes in a graph represent labeled and unlabeled instances and edge weights represent the similarity between them. The structural information encoded in the graph is then used to regularize a model (Zhu, 2005). There are two paradigms in semi-supervised learning: 1) inductive – learning a function with which predictions can be made on unobserved instances, 2) transductive – no explicit function is learned and predictions can only be made on observed instances. As mentioned before, inductive semi-supervised learning is preferable over the transductive approach since it avoids building the graph each time it needs to infer the labels for the unlabeled instances.

In our work, we use a graph-based inductive deep learning approach proposed by Yang et al. (2016) to learn features in a deep learning model by predicting contextual (i.e., neighboring) nodes in the graph. However, our approach is different from Yang et al. (2016) in several ways. First, we construct the graph by computing the distance between tweets based on word embeddings. Second, instead of using count-based features, we use a convolutional neural network (CNN) to compose high-level features from the distributed representation of the words in a tweet. Finally, for context prediction, instead of performing a random walk, we select nodes based on their similarity in the graph. Similar similarity-based graph has shown impressive results in learning sentence representations (Saha et al., 2017).

In the literature, the proposed approaches for domain adaptation include supervised, semi-supervised and unsupervised. It also varies from linear kernelized approach (Blitzer et al., 2006) to non-linear deep neural network techniques (Glorot et al., 2011; Ganin et al., 2016). One direction of research is to focus on feature space distribution matching by reweighting the samples from the source domain (Gong et al., 2013) to map source into target. The overall idea is to learn a good feature representation that is invariant across domains. In the deep learning paradigm, Glorot et al. (Glorot et al., 2011) used Stacked Denoising Auto-Encoders (SDAs) for domain adaptation. SDAs learn a robust feature representation, which is artificially corrupted with small Gaussian noise. *Adversarial training* of neural networks has shown big impact recently, especially in areas such as computer vision, where generative unsupervised models have proved capable of synthesizing new images (Goodfellow et al., 2014; Radford et al., 2015; Makhzani et al., 2015). Ganin et al. (2016) proposed domain adversarial neural networks (DANN) to learn discriminative but at the same time domain-invariant representations, with domain adaptation as a target. We extend this work by combining with semi-supervised graph embedding for unsupervised domain adaptation.

In a recent work, Kipf and Welling (2016) present CNN applied directly on graph-structured datasets - citation networks and on a knowledge graph dataset. Their study demonstrate that graph convolution network for semi-supervised classification performs better compared to other graph based approaches.

6 Conclusions

In this paper, we presented a deep learning framework that performs domain adaptation with adversarial training and graph-based semi-supervised learning to leverage labeled and unlabeled data from related events. We use a convolutional neural network to compose high-level representation from the input, which is then passed to three components that perform supervised training, semi-supervised learning and domain adversarial training. For domain adaptation, we considered a scenario, where we have only unlabeled data in the target event. Our evaluation on two crisis-related tweet datasets demonstrates that by combining domain adversarial training with semi-supervised learning, our model gives significant improvements over their respective baselines. We have also presented results of batch-wise incremental training of the graph-based semi-supervised approach and show approximation regarding the number of labeled examples required to get an acceptable performance at the onset of an event.

Abstract

Existing automated essay scoring (AES) models rely on rated essays for the target prompt as training data. Despite their successes in prompt-dependent AES, how to effectively predict essay ratings under a prompt-independent setting remains a challenge, where the rated essays for the target prompt are not available. To close this gap, a two-stage deep neural network (TDNN) is proposed. In particular, in the first stage, using the rated essays for non-target prompts as the training data, a shallow model is learned to select essays with an extreme quality for the target prompt, serving as pseudo training data; in the second stage, an end-to-end hybrid deep model is proposed to learn a prompt-dependent rating model consuming the pseudo training data from the first step. Evaluation of the proposed TDNN on the standard ASAP dataset demonstrates a promising improvement for the prompt-independent AES task.

1 Introduction

Automated essay scoring (AES) utilizes natural language processing and machine learning techniques to automatically rate essays written for a target prompt (Dikli, 2006). Currently, the AES systems have been widely used in large-scale English writing tests, e.g. Graduate Record Examination (GRE), to reduce the human efforts in the writing assessments (Attali and Burstein, 2006).

Existing AES approaches are prompt-dependent, where, given a target prompt, rated essays for this particular prompt are required for training (Dikli, 2006; Williamson, 2009; Foltz et al., 1999). While the established models are effective (Chen and He, 2013; Taghipour and Ng, 2016; Alikaniotis et al., 2016; Cummins et al., 2016; Dong et al., 2017), we argue that the models for prompt-independent AES are also desirable to allow for better feasibility and flexibility of AES systems especially when the rated essays for a target prompt are difficult to obtain or even unaccessible. For example, in a writing test within a small class, students are asked to write essays for a target prompt without any rated examples, where the prompt-dependent methods are unlikely to provide effective AES due to the lack of training data. Prompt-independent AES, however, has drawn little attention in the literature, where there only exists unrated essays written for the target prompt, as well as the rated essays for several non-target prompts.

We argue that it is not straightforward, if possible, to apply the established prompt-dependent AES methods for the mentioned prompt-independent scenario. On one hand, essays for different prompts may differ a lot in the uses of vocabulary, the structure, and the grammatic characteristics; on the other hand, however, established prompt-dependent AES models are designed to learn from these prompt-specific features, including the on/off-topic degree, the *tf-idf* weights of topical terms (Attali and Burstein, 2006; Dikli, 2006), and the n-gram features extracted from word semantic embeddings (Dong and Zhang, 2016; Alikaniotis et al., 2016). Consequently, the prompt-dependent models can hardly learn generalized rules from rated essays for non-target prompts, and are not suitable for the prompt-independent AES.

Being aware of this difficulty, to this end, a two-stage deep neural network, coined as *TDNN*, is proposed to tackle the prompt-independent AES problem. In particular, to mitigate the lack of the prompt-dependent labeled data, at the first stage, a shallow model is trained on a number of rated essays for several non-target prompts; given a target prompt and a set of essays to rate, the trained model is employed to generate pseudo training data by selecting essays with the extreme quality. At the second stage, a novel end-to-end hybrid deep neural network learns prompt-dependent features from these selected training data, by considering semantic, part-of-speech, and syntactic features.

The contributions in this paper are threefold: 1) a two-stage learning framework is proposed to bridge the gap between the target and non-target prompts, by only consuming rated essays for non-target prompts as training data; 2) a novel deep model is proposed to learn from pseudo labels by considering semantic, part-of-speech, and syntactic features; and most importantly, 3) to the best of our knowledge, the proposed TDNN is actually the first approach dedicated to addressing the prompt-independent AES. Evaluation on the standard ASAP dataset demonstrates the effectiveness of the proposed method.

The rest of this paper is organized as follows. In Section 2, we describe our novel TDNN model, including the two-stage framework and the proposed deep model. Following that, we describe the setup of our empirical study in Section 3, thereafter present the results and provide analyzes in Section 4. Section 5 recaps existing literature and put our work in context, before drawing final conclusions in Section 6.

2 Two-stage Deep Neural Network for AES

In this section, the proposed two-stage deep neural network (TDNN) for prompt-independent AES is described. To accurately rate an essay, on one hand, we need to consider its pertinence to the given prompt; on the other hand, the organization, the analyzes, as well as the uses of the vocabulary are all crucial for the assessment. Henceforth, both prompt-dependent and -independent factors should be considered, but the latter ones actually do not require prompt-dependent training data. Accordingly, in the proposed framework, a supervised ranking model is first trained to learn from prompt-independent data, hoping to roughly assess essays without considering the prompt; subsequently, given the test dataset, namely, a set of essays for a target prompt, a subset of essays are selected as positive and negative training data based on the prediction of the trained model from the first stage; ultimately, a novel deep model is proposed to learn both prompt-dependent and -independent factors on this selected subset. As indicated in Figure 1, the proposed framework includes two stages.

2.1 Overview

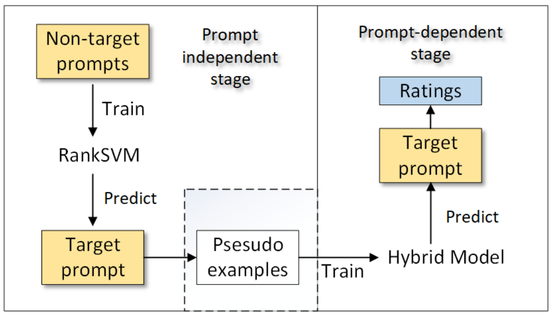

Figure 1: The architecture of the TDNN framework for prompt-independent AES.

Prompt-independent stage. Only the prompt-independent factors are considered to train a shallow model, aiming to recognize the essays with the extreme quality in the test dataset, where the rated essays for non-target prompts are used for training. Intuitively, one could recognize essays with the highest and the lowest scores correctly by solely examining their quality of writing, e.g., the number of typos, without even understanding them, and the prompt-independent features such as the number of grammatic and spelling errors should be sufficient to fulfill this screening procedure. Accordingly, a supervised model trained solely on prompt-independent features is employed to identify the essays with the highest and lowest scores in a given set of essays for the target prompt, which are used as the positive and negative training data in the follow-up prompt-dependent learning phase.

Prompt-dependent stage. Intuitively, most essays are with a quality in between the extremes, requiring a good understanding of their meaning to make an accurate assessment, e.g., whether the examples from the essay are convincing or whether the analyzes are insightful, making the consideration of prompt-dependent features crucial. To achieve that, a model is trained to learn from the comparison between essays with the highest and lowest scores for the target prompt according to the predictions from the first step. Akin to the settings in transductive transfer learning (Pan and

Yang, 2010), given essays for a particular prompt, quite a few confident essays at two extremes are selected and are used to train another model for a fine-grained content-based prompt-dependent assessment. To enable this, a powerful deep model is proposed to consider the content of the essays from different perspectives using semantic, part-of-speech (POS) and syntactic network. After being trained with the selected essays, the deep model is expected to memorize the properties of a good essay in response to the target prompt, thereafter accurately assessing all essays for it. In Section 2.2, building blocks for the selection of the training data and the proposed deep model are described in details.

2.2 Building Blocks

Select confident essays as training data. The identification of the extremes is relatively simple, where a RankSVM (Joachims, 2002) is trained on essays for different non-target prompts, avoiding the risks of over-fitting some particular prompts. A set of established prompt-independent features are employed, which are listed in Table 2. Given a prompt and a set of essays for evaluation, to begin with, the trained RankSVM is used to assign prediction scores to individual prompt-essay pairs, which are uniformly transformed into a 10-point scale. Thereafter, the essays with predicted scores in $[0, 4]$ and $[8, 10]$ are selected as negative and positive examples respectively, serving as the bad and good templates for training in the next stage. Intuitively, an essay with a score beyond eight out of a 10-point scale is considered good, while the one receiving less than or equal to four, is considered to be with a poor quality.

A hybrid deep model for fine-grained assessment. To enable a prompt-dependent assessment, a model is desired to comprehensively capture the ways in which a prompt is described or discussed in an essay. In this paper, semantic meaning, part-of-speech (POS), and the syntactic taggings of the token sequence from an essay are considered, grasping the quality of an essay for a target prompt. The model architecture is summarized in Figure 2. Intuitively, the model learns the semantic meaning of an essay by encoding it in terms of a sequence of word embeddings, denoted as $\overrightarrow{e}_{sem}$, hoping to understand what the essay is about; in addition, the part-of-speech information is encoded as a sequence of POS taggings, coined as $\overrightarrow{e}_{pos}$; ultimately, the structural connections between different components in an essay (e.g., terms or phrases) are further captured via syntactic network, leading to $\overrightarrow{e}_{synt}$, where the model learns the organization of the essay. Akin to (Li et al., 2015) and (Zhou and Xu, 2015), bi-LSTM is employed as a basic component to encode a sequence. Three features are separately captured using the stacked bi-LSTM layers as building blocks to encode different embeddings, whose outputs are subsequently concatenated and fed into several dense layers, generating the ultimate rating. In the following, the architecture of the model is described in details.

- *Semantic embedding.* Akin to the existing works (Alikaniotis et al., 2016; Taghipour and Ng, 2016), semantic word embeddings, namely, the pre-trained 50-dimension GloVe (Pennington et al., 2014), are employed. On top of the word embeddings, two bi-LSTM layers are stacked, namely, the essay layer is constructed on top of the sentence layer, ending up with the semantic representation of the whole essay, which is denoted as $\overrightarrow{e}_{sem}$ in Figure 2.

- *Part-Of-Speech (POS) embeddings* for individual terms are first generated by the Stanford Tagger (Toutanova et al., 2003), where 36 different POS tags present. Accordingly, individual words are embedded with 36-dimensional one-hot representation, and is transformed to a 50-dimensional vector through a lookup layer. After that, two bi-LSTM layers are stacked, leading to $\overrightarrow{e}_{pos}$. Take Figure 3 for example, given a sentence "Attention please, here is an example.", it is first converted into a POS sequence using the tagger, namely, VB, VBP, RB, VBZ, DT, NN; thereafter it is further mapped to vector space through one-hot embedding and a lookup layer.

- *Syntactic embedding* aims at encoding an essay in terms of the syntactic relationships among different syntactic components, by encoding an essay recursively. The Stanford Parser (Socher et al., 2013) is employed to label the syntactic structure of words and phrases in sentences, accounting for 59 different types in total. Similar to (Tai et al., 2015), we opt for three stacked bi-LSTM, aiming at encoding individual phrases, sentences, and ultimately the whole essay in sequence. In particular, according to the hierarchical structure from a parsing tree, the phrase-level bi-LSTM first encodes different phrases by consuming syntactic

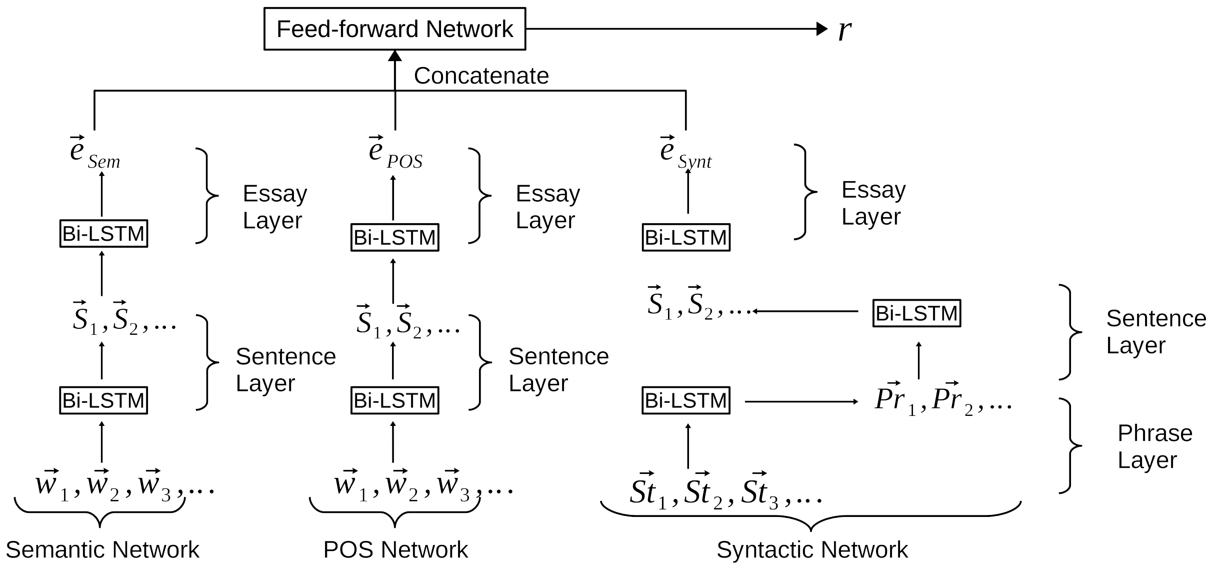

Figure 2: The model architecture of the proposed hybrid deep learning model.

embeddings ($\overrightarrow{St_i}$ in Figure 2) from a lookup table of individual syntactic units in the tree; thereafter, the encoded dense layers in individual sentences are further consumed by a sentence-level bi-LSTM, ending up with sentence-level syntactic representations, which are ultimately combined by the essay-level bi-LSTM, resulting in $\vec{e}_{synt}$. For example, the parsed tree for a sentence "Attention please, here is an example." is displayed in Figure 3. To start with, the sentence is parsed into ((NP VP)(NP VP NP)), and the dense embeddings are fetched from a lookup table for all tokens, namely, NP and VP; thereafter, the phrase-level bi-LSTM encodes (NP VP) and (NP VP NP) separately, which are further consumed by the sentence-level bi-LSTM. Afterward, essay-level bi-LSTM further combines the representations of different sentences into $\vec{e}_{synt}$.

      (NP (DT an) (NN example)))
    (. .)))
```

Figure 3: An example of the context-free phrase structure grammar tree.

- *Combination.* A feed-forward network linearly transforms the concatenated representations of an essay from the mentioned three perspectives into a scalar, which is further normalized into $[0, 1]$ with a sigmoid function.

2.3 Objective and Training

Objective. Mean square error (MSE) is optimized, which is widely used as a loss function in regression tasks. Given N pairs of a target prompt p_i and an essay e_i, MSE measures the average value of square error between the normalized gold standard rating $r^*(p_i, e_i)$ and the predicted rating $r(p_i, e_i)$ assigned by the AES model, as summarized in Equation 1.

$$\frac{1}{N}\sum_{i=1}^{N}\left(r(p_i, e_i) - r^*(p_i, e_i)\right)^2 \tag{1}$$

Optimization. Adam (Kingma and Ba, 2014) is employed to minimize the loss over the training data. The initial learning rate η is set to 0.01 and the gradient is clipped between $[-10, 10]$ during training. In addition, dropout (Srivastava et al., 2014) is introduced for regularization with a dropout rate of 0.5, and 64 samples are used in each batch with batch normalization (Ioffe and Szegedy, 2015). 30% of the training data are reserved for validation. In addition, early stopping (Yao et al., 2007) is employed according to the validation loss, namely, the training is terminated if no decrease of the loss is observed for ten consecutive epochs. Once training is finished,

Prompt	#Essays	Avg Length	Score Range
1	1783	350	2-12
2	1800	350	1-6
3	1726	150	0-3
4	1772	150	0-3
5	1805	150	0-4
6	1800	150	0-4
7	1569	250	0-30
8	723	650	0-60

Table 1: Statistics for the ASAP dataset.

akin to (Dong et al., 2017), the model with the best quadratic weighted kappa on the validation set is selected.

3 Experimental Setup

Dataset. The Automated Student Assessment Prize (ASAP) dataset has been widely used for AES (Alikaniotis et al., 2016; Chen and He, 2013; Dong et al., 2017), and is also employed as the prime evaluation instrument herein. In total, ASAP consists of eight sets of essays, each of which associates to one prompt, and is originally written by students between Grade 7 and Grade 10. As summarized in Table 1, essays from different sets differ in their rating criteria, length, as well as the rating distribution[1].

Cross-validation. To fully employ the rated data, a prompt-wise eight-fold cross validation on the ASAP is used for evaluation. In each fold, essays corresponding to a prompt is reserved for testing, and the remaining essays are used as training data.

Evaluation metric. The model outputs are first uniformly re-scaled into $[0, 10]$, mirroring the range of ratings in practice. Thereafter, akin to (Yannakoudakis et al., 2011; Chen and He, 2013; Alikaniotis et al., 2016), we report our results primarily based on the quadratic weighted Kappa (QWK), examining the agreement between the predicted ratings and the ground truth. Pearson correlation coefficient (PCC) and Spearman rank-order correlation coefficient (SCC) are also reported. The correlations obtained from individual folds, as well as the average over all eight folds, are reported as the ultimate results.

Competing models. Since the prompt-independent AES is of interests in this work, the existing AES models are adapted for prompt-independent rating prediction, serving as baselines. This is due to the facts that the prompt-dependent and -independent models differ a lot in terms of problem settings and model designs, especially in their requirements for the training data, where the latter ones release the prompt-dependent requirements and thereby are accessible to more data.

No.	Feature
1	Mean & variance of word length in characters
2	Mean & variance of sentence length in words
3	Essay length in characters and words
4	Number of prepositions and commas
5	Number of unique words in an essay
6	Mean number of clauses per sentence
7	Mean length of clauses
8	Maximum number of clauses of a sentence in an essay
9	Number of spelling errors
10	Average depth of the parser tree of each sentence in an essay
11	Average depth of each leaf node in the parser tree of each sentence

Table 2: Handcrafted features used in learning the prompt-independent RankSVM.

- **RankSVM**, using handcrafted features for AES (Yannakoudakis et al., 2011; Chen et al., 2014), is trained on a set of pre-defined prompt-independent features as listed in Table 2, where the features are standardized beforehand to remove the mean and variance. The RankSVM is also used for the prompt-independent stage in our proposed TDNN model. In particular, the linear kernel RankSVM[2] is employed, where C is set to 5 according to our pilot experiments.

- **2L-LSTM.** Two-layer bi-LSTM with GloVe for AES (Alikaniotis et al., 2016) is employed as another baseline. Regularized word embeddings are dropped to avoid over-fitting the prompt-specific features.

- **CNN-LSTM.** This model (Taghipour and Ng, 2016) employs a convolutional (CNN) layer over one-hot representations of words, followed by an LSTM layer to encode word sequences in a given essay. A linear layer with sigmoid activation function is then employed to predict the essay rating.

- **CNN-LSTM-ATT.** This model (Dong et al., 2017) employs a CNN layer to encode word sequences into sentences, followed by an LSTM layer to generate the essay representation. An attention mechanism is added to model the influence of individual sentences on the final essay representation.

[1]Details of this dataset can be found at `https://www.kaggle.com/c/asap-aes`.

[2]`http://svmlight.joachims.org/`

For the proposed TDNN model, as introduced in Section 2.2, different variants of TDNN are examined by using one or multiple components out of the semantic, POS and the syntactic networks. The combinations being considered are listed in the following. In particular, the dimensions of POS tags and syntactic network are fixed to 50, whereas the sizes of the hidden units in LSTM, as well as the output units of the linear layers are tuned by grid search.

- **TDNN(Sem)** only includes the semantic building block, which is similar to the two-layer LSTM neural network from (Alikaniotis et al., 2016) but without regularizing the word embeddings;
- **TDNN(Sem+POS)** employs the semantic and the POS building blocks;
- **TDNN(Sem+Synt)** uses the semantic and the syntactic network building blocks;
- **TDNN(POS+Synt)** includes the POS and the syntactic network building blocks;
- **TDNN(ALL)** employs all three building blocks.

The use of POS or syntactic network alone is not presented for brevity given the facts that they perform no better than TDNN(POS+Synt) in our pilot experiments. Source code of the TDNN model is publicly available to enable further comparison[3].

4 Results and Analyzes

In this section, the evaluation results for different competing methods are compared and analyzed in terms of their agreements with the manual ratings using three correlation metrics, namely, QWK, PCC and SCC, where the best results for each prompt is highlighted in bold in Table 3.

It can be seen that, for seven out of all eight prompts, the proposed TDNN variants outperform the baselines by a margin in terms of QWK, and the TDNN variant with semantic and syntactic features, namely, TDNN(Sem+Synt), consistently performs the best among different competing methods. More precisely, as indicated in the bottom right corner in Table 3, on average, TDNN(Sem+Synt) outperforms the baselines by at least 25.52% under QWK, by 10.28% under PCC, and by 15.66% under SCC, demonstrating that the proposed model not only correlates better with the manual ratings in terms of QWK, but also linearly (PCC) and monotonically (SCC) correlates better with the manual ratings. As for the four baselines, note that, the relatively underperformed deep models suffer from larger variances of performance under different prompts, e.g., for prompts two and eight, 2L-LSTM's QWK is lower than 0.3. This actually confirms our choice of RankSVM for the first stage in TDNN, since a more complicated model (like 2L-LSTM) may end up with learning prompt-dependent signals, making it unsuitable for the prompt-independent rating prediction. As a comparison, RankSVM performs more stable among different prompts.

As for the different TDNN variants, it turns out that the joint uses of syntactic network with semantic or POS features can lead to better performances. This indicates that, when learning the prompt-dependent signals, apart from the widely-used semantic features, POS features and the sentence structure taggings (syntactic network) are also essential in learning the structure and the arrangement of an essay in response to a particular prompt, thereby being able to improve the results. It is also worth mentioning, however, when using all three features, the TDNN actually performs worse than when only using (any) two features. One possible explanation is that the uses of all three features result in a more complicated model, which over-fits the training data.

In addition, recall that the prompt-independent RankSVM model from the first stage enables the proposed TDNN in learning prompt-dependent information without manual ratings for the target prompt. Therefore, one would like to understand how good the trained RankSVM is in feeding training data for the model in the second stage. In particular, the precision, recall and F-score (P/R/F) of the essays selected by RanknSVM, namely, the negative ones rated between $[0, 4]$, and the positive ones rated between $[8, 10]$, are displayed in Figure 4. It can be seen that the P/R/F scores of both positive and negative classes differ a lot among different prompts. Moreover, it turns out that the P/R/F scores do not necessarily correlate with the performance of the TDNN model. Take TDNN(Sem+Synt), the best TDNN variant, as an example: as indicated in Table 4, the performance and the P/R/F scores of the pseudo examples are only weakly correlated in most cases.

To gain a better understanding in how the quality of pseudo examples affects the performance of TDNN, the sanctity of the selected essays are examined. In Figure 5, the relative precision of

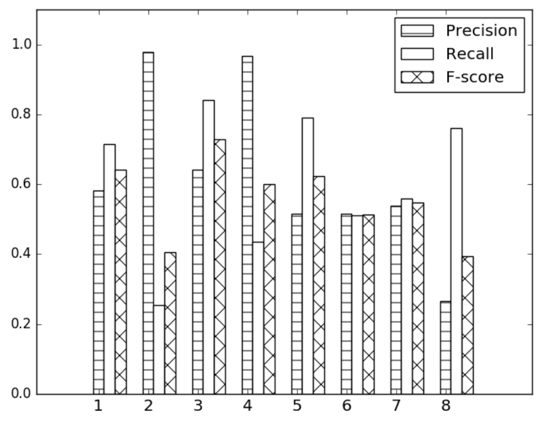
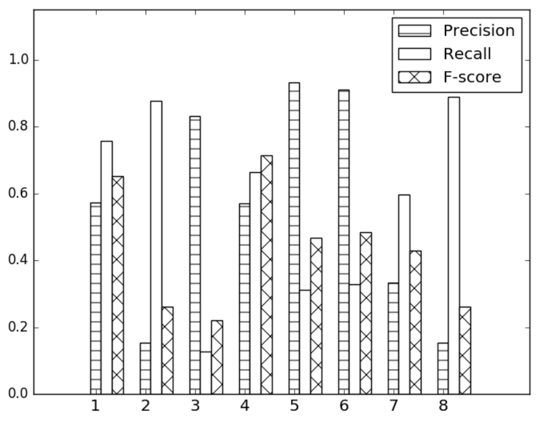
Table 5: The numbers of the selected positive and negative essays for each prompt.

the selected positive and negative training data by RankSVM are displayed for all eight prompts in terms of their concordance with the manual ratings, by computing the number of positive (negative) essays that are better (worse) than all negative (positive) essays. It can be seen that, such relative precision is at least 80% and mostly beyond 90% on different prompts, indicating that the overlap of the selected positive and negative essays are fairly small, guaranteeing that the deep model in the second stage at least learns from correct labels, which are crucial for the success of our TDNN model.

Beyond that, we further investigate the class balance of the selected training data from the first



(a) Negative



(b) Positive

Figure 4: The precision, recall and F-score of the pseudo negative or positive examples, which are rated within $[0, 4]$ or $[8, 10]$ by RankSVM.

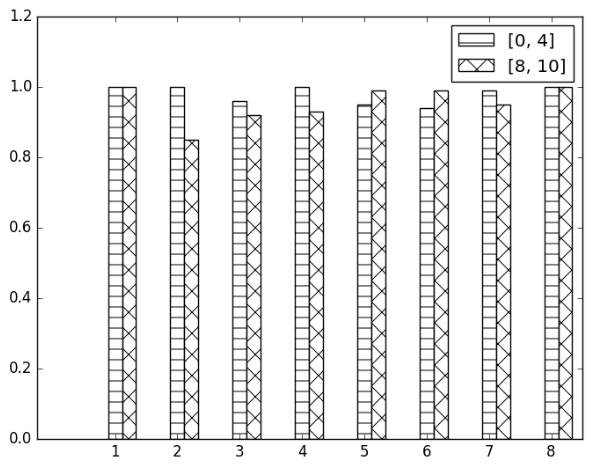


Figure 5: The sanctity of the selected positive and negative essays by RankSVM. The x-axis indicates different prompts and the y-axis is the relative precision.

stage, which could also influence the ultimate results. The number of selected positive and negative essays are reported in Table 5, where for prompts three and eight the training data suffers from serious imbalanced problem, which may explain their lower performance (namely, the two lowest QWKs among different prompts). On one hand, this is actually determined by real distribution of ratings for a particular prompt, e.g., how many essays are with an extreme quality for a given prompt in the target data. On the other hand, a fine-grained tuning of the RankSVM (e.g., tuning C_+ and C_- for positive and negative examples separately) may partially resolve the problem, which is left for the future work.

5 Related Work

Classical regression and classification algorithms are widely used for learning the rating model based on a variety of text features including lexical, syntactic, discourse and semantic features (Larkey, 1998; Rudner, 2002; Attali and Burstein, 2006; Mcnamara et al., 2015; Phandi et al., 2015). There are also approaches that see AES as a preference ranking problem by applying learning to ranking algorithms to learn the rating model. Results show improvement of learning to rank approaches over classical regression and classification algorithms (Chen et al., 2014; Yannakoudakis et al., 2011). In addition, Chen & He propose to incorporate the evaluation metric into the loss function of listwise learning to rank for AES (Chen and He, 2013).

Recently, there have been efforts in developing AES approaches based on deep neural networks (DNN), for which feature engineering is not required. Taghipour & Ng explore a variety of neural network model architectures based on recurrent neural networks which can effectively encode the information required for essay scoring and learn the complex connections in the data through the non-linear neural layers (Taghipour and Ng, 2016). Alikaniotis et al. introduce a neural network model to learn the extent to which specific words contribute to the text's score, which is embedded in the word representations. Then a two-layer bi-directional Long-Short Term Memory networks (bi-LSTM) is used to learn the meaning of texts, and finally the essay score is predicted through a mutli-layer feed-forward network (Alikaniotis et al., 2016). Dong & Zhang employ a hierarchical convolutional neural network (CNN) model, with a lower layer representing sentence structure and an upper layer representing essay structure based on sentence representations, to learn features automatically (Dong and Zhang, 2016). This model is later improved by employing attention layers. Specifically, the model learns text representation with LSTMs which can model the coherence and co-reference among sequences of words and sentences, and uses attention pooling to capture more relevant words and sentences that contribute to the final quality of essays (Dong et al., 2017). Song et al. propose a deep model for identifying discourse modes in an essay (Song et al., 2017).

While the literature has shown satisfactory performance of prompt-dependent AES, how to achieve effective essay scoring in a prompt-independent setting remains to be explored. Chen & He studied the usefulness of prompt-independent text features and achieved a human-machine rating agreement slightly lower than the use of all text features (Chen and He, 2013) for prompt-dependent essay scoring prediction. A constrained multi-task pairwise preference learning approach was proposed in (Cummins et al., 2016) to combine essays from multiple prompts for training. However, as shown by (Dong and Zhang, 2016; Zesch et al., 2015; Phandi et al., 2015), straightforward applications of existing AES methods for prompt-independent AES lead to a poor performance.

6 Conclusions & Future Work

This study aims at addressing the prompt-independent automated essay scoring (AES), where no rated essay for the target prompt is available. As demonstrated in the experiments, two kinds of established prompt-dependent AES models, namely, RankSVM for AES (Yannakoudakis et al., 2011; Chen et al., 2014) and the deep models for AES (Alikaniotis et al., 2016; Taghipour and Ng, 2016; Dong et al., 2017), fail to provide satisfactory performances, justifying our arguments in Section 1 that the application of established prompt-dependent AES models on prompt-independent AES is not straightforward. Therefore, a two-stage TDNN learning framework was proposed to utilize the prompt-independent features to generate pseudo training data for the target prompt, on which a hybrid deep neural network model is proposed to learn a rating model consuming semantic, part-of-speech, and syntactic signals. Through the experiments on the ASAP dataset, the proposed TDNN model outperforms the baselines, and leads to promising improvement in the human-machine agreement.

Given that our approach in this paper is similar to the methods for transductive transfer learning (Pan and Yang, 2010), we argue that the proposed TDNN could be further improved by migrating the non-target training data to the target prompt (Busto and Gall, 2017). Further study of the uses of transfer learning algorithms on prompt-independent AES needs to be undertaken.

Abstract

The encoder-decoder dialog model is one of the most prominent methods used to build dialog systems in complex domains. Yet it is limited because it cannot output interpretable actions as in traditional systems, which hinders humans from understanding its generation process. We present an unsupervised discrete sentence representation learning method that can integrate with any existing encoder-decoder dialog models for interpretable response generation. Building upon variational autoencoders (VAEs), we present two novel models, DI-VAE and DI-VST that improve VAEs and can discover interpretable semantics via either auto encoding or context predicting. Our methods have been validated on real-world dialog datasets to discover semantic representations and enhance encoder-decoder models with interpretable generation.[1]

1 Introduction

Classic dialog systems rely on developing a meaning representation to represent the utterances from both the machine and human users (Larsson and Traum, 2000; Bohus et al., 2007). The dialog manager of a conventional dialog system outputs the system's next action in a semantic frame that usually contains hand-crafted dialog acts and slot values (Williams and Young, 2007). Then a natural language generation module is used to generate the system's output in natural language based on the given semantic frame. This approach suffers from generalization to more complex domains because it soon become intractable to manually design a frame representation that covers all of the fine-grained system actions. The recently developed neural dialog system is one of the most prominent frameworks for developing dialog agents in complex domains. The basic model is based on encoder-decoder networks (Cho et al., 2014) and can learn to generate system responses without the need for hand-crafted meaning representations and other annotations.

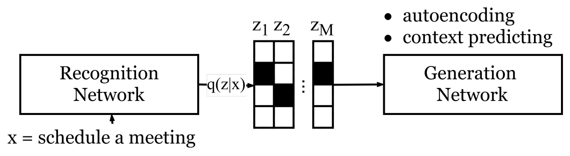

Figure 1: Our proposed models learn a set of discrete variables to represent sentences by either autoencoding or context prediction.

Although generative dialog models have advanced rapidly (Serban et al., 2016; Li et al., 2016; Zhao et al., 2017), they cannot provide interpretable system actions as in the conventional dialog systems. This inability limits the effectiveness of generative dialog models in several ways. First, having interpretable system actions enables human to understand the behavior of a dialog system and better interpret the system intentions. Also, modeling the high-level decision-making policy in dialogs enables useful generalization and data-efficient domain adaptation (Gašić et al., 2010). Therefore, the motivation of this paper is to develop an unsupervised neural recognition model that can discover interpretable meaning representations of utterances (denoted as *latent actions*) as a set of discrete latent variables from a large unlabelled corpus as shown in Figure 1. The discovered meaning representations will then be integrated with encoder decoder networks to achieve interpretable dialog generation while preserving

[1]Data and code are available at https://github.com/snakeztc/NeuralDialog-LAED.

all the merit of neural dialog systems.

We focus on learning discrete latent representations instead of dense continuous ones because discrete variables are easier to interpret (van den Oord et al., 2017) and can naturally correspond to categories in natural languages, e.g. topics, dialog acts and etc. Despite the difficulty of learning discrete latent variables in neural networks, the recently proposed Gumbel-Softmax offers a reliable way to back-propagate through discrete variables (Maddison et al., 2016; Jang et al., 2016). However, we found a simple combination of sentence variational autoencoders (VAEs) (Bowman et al., 2015) and Gumbel-Softmax fails to learn meaningful discrete representations. We then highlight the anti-information limitation of the evidence lowerbound objective (ELBO) in VAEs and improve it by proposing Discrete Information VAE (DI-VAE) that maximizes the mutual information between data and latent actions. We further enrich the learning signals beyond auto encoding by extending Skip Thought (Kiros et al., 2015) to Discrete Information Variational Skip Thought (DI-VST) that learns sentence-level distributional semantics. Finally, an integration mechanism is presented that combines the learned latent actions with encoder decoder models.

The proposed systems are tested on several real-world dialog datasets. Experiments show that the proposed methods significantly outperform the standard VAEs and can discover meaningful latent actions from these datasets. Also, experiments confirm the effectiveness of the proposed integration mechanism and show that the learned latent actions can control the sentence-level attributes of the generated responses and provide human-interpretable meaning representations.

2 Related Work

Our work is closely related to research in latent variable dialog models. The majority of models are based on Conditional Variational Autoencoders (CVAEs) (Serban et al., 2016; Cao and Clark, 2017) with continuous latent variables to better model the response distribution and encourage diverse responses. Zhao et al., (2017) further introduced dialog acts to guide the learning of the CVAEs. Discrete latent variables have also been used for task-oriented dialog systems (Wen et al., 2017), where the latent space is used to represent intention. The second line of related work is enriching the dialog context encoder with more fine-grained information than the dialog history. Li et al., (2016) captured speakers' characteristics by encoding background information and speaking style into the distributed embeddings. Xing et al., (2016) maintain topic encoding based on Latent Dirichlet Allocation (LDA) (Blei et al., 2003) of the conversation to encourage the model to output more topic coherent responses.

The proposed method also relates to sentence representation learning using neural networks. Most work learns continuous distributed representations of sentences from various learning signals (Hill et al., 2016), e.g. the Skip Thought learns representations by predicting the previous and next sentences (Kiros et al., 2015). Another area of work focused on learning regularized continuous sentence representation, which enables sentence generation by sampling the latent space (Bowman et al., 2015; Kim et al., 2017). There is less work on discrete sentence representations due to the difficulty of passing gradients through discrete outputs. The recently developed Gumbel Softmax (Jang et al., 2016; Maddison et al., 2016) and vector quantization (van den Oord et al., 2017) enable us to train discrete variables. Notably, discrete variable models have been proposed to discover document topics (Miao et al., 2016) and semi-supervised sequence transaction (Zhou and Neubig, 2017)

Our work differs from these as follows: (1) we focus on learning interpretable variables; in prior research the semantics of latent variables are mostly ignored in the dialog generation setting. (2) we improve the learning objective for discrete VAEs and overcome the well-known posterior collapsing issue (Bowman et al., 2015; Chen et al., 2016). (3) we focus on unsupervised learning of salient features in dialog responses instead of hand-crafted features.

3 Proposed Methods

Our formulation contains three random variables: the dialog context $\mathbf{c}$, the response $\mathbf{x}$ and the latent action $\mathbf{z}$. The context often contains the discourse history in the format of a list of utterances. The response is an utterance that contains a list of word tokens. The latent action is a set of discrete variables that define high-level attributes of $\mathbf{x}$. Before introducing the proposed framework, we first identify two key properties that are essential in order for $\mathbf{z}$ to be *interpretable*:

1. $\mathbf{z}$ should capture salient sentence-level features about the response $\mathbf{x}$.
2. The meaning of latent symbols $\mathbf{z}$ should be independent of the context $\mathbf{c}$.

The first property is self-evident. The second can be explained: assume $\mathbf{z}$ contains a single discrete variable with K classes. Since the context $\mathbf{c}$ can be any dialog history, if the meaning of each class changes given a different context, then it is difficult to extract an intuitive interpretation by only looking at all responses with class $k \in [1, K]$. Therefore, the second property looks for latent actions that have *context-independent semantics* so that each assignment of $\mathbf{z}$ conveys the same meaning in all dialog contexts.

With the above definition of interpretable latent actions, we first introduce a recognition network $\mathcal{R} : q_{\mathcal{R}}(\mathbf{z}|\mathbf{x})$ and a generation network $\mathcal{G}$. The role of $\mathcal{R}$ is to map an sentence to the latent variable $\mathbf{z}$ and the generator $\mathcal{G}$ defines the learning signals that will be used to train $\mathbf{z}$'s representation. Notably, our recognition network $\mathcal{R}$ does not depend on the context $\mathbf{c}$ as has been the case in prior work (Serban et al., 2016). The motivation of this design is to encourage $\mathbf{z}$ to capture context-independent semantics, which are further elaborated in Section 3.4. With the $\mathbf{z}$ learned by $\mathcal{R}$ and $\mathcal{G}$, we then introduce an encoder decoder network $\mathcal{F} : p_{\mathcal{F}}(\mathbf{x}|\mathbf{z}, \mathbf{c})$ and and a policy network $\pi : p_{\pi}(\mathbf{z}|\mathbf{c})$. At test time, given a context $\mathbf{c}$, the policy network and encoder decoder will work together to generate the next response via $\tilde{\mathbf{x}} = p_{\mathcal{F}}(\mathbf{x}|\mathbf{z} \sim p_{\pi}(\mathbf{z}|\mathbf{c}), \mathbf{c})$. In short, $\mathcal{R}$, $\mathcal{G}$, $\mathcal{F}$ and π are the four components that comprise our proposed framework. The next section will first focus on developing $\mathcal{R}$ and $\mathcal{G}$ for learning interpretable $\mathbf{z}$ and then will move on to integrating $\mathcal{R}$ with $\mathcal{F}$ and π in Section 3.3.

3.1 Learning Sentence Representations from Auto-Encoding

Our baseline model is a sentence VAE with discrete latent space. We use an RNN as the recognition network to encode the response $\mathbf{x}$. Its last hidden state $h^{\mathcal{R}}_{|\mathbf{x}|}$ is used to represent $\mathbf{x}$. We define $\mathbf{z}$ to be a set of K-way categorical variables $\mathbf{z} = \{\mathbf{z}_1 ... \mathbf{z}_m ... \mathbf{z}_M\}$, where M is the number of variables. For each $\mathbf{z}_m$, its posterior distribution is defined as $q_{\mathcal{R}}(\mathbf{z}_m|\mathbf{x}) = \text{Softmax}(W_q h^{\mathcal{R}}_{|\mathbf{x}|} + b_q)$. During training, we use the Gumbel-Softmax trick to sample from this distribution and obtain low-variance gradients. To map the latent samples to the initial state of the decoder RNN, we define $\{e_1 ... e_m ... e_M\}$ where $e_m \in \mathbb{R}^{K \times D}$ and D is the generator cell size. Thus the initial state of the generator is: $h^{\mathcal{G}}_0 = \sum_{m=1}^{M} e_m(\mathbf{z}_m)$. Finally, the generator RNN is used to reconstruct the response given $h^{\mathcal{G}}_0$. VAEs is trained to maxmimize the evidence lowerbound objective (ELBO) (Kingma and Welling, 2013). For simplicity, later discussion drops the subscript m in $\mathbf{z}_m$ and assumes a single latent $\mathbf{z}$. Since each $\mathbf{z}_m$ is independent, we can easily extend the results below to multiple variables.

3.1.1 Anti-Information Limitation of ELBO

It is well-known that sentence VAEs are hard to train because of the posterior collapse issue. Many empirical solutions have been proposed: weakening the decoder, adding auxiliary loss etc. (Bowman et al., 2015; Chen et al., 2016; Zhao et al., 2017). We argue that the posterior collapse issue lies in ELBO and we offer a novel decomposition to understand its behavior. First, instead of writing ELBO for a single data point, we write it as an expectation over a dataset:

$$\begin{aligned}\mathcal{L}_{\text{VAE}} = \mathbb{E}_{\mathbf{x}}[&\mathbb{E}_{q_{\mathcal{R}}(\mathbf{z}|\mathbf{x})}[\log p_{\mathcal{G}}(\mathbf{x}|\mathbf{z})] \\ &- \text{KL}(q_{\mathcal{R}}(\mathbf{z}|\mathbf{x}) \| p(\mathbf{z}))]\end{aligned} \tag{1}$$

We can expand the KL term as Eq. 2 (derivations in Appendix A.1) and rewrite ELBO as:

$$\begin{aligned}\mathbb{E}_{\mathbf{x}}[\text{KL}(q_{\mathcal{R}}(\mathbf{z}|\mathbf{x}) \| p(\mathbf{z}))] = \\ I(Z, X) + \text{KL}(q(\mathbf{z}) \| p(\mathbf{z}))\end{aligned} \tag{2}$$

$$\begin{aligned}\mathcal{L}_{\text{VAE}} = &\mathbb{E}_{q(\mathbf{z}|\mathbf{x})p(\mathbf{x})}[\log p(\mathbf{x}|\mathbf{z})] \\ &- I(Z, X) - \text{KL}(q(\mathbf{z}) \| p(\mathbf{z}))\end{aligned} \tag{3}$$

where $q(\mathbf{z}) = \mathbb{E}_{\mathbf{x}}[q_{\mathcal{R}}(\mathbf{z}|\mathbf{x})]$ and $I(Z, X)$ is the mutual information between Z and X. This expansion shows that the KL term in ELBO is trying to reduce the mutual information between latent variables and the input data, which explains why VAEs often ignore the latent variable, especially when equipped with powerful decoders.

3.1.2 VAE with Information Maximization and Batch Prior Regularization

A natural solution to correct the anti-information issue in Eq. 3 is to maximize both the data likelihood lowerbound and the mutual information between $\mathbf{z}$ and the input data:

$$\mathcal{L}_{\text{VAE}} + I(Z, X) = \mathbb{E}_{q_{\mathcal{R}}(\mathbf{z}|\mathbf{x})p(\mathbf{x})}[\log p_{\mathcal{G}}(\mathbf{x}|\mathbf{z})] - \text{KL}(q(\mathbf{z})\|p(\mathbf{z})) \tag{4}$$

Therefore, jointly optimizing ELBO and mutual information simply cancels out the information-discouraging term. Also, we can still sample from the prior distribution for generation because of $\text{KL}(q(\mathbf{z})\|p(\mathbf{z}))$. Eq. 4 is similar to the objectives used in adversarial autoencoders (Makhzani et al., 2015; Kim et al., 2017). Our derivation provides a theoretical justification to their superior performance. Notably, Eq. 4 arrives at the same loss function proposed in infoVAE (Zhao S et al., 2017). However, our derivation is different, offering a new way to understand ELBO behavior.

The remaining challenge is how to minimize $\text{KL}(q(\mathbf{z})\|p(\mathbf{z}))$, since $q(\mathbf{z})$ is an expectation over $q(\mathbf{z}|\mathbf{x})$. When $\mathbf{z}$ is continuous, prior work has used adversarial training (Makhzani et al., 2015; Kim et al., 2017) or Maximum Mean Discrepancy (MMD) (Zhao S et al., 2017) to regularize $q(\mathbf{z})$. It turns out that minimizing $\text{KL}(q(\mathbf{z})\|p(\mathbf{z}))$ for discrete $\mathbf{z}$ is much simpler than its continuous counterparts. Let $\mathbf{x}_n$ be a sample from a batch of N data points. Then we have:

$$q(\mathbf{z}) \approx \frac{1}{N}\sum_{n=1}^{N} q(\mathbf{z}|\mathbf{x}_n) = q'(\mathbf{z}) \tag{5}$$

where $q'(\mathbf{z})$ is a mixture of softmax from the posteriors $q(\mathbf{z}|\mathbf{x}_n)$ of each $\mathbf{x}_n$. We can approximate $\text{KL}(q(\mathbf{z})\|p(\mathbf{z}))$ by:

$$\text{KL}(q'(\mathbf{z})\|p(\mathbf{z})) = \sum_{k=1}^{K} q'(\mathbf{z}=k) \log \frac{q'(\mathbf{z}=k)}{p(\mathbf{z}=k)} \tag{6}$$

We refer to Eq. 6 as Batch Prior Regularization (BPR). When N approaches infinity, $q'(\mathbf{z})$ approaches the true marginal distribution of $q(\mathbf{z})$. In practice, we only need to use the data from each mini-batch assuming that the mini batches are randomized. Last, BPR is fundamentally different from multiplying a coefficient < 1 to anneal the KL term in VAE (Bowman et al., 2015). This is because BPR is a non-linear operation *log_sum_exp*. For later discussion, we denote our discrete infoVAE with BPR as DI-VAE.

3.2 Learning Sentence Representations from the Context

DI-VAE infers sentence representations by reconstruction of the input sentence. Past research in distributional semantics has suggested the meaning of language can be inferred from the adjacent context (Harris, 1954; Hill et al., 2016). The distributional hypothesis is especially applicable to dialog since the utterance meaning is highly contextual. For example, the dialog act is a well-known utterance feature and depends on dialog state (Austin, 1975; Stolcke et al., 2000). Thus, we introduce a second type of latent action based on sentence-level distributional semantics.

Skip thought (ST) is a powerful sentence representation that captures contextual information (Kiros et al., 2015). ST uses an RNN to encode a sentence, and then uses the resulting sentence representation to predict the previous and next sentences. Inspired by ST's robust performance across multiple tasks (Hill et al., 2016), we adapt our DI-VAE to Discrete Information Variational Skip Thought (DI-VST) to learn discrete latent actions that model distributional semantics of sentences. We use the same recognition network from DI-VAE to output $\mathbf{z}$'s posterior distribution $q_{\mathcal{R}}(\mathbf{z}|\mathbf{x})$. Given the samples from $q_{\mathcal{R}}(\mathbf{z}|\mathbf{x})$, two RNN generators are used to predict the previous sentence $\mathbf{x}_p$ and the next sentences $\mathbf{x}_n$. Finally, the learning objective is to maximize:

$$\mathcal{L}_{\text{DI-VST}} = \mathbb{E}_{q_{\mathcal{R}}(\mathbf{z}|\mathbf{x})p(\mathbf{x}))}[\log(p^n_{\mathcal{G}}(\mathbf{x}_n|\mathbf{z})p^p_{\mathcal{G}}(\mathbf{x}_p|\mathbf{z}))] - \text{KL}(q(\mathbf{z})\|p(\mathbf{z})) \tag{7}$$

3.3 Integration with Encoder Decoders

We now describe how to integrate a given $q_{\mathcal{R}}(\mathbf{z}|\mathbf{x})$ with an encoder decoder and a policy network. Let the dialog context $\mathbf{c}$ be a sequence of utterances. Then a dialog context encoder network can encode the dialog context into a distributed representation $h^e = \mathcal{F}^e(\mathbf{c})$. The decoder $\mathcal{F}^d$ can generate the responses $\tilde{\mathbf{x}} = \mathcal{F}^d(h^e, \mathbf{z})$ using samples from $q_{\mathcal{R}}(\mathbf{z}|\mathbf{x})$. Meanwhile, we train π to predict the aggregated posterior $\mathbb{E}_{p(\mathbf{x}|\mathbf{c})}[q_{\mathcal{R}}(\mathbf{z}|\mathbf{x})]$ from $\mathbf{c}$ via maximum likelihood training. This model is referred as Latent Action Encoder Decoder (LAED) with the following objective.

$$\mathcal{L}_{\text{LAED}}(\theta_{\mathcal{F}}, \theta_\pi) = \mathbb{E}_{q_{\mathcal{R}}(\mathbf{z}|\mathbf{x})p(\mathbf{x},\mathbf{c})}[\log p_\pi(\mathbf{z}|\mathbf{c}) + \log p_{\mathcal{F}}(\mathbf{x}|\mathbf{z},\mathbf{c})] \tag{8}$$

Also simply augmenting the inputs of the decoders with latent action does not guarantee that the generated response exhibits the attributes of the give action. Thus we use the controllable text generation framework (Hu et al., 2017) by introducing $\mathcal{L}_{\text{Attr}}$, which reuses the same recognition network $q_{\mathcal{R}}(\mathbf{z}|\mathbf{x})$ as a fixed discriminator to penalize the decoder if its generated responses do not reflect the attributes in $\mathbf{z}$.

$$\mathcal{L}_{\text{Attr}}(\theta_{\mathcal{F}}) = \mathbb{E}_{q_{\mathcal{R}}(\mathbf{z}|\mathbf{x})p(\mathbf{c},\mathbf{x})}[\log q_{\mathcal{R}}(\mathbf{z}|\mathcal{F}(\mathbf{c},\mathbf{z}))] \tag{9}$$

Since it is not possible to propagate gradients through the discrete outputs at $\mathcal{F}^d$ at each word step, we use a deterministic continuous relaxation (Hu et al., 2017) by replacing output of $\mathcal{F}^d$ with the probability of each word. Let $\mathbf{o}_t$ be the normalized probability at step $t \in [1, |\mathbf{x}|]$, the inputs to $q_{\mathcal{R}}$ at time t are then the sum of word embeddings weighted by $\mathbf{o}_t$, i.e. $h_t^{\mathcal{R}} = \text{RNN}(h_{t-1}^{\mathcal{R}}, \mathbf{E}\mathbf{o}_t)$ and $\mathbf{E}$ is the word embedding matrix. Finally this loss is combined with $\mathcal{L}_{\text{LAED}}$ and a hyperparameter λ to have Attribute Forcing LAED.

$$\mathcal{L}_{\text{attrLAED}} = \mathcal{L}_{\text{LAED}} + \lambda\mathcal{L}_{\text{Attr}} \tag{10}$$

3.4 Relationship with Conditional VAEs

It is not hard to see $\mathcal{L}_{\text{LAED}}$ is closely related to the objective of CVAEs for dialog generation (Serban et al., 2016; Zhao et al., 2017), which is:

$$\mathcal{L}_{\text{CVAE}} = \mathbb{E}_q[\log p(\mathbf{x}|\mathbf{z},\mathbf{c})] - \text{KL}(q(\mathbf{z}|\mathbf{x},\mathbf{c})\|p(\mathbf{z}|\mathbf{c})) \tag{11}$$

Despite their similarities, we highlight the key differences that prohibit CVAE from achieving interpretable dialog generation. First $\mathcal{L}_{\text{CVAE}}$ encourages $I(\mathbf{x},\mathbf{z}|\mathbf{c})$ (Agakov, 2005), which learns $\mathbf{z}$ that capture context-dependent semantics. More intuitively, $\mathbf{z}$ in CVAE is trained to generate $\mathbf{x}$ via $p(\mathbf{x}|\mathbf{z},\mathbf{c})$ so the meaning of learned $\mathbf{z}$ can only be interpreted along with its context $\mathbf{c}$. Therefore this violates our goal of learning context-independent semantics. Our methods learn $q_{\mathcal{R}}(\mathbf{z}|\mathbf{x})$ that only depends on $\mathbf{x}$ and trains $q_{\mathcal{R}}$ separately to ensure the semantics of $\mathbf{z}$ are interpretable standalone.

4 Experiments and Results

The proposed methods are evaluated on four datasets. The first corpus is Penn Treebank (PTB) (Marcus et al., 1993) used to evaluate sentence VAEs (Bowman et al., 2015). We used the version pre-processed by Mikolov (Mikolov et al., 2010). The second dataset is the Stanford Multi-Domain Dialog (SMD) dataset that contains 3,031 human-Woz, task-oriented dialogs collected from 3 different domains (navigation, weather and scheduling) (Eric and Manning, 2017). The other two datasets are chat-oriented data: Daily Dialog (DD) and Switchboard (SW) (Godfrey and Holliman, 1997), which are used to test whether our methods can generalize beyond task-oriented dialogs but also to to open-domain chatting. DD contains 13,118 multi-turn human-human dialogs annotated with dialog acts and emotions. (Li et al., 2017). SW has 2,400 human-human telephone conversations that are annotated with topics and dialog acts. SW is a more challenging dataset because it is transcribed from speech which contains complex spoken language phenomenon, e.g. hesitation, self-repair etc.

4.1 Comparing Discrete Sentence Representation Models

The first experiment used PTB and DD to evaluate the performance of the proposed methods in learning discrete sentence representations. We implemented DI-VAE and DI-VST using GRU-RNN (Chung et al., 2014) and trained them using Adam (Kingma and Ba, 2014). Besides the proposed methods, the following baselines are compared. **Unregularized models**: removing the $\text{KL}(q|p)$ term from DI-VAE and DI-VST leads to a simple discrete autoencoder (DAE) and discrete skip thought (DST) with stochastic discrete hidden units. **ELBO models**: the basic discrete sentence VAE (DVAE) or variational skip thought (DVST) that optimizes ELBO with regularization term $\text{KL}(q(\mathbf{z}|\mathbf{x})\|p(\mathbf{z}))$. We found that standard training failed to learn informative latent actions for either DVAE or DVST because of the posterior collapse. Therefore, KL-annealing (Bowman et al., 2015) and bag-of-word loss (Zhao et al., 2017) are used to force these two models learn meaningful representations. We also include the results for VAE with continuous latent variables reported on the same PTB (Zhao et al., 2017). Additionally, we report the perplexity from a standard GRU-RNN language model (Zaremba et al., 2014).

The evaluation metrics include reconstruction perplexity (PPL), $\text{KL}(q(\mathbf{z})\|p(\mathbf{z}))$ and the mutual information between input data and latent variables $I(\mathbf{x}, \mathbf{z})$. Intuitively a good model should achieve low perplexity and KL distance, and simultaneously achieve high $I(\mathbf{x}, \mathbf{z})$. The discrete latent space for all models are M=20 and K=10. Mini-batch size is 30.

Dom	Model	PPL	KL$(q\|p)$	$I(\mathbf{x}, \mathbf{z})$
PTB	RNNLM	116.22	-	-
	VAE	73.49	15.94*	-
	DAE	66.49	2.20	0.349
	DVAE	70.84	0.315	0.286
	DI-VAE	**52.53**	**0.133**	**1.18**
DD	RNNLM	31.15	-	-
	DST	$\mathbf{x}_p$:28.23 $\mathbf{x}_n$:28.16	0.588	**1.359**
	DVST	$\mathbf{x}_p$:30.36 $\mathbf{x}_n$:30.71	**0.007**	0.081
	DI-VST	$\mathbf{x}_p$:**28.04** $\mathbf{x}_n$:**27.94**	0.088	1.028

Table 1: Results for various discrete sentence representations. The KL for VAE is KL$(q(\mathbf{z}|\mathbf{x})\|p(\mathbf{z}))$ instead of KL$(q(\mathbf{z})\|p(\mathbf{z}))$ (Zhao et al., 2017)

Table 1 shows that all models achieve better perplexity than an RNNLM, which shows they manage to learn meaningful $q(\mathbf{z}|\mathbf{x})$. First, for auto-encoding models, DI-VAE is able to achieve the best results in all metrics compared other methods. We found DAEs quickly learn to reconstruct the input but they are prone to overfitting during training, which leads to lower performance on the test data compared to DI-VAE. Also, since there is no regularization term in the latent space, $q(\mathbf{z})$ is very different from the $p(\mathbf{z})$ which prohibits us from generating sentences from the latent space. In fact, DI-VAE enjoys the same linear interpolation properties reported in (Bowman et al., 2015) (See Appendix A.2). As for DVAEs, it achieves zero $I(\mathbf{x}, \mathbf{z})$ in standard training and only manages to learn some information when training with KL-annealing and bag-of-word loss. On the other hand, our methods achieve robust performance without the need for additional processing. Similarly, the proposed DI-VST is able to achieve the lowest PPL and similar KL compared to the strongly regularized DVST. Interestingly, although DST is able to achieve the highest $I(\mathbf{x}, \mathbf{z})$, but PPL is not further improved. These results confirm the effectiveness of the proposed BPR in terms of regularizing $q(\mathbf{z})$ while learning meaningful posterior $q(\mathbf{z}|\mathbf{x})$.

In order to understand BPR's sensitivity to batch size N, a follow-up experiment varied the batch size from 2 to 60 (If N=1, DI-VAE is equivalent to DVAE). Figure 2 show that as N increases,

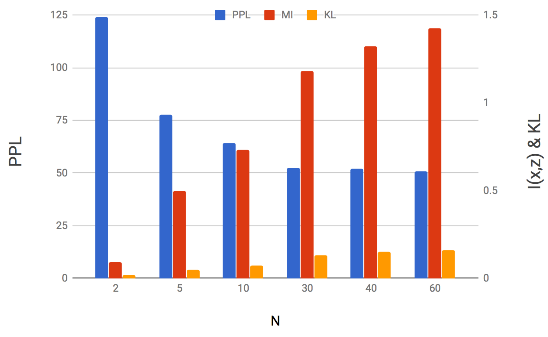

Figure 2: Perplexity and $I(\mathbf{x}, \mathbf{z})$ on PTB by varying batch size N. BPR works better for larger N.

perplexity, $I(\mathbf{x}, \mathbf{z})$ monotonically improves, while KL$(q\|p)$ only increases from 0 to 0.159. After $N > 30$, the performance plateaus. Therefore, using mini-batch is an efficient trade-off between $q(\mathbf{z})$ estimation and computation speed.

The last experiment in this section investigates the relation between representation learning and the dimension of the latent space. We set a fixed budget by restricting the maximum number of modes to be about 1000, i.e. $K^M \approx 1000$. We then vary the latent space size and report the same evaluation metrics. Table 2 shows that models with multiple small latent variables perform significantly better than those with large and few latent variables.

K, M	K^M	PPL	KL$(q\|p)$	$I(\mathbf{x}, \mathbf{z})$
1000, 1	1000	75.61	0.032	0.335
10, 3	1000	71.42	0.071	0.607
4, 5	1024	68.43	0.088	0.809

Table 2: DI-VAE on PTB with different latent dimensions under the same budget.

4.2 Interpreting Latent Actions

The next question is to interpret the meaning of the learned latent action symbols. To achieve this, the latent action of an utterance $\mathbf{x}_n$ is obtained from a greedy mapping: $a_n = \text{argmax}_k\, q_{\mathcal{R}}(\mathbf{z} = k|\mathbf{x}_n)$. We set M=3 and K=5, so that there are at most 125 different latent actions, and each $\mathbf{x}_n$ can now be represented by a_1-a_2-a_3, e.g. "How are you?" $\rightarrow$ 1-4-2. Assuming that we have access to manually clustered data according to certain classes (e.g. dialog acts), it is unfair to use classic cluster measures (Vinh et al., 2010) to evaluate the clusters from latent actions. This is because the uniform prior $p(\mathbf{z})$ evenly distribute the data to all possible latent actions, so that it is expected that frequent classes will be assigned to several latent actions. Thus we utilize the *homogeneity* metric (Rosenberg and Hirschberg, 2007) that measures if each latent action contains only members of a single class. We tested this on the SW and DD, which contain human annotated features and we report the latent actions' homogeneity w.r.t these features in Table 3. On DD, results show DI-VST works better than DI-VAE in terms of creating actions that are more coherent for emotion and dialog acts. The results are interesting on SW since DI-VST performs worse on dialog acts than DI-VAE. One reason is that the dialog acts in SW are more fine-grained (42 acts) than the ones in DD (5 acts) so that distinguishing utterances based on words in $\mathbf{x}$ is more important than the information in the neighbouring utterances.

	SW		**DD**	
	Act	Topic	Act	Emotion
DI-VAE	0.48	0.08	0.18	0.09
DI-VST	0.33	0.13	0.34	0.12

Table 3: Homogeneity results (bounded [0, 1]).

We then apply the proposed methods to SMD which has no manual annotation and contains task-oriented dialogs. Two experts are shown 5 randomly selected utterances from each latent action and are asked to give an action name that can describe as many of the utterances as possible. Then an Amazon Mechanical Turk study is conducted to evaluate whether other utterances from the same latent action match these titles. 5 workers see the action name and a different group of 5 utterances from that latent action. They are asked to select all utterances that belong to the given actions, which tests the homogeneity of the utterances falling in the same cluster. Negative samples are included to prevent random selection. Table 4 shows that both methods work well and DI-VST achieved better homogeneity than DI-VAE.

Since DI-VAE is trained to reconstruct its input and DI-VST is trained to model the context, they group utterances in different ways. For example, DI-VST would group "Can I get a restaurant", "I am looking for a restaurant" into one action where DI-VAE may denote two actions for them. Finally, Table 4.2 shows sample annotation results, which show cases of the different types of latent actions discovered by our models.

Model	Exp Agree	Worker κ	Match Rate
DI-VAE	85.6%	0.52	71.3%
DI-VST	93.3%	0.48	74.9%

Table 4: Human evaluation results on judging the homogeneity of latent actions in SMD.

Model	**Action**	**Sample utterance**
DI-VAE	scheduling	- sys: okay, scheduling a yoga activity with Tom for the 8th at 2pm. - sys: okay, scheduling a meeting for 6 pm on Tuesday with your boss to go over the quarterly report.
	requests	- usr: find out if it 's supposed to rain - usr: find nearest coffee shop
DI-VST	ask schedule info	- usr: when is my football activity and who is going with me? - usr: tell me when my dentist appointment is?
	requests	- usr: how about other coffee? - usr: 11 am please

Table 5: Example latent actions discovered in SMD using our methods.

4.3 Dialog Response Generation with Latent Actions

Finally we implement an LAED as follows. The encoder is a hierarchical recurrent encoder (Serban et al., 2016) with bi-directional GRU-RNNs as the utterance encoder and a second GRU-RNN as the discourse encoder. The discourse encoder output its last hidden state $h^e_{|\mathbf{x}|}$. The decoder is another GRU-RNN and its initial state of the decoder is obtained by $h^d_0 = h^e_{|\mathbf{x}|} + \sum_{m=1}^{M} e_m(\mathbf{z}_m)$, where $\mathbf{z}$ comes from the recognition network of the proposed methods. The policy network π is a 2-layer multi-layer perceptron (MLP) that models $p_\pi(\mathbf{z}|h^e_{|\mathbf{x}|})$. We use up to the previous 10 utterances as the dialog context and denote the LAED using DI-VAE latent actions as AE-ED and the one uses DI-VST as ST-ED.

First we need to confirm whether an LAED can generate responses that are consistent with the semantics of a given $\mathbf{z}$. To answer this, we use a pre-trained recognition network $\mathcal{R}$ to check if a generated response carries the attributes in the given action. We generate dialog responses on a test dataset via $\tilde{\mathbf{x}} = \mathcal{F}(\mathbf{z} \sim \pi(\mathbf{c}), \mathbf{c})$ with greedy RNN decoding. The generated responses are passed into the $\mathcal{R}$ and we measure *attribute accuracy* by counting $\tilde{\mathbf{x}}$ as correct if $\mathbf{z} = \text{argmax}_k\, q_{\mathcal{R}}(k|\tilde{\mathbf{x}})$. Table 4.3 shows our generated responses are highly consistent with the given latent actions. Also, latent actions from DI-VAE achieve higher attribute accuracy than the ones from DI-VST, because $\mathbf{z}$ from auto-encoding is explicitly trained for $\mathbf{x}$ reconstruction. Adding $\mathcal{L}_{attr}$ is effective in forcing the decoder to take $\mathbf{z}$ into account during its generation, which helps the most in more challenging open-domain chatting data, e.g. SW and DD. The accuracy of ST-ED on SW is worse than the other two datasets. The reason is that SW contains many short utterances that can be either a continuation of the same speaker or a new turn from the other speaker, whereas the responses in the other two domains are always followed by a different speaker. The more complex context pattern in SW may require special treatment. We leave it for future work.

Domain	AE-ED	$+L_{\text{attr}}$	ST-ED	$+L_{\text{attr}}$
SMD	93.5%	94.8%	91.9%	93.8%
DD	88.4%	93.6%	78.5%	86.1%
SW	84.7%	94.6%	57.3%	61.3%

Table 6: Results for attribute accuracy with and without attribute loss.

The second experiment checks if the policy network π is able to predict the right latent action given just the dialog context. We report both accuracy, i.e. $\text{argmax}_k\, q_{\mathcal{R}}(k|\mathbf{x}) = \text{argmax}_{k'}\, p_{\pi}(k'|\mathbf{c})$ and perplexity of $p_{\pi}(\mathbf{z}|\mathbf{c})$. The perplexity measure is more useful for open domain dialogs because decision-making in complex dialogs is often one-to-many given a similar context (Zhao et al., 2017). Table 7 shows the prediction scores on the three dialog datasets. These scores provide useful insights to understand the complexity of a dialog dataset. For example, accuracy on open-domain chatting is harder than the task-oriented SMD data. Also, it is intuitive that predicting system actions is easier than predicting user actions on SMD. Also, in general the prediction scores for ST-ED are higher the ones for AE-ED. The reason is related to our previous discussion about the granularity of the latent actions. Since latent actions from DI-VST mainly model the the type of utterances used in certain types of context, it is easier for the policy network to predict latent actions from DI-VST. Therefore, choosing the type of latent actions is a design choice and depends on the type of interpretability that is needed. We finish with an example generated from the two variants of LAED on SMD as shown in Table 8. Given a dialog context, our systems are able to output a probability distribution over different latent actions that have interpretable meaning along with their natural language realizations.

	SMD	
AE-ED	3.045 (51.5% sys 52.4% usr 50.5%)	
ST-ED	1.695 (75.5% sys 82.1% usr 69.2%)	
	DD	SW
AE-ED	4.47 (35.8%)	4.46 (31.68%)
ST-ED	3.89 (47.5%)	3.68 (33.2%)

Table 7: Performance of policy network. $\mathcal{L}_{attr}$ is included in training.

c	**usr**: Where does my friend live?	
Model	Action	Generated Responses
AE-ED	give loc info $p(\mathbf{z}\|\mathbf{c})$=0.34	- Tom is at 753 University Ave, and a road block. - Comfort Inn is at 7 miles away.
	give user info $p(\mathbf{z}\|\mathbf{c})$=0.22	- Your home address is 5671 barringer street. - Your home is at 10 ames street.
ST-ED	give loc info $p(\mathbf{z}\|\mathbf{c})$=0.93	- Jill's house is 8 miles away at 347 Alta Mesa Ave. - Jill lives at 347 Alta Mesa Ave.

Table 8: Interpretable dialog generation on SMD with top probable latent actions. AE-ED predicts more fine-grained but more error-prone actions.

5 Conclusion and Future Work

This paper presents a novel unsupervised framework that enables the discovery of discrete latent actions and interpretable dialog response generation. Our main contributions reside in the two sentence representation models DI-VAE and DI-VST, and their integration with the encoder decoder models. Experiments show the proposed methods outperform strong baselines in learning discrete latent variables and showcase the effectiveness of interpretable dialog response generation. Our findings also suggest promising future research directions, including learning better context-based latent actions and using reinforcement learning to adapt policy networks. We believe that this work is an important step forward towards creating generative dialog models that can not only generalize to large unlabelled datasets in complex domains but also be explainable to human users.

Abstract

In conversation, a general response (e.g., "I don't know") could correspond to a large variety of input utterances. Previous generative conversational models usually employ a single model to learn the relationship between different utterance-response pairs, thus tend to favor general and trivial responses which appear frequently. To address this problem, we propose a novel controlled response generation mechanism to handle different utterance-response relationships in terms of specificity. Specifically, we introduce an explicit specificity control variable into a sequence-to-sequence model, which interacts with the usage representation of words through a Gaussian Kernel layer, to guide the model to generate responses at different specificity levels. We describe two ways to acquire distant labels for the specificity control variable in learning. Empirical studies show that our model can significantly outperform the state-of-the-art response generation models under both automatic and human evaluations.

1 Introduction

Human-computer conversation is a critical and challenging task in AI and NLP. There have been two major streams of research in this direction, namely task oriented dialog and general purpose dialog (i.e., chit-chat). Task oriented dialog aims to help people complete specific tasks such as buying tickets or shopping, while general purpose dialog attempts to produce natural and meaningful conversations with people regarding a wide range of topics in open domains (Perez-Marin, 2011; Sordoni et al.). In recent years, the latter has attracted much attention in both academia and industry as a way to explore the possibility in developing a general purpose AI system in language (e.g., chatbots).

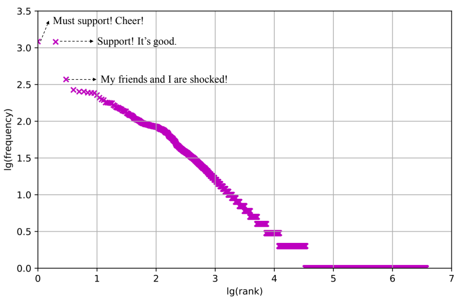

Figure 1: Rank-frequency distribution of the responses in the chit-chat corpus, with x and y axes being lg(rank order) and lg(frequency) respectively.

A widely adopted approach to general purpose dialog is learning a generative conversational model from large scale social conversation data. Most methods in this line are constructed within the statistical machine translation (SMT) framework, where a sequence-to-sequence (Seq2Seq) model is learned to "translate" an input utterance into a response. However, general purpose dialog is intrinsically different from machine translation. In machine translation, since every sentence and its translation are semantically equivalent, there exists a 1-to-1 relationship between them. However, in general purpose dialog, a general response (e.g., "I don't know") could correspond to a large variety of input utterances. For example, in the chit-chat corpus used in this study (as shown in Figure 1), the top three most frequently appeared responses are "Must support! Cheer!", "Support! It's good.", and "My friends and I are shocked!", where the response "Must support! Cheer!" is used for 1216 different input utterances. Previous Seq2Seq models, which treat all the utterance-response pairs uniformly and employ a single model to learn the relationship between them, will inevitably favor such general responses with high frequency. Although these responses are safe for replying different utterances, they are boring and trivial since they carry little information, and may quickly lead to an end of the conversation.

There have been a few efforts attempting to address this issue in literature. Li et al. (2016a) proposed to use the Maximum Mutual Information (MMI) as the objective to penalize general responses. It could be viewed as a post-processing approach which did not solve the generation of trivial responses fundamentally. Xing et al. (2017) pre-defined a set of topics from an external corpus to guide the generation of the Seq2Seq model. However, it is difficult to ensure that the topics learned from the external corpus are consistent with that in the conversation corpus, leading to the introduction of additional noises. Zhou et al. (2017) introduced latent responding factors to model multiple responding mechanisms. However, these latent factors are usually difficult in interpretation and it is hard to decide the number of the latent factors.

In our work, we propose a novel controlled response generation mechanism to handle different utterance-response relationships in terms of specificity. The key idea is inspired by our observation on everyday conversation between humans. In human-human conversation, people often actively control the specificity of responses depending on their own response purpose (which might be affected by a variety of underlying factors like their current mood, knowledge state and so on). For example, they may provide some interesting and specific responses if they like the conversation, or some general responses if they want to end it. They may provide very detailed responses if they are familiar with the topic, or just "I don't know" otherwise. Therefore, we propose to simulate the way people actively control the specificity of the response.

We employ a Seq2Seq framework and further introduce an explicit specificity control variable to represent the response purpose of the agent. Meanwhile, we assume that each word, beyond the semantic representation which relates to its meaning, also has another representation which relates to the usage preference under different response purpose. We name this representation as the usage representation of words. The specificity control variable then interacts with the usage representation of words through a Gaussian Kernel layer, and guides the Seq2Seq model to generate responses at different specificity levels. We refer to our model as Specificity Controlled Seq2Seq model (SC-Seq2Seq). Note that unlike the work by (Xing et al., 2017), we do not rely on any external corpus to learn our model. All the model parameters are learned on the same conversation corpus in an end-to-end way.

We employ distant supervision to train our SC-Seq2Seq model since the specificity control variable is unknown in the raw data. We describe two ways to acquire distant labels for the specificity control variable, namely Normalized Inverse Response Frequency (NIRF) and Normalized Inverse Word Frequency (NIWF). By using normalized values, we restrict the specificity control variable to be within a pre-defined continuous value range with each end has very clear meaning on the specificity. This is significantly different from the discrete latent factors in (Zhou et al., 2017) which are difficult in interpretation.

We conduct an empirical study on a large public dataset, and compare our model with several state-of-the-art response generation methods. Empirical results show that our model can generate either general or specific responses, and significantly outperform existing methods under both automatic and human evaluations.

2 Related Work

In this section, we briefly review the related work on conversational models and response specificity.

2.1 Conversational Models

Automatic conversation has attracted increasing attention over the past few years. At the very beginning, people started the research using hand-crafted rules and templates (Walker et al., 2001; Williams et al., 2013; Henderson et al., 2014). These approaches required little data for training but huge manual effort to build the model, which is very time-consuming. For now, conversational models fall into two major categories: retrieval-based and generation-based. Retrieval-based conversational models search the most suitable response from candidate responses using different schemas (Kearns, 2000; Wang et al., 2013; Yan et al., 2016). These methods rely on pre-existing responses, thus are difficult to be extended to open domains (Zhou et al., 2017). With the large amount of conversation data available on the Internet, generation-based conversational models developed within a SMT framework (Ritter et al., 2011; Cho et al., 2014; Bahdanau et al., 2015) show promising results. Shang et al. (2015) generated replies for short-text conversation by encoder-decoder-based neural network with local and global attentions. Serban et al. (2016) built an end-to-end dialogue system using generative hierarchical neural network. Gu et al. (2016) introduced copynet to simulate the repeating behavior of humans in conversation. Similarly, our model is also based on the encoder-decoder framework.

2.2 Response Specificity

Some recent studies began to focus on generating more specific or informative responses in conversation. It is also called a diversity problem since if each response is more specific, it would be more diverse between responses of different utterances. As an early work, Li et al. (2016a) used Maximum Mutual Information (MMI) as the objective to penalize general responses. Later, Li et al. (2017) proposed a data distillation method, which trains a series of generative models at different levels of specificity and uses a reinforcement learning model to choose the model best suited for decoding depending on the conversation context. These methods circumvented the general response issue by using either a post-processing approach or a data selection approach.

Besides, Li et al. (2016b) tried to build a personalized conversation engine by adding extra personal information. Xing et al. (2017) incorporated the topic information from an external corpus into the Seq2Seq framework to guide the generation. However, external dataset may not be always available or consistent with the conversation dataset in topics. Zhou et al. (2017) introduced latent responding factors to the Seq2Seq model to avoid generating safe responses. However, these latent factors are usually difficult in interpretation and hard to decide the number.

Moreover, Mou et al. (2016) proposed a content-introducing approach to generate a response based on a predicted keyword. Yao et al. (2016) attempted to improve the specificity with the reinforcement learning framework by using the averaged IDF score of the words in the response as a reward. Shen et al. (2017) presented a conditional variational framework for generating specific responses based on specific attributes. Unlike these existing methods, we introduce an explicit specificity control variable into a Seq2Seq model to handle different utterance-response relationships in terms of specificity.

3 Specificity Controlled Seq2Seq Model

In this section, we present the Specificity Controlled Seq2Seq model (SC-Seq2Seq), a novel Seq2Seq model designed for actively controlling the generated responses in terms of specificity.

3.1 Model Overview

The basic idea of a generative conversational model is to learn the mapping from an input utterance to its response, typically using an encoder-decoder framework. Formally, given an input utterance sequence $\mathbf{X} = (x_1, x_2, \dots, x_T)$ and a target response sequence $\mathbf{Y} = (y_1, y_2, \dots, y_{T'})$, a neural Seq2Seq model is employed to learn $p(\mathbf{Y}|\mathbf{X})$ based on the training corpus $\mathcal{D} = \{(\mathbf{X}, \mathbf{Y})|\mathbf{Y} \text{ is the response of } \mathbf{X}\}$. By maximizing the likelihood of all the utterance-response pairs with a single mapping mechanism, the learned Seq2Seq model will inevitably favor those general responses that can correspond to a large variety of input utterances.

To address this issue, we assume that there are different mapping mechanisms between utterance-response pairs with respect to their specificity relation. Rather than involving some latent factors, we propose to introduce an explicit variable s into a Seq2Seq model to handle different utterance-response mappings in terms of specificity. By doing so, we hope that (1) s would have explicit meaning on specificity, and (2) s could not only interpret but also actively control the generation of the response $\mathbf{Y}$ given the input utterance $\mathbf{X}$. The goal of our model becomes to learn $p(\mathbf{Y}|\mathbf{X}, s)$ over the corpus $\mathcal{D}$, where we acquire distant labels for s from the same corpus for learning. The overall architecture of SC-Seq2Seq is depicted in Figure 2, and we will detail our model as follows.

3.1.1 Encoder

The encoder is to map the input utterance $\mathbf{X}$ into a compact vector that can capture its essential topics. Specifically, we use a bi-directional GRU (Cho et al., 2014) as the utterance encoder, and each word x_i is firstly represented by its semantic representation $\mathbf{e}_i$ mapped by semantic embedding

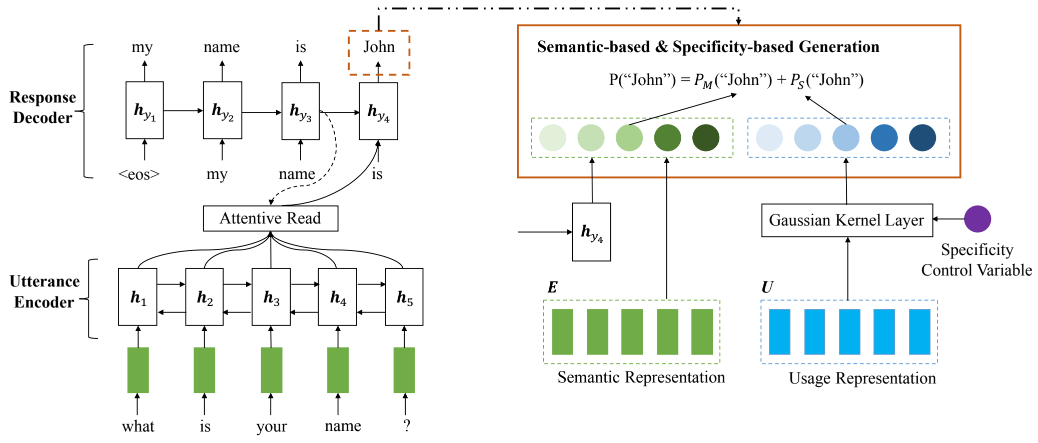

Figure 2: The overall architecture of SC-Seq2Seq model.

matrix $\mathbf{E}$ as the input of the encoder. Then, the encoder represents the utterance $\mathbf{X}$ as a series of hidden vectors $\{\mathbf{h}_t\}_{t=1}^{T}$ modeling the sequence from both forward and backward directions. Finally, we use the final backward hidden state as the initial hidden state of the decoder.

3.1.2 Decoder

The decoder is to generate a response $\mathbf{Y}$ given the hidden representations of the input utterance $\mathbf{X}$ under some specificity level denoted by the control variable s. Specifically, at step t, we define the probability of generating any target word y_t by a "mixture" of probabilities:

$$p(y_t) = \beta p_M(y_t) + \gamma p_S(y_t), \tag{1}$$

where $p_M(y_t)$ denotes the semantic-based generation probability, $p_S(y_t)$ denotes the specificity-based generation probability, β and γ are the coefficients.

Specifically, $p_M(y_t)$ is defined the same as that in traditional Seq2Seq model (Sutskever et al., 2014):

$$p_M(y_t = w) = \mathbf{w}^{\mathrm{T}}(\mathbf{W}_M^h \cdot \mathbf{h}_{y_t} + \mathbf{W}_M^e \cdot \mathbf{e}_{t-1} + \mathbf{b}_M), \tag{2}$$

where $\mathbf{w}$ is a one-hot indicator vector of the word w and $\mathbf{e}_{t-1}$ is the semantic representation of the $t-1$-th generated word in decoder. $\mathbf{W}_M^h$, $\mathbf{W}_M^e$ and $\mathbf{b}_M$ are parameters. $\mathbf{h}_{y_t}$ is the t-th hidden state in the decoder which is computed by:

$$\mathbf{h}_{y_t} = f(y_{t-1}, \mathbf{h}_{y_{t-1}}, \mathbf{c}_t), \tag{3}$$

where f is a GRU unit and $\mathbf{c}_t$ is the context vector to allow the decoder to pay different attention to different parts of input at different steps (Bahdanau et al., 2015).

$p_S(y_t)$ denotes the generation probability of the target word given the specificity control variable s. Here we introduce a Gaussian Kernel layer to define this probability. Specifically, we assume that each word, beyond its semantic representation $\mathbf{e}$, also has a usage representation $\mathbf{u}$ mapped by usage embedding matrix $\mathbf{U}$. The usage representation of a word denotes its usage preference under different specificity. The specificity control variable s then interacts with the usage representations through the Gaussian Kernel layer to produce the specificity-based generation probability $p_S(y_t)$:

$$p_S(y_t = w) = \frac{1}{\sqrt{2\pi}\sigma}\exp(-\frac{(\Psi_S(\mathbf{U},\mathbf{w}) - s)^2}{2\sigma^2}),$$
$$\Psi_S(\mathbf{U},\mathbf{w}) = \sigma(\mathbf{w}^{\mathrm{T}}(\mathbf{U} \cdot \mathbf{W}_U + \mathbf{b}_U)), \tag{4}$$

where σ^2 is the variance, and $\Psi_S(\cdot)$ maps the word usage representation into a real value with the specificity control variable s as the mean of the Gaussian distribution. $\mathbf{W}_U$ and $\mathbf{b}_U$ are parameters to be learned. Note here in general we can use any real-value function to define $\Psi_S(\mathbf{U},\mathbf{w})$. In this work, we use the sigmoid function $\sigma(\cdot)$ for $\Psi_S(\mathbf{U},\mathbf{w})$ since we want to define s within the range [0,1] so that each end has very clear meaning on the specificity, i.e., 0 denotes the most general response while 1 denotes the most specific response. In the next section, we will also keep this property when we define the distant label for the control variable.

3.2 Distant Supervision

We train our SC-Seq2Seq model by maximizing the log likelihood of generating responses over the training set $\mathcal{D}$:

$$\mathcal{L} = \sum_{(\mathbf{X},\mathbf{Y})\in\mathcal{D}} \log P(\mathbf{Y}|\mathbf{X}, s; \theta). \tag{5}$$

where θ denotes all the model parameters. Note here since s is an explicit control variable in our model, we need the triples $(\mathbf{X}, \mathbf{Y}, s)$ for training. However, s is not directly available in the raw conversation corpus, thus we acquire distant labels for s to learn our model. We introduce two ways of distant supervision on the specificity control variable s, namely Normalized Inverse Response Frequency (NIRF) and Normalized Inverse Word Frequency (NIWF).

3.2.1 Normalized Inverse Response Frequency

Normalized Inverse Response Frequency (NIRF) is based on the assumption that a response is more general if it corresponds to more input utterances in the corpus. Therefore, we use the inverse frequency of a response in a conversation corpus to indicate its specificity level. Specifically, we first build the response collection $\mathcal{R}$ by extracting all the responses from $\mathcal{D}$. For a response $\mathbf{Y} \in \mathcal{R}$, let $f_{\mathbf{Y}}$ denote its corpus frequency in $\mathcal{R}$, we compute its Inverse Response Frequency (IRF) as:

$$\mathrm{IRF}_{\mathbf{Y}} = \log(1 + |\mathcal{R}|)/f_{\mathbf{Y}}, \tag{6}$$

where $|\mathcal{R}|$ denotes the size of the response collection $\mathcal{R}$. Next, we use the min-max normalization method (Jain et al., 2005) to obtain the NIRF value. Namely,

$$\mathrm{NIRF}_{\mathbf{Y}} = \frac{\mathrm{IRF}_{\mathbf{Y}} - \min_{\mathbf{Y}' \in \mathcal{R}}(\mathrm{IRF}_{\mathbf{Y}'})}{\max_{\mathbf{Y}' \in \mathcal{R}}(\mathrm{IRF}_{\mathbf{Y}'}) - \min_{\mathbf{Y}' \in \mathcal{R}}(\mathrm{IRF}_{\mathbf{Y}'})}. \tag{7}$$

where $\max(\mathrm{IRF}_{\mathcal{R}})$ and $\min(\mathrm{IRF}_{\mathcal{R}})$ denotes the maximal and minimum IRF value in $\mathcal{R}$ respectively. The NIRF value is then used as the distant label of s in training. Note here by using normalized values, we aim to constrain the specificity control variable s to be within the pre-defined continuous value range [0,1].

3.2.2 Normalized Inverse Word Frequency

Normalized Inverse Word Frequency (NIWF) is based on the assumption that the specificity level of a response depends on the collection of words it contains, and the sentence is more specific if it contains more specific words. Hence, we can use the inverse corpus frequency of the words to indicate the specificity level of a response. Specifically, for a word y in the response $\mathbf{Y}$, we first obtain its Inverse Word Frequency (IWF) by:

$$\mathrm{IWF}_{y} = \log(1 + |\mathcal{R}|)/f_{y}, \tag{8}$$

where f_y denotes the number of responses in $\mathcal{R}$ containing the word y. Since a response usually contains a collection of words, there would be multiple ways to define the response-level IWF value, e.g., sum, average, minimum or maximum of the IWF values of all the words. In our work, we find that the best performance can be achieved by using the maximum of the IWF of all the words in $\mathbf{Y}$ to represent the response-level IWF by

$$\mathrm{IWF}_{\mathbf{Y}} = \max_{y \in \mathbf{Y}}(\mathrm{IWF}_{y}). \tag{9}$$

This is reasonable since a response is specific as long as it contains some specific words. We do not require all the words in a response to be specific, thus sum, average, and minimum would not be appropriate operators for computing the response-level IWF. Again, we use min-max normalization to obtain the NIWF value for the response $\mathbf{Y}$.

3.3 Specificity Controlled Response Generation

Given a new input utterance, we can employ the learned SC-Seq2Seq model to generate responses at different specificity levels by varying the control variable s. In this way, we can simulate human conversations where one can actively control the response specificity depending on his/her own mind. When we apply our model to a chatbot, there might be different ways to use the control variable for conversation in practice. If we want the agent to always generate informative responses, we can set s to 1 or some values close to 1. If we want the agent to be more dynamic, we can sample s within the range [0,1] to enrich the styles in the response. We may further employ some reinforcement learning technique to learn to adjust the control variable depending on users' feedbacks. This would make the agent even more vivid, and we leave this as our future work.

4 Experiment

In this section, we conduct experiments to verify the effectiveness of our proposed model.

4.1 Dataset Description

We conduct our experiments on the public Short Text Conversation (STC) dataset[1] released in NTCIR-13. STC maintains a large repository of post-comment pairs from the Sina Weibo which is one of the popular Chinese social sites.

[1]http://ntcirstc.noahlab.com.hk/STC2/stc-cn.htm

Utterance-response pairs	3,788,571
Utterance vocabulary #w	120,930
Response vocabulary #w	524,791
Utterance max #w	38
Utterance avg #w	13
Response max #w	74
Response avg #w	10

Table 1: Short Text Conversation (STC) data statistics: #w denotes the number of Chinese words.

STC dataset contains roughly 3.8 million post-comment pairs, which could be used to simulate the utterance-response pairs in conversation. We employ the Jieba Chinese word segmenter[2] to tokenize the utterances and responses into sequences of Chinese words, and the detailed dataset statistics are shown in Table 1. We randomly selected two subsets as the development and test dataset, each containing 10k pairs. The left pairs are used for training.

4.2 Baselines Methods

We compare our proposed SC-Seq2Seq model against several state-of-the-art baselines: (1) **Seq2Seq-att**: the standard Seq2Seq model with the attention mechanism (Bahdanau et al., 2015); (2) **MMI-bidi**: the Seq2Seq model using Maximum Mutual Information (MMI) as the objective function to reorder the generated responses (Li et al., 2016a); (3) **MARM**: the Seq2Seq model with a probabilistic framework to model the latent responding mechanisms (Zhou et al., 2017); (4) **Seq2Seq+IDF**: an extension of Seq2Seq-att by optimizing specificity under the reinforcement learning framework, where the reward is calculated as the sentence level IDF score of the generated response (Yao et al., 2016). We refer to our model trained using NIRF and NIWF as **SC-Seq2Seq**$_{\text{NIRF}}$ and **SC-Seq2Seq**$_{\text{NIWF}}$ respectively.

4.3 Implementation Details

As suggested in (Shang et al., 2015), we construct two separate vocabularies for utterances and responses by using 40,000 most frequent words on each side in the training data, covering 97.7% words in utterances and 96.1% words in responses respectively. All the remaining words are replaced by a special token <UNK> symbol.

We implemented our model in Tensorflow[3]. We tuned the hyper-parameters via the development set. Specifically, we use one layer of bi-directional GRU for encoder and another uni-directional GRU for decoder, with the GRU hidden unit size set as 300 in both the encoder and decoder. The dimension of semantic word embeddings in both utterances and responses is 300, while the dimension of usage word embeddings in responses is 50. We apply the Adam algorithm (Kingma and Ba, 2015) for optimization, where the parameters of Adam are set as in (Kingma and Ba, 2015). The variance σ^2 of the Gaussian Kernel layer is set as 1, and all other trainable parameters are randomly initialized by uniform distribution within [-0.08,0.08]. The mini-batch size for the update is set as 128. We clip the gradient when its norm exceeds 5.

Our model is trained on a Tesla K80 GPU card, and we run the training for up to 12 epochs, which takes approximately five days. We select the model that achieves the lowest perplexity on the development dataset, and we report results on the test dataset.

4.4 Evaluation Methodologies

For evaluation, we follow the existing work and employ both automatic and human evaluations: (1) **distinct-1 & distinct-2** (Li et al., 2016a): we count numbers of distinct unigrams and bigrams in the generated responses, and divide the numbers by total number of generated unigrams and bigrams. Distinct metrics (both the numbers and the ratios) can be used to evaluate the specificity/diversity of the responses. (2) **BLEU** (Papineni et al., 2002): BLEU has been proved strongly correlated with human evaluations. BLEU-n measures the average n-gram precision on a set of reference sentences. (3) **Average & Extrema** (Serban et al., 2017): Average and Extrema projects the generated response and the ground truth response into two separate vectors by taking the mean over the word embeddings or taking the extremum of each dimension respectively, and then computes the cosine similarity between them. (4) **Human evaluation**: Three labelers with rich Weibo experience were recruited to conduct evaluation. Responses from different models are randomly mixed for labeling. Labelers refer to 300 random sampled test utterances and score the quality of the responses with the following criteria: 1) **+2**: the response is not only semantically relevant and grammatical, but also informat-

ive and interesting; 2) **+1**: the response is grammatical and can be used as a response to the utterance, but is too trivial (e.g., "I don't know"); 3) **+0**: the response is semantically irrelevant or ungrammatical (e.g., grammatical errors or UNK). Agreements to measure inter-rater consistency among three labelers are calculated with the Fleiss' kappa (Fleiss and Cohen, 1973).

4.5 Evaluation Results

Model Analysis: We first analyze our models trained with different distant supervision information. For each model, given a test utterance, we vary the control variable s by setting it to five different values (i.e., 0, 0.2, 0.5, 0.8, 1) to check whether the learned model can actually achieve different specificity levels. As shown in Table 2, we find that: (1) The SC-Seq2Seq model trained with NIRF cannot work well. The test performances are almost the same with different s value. This is surprising since the NIRF definition seems to be directly corresponding to the specificity of a response. By conducting further analysis, we find that even though the conversation dataset is large, it is still limited and a general response could appear very few times in this corpus. In other words, the inverse frequency of a response is very weakly correlated with its response specificity. (2) The SC-Seq2Seq model trained with NIWF can achieve our purpose. By varying the control variable s from 0 to 1, the generated responses turn from general to specific as measured by the distinct metrics. The results indicate that the max inverse word frequency in a response is a good distant label for the response specificity. (3) When we compare the generated responses against ground truth data, we find the SC-Seq2Seq$_{\text{NIWF}}$ model with the control variable s set to 0.5 can achieve the best performances. The results indicate that there are diverse responses in real data in terms of specificity, and it is necessary to take a balanced setting if we want to fit the ground truth.

Baseline Comparison: The performance comparisons between our model and the baselines are shown in Table 3. We have the following observations: (1) By using MMI as the objective, MMI-bidi can improve the specificity (in terms of distinct ratios) over the traditional Seq2Seq-att model. (2) MARM can achieve the best distinct ratios among the baseline methods, but the worst in terms of the distinct numbers. The results indicate that MARM tends to generate specific but very short responses. Meanwhile, its low BLEU scores also show that the responses generated by MARM deviate from the ground truth significantly. (3) By using the IDF information as the reward to train

	+2	+1	+0	kappa
Seq2Seq-att	29.32%	25.27%	45.41%	0.448
MMI-bidi	30.40%	24.85%	44.75%	0.471
MARM	20.11%	27.96%	51.93%	0.404
Seq2Seq+IDF	28.81%	23.87%	47.33%	0.418
SC-Seq2Seq$_{\text{NIWF,s=1}}$	42.47%	14.29%	43.24%	0.507
SC-Seq2Seq$_{\text{NIWF,s=0.5}}$	20.62%	40.16%	39.22%	0.451
SC-Seq2Seq$_{\text{NIWF,s=0}}$	14.34%	46.38%	39.28%	0.526

Table 4: Results on the human evaluation.

the Seq2Seq model, the Seq2Seq+IDF does not show much advantages, but only achieves comparable results as MMI-bidi. (4) By setting the control variable s to 1, our SC-Seq2Seq$_{\text{NIWF}}$ model can achieve the best specificity performance as evaluated by the distinct metrics. By setting the control variable s to 0.5, our SC-Seq2Seq$_{\text{NIWF}}$ model can best fit the ground truth data as evaluated by the BLEU scores, Average and Extrema. All the improvements over the baseline models are statistically significant (p-value < 0.01). These results demonstrate the effectiveness as well as the flexibility of our controlled generation model.

Table 4 shows the human evaluation results. We can observe that: (1) SC-Seq2Seq$_{\text{NIWF,s=1}}$ generates the most informative responses and interesting (labeled as "+2") and the least general responses than all the baseline models. Meanwhile, SC-Seq2Seq$_{\text{NIWF,s=0}}$ generates the most general responses (labeled as "+1"); (2) MARM generates the most bad responses (labeled as "+0"), which indicates the drawbacks of the unknown latent responding mechanisms; (3) The kappa values of our models are all larger than 0.4, considered as "moderate agreement" regarding quality of responses. The largest kappa value is achieved by SC-Seq2Seq$_{\text{NIWF,s=0}}$, which seems reasonable since it is easy to reach an agreement on general responses. Sign tests demonstrate the improvements of SC-Seq2Seq$_{\text{NIWF,s=1}}$ to the baseline models are statistically significant (p-value < 0.01). All the human judgement results again demonstrate the effectiveness of our controlled generation mechanism.

4.6 Case Study

To better understand how different models perform, we conduct some case studies. We randomly sample three utterances from the test dataset, and show the responses generated by different models.

Utterance	三室一厅的帐篷，你值得拥有！A tent with three rooms and one hall, you're worth it!
Seq2Seq-att	这个不错，很好！It looks good, very good!
MMI-bidi	这个不错，我喜欢。It looks good, I like it.
MARM	不错。Good.
Seq2Seq+IDF	帐篷不错。The tent is good.
s=1	我想知道这帐篷是什么牌子的？I want to know what the brand of this tent is?
s=0.8	我想知道这是在哪买的？I want to know where to buy it?
s=0.5	我也想买一个,可惜买不起！I want one too, but it's a pity that I can't afford it.
s=0.2	不错不错！Good, good.
s=0	真的吗？Really?
Utterance	哎哟! 被发现了! 汤唯有必要那么美吗? Oh! Got caught! Why is Tang Wei so beautiful?
Seq2Seq-att	我超喜欢她！I really like her!
MMI-bidi	好美。我超喜欢她！So beautiful. I really like her!
MARM	我不喜欢汤唯。I don't like Tang Wei.
Seq2Seq+IDF	我超喜欢她的，我喜欢。I really like her, I like.
s=1	我超喜欢她的眼妆，她的气质很美！I really like her eye make-up, and her temperament is so beautiful!
s=0.8	我超喜欢她的，她的眼睛很雪亮！I really like her, and her eyes are so bright!
s=0.5	我觉得她很美，很喜欢她！I think she is very beautiful, and I really like her!
s=0.2	我觉得她很美！I think she is very beautiful.
s=0	是的。Yes.
Utterance	将来也要养一只这么乖的的萨摩，让它陪着孩子一起长大。I will keep such a sweet samoyed, and let it accompany my children to grow up.
Seq2Seq-att	这不是萨摩吗? Is it a samoyed?
MMI-bidi	好可爱的萨摩。What a lovely samoyed.
MARM	好可爱啊。So lovely.
Seq2Seq+IDF	好可爱的狗狗。What a lovely dog.
s=1	萨摩耶好可爱，真想养一只! The samoyed is so lovely, and I really want to keep one!
s=0.8	萨摩好可爱，好想掐掐。The samoyed is so lovely, and I really want to pinch it.
s=0.5	好可爱的狗狗，好可爱的狗狗。What a lovely dog, what a lovely dog.
s=0.2	好可爱！好可爱！So lovely, so lovely!
s=0	好可爱！So lovely!

Table 5: Examples of response generation from the STC test data. s = 1, 0.8, 0.5, 0.2, 0 are the outputs of our SC-Seq2Seq$_{\text{NIWF}}$ with different s values.

As shown in Table 5, we can find that: (1) The responses generated by the four baselines are often quite general and short, which may quickly lead to an end of the conversation. (2) SC-Seq2Seq$_{\text{NIWF}}$ with large control variable values (i.e., $s > 0.5$) can generate very long and specific responses. In these responses, we can find many informative words. For example, in case 2 with s as 1 and 0.8, we can find words like "眼妆(eye make-up)", "气质(temperament)" and "雪亮(bright)" which are quite specific and strongly related to the conversation topic of "beauty". (3) When we decrease the control variable value, the generated responses become more and more general and shorter from our SC-Seq2Seq$_{\text{NIWF}}$ model.

爸爸(dad)		水果(fruits)		脂肪肝(fatty liver)		单反相机(DSLR)	
Usage	Semantic	Usage	Semantic	Usage	Semantic	Usage	Semantic

Table 6: Target words and their top-5 similar words under usage and semantic representations respectively.

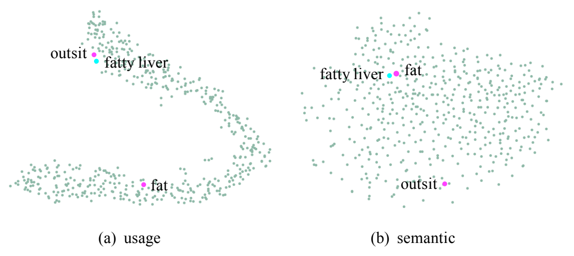

Figure 3: t-SNE embeddings of usage and semantic vectors.

4.7 Analysis on Usage Representations

We also conduct some analysis to understand the usage representations of words introduced in our model. We randomly sample 500 words from our SC-Seq2Seq$_{\text{NIWF}}$ and apply t-SNE (Maaten and Hinton, 2008) to visualize both usage and semantic embeddings. As shown in Figure 3, we can see that the two distributions are significantly different. In the usage space, words like "脂肪肝(fatty liver)" and "久坐(outsit)" lie closely which are both specific words, and both are far from the general words like "胖(fat)". On the contrary, in the semantic space, "脂肪肝(fatty liver)" is close to "胖(fat)" since they are semantically related, and both are far from the word "久坐(outsit)". Furthermore, given some sampled target words, we also show the top-5 similar words based on cosine similarity under both representations in Table 6. Again, we can see that the nearest neighbors of a same word are quite different under two representations. Neighbors based on semantic representations are semantically related, while neighbors based on usage representations are not so related but with similar specificity levels.

5 Conclusion

We propose a novel controlled response generation mechanism to handle different utterance-response relationships in terms of specificity. We introduce an explicit specificity control variable into the Seq2Seq model, which interacts with the usage representation of words to generate responses at different specificity levels. Empirical results showed that our model can generate either general or specific responses, and significantly outperform state-of-the-art generation methods.

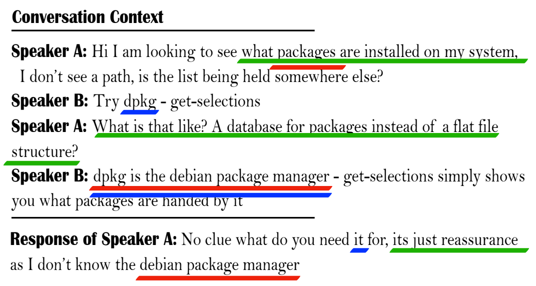
Abstract

Human generates responses relying on semantic and functional dependencies, including coreference relation, among dialogue elements and their context. In this paper, we investigate matching a response with its multi-turn context using dependency information based entirely on attention. Our solution is inspired by the recently proposed Transformer in machine translation (Vaswani et al., 2017) and we extend the attention mechanism in two ways. First, we construct representations of text segments at different granularities solely with stacked self-attention. Second, we try to extract the truly matched segment pairs with attention across the context and response. We jointly introduce those two kinds of attention in one uniform neural network. Experiments on two large-scale multi-turn response selection tasks show that our proposed model significantly outperforms the state-of-the-art models.

1 Introduction

Building a chatbot that can naturally and consistently converse with human-beings on open-domain topics draws increasing research interests in past years. One important task in chatbots is *response selection*, which aims to select the best-matched response from a set of candidates given the context of a conversation. Besides playing a critical role in *retrieval-based chatbots* (Ji et al., 2014), response selection models have been used in *automatic evaluation of dialogue generation* (Lowe et al., 2017) and the discriminator of *GAN*-based (Generative Adversarial Networks) neural dialogue generation (Li et al., 2017).



Conversation Context

Speaker A: Hi I am looking to see what packages are installed on my system, I don't see a path, is the list being held somewhere else?
Speaker B: Try dpkg - get-selections
Speaker A: What is that like? A database for packages instead of a flat file structure?
Speaker B: dpkg is the debian package manager - get-selections simply shows you what packages are handed by it

Response of Speaker A: No clue what do you need it for, its just reassurance as I don't know the debian package manager

Figure 1: Example of human conversation on Ubuntu system troubleshooting. Speaker A is seeking for a solution of package management in his/her system and speaker B recommend using, the debian package manager, dpkg. But speaker A does not know dpkg, and asks a *backchannel-question* (Stolcke et al., 2000), i.e., "no clue what do you need it for?", aiming to double-check if dpkg could solve his/her problem. Text segments with underlines in the same color across context and response can be seen as matched pairs.

Early studies on response selection only use the last utterance in context for matching a reply, which is referred to as *single-turn response selection* (Wang et al., 2013). Recent works show that the consideration of a multi-turn context can facilitate selecting the next utterance (Zhou et al., 2016; Wu et al., 2017). The reason why richer contextual information works is that human generated responses are heavily dependent on the previous dialogue segments at different granularities (words, phrases, sentences, etc), both semantically and functionally, over multiple turns rather than one turn (Lee et al., 2006; Traum and Heeman, 1996). Figure 1 illustrates semantic connectivities between segment pairs across context and response. As demonstrated, generally there are two kinds of matched segment pairs at different granularities across context and response: (1) surface text relevance, for example the lexical overlap of words "packages"-"package" and phrases "debian package manager"-"debian pack-

[*]Equally contributed.
[†] Work done as a visiting scholar at Baidu. Wayne Xin Zhao is an associate professor of Renmin University of China and can be reached at batmanfly@ruc.edu.cn.

age manager". (2) latent dependencies upon which segments are semantically/functionally related to each other. Such as the word "it" in the response, which refers to "dpkg" in the context, as well as the phrase "its just reassurance" in the response, which latently points to "what packages are installed on my system", the question that speaker A wants to double-check.

Previous studies show that capturing those matched segment pairs at different granularities across context and response is the key to multi-turn response selection (Wu et al., 2017). However, existing models only consider the textual relevance, which suffers from matching response that latently depends on previous turns. Moreover, Recurrent Neural Networks (RNN) are conveniently used for encoding texts, which is too costly to use for capturing multi-grained semantic representations (Lowe et al., 2015; Zhou et al., 2016; Wu et al., 2017). As an alternative, we propose to match a response with multi-turn context using dependency information based entirely on attention mechanism. Our solution is inspired by the recently proposed Transformer in machine translation (Vaswani et al., 2017), which addresses the issue of sequence-to-sequence generation only using attention, and we extend the key attention mechanism of Transformer in two ways:

self-attention By making a sentence attend to itself, we can capture its intra word-level dependencies. Phrases, such as "debian package manager", can be modeled with word-level self-attention over word-embeddings, and sentence-level representations can be constructed in a similar way with phrase-level self-attention. By hierarchically stacking self-attention from word embeddings, we can gradually construct semantic representations at different granularities.

cross-attention By making context and response attend to each other, we can generally capture dependencies between those latently matched segment pairs, which is able to provide complementary information to textual relevance for matching response with multi-turn context.

We jointly introduce self-attention and cross-attention in one uniform neural matching network, namely the Deep Attention Matching Network (DAM), for multi-turn response selection. In practice, DAM takes each single word of an utterance in context or response as the centric-meaning of an abstractive semantic segment, and hierarchically enriches its representation with stacked self-attention, gradually producing more and more sophisticated segment representations surrounding the centric-word. Each utterance in context and response are matched based on segment pairs at different granularities, considering both textual relevance and dependency information. In this way, DAM generally captures matching information between the context and the response from word-level to sentence-level, important matching features are then distilled with convolution & max-pooling operations, and finally fused into one single matching score via a single-layer perceptron.

We test DAM on two large-scale public multi-turn response selection datasets, the Ubuntu Corpus v1 and Douban Conversation Corpus. Experimental results show that our model significantly outperforms the state-of-the-art models, and the improvement to the best baseline model on $\mathbf{R}_{10}@1$ is over 4%. What is more, DAM is expected to be convenient to deploy in practice because most attention computation can be fully parallelized (Vaswani et al., 2017). Our contributions are two-folds: (1) we propose a new matching model for multi-turn response selection with self-attention and cross-attention. (2) empirical results show that our proposed model significantly outperforms the state-of-the-art baselines on public datasets, demonstrating the effectiveness of self-attention and cross-attention.

2 Related Work

2.1 Conversational System

To build an automatic conversational agent is a long cherished goal in Artificial Intelligence (AI) (Turing, 1950). Previous researches include *task-oriented dialogue system*, which focuses on completing tasks in vertical domain, and *chatbots*, which aims to consistently and naturally converse with human-beings on open-domain topics. Most modern chatbots are data-driven, either in a fashion of information-retrieval (Ji et al., 2014; Banchs and Li, 2012; Nio et al., 2014; Ameixa et al., 2014) or sequence-generation (Ritter et al., 2011). The retrieval-based systems enjoy the advantage of informative and fluent responses because it searches a large dialogue repository and selects

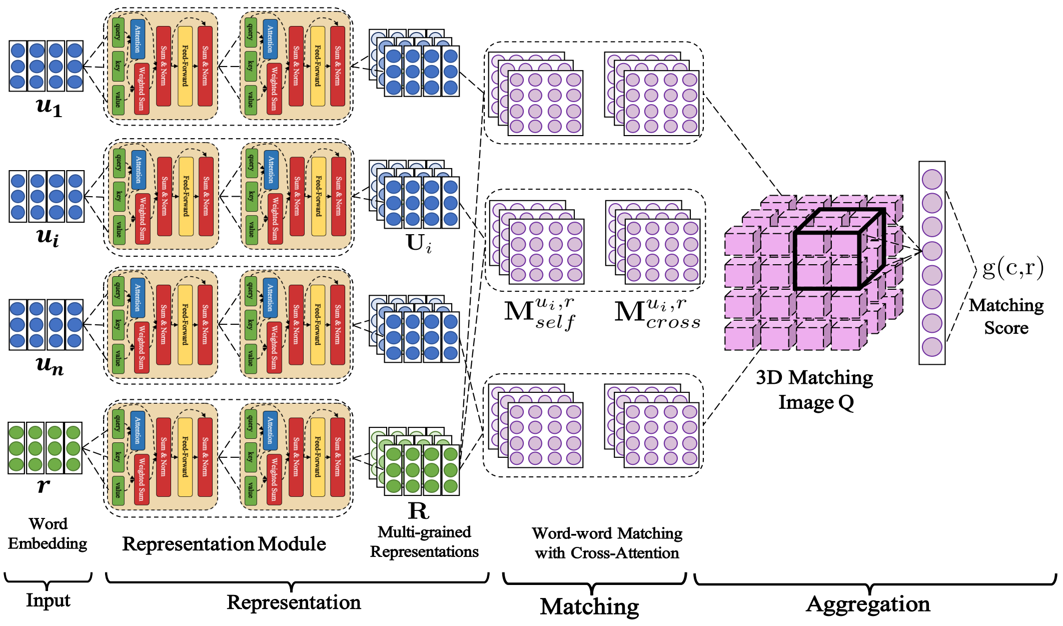


Figure 2: Overview of Deep Attention Matching Network.

candidate that best matches the current context. The generation-based models, on the other hand, learn patterns of responding from dialogues and can directly generalize new responses.

2.2 Response Selection

Researches on response selection can be generally categorized into *single-turn* and *multi-turn*. Most early studies are single-turn that only consider the last utterance for matching response (Wang et al., 2013, 2015). Recent works extend it to multi-turn conversation scenario, Lowe et al.,(2015) and Zhou et al.,(2016) use RNN to read context and response, use the last hidden states to represent context and response as two semantic vectors, and measure their relevance. Instead of only considering the last states of RNN, Wu et al.,(2017) take hidden state at each time step as a text segment representation, and measure the distance between context and response via segment-segment matching matrixes. Nevertheless, matching with dependency information is generally ignored in previous works.

2.3 Attention

Attention has been proven to be very effective in Natural Language Processing (NLP) (Bahdanau et al., 2015; Yin et al., 2016; Lin et al., 2017) and other research areas (Xu et al., 2015). Recently, Vaswani et al.,(2017) propose a novel sequence-to-sequence generation network, the Transformer, which is entirely based on attention. Not only Transformer can achieve better translation results than convenient RNN-based models, but also it is very fast in training/predicting as the computation of attention can be fully parallelized. Previous works on attention mechanism show the superior ability of attention to capture semantic dependencies, which inspires us to improve multi-turn response selection with attention mechanism.

3 Deep Attention Matching Network

3.1 Problem Formalization

Given a dialogue data set $\mathcal{D} = \{(c, r, y)_Z\}_{Z=1}^{N}$, where $c = \{u_0, ..., u_{n-1}\}$ represents a conversation context with $\{u_i\}_{i=0}^{n-1}$ as utterances and r as a response candidate. $y \in \{0, 1\}$ is a binary label, indicating whether r is a proper response for c. Our goal is to learn a matching model $g(c, r)$ with $\mathcal{D}$, which can measure the relevance between any context c and candidate response r.

3.2 Model Overview

Figure 2 gives an overview of DAM, which generally follows the **representation-matching-aggregation** framework to match response with multi-turn context. For each utterance $u_i = [w_{u_i,k}]_{k=0}^{n_{u_i}-1}$ in a context and its response candidate $r = [w_{r,t}]_{t=0}^{n_r-1}$, where n_{u_i} and n_r stand for the numbers of words, DAM first looks up a shared word embedding table and represents u_i and r as sequences of word embeddings, namely $\mathbf{U}_i^0 =$

$[e^0_{u_i,0}, ..., e^0_{u_i,n_{u_i}-1}]$ and $\mathbf{R}^0 = [e^0_{r,0}, ..., e^0_{r,n_r-1}]$ respectively, where $e \in \mathbb{R}^d$ denotes a d-dimension word embedding.

A representation module then starts to construct semantic representations at different granularities for u_i and r. Practically, L identical layers of self-attention are hierarchically stacked, each l^{th} self-attention layer takes the output of the $l-1^{th}$ layer as its input, and composites the input semantic vectors into more sophisticated representations based on self-attention. In this way, multi-grained representations of u_i and r are gradually constructed, denoted as $[\mathbf{U}^l_i]^L_{l=0}$ and $[\mathbf{R}^l]^L_{l=0}$ respectively.

Given $[\mathbf{U}^0_i, ..., \mathbf{U}^L_i]$ and $[\mathbf{R}^0, ..., \mathbf{R}^L]$, utterance u_i and response r are then matched with each other in a manner of segment-segment similarity matrix. Practically, for each granularity $l \in [0...L]$, two kinds of matching matrixes are constructed, i.e., the self-attention-match $\mathbf{M}^{u_i,r,l}_{self}$ and cross-attention-match $\mathbf{M}^{u_i,r,l}_{cross}$, measuring the relevance between utterance and response with textual information and dependency information respectively.

Those matching scores are finally merged into a 3D matching image $\mathbf{Q}$[1]. Each dimension of $\mathbf{Q}$ represents *each utterance in context*, *each word in utterance* and *each word in response* respectively. Important matching information between segment pairs across multi-turn context and candidate response is then extracted via convolution with max-pooling operations, and further fused into one matching score via a single-layer perceptron, representing the matching degree between the response candidate and the whole context.

Specifically, we use a shared component, the Attentive Module, to implement both self-attention in representation and cross-attention in matching. We will discuss in detail the implementation of Attentive Module and how we used it to implement both self-attention and cross-attention in following sections.

3.3 Attentive Module

Figure 3 shows the structure of Attentive Module, which is similar to that used in Transformer (Vaswani et al., 2017). Attentive Module has three input sentences: the query sentence, the key sentence and the value sentence, namely $\mathcal{Q} = [e_i]^{n_\mathcal{Q}-1}_{i=0}, \mathcal{K} = [e_i]^{n_\mathcal{K}-1}_{i=0}, \mathcal{V} = [e_i]^{n_\mathcal{V}-1}_{i=0}$ respectively, where $n_\mathcal{Q}$, $n_\mathcal{K}$ and $n_\mathcal{V}$ denote the number of words in each sentence and e_i stands for a d-dimension embedding, $n_\mathcal{K}$ is equal to $n_\mathcal{V}$. The Attentive Module first takes each word in the query sentence to attend to words in the key sentence via Scaled Dot-Product Attention (Vaswani et al., 2017), then applies those attention results upon the value sentence, which is defined as:

[1]We refer to it as **Q** because it is like a cube.

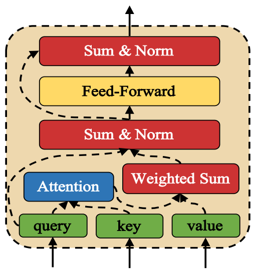

Figure 3: Attentive Module.

$$Att(\mathcal{Q}, \mathcal{K}) = \left[softmax\left(\frac{\mathcal{Q}[i] \cdot \mathcal{K}^T}{\sqrt{d}}\right)\right]^{n_\mathcal{Q}-1}_{i=0} \quad (1)$$

$$\mathcal{V}_{att} = Att(\mathcal{Q}, \mathcal{K}) \cdot \mathcal{V} \in \mathbb{R}^{n_\mathcal{Q} \times d} \quad (2)$$

where $\mathcal{Q}[i]$ is the i^{th} embedding in the query sentence $\mathcal{Q}$. Each row of $\mathcal{V}_{att}$, denoted as $\mathcal{V}_{att}[i]$, stores the fused semantic information of words in the value sentence that possibly have dependencies to the i^{th} word in query sentence. For each i, $\mathcal{V}_{att}[i]$ and $\mathcal{Q}[i]$ are then added up together, compositing them into a new representation that contains their joint meanings. A layer normalization operation (Ba et al., 2016) is then applied, which prevents vanishing or exploding of gradients. A feed-forward network **FFN** with RELU (LeCun et al., 2015) activation is then applied upon the normalization result, in order to further process the fused embeddings, defined as:

$$\mathbf{FFN}(x) = max(0, xW_1 + b_1)W_2 + b_2 \quad (3)$$

where, x is a 2D-tensor in the same shape of query sentence $\mathcal{Q}$ and W_1, b_1, W_2, b_2 are learnt parameters. This kind of activation is empirically useful in other works, and we also adapt it in our model. The result $\mathbf{FFN}(x)$ is a 2D-tensor that has the same shape as x, $\mathbf{FFN}(x)$ is then residually added (He et al., 2016) to x, and the fusion result is then normalized as the final outputs. We refer to the whole Attentive Module as:

$$\mathbf{AttentiveModule}(\mathcal{Q}, \mathcal{K}, \mathcal{V}) \quad (4)$$

As described, Attentive Module can capture dependencies across query sentence and key sentence, and further use the dependency information to composite elements in the query sentence and the value sentence into compositional representations. We exploit this property of the Attentive Module to construct multi-grained semantic representations as well as match with dependency information.

3.4 Representation

Given $\mathbf{U}_i^0$ or $\mathbf{R}^0$, the word-level embedding representations for utterance u_i or response r, DAM takes $\mathbf{U}_i^0$ ro $\mathbf{R}^0$ as inputs and hierarchically stacks the Attentive Module to construct multi-grained representations of u_i and r, which is formulated as:

$$\mathbf{U}_i^{l+1} = \textbf{AttentiveModule}(\mathbf{U}_i^l, \mathbf{U}_i^l, \mathbf{U}_i^l) \quad (5)$$

$$\mathbf{R}^{l+1} = \textbf{AttentiveModule}(\mathbf{R}^l, \mathbf{R}^l, \mathbf{R}^l) \quad (6)$$

where l ranges from 0 to $L-1$, denoting the different levels of granularity. By this means, words in each utterance or response repeatedly function together to composite more and more holistic representations, we refer to those multi-grained representations as $[\mathbf{U}_i^0, ..., \mathbf{U}_i^L]$ and $[\mathbf{R}^0, ..., \mathbf{R}^L]$ hereafter.

3.5 Utterance-Response Matching

Given $[\mathbf{U}_i^l]_{l=0}^L$ and $[\mathbf{R}^l]_{l=0}^L$, two kinds of segment-segment matching matrixes are constructed at each level of granularity l, i.e., the self-attention-match $\mathbf{M}_{self}^{u_i,r,l}$ and cross-attention-match $\mathbf{M}_{cross}^{u_i,r,l}$. $\mathbf{M}_{self}^{u_i,r,l}$ is defined as:

$$\mathbf{M}_{self}^{u_i,r,l} = \{\mathbf{U}_i^l[k]^T \cdot \mathbf{R}^l[t]\}_{n_{u_i} \times n_r} \quad (7)$$

in which, each element in the matrix is the dot-product of $\mathbf{U}_i^l[k]$ and $\mathbf{R}^l[t]$, the k^{th} embedding in $\mathbf{U}_i^l$ and the t^{th} embedding in $\mathbf{R}^l$, reflecting the textual relevance between the k^{th} segment in u_i and t^{th} segment in r at the l^{th} granularity. The cross-attention-match matrix is based on cross-attention, which is defined as:

$$\widetilde{\mathbf{U}}_i^l = \textbf{AttentiveModule}(\mathbf{U}_i^l, \mathbf{R}^l, \mathbf{R}^l) \quad (8)$$

$$\widetilde{\mathbf{R}}^l = \textbf{AttentiveModule}(\mathbf{R}^l, \mathbf{U}_i^l, \mathbf{U}_i^l) \quad (9)$$

$$\mathbf{M}_{cross}^{u_i,r,l} = \{\widetilde{\mathbf{U}}_i^l[k]^T \cdot \widetilde{\mathbf{R}}^l[t]\}_{n_{u_i} \times n_r} \quad (10)$$

where we use Attentive Module to make $\mathbf{U}_i^l$ and $\mathbf{R}^l$ crossly attend to each other, constructing two new representations for both of them, written as $\widetilde{\mathbf{U}}_i^l$ and $\widetilde{\mathbf{R}}^l$ respectively. Both $\widetilde{\mathbf{U}}_i^l$ and $\widetilde{\mathbf{R}}^l$ implicitly capture semantic structures that cross the utterance and response. In this way, those inter-dependent segment pairs are close to each other in representations, and dot-products between those latently inter-dependent pairs could get increased, providing dependency-aware matching information.

3.6 Aggregation

DAM finally aggregates all the segmental matching degrees across each utterance and response into a 3D matching image $\mathbf{Q}$, which is defined as:

$$\mathbf{Q} = \{\mathbb{Q}_{i,k,t}\}_{n \times n_{u_i} \times n_r} \quad (11)$$

where each pixel $\mathbb{Q}_{i,k,t}$ is formulated as:

$$\mathbb{Q}_{i,k,t} = [\mathbf{M}_{self}^{u_i,r,l}[k,t]]_{l=0}^L \oplus [\mathbf{M}_{cross}^{u_i,r,l}[k,t]]_{l=0}^L \quad (12)$$

$\oplus$ is concatenation operation, and each pixel has $2(L+1)$ channels, storing the matching degrees between one certain segment pair at different levels of granularity. DAM then leverages two-layered 3D convolution with max-pooling operations to distill important matching features from the whole image. The operation of 3D convolution with max-pooling is the extension of typical 2D convolution, whose filters and strides are 3D cubes[2]. We finally compute matching score $g(c,r)$ based on the extracted matching features $f_{match}(c,r)$ via a single-layer perceptron, which is formulated as:

$$g(c,r) = \sigma(W_3 f_{match}(c,r) + b_3) \quad (13)$$

where W_3 and b_3 are learnt parameters, and σ is sigmoid function that gives the probability if r is a proper candidate to c. The loss function of DAM is the negative log likelihood, defined as:

$$p(y|c,r) = g(c,r)y + (1-g(c,r))(1-y) \quad (14)$$

$$L(\cdot) = -\sum_{(c,r,y)\in\mathcal{D}} log(p(y|c,r)) \quad (15)$$

Table 1: Experimental results of DAM and other comparison approaches on Ubuntu Corpus V1 and Douban Conversation Corpus.

4.1 Dataset

We test DAM on two public multi-turn response selection datasets, the Ubuntu Corpus V1 (Lowe et al., 2015) and the Douban Conversation Corpus (Wu et al., 2017). The former one contains multi-turn dialogues about Ubuntu system troubleshooting in English and the later one is crawled from a Chinese social networking on open-domain topics. The Ubuntu training set contains 0.5 million multi-turn contexts, and each context has one positive response that generated by human and one negative response which is randomly sampled. Both validation and testing sets of Ubuntu Corpus have 50k contexts, where each context is provided with one positive response and nine negative replies. The Douban corpus is constructed in a similar way to the Ubuntu Corpus, except that its validation set contains 50k instances with 1:1 positive-negative ratios and the testing set of Douban corpus is consisted of 10k instances, where each context has 10 candidate responses, collected via a tiny inverted-index system (Lucene[3]), and labels are manually annotated.

4.2 Evaluation Metric

We use the same evaluation metrics as in previous works (Wu et al., 2017). Each comparison model is asked to select k best-matched response from n available candidates for the given conversation context c, and we calculate the recall of the true positive replies among the k selected ones as the main evaluation metric, denoted as $\mathbf{R}_n@k = \frac{\sum_{i=1}^{k} y_i}{\sum_{i=1}^{n} y_i}$, where y_i is the binary label for each candidate. In addition to $\mathbf{R}_n@k$, we use MAP (Mean Average Precision) (Baeza-Yates et al., 1999), MRR (Mean Reciprocal Rank) (Voorhees et al., 1999), and Precision-at-one $P@1$ especially for Douban corpus, following the setting of previous works (Wu et al., 2017).

4.3 Comparison Methods

RNN-based models : Previous best performing models are based on RNNs, we choose representative models as baselines, including SMN$_{dynamic}$(Wu et al., 2017), Multiview(Zhou et al., 2016), DualEncoder$_{lstm}$ and DualEncoder$_{bilstm}$ (Lowe et al., 2015), DL2R (Yan et al., 2016), Match-LSTM (Wang and Jiang, 2017) and MV-LSTM (Pang et al., 2016), where SMN$_{dynamic}$ achieves the best scores against all the other published works, and we take it as our state-of-the-art baseline.

Ablation : To verify the effects of multi-grained representation, we setup two comparison models, i.e., DAM$_{first}$ and DAM$_{last}$, which dispense with the multi-grained representations in DAM, and use representation results from the 0th layer and Lth layer of self-attention instead. Moreover, we setup DAM$_{self}$ and DAM$_{cross}$, which only use self-attention-match or cross-attention-match respectively, in order to examine the effectiveness of both self-attention-match and cross-attention-match.

4.4 Model Training

We copy the reported evaluation results of all baselines for comparison. DAM is implemented in tensorflow[4], and the used vocabularies, word em-

[3]https://lucenent.apache.org/

[4]https://www.tensorflow.org. Our code and data will be available at https://github.com/baidu/Dialogue/DAM

bedding sizes for Ubuntu corpus and Douban corpus are all set as same as the SMN (Wu et al., 2017). We consider at most 9 turns and 50 words for each utterance (response) in our experiments, word embeddings are pre-trained using training sets via word2vec (Mikolov et al., 2013), similar to previous works. We use zero-pad to handle the variable-sized input and parameters in **FFN** are set to 200, same as word-embedding size. We test stacking 1-7 self-attention layers, and reported our results with 5 stacks of self-attention because it gains the best scores on validation set. The 1st convolution layer has 32 [3,3,3] filters with [1,1,1] stride, and its max-pooling size is [3,3,3] with [3,3,3] stride. The 2nd convolution layer has 16 [3,3,3] filters with [1,1,1] stride, and its max-pooling size is also [3,3,3] with [3,3,3] stride. We tune DAM and the other ablation models with adam optimizer (Le et al., 2011) to minimize loss function defined in Eq 15. Learning rate is initialized as 1e-3 and gradually decreased during training, and the batch-size is 256. We use validation sets to select the best models and report their performances on test sets.

4.5 Experiment Result

Table 1 shows the evaluation results of DAM as well as all comparison models. As demonstrated, DAM significantly outperforms other competitors on both Ubuntu Corpus and Douban Conversation Corpus, including SMN$_{dynamic}$, which is the state-of-the-art baseline, demonstrating the superior power of attention mechanism in matching response with multi-turn context. Besides, both the performances of DAM$_{first}$ and DAM$_{self}$ decrease a lot compared with DAM, which shows the effectiveness of self-attention and cross-attention. Both DAM$_{first}$ and DAM$_{last}$ underperform DAM, which demonstrates the benefits of using multi-grained representations. Also the absence of self-attention-match brings down the precision, as shown in DAM$_{cross}$, exhibiting the necessity of jointly considering textual relevance and dependency information in response selection.

One notable point is that, while DAM$_{first}$ is able to achieve close performance to SMN$_{dynamic}$, it is about 2.3 times faster than SMN$_{dynamic}$ in our implementation as it is very simple in computation. We believe that DAM$_{first}$ is more suitable to the scenario that has limitations in computation time or memories but requires high precise, such as industry application or working as an component in other neural networks like GANs.

5 Analysis

We use the Ubuntu Corpus for analyzing how self-attention and cross-attention work in DAM from both quantity analysis as well as visualization.

5.1 Quantity Analysis

We first study how DAM performs in different utterance number of context. The left part in Figure 4 shows the changes of $\mathbf{R}_{10}@1$ on Ubuntu Corpus across contexts with different number of utterance. As demonstrated, while being good at matching response with long context that has more than 4 utterances, DAM can still stably deal with short context that only has 2 turns.

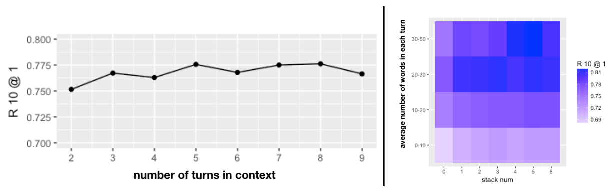

Figure 4: DAM's performance on Ubuntu Corpus across different contexts. The left part shows the performance in different utterance number of context. The right part shows performance in different average utterance text length of context as well as self-attention stack depth.

Moreover, the right part of Figure 4 gives the comparison of performance across different contexts with different average utterance text length and self-attention stack depth. As demonstrated, stacking self-attention can consistently improve matching performance for contexts having different average utterance text length, implying the stability advantage of using multi-grained semantic representations. The performance of matching short utterances, that have less than 10 words, is obviously lower than the other longer ones. This is because the shorter the utterance text is, the fewer information it contains, and the more difficult for selecting the next utterance, while stacking self-attention can still help in this case. However for long utterances like containing more than 30 words, stacking self-attention can significantly improve the matching performance, which means that the more information an utterance contains, the more stacked self-attention it needs to capture its intra semantic structures.

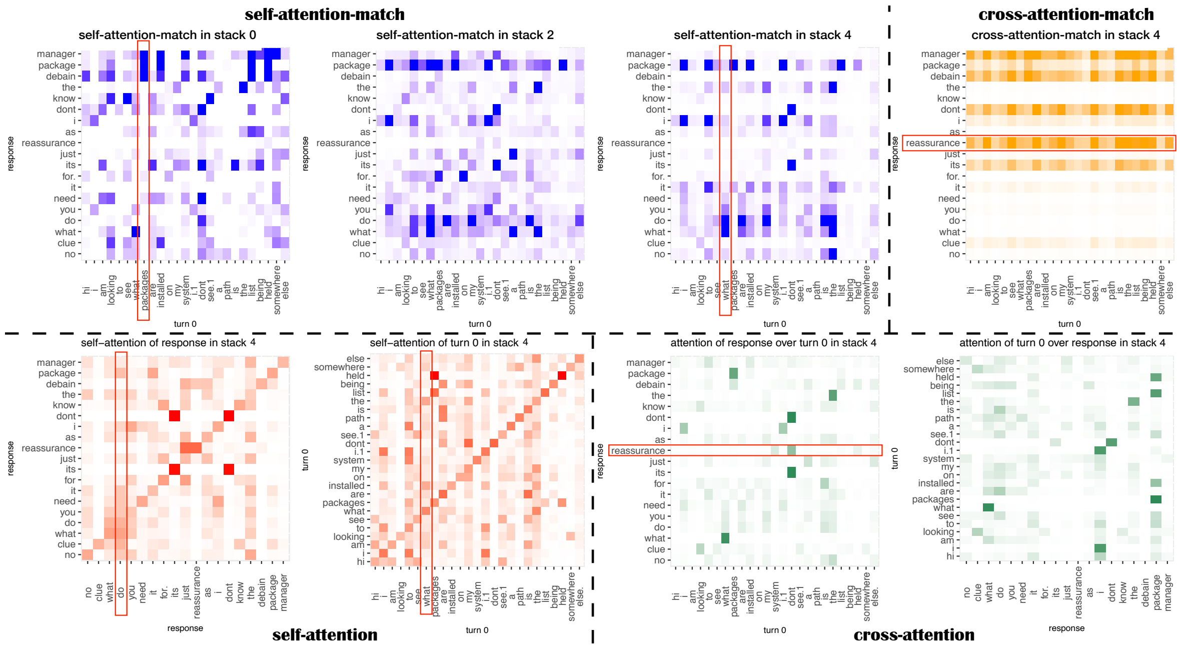

Figure 5: Visualization of self-attention-match, cross-attention-match as well as the distribution of self-attention and cross-attention in matching response with the first utterance in Figure 1. Each colored grid represents the matching degree or attention score between two words. The deeper the color is, the more important this grid is.

5.2 Visualization

We study the case in Figure 1 for analyzing in detail how self-attention and cross-attention work. Practically, we apply a softmax operation over self-attention-match and cross-attention-match, to examine the variance of dominating matching pairs during stacking self-attention or applying cross-attention. Figure 5 gives the visualization results of the 0th, 2nd and 4th self-attention-match matrixes, the 4th cross-attention-match matrix, as well as the distribution of self-attention and cross-attention in the 4th layer in matching response with the first utterance (turn 0) due to space limitation. As demonstrated, important matching pairs in *self-attention-match in stack 0* are nouns, verbs, like "package" and "packages", those are similar in topics. However matching scores between prepositions or pronouns pairs, such as "do" and "what", become more important in *self-attention-match in stack 4*. The visualization results of self-attention show the reason why matching between prepositions or pronouns matters, as demonstrated, self-attention generally capture the semantic structure of "no clue what do you need package manager" for "do" in response and "what packages are installed" for "what" in utterance, making segments surrounding "do" and "what" close to each other in representations, thus increases their dot-product results.

Also as shown in Figure 5, self-attention-match and cross-attention-match capture complementary information in matching utterance with response. Words like "reassurance" and "its" in response significantly get larger matching scores in cross-attention-match compared with self-attention-match. According to the visualization of cross-attention, "reassurance" generally depends on "system" "don't" and "held" in utterance, which makes it close to words like "list", "installed" or "held" of utterance. Scores of cross-attention-match trend to centralize on several segments, which probably means that those segments in response generally capture structure-semantic information across utterance and response, amplifying their matching scores against the others.

5.3 Error Analysis

To understand the limitations of DAM and where the future improvements might lie, we analyze 100 strong bad cases from test-set that fail in $\mathbf{R}_{10}$@5. We find two major kinds of bad cases: (1) **fuzzy-candidate**, where response candidates are basically proper for the conversation context, except for a few improper details. (2) **logical-error**, where response candidates are wrong due to logical mismatch, for example, given a conversation context **A:** "I just want to stay at home tomorrow.", **B:** "Why not go hiking? I can go with you.", response candidate like "Sure, I was planning to go out tomorrow." is logically wrong because it is contradictory to the first utterance of speaker A. We believe generating adversarial examples, rather than randomly sampling, during training procedure may be a good idea for addressing both **fuzzy-candidate** and **logical-error**, and to capture logic-level information hidden behind conversation text is also worthy to be studied in the future.

6 Conclusion

In this paper, we investigate matching a response with its multi-turn context using dependency information based entirely on attention. Our solution extends the attention mechanism of Transformer in two ways: (1) using stacked self-attention to harvest multi-grained semantic representations. (2) utilizing cross-attention to match with dependency information. Empirical results on two large-scale datasets demonstrate the effectiveness of self-attention and cross-attention in multi-turn response selection. We believe that both self-attention and cross-attention could benefit other research area, including spoken language understanding, dialogue state tracking or seq2seq dialogue generation. We would like to explore in depth how attention can help improve neural dialogue modeling for both chatbots and task-oriented dialogue systems in our future work.

Abstract

Generating emotional language is a key step towards building empathetic natural language processing agents. However, a major challenge for this line of research is the lack of large-scale labeled training data, and previous studies are limited to only small sets of human annotated sentiment labels. Additionally, explicitly controlling the emotion and sentiment of generated text is also difficult. In this paper, we take a more radical approach: we exploit the idea of leveraging Twitter data that are naturally labeled with emojis.

We collect a large corpus of Twitter conversations that include emojis in the response and assume the emojis convey the underlying emotions of the sentence. We investigate several conditional variational autoencoders training on these conversations, which allow us to use emojis to control the emotion of the generated text. Experimentally, we show in our quantitative and qualitative analyses that the proposed models can successfully generate high-quality abstractive conversation responses in accordance with designated emotions.

Figure 1: An example Twitter conversation with emoji in the response (top). We collected a large amount of these conversations, and trained a reinforced conditional variational autoencoder model to automatically generate abstractive emotional responses given any emoji.

1 Introduction

A critical research problem for artificial intelligence is to design intelligent agents that can perceive and generate human emotions. In the past decade, there has been significant progress in sentiment analysis (Pang et al., 2002, 2008; Liu, 2012) and natural language understanding—e.g., classifying the sentiment of online reviews. To build empathetic conversational agents, machines must also have the ability to learn to generate emotional sentences.

One of the major challenges is the lack of large-scale, manually labeled emotional text datasets. Due to the cost and complexity of manual annotation, most prior research studies primarily focus on small-sized labeled datasets (Pang et al., 2002; Maas et al., 2011; Socher et al., 2013), which are not ideal for training deep learning models with a large number of parameters.

In recent years, a handful of medium to large scale, emotional corpora in the area of emotion analysis (Go et al., 2016) and dialog (Li et al., 2017b) are proposed. However, all of them are limited to a traditional, small set of labels, for example, "happiness," "sadness," "anger," etc. or simply binary "positive" and "negative." Such coarse-grained classification labels make it difficult to capture the nuances of human emotion.

To avoid the cost of human annotation, we propose the use of naturally-occurring emoji-rich Twitter data. We construct a dataset using Twitter conversations with emojis in the response. The fine-grained emojis chosen by the users in the response can be seen as the natural label for the emotion of the response.

We assume that the emotions and nuances of emojis are established through the extensive usage by Twitter users. If we can create agents that are able to imitate Twitter users' language style when using those emojis, we claim that, to some extent, we have captured those emotions. Using a large collection of Twitter conversations, we then trained a conditional generative model to automatically generate the emotional responses. Figure 1 shows an example.

To generate emotional responses in dialogs, another technical challenge is to control the target emotion labels. In contrast to existing work (Huang et al., 2017) that uses information retrieval to generate emotional responses, the research question we are pursuing in this paper, is to design novel techniques that can generate abstractive responses of any given arbitrary emotions, without having human annotators to label a huge amount of training data.

To control the target emotion of the response, we investigate several encoder-decoder generation models, including a standard attention-based SEQ2SEQ model as the base model, and a more sophisticated CVAE model (Kingma and Welling, 2013; Sohn et al., 2015), as VAE is recently found convenient in dialog generation (Zhao et al., 2017).

To explicitly improve emotion expression, we then experiment with several extensions to the CVAE model, including a hybrid objective with policy gradient. The performance in emotion expression is automatically evaluated by a separate sentence-to-emoji classifier (Felbo et al., 2017). Additionally, we conducted a human evaluation to assess the quality of the generated emotional text.

Results suggest that our method is capable of generating state-of-the-art emotional text at scale. Our main contributions are three-fold:

- We provide a publicly available, large-scale dataset of Twitter conversation-pairs naturally labeled with fine-grained emojis.

- We are the first to use naturally labeled emojis for conducting large-scale emotional response generation for dialog.

- We apply several state-of-the-art generative models to train an emotional response generation system, and analysis confirms that our models deliver strong performance.

In the next section, we outline related work on sentiment analysis and emoji on Twitter data, as well as neural generative models. Then, we will introduce our new emotional research dataset and formalize the task. Next, we will describe the neural models we applied for the task. Finally, we will show automatic evaluation and human evaluation results, and some generated examples. Experiment details can be found in supplementary materials.

2 Related Work

In natural language processing, sentiment analysis (Pang et al., 2002) is an area that involves designing algorithms for understanding emotional text. Our work is aligned with some recent studies on using emoji-rich Twitter data for sentiment classification. Eisner et al. (2016) proposes a method for training emoji embedding EMOJI2VEC, and combined with word2vec (Mikolov et al., 2013), they apply the embeddings for sentiment classification. DeepMoji (Felbo et al., 2017) is closely related to our study: It makes use of a large, naturally labeled Twitter emoji dataset, and train an attentive bi-directional long short-term memory network (Hochreiter and Schmidhuber, 1997) model for sentiment analysis. Instead of building a sentiment classifier, our work focuses on generating emotional responses, given the context and the target emoji.

Our work is also in line with the recent progress of the application of Variational Autoencoder (VAE) (Kingma and Welling, 2013) in dialog generation. VAE (Kingma and Welling, 2013) encodes data in a probability distribution, and then samples from the distribution to generate examples. However, the original frameworks do not support end-to-end generation. Conditional VAE (CVAE) (Sohn et al., 2015; Larsen et al., 2015) was proposed to incorporate conditioning option in the generative process. Recent research in dialog generation shows that language generated by VAE models enjoy significantly greater diversity than traditional SEQ2SEQ models (Zhao et al., 2017), which is a preferable property toward building a true-to-life dialog agents.

In dialog research, our work aligns with recent advances in sequence-to-sequence models (Sutskever et al., 2014) using long short-term memory networks (Hochreiter and Schmidhuber, 1997). A slightly altered version of this model serves as our base model. Our modification enabled it to condition on single emojis. Li

Table 1: All 64 emoji labels, and number of conversations labeled by each emoji.

et al. (2016) use a reinforcement learning algorithm to improve the vanilla sequence-to-sequence model for non-task-oriented dialog systems, but their reinforced and its follow-up adversarial models (Li et al., 2017a) also do not model emotions or conditional labels. Zhao et al. (2017) recently introduced conditional VAE for dialog modeling, but neither did they model emotions in the conversations, nor explore reinforcement learning to improve results. Given a dialog history, Xie et. al.'s work recommends suitable emojis for current conversation. Xie et. al. (2016)compress the dialog history to vector representation through a hierarchical RNN and then map it to a emoji by a classifier, while in our model, the representation for original tweet, combined with the emoji embedding, is used to generate a response.

3 Dataset

We start by describing our dataset and approaches to collecting and processing the data. Social media is a natural source of conversations, and people use emojis extensively within their posts. However, not all emojis are used to express emotion and frequency of emojis are unevenly distributed. Inspired by DeepMoji (Felbo et al., 2017), we use 64 common emojis as labels (see Table 1), and collect a large corpus of Twitter conversations containing those emojis. Note that emojis with the difference only in skin tone are considered the same emoji.

Before: @amy ❤️ miss you soooo much!!! 😭 😭😭

After: ❤️ miss you soo much! 😭

Label: 😭

Figure 2: An artificial example illustrating preprocess procedure and choice of emoji label. Note that emoji occurrences in responses are counted before the deduplication process.

3.1 Data Collection

We crawled conversation pairs consisting of an original post and a response on Twitter from 12th to 14th of August, 2017. The response to a conversation must include at least one of the 64 emoji labels. Due to the limit of Twitter streaming API, tweets are filtered on the basis of words. In our case, a tweet can be reached only if at least one of the 64 emojis is used as a word, meaning it has to be a single character separated by blank space. However, this kind of tweets is arguably cleaner, as it is often the case that this emoji is used to wrap up the whole post and clusters of repeated emojis are less likely to appear in such tweets.

For both original tweets and responses, only English tweets without multimedia contents (such as URL, image or video) are allowed, since we assume that those contents are as important as the text itself for the machine to understand the conversation. If a tweet contains less than three alphabetical words, the conversation is not included in the dataset.

3.2 Emoji Labeling

Then we label responses with emojis. If there are multiple types of emoji in a response, we use the emoji with most occurrences inside the response. Among those emojis with same occurrences, we choose the least frequent one across the whole corpus, on the hypothesis that less frequent tokens better represent what the user wants to express. See Figure 2 for example.

3.3 Data Preprocessing

During preprocessing, all mentions and hashtags are removed, and punctuation[1] and emojis are separated if they are adjacent to words. Words with digits are all treated as the same special token.

In some cases, users use emojis and symbols in a cluster to express emotion extensively. To normalize the data, words with more than two repeated letters, symbol strings of more than one repeated punctuation symbols or emojis are shortened, for example, '!!!!' is shortened to '!', and 'yessss' to 'yess'. Note that we do not reduce duplicate letters completely and convert the word to the 'correct' spelling ('yes' in the example) since the length of repeated letters represents the intensity of emotion. By distinguishing 'yess' from 'yes', the emotional intensity is partially preserved in our dataset.

Then all symbols, emojis, and words are tokenized. Finally, we build a vocabulary of size 20K according to token frequency. Any tokens outside the vocabulary are replaced by the same special token.

We randomly split the corpus into 596,959 /32,600/32,600 conversation pairs for train /validation/test set[2]. Distribution of emoji labels within the corpus is presented in Table 1.

4 Generative Models

In this work, our goal is to generate emotional responses to tweets with the emotion specified by an emoji label. We assembled several generative models and trained them on our dataset.

4.1 Base: Attention-Based Sequence-to-Sequence Model

Traditional studies use deep recurrent architecture and encoder-decoder models to generate conversation responses, mapping original texts to target responses. Here we use a sequence-to-sequence (SEQ2SEQ) model (Sutskever et al., 2014) with global attention mechanism (Luong et al., 2015) as our base model (See Figure 3).

We use randomly initialized embedding vectors to represent each word. To specifically model the

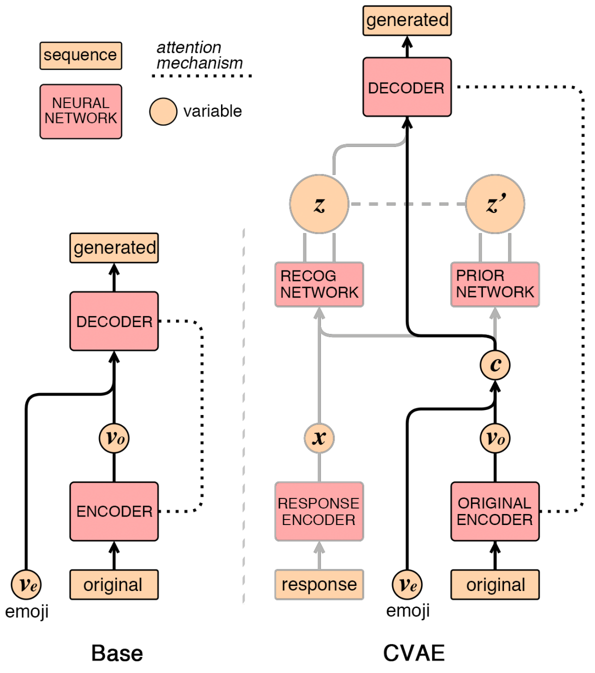

Figure 3: From bottom to top is a forward pass of data during training. **Left**: the base model encodes the original tweets in v_o, and generates responses by decoding from the concatenation of v_o and the embedded emoji, v_e. **Right**: In the CVAE model, all additional components (outlined in gray) can be added incrementally to the base model. A separate encoder encodes the responses in x. Recognition network inputs x and produces the latent variable z by reparameterization trick. During training, The latent variable z is concatenated with v_o and v_e and fed to the decoder.

emotion, we compute the embedding vector of the emoji label the same way as word embeddings. The emoji embedding is further reduced to smaller size vector v_e through a dense layer. We pass the embeddings of original tweets through a bidirectional RNN encoder of GRU cells (Schuster and Paliwal, 1997; Chung et al., 2014). The encoder outputs a vector v_o that represents the original tweet. Then v_o and v_e are concatenated and fed to a 1-layer RNN decoder of GRU cells. A response is then generated from the decoder.

4.2 Conditional Variational Autoencoder (CVAE)

Having similar encoder-decoder structures, SEQ2SEQ can be easily extended to a Conditional Variational Autoencoder (CVAE) (Sohn et al., 2015). Figure 3 illustrates the model: response encoder, recognition network, and prior network

[1]Emoticons (e.g. ':)', '(-:') are made of mostly punctuation marks. They are not examined in this paper. Common emoticons are treated as words during preprocessing.

[2]We will release the dataset with all tweets in its original form before preprocessing. To comply with Twitter's policy, we will include the tweet IDs in our release, and provide a script for downloading the tweets using the official API. No information of the tweet posters is collected.

are added on top of the SEQ2SEQ model. Response encoder has the same structure to original tweet encoder, but it has separate parameters. We use embeddings to represent Twitter responses and pass them through response encoder.

Mathematically, CVAE is trained by maximizing a variational lower bound on the conditional likelihood of x given c, according to:

$$p(x|c) = \int p(x|z,c)p(z|c)dz \tag{1}$$

z, c and x are random variables. z is the latent variable. In our case, the condition $c = [v_o; v_e]$, target x represents the response. Decoder is used to approximate $p(x|z,c)$, denoted as $p_D(x|z,c)$. Prior network is introduced to approximate $p(z|c)$, denoted as $p_P(z|c)$. Recognition network $q_R(z|x,c)$ is introduced to approximate true posterior $p(z|x,c)$ and will be absent during generation phase. By assuming that the latent variable has a multivariate Gaussian distribution with a diagonal covariance matrix, the lower bound to $\log p(x|c)$ can then be written by:

$$\begin{aligned}-\mathcal{L}(\theta_D,\theta_P,\theta_R;x,c) = \mathrm{KL}(q_R(z|x,c)||p_P(z|c))\\ -\mathbb{E}_{q_R(z|x,c)}(\log p_D(x|z,c))\end{aligned} \tag{2}$$

θ_D, θ_P, θ_R are parameters of those networks.

In recognition/prior network, we first pass the variables through an MLP to get the mean and log variance of z's distribution. Then we run a reparameterization trick (Kingma and Welling, 2013) to sample latent variables. During training, z by the recognition network is passed to the decoder and trained to approximate z' by the prior network. While during testing, the target response is absent, and z' by the prior network is passed to the decoder.

Our CVAE inherits the same attention mechanism from the base model connecting the original tweet encoder to the decoder, which makes our model deviate from previous works of CVAE on text data. Based on the attention memory as well as c and z, a response is finally generated from the decoder.

When handling text data, the VAE models that apply recurrent neural networks as the structure of their encoders/decoders may first learn to ignore the latent variable, and explain the data with the more easily optimized decoder. The latent variables lose its functionality, and the VAE deteriorates to a plain SEQ2SEQ model mathematically (Bowman et al., 2015). Some previous methods effectively alleviate this problem. Such methods are also important to keep a balance between the two items of the loss, namely KL loss and reconstruction loss. We use techniques of KL annealing, early stopping (Bowman et al., 2015) and bag-of-word loss (Zhao et al., 2017) in our models. The general loss with bag-of-word loss (see supplementary materials for details) is rewritten as:

$$\mathcal{L}' = \mathcal{L} + \mathcal{L}_{bow} \tag{3}$$

4.3 Reinforced CVAE

In order to further control the emotion of our generation more explicitly, we combine policy gradient techniques on top of the CVAE above and proposed Reinforced CVAE model for our task. We first train an emoji classifier on our dataset separately and fix its parameters thereafter. The classifier is used to produce reward for the policy training. It is a skip connected model of Bidirectional GRU-RNN layers (Felbo et al., 2017).

During the policy training, we first get the generated response x' by passing x and c through the CVAE, then feeding generation x' to classifier and get the probability of the emoji label as reward R. Let θ be parameters of our network, REINFORCE algorithm (Williams, 1992) is used to maximize the expected reward of generated responses:

$$\mathcal{J}(\theta) = \mathbb{E}_{p(x|c)}(R_\theta(x,c)) \tag{4}$$

The gradient of Equation 4 is approximated using the likelihood ratio trick (Glynn, 1990; Williams, 1992):

$$\nabla\mathcal{J}(\theta) = (R - r)\nabla\sum_{t}^{|x|}\log p(x_t|c, x_{1:t-1}) \tag{5}$$

r is the baseline value to keep estimate unbiased and reduce its variance. In our case, we directly pass x through emoji classifier and compute the probability of the emoji label as r. The model then encourages response generation that has $R > r$.

As REINFORCE objective is unrelated to response generation, it may make the generation model quickly deteriorate to some generic responses. To stabilize the training process, we propose two straightforward techniques to constrain the policy training:

1. Adjust rewards according to the position of the emoji label when all labels are ranked from high to low in order of the probability given by the emoji classifier. When the probability of the emoji label is of high rank among all possible emojis, we assume that the model has succeeded in emotion expression, thus there is no need to adjust parameters toward higher probability in this response. Modified policy gradient is written as:

$$\nabla \mathcal{J}'(\theta) = \alpha(R - r)\nabla \sum_{t}^{|x|} \log p(x_t|c, x_{1:t-1}) \tag{6}$$

   where $\alpha \in [0, 1]$ is a variant coefficient. The higher R ranks in all types of emoji label, the closer α is to 0.

2. Train Reinforced CVAE by a hybrid objective of REINFORCE and variational lower bound objective, learning towards both emotion accuracy and response appropriateness:

$$\mathbf{min}_{\theta}\mathcal{L}'' = \mathcal{L}' - \lambda\mathcal{J}' \tag{7}$$

   λ is a balancing coefficient, which is set to 1 in our experiments.

The algorithm outlining the training process of Reinforced CVAE can be found in the supplementary materials.

5 Experimental Results and Analyses

We conducted several experiments to finalize the hyper-parameters of our models (Table 2). During training, fully converged base SEQ2SEQ model is used to initialize its counterparts in CVAE models. Pretraining is vital to the success of our models since it is essentially hard for them to learn a latent variable space from total randomness. For more details, please refer to the supplementary materials.

In this section, we first report and analyze the general results of our models, including perplexity, loss and emotion accuracy. Then we take a closer look at the generation quality as well as our models' capability of expressing emotion.

5.1 General

To generally evaluate the performance of our models, we use generation perplexity and top-1/top-5 emoji accuracy on the test set. Perplexity indicates how much difficulty the model is having when generating responses. We also use top-5 emoji accuracy, since the meaning of different emojis may overlap with only a subtle difference. The machine may learn that similarity and give multiple possible labels as the answer.

Model	Perplexity	Emoji Accuracy Top1	Emoji Accuracy Top5
	Development		
Base	127.0	34.2%	57.6%
CVAE	37.1	40.7%	75.3%
Reinforced CVAE	38.1	42.2%	76.9%
	Test		
Base	130.6	33.9%	58.1%
CVAE	36.9	41.4%	75.1%
Reinforced CVAE	38.3	42.1%	77.3%

Table 2: Generation perplexity and emoji accuracy of the three models.

Note that we use the same emoji classifier for evaluation. Its accuracy (see supplementary materials) may not seem perfect, but it is the state-of-the-art emoji classifier given so many classes. Also, it's reasonable to use the same classifier in training for automated evaluation, as is in (Hu et al., 2017). We can obtain meaningful results as long as the classifier is able to capture the semantic relationship between emojis (Felbo et al., 2017).

As is shown in Table 2, CVAE significantly reduces the perplexity and increases the emoji accuracy over base model. Reinforced CVAE also adds to the emoji accuracy at the cost of a slight increase in perplexity. These results confirm that proposed methods are effective toward the generation of emotional responses.

When converged, the KL loss is 27.0/25.5 for the CVAE/Reinforced CVAE respectively, and reconstruction loss 42.2/40.0. The models achieved a balance between the two items of loss, confirming that they have successfully learned a meaningful latent variable.

5.2 Generation Diversity

SEQ2SEQ generates in a monotonous way, as several generic responses occur repeatedly, while the generation of CVAE models is of much more diversity. To showcase this disparity, we calculated the type-token ratios of unigrams/bigrams/trigrams in generated responses as

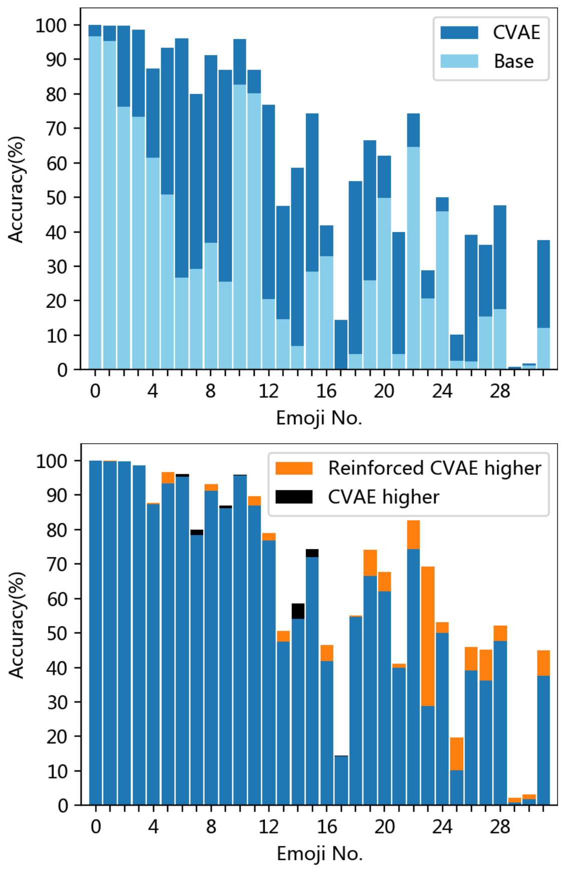

Figure 4: Top5 emoji accuracy of the first 32 emoji labels. Each bar represents an emoji and its length represents how many of all responses to the original tweets are top5 accurate. Different colors represent different models. Emojis are numbered in the order of frequencies in the dataset. No.0 is 😂, for instance, No.1 😭 and so on.
Top: CVAE v. Base.
Bottom: Reinforced CVAE v. CVAE. If Reinforced CVAE scores higher, the margin is marked in orange. If lower, in black.

the diversity score.

As shown in Table 3, results show that CVAE models beat the base models by a large margin. Diversity scores of Reinforced CVAE are reasonably compromised since it's generating more emotional responses.

5.3 Controllability of Emotions

There are potentially multiple types of emotion in reaction to an utterance. Our work makes it possible to generate a response to an arbitrary emotion by conditioning the generation on a specific type of emoji. In this section, we generate one response in reply to each original tweet in the dataset and condition on each emoji of the selected 64 emojis. We may have recorded some original tweets with different replies in the dataset, but an original tweet only need to be used once for each emoji, so we eliminate duplicate original tweets in the dataset. There are 30,299 unique original tweets in the test set.

Figure 4 shows the top-5 accuracy of each type of the first 32 emoji labels when the models generates responses from the test set conditioning on the same emoji. The results show that CVAE models increase the accuracy over every type of emoji label. Reinforced CVAE model sees a bigger increase on the less common emojis, confirming the effect of the emoji-specified policy training.

Model	Unigram	Bi-	Tri-
Base	0.0061	0.0199	0.0362
CVAE	0.0191	0.131	0.365
Reinforced CVAE	0.0160	0.118	0.337
Target responses	0.0353	0.370	0.757

Table 3: Type-token ratios of the generation by the three models. Scores of tokenized human-generated target responses are given for reference.

Setting	Model v. Base	Win	Lose	Tie
reply	CVAE	42.4%	43.0%	14.6%
reply	Reinforced CVAE	40.6%	39.6%	19.8%
emoji	CVAE	48.4%	26.2%	25.4%
emoji	Reinforced CVAE	50.0%	19.6%	30.4%

Table 4: Results of human evaluation. Tests are conducted pairwise between CVAE models and the base model.

5.4 Human Evaluation

We employed crowdsourced judges to evaluate a random sample of 100 items (Table 4), each being assigned to 5 judges on the Amazon Mechanical Turk. We present judges original tweets and generated responses. In the first setting of human evaluation, judges are asked to decide which one of the two generated responses better reply the original tweet. In the second setting, the emoji label is presented with the item discription, and judges are asked to pick one of the two generated responses that they decide better fits this emoji. (These two settings of evaluation are conducted separately so that it will not affect judges' verdicts.) Order of two generated responses under one item is permuted. Ties are permitted for an-

Content	sorry guys , was gunna stream tonight but i ’m still feeling like crap and my voice disappeared . i will make it up to you		
Target Emotion	😘	🙏	😢
Base	i ’m sorry you ’re going to be missed it	i ’m sorry for your loss	i ’m sorry you ’re going to be able to get it
CVAE	hope you are okay hun !	hi jason , i ’ll be praying for you	im sorry u better suck u off
Reinforced CVAE	hope you ’re feeling it	hope you had a speedy recovery man ! hope you feel better soon , please get well soon	dude i ’m so sorry for that i wanna hear it and i ’m sorry i can ’t go to canada with you but i wanna be away from canada
Content	add me in there my bro 🙏		
Target Emotion	😜	💪	💔
Base	i ’m not sure you ’ll be there	i ’m here for you	i ’m not ready for you
CVAE	you know , you need to tell me in your hometown !	you will be fine bro , i ’ll be in the gym for you	i can ’t wait 😔
Reinforced CVAE	you might have to get me hip hop off .	good luck bro ! this is about to be healthy	i ’m still undecided and i ’m still waiting
Content	don ’t tell me match of the day is delayed because of this shit		
Target Emotion	😂	👍	😞
Base	i ’m not even a fan of the game	i ’m not sure if you ever have any chance to talk to someone else	i ’m sorry i ’m not doubting you
CVAE	you can ’t do it bc you ’re in my mentions	see now a good point	hiya , unfortunately , it ’s not
Reinforced CVAE	oh my god i ’m saying this as long as i remember my twitter	fab mate , you ’ll enjoy the game and you ’ll get a win	it ’s the worst

Target Emotion	😊	😒	😞
Base	i ’m glad you enjoyed it	i ’m not gonna lie	i ’m sorry i ’m not laughing
CVAE	good ! have a good time	i don ’t plan on that	me too . but it ’s a lot of me .
Reinforced CVAE	thank you for your tweet , you didn ’t know how much i guess	that ’s a bad idea , u gotta hit me up on my phone	i feel bad at this and i hope you can make a joke

Table 5: Some examples from our generated emotional responses. Context is the original tweet, and target emotion is specified by the emoji. Following are the responses generated by each of the three models based on the context and the target emotion.

swers. We batch five items as one assignment and insert an item with two identical outputs as the sanity check. Anyone who failed to choose “tie” for that item is considered as a careless judge and is therefore rejected from our test.

We then conducted a simplified Turing test. Each item we present judges an original tweet, its reply by a human, and its response generated from Reinforced CVAE model. We ask judges to decide which of the two given responses is written by a human. Other parts of the setting are similar to above-mentioned tests. It turned out 18% of the test subjects mistakenly chose machine-generated responses as human written, and 27% stated that they were not able to distinguish between the two responses.

In regard of the inter-rater agreement, there are four cases. The ideal situation is that all five judges choose the same answer for a item, and in the worst-case scenario, at most two judges choose the same answer. In light of this, we have counted that 32%/33%/31%/5% of all items have 5/4/3/2 judges in agreement, showing that our experiment has a reasonably reliable inter-rater agreement.

5.5 Case Study

We sampled some generated responses from all three models, and list them in Figure 5. Given an original tweet, we would like to generate responses with three different target emotions.

SEQ2SEQ only chooses to generate most frequent expressions, forming a predictable pattern for its generation (See how every sampled response by the base model starts with "I'm"). On the contrary, generation from the CVAE model is diverse, which is in line with previous quantitative analysis. However, the generated responses are sometimes too diversified and unlikely to reply to the original tweet.

Reinforced CVAE somtetimes tends to generate a lengthy response by stacking up sentences (See the responses to the first tweet when conditioning on the 'folded hands' emoji and the 'sad face' emoji). It learns to break the length limit of sequence generation during hybrid training, since the variational lower bound objective is competing with REINFORCE objective. The situation would be more serious is λ in Equation 7 is set higher. However, this phenomenon does not impair the fluency of generated sentences, as can be seen in Figure 5.

6 Conclusion and Future Work

In this paper, we investigate the possibility of using naturally annotated emoji-rich Twitter data for emotional response generation. More specifically, we collected more than half a million Twitter conversations with emoji in the response and assumed that the fine-grained emoji label chosen by the user expresses the emotion of the tweet. We applied several state-of-the-art neural models to learn a generation system that is capable of giving a response with an arbitrarily designated emotion. We performed automatic and human evaluations to understand the quality of generated responses. We trained a large scale emoji classifier and ran the classifier on the generated responses to evaluate the emotion accuracy of the generated response. We performed an Amazon Mechanical Turk experiment, by which we compared our models with a baseline sequence-to-sequence model on metrics of relevance and emotion. Experimentally, it is shown that our model is capable of generating high-quality emotional responses, without the need of laborious human annotations. Our work is a crucial step towards building intelligent dialog agents. We are also looking forward to transferring the idea of naturally-labeled emojis to task-oriented dialog and multi-turn dialog generation problems. Due to the nature of social media text, some emotions, such as fear and disgust, are underrepresented in the dataset, and the distribution of emojis is unbalanced to some extent. We will keep accumulating data and increase the ratio of underrepresented emojis, and advance toward more sophisticated abstractive generation methods.

Abstract

Taylor's law describes the fluctuation characteristics underlying a system in which the variance of an event within a time span grows by a power law with respect to the mean. Although Taylor's law has been applied in many natural and social systems, its application for language has been scarce. This article describes a new quantification of Taylor's law in natural language and reports an analysis of over 1100 texts across 14 languages. The Taylor exponents of written natural language texts were found to exhibit almost the same value. The exponent was also compared for other language-related data, such as the child-directed speech, music, and programming language code. The results show how the Taylor exponent serves to quantify the fundamental structural complexity underlying linguistic time series. The article also shows the applicability of these findings in evaluating language models.

1 Introduction

Taylor's law characterizes how the variance of the number of events for a given time and space grows with respect to the mean, forming a power law. It is a quantification method for the clustering behavior of a system. Since the pioneering studies of this concept (Smith, 1938; Taylor, 1961), a substantial number of studies have been conducted across various domains, including ecology, life science, physics, finance, and human dynamics, as well summarized in (Eisler, Bartos, and Kertész, 2007).

[*]kobayashi@cl.rcast.u-tokyo.ac.jp
[†]kumiko@cl.rcast.u-tokyo.ac.jp

More recently, Cohen and Xu (2015) reported Taylor exponents for random sampling from various distributions, and Calif and Schmitt (2015) reported Taylor's law in wind energy data using a non-parametric regression. Those two papers also refer to research about Taylor's law in a wide range of fields.

Despite such diverse application across domains, there has been little analysis based on Taylor's law in studying natural language. The only such report, to the best of our knowledge, is Gerlach and Altmann (2014), but they measured the mean and variance by means of the vocabulary size within a document. This approach essentially differs from the original concept of Taylor analysis, which fundamentally counts the number of events, and thus the theoretical background of Taylor's law as presented in Eisler, Bartos, and Kertész (2007) cannot be applied to interpret the results.

For the work described in this article, we applied Taylor's law for texts, in a manner close to the original concept. We considered lexical fluctuation within texts, which involves the co-occurrence and burstiness of word alignment. The results can thus be interpreted according to the analytical results of Taylor's law, as described later. We found that the Taylor exponent is indeed a characteristic of texts and is universal across various kinds of texts and languages. These results are shown here for data including over 1100 single-author texts across 14 languages and large-scale newspaper data.

Moreover, we found that the Taylor exponents for other symbolic sequential data, including child-directed speech, programming language code, and music, differ from those for written natural language texts, thus distinguishing different kinds of data sources. The Taylor exponent in this sense could categorize and quantify the structural complexity of language. The Chomsky hierarchy (Chomsky, 1956) is, of course, the most important framework for such categorization. The Taylor exponent is another way to quantify the complexity of natural language: it allows for continuous quantification based on lexical fluctuation.

Since the Taylor exponent can quantify and characterize one aspect of natural language, our findings are applicable in computational linguistics to assess language models. At the end of this article, in §5, we report how the most basic character-based long short-term memory (LSTM) unit produces texts with a Taylor exponent of 0.50, equal to that of a sequence of independent and identically distributed random variables (an i.i.d. sequence). This shows how such models are limited in producing consistent co-occurrence among words, as compared with a real text. Taylor analysis thus provides a possible direction to reconsider the limitations of language models.

2 Related Work

This work can be situated as a study to quantify the complexity underlying texts. As summarized in (Tanaka-Ishii and Aihara, 2015), measures for this purpose include the entropy rate (Takahira, Tanaka-Ishii, and Lukasz, 2016; Bentz et al., 2017) and those related to the scaling behaviors of natural language. Regarding the latter, certain power laws are known to hold universally in linguistic data. The most famous among these are Zipf's law (Zipf, 1965) and Heaps' law (Heaps, 1978). Other, different kinds of power laws from Zipf's law are obtained through various methods of fluctuation analysis, but the question of how to quantify the fluctuation existing in language data has been controversial. Our work is situated as one such case of fluctuation analysis.

In real data, the occurrence timing of a particular event is often biased in a bursty, clustered manner, and fluctuation analysis quantifies the degree of this bias. Originally, this was motivated by a study of how floods of the Nile River occur in clusters (i.e., many floods coming after an initial flood) (Hurst, 1951). Such clustering phenomena have been widely reported in both natural and social domains (Eisler, Bartos, and Kertész, 2007).

Fluctuation analysis for language originates in (Ebeling and Pöeschel, 1994), which applied the approach to characters. That work corresponds to observing the average of the variances of each character's number of occurrences within a time span. Their method is strongly related to ours but different from two viewpoints: (1) Taylor analysis considers the variance with respect to the mean, rather than time; and (2) Taylor analysis does not average results over all elements. Because of these differences, the method in (Ebeling and Pöeschel, 1994) cannot distinguish real texts from an i.i.d. process when applied to word sequences (Takahashi and Tanaka-Ishii, 2018).

Event clustering phenomena cause a sequence to resemble itself in a self-similar manner. Therefore, studies of the fluctuation underlying a sequence can take another form of *long-range correlation analysis*, to consider the similarity between two subsequences underlying a time series. This approach requires a function to calculate the similarity of two sequences, and the autocorrelation function (ACF) is the main function considered. Since the ACF only applies to numerical data, both Altmann, Pierrehumbert, and Motter (2009) and Tanaka-Ishii and Bunde (2016) applied long-range correlation analysis by transforming text into intervals and showed how natural language texts are long-range correlated. Another recent work (Lin and Tegmark, 2016) proposed using mutual information instead of the ACF. Mutual information, however, cannot detect the long-range correlation underlying texts. All these works studied correlation phenomena via only a few texts and did not show any underlying universality with respect to data and language types. One reason is that analysis methods for long-range correlation are nontrivial to apply to texts.

Overall, the analysis based on Taylor's law in the present work belongs to the former approach of fluctuation analysis and shows the law's vast applicability and stability for written texts and even beyond, quantifying universal complexity underlying human linguistic sequences.

3 Measuring the Taylor Exponent

3.1 Proposed method

Given a set of elements W (words), let $X = X_1, X_2, \ldots, X_N$ be a discrete time series of length N, where $X_i \in W$ for all $i = 1, 2, \ldots, N$, i.e., each X_i represents a word. For a given segment length $\Delta t \in \mathbb{N}$ (a positive integer), a data sample X is segmented by the length Δt. The number of occurrences of a specific word $w_k \in W$ is counted for every segment, and the mean μ_k and standard deviation σ_k across segments are obtained. Doing this for all word kinds $w_1, \ldots, w_{|W|} \in W$ gives the distribution of σ with respect to μ. Following a previous work (Eisler, Bartos, and Kertész, 2007), in this article Taylor's law is defined to hold when μ and σ are correlated by a power law in the following way:

$$\sigma \propto \mu^{\alpha}. \tag{1}$$

Experimentally, the Taylor exponent α is known to take a value within the range of $0.5 \leq \alpha \leq 1.0$ across a wide variety of domains as reported in (Eisler, Bartos, and Kertész, 2007), including finance, meteorology, agriculture, and biology. Mathematically, it is analytically proven that $\alpha = 0.5$ for an i.i.d process, and the proof is included as Supplementary Material.

On the other hand, $\alpha = 1.0$ when all segments *always contain the same proportion of the elements of* W. For example, suppose that $W = \{a, b\}$. If b always occurs twice as often as a in all segments (e.g., three a and six b in one segment, two a and four b in another, etc.), then both the mean and standard deviation for b are twice those for a, so the exponent is 1.0.

In a real text, this cannot occur for all W, so $\alpha < 1.0$ for natural language text. Nevertheless, for a subset of words in W, this could happen, especially for a template-like sequence. For instance, consider a programming statement: `while (i < 1000) do i-`. Here, the words `while` and `do` always occur once, whereas `i` always occurs twice. This example shows that the exponent indicates how consistently words depend on each other in W, i.e., how words co-occur systematically in a coherent manner, thus indicating that the Taylor exponent is partly related to grammaticality.

To measure the Taylor exponent α, the mean and standard deviation are computed for every word kind[1] and then plotted in log-log coordinates. The number of points in this work was the number of different words. We fitted the points to a linear function in log-log coordinates by the least-squares method. We naturally took the logarithm of both $c\mu^{\alpha}$ and σ to estimate the exponent, because Taylor's law is a power law. The coefficient $\hat{c}$, and exponent $\hat{\alpha}$ are then estimated as the following:

$$\begin{aligned} \hat{c}, \hat{\alpha} &= \arg\min_{c,\alpha} \epsilon(c, \alpha), \\ \epsilon(c, \alpha) &= \sqrt{\frac{1}{|W|}\sum_{k=1}^{|W|}(\log \sigma_k - \log c\mu_k^{\alpha})^2}. \end{aligned}$$

This fit function could be a problem depending on the distribution of errors between the data points and the regression line. As seen later, the error distribution seems to differ with the kind of data: for a random source the error seems Gaussian, and so the above formula is relevant, whereas for real data, the distribution is biased. Changing the fit function according to the data source, however, would cause other essential problems for fair comparison. Here, because Cohen and Xu (2015) reported that most empirical works on Taylor's law used least-squares regression (including their own), this work also uses the above scheme[2], with the error defined as $\epsilon(\hat{c}, \hat{\alpha})$.

3.2 Data

Table 1 lists all the data used for this article. The data consisted of natural language texts, language-related sequences, and randomized data, listed as different blocks in the table. The natural language texts consisted of 1142 single-author long texts (first block, extracted from Project Gutenberg and Aozora Bunko across 14 languages[3], with the second block listing individual samples taken from Project Gutenberg together with the complete works of Shakespeare), and newspapers (third block, from the Gigaword corpus, available from the Linguistic Data Consortium in English, Chinese, and other major languages). Other sequences appear in the fourth block: the enwiki8 100-MB dump dataset (consisting of tag-annotated text from English Wikipedia), the 10 longest child-directed speech utterances in CHILDES data[4] (preprocessed by extracting only children's utterances), four program sources (in Lisp, Haskell, C++, and Python, crawled from

[1] In this work, words are not lemmatized, e.g. "say," "said," and "says" are all considered different words. This was chosen so in this work because the Taylor exponent considers systematic co-occurrence of words, and idiomatic phrases should thus be considered in their original forms.

[2] The code for estimating the exponent is available from https://github.com/Group-TanakaIshii/word_taylor.

[3] All texts above a size threshold (1 megabyte) were extracted from the two archives, resulting in 1142 texts.

[4] Child Language Data Exchange System (MacWhinney, 2000; Bol, 1995; Lieven, Salomo, and Tomasello, 2009; Rondal, 1985; Behrens, 2006; Gil and Tadmor, 2007; Oshima-Takane et al., 1995; Smoczynska, 1985; Anđelković, Ševa, and Moskovljević, 2001; Benedet et al., 2004; Plunkett and Strömqvist, 1992)

Table 1: Data we used in this article. For each dataset, length is the number of words, vocabulary is the number of different words. For detail of the data kind, see §3.2.

large representative archives, parsed, and stripped of natural language comments), and 12 pieces of musical data (long symphonies and so forth, transformed from MIDI into text with the software SMF2MML[5], with annotations removed).

As for the randomized data listed in the last block, we took the text of *Moby Dick* and generated 10 different shuffled samples and bigram-generated sequences. We also introduced LSTM-generated texts to consider the utility of our findings, as explained in §5.

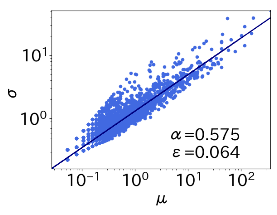
4 Taylor Exponents for Real Data

Figure 1 shows typical distributions for natural language texts, with two single-author texts ((a) and (b)) and two multiple-author texts (newspapers, (c) and (d)), in English and Chinese, respectively. The segment size was $\Delta t = 5620$ words[6], i.e., each segment had 5620 words and the horizontal axis indicates the averaged frequency of a specific word within a segment of 5620 words.

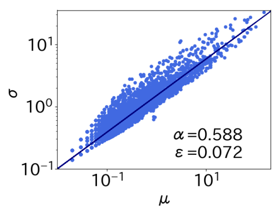
The points at the upper right represent the most frequent words, whereas those at the lower left represent the least frequent. Although the plots exhibited different distributions, they could globally be considered roughly aligned in a power-law

[5]`http://shaw.la.coocan.jp/smf2mml/`

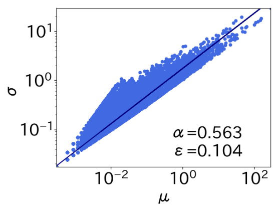
[6] In comparison, Figure 6 shows the effect on the exponent of varying Δt. As seen in that figure, larger Δt increased the differences in exponent among different data sets, making the differences more distinguishable. Thus, Δt had better be as large as possible while keeping μ and σ computable. For this article, we chose $\Delta t = 5620$, which was one of the Δt values used in Figure 6.



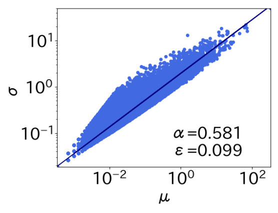
(a) Moby Dick



(b) Hong Lou Meng



(c) Wall Street Journal



(d) People's Daily

Figure 1: Examples of Taylor's law for natural language texts. *Moby Dick* and *Hong Lou Meng* are representative of single-author texts, and the two newspapers are representative of multiple-author texts, in English and Chinese, respectively. Each point represents a kind of word. The values of σ and μ for each word kind are plotted across texts within segments of size $\Delta t = 5620$. The Taylor exponents obtained by the least-squares method were all around 0.58.

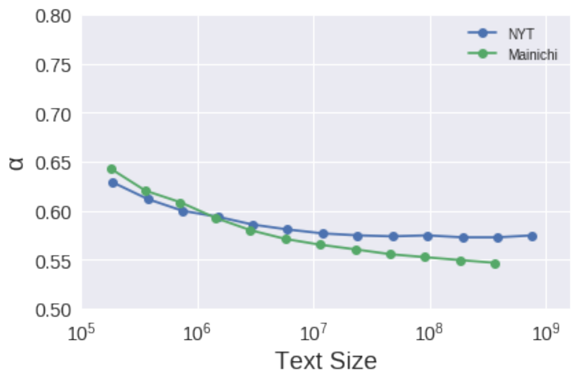


Figure 2: Taylor exponent $\hat{\alpha}$ (vertical axis) calculated for the two largest texts: The New York Times and The Mainichi newspapers. To evaluate the exponent's dependence on the text size, parts of each text were taken and the exponents were calculated for those parts, with points taken logarithmically. The window size was $\Delta t = 5620$. As the text size grew, the Taylor exponent slightly decreased.

manner. This finding is non-trivial, as seen in other analyses based on Taylor's law (Eisler, Bartos, and Kertész, 2007). The exponent α was almost the same even though English and Chinese are different languages using different kinds of script.

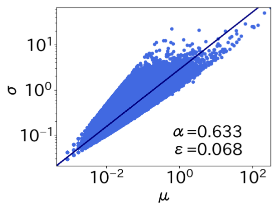
As explained in §3.1, the Taylor exponent indicates the degree of consistent co-occurrence among words. The value of 0.58 obtained here suggests that the words of natural language texts are not strongly or consistently coherent with respect to each other. Nevertheless, the value is well above 0.5, and for the real data listed in Table 1 (first to third blocks), not a single sample gave an exponent as low as 0.5.

Although the overall global tendencies in Figure 1 followed power laws, many points deviated significantly from the regression lines. The words with the greatest fluctuation were often keywords. For example, among words in *Moby Dick* with large μ, those with the largest σ included *whale*, *captain*, and *sailor*, whereas those with the smallest σ included functional words such as *to*, *that*, and *with*.

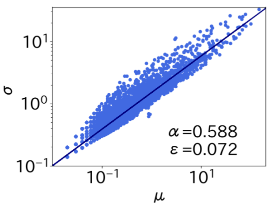
The Taylor exponent depended only slightly on the data size. Figure 2 shows this dependency for the two largest data sets used, The New York Times (NYT, 1.5 billion words) and The Mainichi (24 years) newspapers. When the data size was increased, the exponent exhibited a slight tendency to decrease. For the NYT, the decrease seemed to have a lower limit, as the figure shows that the exponent stabilized at around 10^7 words.

The reason for this decrease can be explained as follows. The Taylor exponent becomes larger when some words occur in a clustered manner. Making the text size larger increases the number of segments (since Δt was fixed in this experiment). If the number of clusters does not increase as fast as the increase in the number of segments, then the number of clusters per segment becomes smaller, leading to a smaller exponent. In other words, the influence of each consecutive co-occurrence of a particular word decays slightly as the overall text size grows.

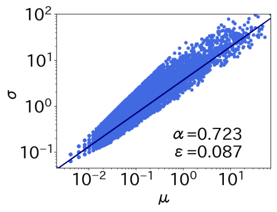
Analysis of different kinds of data showed how the Taylor exponent differed according to the data source. Figure 3 shows plots for samples from enwiki8 (tagged Wikipedia), the child-directed speech of Thomas (taken from CHILDES), programming language data sets, and music. The distributions appear different from those for the natural language texts, and the exponents were significantly larger. This means that these data sets contained expressions with fixed forms much more frequently than did the natural language texts.



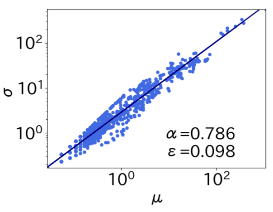
(a) enwiki8 (Wikipedia, tagged)



(b) Thomas (CHILDES)



(c) Lisp



(d) Bach's *St Matthew Passion*

Figure 3: Examples of Taylor's law for alternative data sets listed in Table 1: enwiki8 (tag-annotated Wikipedia), Thomas (longest in CHILDES), Lisp source code, and the music of Bach's *St Matthew Passion*. These examples exhibited larger Taylor exponents than did typical natural language texts.

Figure 4 summarizes the overall picture among the different data sources. The median and quantiles of the Taylor exponent were calculated for the different kinds of data listed in Table 1. The first two boxes show results with an exponent of 0.50. These results were each obtained from 10 random samples of the randomized sequences. We will return to these results in the next section.

The remaining boxes show results for real data. The exponents for texts from Project Gutenberg ranged from 0.53 to 0.68. Figure 5 shows a histogram of these texts with respect to the value of $\hat{\alpha}$. The number of texts decreased significantly at a value of 0.63, showing that the distribution of the Taylor exponent was rather tight. The kinds of texts at the upper limit of exponents for Project Gutenberg included structured texts of fixed style, such as dictionaries, lists of histories, and Bibles.

The majority of texts were in English, followed by French and then other languages, as listed in Table 1. Whether α distinguishes languages is a difficult question. The histogram suggests that Chinese texts exhibited larger values than did texts in Indo-European languages. We conducted a statistical test to evaluate whether this difference was significant as compared to English. Since the numbers of texts were very different, we used the non-parametric statistical test of the Brunner-Munzel method, among various possible methods, to test a null hypothesis of whether α was equal for the two distributions (Brunner and Munzel, 2000). The p-value for Chinese was $p = 1.24 \times 10^{-16}$, thus rejecting the null hypothesis at the significance level of 0.01. This confirms that α was generally larger for Chinese texts than for English texts. Similarly, the null hypothesis was rejected for Finnish and French, but it was accepted for German and Japanese at the 0.01 significance level. Since Japanese was accepted despite its large difference from English, we could not conclude whether the Taylor exponent distinguishes languages.

Turning to the last four columns of Figure 4, representing the enwiki8, child-directed speech (CHILDES), programming language, and music data, the Taylor exponents clearly differed from those of the natural language texts. Given the template-like nature of these four data sources, the results were somewhat expected. The kind of data thus might be distinguishable using the Taylor exponent. To confirm this, however, would require assembling a larger data set. Applying this approach with Twitter data and adult utterances would produce interesting results and remains for our future work.

The Taylor exponent also differed according to Δt, and Figure 6 shows the dependence of $\hat{\alpha}$ on Δt. For each kind of data shown in Figure 4, the mean exponent is plotted for various Δt. As reported in (Eisler, Bartos, and Kertész, 2007), the exponent is known to grow when the segment size gets larger. The reason is that words occur in a bursty, clustered manner at all length scales: no matter how large the segment size becomes, a segment will include either many or few instances of a given word, leading to larger variance growth. This phenomenon suggests how word co-occurrences in natural language are self-similar. The Taylor exponent is initially 0.5 when the segment size is very small. This can be analytically explained as follows (Eisler, Bartos, and Kertész, 2007). Consider the case of Δt=1. Let n be the frequency of a particular word in a segment. We have $\langle n \rangle \ll 1.0$, because the possibility of a specific word appearing in a segment becomes very small. Because $\langle n \rangle^2 \approx 0$, $\sigma^2 = \langle n^2 \rangle - \langle n \rangle^2 \approx \langle n^2 \rangle$. Because $n = 1$ or 0 (with Δt=1), $\langle n^2 \rangle = \langle n \rangle = \mu$. Thus, $\sigma^2 \approx \mu$.

Overall, the results show the possibility of ap-

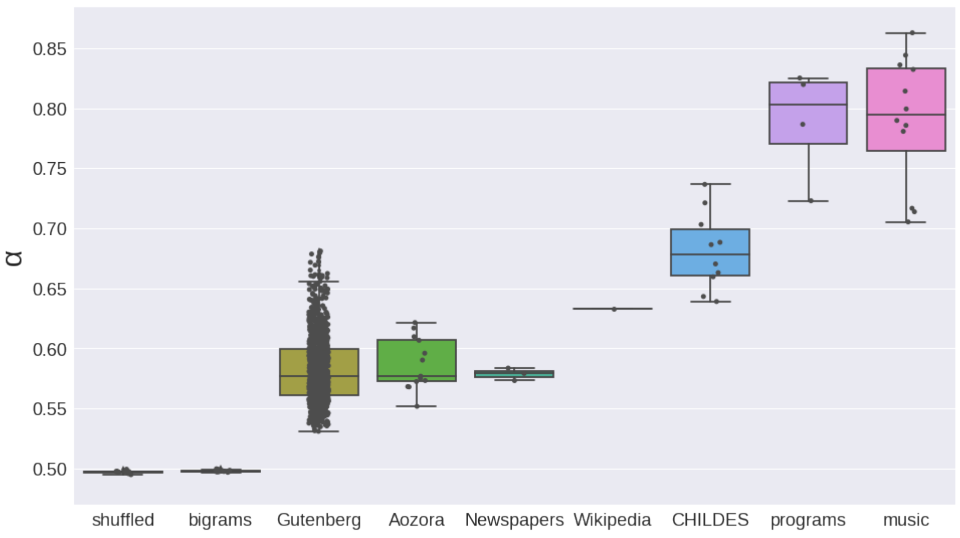


Figure 4: Box plots of the Taylor exponents for different kinds of data. Each point represents one sample, and samples from the same kind of data are contained in each box plot. The first two boxes are for the randomized data, while the remaining boxes are for real data, including both the natural language texts and language-related sequences. Each box ranges between the quantiles, with the middle line indicating the median, the whiskers showing the maximum and minimum, and some extreme values lying beyond.

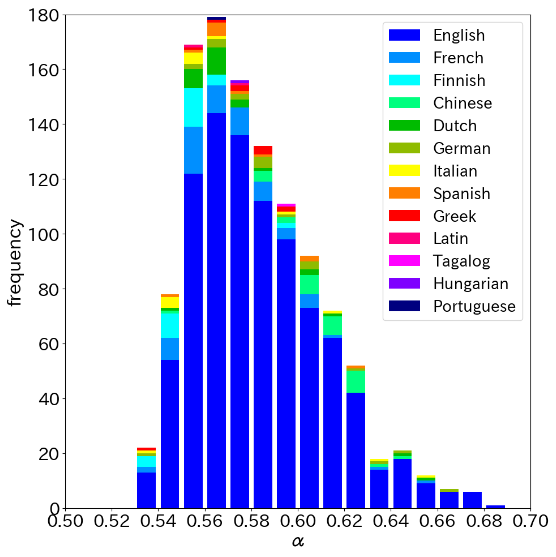

Figure 5: Histogram of Taylor exponents for long texts in Project Gutenberg (1129 texts). The legend indicates the languages, in frequency order. Each bar shows the number of texts with that value of $\hat{\alpha}$. Because of the skew of languages in the original conception of Project Gutenberg, the majority of the texts are in English, shown in blue, whereas texts in other languages are shown in other colors. The histogram shows how the Taylor exponent ranged fairly tightly around the mean, and natural language texts with an exponent larger than 0.63 were rare.

plying Taylor's exponent to quantify the complexity underlying coherence among words. Grammatical complexity was formalized by Chomsky via the Chomsky hierarchy (Chomsky, 1956), which describes grammar via rewriting rules. The constraints placed on the rules distinguish four different levels of grammar: regular, context-free, context-sensitive, and phrase structure. As indicated in (Badii and Politi, 1997), however, this does not quantify the complexity on a *continuous* scale. For example, we might want to quantify the complexity of child-directed speech as compared to that of adults, and this could be addressed in only a limited way through the Chomsky hierarchy. Another point is that the hierarchy is sentence-based and does not consider fluctuation in the kinds of words appearing.

5 Evaluation of Machine-Generated Text by the Taylor Exponent

The main contribution of this paper is the findings of Taylor's law behavior for real texts as presented thus far. This section explains the applicability of these findings, through results obtained with baseline language models.

As mentioned previously, i.i.d. mathematical processes have a Taylor exponent of 0.50. We show here that, even if a process is not trivially i.i.d., the exponent often takes a value of 0.50

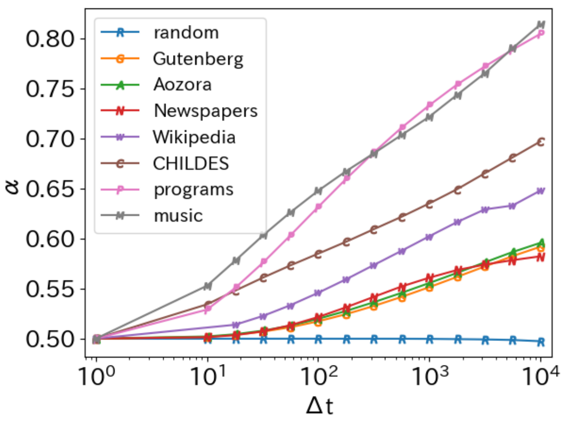

Figure 6: Growth of $\hat{\alpha}$ with respect to Δt, averaged across data sets within each data kind. The plot labeled "random" shows the average for the two datasets of randomized text from Moby Dick (shuffled and bigrams, as explained in §5). Since this analysis required a large amount of computation, for the large data sets (such as newspaper and programming language data), 4 million words were taken from each kind of data and used here. When Δt was small, the Taylor exponent was close to 0.5, as theoretically described in the main text. As Δt was increased, the value of $\hat{\alpha}$ grew. The maximum Δt was about 10,000, or about one-tenth of the length of one long literary text. For the kinds of data investigated here, $\hat{\alpha}$ grew almost linearly. The results show that, at a given Δt, the Taylor exponent has some capability to distinguish different kinds of text data.

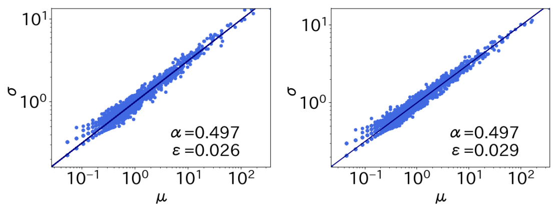
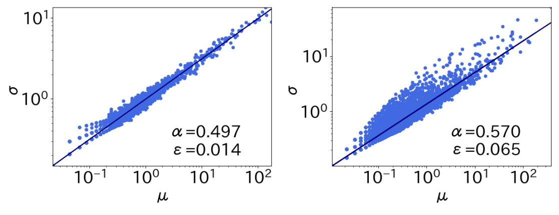


(a) Moby Dick (shuffled) (b) Moby Dick (bigram)

Figure 7: Taylor analysis of a shuffled text of *Moby Dick* and a randomized text generated by a bigram model. Both exhibited an exponent of 0.50.

for random processes, including texts produced by standard language models such as n-gram based models. A more complete work in this direction is reported in (Takahashi and Tanaka-Ishii, 2018).

Figure 7 shows samples from each of two simple random processes. Figure 7a shows the behavior of a shuffled text of *Moby Dick*. Obviously,



(a) Text produced by LSTM (3-layer stacked character-based)

(b) Machine-translated text using neural language model

Figure 8: Taylor analysis for two texts produced by standard neural language models: (a) a stacked LSTM model that learned the complete works of Shakespeare; and (b) a machine translation of *Les Misérables* (originally in French, translated into English), from a neural language model.

since the sequence was almost i.i.d. following Zipf distribution, the Taylor exponent was 0.50. Given that the Taylor exponent becomes larger for a sequence with words dependent on each other, as explained in §3, we would expect that a sequence generated by an n-gram model would exhibit an exponent larger than 0.50. The simplest such model is the bigram model, so a sequence of 300,000 words was probabilistically generated using a bigram model of *Moby Dick*. Figure 7b shows the Taylor analysis, revealing that the exponent remained 0.50.

This result does not depend much on the quality of the individual samples. The first and second box plots in Figure 4 show the distribution of exponents for 10 different samples for the shuffled and bigram-generated texts, respectively. The exponents were all around 0.50, with small variance.

State-of-the-art language models are based on neural models, and they are mainly evaluated by perplexity and in terms of the performance of individual applications. Since their architecture is complex, quality evaluation has become an issue. One possible improvement would be to use an evaluation method that qualitatively differs from judging application performance. One such method is to verify whether the properties underlying natural language hold for texts generated by language models. The Taylor exponent is one such possibility, among various properties of natural language texts.

As a step toward this approach, Figure 8 shows two results produced by neural language models. Figure 8a shows the result for a sample of 2 million characters produced by a standard (three-layer) stacked character-based LSTM unit that learned the complete works of Shakespeare. The model was optimized to minimize the cross-entropy with a stochastic gradient algorithm to predict the next character from the previous 128 characters. See (Takahashi and Tanaka-Ishii, 2017) for the details of the experimental settings. The Taylor exponent of the generated text was 0.50. This indicates that the character-level language model could not capture or reproduce the word-level clustering behavior in text. This analysis sheds light on the quality of the language model, separate from the prediction accuracy.

The application of Taylor's law for a wider range of language models appears in (Takahashi and Tanaka-Ishii, 2018). Briefly, state-of-the-art word-level language models can generate text whose Taylor exponent is larger than 0.50 but smaller than that of the dataset used for training. This indicates both the capability of modeling burstiness in text and the room for improvement. Also, the perplexity values correlate well with the Taylor exponents. Therefore, Taylor exponent can reasonably serve for evaluating machine-generated text.

In contrast to character-level neural language models, neural-network-based machine translation (NMT) models are, in fact, capable of maintaining the burstiness of the original text. Figure 8b shows the Taylor analysis for a machine-translated text of *Les Misérables* (from French to English), obtained from Google NMT (Wu et al., 2016). We split the text into 5000-character portions because of the API's limitation (See (Takahashi and Tanaka-Ishii, 2017) for the details). As is expected and desirable, the translated text retains the clustering behavior of the original text, as the Taylor exponent of 0.57 is equivalent to that of the original text.

6 Conclusion

We have proposed a method to analyze whether a natural language text follows Taylor's law, a scaling property quantifying the degree of consistent co-occurrence among words. In our method, a sequence of words is divided into given segments, and the mean and standard deviation of the frequency of every kind of word are measured. The law is considered to hold when the standard deviation varies with the mean according to a power law, thus giving the Taylor exponent.

Theoretically, an i.i.d. process has a Taylor exponent of 0.5, whereas larger exponents indicate sequences in which words co-occur systematically. Using over 1100 texts across 14 languages, we showed that written natural language texts follow Taylor's law, with the exponent distributed around 0.58. This value differed greatly from the exponents for other data sources: enwiki8 (tagged Wikipedia, 0.63), child-directed speech (CHILDES, around 0.68), and programming language and music data (around 0.79). These Taylor exponents imply that a written text is more complex than programming source code or music with regard to fluctuation of its components. None of the real data exhibited an exponent equal to 0.5. We conducted more detailed analysis varying the data size and the segment size.

Taylor's law and its exponent can also be applied to evaluate machine-generated text. We showed that a character-based LSTM language model generated text with a Taylor exponent of 0.5. This indicates one limitation of that model.

Our future work will include an analysis using other kinds of data, such as Twitter data and adult utterances, and a study of how Taylor's law relates to grammatical complexity for different sequences. Another direction will be to apply fluctuation analysis in formulating a statistical test to evaluate the structural complexity underlying a sequence.

Abstract

Language variation and change are driven both by individuals' internal cognitive processes and by the social structures through which language propagates. A wide range of computational frameworks have been proposed to connect these drivers. We compare the strengths and weaknesses of existing approaches and propose a new analytic framework which combines previous network models' ability to capture realistic social structure with practically and more elegant computational properties. The framework privileges the process of language acquisition and embeds learners in a social network but is modular so that population structure can be combined with different acquisition models. We demonstrate two applications for the framework: a test of practical concerns that arise when modeling acquisition in a population setting and an application of the framework to recent work on phonological mergers in progress.

1 Introduction

The process of language change should be thought of as a two-step cycle in which 1) individuals acquire their native languages from their predecessors then 2) pass them on to their successors. Small changes accrue over time this way and create both small-scale interpersonal variation and large-scale typological differences. It is easy to draw a strong analogy here between linguistic evolution and biological evolution. Both feature classic descent with modification, except while phenotypes are transmitted through genes and acted on by natural selection, language is both transmitted through and constrained by the individual (Cavalli-Sforza and Feldman, 1981; Ritt, 2004, etc.).

But while evolution, linguistic or otherwise, is driven by forces acting on the individual, it unfolds on the level of populations (Cavalli-Sforza and Feldman, 1981). The influence of community-level social factors on the path of language change is a major focus of sociolinguistics (Labov, 2001; Milroy and Milroy, 1985; Rogers Everett, 1995). Ideally, one could observe population-level variation unfold in real time while testing out individual factors, but this is impossible because nobody can travel back in time or fit entire natural environments into a lab. Change that has already happened is out of reach, and change in progress is buried in a world of confounds. The classic sociolinguistic method instead approaches the problem by inferring causal factors from patterns discovered in field interviews and corpora (Labov, 1994; Labov et al., 2005, etc.). This is the primary source of empirical data in the field and the only way to look at language change in a naturalistic setting, but it is limited in that it cannot test cause and effect directly. More recently, controlled experimental studies have emerged as a complementary line of research which manipulate causal factors directly (Johnson et al., 1999; Campbell-Kibler, 2009, etc.), but are inherently removed natural time and scale. A third approach, the one we build upon here, relies on computational modeling to simulate how sociolinguistic factors might work together in larger populations (Klein, 1966; Blythe and Croft, 2012; Kauhanen, 2016, etc.).

It has long been argued that language acquisition is the primary cause of language change (Sweet, 1899; Lightfoot, 1979; Niyogi, 1998, etc.). In the last few decades, this connection has been modeled computationally (Gibson and Wexler, 1994; Kirby et al., 2000; Yang, 2000,

Proceedings of the 56th Annual Meeting of the Association for Computational Linguistics (Long Papers), pages 1149–1159
Melbourne, Australia, July 15 - 20, 2018. ©2018 Association for Computational Linguistics

etc.), leading to the strong conclusion that change is the inevitable consequence of mixed linguistic input or finite learning periods (Niyogi and Berwick, 1996), even if children are "perfect" learners. An important result connecting the learner and population emphasizes the need for this line of work: the space of paths of change available in populations is formally larger than the paths available to linear chains of iterated learners. Niyogi and Berwick (2009) prove formally that even *perfectly-mixed* (i.e., uniform and homogeneous social network) populations admit phase transitions in the path of change unavailable to chains of single learners commonly implemented in iterated learning (Kirby et al., 2000). This suggests that small-population experimental studies in sociolinguistics and in child language acquisition do not paint the full picture of language change.

We introduce a new framework for modeling language change in populations. It has an outer loop to represent generational progression, but it replaces the inner loop which calculates randomized interactions between agents with a single formula that is defined generally enough to allow the simulation of a wide range of scenarios. It builds upon the principled formalism described by Niyogi and Berwick (1996, et seq.), privileging the acquisition model and separating it from the population model. The resulting modular framework is described in the following sections. First, Section 1.1 presents a survey of previous simulation work followed by a description of the new population model in Section 2. Next, Section 3 addresses practical concerns relating population size to assumptions about language acquisition. Finally, Section 4 introduces a case study on phonological change which demonstrates the need for appropriate models both of acquisition and populations.

1.1 Related Work

Computational models for the propagation of linguistic variation have been employed with a variety of research goals in mind. Every paper implements its own framework with few exceptions, so comparison across studies is difficult. Additionally, since each model is essentially 'boutique,' it is always possible that models are designed consciously or unconsciously to achieve a specific outcome rather driven by underlying principles. We group these frameworks into three classes according to their implementation, *swarm*, *network*, and *algebraic*, and discusses their strengths and weaknesses.

The first class, called *swarm* here, models populations as collections of agents placed on a grid. They "swarm" around randomly according to some movement function, and "interact" when they occupy adjacent grid spaces (Satterfield, 2001; Harrison et al., 2002; Ke et al., 2008; Stanford and Kenny, 2013). This tends toward concrete interpretation, for example, more mobile populations are expressed directly by more mobile agents. They capture Bloomfield (1933)'s "principle of density" which describes the observation that geographically or socially close individuals interact more frequently than those farther away. On the other hand, they provide little control over network structure, relying on series of explicit movement constraints in order to direct their agents, and since each one moves randomly at each iteration, these models have potentially thousands of degrees of freedom. Such simulations should be run many times if any sort of statistically expected results are to be computed.

The second class, *network* frameworks, model speakers as nodes and interaction probabilities as weighted edges on network graphs (Minett and Wang, 2008; Baxter et al., 2009; Fagyal et al., 2010; Blythe and Croft, 2012; Kauhanen, 2016). These frameworks offer precise control over social network structure and can test specific community models from within sociolinguistics. However, implementations usually proceed by some kind of iterative probabilistic node-pair selection process, and in this way suffer from the same statistical pitfalls as swarm frameworks. In contrast to swarm models, interaction is rigidly restricted to immediately connected nodes, so to achieve gradient interaction probabilities, edges must be frequently updated or nearly fully-connected graphs with carefully assigned edge weights would need to be constructed and motivated.

The third class, *algebraic* frameworks, present analytic methods for determining the state of the network at the end of each iteration rather than relying on stochastic simulation of individual agents (Niyogi and Berwick, 1996, 1997; Yang, 2000; Baxter et al., 2006; Minett and Wang, 2008; Niyogi and Berwick, 2009). Removing that inner loop is a more mathematically elegant approach and avoids dealing unnecessarily with statistics behind random trials. Removing that loop speeds up calculation as well, making larger simulations more tractable than with network or swarm frameworks. But this power is achieved by sacrificing the social network. Up to this point, such models have, to our knowledge, only been defined over perfectly-mixed (i.e., no network effects) populations. That assumption is useful for reasoning about the mathematical theory behind language change, but it hinders such models' utility in empirical studies. For example, though Baxter et al. (2006) and Minett and Wang (2008) implement algebraic models for perfectly mixed populations, they fall back on network models to model network effects.

2 Framework for Transmission in Social Networks

Algebraic frameworks have their mathematical advantage, but network frameworks provide a richer model for representing real-world population structures and swarm models capture density effects by default. An ideal framework would combine the benefits of all three of these. Here we do just that. We introduce a framework that instantiates Niyogi and Berwick (1996)'s acquisition-driven formalism where change is handled explicitly as a two-step alternation between individual learners learning and populations interacting. It provides an analytic solution to the state of a network structure over which swarm-like behavior can be modeled.

We begin by conceptualizing the framework in terms of agents traveling probabilistically over a network structure as in Algo. 1 before introducing the analytic solution. There is an individual standing at every node in the graph, and at every iteration, each individual begins at some location and travels along the network's edges, at each step deciding to continue on or to stop and interact with the agent at that node. Any two agents with a non-zero weight path between them could potentially interact, so the overall probability of an interaction is a function of the shape of the network and the decay rate of the step probability. The shorter and higher weighted the path between two agents, the more likely they are to interact. This corresponds to the gradient interaction probabilities of swarm frameworks.

Algorithm 1: One iteration of the propagation model conceptualized on the level of an individual agent

```
for each individual node do
    Begin traveling;
    while traveling do
        Randomly select an outgoing edge by
          weight and follow it OR stop travel;
        increase chance of stopping next time;
    end
    Interact with the individual at the current
      node;
end
```

2.1 Representing the Network

Social networks are typically conceived of as graph structures with individuals as vertices and the social or geographical connections between individuals as edges, and this allows for a great deal of flexibility. If edges are undirected, then all interactions are equal and bidirectional, but if edges are directed, interactions may or may not be. Edges can be weighted to represent likelihood of interaction or some measure of social valuation, and this too can vary over time. Lastly, it is possible to add and remove nodes themselves to capture births, deaths, or migration.

The network structure is represented computationally here as an adjacency matrix $\mathbf{A}$. In a population of n individuals, this is $n \times n$ where each element a_{ij} is the weight of the connection from individual j to individual i. The matrix must be column stochastic (all columns sum to 1 and contain only positive elements) so that edge weights can be interpreted as probabilities. The special case where the matrix is symmetric (every $a_{ij} = a_{ji}$) models undirected edges, and more strongly, the model reduces to perfectly-mixed populations when each $a_{ij} = \frac{1}{n}$.

We define a notion of *communities* over the nodes of the network in order to add the option to categorize groups of individuals. Membership among c communities is identified with an $n \times c$ indicator matrix $\mathbf{C}$. Depending on the problem at hand, it is possible to calculate the average behavior of the learners within each community directly without having to calculate the behavior of each individual member.

2.2 Propagation in the Network

In a typical network model, the edge weights between nodes in $\mathbf{A}$ are interpreted directly as interaction probabilities, meaning that individuals only ever interact with their immediate graph neighbors. We take a different approach by allowing the agents to "travel" and potentially interact with any other agent whose node is connected by a path of non-zero edges. If the number of traveling steps were fixed at k, the probability of each pair interacting would be defined as $\mathbf{A}^k$. It is more complicated for us since the number of steps traveled is a random variable. The probability of j interacting with i ($p(ij)$) is the probability of them interacting after k steps times the probability of k for all values of k as in Eqn. 1. Combining this intuition with $\mathbf{A}$ yields the interaction probabilities for all i, j pairs.

$$p(ij) = \sum_k p(ij|k \text{ steps})\, p(k \text{ steps}) \tag{1}$$

The pattern of linguistic variants or grammars (in the formal sense where grammar g is the intensional equivalent of language L_g) within a network unfolds as a dynamical system over the course of many iterations, and learners' positions within the network mediate which ones they eventually acquire. In a system with g grammars and n individuals, a $n \times g$ row-stochastic matrix $\mathbf{G}$ specifies the probability with which each community expresses each grammar. Given this notion of interaction and the specification of grammars expressed within a network, it is possible to compute the distribution of grammars presented to each learner. This is the learners' linguistic environment and is represented by a matrix $\mathbf{E}$ in the same form as $\mathbf{G}^\top$.

An *environment function* $\mathcal{E}_n(\mathbf{G}_t, \mathbf{A}) = \mathbf{E}_{t+1}$ shown in Eqn. 2 calculates $\mathbf{E}$ by first calculating all the interaction probabilities in the network then multiplying those by the grammars which every agent expresses to get the environment $\mathbf{E}$. The α parameter from the geometric distribution[1] defines the travel decay rate. A lower α defines conceptually more mobile agents.

More generally, $\mathcal{E}_n$ is a special case of $\mathcal{E}(\mathbf{G}_t, \mathbf{C}_t, \mathbf{A}_t) = \mathbf{E}_{t+1}$ where the number of communities equals the number of individuals ($c = n$). $\mathbf{C}$ becomes the identity matrix without loss of generality, so the network's initial condition does not have to be defined explicitly. For any other community definition, an initial condition has to be defined as in Eqn. 3 which specifies the starting point in the network that each agent conceptually begins traveling from. The output of $\mathcal{E}$ is a $g \times c$ matrix giving the environment of the average agent in each community.[2]

$$\mathcal{E}_n(\mathbf{G}_t, \mathbf{A}) = \mathbf{G}_t^\top \alpha\, (\mathbf{I} - (1-\alpha)\mathbf{A})^{-1} \tag{2}$$
$$\mathcal{E}(\mathbf{G}_t, \mathbf{C}, \mathbf{A}) = \mathcal{E}_n(\mathbf{G}_t, \mathbf{A})\mathbf{C}(\mathbf{C}^\top\mathbf{C})^{-1} \tag{3}$$

The output of $\mathcal{E}$ must be broadcast to $g \times n$, which would result in the loss of some information unless the assumption can be made that each community is internally uniform. However, when that assumption can be made, the $n \times n$ adjacency matrix admits a $c \times c$ equitable partition $\mathbf{A}^\pi$ (Eqn. 4) (Schaub et al., 2016) which permits an alternate environment function $\mathcal{E}_{EP}(\mathbf{G}_t, \mathbf{C}, \mathbf{A})$ shown in Eqn. 5 that is equivalent to the lossless $\mathcal{E}_n$ if $\mathbf{A}$. If $n \gg c$, $\mathcal{E}_{EP}$ is much faster to calculate because it only inverts a small $c \times c$ matrix rather than a large $n \times n$. This makes it feasible to run much larger simulations than what has been done in the past.

$$\mathbf{A}^\pi = (\mathbf{C}^\top\mathbf{C})^{-1}\mathbf{C}^\top\mathbf{A}\mathbf{C} \tag{4}$$
$$\mathcal{E}_{EP} = \alpha\mathbf{G}^\top\mathbf{C}\,(\mathbf{I} - (1-\alpha)\mathbf{A}^\pi)^{-1}\,(\mathbf{C}^\top\mathbf{C})^{-1} \tag{5}$$

2.3 Learning in the Network

The environment function describes what inputs $\mathbf{E}_{t+1}$ are available to learners given the language expressed by the mature speakers of the previous age cohort with grammars $\mathbf{G_t}$. The second component of the framework describes the learning algorithm $\mathcal{A}(\mathbf{E}_{t+1}) = \mathbf{G}_{t+1}$, how individuals respond to their input environment. The resulting $\mathbf{G}_{t+1}$ describes which grammars those learners will eventually contribute to the subsequent generation's environment $\mathbf{E}_{t+2}$. This back-and-forth between adults' grammars $\mathbf{G}$ and childrens' environment $\mathbf{E}$ is the two-step cycle of language change (Fig. 1).

In *neutral change*, learners would acquire grammars at the rates that they are expressed in their environments, but there is good reason to believe

[1] In this paper, jump probabilities decay according to a geometric distribution, but other distributions including the Poisson have been implemented as well.

[2] $(\mathbf{I} - (1-\alpha)\mathbf{A})^{-1}$ and $\mathbf{C}(\mathbf{C}^\top\mathbf{C})^{-1}$ can be pre-computed if network structure does not change over time.

$$\ldots \mathbf{G_t} \rightarrow \mathbf{E_{t+1}} \rightarrow \mathbf{G_{t+1}} \ldots \mathbf{G_{t+i}} \rightarrow \mathbf{E_{t+i+1}} \ldots$$

Figure 1: Language change as an alternation between **G** and **E** matrices

that most language change involves differential fitness between competing variants, and most non-trivial learning algorithms yield some kind of fitness (Kroch, 1989; Yang, 2000; Blythe and Croft, 2012, etc.), so $\mathcal{A}$ is rarely neutral. A neutral and simple advantaged model are both considered in Section 3, and a more complex learning algorithm is described for Section 4.

3 Application: Testing Assumptions

The general nature of the framework described here renders it suitable for reproducing the results of previous works and evaluating their assumptions. To demonstrate this, we reproduce the major result from Kauhanen (2016), which tested the behavior of neutral change in networks of single-grammar learners, in order to dissect two of its primary assumptions. Implemented in a typical network framework, the original setup contains $n = 200$ individuals in probabilistically generated centralized networks in which individuals mature categorically to the single most frequent grammar in their input. The author found that categorical neutral change produced chaotic paths of change regardless of network shape and that periodically "rewiring" some of the network edges smoothed this out. Without commenting on rewiring, we find that the combination of n and choice of categorical learners conspire to create the chaotic results.

We create two communities, both centralized along the lines of the single cluster in Kauhanen (2016), initialize all members of cluster 1 with grammar g_1 and all members of cluster 2 with grammar g_2, and additional edges are added between members of clusters 1 and 2 to allow interaction. **G** is converted to an indicator matrix at the end of each learning iteration by rounding values to 0 and 1 in order to model categorical learners who only internalize the most common grammar in their inputs as in the original model.

In a pair of infinitely large clusters or two clusters where individuals are permitted to learn a probabilistic distribution of grammars, each cluster should homogenize to a 50/50 distribution of g_1 and g_2 after some number of iterations depending on the specifics of the network shape and setting for α creating the red curves in Fig. 2. At $n = 20000$, each of 10 trials roughly follows the path of the predicted curve, but when run at the original $n = 200$ for 10 trials, this produces the type of chaotic behavior which Kauhanen (2016) attempts to repair. The outcome appears to be the result of an assumption made out of convenience ($n = 200$) rather than a principled decision.

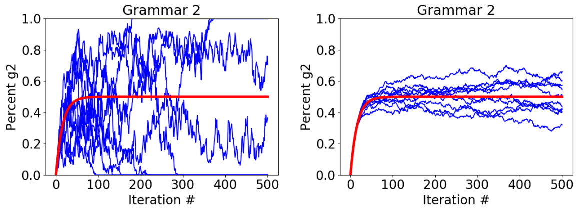

Figure 2: Predicted curve (red); neutral change at $n = 200$ (left; Kauhanen (2016)); neutral change at $n = 20000$ (right)

To further explore the impact of the population size assumption, we experiment on a model of advantaged change, which is typically contrasted with neutral change because of its tendency to produce "well-behaved" S-curve change (Blythe and Croft, 2012; Kauhanen, 2016). This time, only a single cluster is created, and the advantaged grammar is initially assigned to 1% of the population. As seen in Figure 3, results are chaotic for $n = 200$ once again and near predicted for $n = 20000$. This is important because at $n = 200$, advantaged change is chaotic, and most simulations both rise and fall. An experimenter who only studied advantaged change in small population might concluded that it is as ill-behaved as neutral change. While the conclusions that Kauhanen (2016) draws appear valid for $n = 200$, it is not clear to what extent they can be projected onto larger populations. This demonstrates the need for carefully choosing one's modeling assumptions and testing them out when possible.

4 Application: Mergers in Progress

The acquisition of phonological mergers in mixed input settings presents an interesting problem. It appears that mergers have an inherent advantage because they tend to spread at the expense of distinctions, and once they begin, they are rarely reversed (Labov, 1994). Yang (2009)'s acquisition model quantifies this advantage as the relatively

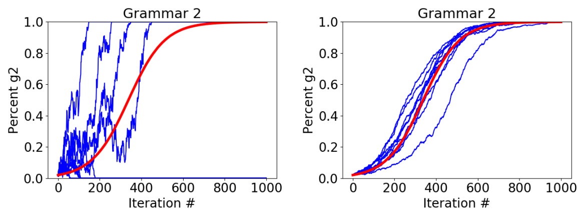

Figure 3: predicted curve (red); advantaged change at $n = 200$ (left; cf. Kauhanen (2016)); advantaged change at $n = 20000$ (right)

lower chance of misinterpretation if a listener assumes the merged grammar instead of the non-merged grammar once a sufficient proportion of the environment is merged. Applied to Johnson (2007)'s detailed population study of the frontier of the COT-CAUGHT merger in the small towns along the border between Rhode Island and Massachusetts, this accurately predicts the ratio of merged input for a child to acquire the merged grammar, however when applied to a perfectly mixed population of learners, it fails to model the spread of the merged grammar in the population. Yang's model is input-driven, so it is conducive to simulation with minimal assumptions past those drawn from the empirical data. We test the behavior of this learning model in a typical population network and demonstrate that it produces a reasonable path of change.

4.1 Background

The COT-CAUGHT *merger*, also called the *low back merger* describes the phenomenon present in varieties of North American English spoken in eastern New England, western Pennsylvania, the American West, and Canada among others where the vowel in words like *cot* and the vowel in words like *caught* have come to be pronounced the same (Labov et al., 2005, pp. 58-65). The geographical extent of the merger is currently expanding, which might be expected if the merger has a cognitive or social advantage associated with it. Johnson (2007)'s study of the merger's frontier on the border Rhode Island and Massachusetts uncovered an interesting social dynamic that illustrates the merger's speed: there are families where the parents and older siblings non-merged, but the younger siblings are. The merger has swept through in only a few years and passed between the siblings.

Yang (2009) seeks to understand why mergers have an advantage from a cognitive perspective, and his model treats the acquisition of mergers as an evolutionary process. Learners who receive both merged (M_+) and non-merged (M_-) input entertain both a merged (g_+) and non-merged (g_-) grammar and reward whichever grammar successfully parses the input. This kind of variational learner (Yang, 2000) is essentially an adaptation of the classic evolutionary Linear Reward Punishment model (Bush and Mosteller, 1953). The fitness of each grammar is the probability in the limit that it will fail to parse any given input, and since it is virtually always the case that this probability is different for both grammars, fitness is virtually always asymmetric. The variational learner is characterized as follows.

Given two grammars and an input token s, The learner parses s with g_1 with probability p and with g_2 with probability $q = 1 - p$. p is rewarded according to whether the choice of g successfully parses s ($g \to s$) or it fails to ($g \nrightarrow s$), where γ is some small constant.

$$p' = \begin{cases} p + \gamma q, & g \to s \\ (1-\gamma)p, & g \nrightarrow s \end{cases}$$

Given a specific problem, one can calculate a *penalty probability* C for each g, the proportion of input that would cause $g \nrightarrow s$. The grammar with the lower C has the advantage, so the other one will be driven down in the long run. C can be estimated from type frequencies in a corpus, and the model is non-parametric because these values do not depend on γ.

$$\lim_{t\to\infty} p_t = \frac{C_2}{C_1 + C_2} \qquad \lim_{t\to\infty} q_t = \frac{C_1}{C_1 + C_2}$$

To understand the COT-CAUGHT merger empirically, one must reason about what kind of input would trigger a penalty and then calculate the penalty probabilities of the merged grammar C_+ and non-merged grammar C_- from a corpus. This model considers parsing failure to be the rate of initial misinterpretation, and for a vowel merger, the only inputs that could create an initial misinterpretation are minimal pairs because they become homophones. Examples of COT-CAUGHT minimal pairs include *cot-caught*, *Don-Dawn*, *stock-stalk*, *odd-awed*, *collar-caller*, and so on.

The merged g_+ grammar collapses would-be minimal pairs into homophones, so the penalty rate C_+ comes down to lexical access. Under the observation that more frequent homophones are retrieved first regardless of syntactic context (Caramazza et al., 2001), g_+ listeners only suffer initial misinterpretation when the less frequent member of a pair is uttered regardless of the rate of M_+. If H is the sum token frequency of all minimal pairs and h^i_o, h^i_{oh} are the frequencies of the ith pair's members, then $C+$ is calculated by Eqn. 6.

In contrast, g_- listeners are sensitive to the phonemic distinction, so they misinterpret M_- input at the rate of mishearing one vowel for the other ϵ (Peterson and Barney, 1952) (second half of Eqn. 7). And given M_+ input, they misinterpret whenever they hear the phoneme which g_- does not expect (e.g., a merged speaker pronouncing *cot* with the CAUGHT vowel) times the probability of *not* mishearing that vowel (1-ϵ) plus ϵ times the probability of hearing the right vowel (i.e., the merged speaker pronounces *cot* with the COT vowel but it is misheard anyway) (first half of Eqn. 7). Since g_- misinterpretation rates are a function of the rate of M_+ (p) in the environment, there is a threshold of M_+ speakers above which the merged grammar has a fitness advantage over the non-merged one.

$$C_+ = \frac{1}{H}\sum_i \min(h^i_o, h^i_{oh}) \tag{6}$$

$$C_- = \frac{1}{H}\sum_i \big[p_0((1-\epsilon_{oh})h^i_o + \epsilon_{oh}h^i_{oh}) \tag{7}$$
$$+q_0(\epsilon_{oh}h^i_o + \epsilon_{oh}h^i_{oh})\big]$$

Calculating this threshold for the frequent minimal pairs that Yang extracts from the Wortschatz project (Biemann et al., 2004) corpus[3] and mishearing rates from Peterson and Barney (1952), the Yang model predicts that a learner exposed to at least $\sim$ 17% COT-CAUGHT-merged input will acquire the merger. This threshold represents a strong advantage for M_+ because it is well under the 50% threshold expected for neutral (non-advantaged) change and it is very close to what was found in Johnson (2007)'s sociolinguistic study. It predicts that younger children may have g_+ while their parents and even older siblings have g_- if the 17% threshold was crossed in **E** after the acquisition period of the older sibling but before that of the younger sibling.

4.2 Model Setup

All the mechanics behind the learning model reduce to a simple statement: *learners acquires g_+ iff $>$ 17% of their input is M_+ and they acquire g_- otherwise*. However, this kind of categorical learner in a perfectly-mixed population leads to immediate fixation at either g_- or g_+ in a single iteration, since the proportion of g_+ speakers in the population is equivalent to the proportion of M_+ input in every learner's environment. This is not realistic change. Clearly, social network structure is at least as important as the learning algorithm in modeling the spread of the merger.

We model the change in a non-uniform social network of 100 centralized clusters of 75 individuals each. 75 was chosen as half Dunbar's number, the maximum number of reliable social connections that an adult can maintain (Dunbar, 2010). There are two grammars, g_+ and g_-, and learners internalize one or the other according to the 17% threshold of M_+ in their input. One cluster represents the source of the merger and is initialized at 100% g_+, while the rest begin 100% g_-. Inter-cluster connections are chosen randomly so that some connections are between central members of the clusters and some are between peripheral members. The one merged cluster is connected to half the other clusters representing those at the frontier of the change, and each other cluster is connected to five randomly chosen ones.[4] This network structure echoes work in sociolinguistics, in particular, Milroy and Milroy (1985)'s notion of *strong* and *weak* connections in language change, where weak connections between social clusters are particularly important for propagation of a change.

Propagation of the merged grammar is calculated by $\mathcal{E}_n$ because we are interested in the behavior of individuals without loss of precision and because it cannot be assumed that each cluster is internally uniform.[5] Since the spread of the merger has been rapid enough to detect over a period of a few years, iterations are modeled as short age co-

[3]*Don* (1052) – *Dawn* (736); *collar* (403) – *caller* (23); *knotty* (25) – *naughty* (195); *odd* (830) – *awed* (80); *Otto* (67) – *auto* (260); *tot* (9) – *taught* (1327); *cot* (39) – *caught* (2444); *pond* (258) – *pawned* (31); *hock* (25) – *hawk* (127); *nod* (180) – *gnawed* (53); *sod* (30) – *sawed* (37)

[4]Originally, the clusters were set up as a "stepping-stone" chain with the merged community at one end, and that produced a similar S-curve. The structure presented here is more geographically plausible but not crucial for the results.

[5]$\alpha = 0.45$.

horts rather than full generations in the first experiments by updating only a randomly chosen 10% of nodes at each iteration because only a fraction of the population is learning at any given time. A model where every node is updated is investigated as well.

4.3 Results

The behavior of this simulation is shown graphically in Figure 4. The fine/colored lines indicate the rate of M_+ within each initially non-merged cluster, and the bold/black line shows the average rate across all initially non-merged. The merger spreads from cluster to cluster in succession over the "weak" inter-cluster connections and through each cluster over the 'strong' connections before moving on to the next ones.

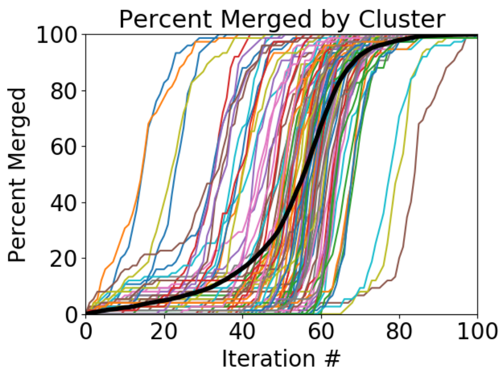

Figure 4: Spread of merger across communities (fine/colored) and population average (bold/black)

Most individual clusters exhibit a period of time in which only a few *early adopter* (Rogers Everett, 1995) members have the merger, a period of rapid diffusion of the merger, then some time where a few *laggards* resist the merger. As a result, most clusters exhibit an S-like shape. A few clusters change rapidly because of their especially well-connected positions in the network, and some lag behind the rest because they are poorly connected to the rest of the network. More interestingly, the population-wide average, the population-level data at the kind of granularity that is often studied, yields a smooth S-curve with a shallower slope than the individual clusters. The fact that it arises naturally here in a network that conforms with typical network shapes but was otherwise randomly generated is encouraging because the experiment was not set up so that it would produce such a curve, and the steep rate of change in individual clusters is what is expected for a change that is rapid enough to affect siblings differently.

In the above simulation, only a fraction of nodes were updated at each iteration in order to model a rapid change. In order to confirm that this choice is not affecting the results and to test a purer implementation of the framework presented here, we remove that constraint and update every node at each iteration. Figure 5 shows what happens over 20 iterations in a network that is otherwise identical but with 2/5 as many inter-cluster connections as the original. A qualitatively similar pattern arises, so the choice to update only a fraction of the population is not crucially affecting the results.

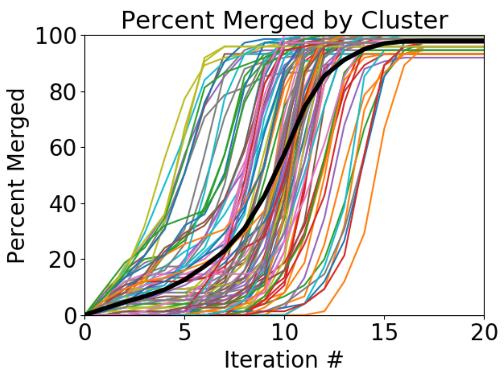

Figure 5: Spread of merger across communities (fine/colored) and population average (bold/black)

In all experiments so far, social connections were fixed at the first iteration even though connections in real populations tend to change over time. To investigate that modeling assumption, we perform another simulation in which connections are randomly updated both within and across clusters at each iteration akin to Kauhanen (2016)'s rewiring. The result as shown in Figure 6 is similar to before, with one major difference. The individual clusters transition more closely in time because no individual cluster remains poorly connected or especially well connected throughout the entire simulation.

Finally, we test our assumptions about population size by repeating the experiments on a smaller network of 40 clusters of 18 individuals. The results are qualitatively similar, but the S-curve appears to be more sensitive to probabilistic connections in the network. To explore this, we present the average network-wide rate of (M_+) across 10 trials, revealing that an S-like curve is formed each time but that its slope varies. A few trials never

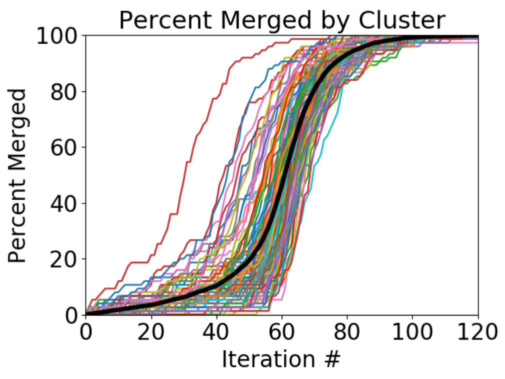

Figure 6: Spread of merger within communities (fine/colored) and as population average (bold/black). Network updated.

reach 100% because some of the clusters are not connected to the innovative one. The slope varies between trials, indicating that the rate of change is a function of both the population structure and the learning algorithm, but the network size does not substantially affect these results.

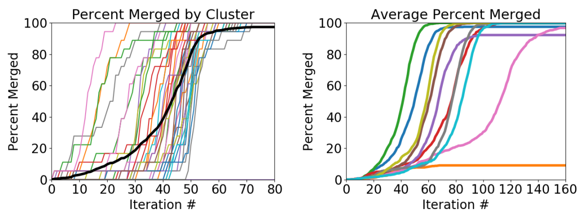

Figure 7: Single small network trial (left); average curves from 10 trials (right)

5 Discussion

The algebraic-network framework for modeling population-level language change presented here has substantial practical and theoretical advantages over previous ones. It is much simpler computationally than previous frameworks because it calculates the statistically expected behavior of each generation analytically and therefore removes the entire inner loop of calculating stochastic inter-agent interactions from the simulation. It follows the Niyogi and Berwick (1996) formalism for language change which presents a clean and modular way of reasoning about the problem and promotes the centrality of language acquisition.

In addition to the core algorithm, the framework offers enough flexibility to represent a wide variety of processes from the highly abstract (e.g., Kauhanen (2016)) to those grounded in sociolinguistic and acquisition research (e.g., Yang (2009)). In our investigation of Kauhanen's basic assumptions, we discover how seemingly innocuous decisions about population size and learning conspire to drive simulation results. If learners are conceived as categorical learners, population size becomes a deciding factor in the path of change. So while the original results are interesting and meaningful, they may only valid for small (on the order of 10^2) populations.

In our simulation of the spread of the COT-CAUGHT merger, we show how a cognitively-motivated model of acquisition requires a network model in order to represent population-level language change. The population is represented as a collection of individual clusters based on sociological work, but the clusters themselves are connected randomly. The fact that S-curves arise naturally from these networks underscores their centrality to language change.

One problem that this line of simulation work has always faced has been the lack of viable comparison between models because every study implements its own learning, network, and interaction models. The modular nature of our framework advances against this trend since it is now possible to hold the population model constant while slotting in various learning models to test them against one another and vice-versa. Finally, since this framework reduces to Niyogi & Berwick's models in perfectly-mixed populations, it can be used to reason about the formal dynamics of language change as well.

Without simulation, it would be difficult or impossible to undercover the interplay between acquisition and social structure on the propagation of language change. Neither factor alone can account for the theoretical or empirically observed patterns. Simulations of this kind which explicitly model both simultaneously is well equipped to provide insights that fieldwork and laboratory work cannot. As such, it is an invaluable complement to those more traditional methodologies.

Prefix Lexicalization of Synchronous CFGs using Synchronous TAG

Logan Born and **Anoop Sarkar**

School of Computing Science
{loborn,anoop}@sfu.ca

Abstract

We show that an ε-free, chain-free synchronous context-free grammar (SCFG) can be converted into a weakly equivalent synchronous tree-adjoining grammar (STAG) which is prefix lexicalized. This transformation at most doubles the grammar's rank and cubes its size, but we show that in practice the size increase is only quadratic. Our results extend Greibach normal form from CFGs to SCFGs and prove new formal properties about SCFG, a formalism with many applications in natural language processing.

1 Introduction

Greibach normal form (GNF; Greibach, 1965) is an important construction in formal language theory which allows every context-free grammar (CFG) to be rewritten so that the first character of each rule is a terminal symbol. A grammar in GNF is said to be prefix lexicalized, because the prefix of every production is a lexical item. GNF has a variety of theoretical and practical applications, including for example the proofs of the famous theorems due to Shamir and Chomsky-Schützenberger (Shamir, 1967; Chomsky and Schützenberger, 1963; Autebert et al., 1997). Other applications of prefix lexicalization include proving coverage of parsing algorithms (Gray and Harrison, 1972) and decidability of equivalence problems (Christensen et al., 1995).

By using prefix lexicalized synchronous context-free grammars (SCFGs), Watanabe et al. (2006) and Siahbani et al. (2013) obtain asymptotic and empirical speed improvements on a machine translation task. Using a prefix lexicalized grammar ensures that target sentences can be generated from left to right, which allows the use of beam search to constrain their decoder's search space as it performs a left-to-right traversal of translation hypotheses. To achieve these results, new grammars had to be heuristically constrained to include only prefix lexicalized productions, as there is at present no way to automatically convert an existing SCFG to a prefix lexicalized form.

This work investigates the formal properties of prefix lexicalized synchronous grammars as employed by Watanabe et al. (2006) and Siahbani et al. (2013), which have received little theoretical attention compared to non-synchronous prefix lexicalized grammars. To this end, we first prove that SCFG is not closed under prefix lexicalization. Our main result is that there is a method for prefix lexicalizing an SCFG by converting it to an equivalent grammar in a different formalism, namely synchronous tree-adjoining grammar (STAG) in regular form. Like the GNF transformation for CFGs, our method at most cubes the grammar size, but we show empirically that the size increase is only quadratic for grammars used in existing NLP tasks. The rank is at most doubled, and we maintain $O(n^{3k})$ parsing complexity for grammars of rank k. We conclude that although SCFG does not have a prefix lexicalized normal form like GNF, our conversion to prefix lexicalized STAG offers a practical alternative.

2 Background

2.1 SCFG

An SCFG is a tuple $G = (N, \Sigma, P, S)$ where N is a finite nonterminal alphabet, Σ is a finite terminal alphabet, $S \in N$ is a distinguished nonterminal called the start symbol, and P is a finite set of synchronous rules of the form

(1) $$\langle A_1 \to \alpha_1, A_2 \to \alpha_2 \rangle$$

for some $A_1, A_2 \in N$ and strings $\alpha_1, \alpha_2 \in (N \cup \Sigma)^*$.[1] Every nonterminal which appears in α_1

[1]A variant formalism exists which requires that $A_1 = A_2$; this is called syntax-directed transduction grammar (Lewis and Stearns, 1968) or syntax-directed translation schemata (Aho and Ullman, 1969). This variant is weakly equivalent to SCFG, but SCFG has greater strong generative capacity (Crescenzi et al., 2015).

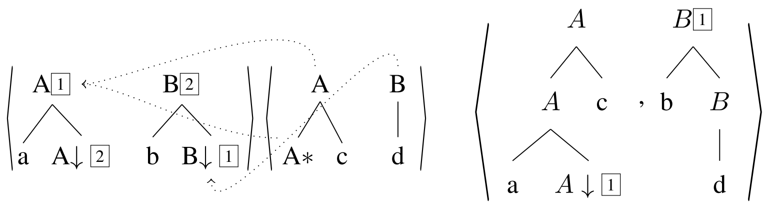

Figure 1: An example of synchronous rewriting in an STAG (left) and the resulting tree pair (right).

must be linked to exactly one nonterminal in α_2, and *vice versa*. We write these links using numerical annotations, as in (2).

(2) $\langle A \to A\boxed{1}B\boxed{2}, B \to B\boxed{2}A\boxed{1}\rangle$

An SCFG has rank k if no rule in the grammar contains more than k pairs of linked nodes.

In every step of an SCFG derivation, we rewrite one pair of linked nonterminals with a rule from P, in essentially the same way we would rewrite a single nonterminal in a non-synchronous CFG. For example, (3) shows linked A and B nodes being rewritten using (2):

(3)
$\langle X\boxed{1}A\boxed{2}, B\boxed{2}Y\boxed{1}\rangle \Rightarrow \langle X\boxed{1}A\boxed{2}B\boxed{3}, B\boxed{3}A\boxed{2}Y\boxed{1}\rangle$

Note how the $\boxed{1}$ and $\boxed{2}$ in rule (2) are renumbered to $\boxed{2}$ and $\boxed{3}$ during rewriting, to avoid an ambiguity with the $\boxed{1}$ already present in the derivation.

An SCFG derivation is complete when it contains no more nonterminals to rewrite. A completed derivation represents a string pair generated by the grammar.

2.2 STAG

An STAG (Shieber, 1994) is a tuple $G = (N, \Sigma, T, S)$ where N is a finite nonterminal alphabet, Σ is a finite terminal alphabet, $S \in N$ is a distinguished nonterminal called the start symbol, and T is a finite set of synchronous tree pairs of the form

(4) $\langle t_1, t_2\rangle$

where t_1 and t_2 are elementary trees as defined in Joshi et al. (1975). A *substitution site* is a leaf node marked by $\downarrow$ which may be rewritten by another tree; a *foot node* is a leaf marked by $*$ that may be used to rewrite a tree-internal node. Every substitution site in t_1 must be linked to exactly one nonterminal in t_2, and *vice versa*. As in SCFG, we write these links using numbered annotations; rank is defined for STAG the same way as for SCFG.

In every step of an STAG derivation, we rewrite one pair of linked nonterminals with a tree pair from T, using the same substitution and adjunction operations defined for non-synchronous TAG. For example, Figure 1 shows linked A and B nodes being rewritten and the tree pair resulting from this operation. See Joshi et al. (1975) for details about the underlying TAG formalism.

2.3 Terminology

We use *synchronous production* as a cover term for either a synchronous rule in an SCFG or a synchronous tree pair in an STAG.

Following Siahbani et al. (2013), we refer to the left half of a synchronous production as the source side, and the right half as the target side; this terminology captures the intuition that synchronous grammars model translational equivalence between a source phrase and its translation into a target language. Other authors refer to the two halves as the left and right components (Crescenzi et al., 2015) or, viewing the grammar as a transducer, the input and the output (Engelfriet et al., 2017).

We call a grammar ε-free if it contains no productions whose source or target side produces only the empty string ε.

2.4 Synchronous Prefix Lexicalization

Previous work (Watanabe et al., 2006; Siahbani et al., 2013) has shown that it is useful for the target side of a synchronous grammar to start with a terminal symbol. For this reason, we define a synchronous grammar to be prefix lexicalized when the leftmost character of the target side[2] of every synchronous production in that grammar is a terminal symbol.

Formally, this means that every synchronous rule in a prefix lexicalized SCFG (PL-SCFG) is

[2]All of the proofs in this work admit a symmetrical variant which prefix lexicalizes the source side instead of the target. We are not aware of any applications in NLP where source-side prefix lexicalization is useful, so we do not address this case.

of the form

(5) $$\langle A_1 \rightarrow \alpha_1, A_2 \rightarrow a\alpha_2 \rangle$$

where $A_1, A_2 \in N, \alpha_1, \alpha_2 \in (N \cup \Sigma)^*$ and $a \in \Sigma$.

Every synchronous tree pair in a prefix lexicalized STAG (PL-STAG) is of the form

(6) 
where $A_1, A_2 \in N, \alpha_1, \alpha_2 \in (N \cup \Sigma)^*$ and $a \in \Sigma$.

3 Closure under Prefix Lexicalization

We now prove that the class SCFG is not closed under prefix lexicalization.

Theorem 1. *There exists an SCFG which cannot be converted to an equivalent PL-SCFG.*

Proof. The SCFG in (7) generates the language $L = \{\langle a^i b^j c^i, b^j a^i \rangle \mid i \geq 0, j \geq 1\}$, but this language cannot be generated by any PL-SCFG:

(7)
$$\begin{array}{ll}
\langle S \rightarrow A\boxed{1}, & S \rightarrow A\boxed{1} \rangle \\
\langle A \rightarrow aA\boxed{1}c, & A \rightarrow A\boxed{1}a \rangle \\
\langle A \rightarrow bB\boxed{1}, & A \rightarrow bB\boxed{1} \rangle \\
\langle A \rightarrow b, & A \rightarrow b \rangle \\
\langle B \rightarrow bB\boxed{1}, & B \rightarrow bB\boxed{1} \rangle \\
\langle B \rightarrow b, & B \rightarrow b \rangle
\end{array}$$

Suppose, for the purpose of contradiction, that some PL-SCFG does generate L; call this grammar G. Then the following derivations must all be possible in G for some nontermials U, V, X, Y:

i) $\langle U\boxed{1}, V\boxed{1} \rangle \Rightarrow^* \langle b^k U\boxed{1} b^m, b^n V\boxed{1} b^p \rangle$, where $k + m = n + p$ and $n \geq 1$

ii) $\langle X\boxed{1}, Y\boxed{1} \rangle \Rightarrow^* \langle a^q X\boxed{1} c^q, a^r Y\boxed{1} a^s \rangle$, where $q = r + s$ and $r \geq 1$

iii) $\langle S\boxed{1}, S\boxed{1} \rangle \Rightarrow^* \langle \alpha_1 X\boxed{1} \alpha_2, b\alpha_3 Y\boxed{1} \alpha_4 \rangle$, where $\alpha_1, ..., \alpha_4 \in (N \cup \Sigma)^*$

iv) $\langle X\boxed{1}, Y\boxed{1} \rangle \Rightarrow^* \langle \alpha_5 U\boxed{1} \alpha_6, \alpha_7 V\boxed{1} \alpha_8 \rangle$, where $\alpha_5, \alpha_6, \alpha_8 \in (N \cup \Sigma)^*$, $\alpha_7 \in \Sigma(N \cup \Sigma)^*$

i and ii follow from the same arguments used in the pumping lemma for (non-synchronous) context free languages (Bar-Hillel et al., 1961): strings in L can contain arbitrarily many as, bs, and cs, so there must exist some pumpable cycles which generate these characters. In i, $k + m = n + p$ because the final derived strings must contain an equal number of bs, and $n \geq 1$ because G is prefix lexicalized; in ii the constraints on q, r and s follow likewise from L. iii follows from the fact that, in order to pump on the cycle in ii, this cycle must be reachable from the start symbol. iv follows from the fact that a context-free production cannot generate a discontinuous span. Once the cycle in i has generated a b, it is impossible for ii to generate an a on one side of the b and a c on the other. Therefore i must always be derived strictly later than ii, as shown in iv.

Now we obtain a contradiction. Given that G can derive all of i through iv, the following derivation is also possible:

(8)
$$\begin{array}{ll}
 & \langle S\boxed{1}, S\boxed{1} \rangle \\
\Rightarrow^* & \langle \alpha_1 X\boxed{1} \alpha_2, b\alpha_3 Y\boxed{1} \alpha_4 \rangle \\
\Rightarrow^* & \langle \alpha_1 a^q X\boxed{1} c^q \alpha_2, b\alpha_3 a^r Y\boxed{1} a^s \alpha_4 \rangle \\
\Rightarrow^* & \langle \alpha_1 a^q \alpha_5 U\boxed{1} \alpha_6 c^q \alpha_2, b\alpha_3 a^r \alpha_7 V\boxed{1} \alpha_8 a^s \alpha_4 \rangle \\
\Rightarrow^* & \langle \alpha_1 a^q \alpha_5 b^k U\boxed{1} b^m \alpha_6 c^q \alpha_2, \\
 & \quad b\alpha_3 a^r \alpha_7 b^n V\boxed{1} b^p \alpha_8 a^s \alpha_4 \rangle
\end{array}$$

But since $n, r \geq 1$, the target string derived this way contains an a before a b and does not belong to L.

This is a contradiction: if G is a PL-SCFG then it must generate i through iv, but if so then it also generates strings which do not belong to L. Thus no PL-SCFG can generate L, and SCFG must not be closed under prefix lexicalization. ■

There also exist grammars which cannot be prefix lexicalized because they contain cyclic chain rules. If an SCFG can derive something of the form $\langle X\boxed{1}, Y\boxed{1} \rangle \Rightarrow^* \langle xX\boxed{1}, Y\boxed{1} \rangle$, then it can generate arbitrarily many symbols in the source string without adding anything to the target string. Prefix lexicalizing the grammar would force it to generate some terminal symbol in the target string at each step of the derivation, making it unable to generate the original language where a source string may be unboundedly longer than its corresponding target. We call an SCFG chain-free if it does not contain a cycle of chain rules of this form. The remainder of this paper focuses on chain-free grammars, like (7), which cannot be converted to PL-SCFG despite containing no such cycles.

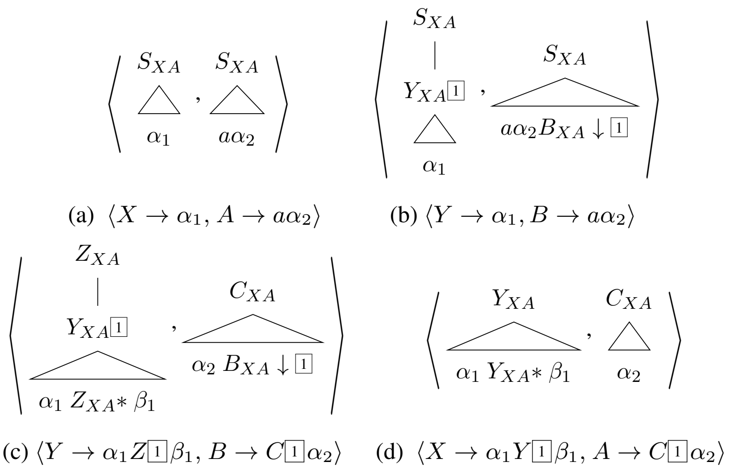
4 Prefix Lexicalization using STAG

We now present a method for prefix lexicalizing an SCFG by converting it to an STAG.

$$\langle X\boxed{1}, A\boxed{1}\rangle \Rightarrow \langle \alpha_1 Y_1\boxed{1}\beta_1, B_1\boxed{1}\gamma_1\rangle \Rightarrow \langle \alpha_1\alpha_2 Y_2\boxed{1}\beta_2\beta_1, B_2\boxed{1}\gamma_2\gamma_1\rangle$$

$$\Rightarrow^* \langle \alpha_1\cdots\alpha_t Y_t\boxed{1}\beta_t\cdots\beta_1, B_t\boxed{1}\gamma_t\cdots\gamma_1\rangle \Rightarrow \langle \alpha_1\cdots\alpha_t\alpha_{t+1}\beta_t\cdots\beta_1, a\gamma_{t+1}\gamma_t\cdots\gamma_1\rangle$$

Figure 2: A target-side terminal leftmost derivation. $a \in \Sigma$; $X, A, Y_i, B_i \in N$; and $\alpha_i, \beta_i, \gamma_i \in (N \cup \Sigma)^*$.



(a) $\langle X \to \alpha_1, A \to a\alpha_2\rangle$ (b) $\langle Y \to \alpha_1, B \to a\alpha_2\rangle$

(c) $\langle Y \to \alpha_1 Z\boxed{1}\beta_1, B \to C\boxed{1}\alpha_2\rangle$ (d) $\langle X \to \alpha_1 Y\boxed{1}\beta_1, A \to C\boxed{1}\alpha_2\rangle$

Figure 3: Tree-pairs in G_{XA} and the rules in G from which they derive.

Theorem 2. *Given a rank-k SCFG G which is ε-free and chain-free, an STAG H exists such that H is prefix lexicalized and $L(G) = L(H)$. The rank of H is at most 2k, and $|H| = O(|G|^3)$.*

Proof. Let $G = (N, \Sigma, P, S)$ be an ε-free, chain-free SCFG. We provide a constructive method for prefix lexicalizing the target side of G.

We begin by constructing an intermediate grammar G_{XA} for each pair of nonterminals $X, A \in N \setminus \{S\}$. For each pair $X, A \in N \setminus \{S\}$, G_{XA} will be constructed to generate the language of sentential forms derivable from $\langle X\boxed{1}, A\boxed{1}\rangle$ via a target-side terminal leftmost derivation (TTLD). A TTLD is a derivation of the form in Figure 2, where the leftmost nonterminal in the target string is expanded until it produces a terminal symbol as the first character. We write $\langle X\boxed{1}, A\boxed{1}\rangle \Rightarrow^*_{TTLD} \langle u, v\rangle$ to mean that $\langle X\boxed{1}, A\boxed{1}\rangle$ derives $\langle u, v\rangle$ by way of a TTLD; in this notation, $L_{XA} = \{\langle u, v\rangle | \langle X\boxed{1}, A\boxed{1}\rangle \Rightarrow^*_{TTLD} \langle u, v\rangle\}$ is the language of sentential forms derivable from $\langle X\boxed{1}, A\boxed{1}\rangle$ via a TTLD.

Given $X, A \in N \setminus \{S\}$ we formally define G_{XA} as an STAG over the terminal alphabet $\Sigma_{XA} = N \cup \Sigma$ and nonterminal alphabet $N_{XA} = \{Y_{XA} | Y \in N\}$, with start symbol S_{XA}. N_{XA} contains nonterminals indexed by XA to ensure that two intermediate grammars G_{XA} and G_{YB} do not interact as long as $\langle X, A\rangle \neq \langle Y, B\rangle$.

G_{XA} contains four kinds of tree pairs: [3]

- For each rule in G of the form $\langle X \to \alpha_1, A \to a\alpha_2\rangle$, $a \in \Sigma$, $\alpha_i \in (N\cup\Sigma)^*$, we add a tree pair of the form in Figure 3(a).
- For each rule in G of the form $\langle Y \to \alpha_1, B \to a\alpha_2\rangle$, $a \in \Sigma$, $\alpha_i \in (N\cup\Sigma)^*$, $Y, B \in N \setminus \{S\}$, we add a tree pair of the form in Figure 3(b).
- For each rule in G of the form $\langle Y \to \alpha_1 Z\boxed{1}\beta_1, B \to C\boxed{1}\alpha_2\rangle$, $Y, Z, B, C \in N \setminus \{S\}$, $\alpha_i, \beta_i \in (N \cup \Sigma)^*$, we add a tree pair of the form in Figure 3(c).

  As a special case, if $Y = Z$ we collapse the root node and adjunction site to produce a tree pair of the following form:

(9) $Z_{XA}\boxed{1}$
$\alpha_1 Z_{XA} * \beta_1$
C_{XA}
$\alpha_2 B_{XA}\downarrow\boxed{1}$

- For each rule in G of the form $\langle X \to \alpha_1 Y\boxed{1}\beta_1, A \to C\boxed{1}\alpha_2\rangle$, $Y, C \in N$, $\alpha_i, \beta_i \in (N \cup \Sigma)^*$, we add a tree pair of the form in Figure 3(d).

[3]In all cases, we assume that symbols in N (not N_{XA}) retain any links they bore in the original grammar, even though they belong to the terminal alphabet in G_{XA} and therefore do not participate in rewriting operations. In the final constructed grammar, these symbols will belong to the nonterminal alphabet again, and the links will function normally.

$$\langle A \to B\boxed{2}cA\boxed{1}, A \to A\boxed{1}cB\boxed{2}\rangle$$

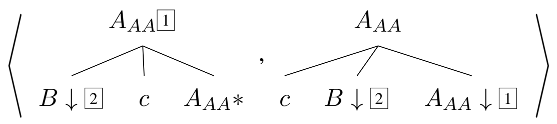

Figure 4: An SCFG rule and a tree pair based off that rule, taken from an intermediate grammar G_{AA}. The tree pair is formed according to the pattern illustrated in Figure 3(c). Observe that the B nodes retain the link they bore in the original rule. This link is not functional in the intermediate grammar (that is, it cannot be used for synchronous rewriting) because $B \notin N_{AA}$, but it will be functional when this tree pair is added to the final grammar H.

Figure 4 gives a concrete example of constructing an intermediate grammar tree pair on the basis of an SCFG rule.

Lemma 1. *G_{XA} generates the language L_{XA}.*

Proof. This can be shown by induction over derivations of increasing length. The proof is straightforward but very long, so we provide only a sketch; the complete proof is provided in the supplementary material.

As a base case, observe that a tree of the shape in Figure 3(a) corresponds straightforwardly to the derivation

(10) $$\langle X\boxed{1}, A\boxed{1}\rangle \Rightarrow \langle \alpha_1, a\alpha_2\rangle$$

which is a TTLD starting from $\langle X, A\rangle$. By construction, therefore, every TTLD of the shape in (10) corresponds to some tree in G_{XA} of shape 3(a); likewise every derivation in G_{XA} comprising a single tree of shape 3(a) corresponds to a TTLD of the shape in (10).

As a second base case, note that a tree of the shape in Figure 3(b) corresponds to the last step of a TTLD like (11):

(11) $$\langle X\boxed{1}, A\boxed{1}\rangle \Rightarrow^*_{TTLD} \langle uY\boxed{1}v, B\boxed{1}w\rangle$$
$$\Rightarrow \langle u\alpha_1 v, a\alpha_2 w\rangle$$

In the other direction, the last step of any TTLD of the shape in (11) will involve some rule of the shape $\langle Y \to \alpha_1, B \to a\alpha_2\rangle$; by construction G_{XA} must contain a corresponding tree pair of shape 3(b).

Together, these base cases establish a one-to-one correspondence between single-tree derivations in G_{XA} and the last step of a TTLD starting from $\langle X, A\rangle$.

Now, assume that the last n steps of every TTLD starting from $\langle X, A\rangle$ correspond to some derivation over n trees in G_{XA}, and *vice versa*. Then the last $n + 1$ steps of that TTLD will also correspond to some $n + 1$ tree derivation in G_{XA}, and *vice versa*.

To see this, consider the step $n + 1$ steps before the end of the TTLD. This step may be in the middle of the derivation, or it may be the first step of the derivation. If it is in the middle, then this step must involve a rule of the shape

(12) $$\langle Y \to \alpha_1 Z\boxed{1}\beta_1, B \to C\boxed{1}\alpha_2\rangle$$

The existence of such a rule in G implies the existence of a corresponding tree in G_{XA} of the shape in Figure 3(c). Adding this tree to the existing n-tree derivation yields a new $n + 1$ tree derivation corresponding to the last $n + 1$ steps of the TTLD.[4] In the other direction, if the $n + 1$th tree[5] of a derivation in G_{XA} is of the shape in Figure 3(c), then this implies the existence of a production in G of the shape in (12). By assumption the first n trees of the derivation in G_{XA} correspond to some TTLD in G; by prepending the rule from (12) to this TTLD we obtain a new TTLD of length $n + 1$ which corresponds to the entire $n + 1$ tree derivation in G_{XA}.

Finally, consider the case where the TTLD is only $n + 1$ steps long. The first step must involve a rule of the form

(13) $$\langle X \to \alpha_1 Y\boxed{1}\beta_1, A \to C\boxed{1}\alpha_2\rangle$$

The existence of such a rule implies the existence of a corresponding tree in G_{XA} of the shape in Figure 3(d). Adding this tree to the derivation which corresponds to the last n steps of the TTLD yields a new $n+1$ tree derivation corresponding to the entire $n + 1$ step TTLD. In the other direction, if the last tree of an $n + 1$ tree derivation in G_A is of the shape in Figure 3(d), then this implies the

[4]It is easy to verify by inspection of Figure 3 that whenever one rule from G can be applied to the output of another rule, then the tree pairs in G_{XA} which correspond to these rules can compose with one another. Thus we can add the new tree to the existing derivation and be assured that it will compose with one of the trees that is already present.

[5]Although trees in G_{XA} may contain symbols from the nonterminal alphabet of G, these symbols belong to the *terminal* alphabet in G_{XA}. Only nonterminals in N_{XA} will be involved in this derivation, and by construction there is at most one such nonterminal per tree. Thus a well-formed derivation structure in G_{XA} will never branch, and we can refer to the $n + 1$th tree pair as the one which is at depth n in the derivation structure.

existence of a production in G of the shape in (13). By assumption the first n trees of the derivation in G_{XA} correspond to some TTLD in G; by prepending the rule from (13) to this TTLD we obtain a new TTLD of length $n + 1$ which corresponds to the entire $n + 1$ tree derivation in G_{XA}.

Taken together, these cases establish a one-to-one correspondence between derivations in G_{XA} and TTLDs which start from $\langle X, A\rangle$; in turn they confirm that G_{XA} generates the desired language L_{XA}. □

Once we have constructed an intermediate grammar G_{XA} for each $X, A \in N \setminus \{S\}$, we obtain the final STAG H as follows:

1. Convert the input SCFG G to an equivalent STAG. For each rule $\langle A_1 \to \alpha_1, A_2 \to \alpha_2\rangle$, where $A_i \in N$, $\alpha_i \in (N \cup \Sigma)^*$, create a tree pair of the form

   (14)
   
   where each pair of linked nonterminals in the original rule become a pair of linked substitution sites in the tree pair. The terminal and nonterminal alphabets and start symbol are unchanged. Call the resulting STAG H.

2. For all $X, A \in N \setminus \{S\}$, add all of the tree pairs from the intermediate grammar G_{XA} to the new grammar H. Expand N to include the new nonterminal symbols in N_{XA}.

3. For every $X, A \in N$, in all tree pairs where the target tree's leftmost leaf is labeled with A and this node is linked to an X, replace this occurrence of A with S_{XA}. Also replace the linked node in the source tree.

4. For every $X, A \in N$, let R_{XA} be the set of all tree pairs rooted in S_{XA}, and let T_{XA} be the set of all tree pairs whose target tree's leftmost leaf is labeled with S_{XA}. For every $\langle s, t\rangle \in T_{XA}$ and every $\langle s', t'\rangle \in R_{XA}$, substitute or adjoin s' and t' into the linked S_{XA} nodes in s and t, respectively. Add the derived trees to H.

5. For all $X, A \in N$, let T_{XA} be defined as above. Remove all tree pairs in T_{XA} from H.

6. For all $X, A \in N$, let R_{XA} be defined as above. Remove all tree pairs in R_{XA} from H.

We now claim that H generates the same language as the original grammar G, and all of the target trees in H are prefix lexicalized.

The first claim follows directly from the construction. Step 1 merely rewrites the grammar in a new formalism. From Lemma 1 it is clear that steps 2–3 do not change the generated language: the set of string pairs generable from a pair of S_{XA} nodes is identical to the set generable from $\langle X, A\rangle$ in the original grammar. Step 4 replaces some nonterminals by all possible alternatives; steps 5–6 then remove the trees which were used in step 4, but since all possible combinations of these trees have already been added to the grammar, removing them will not alter the language.

The second claim follows from inspection of the tree pairs generated in Figure 3. Observe that, by construction, for all $X, A \in N$ every target tree rooted in S_{XA} is prefix lexicalized. Thus the trees created in step 4 are all prefix lexicalized variants of non-lexicalized tree pairs; steps 5–6 then remove the non-lexicalized trees from the grammar. ■

Figure 5 gives an example of this transformation applied to a small grammar. Note how A nodes at the left edge of the target trees end up rewritten as S_{AA} nodes, as per step 4 of the transformation.

5 Complexity & Formal Properties

Our conversion generates a subset of the class of prefix lexicalized STAGs in regular form, which we abbreviate to PL-RSTAG (regular form for TAG is defined in Rogers 1994). This section discusses some formal properties of PL-RSTAG.

Generative Capacity PL-RSTAG is weakly equivalent to the class of ε-free, chain-free SCFGs: this follows immediately from the proof that our transformation does not change the language generated by the input SCFG. Note that every TAG in regular form generates a context-free language (Rogers, 1994).

Alignments and Reordering PL-RSTAG generates the same set of reorderings (alignments) as SCFG. Observe that our transformation does not cause nonterminals which were linked in the original grammar to become unlinked, as noted for example in Figure 4. Thus subtrees which are gener-

$$\begin{array}{ll}\langle S \to B\boxed{2}cA\boxed{1}, & S \to A\boxed{1}cB\boxed{2}\rangle \\ \langle A \to B\boxed{2}cA\boxed{1}, & A \to A\boxed{1}cB\boxed{2}\rangle \\ \langle A \to a, & A \to a\rangle \\ \langle B \to b, & B \to b\rangle\end{array}$$

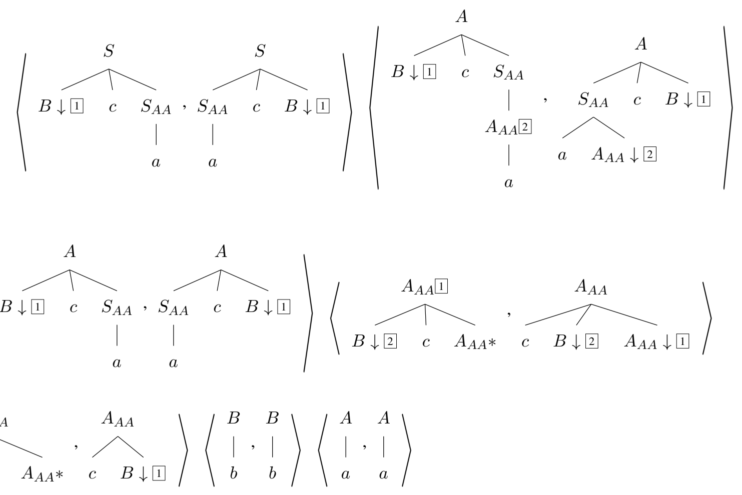

Figure 5: An SCFG and the STAG which prefix lexicalizes it. Non-productive trees have been omitted.

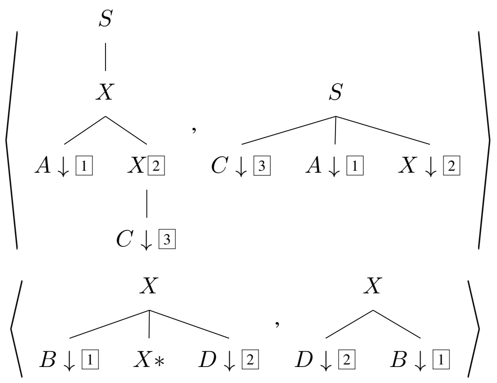
Grammar	$\lvert G\rvert$	$\lvert H\rvert$	% of G prefix lexicalized	$\log_{\lvert G\rvert}(\lvert H\rvert)$
Siahbani and Sarkar (2014a) (Zh-En)	18.5M	23.6T	63%	1.84
Example (7)	6	14	66%	1.47
ITG (10000 translation pairs)	10,003	170,000	99.97%	1.31

Table 1: Grammar sizes before and after prefix lexicalization, showing $O(n^2)$ size increase instead of the worst case $O(n^3)$. $|G|$ and $|H|$ give the grammar size before and after prefix lexicalization; $\log_{|G|}|H|$ is the increase as a power of the initial size. We also show the percentage of productions which are already prefix lexicalized in G.

ated by linked nonterminals in the original grammar will still be generated by linked nonterminals in the final grammar, so no reordering information is lost or added.[6] This result holds despite the fact that our transformation is only applicable to chain-free grammars: chain rules cannot introduce any reorderings, since by definition they involve only a single pair of linked nonterminals.

Grammar Rank If the input SCFG G has rank k, then the STAG H produced by our transformation has rank at most $2k$. To see this, observe that the construction of the intermediate grammars increases the rank by at most 1 (see Figure 3(b)). When a prefix lexicalized tree is substituted at the left edge of a non-lexicalized tree, the link on the substitution site will be consumed, but up to $k+1$ new links will be introduced by the substituting tree, so that the final tree will have rank at most $2k$.

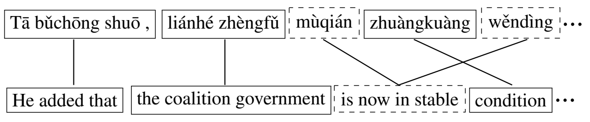
In the general case, rank-k STAG is more powerful than rank-k SCFG; for example, a rank-4 SCFG is required to generate the reordering in $\langle S \to A\boxed{1}B\boxed{2}C\boxed{3}D\boxed{4}, S \to C\boxed{3}A\boxed{1}D\boxed{4}B\boxed{2}\rangle$ (Wu, 1997), but this reordering is captured by the following rank-3 STAG:



For this reason, we speculate that it is possible to further transform the grammars produced by our lexicalization in order to reduce their rank, but the details of this transformation remain as future work.

This potentially poses a solution to an issue raised by Siahbani and Sarkar (2014b). On a Chinese-English translation task, they find that sentences like (15) involve reorderings which cannot be captured by a rank-2 prefix lexicalized SCFG:

(15)



If rank-k PL-RSTAG is more powerful than rank-k

[6]Although we consume one link whenever we substitute a prefix lexicalized tree at the left edge of an unlexicalized tree, that link can still be remembered and used to reconstruct the reorderings which occurred between the two sentences.

SCFG, using a PL-RSTAG here would permit capturing more reorderings without using grammars of higher rank.

Parse Complexity Because the grammar produced is in regular form, each side can be parsed in time $O(n^3)$ (Rogers, 1994), for an overall parse complexity of $O(n^{3k})$, where n is sentence length and k is the grammar rank.

Grammar Size and Experiments If H is the PL-RSTAG produced by applying our transformation to an SCFG G, then H contains $O(|G|^3)$ elementary tree pairs, where $|G|$ is the number of synchronous productions in G. When the set of nonterminals N is small compared to $|G|$, a tighter bound is given by $O(|G|^2|N|^2)$.

Table 1 shows the actual size increase on a variety of grammars: here $|G|$ is the size of the initial grammar, $|H|$ is the size after applying our transformation, and the increase is expressed as a power of the original grammar size. We apply our transformation to the grammar from Siahbani and Sarkar (2014a), which was created for a Chinese-English translation task known to involve complex reorderings that cannot be captured by PL-SCFG (Siahbani and Sarkar, 2014b). We also consider the grammar in (7) and an ITG (Wu, 1997) containing 10,000 translation pairs, which is a grammar of the sort that has previously been used for word alignment tasks (cf Zhang and Gildea 2005). We always observe an increase within $O(|G|^2)$ rather than the worst-case $O(|G|^3)$, because $|N|$ is small relative to $|G|$ in most grammars used for NLP tasks.

We also investigated how the proportion of prefix lexicalized rules in the original grammar affects the overall size increase. We sampled grammars with varying proportions of prefix lexicalized rules from the grammar in Siahbani and Sarkar (2014a); Table 2 shows the result of lexicalizing these samples. We find that the worst case size increase occurs when 50% of the original grammar is already prefix lexicalized. This is because the size increase depends on both the number of prefix lexicalized trees in the intermediate grammars (which grows with the proportion of lexicalized rules) and the number of productions which need to be lexicalized (which shrinks as the proportion of prefix lexicalized rules increases). At 50%, both factors contribute appreciably to the grammar size, analogous to how the function $f(x) = x(1 - x)$ takes its maximum at $x = 0.5$.

$\|G\|$	$\|H\|$	% of G prefix lexicalized	$\log_{\|G\|}(\|H\|)$
15k	42.4M	10%	1.83
15k	74.9M	20%	1.89
15k	97.8M	30%	1.91
15k	112M	40%	1.93
15k	118M	50%	1.93
15k	114M	60%	1.93
15k	102M	70%	1.92
15k	78.2M	80%	1.89
15k	43.6M	90%	1.83

Table 2: Effect of prefix lexicalized rules in G on final grammar size.

6 Applications

The LR decoding algorithm from Watanabe et al. (2006) relies on prefix lexicalized rules to generate a prefix of the target sentence during machine translation. At each step, a translation hypothesis is expanded by rewriting the leftmost nonterminal in its target string using some grammar rule; the prefix of this rule is appended to the existing translation and the remainder of the rule is pushed onto a stack, in reverse order, to be processed later. Translation hypotheses are stored in stacks according to the length of their translated prefix, and beam search is used to traverse these hypotheses and find a complete translation. During decoding, the source side is processed by an Earley-style parser, with the dot moving around to process nonterminals in the order they appear on the target side.

Since the trees on the target side of our transformed grammar are all of depth 1, and none of these trees can compose via the adjunction operation, they can be treated like context-free rules and used as-is in this decoding algorithm. The only change required to adapt LR decoding to use a PL-RSTAG is to make the source side use a TAG parser instead of a CFG parser; an Earley-style parser for TAG already exists (Joshi and Schabes, 1997), so this is a minor adjustment.

Combined with the transformation in Section 4, this suggests a method for using LR decoding without sacrificing translation quality. Previously, LR decoding required the use of heuristically generated PL-SCFGs, which cannot model some reorderings (Siahbani and Sarkar, 2014a). Now, an SCFG tailored for a translation task can be transformed directly to PL-RSTAG and used for decoding; unlike a heuristically induced PL-SCFG, the transformed PL-RSTAG will generate the same language as the original SCFG which is known to handle more reorderings.

Note that, since applying our transformation may double the rank of a grammar, this method may prove prohibitively slow. This highlights the need for future work to examine the generative power of rank-k PL-RSTAG relative to rank-k SCFG in the interest of reducing the rank of the transformed grammar.

7 Related Work

Our work continues the study of TAGs and lexicalization (e.g. Joshi et al. 1975; Schabes and Waters 1993). Schabes and Waters (1995) show that TAG can strongly lexicalize CFG, whereas CFG only weakly lexicalizes itself; we show a similar result for SCFGs. Kuhlmann and Satta (2012) show that TAG is not closed under strong lexicalization, and Maletti and Engelfriet (2012) show how to strongly lexicalize TAG using simple context-free tree grammars (CFTGs).

Other extensions of GNF to new grammar formalisms include Dymetman (1992) for definite clause grammars, Fernau and Stiebe (2002) for CF valence grammars, and Engelfriet et al. (2017) for multiple CFTGs. Although multiple CFTG subsumes SCFG (and STAG), Engelfriet et al.'s result appears to guarantee only that *some* side of every synchronous production will be lexicalized, whereas our result guarantees that it is always the target side that will be prefix lexicalized.

Lexicalization of synchronous grammars was addressed by Zhang and Gildea (2005), but they consider lexicalization rather than prefix lexicalization, and they only consider SCFGs of rank 2. They motivate their results using a word alignment task, which may be another possible application for our lexicalization.

Analogous to our closure result, Aho and Ullman (1969) prove that SCFG does not admit a normal form with bounded rank like Chomsky normal form.

Blum and Koch (1999) use intermediate grammars like our G_{XA}s to transform a CFG to GNF. Another GNF transformation (Rosenkrantz, 1967) is used by Schabes and Waters (1995) to define Tree Insertion Grammars (which are also weakly equivalent to CFG).

We rely on Rogers (1994) for the claim that our transformed grammars generate context-free languages despite allowing wrapping adjunction; an alternative proof could employ the results of Swanson et al. (2013), who develop their own context-free TAG variant known as osTAG.

Kaeshammer (2013) introduces the class of synchronous linear context-free rewriting systems to model reorderings which cannot be captured by a rank-2 SCFG. In the event that rank-k PL-RSTAG is more powerful than rank-k SCFG, our work can be seen as an alternative approach to the same problem.

Finally, Nesson et al. (2008) present an algorithm for reducing the rank of an STAG on-the-fly during parsing; this presents a promising avenue for proving a smaller upper bound on the rank increase caused by our transformation.

8 Conclusion and Future Work

We have demonstrated a method for prefix lexicalizing an SCFG by converting it to an equivalent STAG. This process is applicable to any SCFG which is ε- and chain-free. Like the original GNF transformation for CFGs our construction at most cubes the grammar size, though when applied to the kinds of synchronous grammars used in machine translation the size is merely squared. Our transformation preserves all of the alignments generated by SCFG, and retains properties such as $O(n^{3k})$ parsing complexity for grammars of rank k. We plan to verify whether rank-k PL-RSTAG is more powerful than rank-k SCFG in future work, and to reduce the rank of the transformed grammar if possible. We further plan to empirically evaluate our lexicalization on an alignment task and to offer a comparison against the lexicalization due to Zhang and Gildea (2005).

Abstract

In this work, we propose a novel constituency parsing scheme. The model predicts a vector of real-valued scalars, named syntactic distances, for each split position in the input sentence. The syntactic distances specify the order in which the split points will be selected, recursively partitioning the input, in a top-down fashion. Compared to traditional shift-reduce parsing schemes, our approach is free from the potential problem of compounding errors, while being faster and easier to parallelize. Our model achieves competitive performance amongst single model, discriminative parsers in the PTB dataset and outperforms previous models in the CTB dataset.

1 Introduction

Devising fast and accurate constituency parsing algorithms is an important, long-standing problem in natural language processing. Parsing has been useful for incorporating linguistic prior in several related tasks, such as relation extraction, paraphrase detection (Callison-Burch, 2008), and more recently, natural language inference (Bowman et al., 2016) and machine translation (Eriguchi et al., 2017).

Neural network-based approaches relying on dense input representations have recently achieved competitive results for constituency parsing (Vinyals et al., 2015; Cross and Huang, 2016; Liu and Zhang, 2017b; Stern et al., 2017a). Generally speaking, either these approaches produce the parse tree sequentially, by governing the sequence of transitions in a transition-based parser (Nivre, 2004; Zhu et al., 2013; Chen and Manning, 2014; Cross and Huang, 2016), or use a chart-based approach by estimating non-linear potentials and performing exact structured inference by dynamic programming (Finkel et al., 2008; Durrett and Klein, 2015; Stern et al., 2017a).

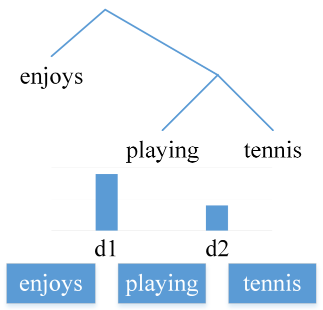

Figure 1: An example of how syntactic distances ($d1$ and $d2$) describe the structure of a parse tree: consecutive words with larger predicted distance are split earlier than those with smaller distances, in a process akin to divisive clustering.

Transition-based models decompose the structured prediction problem into a sequence of local decisions. This enables fast greedy decoding but also leads to compounding errors because the model is never exposed to its own mistakes during training (Daumé et al., 2009). Solutions to this problem usually complexify the training procedure by using structured training through beam-search (Weiss et al., 2015; Andor et al., 2016) and dynamic oracles (Goldberg and Nivre, 2012; Cross and Huang, 2016). On the other hand, chart-based models can incorporate structured loss functions during training and benefit from exact inference via the CYK algorithm but suffer from higher computational cost during decoding (Durrett and Klein, 2015; Stern et al., 2017a).

In this paper, we propose a novel, fully-parallel model for constituency parsing, based on the concept of "syntactic distance", recently introduced by (Shen et al., 2017) for language modeling. To construct a parse tree from a sentence, one can proceed in a top-down manner, recursively splitting larger constituents into smaller constituents, where the order of the splits defines the hierarchical structure. The syntactic distances are defined for each possible split point in the sentence. The order induced by the syntactic distances fully specifies the order in which the sentence needs to be recursively split into smaller constituents (Figure 1): in case of a binary tree, there exists a one-to-one correspondence between the ordering and the tree. Therefore, our model is trained to reproduce the ordering between split points induced by the ground-truth distances by means of a margin rank loss (Weston et al., 2011). Crucially, our model works *in parallel*: the estimated distance for each split point is produced independently from the others, which allows for an easy parallelization in modern parallel computing architectures for deep learning, such as GPUs. Along with the distances, we also train the model to produce the constituent labels, which are used to build the fully labeled tree.

Our model is fully parallel and thus does not require computationally expensive structured inference during training. Mapping from syntactic distances to a tree can be efficiently done in $\mathcal{O}(n \log n)$, which makes the decoding computationally attractive. Despite our strong conditional independence assumption on the output predictions, we achieve good performance for single model discriminative parsing in PTB (91.8 F1) and CTB (86.5 F1) matching, and sometimes outperforming, recent chart-based and transition-based parsing models.

2 Syntactic Distances of a Parse Tree

In this section, we start from the concept of syntactic distance introduced in Shen et al. (2017) for unsupervised parsing via language modeling and we extend it to the supervised setting. We propose two algorithms, one to convert a parse tree into a compact representation based on distances between consecutive words, and another to map the inferred representation back to a complete parse tree. The representation will later be used for supervised training. We formally define the syntactic distances of a parse tree as follows:

Algorithm 1 Binary Parse Tree to Distance
($\cup$ represents the concatenation operator of lists)

```
1: function DISTANCE(node)
2:     if node is leaf then
3:         $\mathbf{d} \leftarrow []$
4:         $\mathbf{c} \leftarrow []$
5:         $\mathbf{t} \leftarrow [\text{node.tag}]$
6:         $h \leftarrow 0$
7:     else
8:         $\text{child}_l, \text{child}_r \leftarrow$ children of node
9:         $\mathbf{d}_l, \mathbf{c}_l, \mathbf{t}_l, h_l \leftarrow \text{Distance}(\text{child}_l)$
10:        $\mathbf{d}_r, \mathbf{c}_r, \mathbf{t}_r, h_r \leftarrow \text{Distance}(\text{child}_r)$
11:        $h \leftarrow \max(h_l, h_r) + 1$
12:        $\mathbf{d} \leftarrow \mathbf{d}_l \cup [h] \cup \mathbf{d}_r$
13:        $\mathbf{c} \leftarrow \mathbf{c}_l \cup [\text{node.label}] \cup \mathbf{c}_r$
14:        $\mathbf{t} \leftarrow \mathbf{t}_l \cup \mathbf{t}_r$
15:    end if
16:    return $\mathbf{d}, \mathbf{c}, \mathbf{t}, h$
17: end function
```

Definition 2.1. Let $\mathbf{T}$ be a parse tree that contains a set of leaves $(w_0, ..., w_n)$. The height of the lowest common ancestor for two leaves (w_i, w_j) is noted as $\tilde{d}_j^i$. The syntactic distances of $\mathbf{T}$ can be any vector of scalars $\mathbf{d} = (d_1, ..., d_n)$ that satisfy:

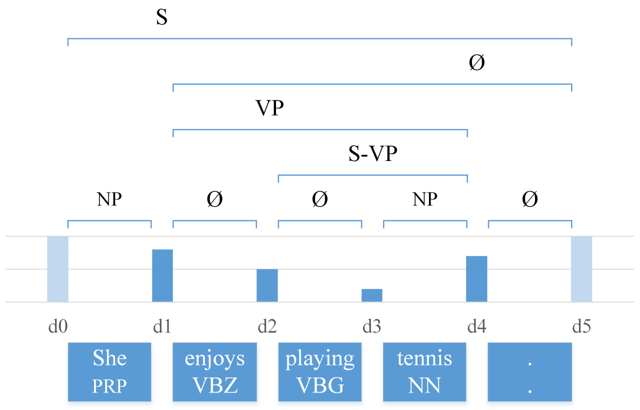
$$\text{sign}(d_i - d_j) = \text{sign}(\tilde{d}_i^{i-1} - \tilde{d}_j^{j-1}) \qquad (1)$$

In other words, $\mathbf{d}$ induces the same ranking order as the quantities $\tilde{d}_i^j$ computed between pairs of consecutive words in the sequence, i.e. $(\tilde{d}_1^0, ..., \tilde{d}_n^{n-1})$. Note that there are $n-1$ syntactic distances for a sentence of length n.

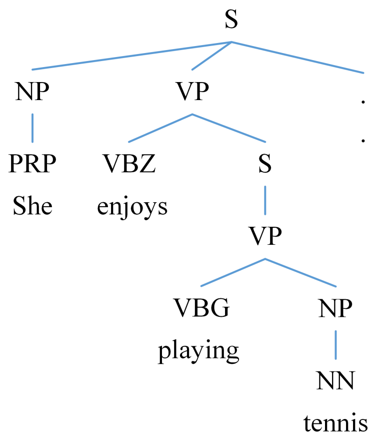
Example 2.1. Consider the tree in Fig. 1 for which $\tilde{d}_1^0 = 2$, $\tilde{d}_2^1 = 1$. An example of valid syntactic distances for this tree is any $\mathbf{d} = (d_1, d_2)$ such that $d_1 > d_2$.

Given this definition, the parsing model predicts a sequence of scalars, which is a more natural setting for models based on neural networks, rather than predicting a set of spans. For comparison, in most of the current neural parsing methods, the model needs to output a sequence of transitions (Cross and Huang, 2016; Chen and Manning, 2014).

Let us first consider the case of a binary parse tree. Algorithm 1 provides a way to convert it to a tuple $(\mathbf{d}, \mathbf{c}, \mathbf{t})$, where $\mathbf{d}$ contains the height of the inner nodes in the tree following a left-to-right (in order) traversal, $\mathbf{c}$ the constituent labels for each node in the same order and $\mathbf{t}$ the part-of-speech



(a) Boxes in the bottom are words and their corresponding POS tags predicted by an external tagger. The vertical bars in the middle are the syntactic distances, and the brackets on top of them are labels of constituents. The bottom brackets are the predicted unary label for each words, and the upper brackets are predicted labels for other constituent.



(b) The corresponding inferred grammar tree.

Figure 2: Inferring the parse tree with Algorithm 2 given distances, constituent labels, and POS tags. Starting with the full sentence, we pick split point 1 (as it is assigned to the larger distance) and assign label S to span (0,5). The left child span (0,1) is assigned with a tag PRP and a label NP, which produces an unary node and a terminal node. The right child span (1,5) is assigned the label ∅, coming from implicit binarization, which indicates that the span is not a real constituent and all of its children are instead direct children of its parent. For the span (1,5), the split point 4 is selected. The recursion of splitting and labeling continues until the process reaches a terminal node.

Algorithm 2 Distance to Binary Parse Tree

```
1:  function TREE($\mathbf{d}$,$\mathbf{c}$,$\mathbf{t}$)
2:      if $\mathbf{d} = []$ then
3:          node ← Leaf($\mathbf{t}$)
4:      else
5:          $i \leftarrow \arg\max_i(\mathbf{d})$
6:          child$_l$ ← Tree($\mathbf{d}_{<i}$, $\mathbf{c}_{<i}$, $\mathbf{t}_{<i}$)
7:          child$_r$ ← Tree($\mathbf{d}_{>i}$, $\mathbf{c}_{>i}$, $\mathbf{t}_{\geq i}$)
8:          node ← Node(child$_l$, child$_r$, $\mathbf{c}_i$)
9:      end if
10:     return node
11: end function
```

(POS) tags of each word in the left-to-right order. $\mathbf{d}$ is a valid vector of syntactic distances satisfying Definition 2.1.

Once a model has learned to predict these variables, Algorithm 2 can reconstruct a unique binary tree from the output of the model $(\hat{\mathbf{d}}, \hat{\mathbf{c}}, \hat{\mathbf{t}})$. The idea in Algorithm 2 is similar to the top-down parsing method proposed by Stern et al. (2017a), but differs in one key aspect: at each recursive call, there is no need to estimate the confidence for every split point. The algorithm simply chooses the split point i with the maximum $\hat{d}_i$, and assigns to the span the predicted label $\hat{c}_i$. This makes the running time of our algorithm to be in $\mathcal{O}(n \log n)$, compared to the $\mathcal{O}(n^2)$ of the greedy top-down algorithm by (Stern et al., 2017a). Figure 2 shows an example of the reconstruction of parse tree. Alternatively, the tree reconstruction process can also be done in a bottom-up manner, which requires the recursive composition of adjacent spans according to the ranking induced by their syntactic distance, a process akin to agglomerative clustering.

One potential issue is the existence of unary and n-ary nodes. We follow the method proposed by Stern et al. (2017a) and add a special empty label ∅ to spans that are not themselves full constituents but simply arise during the course of implicit binarization. For the unary nodes that contains one nonterminal node, we take the common approach of treating these as additional atomic labels alongside all elementary nonterminals (Stern et al., 2017a). For all terminal nodes, we determine whether it belongs to a unary chain or not by predicting an additional label. If it is predicted with a label different from the empty label, we conclude that it is a direct child of a unary constituent with that label. Otherwise if it is predicted to have an empty label, we conclude that it is a child of a bigger constituent which has other constituents or words as its siblings.

An n-ary node can arbitrarily be split into binary nodes. We choose to use the leftmost split point. The split point may also be chosen based on model prediction during training. Recovering an n-ary parse tree from the predicted binary tree simply requires removing the empty nodes and split combined labels corresponding to unary chains.

Algorithm 2 is a divide-and-conquer algorithm. The running time of this procedure is $\mathcal{O}(n \log n)$. However, the algorithm is naturally adapted for execution in a parallel environment, which can further reduce its running time to $\mathcal{O}(\log n)$.

3 Learning Syntactic Distances

We use neural networks to estimate the vector of syntactic distances for a given sentence. We use a modified hinge loss, where the target distances are generated by the tree-to-distance conversion given by Algorithm 1. Section 3.1 will describe in detail the model architecture, and Section 3.2 describes the loss we use in this setting.

3.1 Model Architecture

Given input words $\mathbf{w} = (w_0, w_1, ..., w_n)$, we predict the tuple $(\mathbf{d}, \mathbf{c}, \mathbf{t})$. The POS tags $\mathbf{t}$ are given by an external Part-Of-Speech (POS) tagger. The syntactic distances $\mathbf{d}$ and constituent labels $\mathbf{c}$ are predicted using a neural network architecture that stacks recurrent (LSTM (Hochreiter and Schmidhuber, 1997)) and convolutional layers.

Words and tags are first mapped to sequences of embeddings $\mathbf{e}_0^{\mathrm{w}}, ..., \mathbf{e}_n^{\mathrm{w}}$ and $\mathbf{e}_0^{\mathrm{t}}, ..., \mathbf{e}_n^{\mathrm{t}}$. Then the word embeddings and the tag embeddings are concatenated together as inputs for a stack of bidirectional LSTM layers:

$$\mathbf{h}_0^{\mathrm{w}}, ..., \mathbf{h}_n^{\mathrm{w}} = \mathrm{BiLSTM}_{\mathrm{w}}([\mathbf{e}_0^{\mathrm{w}}, \mathbf{e}_0^{\mathrm{t}}], ..., [\mathbf{e}_n^{\mathrm{w}}, \mathbf{e}_n^{\mathrm{t}}]) \tag{2}$$

where $\mathrm{BiLSTM}_{\mathrm{w}}(\cdot)$ is the word-level bidirectional layer, which gives the model enough capacity to capture long-term syntactical relations between words.

To predict the constituent labels for each word, we pass the hidden states representations $\mathbf{h}_0^{\mathrm{w}}, ..., \mathbf{h}_n^{\mathrm{w}}$ through a 2-layer network $\mathrm{FF}_c^{\mathrm{w}}$, with softmax output:

$$p(c_i^{\mathbf{w}}|\mathbf{w}) = \mathrm{softmax}(\mathrm{FF}_c^{\mathrm{w}}(\mathbf{h}_i^{\mathrm{w}})) \tag{3}$$

To compose the necessary information for inferring the syntactic distances and the constituency label information, we perform an additional convolution:

$$\mathbf{g}_1^{\mathrm{s}}, \ldots, \mathbf{g}_n^{\mathrm{s}} = \mathrm{CONV}(\mathbf{h}_0^{\mathrm{w}}, ..., \mathbf{h}_n^{\mathrm{w}}) \tag{4}$$

where $\mathbf{g}_i^{\mathrm{s}}$ can be seen as a draft representation for each split position in Algorithm 2. Note that the subscripts of g_i^ss start with 1, since we have $n-1$ positions as non-terminal constituents. Then, we stack a bidirectional LSTM layer on top of $\mathbf{g}_i^{\mathrm{s}}$:

$$\mathbf{h}_1^{\mathrm{s}}, ..., \mathbf{h}_n^{\mathrm{s}} = \mathrm{BiLSTM}_{\mathrm{s}}(\mathbf{g}_1^{\mathrm{s}}, \ldots, \mathbf{g}_n^{\mathrm{s}}) \tag{5}$$

where $\mathrm{BiLSTM}_{\mathrm{s}}$ fine-tunes the representation by conditioning on other split position representations. Interleaving between LSTM and convolution layers turned out empirically to be the best choice over multiple variations of the model, including using self-attention (Vaswani et al., 2017) instead of LSTM.

To calculate the syntactic distances for each position, the vectors $\mathbf{h}_1^{\mathrm{s}}, \ldots, \mathbf{h}_n^{\mathrm{s}}$ are transformed through a 2-layer feed-forward network FF_d with a single output unit (this can be done in parallel with 1x1 convolutions), with no activation function at the output layer:

$$\hat{d}_i = \mathrm{FF}_d(\mathbf{h}_i^s), \tag{6}$$

For predicting the constituent labels, we pass the same representations $\mathbf{h}_1^{\mathrm{s}}, \ldots, \mathbf{h}_n^{\mathrm{s}}$ through another 2-layer network $\mathrm{FF}_c^{\mathrm{s}}$, with softmax output.

$$p(c_i^{\mathrm{s}}|\mathbf{w}) = \mathrm{softmax}(\mathrm{FF}_c^{\mathrm{s}}(\mathbf{h}_i^{\mathrm{s}})) \tag{7}$$

The overall architecture is shown in Figure 2a. Since the output $(\mathbf{d}, \mathbf{c}, \mathbf{t})$ can be unambiguously transfered to a unique parse tree, the model implicitly makes all parsing decisions inside the recurrent and convolutional layers.

3.2 Objective

Given a set of training examples $\mathcal{D} = \{\langle \mathbf{d}_k, \mathbf{c}_k, \mathbf{t}_k, \mathbf{w}_k \rangle\}_{k=1}^K$, the training objective is the sum of the prediction losses of syntactic distances $\mathbf{d}_k$ and constituent labels $\mathbf{c}_k$.

Due to the categorical nature of variable $\mathbf{c}$, we use a standard softmax classifier with a cross-entropy loss L_{label} for constituent labels, using the estimated probabilities obtained in Eq. 3 and 7.

A naïve loss function for estimating syntactic distances is the mean-squared error (MSE):

$$L_{\text{dist}}^{\text{mse}} = \sum_i (d_i - \hat{d}_i)^2 \tag{8}$$

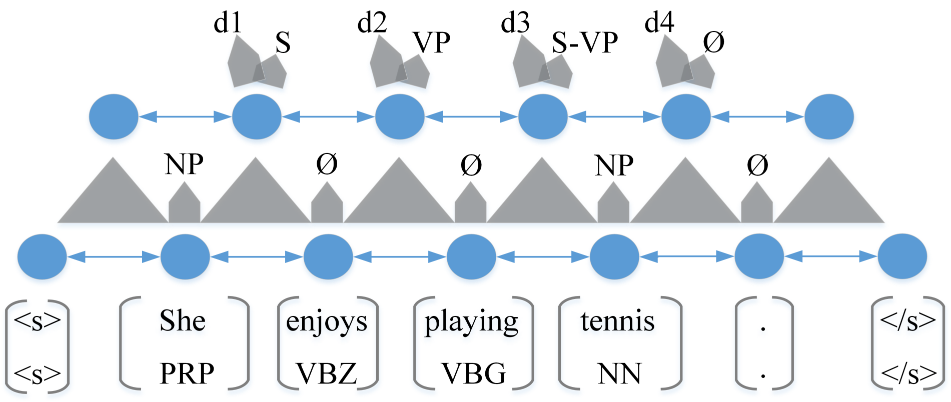


Figure 3: The overall visualization of our model. Circles represent hidden states, triangles represent convolution layers, block arrows represent feed-forward layers, arrows represent recurrent connections. The bottom part of the model predicts unary labels for each input word. The $\emptyset$ is treated as a special label together with other labels. The top part of the model predicts the syntactic distances and the constituent labels. The inputs of model are the word embeddings concatenated with the POS tag embeddings. The tags are given by an external Part-Of-Speech tagger.

The MSE loss forces the model to regress on the exact value of the true distances. Given that only the *ranking* induced by the ground-truth distances in $\mathbf{d}$ is important, as opposed to the absolute values themselves, using an MSE loss over-penalizes the model by ignoring ranking equivalence between different predictions.

Therefore, we propose to minimize a pair-wise learning-to-rank loss, similar to those proposed in (Burges et al., 2005). We define our loss as a variant of the hinge loss as:

$$L_{\text{dist}}^{\text{rank}} = \sum_{i,j>i} [1 - \text{sign}(d_i - d_j)(\hat{d}_i - \hat{d}_j)]^+, \quad (9)$$

where $[x]^+$ is defined as $\max(0, x)$. This loss encourages the model to reproduce the full ranking order induced by the ground-truth distances. The final loss for the overall model is just the sum of individual losses $L = L_{\text{label}} + L_{\text{dist}}^{\text{rank}}$.

4 Experiments

We evaluate our model described above on 2 different datasets, the standard Wall Street Journal (WSJ) part of the Penn Treebank (PTB) dataset, and the Chinese Treebank (CTB) dataset.

For evaluating the F1 score, we use the standard `evalb`[1] tool. We provide both labeled and unlabeled F1 score, where the former takes into consideration the constituent label for each predicted constituent, while the latter only considers the position of the constituents. In the tables below, we report the labeled F1 scores for comparison with previous work, as this is the standard metric usually reported in the relevant literature.

4.1 Penn Treebank

For the PTB experiments, we follow the standard train/valid/test separation and use sections 2-21 for training, section 22 for development and section 23 for test set. Following this split, the dataset has 45K training sentences and 1700, 2416 sentences for valid/test respectively. The placeholders with the `-NONE-` tag are stripped from the dataset during preprocessing. The POS tags are predicted with the Stanford Tagger (Toutanova et al., 2003).

We use a hidden size of 1200 for each direction on all LSTMs, with 0.3 dropout in all the feed-forward connections, and 0.2 recurrent connection dropout (Merity et al., 2017). The convolutional filter size is 2. The number of convolutional channels is 1200. As a common practice for neural network based NLP models, the embedding layer that maps word indexes to word embeddings is randomly initialized. The word embeddings are sized 400. Following (Merity et al., 2017), we randomly swap an input word embedding during training with the zero vector with probability of 0.1. We found this helped the model to generalize better. Training is conducted with Adam algorithm with l2 regularization decay 1×10^{-6}. We pick the result obtaining the highest labeled F1

on the validation set, and report the corresponding test F1, together with other statistics. We report our results in Table 1. Our best model obtains a labeled F1 score of 91.8 on the test set (Table 1). Detailed dev/test set performances, including label accuracy is reported in Table 3.

Our model performs achieves good performance for single-model constituency parsing trained without external data. The best result from (Stern et al., 2017b) is obtained by a generative model. Very recently, we came to knowledge of Gaddy et al. (2018), which uses character-level LSTM features coupled with chart-based parsing to improve performance. Similar sub-word features can be also used in our model. We leave this investigation for future works. For comparison, other models obtaining better scores either use ensembles, benefit from semi-supervised learning, or recur to re-ranking of a set of candidates.

4.2 Chinese Treebank

We use the Chinese Treebank 5.1 dataset, with articles 001-270 and 440-1151 for training, articles

301-325 as development set, and articles 271-300 for test set. This is a standard split in the literature (Liu and Zhang, 2017b). The `-NONE-` tags are stripped as well. The hidden size for the LSTM networks is set to 1200. We use a dropout rate of 0.4 on the feed-forward connections, and 0.1 recurrent connection dropout. The convolutional layer has 1200 channels, with a filter size of 2. We use 400 dimensional word embeddings. During training, input word embeddings are randomly swapped with the zero vector with probability of 0.1. We also apply a l2 regularization weighted by 1×10^{-6} on the parameters of the network. Table 2 reports our results compared to other benchmarks. To the best of our knowledge, we set a new state-of-the-art for single-model parsing achieving 86.5 F1 on the test set. The detailed statistics are shown in Table 3.

4.3 Ablation Study

We perform an ablation study by removing components from a network trained with the best set of hyperparameters, and re-train the ablated version from scratch. This gives an idea of the relative contributions of each of the components in the model. Results are reported in Table 4. It seems that the top LSTM layer has a relatively big impact on performance. This may give additional capacity to the model for capturing long-term dependencies useful for label prediction. We also exper-

dev/test result		Prec.	Recall	F1	label accuracy
PTB	labeled	91.7/92.0	91.8/91.7	91.8/91.8	94.9/95.4%

imented by using 300D GloVe (Pennington et al., 2014) embedding for the input layer but this didn't yield improvements over the model's best performance. Unsurprisingly, the model trained with MSE loss underperforms considerably a model trained with the rank loss.

4.4 Parsing Speed

The prediction of syntactic distances can be batched in modern GPU architectures. The distance to tree conversion is a $\mathcal{O}(n \log n)$ (n stand for the number of words in the input sentence) divide-and-conquer algorithm. We compare the parsing speed of our parser with other state-of-the-art neural parsers in Table 5. As the syntactic distance computation can be performed in parallel within a GPU, we first compute the distances in a batch, then we iteratively decode the tree with Algorithm 2. It is worth to note that this comparison may be unfair since some of the reported results may use very different hardware settings. We couldn't find the source code to re-run them on our hardware, to give a fair enough comparison. In our setting, we use an NVIDIA TITAN Xp graphics card for running the neural network part, and the distance to tree inference is run on an Intel Core i7-6850K CPU, with 3.60GHz clock speed.

5 Related Work

Parsing natural language with neural network models has recently received growing attention. These models have attained state-of-the-art results for dependency parsing (Chen and Manning, 2014) and constituency parsing (Dyer et al., 2016; Cross and Huang, 2016; Coavoux and Crabbé, 2016). Early work in neural network based parsing directly use a feed-forward neural network to predict parse trees (Chen and Manning, 2014). Vinyals et al. (2015) use a sequence-to-sequence framework where the decoder outputs a linearized version of the parse tree given an input sentence. Generally, in these models, the correctness of the output tree is not strictly ensured (although empirically observed).

Other parsing methods ensure structural consistency by operating in a transition-based setting (Chen and Manning, 2014) by parsing either in the top-down direction (Dyer et al., 2016; Liu and Zhang, 2017b), bottom-up (Zhu et al., 2013; Watanabe and Sumita, 2015; Cross and Huang, 2016) and recently in-order (Liu and Zhang, 2017a). Transition-based methods generally suffer from compounding errors due to exposure bias: during testing, the model is exposed to a very different regime (i.e. decisions sampled from the model itself) than what was encountered during training (i.e. the ground-truth decisions) (Daumé et al., 2009; Goldberg and Nivre, 2012). This can have catastrophic effects on test performance but can be mitigated to a certain extent by using beam-search instead of greedy decoding. (Stern et al., 2017b) proposes an effective inference method for generative parsing, which enables direct decoding in those models. More complex training methods have been devised in order to alleviate this problem (Goldberg and Nivre, 2012; Cross and Huang, 2016). Other efforts have been put into neural chart-based parsing (Durrett and Klein, 2015; Stern et al., 2017a) which ensure structural consistency and offer exact inference with CYK algorithm. (Gaddy et al., 2018) includes a simplified CYK-style inference, but the complexity still remains in $O(n^3)$.

In this work, our model learns to produce a particular representation of a tree in parallel. Representations can be computed in parallel, and the conversion from representation to a full tree can efficiently be done with a divide-and-conquer algorithm. As our model outputs decisions in parallel, our model doesn't suffer from the exposure bias. Interestingly, a series of recent works, both in machine translation (Gu et al., 2018) and speech synthesis (Oord et al., 2017), considered the sequence of output variables conditionally independent given the inputs.

6 Conclusion

We presented a novel constituency parsing scheme based on predicting real-valued scalars, named syntactic distances, whose ordering identify the sequence of top-down split decisions. We employ a neural network model that predicts the distances $\mathbf{d}$ and the constituent labels $\mathbf{c}$. Given the algorithms presented in Section 2, we can build an unambiguous mapping between each $(\mathbf{d}, \mathbf{c}, \mathbf{t})$ and a parse tree. One peculiar aspect of our model is that it predicts split decisions *in parallel*. Our experiments show that our model can achieve strong performance compare to previous models, while being significantly more efficient. Since the architecture of model is no more than a stack of standard recurrent and convolution layers, which are essential components in most academic and industrial deep learning frameworks, the deployment of this method would be straightforward.

Abstract

We introduce Latent Vector Grammars (LVeGs), a new framework that extends latent variable grammars such that each nonterminal symbol is associated with a continuous vector space representing the set of (infinitely many) subtypes of the nonterminal. We show that previous models such as latent variable grammars and compositional vector grammars can be interpreted as special cases of LVeGs. We then present Gaussian Mixture LVeGs (GM-LVeGs), a new special case of LVeGs that uses Gaussian mixtures to formulate the weights of production rules over subtypes of nonterminals. A major advantage of using Gaussian mixtures is that the partition function and the expectations of subtype rules can be computed using an extension of the inside-outside algorithm, which enables efficient inference and learning. We apply GM-LVeGs to part-of-speech tagging and constituency parsing and show that GM-LVeGs can achieve competitive accuracies. Our code is available at https://github.com/zhaoyanpeng/lveg.

1 Introduction

In constituency parsing, refining coarse syntactic categories of treebank grammars (Charniak, 1996) into fine-grained subtypes has been proven effective in improving parsing results. Previous approaches to refining syntactic categories use tree annotations (Johnson, 1998), lexicalization (Charniak, 2000; Collins, 2003), or linguistically motivated category splitting (Klein and Manning, 2003). Matsuzaki et al. (2005) introduce latent variable grammars, in which each syntactic category (represented by a nonterminal) is split into a fixed number of subtypes and a discrete latent variable is used to indicate the subtype of the nonterminal when it appears in a specific parse tree. Since the latent variables are not observable in treebanks, the grammar is learned using expectation-maximization. Petrov et al. (2006) present a split-merge approach to learning latent variable grammars, which hierarchically splits each nonterminal and merges ineffective splits. Petrov and Klein (2008b) further allow a nonterminal to have different splits in different production rules, which results in a more compact grammar.

Recently, neural approaches become very popular in natural language processing (NLP). An important technique in neural approaches to NLP is to represent discrete symbols such as words and syntactic categories with continuous vectors or embeddings. Since the distances between such vector representations often reflect the similarity between the corresponding symbols, this technique facilitates more informed smoothing in learning functions of symbols (e.g., the probability of a production rule). In addition, what a symbol represents may subtly depend on its context, and a continuous vector representation has the potential of representing each instance of the symbol in a more precise manner. For constituency parsing, recursive neural networks (Socher et al., 2011) and their extensions such as compositional vector grammars (Socher et al., 2013) can be seen as representing nonterminals in a context-free grammar with continuous vectors. However, exact inference in these models is intractable.

In this paper, we introduce latent vector grammars (LVeGs), a novel framework of grammars with fine-grained nonterminal subtypes. A LVeG associates each nonterminal with a continuous vector space that represents the set of (infinitely many) subtypes of the nonterminal. For each instance of a nonterminal that appears in a parse tree, its subtype is represented by a latent vector. For each production rule over nonterminals, a non-negative continuous function specifies the weight of any fine-grained production rule over subtypes of the nonterminals. Compared with latent variable grammars which assume a small fixed number of subtypes for each nonterminal, LVeGs assume an unlimited number of subtypes and are potentially more expressive. By having weight functions of varying smoothness for different production rules, LVeGs can also control the level of subtype granularity for different productions, which has been shown to improve the parsing accuracy (Petrov and Klein, 2008b). In addition, similarity between subtypes of a nonterminal can be naturally modeled by the distance between the corresponding vectors, so by using continuous and smooth weight functions we can ensure that similar subtypes will have similar syntactic behaviors.

We further present Gaussian Mixture LVeGs (GM-LVeGs), a special case of LVeGs that uses mixtures of Gaussian distributions as the weight functions of fine-grained production rules. A major advantage of GM-LVeGs is that the partition function and the expectations of fine-grained production rules can be computed using an extension of the inside-outside algorithm. This makes it possible to efficiently compute the gradients during discriminative learning of GM-LVeGs. We evaluate GM-LVeGs on part-of-speech tagging and constituency parsing on a variety of languages and corpora and show that GM-LVeGs achieve competitive results.

It shall be noted that many modern state-of-the-art constituency parsers predict how likely a constituent is based on not only local information (such as the production rules used in composing the constituent), but also contextual information of the constituent. For example, the neural CRF parser (Durrett and Klein, 2015) looks at the words before and after the constituent; and RNNG (Dyer et al., 2016) looks at the constituents that are already predicted (in the stack) and the words that are not processed (in the buffer). In this paper, however, we choose to focus on the basic framework and algorithms of LVeGs and leave the incorporation of contextual information for future work. We believe that by laying a solid foundation for LVeGs, our work can pave the way for many interesting extensions of LVeGs in the future.

2 Latent Vector Grammars

A latent vector grammar (LVeG) considers subtypes of nonterminals as continuous vectors and associates each nonterminal with a latent vector space representing the set of its subtypes. For each production rule, the LVeG defines a weight function over the subtypes of the nonterminal involved in the production rule. In this way, it models the space of refinements of the production rule.

2.1 Model Definition

A latent vector grammar is defined as a 5-tuple $\mathcal{G} = (N, S, \Sigma, R, W)$, where N is a finite set of nonterminal symbols, $S \in N$ is the start symbol, Σ is a finite set of terminal symbols such that $N \cap \Sigma = \varnothing$, R is a set production rules of the form $X \to \gamma$ where $X \in N$ and $\gamma \in (N \cup \Sigma)^*$, W is a set of rule weight functions indexed by production rules in R (to be defined below). In the following discussion, we consider R in the Chomsky normal form (CNF) for clarity of presentation. However, it is straightforward to extend our formulation to the general case.

Unless otherwise specified, we always use capital letters $A, B, C, \dots$ for nonterminal symbols and use bold lowercase letters $\mathbf{a}, \mathbf{b}, \mathbf{c}, \dots$ for their subtypes. Note that subtypes are represented by continuous vectors. For a production rule of the form $A \to BC$, its weight function is $W_{A \to BC}(\mathbf{a}, \mathbf{b}, \mathbf{c})$. For a production rule of the form $A \to w$ where $w \in \Sigma$, its weight function is $W_{A \to w}(\mathbf{a})$. The weight functions should be non-negative, continuous and smooth, and hence fine-grained production rules of similar subtypes of a nonterminal would have similar weight assignments. Rule weights can be normalized such that $\sum_{B,C} \int_{\mathbf{b},\mathbf{c}} W_{A \to BC}(\mathbf{a}, \mathbf{b}, \mathbf{c}) d\mathbf{b} d\mathbf{c} = 1$, which leads to a probabilistic context-free grammar (PCFG). Whether the weights are normalized or not leads to different model classes and accordingly different estimation methods. However, the two model classes are proven equivalent by Smith and Johnson (2007).

2.2 Relation to Other Models

Latent variable grammars (LVGs) (Matsuzaki et al., 2005; Petrov et al., 2006) associate each nonterminal with a discrete latent variable, which is used to indicate the subtype of the nonterminal when it appears in a parse tree. Through nonterminal-splitting and the expectation-maximization algorithm, fine-grained production rules can be automatically induced from a treebank.

We show that LVGs can be seen as a special case of LVeGs. Specifically, we can use one-hot vectors in LVeGs to represent latent variables in LVGs and define weight functions in LVeGs accordingly. Consider a production rule $r : A \to BC$. In a LVG, each nonterminal is split into a number of subtypes. Suppose A, B, and C are split into n_A, n_B, and n_C subtypes respectively. a_x is the x-th subtype of A, b_y is the y-th subtype of B, and c_z is the z-th subtype of C. $a_x \to b_y c_z$ is a fine-grained production rule of $A \to BC$, where $x = 1, \ldots, n_A$, $y = 1, \ldots, n_B$, and $z = 1, \ldots, n_C$. The probabilities of all the fine-grained production rules can be represented by a rank-3 tensor $\Theta_{A \to BC} \in \mathbb{R}^{n_A \times n_B \times n_C}$. To cast the LVG as a LVeG, we require that the latent vectors in the LVeG must be one-hot vectors. We achieve this by defining weight functions that output zero if any of the input vectors is not one-hot. Specifically, we define the weight function of the production rule $A \to BC$ as:

$$W_r(\mathbf{a}, \mathbf{b}, \mathbf{c}) = \sum_{x,y,z} \Theta_{A \to BC} \mathbf{cba} \times (\delta(\mathbf{a} - \mathbf{a}_x) \times \delta(\mathbf{b} - \mathbf{b}_y) \times \delta(\mathbf{c} - \mathbf{c}_z)) \,, \qquad (1)$$

where $\delta(\cdot)$ is the Dirac delta function, $\mathbf{a}_x \in \mathbb{R}^{n_A}$, $\mathbf{b}_y \in \mathbb{R}^{n_B}$, $\mathbf{c}_z \in \mathbb{R}^{n_C}$ are one-hot vectors (which are zero everywhere with the exception of a single 1 at the x-th index of $\mathbf{a}_x$, the y-th index of $\mathbf{b}_y$, and the z-th index of $\mathbf{c}_z$) and $\Theta_{A \to BC}$ is multiplied sequentially by $\mathbf{c}$, $\mathbf{b}$, and $\mathbf{a}$.

Compared with LVGs, LVeGs have the following advantages. While a LVG contains a finite, typically small number of subtypes for each nonterminal, a LVeG uses a continuous space to represent an infinite number of subtypes. When equipped with weight functions of sufficient complexity, LVeGs can represent more fine-grained syntactic categories and production rules than LVGs. By controlling the complexity and smoothness of the weight functions, a LVeG is also capable of representing any level of subtype granularity. Importantly, this allows us to change the level of subtype granularity for the same nonterminal in different production rules, which is similar to multi-scale grammars (Petrov and Klein, 2008b). In addition, with a continuous space of subtypes in a LVeG, similarity between subtypes can be naturally modeled by their distance in the space and can be automatically learned from data. Consequently, with continuous and smooth weight functions, fine-grained production rules over similar subtypes would have similar weights in LVeGs, eliminating the need for the extra smoothing steps that are necessary in training LVGs.

Compositional vector grammars (CVGs) (Socher et al., 2013), an extension of recursive neural networks (RNNs) (Socher et al., 2011), can also be seen as a special case of LVeGs. For a production rule $r : A \to BC$, a CVG can be interpreted as specifying its weight function $W_r(\mathbf{a}, \mathbf{b}, \mathbf{c})$ in the following way. First, a neural network f indexed by B and C is used to compute a parent vector $\mathbf{p} = f_{BC}(\mathbf{b}, \mathbf{c})$. Next, the score of the parent vector is computed using a base PCFG and a vector $\mathbf{v}_{BC}$:

$$s(\mathbf{p}) = \mathbf{v}_{BC}^T \mathbf{p} + \log P(A \to BC) \,, \qquad (2)$$

where $P(A \to BC)$ is the rule probability from the base PCFG. Then, the weight function of the production rule $A \to BC$ is defined as:

$$W_r(\mathbf{a}, \mathbf{b}, \mathbf{c}) = \exp\left(s(\mathbf{p})\right) \times \delta(\mathbf{a} - \mathbf{p}) \,. \qquad (3)$$

This form of weight functions in CVGs leads to point estimation of latent vectors in a parse tree, i.e., for each nonterminal in a given parse tree, only one subtype in the whole subtype space would lead to a non-zero weight of the parse. In addition, different parse trees of the same substring typically lead to different point estimations of the subtype vector at the root nonterminal. Consequently, CVGs cannot use dynamic programming for inference and hence have to resort to greedy search or beam search.

3 Gaussian Mixture LVeGs

A major challenge in applying LVeGs to parsing is that it is impossible to enumerate the infinite number of subtypes. Previous work such as CVGs resorts to point estimation and greedy search. In this section we present Gaussian Mixture LVeGs (GM-LVeGs), which use mixtures of Gaussian distributions as the weight functions in LVeGs. Because Gaussian mixtures have the nice property of being closed under product, summation, and marginalization, we can compute the partition function and the expectations of fine-grained production rules using dynamic programming. This in turn makes efficient learning and parsing possible.

3.1 Representation

In a GM-LVeG, the weight function of a production rule r is defined as a Gaussian mixture containing K_r mixture components:

$$W_r(\mathbf{r}) = \sum_{k=1}^{K_r} \rho_{r,k} \mathcal{N}(\mathbf{r}|\boldsymbol{\mu}_{r,k}, \boldsymbol{\Sigma}_{r,k}) \,, \tag{4}$$

where $\mathbf{r}$ is the concatenation of the latent vectors of the nonterminals in r, which denotes a fine-grained production rule of r. $\rho_{r,k} > 0$ is the k-th mixture weight (the mixture weights do not necessarily sum up to 1), $\mathcal{N}(\mathbf{r}|\boldsymbol{\mu}_{r,k}, \boldsymbol{\Sigma}_{r,k})$ is the k-th Gaussian distribution parameterized by mean $\boldsymbol{\mu}_{r,k}$ and covariance matrix $\boldsymbol{\Sigma}_{r,k}$, and K_r is the number of mixture components, which can be different for different production rules. Below we write $\mathcal{N}(\mathbf{r}|\boldsymbol{\mu}_{r,k}, \boldsymbol{\Sigma}_{r,k})$ as $\mathcal{N}_{r,k}(\mathbf{r})$ for brevity. Given a production rule of the form $A \to BC$, the GM-LVeG expects $\mathbf{r} = [\mathbf{a}; \mathbf{b}; \mathbf{c}]$ and $\mathbf{a}, \mathbf{b}, \mathbf{c} \in \mathbb{R}^d$, where d is the dimension of the vectors $\mathbf{a}, \mathbf{b}, \mathbf{c}$. We use the same dimension for all the subtype vectors.

For the sake of computational efficiency, we use diagonal or spherical Gaussian distributions, whose covariance matrices are diagonal, so that the inverse of covariance matrices in Equation 15–16 can be computed in linear time. A spherical Gaussian has a diagonal covariance matrix where all the diagonal elements are equal, so it has fewer free parameters than a diagonal Gaussian and results in faster learning and parsing. We empirically find that spherical Gaussians lead to slightly better balance between the efficiency and the parsing accuracy than diagonal Gaussians.

3.2 Parsing

The goal of parsing is to find the most probable parse tree T^* with unrefined nonterminals for a sentence $\mathbf{w}$ of n words $w_{1:n} = w_1 \ldots w_n$. This is formally defined as:

$$T^* = \operatorname*{argmax}_{T \in G(\mathbf{w})} P(T|\mathbf{w}) \,, \tag{5}$$

where $G(\mathbf{w})$ denotes the set of parse trees with unrefined nonterminals for $\mathbf{w}$. In a PCFG, T^* can be found using dynamic programming such as the CYK algorithm. However, parsing becomes intractable with LVeGs, and even with LVGs, the special case of LVeGs.

A common practice in parsing with LVGs is to use max-rule parsing (Petrov et al., 2006; Petrov and Klein, 2007). The basic idea of max-rule parsing is to decompose the posteriors over parses into the posteriors over production rules approximately. This requires calculating the expected counts of unrefined production rules in parsing the input sentence. Since Gaussian mixtures are closed under product, summation, and marginalization, in GM-LVeGs the expected counts can be calculated using the inside-outside algorithm in the following way. Given a sentence $w_{1:n}$, we first calculate the inside score $s_{\mathbf{I}}^A(\mathbf{a}, i, j)$ and outside score $s_{\mathbf{O}}^A(\mathbf{a}, i, j)$ for a nonterminal A over a span $w_{i:j}$ using Equation 6 and Equation 7 in Table 1 respectively. Note that both $s_{\mathbf{I}}^A(\mathbf{a}, i, j)$ and $s_{\mathbf{O}}^A(\mathbf{a}, i, j)$ are mixtures of Gaussian distributions of the subtype vector $\mathbf{a}$. Next, using Equation 8 in Table 1, we calculate the score $s(A \to BC, i, k, j)$ $(1 \le i \le k < j \le n)$, where $\langle A \to BC, i, k, j \rangle$ represents a production rule $A \to BC$ with nonterminals A, B, and C spanning words $w_{i:j}$, $w_{i,k}$, and $w_{k+1:j}$ respectively in the sentence $w_{1:n}$. Then the expected count (or posterior) of $\langle A \to BC, i, k, j \rangle$ is calculated as:

$$q(A \to BC, i, k, j) = \frac{s(A \to BC, i, k, j)}{s_{\mathbf{I}}(S, 1, n)} \,, \tag{9}$$

where $s_{\mathbf{I}}(S, 1, n)$ is the inside score for the start symbol S spanning the whole sentence $w_{1:n}$. After calculating all the expected counts, we can use the MAX-RULE-PRODUCT algorithm (Petrov and Klein, 2007) for parsing, which returns a parse with the highest probability that all the production rules are correct. Its objective function is given by

$$T_q^* = \operatorname*{argmax}_{T \in G(\mathbf{w})} \prod_{e \in T} q(e) \,, \tag{10}$$

where e ranges over all the 4-tuples $\langle A \to BC, i, k, j \rangle$ in the parse tree T. This objective function can be efficiently solved by dynamic programming such as the CYK algorithm.

Although the time complexity of the inside-outside algorithm with GM-LVeGs is polynomial in the sentence length and the nonterminal number, in practice the algorithm is still slow because the number of Gaussian components in the inside and outside scores increases dramatically with the recursion depth. To speed up the computation, we prune Gaussian components in the inside and outside scores using the following technique. Suppose we have a minimum pruning threshold k_{min}

$$s_{\mathbf{I}}^{A}(\mathbf{a},i,j) = \sum_{A\to BC\in R}\sum_{k=i,\cdots,j-1}\iint W_{A\to BC}(\mathbf{a},\mathbf{b},\mathbf{c})\times s_{\mathbf{I}}^{B}(\mathbf{b},i,k)\times s_{\mathbf{I}}^{C}(\mathbf{c},k+1,j)\,d\mathbf{b}d\mathbf{c}\,. \tag{6}$$

$$s_{\mathbf{O}}^{A}(\mathbf{a},i,j) = \sum_{B\to CA\in R}\sum_{k=1,\cdots,i-1}\iint W_{B\to CA}(\mathbf{b},\mathbf{c},\mathbf{a})\times s_{\mathbf{O}}^{B}(\mathbf{b},k,j)\times s_{\mathbf{I}}^{C}(\mathbf{c},k,i-1)\,d\mathbf{b}d\mathbf{c} + \sum_{B\to AC\in R}\sum_{k=j+1,\cdots,n}\iint W_{B\to AC}(\mathbf{b},\mathbf{a},\mathbf{c})\times s_{\mathbf{O}}^{B}(\mathbf{b},i,k)\times s_{\mathbf{I}}^{C}(\mathbf{c},j+1,k)\,d\mathbf{b}d\mathbf{c}\,. \tag{7}$$

$$s(A\to BC,i,k,j) = \iiint W_{A\to BC}(\mathbf{a},\mathbf{b},\mathbf{c})\times s_{\mathbf{O}}^{A}(\mathbf{a},i,j)\times s_{\mathbf{I}}^{B}(\mathbf{b},i,k)\times s_{\mathbf{I}}^{C}(\mathbf{c},k+1,j)\,d\mathbf{a}d\mathbf{b}d\mathbf{c}\,. \tag{8}$$

Table 1: Equation 6: $s_{\mathbf{I}}^{A}(\mathbf{a},i,j)$ is the inside score of a nonterminal A over a span $w_{i:j}$ in the sentence $w_{1:n}$, where $1 \leq i < j \leq n$. Equation 7: $s_{\mathbf{O}}^{A}(\mathbf{a},i,j)$ is the outside score of a nonterminal A over a span $w_{i:j}$ in the sentence $w_{1:n}$, where $1 \leq i \leq j \leq n$. Equation 8: $s(A \to BC, i, k, j)$ is the score of a production rule $A \to BC$ with nonterminals A, B, and C spanning words $w_{i:j}$, $w_{i,k}$, and $w_{k+1:j}$ respectively in the sentence $w_{1:n}$, where $1 \leq i \leq k < j \leq n$.

and a maximum pruning threshold k_{max}. Given an inside or outside score with k_c Gaussian components, if $k_c \leq k_{min}$, then we do not prune any Gaussian component; otherwise, we compute $k_{allow} = \min\{k_{min} + \text{floor}(k_c^{\vartheta}), k_{max}\}$ ($0 \leq \vartheta \leq 1$ is a constant) and keep only k_{allow} components with the largest mixture weights.

In addition to component pruning, we also employ two constituent pruning techniques to reduce the search space during parsing. The first technique is used by Petrov et al. (2006). Before parsing a sentence with a GM-LVeG, we run the inside-outside algorithm with the treebank grammar and calculate the posterior probability of every nonterminal spanning every substring. Then a nonterminal would be pruned from a span if its posterior probability is below a pre-specified threshold p_{min}. When parsing with GM-LVeGs, we only consider the unpruned nonterminals for each span.

The second constituent pruning technique is similar to the one used by Socher et al. (2013). Note that for a strong constituency parser such as the Berkeley parser (Petrov and Klein, 2007), the constituents in the top 200 best parses of a sentence can cover almost all the constituents in the gold parse tree. So we first use an existing constituency parser to run k-best parsing with $k = 200$ on the input sentence. Then we parse with a GM-LVeG and only consider the constituents that appear in the top 200 parses. Note that this method is different from the re-ranking technique because it may produce a parse different from the top 200 parses.

3.3 Learning

Given a training dataset $D = \{(T_i, \mathbf{w}_i) \,|\, i = 1, \ldots, m\}$ containing m samples, where T_i is the gold parse tree with unrefined nonterminals for the sentence $\mathbf{w}_i$, the objective of discriminative learning is to minimize the negative log conditional likelihood:

$$\mathcal{L}(\Theta) = -\log \prod_{i=1}^{m} P(T_i | \mathbf{w}_i; \Theta)\,, \tag{11}$$

where Θ represents the set of parameters of the GM-LVeG.

We optimize the objective function using the Adam (Kingma and Ba, 2014) optimization algorithm. The derivative with respect to Θ_r, the parameters of the weight function $W_r(\mathbf{r})$ of an unrefined production rule r, is calculated as follows (the derivation is in the supplementary material):

$$\frac{\partial \mathcal{L}(\Theta)}{\partial \Theta_r} = \sum_{i=1}^{m} \int \left(\frac{\partial W_r(\mathbf{r})}{\partial \Theta_r} \times \frac{\mathbb{E}_{P(t|\mathbf{w}_i)}[f_r(t)] - \mathbb{E}_{P(t|T_i)}[f_r(t)]}{W_r(\mathbf{r})} \right) d\mathbf{r}\,, \tag{12}$$

where t indicates a parse tree with nonterminal subtypes, and $f_r(t)$ is the number of occurrences of the unrefined rule r in the unrefined parse tree that is obtained by replacing all the subtypes in t with the corresponding nonterminals. The two expectations in Equation 12 can be efficiently computed using the inside-outside algorithm. Because the second expectation is conditioned on the parse tree T_i, in Equation 6 and Equation 7 we can skip all the summations and assign the values of B, C, and k according to T_i.

In GM-LVeGs, Θ_r is the set of parameters in a Gaussian mixture:

$$\Theta_r = \{(\rho_{r,k}, \boldsymbol{\mu}_{r,k}, \boldsymbol{\Sigma}_{r,k}) | k = 1, \dots, K_r\} . \quad (13)$$

According to Equation 12, we need to take the derivatives of $W_r(\mathbf{r})$ respect to $\rho_{r,k}$, $\boldsymbol{\mu}_{r,k}$, and $\boldsymbol{\Sigma}_{r,k}$ respectively:

$$\partial W_r(\mathbf{r}) / \partial \rho_{r,k} = \mathcal{N}_{r,k}(\mathbf{r}) , \quad (14)$$

$$\partial W_r(\mathbf{r}) / \partial \boldsymbol{\mu}_{r,k} = \rho_{r,k} \mathcal{N}_{r,k}(\mathbf{r}) \boldsymbol{\Sigma}_{r,k}^{-1} (\mathbf{r} - \boldsymbol{\mu}_{r,k}) , \quad (15)$$

$$\partial W_r(\mathbf{r}) / \partial \boldsymbol{\Sigma}_{r,k} = \rho_{r,k} \mathcal{N}_{r,k}(\mathbf{r}) \boldsymbol{\Sigma}_{r,k}^{-1} \frac{1}{2} \Big(- I + (\mathbf{r} - \boldsymbol{\mu}_{r,k})(\mathbf{r} - \boldsymbol{\mu}_{r,k})^T \boldsymbol{\Sigma}_{r,k}^{-1} \Big) . \quad (16)$$

Substituting Equation 14–16 into Equation 12, we have the full gradient formulations of all the parameters. In spite of the integral in Equation 12, we can derive a closed-form solution for the gradient of each parameter, which is shown in the supplementary material.

In order to keep each mixture weight $\rho_{r,k}$ positive, we do not directly optimize $\rho_{r,k}$; instead, we set $\rho_{r,k} = \exp(\theta_{\rho_{r,k}})$ and optimize $\theta_{\rho_{r,k}}$ by gradient descent. We use a similar trick to keep each covariance matrix $\boldsymbol{\Sigma}_{r,k}$ positive definite.

Since we use the inside-outside algorithm described in Section 3.2 to calculate the two expectations in Equation 12, we face the same efficiency problem that we encounter in parsing. To speed up the computation,we again use both component pruning and constituent pruning introduced in Section 3.2.

Because gradient descent is often sensitive to the initial values of the parameters, we employ the following informed initialization method. Mixture weights are initialized using the treebank grammar. Suppose in the treebank grammar $P(r)$ is the probability of a production rule r. We initialize the mixture weights in the weight function W_r by $\rho_{r,k} = \alpha \cdot P(r)$ where $\alpha > 1$ is a constant. We initialize all the covariance matrices to identity matrices and initialize each mean with a value uniformly sampled from $[-0.05, 0.05]$.

4 Experiment

We evaluate the GM-LVeG on part-of-speech (POS) tagging and constituency parsing and compare it against its special cases such as LVGs and CVGs. It shall be noted that in this paper we focus on the basic framework of LVeGs and aim to show its potential advantage over previous special cases. It is therefore not our goal to compete with the latest state-of-the-art approaches to tagging and parsing. In particular, we currently do not incorporate contextual information of words and constituents during tagging and parsing, while such information is critical in achieving state-of-the-art accuracy. We will discuss future improvements of LVeGs in Section 5.

4.1 Datasets

Parsing. We use the Wall Street Journal corpus from the Penn English Treebank (WSJ) (Marcus et al., 1994). Following the standard data splitting, we use sections 2 to 21 for training, section 23 for testing, and section 22 for development. We preprocess the treebank using a right-branching binarization procedure to obtain an unannotated X-bar grammar, so that there are only binary and unary production rules. To deal with the problem of unknown words in testing, we adopt the unknown word features used in the Berkeley parser and set the unknown word threshold to 1. Specifically, any word occurring less than two times is replaced by one of the 60 unknown word categories.

Tagging. (1) We use Wall Street Journal corpus from the Penn English Treebank (WSJ) (Marcus et al., 1994). Following the standard data splitting, we use sections 0 to 18 for training, sections 22 to 24 for testing, and sections 19 to 21 for development. (2) The Universal Dependencies treebank 1.4 (UD) (Nivre et al., 2016), in which English, French, German, Russian, Spanish, Indonesian, Finnish, and Italian treebanks are used. We use the original data splitting of these corpora for training and testing. For both WSJ and UD English treebanks, we deal with unknown words in the same way as we do in parsing. For the rest of the data, we use only one unknown word category and the unknown word threshold is also set to 1.

4.2 POS Tagging

POS tagging is the task of labeling each word in a sentence with the most probable part-of-speech tag. Here we focus on POS tagging with Hidden Markov Models (HMMs). Because HMMs are equivalent to probabilistic regular grammars, we can extend HMMs with both LVGs and LVeGs. Specifically, the hidden states in HMMs can be seen as nonterminals in regular grammars and therefore can be associated with latent variables or latent vectors.

We implement two training methods for LVGs. The first (LVG-G) is generative training using expectation-maximization that maximizes the joint probability of the sentence and the tags. The second (LVG-D) is discriminative training using gradient descent that maximizes the conditional probability of the tags given the sentence. In both cases, each nonterminal is split into a fixed number of subtypes. In our experiments we test 1, 2, 4, 8, and 16 subtypes of each nonterminal. Due to the limited space, we only report experimental results of LVG with 16 subtypes for each nonterminal. Full experimental results can be found in the supplementary material.

We experiment with two different GM-LVeGs: GM-LVeG-D with diagonal Gaussians and GM-LVeG-S with spherical Gaussians. In both cases, we fix the number of Gaussian components K_r to 4 and the dimension of the latent vectors d to 3. We do not use any pruning techniques in learning and inference because we find that our algorithm is fast enough with the current setting of K_r and d. We train the GM-LVeGs for 20 epoches and select the models with the best token accuracy on the development data for the final testing.

We report both token accuracy and sentence accuracy of POS tagging in Table 2. It can be seen that, on all the testing data, GM-LVeGs consistently surpass LVGs in terms of both token accuracy and sentence accuracy. GM-LVeG-D is slightly better than GM-LVeG-S in sentence accuracy, producing the best sentence accuracy on 5 of the 9 testing datasets. GM-LVeG-S performs slightly better than GM-LVeG-D in token accuracy on 5 of the 9 datasets. Overall, there is not significant difference between GM-LVeG-D and GM-LVeG-S. However, GM-LVeG-S admits more efficient learning than GM-LVeG-D in practice since it has fewer parameters.

4.3 Parsing

For efficiency, we train GM-LVeGs only on sentences with no more than 50 words (totally 39115 sentences). Since we have found that spherical Gaussians are better than diagonal Gaussians considering both model performance and learning efficiency, here we use spherical Gaussians in the weight functions. The dimension of latent vectors d is set to 3, and all the Gaussian mixtures have $K_r = 4$ components. We use $\alpha = 8$ in initializing mixture weights. We train the GM-LVeG for 15 epoches and select the model with the highest F1 score on the development data for the final testing. We use component pruning in both learning and parsing, with $k_{max} = 50$ and $\vartheta = 0.35$ in both learning and parsing, $k_{min} = 40$ in learning and $k_{min} = 20$ in parsing. During learning we use the first constituent pruning technique with the pruning threshold $p_{min} = 1e - 5$, and during parsing we use the second constituent pruning technique based on the Berkeley parser which produced 133 parses on average for each testing sentence. As can be seen, we use weaker pruning during training than during testing. This is because in training stronger pruning (even if accurate) results in worse estimation of the first expectation in Equation 12, which makes gradient computation less accurate.

We compare LVeGs with CVGs and several variants of LVGs: (1) LVG-G-16 and LVG-D-16, which are LVGs with 16 subtypes for each nonterminal with discriminative and generative training respectively (accuracies obtained from Petrov and Klein (2008a)); (2) Multi-scale grammars (Petrov and Klein, 2008b), trained without using the span features in order for a fair comparison; (3) Berkeley parser (Petrov and Klein, 2007) (accuracies obtained from Petrov and Klein (2008b) because Petrov and Klein (2007) do not report exact match scores). The experimental results are shown in Table 3. It can be seen that GM-LVeG-S produces the best F1 scores on both the development data and the testing data. It surpasses the Berkeley parser by 0.92% in F1 score on the testing data. Its exact match score on the testing data is only slightly lower than that of LVG-D-16.

We further investigate the influence of the latent vector dimension and the Gaussian component number on the efficiency and the parsing accuracy . We experiment on a small dataset (statistics of this dataset are in the supplemental material). We first fix the component number to 4 and experiment with the dimension 2, 3, 4, 5, 6, 7, 8, 9. Then we fix the dimension to 3 and experiment with the component number 2, 3, 4, 5, 6, 7, 8, 9. F1 scores on the development data are shown in the first row in Figure 1. Average time consumed per epoch in learning is shown in the second row in Figure 1. When $K_r = 4$, the best dimension is 5; when $d = 3$, the best Gaussian component number is 3. A higher dimension or a larger Gaussian component number hurts the model performance and requires much more time for learning. Thus

Model	WSJ		English		French		German		Russian		Spanish		Indonesian		Finnish		Italian	
	T	S	T	S	T	S	T	S	T	S	T	S	T	S	T	S	T	S

our choice of $K_r = 4$ and $d = 3$ in GM-LVeGs for parsing is a good balance between the efficiency and the parsing accuracy.

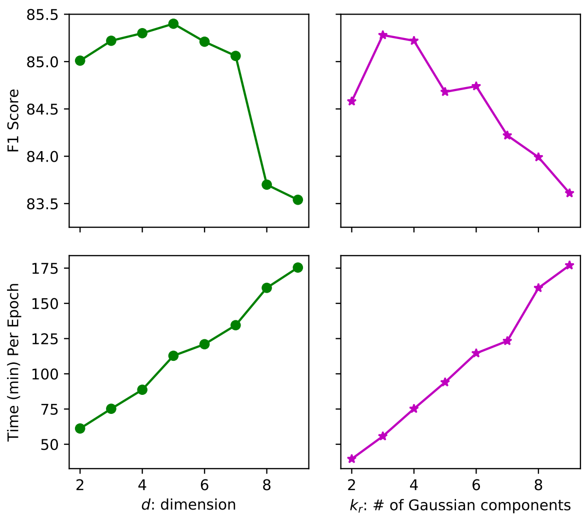

Figure 1: F1 score and average time (min) consumed per epoch in learning. **Left**: # of Gaussian components fixed to 4 with different dimensions; **Right**: dimension of Gaussians fixed to 3 with different # of Gaussian components.

5 Discussion

It shall be noted that in this paper we choose to focus on the basic framework and algorithms of LVeGs, and therefore we leave a few important extensions for future work. One extension is to incorporate contextual information of words and constituents. which is a crucial technique that can be found in most state-of-the-art approaches to parsing or POS tagging. One possible way to utilize contextual information in LVeGs is to allow the words in the context of an anchored production rule to influence the rule's weight function. For example, we may learn neural networks to predict the parameters of the Gaussian mixture weight functions in a GM-LVeG from the pre-trained embeddings of the words in the context.

In GM-LVeGs, we currently use the same number of Gaussian components for all the weight functions. A more desirable way would be automatically determining the number of Gaussian components for each production rule based on the ideal refinement granularity of the rule, e.g., we may need more Gaussian components for NP $\rightarrow$ DT NN than for NP $\rightarrow$ DT JJ, since the latter is rarely used. There are a few possible ways to learn the component numbers such as greedy addition and removal, the split-merge method, and sparsity priors over mixture weights.

An interesting extension beyond LVeGs is to have a single continuous space for subtypes of all the nonterminals. Ideally, subtypes of the same nonterminal or similar nonterminals are close to each other. The benefit is that similarity between nonterminals can now be modeled.

6 Conclusion

We present Latent Vector Grammars (LVeGs) that associate each nonterminal with a latent continuous vector space representing the set of subtypes of the nonterminal. For each production rule, a LVeG defines a continuous weight function over the subtypes of the nonterminals involved in the rule. We show that LVeGs can subsume latent variable grammars and compositional vector grammars as special cases. We then propose Gaussian mixture LVeGs (GM-LVeGs). which formulate weight functions of production rules by mixtures of Gaussian distributions. The partition function and the expectations of fine-grained production rules in GM-LVeGs can be efficiently computed using dynamic programming, which makes learning and inference with GM-LVeGs feasible.

We empirically show that GM-LVeGs can achieve competitive accuracies on POS tagging and constituency parsing.

Extending a Parser to Distant Domains Using a Few Dozen Partially Annotated Examples

Vidur Joshi, Matthew Peters, Mark Hopkins
Allen Institute for AI, Seattle, WA
{vidurj, matthewp, markh}@allenai.org

Abstract

We revisit domain adaptation for parsers in the neural era. First we show that recent advances in word representations greatly diminish the need for domain adaptation when the target domain is syntactically similar to the source domain. As evidence, we train a parser on the Wall Street Journal alone that achieves over 90% F_1 on the Brown corpus. For more syntactically distant domains, we provide a simple way to adapt a parser using only dozens of partial annotations. For instance, we increase the percentage of error-free geometry-domain parses in a held-out set from 45% to 73% using approximately five dozen training examples. In the process, we demonstrate a new state-of-the-art single model result on the Wall Street Journal test set of 94.3%. This is an absolute increase of 1.7% over the previous state-of-the-art of 92.6%.

1 Introduction

Statistical parsers are often criticized for their performance outside of the domain they were trained on. The most straightforward remedy would be more training data in the target domain, but building treebanks (Marcus et al., 1993) is expensive.

In this paper, we revisit this issue in light of recent developments in neural natural language processing. Our paper rests on two observations:

Given [the circle [at the right] with [designated center, designated perpendicular, and radius 5]] .

In [the figure above] , [[AD = 4] , [AB = 3] and [CD = 9]] .

[Diameter AC] is perpendicular [to chord BD] [at E] .

Figure 1: An example of partial annotations. Annotators indicate that a span is a constituent by enclosing it in square brackets.

1. **It is trivial to train on partial annotations using a span-focused model.** Stern et al. (2017a) demonstrated that a parser with minimal dependence between the decisions that produce a parse can achieve state-of-the-art performance. We modify their parser, henceforth MSP, so that it trains directly on individual labeled spans instead of parse trees. This results in a parser that can be trained, with no adjustments to the training regime, from partial sentence bracketings.

2. **The use of contextualized word representations (Peters et al., 2017; McCann et al., 2017) greatly reduces the amount of data needed to train linguistic models.** Contextualized word representations, which encode tokens conditioned on their context in a sentence, have been shown to give significant boosts across a variety of NLP tasks, and also to reduce the amount of data needed by an order of magnitude in some tasks.

Taken together, this suggests a way to rapidly extend a newswire-trained parser to new domains. Specifically, we will show it is possible to achieve large out-of-domain performance improvements using only dozens of partially annotated sentences, like those shown in Figure 1. The resulting parser also does not suffer any degradation on the newswire domain.

Along the way, we provide several other notable contributions:

- We raise the state-of-the-art single-model F_1-score for constituency parsing from 92.6% to 94.3% on the Wall Street Journal (WSJ) test set. A trained model is publicly available.[1]
- We show that, even without domain-specific training data, our parser has much less out-of-domain degradation than previous parsers on "newswire-adjacent" domains like the Brown corpus.
- We provide a version of MSP which predicts its own POS tags (rather than requiring a third-party tagger).

2 The Reconciled Span Parser (RSP)

When we allow annotators to selectively annotate important phenomena, we make the process faster and simpler (Mielens et al., 2015). Unfortunately, this produces a disconnect between the model (which typically asserts the probability of a full parse tree) and the annotation task (which asserts the correctness of some subcomponent, like a constituent span or a dependency arc). There is a body of research (Hwa, 1999; Li et al., 2016) that discusses how to bridge this gap by modifying the training data, training algorithm, or the training objective.

Alternatively, we could just better align the model with the annotation task. Specifically, we could train a parser whose base model predicts exactly what we ask the annotator to annotate, e.g. whether a particular span is a constituent. This makes it trivial to train with partial or full annotations, because the training data reduces to a collection of span labels in either case.

Luckily, recent state-of-the-art results that model NLP tasks as independently classified spans (Stern et al., 2017a) suggest this strategy is currently viable. In this section, we present the Reconciled Span Parser (RSP), a modified version of the Minimal Span Parser (MSP) of Stern et al. (2017a). RSP differs from MSP in the following ways:

- **It is trained on a span classification task.** MSP trains on a maximum margin objective; that is, the loss function penalizes the violation of a margin between the scores of the gold parse and the next highest scoring parse decoded. This couples its training procedure with its decoding procedure, resulting in two versions, a top-down parser and a chart parser. To allow our model to be trained on partial annotations, we change the training task to be the span classification task described below.
- **It uses contextualized word representations instead of predicted part-of-speech tags.** Our model uses contextualized word representations as described in Peters et al. (2018). It does not take part-of-speech-tags as input, eliminating the dependence of the parser on a newswire-trained POS-tagger.

[1]http://allennlp.org/models

2.1 Overview

We will view a parse tree as a labeling of all the spans of a sentence such that:

- Every constituent span is labeled with the sequence of non-terminals assigned to it in the parse tree. For instance, span $(2, 4)$ in Figure 2b is labeled with the sequence $\langle S, \text{VP}\rangle$, as shown in Figure 2a.
- Every non-constituent is labeled with the empty sequence.

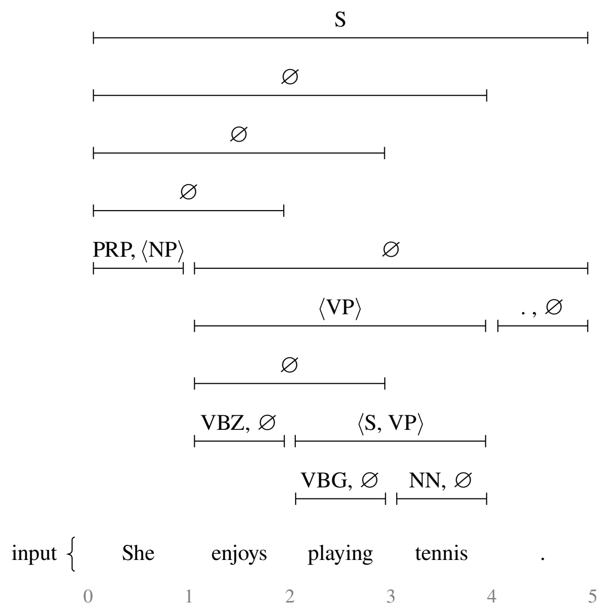
Given a sentence represented by a sequence of tokens x of length n, define $\mathsf{spans}(x) = \{(i, j) \mid 0 \le i < j \le n\}$. Define a *parse* for sentence x as a function $\pi : \mathsf{spans}(x) \mapsto \mathcal{L}$ where $\mathcal{L}$ is the set of all sequences of non-terminal tags, including the empty sequence.

We model the probability of a parse as the independent product of its span labels:

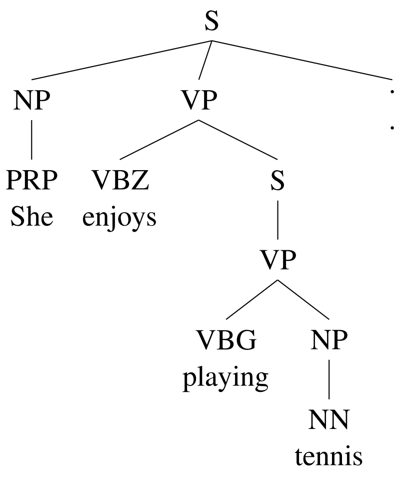
$$\begin{aligned} Pr(\pi|x) &= \prod_{s \in \mathsf{spans}(x)} Pr(\pi(s) \mid x, s) \\ \Rightarrow \log Pr(\pi|x) &= \sum_{s \in \mathsf{spans}(x)} \log Pr(\pi(s) \mid x, s) \end{aligned}$$

Hence, we will train a base model $\sigma(l \mid x, s)$ to estimate the log probability of label l for span s (given sentence x), and we will score the overall parse with:

$$\mathsf{score}(\pi|x) = \sum_{s \in \mathsf{spans}(x)} \sigma(\pi(s) \mid x, s)$$



(a) Spans classified by the parsing procedure. Note that leaves have their part-of-speech tags predicted in addition to their sequence of non-terminals.



(b) The resulting parse tree.

Figure 2: The correspondence between labeled spans and a parse tree. This diagram is adapted from figure 1 in (Stern et al., 2017a).

Note that this probability model accords mass to mis-structured trees (e.g. overlapping spans like (2, 5) and (3, 7) cannot both be constituents of a well-formed tree). We solve the following Integer Linear Program (ILP)[2] to find the highest scoring parse that admits a well-formed tree:

$$\max_{\delta} \sum_{(i,j)\in \mathsf{spans}(x)} v^{+}_{(i,j)}\delta_{(i,j)} + v^{-}_{(i,j)}(1-\delta_{(i,j)})$$

subject to:

$$\begin{aligned} i<k<j<m &\implies \delta_{(i,j)}+\delta_{(k,m)} \le 1 \\ (i,j)\in \mathsf{spans}(x) &\implies \delta_{(i,j)} \in \{0,1\} \end{aligned}$$

where:

$$\begin{aligned} v^{+}_{(i,j)} &= \max_{l \text{ s.t. } l\neq\varnothing} \sigma(l \mid x,(i,j)) \\ v^{-}_{(i,j)} &= \sigma(\varnothing \mid x,(i,j)) \end{aligned}$$

[2]There are a number of ways to reconcile the span conflicts, including an adaptation of the standard dynamic programming chart parsing algorithm to work with spans of an unbinarized tree. However it turns out that the classification model rarely produces span conflicts, so all methods we tried performed equivalently well.

2.2 Classification Model

For our span classification model $\sigma(l \mid x, s)$, we use the model from (Stern et al., 2017a), which leverages a method for encoding spans from (Wang and Chang, 2016; Cross and Huang, 2016). First, it creates a sentence encoding by running a two-layer bidirectional LSTM over the sentence to obtain forward and backward encodings for each position i, denoted by $\boldsymbol{f}_i$ and $\boldsymbol{b}_i$ respectively. Then, spans are encoded by the difference in LSTM states immediately before and after the span; that is, span (i, j) is encoded as the concatenation of the vector differences $\boldsymbol{f}_j - \boldsymbol{f}_{i-1}$ and $\boldsymbol{b}_i - \boldsymbol{b}_{j+1}$. A one-layer feedforward network maps each span representation to a distribution over labels.

Classification Model Parameters and Initializations

We preserve the settings used in Stern et al. (2017a) where possible. As a result, the size of the hidden dimensions of the LSTM and the feedforward network is 250. The dropout ratio for the LSTM is set to 0.4 . Unlike the model it is based on, our model uses word embeddings of length 1124. These result from concatenating a 100 dimension learned word embedding, with a 1024 di-

Parser	Rec	Prec	$\mathbf{F_1}$

mension learned linear combination of the internal states of a bidirectional language model run on the input sentence as described in Peters et al. (2018). We refer to them below as ELMo (Embeddings from Language Models). For the learned embeddings, words with n occurrences in the training data are replaced by $\langle$UNK$\rangle$ with probability $\frac{1+\frac{n}{10}}{1+n}$. This does not affect the ELMo component of the word embeddings. As a result, even common words are replaced with probability at least $\frac{1}{10}$, making the model rely on the ELMo embeddings instead of the learned embeddings. To make the model self-contained, it does not take part-of-speech tags as input. Using a linear layer over the last hidden layer of the classification model, part-of-speech tags are predicted for spans containing single words.

3 Analysis of RSP

3.1 Performance on Newswire

On WSJTEST[3], RSP outperforms (see Table 1) all previous single models trained on WSJTRAIN by a significant margin, raising the state-of-the-art result from 92.6% to 94.3%. Additionally, our predicted part-of-speech tags achieve 97.72%[4] accuracy on WSJTEST.

[3]For all our experiments on the WSJ component of the Penn Treebank (Marcus et al., 1993), we use the standard split which is sections 2-21 for training, henceforth WSJTRAIN, section 22 for development, henceforth WSJDEV, and 23 for testing, henceforth WSJTEST.

[4]The split we used is not standard for part-of-speech tagging. As a result, we do not compare to part-of-speech taggers.

3.2 Beyond Newswire

The Brown Corpus

The Brown corpus (Marcus et al., 1993) is a standard benchmark used to assess WSJ-trained parsers outside of the newswire domain. When (Kummerfeld et al., 2012) parsed the various Brown verticals with the (then state-of-the-art) Charniak parser (Charniak, 2000; Charniak and Johnson, 2005; McClosky et al., 2006a), it achieved F_1 scores between 83% and 86%, even though its F_1 score on WSJTEST was 92.1%.

In Table 3, we discover that RSP does not suffer nearly as much degradation, with an average F_1-score of 90.3%. To determine whether this increased portability is because of the parser architecture or the use of ELMo vectors, we also run MSP on the Brown verticals. We used the Stanford tagger[5] (Toutanova et al., 2003) to tag WSJTRAIN and the Brown verticals so that MSP could be given these at train and test time. We learned that most of the improvement can be attributed to the ELMo word representations. In fact, even if we use MSP with gold POS tags, the average performance is 3.4% below RSP.

Question Bank and Genia

Despite being a standard benchmark for parsing domain adaptation, the Brown corpus has considerable commonality with newswire text. It is primarily composed of well-formed sentences with similar syntactic phenomena. Perhaps the main challenge with the Brown corpus is a difference in vocabulary, rather than a difference in syntax, which may explain the success of RSP, which leverages contextualized embeddings learned from a large corpus.

If we try to run RSP on a more syntactically divergent corpus like QuestionBank[6] (Judge et al., 2006), we find much more performance degradation. This is unsurprising, since WSJTRAIN does not contain many examples of question syntax. But how many examples do we need, to get good performance?

[5]We used the english-left3words-distsim.tagger model from the 2017-06-09 release of the Stanford POS tagger since it achieved the best accuracy on the Brown corpus.

[6]For all our experiments on QuestionBank, we use the following split: sentences 1-1000 and 2001-3000 for training, henceforth QBANKTRAIN, 1001-1500 and 3001-3500 for development, henceforth QBANKDEV, and 1501-2000 and 2501-4000 for testing, henceforth QBANKTEST. This split is described at https://nlp.stanford.edu/data/QuestionBank-Stanford.shtml.

40k	500	85.52	91.01	88.18

Table 5: Performance of RSP on GENIADEV.

For the experiments summarized in table 4 and table 5 involving 40k sentences from WSJTRAIN, we started with RSP trained on WSJTRAIN, and fine-tuned it on minibatches containing an equal number of target domain and WSJTRAIN sentences.

Surprisingly, with only 50 annotated questions (see Table 4), performance on QBANKDEV jumps 5 points, from 89.9% to 94.9%. This is only 1.5% below training with all of WSJTRAIN and QBANKTRAIN. The resulting system improves slightly on WSJTEST getting 94.38%.

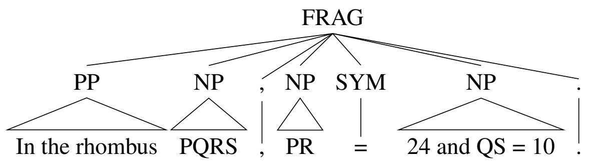
On the more difficult GENIA corpus of biomedical abstracts (Tateisi et al., 2005), we see a similar, if somewhat less dramatic, trend. See Table 5. With 50 annotated sentences, performance on GENIADEV jumps from 79.5% to 86.2%, outperforming all but one parser from David McClosky's thesis (McClosky, 2010) – the one that trains on all 14k sentences from GENIATRAIN and self-trains using 270k sentences from PubMed. That parser achieves 87.6%, which we outperform with just 500 sentences from GENIATRAIN.

These results suggest that it is currently feasible to extend a parser to a syntactically distant domain (for which no gold parses exist) with a couple hours of effort. We explore this possibility in the next section.

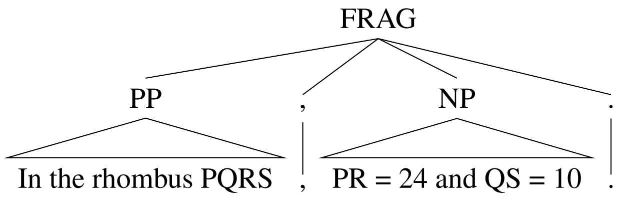
4 Rapid Parser Extension

To create a parser for their geometry question answering system, (Seo et al., 2015) did the following:

- Designed regular expressions to identify mathematical expressions.
- Replaced the identified expressions with dummy words.
- Parsed the resulting sentences.



(a) Training only on WSJTRAIN.



(b) Retraining on partial annotations.

Figure 3: The top-level split for the development sentence "In the rhombus PQRS, PR = 24 and QS = 10." before and after retraining RSP on 63 partially annotated geometry statements.

- Substituted the regex-analyzed expressions for the dummy words in the parses.

It is clear why this was necessary. Figure 3 (top) shows how RSP (trained only on WSJTRAIN) parses the sentence "In the rhombus PQRS, PR = 24 and QS = 10." The result is completely wrong, and useless to a downstream application.

Still, beyond just the inconvenience of building additional infrastructure, there are downsides to the "regex-and-replace" strategy:

1. **It assumes that each expression always maps to the same constituent label.** Consider "$2x = 3y$". This is a verb phrase in the sentence "In the above figure, x is prime and $2x = 3y$." However, it is a noun phrase in the sentence "The equation $2x = 3y$ has 2 solutions." If we replace both instances with the same dummy word, the parser will almost certainly become confused in one of the two instances.

2. **It assumes that each expression is always a constituent.** Suppose that we replace the expression "$AB < 30$" with a dummy word. This means we cannot properly parse a sentence like "When angle $AB < 30$, the lines are parallel," because the constituent "angle AB" no longer exists in the resulting sentence.

3. **It does not handle other syntactic variation.** As we will see in the next section, the geometry domain has a propensity for using right-attaching participial adjective phrases, like "labeled x" in the phrase "the segment labeled x." Encouraging a parser to recognize this syntactic construct is out-of-scope for the "regex-and-replace" strategy.

Instead, we propose directly extending the parser by providing a few domain-specific examples like those in Figure 1. Because RSP's model directly predicts span constituency, we can simply mark up a sentence with the "tricky" domain-specific constituents that the model will not already have learned from WSJTRAIN. For instance, we mark up NOUN-LABEL constructs like "chord BD", and equations like "AD = 4".

From these marked-up sentences, we can extract training instances declaring the constituency of certain spans (like "to chord BD" in the third example) and the implied non-constituency of certain spans (like "perpendicular to chord" in the third example). We also allow annotators to explicitly declare the non-constituency of a span via an alternative markup (not shown).

We do not require annotators to provide span labels (although they can if desired). If a training instance merely declares a span to be a constituent (but does not provide a particular label), then the loss function only records loss when that span is classified as a non-constituent (i.e. any label is ok).

5 Experiments

5.1 Geometry Questions

We took the publicly available training data from (Seo et al., 2015), split the data into sentences, and then annotated each sentence as in Figure 1. Next, we randomly split these sentences into GEOTRAIN and GEODEV[7]. After removing duplicate sentences spanning both sets, we ended up with 63 annotated sentences in GEOTRAIN and 62 in GEODEV. In GEOTRAIN, we made an average of 2.8 constituent declarations and 0.3 (explicit) non-constituent declarations per sentence.

After preparing the data, we started with RSP trained on WSJTRAIN, and fine-tuned it on minibatches containing 50 randomly selected WSJTRAIN sentences, plus all of GEOTRAIN. The results are in table 6. After fine-tuning, the model

[7]GEOTRAIN and GEODEV are available at https://github.com/vidurj/parser-adaptation/tree/master/data.

Training Data	GeoDev		WsjTest
	correct constituents %	error-free %	F_1
WsjTrain	71.9	45.2	94.28
WsjTrain + GeoTrain	87.0	72.6	94.30

- **Given [a circle with [the tangent shown]] .**
- **Find the hypotenuse of [the triangle labeled t] .**
- **Examine [the following diagram with [the square highlighted]] .**

Figure 4: Three partial annotations targeting right-attaching participial adjectives.

gets 87% of the 185 annotations on GeoDev correct, compared with 71.9% before fine-tuning[8]. Moreover, the fraction of sentences with no errors increases from 45.2% to 72.6%. With only a few dozen partially-annotated training examples, not only do we see a large increase in domain performance, but there is also no degradation in the parser's performance on newswire. Some GeoDev parses have enormous qualitative differences, like the example shown in Figure 3.

For the GeoDev sentences on which we get errors after retraining, the errors fall predominantly into three categories. First, approximately 44% have some mishandled math syntax, like failing to recognize "dimensions 16 by 8" as a constituent, or providing a flat structuring of the equation "BAC = 1/4 * ACB" (instead of recognizing "1/4 * ACB" as a subconstituent). Second, approximately 19% have PP-attachment errors. Third, another 19% fail to correctly analyze right-attaching participial adjectives like "labeled x" in the noun phrase "the segment labeled x" or "indicated" in the noun phrase "the center indicated." This phenomenon is unusually frequent in geometry but was insufficiently marked-up in our training examples. For instance, while we have a training instance "Find [the measure of [the angle designated by x]]," it does not explicitly highlight the constituency of "designated by x". This suggests that in practice, this domain adaptation method could benefit from an iterative cycle in which a user assesses the parser's errors on their target domain, creates some partial annotations that address these issues, retrains the parser, and then repeats the process until satisfied. As a proof-of-concept, we invented 3 additional sentences with right-attaching participial adjectives (shown in Figure 4), added them to GeoTrain, and then retrained. Indeed, the handling of participial adjectives in GeoDev improved, increasing the overall percentage of correctly identified constituents to 88.6% and the percentage of error-free sentences to 75.8%.

5.2 Biomedicine and Chemistry

We ran a similar experiment using biomedical and chemistry text, taken from the unannotated data provided by (Nivre et al., 2007). We partially annotated 134 sentences and randomly split them into BioChemTrain (72 sentences) and BioChemDev (62 sentences)[9]. In BioChemTrain, we made an average of 4.2 constituent declarations per sentence. We made no non-constituent declarations.

Again, we started with RSP trained on WsjTrain, and fine-tuned it on minibatches containing annotations from 50 randomly selected Wsj-

[8]This improvement has a p-value of 10^{-4} under the one-sided, two-sample difference between proportions test.

[9]BioChemTrain and BioChemDev are available at https://github.com/vidurj/parser-adaptation/tree/master/data.

TRAIN sentences, plus all of BIOCHEMTRAIN. Table 7 shows the improvement in the percentage of correctly-identified annotated constituents and the percentage of test sentences for which the parse agrees with every annotation. As with the geometry domain, we get significant improvements using only dozens of partially annotated training sentences.

6 Related Work

The two major themes of this paper, domain adaptation and learning from partial annotation, each have a long tradition in natural language processing.

6.1 Domain Adaptation

Domain adaptation has been recognized as a major NLP problem for over a decade (Ben-David et al., 2006; Blitzer et al., 2006; Daumé, 2007; Finkel and Manning, 2009). In particular, domain adaptation for parsers (Plank, 2011; Ma and Xia, 2013) has received considerable attention. Much of this work (McClosky et al., 2006b; Reichart and Rappoport, 2007; Sagae and Tsujii, 2007; Kawahara and Uchimoto, 2008; McClosky et al., 2010; Sagae, 2010; Baucom et al., 2013; Yu et al., 2015) has focused on how to best use co-training (Blum and Mitchell, 1998) or self-training to augment a small domain corpus, or how to best combine models to perform well on a particular domain.

In this work, we focus on the direct impact that just a few dozen partially annotated out-of-domain examples can have, when using a particular neural model with contextualized word representations. Co-training, self-training, and model combination are orthogonal to our approach. Our work is a spiritual successor to (Garrette and Baldridge, 2013), which shows how to train a part-of-speech tagger with a minimal amount of annotation effort.

6.2 Learning from Partial Annotation

Most literature on training parsers from partial annotations (Sassano and Kurohashi, 2010; Spreyer et al., 2010; Flannery et al., 2011; Flannery and Mori, 2015; Mielens et al., 2015) focuses on dependency parsing. (Li et al., 2016) provides a good overview. Here we highlight three important high-level strategies.

The first is "complete-then-train" (Mirroshandel and Nasr, 2011; Majidi and Crane, 2013), which "completes" every partially annotated dependency parse by finding the most likely parse (according to an already trained parser model) that respects the constraints of the partial annotations. These "completed" parses are then used to train a new parser.

The second strategy (Nivre et al., 2014; Li et al., 2016) is similar to "complete-then-train," but integrates parse completion into the training process. At each iteration, new "complete" parses are created using the parser model from the most recent training iteration.

The third strategy (Li et al., 2014, 2016) transforms each partial annotation into a forest of parses that encodes all fully-specified parses permitted by the partial annotation. Then, the training objective is modified to support optimization over these forests.

Our work differs from these in two respects. First, since we are training a constituency parser, our partial annotations are constituent bracketings rather than dependency arcs. Second, and more importantly, we can use the partial annotations for training without modifying either the training algorithm or the training data.

While the bulk of the literature on training from partial annotations focuses on dependency parsing, the earliest papers (Pereira and Schabes, 1992; Hwa, 1999) focus on constituency parsing. These leverage an adapted version of the inside-outside algorithm for estimating the parameters of a probabilistic context-free grammar (PCFG). Our work is not tied to PCFG parsing, nor does it require a specialized training algorithm when going from full annotations to partial annotations.

7 Conclusion

Recent developments in neural natural language processing have made it very easy to build custom parsers. Not only do contextualized word representations help parsers learn the syntax of new domains with very few examples, but they also work extremely well with parsing models that correspond directly with a granular and intuitive annotation task (like identifying whether a span is a constituent). This allows you to train with either full or partial annotations without any change to the training process.

This work provides a convenient path forward for the researcher who requires a parser for their domain, but laments that "parsers don't work outside of newswire." With a couple hours of effort (and a layman's understanding of syntactic building blocks), they can get significant performance improvements. We envision an iterative use case in which a user assesses a parser's errors on their target domain, creates some partial annotations to teach the parser how to fix these errors, then retrains the parser, repeating the process until they are satisfied.

Paraphrase to Explicate: Revealing Implicit Noun-Compound Relations

Abstract

Revealing the implicit semantic relation between the constituents of a noun-compound is important for many NLP applications. It has been addressed in the literature either as a classification task to a set of pre-defined relations or by producing free text paraphrases explicating the relations. Most existing paraphrasing methods lack the ability to generalize, and have a hard time interpreting infrequent or new noun-compounds. We propose a neural model that generalizes better by representing paraphrases in a continuous space, generalizing for both unseen noun-compounds and rare paraphrases. Our model helps improving performance on both the noun-compound paraphrasing and classification tasks.

1 Introduction

Noun-compounds hold an implicit semantic relation between their constituents. For example, a 'birthday cake' is a cake *eaten on* a birthday, while 'apple cake' is a cake *made of* apples. Interpreting noun-compounds by explicating the relationship is beneficial for many natural language understanding tasks, especially given the prevalence of noun-compounds in English (Nakov, 2013).

The interpretation of noun-compounds has been addressed in the literature either by classifying them to a fixed inventory of ontological relationships (e.g. Nastase and Szpakowicz, 2003) or by generating various free text paraphrases that describe the relation in a more expressive manner (e.g. Hendrickx et al., 2013).

Methods dedicated to paraphrasing noun-compounds usually rely on corpus co-occurrences of the compound's constituents as a source of explicit relation paraphrases (e.g. Wubben, 2010; Versley, 2013). Such methods are unable to generalize for unseen noun-compounds. Yet, most noun-compounds are very infrequent in text (Kim and Baldwin, 2007), and humans easily interpret the meaning of a new noun-compound by generalizing existing knowledge. For example, consider interpreting *parsley cake* as a cake made of parsley vs. *resignation cake* as a cake eaten to celebrate quitting an unpleasant job.

We follow the paraphrasing approach and propose a semi-supervised model for paraphrasing noun-compounds. Differently from previous methods, we train the model to predict either a paraphrase expressing the semantic relation of a noun-compound (predicting '[w_2] made of [w_1]' given 'apple cake'), or a missing constituent given a combination of paraphrase and noun-compound (predicting 'apple' given 'cake made of [w_1]'). Constituents and paraphrase templates are represented as continuous vectors, and semantically-similar paraphrase templates are embedded in proximity, enabling better generalization. Interpreting 'parsley cake' effectively reduces to identifying paraphrase templates whose "selectional preferences" (Pantel et al., 2007) on each constituent fit 'parsley' and 'cake'.

A qualitative analysis of the model shows that the top ranked paraphrases retrieved for each noun-compound are plausible even when the constituents never co-occur (Section 4). We evaluate our model on both the paraphrasing and the classification tasks (Section 5). On both tasks, the model's ability to generalize leads to improved performance in challenging evaluation settings.[1]

2 Background

2.1 Noun-compound Classification

Noun-compound classification is the task concerned with automatically determining the semantic relation that holds between the constituents of a noun-compound, taken from a set of pre-defined relations.

Early work on the task leveraged information derived from lexical resources and corpora (e.g. Girju, 2007; Ó Séaghdha and Copestake, 2009; Tratz and Hovy, 2010). More recent work broke the task into two steps: in the first step, a noun-compound representation is learned from the distributional representation of the constituent words (e.g. Mitchell and Lapata, 2010; Zanzotto et al., 2010; Socher et al., 2012). In the second step, the noun-compound representations are used as feature vectors for classification (e.g. Dima and Hinrichs, 2015; Dima, 2016).

The datasets for this task differ in size, number of relations and granularity level (e.g. Nastase and Szpakowicz, 2003; Kim and Baldwin, 2007; Tratz and Hovy, 2010). The decision on the relation inventory is somewhat arbitrary, and subsequently, the inter-annotator agreement is relatively low (Kim and Baldwin, 2007). Specifically, a noun-compound may fit into more than one relation: for instance, in Tratz (2011), *business zone* is labeled as CONTAINED (zone contains business), although it could also be labeled as PURPOSE (zone whose purpose is business).

2.2 Noun-compound Paraphrasing

As an alternative to the strict classification to pre-defined relation classes, Nakov and Hearst (2006) suggested that the semantics of a noun-compound could be expressed with multiple prepositional and verbal paraphrases. For example, *apple cake* is a cake *from*, *made of*, or which *contains* apples.

The suggestion was embraced and resulted in two SemEval tasks. SemEval 2010 task 9 (Butnariu et al., 2009) provided a list of plausible human-written paraphrases for each noun-compound, and systems had to rank them with the goal of high correlation with human judgments. In SemEval 2013 task 4 (Hendrickx et al., 2013), systems were expected to provide a ranked list of paraphrases extracted from free text.

Various approaches were proposed for this task. Most approaches start with a pre-processing step of extracting joint occurrences of the constituents from a corpus to generate a list of candidate paraphrases. Unsupervised methods apply information extraction techniques to find and rank the most meaningful paraphrases (Kim and Nakov, 2011; Xavier and Lima, 2014; Pasca, 2015; Pavlick and Pasca, 2017), while supervised approaches learn to rank paraphrases using various features such as co-occurrence counts (Wubben, 2010; Li et al., 2010; Surtani et al., 2013; Versley, 2013) or the distributional representations of the noun-compounds (Van de Cruys et al., 2013).

One of the challenges of this approach is the ability to generalize. If one assumes that sufficient paraphrases for all noun-compounds appear in the corpus, the problem reduces to ranking the existing paraphrases. It is more likely, however, that some noun-compounds do not have any paraphrases in the corpus or have just a few. The approach of Van de Cruys et al. (2013) somewhat generalizes for unseen noun-compounds. They represented each noun-compound using a compositional distributional vector (Mitchell and Lapata, 2010) and used it to predict paraphrases from the corpus. Similar noun-compounds are expected to have similar distributional representations and therefore yield the same paraphrases. For example, if the corpus does not contain paraphrases for *plastic spoon*, the model may predict the paraphrases of a similar compound such as *steel knife*.

In terms of sharing information between semantically-similar paraphrases, Nulty and Costello (2010) and Surtani et al. (2013) learned "is-a" relations between paraphrases from the co-occurrences of various paraphrases with each other. For example, the specific '[w_2] extracted from [w_1]' template (e.g. in the context of *olive oil*) generalizes to '[w_2] made from [w_1]'. One of the drawbacks of these systems is that they favor more frequent paraphrases, which may co-occur with a wide variety of more specific paraphrases.

2.3 Noun-compounds in other Tasks

Noun-compound paraphrasing may be considered as a subtask of the general paraphrasing task, whose goal is to generate, given a text fragment, additional texts with the same meaning. However, general paraphrasing methods do not guarantee to explicate implicit information conveyed in the original text. Moreover, the most notable source for extracting paraphrases is multiple translations of the same text (Barzilay and McKeown,

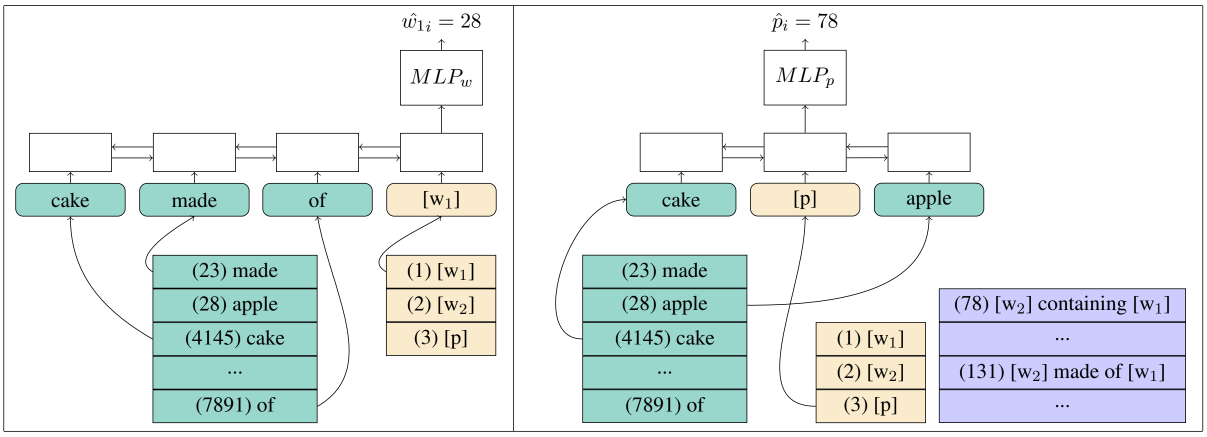

Figure 1: An illustration of the model predictions for w_1 and p given the triplet *(cake, made of, apple)*. The model predicts each component given the encoding of the other two components, successfully predicting '*apple*' given '*cake made of* [w$_1$]', while predicting '[w$_2$] *containing* [w$_1$]' for '*cake* [p] *apple*'.

2001; Ganitkevitch et al., 2013; Mallinson et al., 2017). If a certain concept can be described by an English noun-compound, it is unlikely that a translator chose to translate its foreign language equivalent to an explicit paraphrase instead.

Another related task is Open Information Extraction (Etzioni et al., 2008), whose goal is to extract relational tuples from text. Most system focus on extracting verb-mediated relations, and the few exceptions that addressed noun-compounds provided partial solutions. Pal and Mausam (2016) focused on segmenting multi-word noun-compounds and assumed an is-a relation between the parts, as extracting *(Francis Collins, is, NIH director)* from "NIH director Francis Collins". Xavier and Lima (2014) enriched the corpus with compound definitions from online dictionaries, for example, interpreting *oil industry* as *(industry, produces and delivers, oil)* based on the WordNet definition "industry that produces and delivers oil". This method is very limited as it can only interpret noun-compounds with dictionary entries, while the majority of English noun-compounds don't have them (Nakov, 2013).

3 Paraphrasing Model

As opposed to previous approaches, that focus on predicting a paraphrase template for a given noun-compound, we reformulate the task as a multi-task learning problem (Section 3.1), and train the model to also predict a missing constituent given the paraphrase template and the other constituent. Our model is semi-supervised, and it expects as input a set of noun-compounds and a set of constrained part-of-speech tag-based templates that make valid prepositional and verbal paraphrases. Section 3.2 details the creation of training data, and Section 3.3 describes the model.

3.1 Multi-task Reformulation

Each training example consists of two constituents and a paraphrase (w_2, p, w_1), and we train the model on 3 subtasks: (1) predict p given w_1 and w_2, (2) predict w_1 given p and w_2, and (3) predict w_2 given p and w_1. Figure 1 demonstrates the predictions for subtasks (1) (right) and (2) (left) for the training example (*cake, made of, apple*). Effectively, the model is trained to answer questions such as "what can cake be made of?", "what can be made of apple?", and "what are the possible relationships between cake and apple?".

The multi-task reformulation helps learning better representations for paraphrase templates, by embedding semantically-similar paraphrases in proximity. Similarity between paraphrases stems either from lexical similarity and overlap between the paraphrases (e.g. 'is made of' and 'made of'), or from shared constituents, e.g. '[w$_2$] involved in [w$_1$]' and '[w$_2$] in [w$_1$] industry' can share [w$_1$] = *insurance* and [w$_2$] = *company*. This allows the model to predict a correct paraphrase for a given noun-compound, even when the constituents *do not occur with that paraphrase in the corpus*.

3.2 Training Data

We collect a training set of (w_2, p, w_1, s) examples, where w_1 and w_2 are constituents of a noun-compound $w_1 w_2$, p is a templated paraphrase, and s is the score assigned to the training instance.[2]

[2]We refer to "paraphrases" and "paraphrase templates" interchangeably. In the extracted templates, [w$_2$] always precedes [w$_1$], probably because w$_2$ is normally the head noun.

We use the 19,491 noun-compounds found in the SemEval tasks datasets (Butnariu et al., 2009; Hendrickx et al., 2013) and in Tratz (2011). To extract patterns of part-of-speech tags that can form noun-compound paraphrases, such as '[w$_2$] VERB PREP [w$_1$]', we use the SemEval task training data, but we do not use the lexical information in the gold paraphrases.

Corpus. Similarly to previous noun-compound paraphrasing approaches, we use the Google N-gram corpus (Brants and Franz, 2006) as a source of paraphrases (Wubben, 2010; Li et al., 2010; Surtani et al., 2013; Versley, 2013). The corpus consists of sequences of n terms (for $n \in \{3, 4, 5\}$) that occur more than 40 times on the web. We search for n-grams following the extracted patterns and containing w_1 and w_2's lemmas for some noun-compound in the set. We remove punctuation, adjectives, adverbs and some determiners to unite similar paraphrases. For example, from the 5-gram '*cake made of sweet apples*' we extract the training example *(cake, made of, apple)*. We keep only paraphrases that occurred at least 5 times, resulting in 136,609 instances.

Weighting. Each n-gram in the corpus is accompanied with its frequency, which we use to assign scores to the different paraphrases. For instance, '*cake of apples*' may also appear in the corpus, although with lower frequency than '*cake from apples*'. As also noted by Surtani et al. (2013), the shortcoming of such a weighting mechanism is that it prefers shorter paraphrases, which are much more common in the corpus (e.g. count('*cake made of apples*') $\ll$ count('*cake of apples*')). We overcome this by normalizing the frequencies *for each paraphrase length*, creating a distribution of paraphrases in a given length.

Negative Samples. We add 1% of negative samples by selecting random corpus words w_1 and w_2 that do not co-occur, and adding an example (w_2, [w$_2$] is unrelated to [w$_1$], w_1, s_n), for some predefined negative samples score s_n. Similarly, for a word w_i that did not occur in a paraphrase p we add (w_i, p, UNK, s_n) or (UNK, p, w_i, s_n), where UNK is the unknown word. This may help the model deal with non-compositional noun-compounds, where w_1 and w_2 are unrelated, rather than forcibly predicting some relation between them.

3.3 Model

For a training instance (w_2, p, w_1, s), we predict each item given the encoding of the other two.

Encoding. We use the 100-dimensional pre-trained GloVe embeddings (Pennington et al., 2014), which are fixed during training. In addition, we learn embeddings for the special words [w$_1$], [w$_2$], and [p], which are used to represent a missing component, as in "cake made of [w$_1$]", "[w$_2$] made of apple", and "cake [p] apple".

For a missing component $x \in \{$[p], [w$_1$], [w$_2$]$\}$ surrounded by the sequences of words $v_{1:i-1}$ and $v_{i+1:n}$, we encode the sequence using a bidirectional long-short term memory (bi-LSTM) network (Graves and Schmidhuber, 2005), and take the ith output vector as representing the missing component: $bLS(v_{1:i}, x, v_{i+1:n})_i$.

In bi-LSTMs, each output vector is a concatenation of the outputs of the forward and backward LSTMs, so the output vector is expected to contain information on valid substitutions both with respect to the previous words $v_{1:i-1}$ and the subsequent words $v_{i+1:n}$.

Prediction. We predict a distribution of the vocabulary of the missing component, i.e. to predict w_1 correctly we need to predict its index in the word vocabulary V_w, while the prediction of p is from the vocabulary of paraphrases in the training set, V_p. We predict the following distributions:

$$\begin{aligned}
\hat{p} &= \text{softmax}(W_p \cdot bLS(\vec{w_2}, [p], \vec{w_1})_2) \\
\hat{w_1} &= \text{softmax}(W_w \cdot bLS(\vec{w_2}, \vec{p}_{1:n}, [w_1])_{n+1}) \\
\hat{w_2} &= \text{softmax}(W_w \cdot bLS([w_2], \vec{p}_{1:n}, \vec{w_1})_1)
\end{aligned} \quad (1)$$

where $W_w \in \mathcal{R}^{|V_w| \times 2d}$, $W_p \in \mathcal{R}^{|V_p| \times 2d}$, and d is the embeddings dimension.

During training, we compute cross-entropy loss for each subtask using the gold item and the prediction, sum up the losses, and weight them by the instance score. During inference, we predict the missing components by picking the best scoring index in each distribution:[3]

$$\begin{aligned}
\hat{p}_i &= \text{argmax}(\hat{p}) \\
\hat{w_1}_i &= \text{argmax}(\hat{w_1}) \\
\hat{w_2}_i &= \text{argmax}(\hat{w_2})
\end{aligned} \quad (2)$$

The subtasks share the pre-trained word embeddings, the special embeddings, and the biLSTM parameters. Subtasks (2) and (3) also share W_w, the MLP that predicts the index of a word.

[3]In practice, we pick the k best scoring indices in each distribution for some predefined k, as we discuss in Section 5.

$[w_1]$	$[w_2]$	**Predicted Paraphrases**	$[w_2]$	**Paraphrase**	**Predicted** $[w_1]$	**Paraphrase**	$[w_1]$	**Predicted** $[w_2]$
cataract	surgery	$[w_2]$ of $[w_1]$	surgery	$[w_2]$ to treat $[w_1]$	heart	$[w_2]$ to treat $[w_1]$	cataract	surgery
		$[w_2]$ on $[w_1]$			brain			drug

		$[w_2]$ of $[w_1]$			afternoon			meeting
		$[w_2]$ is made of $[w_1]$			hour			rally
		$[w_2]$ made of $[w_1]$			day			session

Table 1: Examples of top ranked predicted components using the model: predicting the paraphrase given w_1 and w_2 (left), w_1 given w_2 and the paraphrase (middle), and w_2 given w_1 and the paraphrase (right).

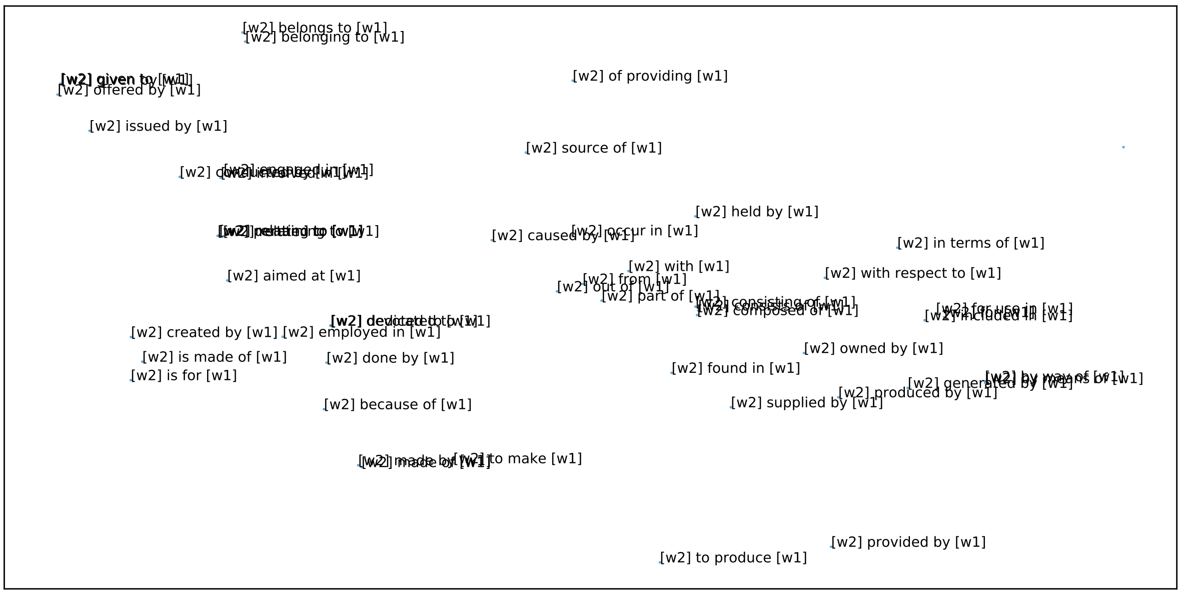

Figure 2: A t-SNE map of a sample of paraphrases, using the paraphrase vectors encoded by the biLSTM, for example $bLS([w_2]$ made of $[w_1])$.

Implementation Details. The model is implemented in DyNet (Neubig et al., 2017). We dedicate a small number of noun-compounds from the corpus for validation. We train for up to 10 epochs, stopping early if the validation loss has not improved in 3 epochs. We use Momentum SGD (Nesterov, 1983), and set the batch size to 10 and the other hyper-parameters to their default values.

4 Qualitative Analysis

To estimate the quality of the proposed model, we first provide a qualitative analysis of the model outputs. Table 1 displays examples of the model outputs for each possible usage: predicting the paraphrase given the constituent words, and predicting each constituent word given the paraphrase and the other word.

The examples in the table are from among the top 10 ranked predictions for each component-pair. We note that most of the (w_2, paraphrase, w_1) triplets in the table do not occur in the training data, but are rather generalized from similar examples. For example, there is no training instance for "company in the software industry" but there is a "firm in the software industry" and a company in many other industries.

While the frequent prepositional paraphrases are often ranked at the top of the list, the model also retrieves more specified verbal paraphrases. The list often contains multiple semantically-similar paraphrases, such as '$[w_2]$ involved in $[w_1]$' and '$[w_2]$ in $[w_1]$ industry'. This is a result of the model training objective (Section 3) which positions the vectors of semantically-similar paraphrases close to each other in the embedding space, based on similar constituents.

To illustrate paraphrase similarity we compute a t-SNE projection (Van Der Maaten, 2014) of the embeddings of all the paraphrases, and draw a sample of 50 paraphrases in Figure 2. The projection positions semantically-similar but lexically-divergent paraphrases in proximity, likely due to many shared constituents. For instance, 'with', 'from', and 'out of' can all describe the relation between food words and their ingredients.

5 Evaluation: Noun-Compound Interpretation Tasks

For quantitative evaluation we employ our model for two noun-compound interpretation tasks. The main evaluation is on retrieving and ranking paraphrases (§5.1). For the sake of completeness, we also evaluate the model on classification to a fixed inventory of relations (§5.2), although it wasn't designed for this task.

5.1 Paraphrasing

Task Definition. The general goal of this task is to interpret each noun-compound to multiple prepositional and verbal paraphrases. In SemEval 2013 Task 4,[4] the participating systems were asked to retrieve a ranked list of paraphrases for each noun-compound, which was automatically evaluated against a similarly ranked list of paraphrases proposed by human annotators.

Model. For a given noun-compound $w_1 w_2$, we first predict the $k = 250$ most likely paraphrases: $\hat{p}_1, ..., \hat{p}_k = \text{argmax}_k \, \hat{p}$, where $\hat{p}$ is the distribution of paraphrases defined in Equation 1.

While the model also provides a score for each paraphrase (Equation 1), the scores have not been optimized to correlate with human judgments. We therefore developed a re-ranking model that receives a list of paraphrases and re-ranks the list to better fit the human judgments.

We follow Herbrich (2000) and learn a pairwise ranking model. The model determines which of two paraphrases of the same noun-compound should be ranked higher, and it is implemented as an SVM classifier using scikit-learn (Pedregosa et al., 2011). For training, we use the available training data with gold paraphrases and ranks provided by the SemEval task organizers. We extract the following features for a paraphrase p:

1. The part-of-speech tags contained in p
2. The prepositions contained in p
3. The number of words in p
4. Whether p ends with the special [w$_1$] symbol
5. $cosine(bLS([w_2], p, [w_1])_2, \vec{V_p}^{\hat{p}_i}) \cdot \hat{p}^{\hat{p}_i}$

where $\vec{V_p}^{\hat{p}_i}$ is the biLSTM encoding of the predicted paraphrase computed in Equation 1 and $\hat{p}^{\hat{p}_i}$ is its confidence score. The last feature incorporates the original model score into the decision, as to not let other considerations such as preposition frequency in the training set take over.

During inference, the model sorts the list of paraphrases retrieved for each noun-compound according to the pairwise ranking. It then scores each paraphrase by multiplying its rank with its original model score, and prunes paraphrases with final score < 0.025. The values for k and the threshold were tuned on the training set.

Evaluation Settings. The SemEval 2013 task provided a scorer that compares words and n-grams from the gold paraphrases against those in the predicted paraphrases, where agreement on a prefix of a word (e.g. in derivations) yields a partial scoring. The overall score assigned to each system is calculated in two different ways. The 'isomorphic' setting rewards both precision and recall, and performing well on it requires accurately reproducing as many of the gold paraphrases as possible, and in much the same order. The 'non-isomorphic' setting rewards only precision, and performing well on it requires accurately reproducing the top-ranked gold paraphrases, with no importance to order.

Baselines. We compare our method with the published results from the SemEval task. The SemEval 2013 baseline generates for each noun-compound a list of prepositional paraphrases in an arbitrary fixed order. It achieves a moderately good score in the non-isomorphic setting by generating a fixed set of paraphrases which are both common and generic. The MELODI system performs similarly: it represents each noun-compound using a compositional distributional vector (Mitchell and Lapata, 2010) which is then used to predict paraphrases from the corpus. The performance of MELODI indicates that the system was rather conservative, yielding a few common paraphrases rather than many specific ones. SFS and IIITH, on the other hand, show a more balanced trade-off between recall and precision.

As a sanity check, we also report the results of a baseline that retrieves ranked paraphrases from the training data collected in Section 3.2. This baseline has no generalization abilities, therefore it is expected to score poorly on the recall-aware isomorphic setting.

[4] https://www.cs.york.ac.uk/semeval-2013/task4

	Method	isomorphic	non-isomorphic
Baselines	SFS (Versley, 2013)	23.1	17.9
	IIITH (Surtani et al., 2013)	23.1	25.8
	MELODI (Van de Cruys et al., 2013)	13.0	54.8
	SemEval 2013 Baseline (Hendrickx et al., 2013)	13.8	40.6
This paper	Baseline	3.8	16.1
	Our method	**28.2**	28.4

Table 2: Results of the proposed method and the baselines on the SemEval 2013 task.

Category	**%**
False Positive	
(1) Valid paraphrase missing from gold	44%
(2) Valid paraphrase, slightly too specific	15%
(3) Incorrect, common prepositional paraphrase	14%
(4) Incorrect, other errors	14%
(5) Syntactic error in paraphrase	8%
(6) Valid paraphrase, but borderline grammatical	5%
False Negative	
(1) Long paraphrase (more than 5 words)	30%
(2) Prepositional paraphrase with determiners	25%
(3) Inflected constituents in gold	10%
(4) Other errors	35%

Table 3: Categories of false positive and false negative predictions along with their percentage.

Results. Table 2 displays the performance of the proposed method and the baselines in the two evaluation settings. Our method outperforms all the methods in the isomorphic setting. In the non-isomorphic setting, it outperforms the other two systems that score reasonably on the isomorphic setting (SFS and IIITH) but cannot compete with the systems that focus on achieving high precision.

The main advantage of our proposed model is in its ability to generalize, and that is also demonstrated in comparison to our baseline performance. The baseline retrieved paraphrases only for a third of the noun-compounds (61/181), expectedly yielding poor performance on the isomorphic setting. Our model, which was trained on the very same data, retrieved paraphrases for all noun-compounds. For example, *welfare system* was not present in the training data, yet the model predicted the correct paraphrases "system of welfare benefits", "system to provide welfare" and others.

Error Analysis. We analyze the causes of the false positive and false negative errors made by the model. For each error type we sample 10 noun-compounds. For each noun-compound, false positive errors are the top 10 predicted paraphrases which are not included in the gold paraphrases, while false negative errors are the top 10 gold paraphrases not found in the top k predictions made by the model. Table 3 displays the manually annotated categories for each error type.

Many false positive errors are actually valid paraphrases that were not suggested by the human annotators (error 1, "discussion by group"). Some are borderline valid with minor grammatical changes (error 6, "force of coalition forces") or too specific (error 2, "life *of women in* community" instead of "life *in* community"). Common prepositional paraphrases were often retrieved although they are incorrect (error 3). We conjecture that this error often stem from an n-gram that does not respect the syntactic structure of the sentence, e.g. a sentence such as "rinse away the oil from baby 's head" produces the n-gram "oil from baby".

With respect to false negative examples, they consisted of many long paraphrases, while our model was restricted to 5 words due to the source of the training data (error 1, "holding done in the case of a share"). Many prepositional paraphrases consisted of determiners, which we conflated with the same paraphrases without determiners (error 2, "mutation of a gene"). Finally, in some paraphrases, the constituents in the gold paraphrase appear in inflectional forms (error 3, "holding of shares" instead of "holding of share").

5.2 Classification

Noun-compound classification is defined as a multiclass classification problem: given a pre-defined set of relations, classify w_1w_2 to the relation that holds between w_1 and w_2. Potentially, the corpus co-occurrences of w_1 and w_2 may contribute to the classification, e.g. '[w$_2$] held at [w$_1$]' indicates a TIME relation. Tratz and Hovy (2010) included such features in their classifier, but ablation tests showed that these features had a relatively small contribution, probably due to the sparseness of the paraphrases. Recently, Shwartz and Waterson (2018) showed that paraphrases may contribute to the classification when represented in a continuous space.

Model. We generate a paraphrase vector representation $\vec{par}(w_1 w_2)$ for a given noun-compound $w_1 w_2$ as follows. We predict the indices of the k most likely paraphrases: $\hat{p}_1, ..., \hat{p}_k = \text{argmax}_k \hat{p}$, where $\hat{p}$ is the distribution on the paraphrase vocabulary V_p, as defined in Equation 1. We then encode each paraphrase using the biLSTM, and average the paraphrase vectors, weighted by their confidence scores in $\hat{p}$:

$$\vec{par}(w_1 w_2) = \frac{\sum_{i=1}^{k} \hat{p}^{\hat{p}_i} \cdot \vec{V_p}^{\hat{p}_i}}{\sum_{i=1}^{k} \hat{p}^{\hat{p}_i}} \quad (3)$$

We train a linear classifier, and represent $w_1 w_2$ in a feature vector $f(w_1 w_2)$ in two variants: paraphrase: $f(w_1 w_2) = \vec{par}(w_1 w_2)$, or integrated: concatenated to the constituent word embeddings $f(w_1 w_2) = [\vec{par}(w_1 w_2), \vec{w_1}, \vec{w_2}]$. The classifier type (logistic regression/SVM), k, and the penalty are tuned on the validation set. We also provide a baseline in which we ablate the paraphrase component from our model, representing a noun-compound by the concatenation of its constituent embeddings $f(w_1 w_2) = [\vec{w_1}, \vec{w_2}]$ (distributional).

Datasets. We evaluate on the Tratz (2011) dataset, which consists of 19,158 instances, labeled in 37 fine-grained relations (`Tratz-fine`) or 12 coarse-grained relations (`Tratz-coarse`).

We report the performance on two different dataset splits to train, test, and validation: a random split in a 75:20:5 ratio, and, following concerns raised by Dima (2016) about lexical memorization (Levy et al., 2015), on a lexical split in which the sets consist of distinct vocabularies. The lexical split better demonstrates the scenario in which a noun-compound whose constituents have not been observed needs to be interpreted based on similar observed noun-compounds, e.g. inferring the relation in *pear tart* based on *apple cake* and other similar compounds. We follow the random and full-lexical splits from Shwartz and Waterson (2018).

Baselines. We report the results of 3 baselines representative of different approaches:
1) **Feature-based** (Tratz and Hovy, 2010): we re-implement a version of the classifier with features from WordNet and Roget's Thesaurus.
2) **Compositional** (Dima, 2016): a neural architecture that operates on the distributional representations of the noun-compound and its constituents. Noun-compound representations are learned with the Full-Additive (Zanzotto et al., 2010) and Matrix (Socher et al., 2012) models. We report the results from Shwartz and Waterson (2018).
3) **Paraphrase-based** (Shwartz and Waterson, 2018): a neural classification model that learns an LSTM-based representation of the joint occurrences of w_1 and w_2 in a corpus (i.e. observed paraphrases), and integrates distributional information using the constituent embeddings.

Dataset & Split	Method	F_1
`Tratz fine` Random	Tratz and Hovy (2010)	**0.739**
	Dima (2016)	0.725
	Shwartz and Waterson (2018)	0.714
	distributional	**0.677**
	paraphrase	0.505
	integrated	0.673
`Tratz fine` Lexical	Tratz and Hovy (2010)	0.340
	Dima (2016)	0.334
	Shwartz and Waterson (2018)	**0.429**
	distributional	0.356
	paraphrase	0.333
	integrated	**0.370**
`Tratz coarse` Random	Tratz and Hovy (2010)	0.760
	Dima (2016)	**0.775**
	Shwartz and Waterson (2018)	0.736
	distributional	0.689
	paraphrase	0.557
	integrated	**0.700**
`Tratz coarse` Lexical	Tratz and Hovy (2010)	0.391
	Dima (2016)	0.372
	Shwartz and Waterson (2018)	**0.478**
	distributional	0.370
	paraphrase	0.345
	integrated	**0.393**

Table 4: Classification results. For each dataset split, the top part consists of baseline methods and the bottom part of methods from this paper. The best performance in each part appears in bold.

Results. Table 4 displays the methods' performance on the two versions of the Tratz (2011) dataset and the two dataset splits. The paraphrase model on its own is inferior to the distributional model, however, the integrated version improves upon the distributional model in 3 out of 4 settings, demonstrating the complementary nature of the distributional and paraphrase-based methods. The contribution of the paraphrase component is especially noticeable in the lexical splits.

As expected, the integrated method in Shwartz and Waterson (2018), in which the paraphrase representation was trained with the objective of classification, performs better than our integrated model. The superiority of both integrated models in the lexical splits confirms that paraphrases are beneficial for classification.

Example Noun-compounds	Gold	Distributional	Example Paraphrases
printing plant	PURPOSE	OBJECTIVE	[w$_2$] engaged in [w$_1$]
marketing expert *development expert*	TOPICAL	OBJECTIVE	[w$_2$] in [w$_1$] [w$_2$] knowledge of [w$_1$]
weight/job loss	OBJECTIVE	CAUSAL	[w$_2$] of [w$_1$]
rubber band *rice cake*	CONTAINMENT	PURPOSE	[w$_2$] made of [w$_1$] [w$_2$] is made of [w$_1$]
laboratory animal	LOCATION/PART-WHOLE	ATTRIBUTE	[w$_2$] in [w$_1$], [w$_2$] used in [w$_1$]

Table 5: Examples of noun-compounds that were correctly classified by the integrated model while being incorrectly classified by distributional, along with top ranked indicative paraphrases.

Analysis. To analyze the contribution of the paraphrase component to the classification, we focused on the differences between the distributional and integrated models on the `Tratz-Coarse` lexical split. Examination of the per-relation F_1 scores revealed that the relations for which performance improved the most in the integrated model were TOPICAL (+11.1 F_1 points), OBJECTIVE (+5.5), ATTRIBUTE (+3.8) and LOCATION/PART_WHOLE (+3.5).

Table 5 provides examples of noun-compounds that were correctly classified by the integrated model while being incorrectly classified by the distributional model. For each noun-compound, we provide examples of top ranked paraphrases which are indicative of the gold label relation.

6 Compositionality Analysis

Our paraphrasing approach at its core assumes compositionality: only a noun-compound whose meaning is derived from the meanings of its constituent words can be rephrased using them. In §3.2 we added negative samples to the training data to simulate non-compositional noun-compounds, which are included in the classification dataset (§5.2). We assumed that these compounds, more often than compositional ones would consist of unrelated constituents (*spelling bee*, *sacred cow*), and added instances of random unrelated nouns with '[w$_2$] is unrelated to [w$_1$]'. Here, we assess whether our model succeeds to recognize non-compositional noun-compounds.

We used the compositionality dataset of Reddy et al. (2011) which consists of 90 noun-compounds along with human judgments about their compositionality in a scale of 0-5, 0 being non-compositional and 5 being compositional. For each noun-compound in the dataset, we predicted the 15 best paraphrases and analyzed the errors. The most common error was predicting paraphrases for idiomatic compounds which may have a plausible concrete interpretation or which originated from one. For example, it predicted that *silver spoon* is simply a *spoon* made of *silver* and that *monkey business* is a *business* that buys or raises *monkeys*. In other cases, it seems that the strong prior on one constituent leads to ignoring the other, unrelated constituent, as in predicting "*wedding* made of *diamond*". Finally, the "unrelated" paraphrase was predicted for a few compounds, but those are not necessarily non-compositional (*application form*, *head teacher*). We conclude that the model does not address compositionality and suggest to apply it only to compositional compounds, which may be recognized using compositionality prediction methods as in Reddy et al. (2011).

7 Conclusion

We presented a new semi-supervised model for noun-compound paraphrasing. The model differs from previous models by being trained to predict both a paraphrase given a noun-compound, and a missing constituent given the paraphrase and the other constituent. This results in better generalization abilities, leading to improved performance in two noun-compound interpretation tasks. In the future, we plan to take generalization one step further, and explore the possibility to use the biLSTM for generating completely new paraphrase templates unseen during training.

Abstract

We explore the notion of subjectivity, and hypothesize that word embeddings learnt from input corpora of varying levels of subjectivity behave differently on natural language processing tasks such as classifying a sentence by sentiment, subjectivity, or topic. Through systematic comparative analyses, we establish this to be the case indeed. Moreover, based on the discovery of the outsized role that sentiment words play on subjectivity-sensitive tasks such as sentiment classification, we develop a novel word embedding *SentiVec* which is infused with sentiment information from a lexical resource, and is shown to outperform baselines on such tasks.

1 Introduction

Distributional analysis methods such as Word2Vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014) have been critical for the success of many large-scale natural language processing (NLP) applications (Collobert et al., 2011; Socher et al., 2013; Goldberg, 2016). These methods employ distributional hypothesis (i.e., words used in the same contexts tend to have similar meaning) to derive distributional meaning via context prediction tasks and produce dense word embeddings.

While there have been active and ongoing research on improving word embedding methods (see Section 5), there is a relative dearth of study on the impact that an input corpus may have on the quality of the word embeddings. The previous preoccupation centers around corpus size, i.e., a larger corpus is perceived to be richer in statistical information. For instance, popular corpora include Wikipedia, Common Crawl, and Google News.

We postulate that there may be variations across corpora owing to factors that affect language use. Intuitively, the many things we write (a work email, a product review, an academic publication, etc.) may each involve certain stylistic, syntactic, and lexical choices, resulting in meaningfully different distributions of word cooccurrences. Consequently, such factors may be encoded in the word embeddings, and input corpora may be differentially informative towards various NLP tasks.

In this work, we are interested in the notion of *subjectivity*. Some NLP tasks, such as sentiment classification, revolve around subjective expressions of likes or dislikes. Others, such as topic classification, revolve around more objective elements of whether a document belongs to a topic (e.g., science, politics). Our central hypothesis is that word embeddings learnt from input corpora of contrasting levels of subjectivity perform differently when classifying sentences by sentiment, subjectivity, or topic. As the *first contribution*, we outline an experimental scheme to explore this hypothesis in Section 2, and conduct a series of controlled experiments in Section 3 establishing that there exists a meaningful difference between word embeddings derived from objective vs. subjective corpora. We further systematically investigate factors that could potentially explain the differences.

Upon discovering from the investigation that sentiment words play a particularly important role in subjectivity-sensitive NLP tasks, such as sentiment classification, as the *second contribution*, in Section 4 we develop *SentiVec*, a novel word embedding method infused with information from lexical resources such as a sentiment lexicon. We further identify two alternative lexical objectives: *Logistic SentiVec* based on discriminative logistic regression, and *Spherical SentiVec* based on soft clustering effect of von Mises-Fisher distributions. In Section 6, the proposed word embeddings show evident improvements on sentiment classification, as compared to the base model Word2Vec and other baselines using the same lexical resource.

2 Data and Methodology

We lay out the methodology for generating word embeddings of contrasting subjectivity, whose effects are tested on several text classification tasks.

2.1 Generating Word Embeddings

As it is difficult to precisely quantify the degree of subjectivity of a corpus, we resort to generating word embeddings from two corpora that contrast sharply in subjectivity, referring to them as the *Objective Corpus* and the *Subjective Corpus*.

Objective Corpus As virtually all contents are written by humans, an absolutely objective corpus (in the philosophical sense) may prove elusive. There are however exemplars where, by construction, a corpus aspires to be as objective as possible, and probably achieves that in practical terms. We postulate that one such corpus is Wikipedia. Its list of policies and guidelines[1], assiduously enforced by an editorial team, specify that an article must be written from a *neutral point of view*, which among other things means *"representing fairly, proportionately, and, as far as possible, without editorial bias, all of the significant views that have been published by reliable sources on a topic."*. Moreover, it is a common resource for training distributional word embeddings and adopted widely by the research community to solve various NLP problems. Hence, in this study, we use Wikipedia as the *Objective Corpus*.

Subjective Corpus By extension, one may then deem a corpus subjective if its content does not at least meet Wikipedia's *neutral point of view* requirement. In other words, if the content is replete with personal feelings and opinions. We posit that product reviews would be one such corpus. For instance, Amazon's Community Guideline[2] states that *"Amazon values diverse opinions"*, and that *"Content you submit should be relevant and based on your own honest opinions and experience."*. Reviews consist of expressive content written by customers, and may not strive for the neutrality of an encyclopedia. We rely on a large corpus of Amazon reviews from various categories (e.g., electronics, jewelry, books, and etc.) (McAuley et al., 2015) as the *Subjective Corpus*.

Word Embeddings For the comparative analysis in Section 3, we employ *Word2Vec* (reviewed below) to generate word embeddings from each corpus. Later on in Section 4, we will propose a new word embedding method called *SentiVec*.

For Word2Vec, we use the Skip-gram model to train distributional word embeddings on the *Objective Corpus* and the *Subjective Corpus* respectively. Skip-gram aims to find word embeddings that are useful for predicting nearby words. The objective is to maximize the context probability:

$$\log \mathcal{L}(W;C) = \sum_{w \in W} \sum_{w' \in C(w)} \log \mathrm{P}(w'|w), \qquad (1)$$

where W is an input corpus and $C(w)$ is the context of token w. The probability of context word w', given observed word w is defined via softmax:

$$\mathrm{P}(w'|w) = \frac{\exp(v_{w'} \cdot v_w)}{\sum_{\hat{w} \in V} \exp(v_{\hat{w}} \cdot v_w)}, \qquad (2)$$

where v_w and $v_{w'}$ are corresponding embeddings and V is the corpus vocabulary. Though theoretically sound, the formulation is computationally impractical and requires tractable approximation.

Mikolov et al. (2013) propose two efficient procedures to optimize (1): Hierarchical Softmax and Negative Sampling (NS). In this work we focus on the widely adopted NS. The intuition is that a "good" model should be able to differentiate observed data from noise. The differentiation task is defined using logistic regression; the goal is to tell apart real context-word pair (w', w) from randomly generated noise pair $(\hat{w}, w)$. Formally,

$$\log \mathcal{L}_{[w',w]} = \log \sigma(v_{w'} \cdot v_w) + \sum_{i=1}^{k} \log \sigma(-v_{\hat{w}_i} \cdot v_w), \qquad (3)$$

where $\sigma(\cdot)$ is a sigmoid function, and $\{\hat{w}_i\}_{i=1}^{k}$ are negative samples. Summing up all the context-word pairs, we derive the NS Skip-gram objective:

$$\log \mathcal{L}_{word2vec}(W;C) = \sum_{w \in W} \sum_{w' \in C(w)} \log \mathcal{L}_{[w',w]}. \qquad (4)$$

Training word embeddings with Skip-gram, we keep the same hyperparameters across all the runs: 300 dimensions for embeddings, $k = 5$ negative samples, and window of 5 tokens. The *Objective*

[1]https://en.wikipedia.org/wiki/Wikipedia:List_of_policies_and_guidelines

[2]https://www.amazon.com/gp/help/customer/display.html?nodeId=201929730

and *Subjective* corpora undergo the same preprocessing, i.e., discarding short sentences (<5 tokens) and rare words (<10 occurrences), removing punctuation, normalizing Unicode symbols.

2.2 Evaluation Tasks

To compare word embeddings, we need a common yardstick. It is difficult to define an inherent quality to word embeddings. Instead, we put them through several evaluation tasks that can leverage word embeddings and standardize their formulations as binary classification tasks. To boil the comparisons down to the essences of word embeddings (which is our central focus), we rely on standardized techniques so as to attribute as much of the differences as possible to the word embeddings. We use logistic regression for classification, and represent a text snippet (e.g., a sentence) in the feature space as the average of the word embeddings of tokens in the snippet (ignoring out-of-vocabulary tokens). The evaluation metric is the average accuracy from 10-fold cross validation.

There are three evaluation tasks of varying degrees of hypothetical subjectivity, as outlined below. Each may involve multiple datasets.

Sentiment Classification Task This task classifies a sentence into either *positive* or *negative*. We use two groups of datasets as follows.

The first group consists of 24 datasets from *UCSD Amazon product data*[3] corresponding to various product categories. Each review has a rating from 1 to 5, which is transformed into *positive* (ratings 4 or 5) or *negative* (ratings 1 or 2) class. For each dataset respectively, we sample 5000 sentences each from the positive and negative reviews. Note that these sentences used for this evaluation task have not participated in the generation of word embeddings. Due to space constraint, in most cases we present the average accuracy across the datasets, but where appropriate we enumerate the results for each dataset.

The second is *Cornell's sentence polarity dataset v1.0*[4] (Pang and Lee, 2005), made up of 5331 each of positive and negative sentences from Rotten Tomatoes movie reviews. The inclusion of this out-of-domain evaluation dataset is useful for examining whether the performance of word embeddings from the *Subjective Corpus* on the first group above may inadvertently be affected by in-domain advantage arising from its Amazon origin.

Subjectivity Classification Task This task classifies a sentence into *subjective* or *objective*. The dataset is *Cornell's subjectivity dataset v1.0*[5], consisting of 5000 subjective sentences derived from Rotten Tomatoes (RT) reviews and 5000 objective sentences derived from IMDB plot summaries (Pang and Lee, 2004). This task is probably less sensitive to the subjectivity within word embeddings than sentiment classification, as determining whether a sentence is subjective or objective should ideally be an objective undertaking.

Topic Classification Task We use the 20 Newsgroups dataset[6] ("bydate" version), whereby the newsgroups are organized into six subject matter groupings. We extract the message body and split them into sentences. Each group's sentences then form the *in-topic* class, and we randomly sample an equivalent number of sentences from the remaining newsgroups to form the *out-of-topic* class. This results in six datasets, each corresponding to a binary classification task. In most cases, we present the average results, and where appropriate we enumerate the results for each dataset. Hypothetically, this task is the least affected by the subjectivity within word embeddings.

3 Comparative Analyses of Subjective vs. Objective Corpora

We conduct a series of comparative analyses under various setups. For each, we compare the performance in the evaluation tasks when using the *Objective Corpus* and the *Subjective Corpus*. Table 1 shows the results for this series of analyses.

Initial Condition Setup I seeks to answer whether there is any difference between word embeddings derived from the *Objective Corpus* and the *Subjective Corpus*. The word embeddings were trained on the whole data respectively. Table 1 shows the corpus statistics and classification accuracies. Evidently, the *Subjective* word embeddings outperform the *Objective* word embeddings on all the evaluation tasks. The margins are largest for sentiment classification (86.5% vs. 81.5% or +5% Amazon, and 78.2% vs. 75.4% or +2.8% on Rotten Tomatoes or RT). For subjectivity and topic classifications, the differences are smaller.

III	Objective	0.29M	1.75B	89M	81.6	75.6	90.6	83.4
	Subjective		1.54B		85.4	77.9	90.6	82.8

Table 1: Controlled comparison of Objective and Subjective corpora

As earlier hypothesized, the sentiment classification task is more sensitive to subjectivity within word embeddings than the other tasks. Therefore, training word embeddings on a subjective corpus may confer an advantage for such tasks. On the other hand, the corpus statistics show a substantial difference in corpus size, which could be an alternative explanation for the outperformance by the *Subjective Corpus* if the larger corpus contains more informative distributional statistics.

Controlling for Corpus Size In Setup II, we keep the number of sentences in both corpora the same, by randomly downsampling sentences in the *Subjective Corpus*. This procedure consequently reduces the number of types and tokens (see Table 1, Setup II, Corpus Statistics). Note that the number of tokens in the *Subjective* corpus is now fewer than in the *Objective*, the latter suffers no change. Yet, even after a dramatic reduction in size, the *Subjective* embeddings still outperform the *Objective* significantly on both datasets of the sentiment classification task (+4% on Amazon and +2.5% on RT), while showing similar performance on subjectivity and topic classifications.

This bolsters the earlier observation that sentiment classification is more sensitive to subjectivity. While there is a small effect due to corpus size difference, the gap in performance between *Subjective* and *Objective* embeddings on sentiment classification is still significant and cannot be explained away by the corpus size alone.

Controlling for Vocabulary While the *Subjective Corpus* has a much smaller vocabulary (i.e., # types), we turn a critical eye on whether its apparent advantage lies in having access to special word types that do not exist in the *Objective Corpus*. In Setup III, we keep the training vocabulary the same for both, removing the types that are present in one corpus but not in the other, so that out-of-vocabulary words are ignored in the training phase. Table 1, Setup III, shows significant reduction in types for both corpora. Yet, the outperformance by the *Subjective* embeddings on the sentiment classification task still stands (+3.8% on Amazon and +2.3% on RT). Moreover, it is so for both Amazon and Rotten Tomatoes datasets, implying that it is not due to close in-domain similarity between the corpora used for training the word embeddings and the classification tasks.

Objective Corpus	*Subjective Corpus*
waste, money, return, love, great, and, loves, refund, Great, This, product, recommend, this, even, Very, returned, easy, not, send, sent, customer, item, broke, defective, her	money, waste, return, and, Great, love, refund, recommend, great, this, loves, even, product, This, Very, easy, item, junk, anyone, Don't, horrible, gift, poor, Do, returned

Table 2: Top words of misclassified sentences

Significant Words To get more insights on the difference between the *Subjective* and *Objective* corpora, we analyze the mistakes word embeddings make on the development folds. At this point we focus on the sentiment classification task and specifically on the Amazon data, which indicates the largest performance differences in the controlled experiments (see Table 1, Setup III).

As words are still the main unit of information in distributional word embeddings, we extract words strongly associated with misclassified sentences. We employed log-odds ratio with informative Dirichlet prior method (Monroe et al., 2008) to quantify this association. It is used to contrast the words in misclassified vs. correctly classified sentences, and accounts for the variance of words and their prior counts taken from a large corpus.

Table 2 shows the top 25 words most associated with the misclassified sentences, sorted by their association scores. On average 50% of the mistakes overlap for both word embeddings, therefore, some of the words are included in both lists. $40 - 44\%$ of these words carry positive or negative sentiment connotations in general (see the underlined words in Table 2), while other words like *return* or *send* may carry sentiment connotation in e-commerce context. We check if a word carries sentiment connotation using sentiment lexicon compiled by Hu and Liu (2004), including 6789 words along with positive or negative labels.

We also observe linguistic negations (i.e., *not*, *Don't*). For instance, the word most associated with the *Objective*-specific mistakes (excluding the *Subjective* misclassified sentences) is *not*, which suggests that perhaps *Subjective* word embedding accommodates better understanding of linguistic negations, which may partially explain the difference. However, our methodology as outlined in Section 2.2 permits exchangeable word order and is not intended to analyze structural interaction between words. We focus on further analysis of sentiment words, leaving linguistic negations in word embeddings for future investigation.

Controlling for Sentiment Words To control for the "amount" of sentiment in the *Subjective* and *Objective* corpora, we use sentiment lexicon compiled by Hu and Liu (2004). For each corpus, we create two subcorpora: *With Sentiment* contains only the sentences with at least one word from the sentiment lexicon, while *Without Sentiment* is the complement. We match the corpora on the number of sentences, downsampling the larger corpus, train word embeddings on each subcorpus, and proceed with the classification experiments. Table 3 shows the results, including that of random word embeddings for reference. Sentiment lexicon has a significant impact on the performance of sentiment and subjectivity classifications, and a smaller impact on topic classification. Without sentiment, the *Subjective* embeddings prove more robust, still outperforming the *Objective* on sentiment classification, while the *Objective* performs close to random word embeddings on Amazon .

In summary, evidences from the series of controlled experiments support the existence of some X-factor to the *Subjective* embeddings, which confers superior performance in subjectivity-sensitive tasks such as sentiment classification.

Corpus	Subcorpus Sentiment?	Sentiment Amazon	Sentiment RT	Subjectivity	Topic
Objective	With	81.8	75.2	90.7	83.1
	Without	76.1	67.2	87.8	82.6
Subjective	With	85.5	78.0	90.3	82.5
	Without	79.8	71.0	89.1	82.2
Random Embeddings		76.1	62.2	80.1	71.5

Table 3: With and without sentiment

4 Sentiment-Infused Word Embeddings

To leverage the consequential sentiment information, we propose a family of methods, called *SentiVec*, for training distributional word embeddings that are infused with information on the sentiment polarity of words. The methods are built upon *Word2Vec* optimization algorithm and make use of available lexical sentiment resources such as SentiWordNet (Baccianella et al., 2010), sentiment lexicon by Hu and Liu (2004), and etc.

SentiVec seeks to satisfy two objectives, namely context prediction and lexical category prediction:

$$\log \mathcal{L} = \log \mathcal{L}_{word2vec}(W;C) + \lambda \log \mathcal{L}_{lex}(W,L), \quad (5)$$

where $\mathcal{L}_{word2vec}(W;C)$ is the Skip-gram objective as in (4); $\mathcal{L}_{lex}(W,L)$ is a lexical objective for corpus W and lexical resource L; and λ is a tradeoff parameter. Lexical resource $L = \{X_i\}_{i=1}^n$ comprises of n word sets, each X_i contains words of the same category. For sentiment classification, we consider *positive* and *negative* word categories.

4.1 Logistic SentiVec

Logistic SentiVec admits lexical resource in the form of two disjoint word sets, $L = \{X_1, X_2\}$, $X_1 \cap X_2 = \emptyset$. The objective is to tell apart which word set of L word w belongs to:

$$\log \mathcal{L}_{lex}(W,L) \quad (6)$$
$$= \sum_{w \in X_1} \log \mathrm{P}(w \in X_1) + \sum_{w \in X_2} \log \mathrm{P}(w \in X_2).$$

We further tie these probabilities together, and cast the objective as a logistic regression problem:

$$\mathrm{P}(w \in X_1) = 1 - \mathrm{P}(w \in X_2) = \sigma(v_w \cdot \tau), \quad (7)$$

where v_w is a word embedding and τ is a direction vector. Since word embeddings are generally invariant to scaling and rotation when used as downstream feature representations, τ can be chosen randomly and fixed during training. We experiment with randomly sampled unit length directions. For simplicity, we also scale embedding v_w to its unit length when computing $v_w \cdot \tau$, which now equals to cosine similarity between v_w and τ.

When v_w is completely aligned with τ, the cosine similarity between them is 1, which maximizes $\mathrm{P}(w \in X_1)$ and favors words in X_1. When v_w is opposite to τ, the cosine similarity equals to -1, which maximizes $\mathrm{P}(w \in X_2)$ and predicts vectors from X_2. Orthogonal vectors have cosine similarity of 0, which makes both $w \in X_1$ and $w \in X_2$ equally probable. Optimizing (6) makes the corresponding word embeddings of X_1 and X_2 gravitate to the opposite semispaces and simulates clustering effect for the words of the same category, while the *Word2Vec* objective prevents words from collapsing to the same directions.

Optimization The objective in (6) permits simple stochastic gradient ascent optimization and can be combined with negative sampling procedure for Skip-gram in (5). The gradient for unnormalized embedding v_w is solved as follows:

$$\left(\log \mathcal{L}_{[w \in X_1]}(D, L)\right)'_{v_{wi}} = \left(\log \mathrm{P}\left(x \in X_1\right)\right)'_{v_{wi}} \\ = \frac{1}{\|v_w\|^2} \sigma\left(-\frac{v_w \cdot \tau}{\|v_w\|}\right)\left(\tau_i \|v_w\| - v_{wi}\frac{v_w \cdot \tau}{\|v_w\|}\right) \tag{8}$$

The optimization equation for v_w, when $w \in X_2$, can be derived analogously.

4.2 Spherical SentiVec

Spherical SentiVec extends *Logistic SentiVec* by dealing with any number of lexical categories, $L = \{X_i\}_{i=1}^n$. As such, the lexical objective takes on generic form:

$$\log \mathcal{L}_{lex}(W, L) = \sum_{i=1}^{n} \sum_{w \in X_i} \log \mathrm{P}\left(w \in X_i\right), \tag{9}$$

Each $\mathrm{P}\left(w \in X_i\right)$ defines embedding generating process. We assume each length-normalized v_w for w of L is generated w.r.t. a mixture model of von Mises-Fisher (vMF) distributions. vMF is a probability distribution on a multidimensional sphere, characterized by parameters μ (mean direction) and κ (concentration parameter). Sampled points are concentrated around μ; the greater the κ, the closer the sampled points are to μ. We consider only unimodal vMF distributions, restricting concentration parameters to be strictly positive. Hereby, each $X_i \in L$ is assigned to vMF distribution parameters (μ_i, κ_i) and the membership probabilities are defined as follows:

$$\mathrm{P}(w \in X_i) = P(v_w; \mu_i, \kappa_i) = \frac{1}{Z_{\kappa_i}} e^{\kappa_i \mu_i \cdot v_w}, \tag{10}$$

where Z_κ is the normalization factor.

The *Spherical SentiVec* lexical objective forces words of every $X_i \in L$ to gravitate towards and concentrate around their direction mean μ_i. As in *Logistic SentiVec*, it simulates clustering effect for the words of the same set. In comparison to the direction vector of *Logistic SentiVec*, mean directions of *Spherical SentiVec* when fixed can substantially influence word embeddings training and must be carefully selected. We optimize the mean directions along with the word embeddings using alternating procedure resembling K-means clustering algorithm. For simplicity, we keep concentration parameters tied, $\kappa_1 = \kappa_2 = ... = \kappa_n = \kappa$, and treat κ as a hyperparameter of this algorithm.

Optimization We derive optimization procedure for updating word embeddings assuming fixed direction means. Like *Logistic SentiVec*, *Spherical SentiVec* can be combined with the negative sampling procedure of Skip-gram. The gradient for unnormalized word embedding v_w is solved by the following equation:

$$\left(\log \mathcal{L}_{[w \in X_i]}\left(W, L\right)\right)'_{v_{wj}} = \kappa_i \frac{\left(\mu_{ij}\|v_w\| - v_{wj}\frac{v_w \cdot \mu_i}{\|v_w\|}\right)}{\|v_w\|^2} \tag{11}$$

Once word embedding v_w $(w \in X_i)$ is updated, we revise direction mean μ_i w.r.t. maximum likelihood estimator:

$$\mu_i = \frac{\sum_{w \in X_i} v_w}{\left\|\sum_{w \in X_i} v_w\right\|}. \tag{12}$$

Updating the direction means in such a way ensures that the lexical objective is non-decreasing. Assuming the stochastic optimization procedure for $\mathcal{L}_{word2vec}$ complies with the same non-decreasing property, the proposed alternating procedure converges.

5 Related Work

There have been considerable research on improving the quality of distributional word embeddings. Bolukbasi et al. (2016) seek to debias word embeddings from gender stereotypes. Rothe and Schütze (2017) incorporate WordNet lexeme and synset information. Mrkšic et al. (2016) encode antonym-synonym relations. Liu et al. (2015) encode ordinal relations such as hypernym and hyponym. Kiela et al. (2015) augment Skip-gram to enforce lexical similarity or relatedness constraints, Bollegala et al. (2016) modify GloVe optimization procedure for the same purpose. Faruqui et al. (2015) employ semantic relations of PPDB, WordNet, FrameNet to *retrofit* word embeddings for various prediction tasks. We use this *Retrofitting* method[7] as a baseline.

Socher et al. (2011) derive multi-word embeddings for sentiment distribution prediction, while we focus on lexical distributional analysis. Maas et al. (2011) and Tang et al. (2016) use document-level sentiment annotations to fit word embeddings, but document annotation might not always be available for distributional analysis on neutral corpora such as Wikipedia. *SentiVec* relies on simple sentiment lexicon instead. *Refining* (Yu et al., 2018) aligns the sentiment scores taken from lexical resource and the cosine similarity scores of corresponding word embeddings. The method generally requires fine-grained sentiment scores for the words, which may not be available in some settings. We use *Refining* as a baseline and adopt coarse-grained sentiment lexicon for this method.

Villegas et al. (2016) compare various distributional word embeddings arising from the same corpus for sentiment classification, whereas we focus on the differentiation in input corpora and propose novel sentiment-infused word embeddings.

6 Experiments

The objective of experiments is to study the efficacy of *Logistic SentiVec* and *Spherical SentiVec* word embeddings on the aforementioned text classification tasks. One natural baseline is *Word2Vec*, as *SentiVec* subsumes its context prediction objective, while further incorporating lexical category prediction. We include two other baselines that can leverage the same lexical resource but in manners different from *SentiVec*, namely: *Retrofitting* (Faruqui et al., 2015) and *Refining* (Yu et al., 2018). For these methods, we generate their word embeddings based on Setup III (see Section 3). All the methods were run multiple times with various hyperparameters, optimized via grid-search; for each we present the best performing setting.

First, we discuss the sentiment classification task. Table 4 shows the unfolded results for the 24 classification datasets of Amazon, as well as for Rotten Tomatoes. For each classification dataset (row), and for the *Objective* and *Subjective* embedding corpora respectively, the best word embedding methods are shown in bold. An asterisk indicates statistically significant[8] results at 5% in comparison to *Word2Vec*. Both *SentiVec* variants outperform *Word2Vec* in the vast majority of the cases. The degree of outperformance is higher for the *Objective* than the *Subjective* word embeddings. This is a reasonable trend given our previous findings in Section 3. As the *Objective Corpus* encodes less information than the *Subjective Corpus* for sentiment classification, the former is more likely to benefit from the infusion of sentiment information from additional lexical resources. Note that the sentiment infusion into the word embeddings comes from separate lexical resources, and does not involve any sentiment classification label.

SentiVec also outperforms the two baselines that benefit from the same lexical resources. *Retrofitting* does not improve upon *Word2Vec*, with the two embeddings essentially indistinguishable (the difference is only noticeable at the second decimal point). *Refining* makes the word embeddings perform worse on the sentiment classification task. One possible explanation is that *Refining* normally requires fine-grained labeled lexicon, where the words are scored w.r.t. the sentiment scale, whereas we use sentiment lexicon of two labels (i.e., positive or negative). *SentiVec* accepts coarse-grained sentiment lexicons, and potentially could be extended to deal with fine-grained labels.

As previously alluded to, topic and subjectivity classifications are less sensitive to the subjectivity within word embeddings than sentiment classification. One therefore would not expect much, if any, performance gain from infusion of sentiment information. However, such infusion should not subtract or harm the quality of word embeddings either. Table 5 shows that the unfolded results for topic classification on the six datasets, and the result for subjectivity classification are similar across methods. Neither the *SentiVec* variants, nor *Retrofitting* and *Refining*, change the subjectivity and topic classification capabilities much, which means that the used sentiment lexicon is targeted only at the sentiment subspace of embeddings.

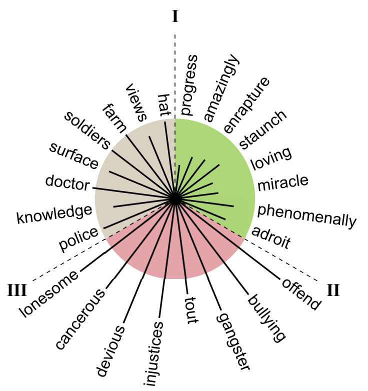
Table 5: Comparison of Word Embeddings on Subjectivity and Topic Classification Tasks

Illustrative Changes in Embeddings To give more insights on the difference between *SentiVec* and *Word2Vec*, we show "flower" diagrams in Figure 1 for *Logistic SentiVec* and Figure 2 for *Spherical SentiVec*. Each is associated with a reference word (e.g., *good* for Figure 1a), and indicates relative changes in cosine distances between the reference word and the testing words surrounding the "flower". Every testing word is associated with a "petal" or black axis extending from the center of the circle. The "petal" length is proportional to the relative distance change in two word embeddings: $\kappa = \frac{d_{SentiVec}(w_{ref}, w_{testing})}{d_{word2vec}(w_{ref}, w_{testing})}$, where $d_{SentiVec}$ and $d_{word2vec}$ are cosine distances between reference w_{ref} and testing $w_{testing}$ words in *SentiVec* and *Word2Vec* embeddings correspondingly. If the distance remains unchanged ($\kappa = 1$), then the "petal" points at the circumference; if the reference and testing words are closer in the *SentiVec* embedding than they are in *Word2Vec* ($\kappa < 1$), the "petal" lies inside the circle; when the distance increases ($\kappa > 1$), the "petal" goes beyond the circle.

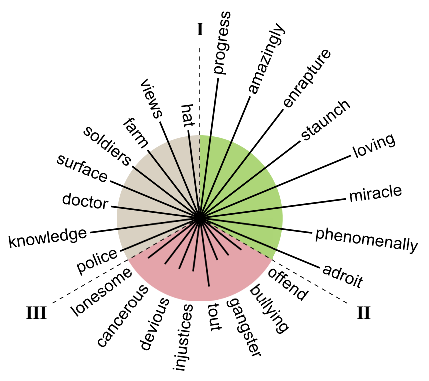
The diagrams are presented for Objective Embeddings[9]. We use three reference words: *good* (positive), *bad* (negative), *time* (neutral); as well as three groups of testing words: green for words randomly sampled from positive lexicon (Sector I-II), red for words randomly sampled from negative lexicon (Sector II-III), and gray for frequent neutral common nouns (Sector III-I).

Figure 1 shows changes produced by *Logistic SentiVec*. For the positive reference word (Figure 1a), the average distance to the green words is shortened, whereas the distance to the red words increases. The reverse is observed for the negative reference word (Figure 1b). This observation

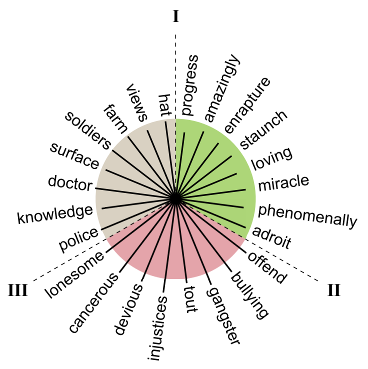
[9]The diagrams for Subjective Embeddings show the same trend, with the moderate changes.



(a) Reference word: **good** (positive)

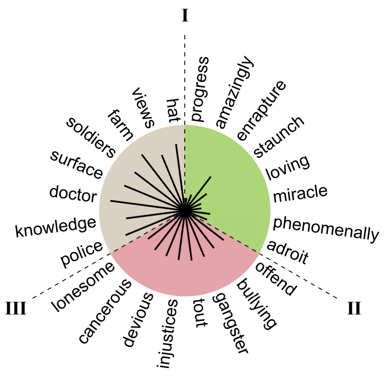


(b) Reference word: **bad** (negative)

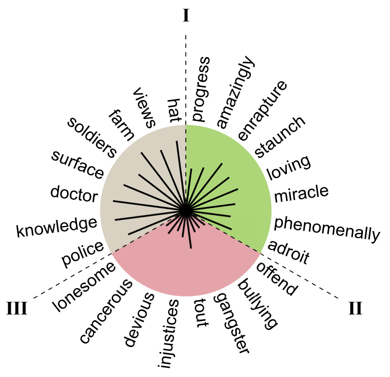


(c) Reference word: **time** (neutral)

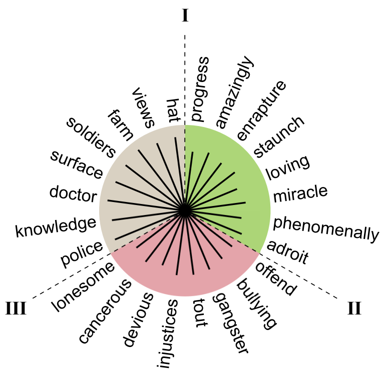
Figure 1: Relative changes in cosine distances in *Logistic SentiVec* contrasted with *Word2Vec*



(a) Reference word: **good** (positive)



(b) Reference word: **bad** (negative)



(c) Reference word: **time** (neutral)

Figure 2: Relative changes in cosine distances in *Spherical SentiVec* contrasted with *Word2Vec*

complies with the lexical objective (7) of *Logistic SentiVec*, which aims to separate the words of two different classes. Note that the gray words suffer only moderate change with respect to positive and negative reference words. For the neutral reference word (Figure 1c), the distances are only moderately affected across all testing groups.

Figure 2 shows that *Spherical SentiVec* tends to make embeddings more compact than *Logistic SentiVec*. As the former's lexical objective (9) is designed for clustering, but not for separation, we look at the comparative strength of the clustering effect on the testing words. For the positive reference word (Figure 2a), the largest clustering effect is achieved for the green words. For the negative reference word (Figure 2b), as expected, the red words are affected the most. The gray words suffer the least change for all the reference words.

In summary, *SentiVec* effectively provides an advantage for subjectivity-sensitive task such as sentiment classification, while not harming the performance of other text classification tasks.

7 Conclusion

We explore the differences between objective and subjective corpora for generating word embeddings, and find that there is indeed a difference in the embeddings' classification task performances. Identifying the presence of sentiment words as one key factor for the difference, we propose a novel method *SentiVec* to train word embeddings that are infused with the sentiment polarity of words derived from a separate sentiment lexicon. We further identify two lexical objectives: *Logistic SentiVec* and *Spherical SentiVec*. The proposed word embeddings show improvements in sentiment classification, while maintaining their performance on subjectivity and topic classifications.

Abstract

Metaphoric expressions are widespread in natural language, posing a significant challenge for various natural language processing tasks such as Machine Translation. Current word embedding based metaphor identification models cannot identify the exact metaphorical words within a sentence. In this paper, we propose an unsupervised learning method that identifies and interprets metaphors at word-level without any preprocessing, outperforming strong baselines in the metaphor identification task. Our model extends to interpret the identified metaphors, paraphrasing them into their literal counterparts, so that they can be better translated by machines. We evaluated this with two popular translation systems for English to Chinese, showing that our model improved the systems significantly.

1 Introduction

Metaphor enriches language, playing a significant role in communication, cognition, and decision making. Relevant statistics illustrate that about one third of sentences in typical corpora contain metaphor expressions (Cameron, 2003; Martin, 2006; Steen et al., 2010; Shutova, 2016). Linguistically, metaphor is defined as a language expression that uses one or several words to represent another concept, rather than taking their literal meanings of the given words in the context (Lagerwerf and Meijers, 2008). Computational metaphor processing refers to modelling non-literal expressions (e.g., metaphor, metonymy, and personification) and is useful for improving many NLP tasks such as Machine Translation (MT) and Sentiment Analysis (Rentoumi et al., 2012). For instance, Google Translate failed in translating *devour* within a sentence, *"She devoured his novels."* (Mohammad et al., 2016), into Chinese. The term was translated into 吞噬, which takes the literal sense of *swallow* and is not understandable in Chinese. Interpreting metaphors allows us to paraphrase them into literal expressions which maintain the intended meaning and are easier to translate.

Metaphor identification approaches based on word embeddings have become popular (Tsvetkov et al., 2014; Shutova et al., 2016; Rei et al., 2017) as they do not rely on hand-crafted knowledge for training. These models follow a similar paradigm in which input sentences are first parsed into phrases and then the metaphoricity of the phrases is identified; they do not tackle word-level metaphor. E.g., given the former sentence *"She devoured his novels."*, the aforementioned methods will first parse the sentence into a verb-direct object phrase *devour novel*, and then detect the clash between *devour* and *novel*, flagging this phrase as a likely metaphor. However, which component word is metaphorical cannot be identified, as important contextual words in the sentence were excluded while processing these phrases. Discarding contextual information also leads to a failure to identify a metaphor when both words in the phrase are metaphorical, but taken out of context they appear literal. E.g., *"This young man knows how to climb the social ladder."* (Mohammad et al., 2016) is a metaphorical expression. However, when the sentence is parsed into a verb-direct object phrase, *climb ladder*, it appears literal.

In this paper, we propose an unsupervised metaphor processing model which can identify and interpret linguistic metaphors at the word-level. Specifically, our model is built upon word embedding methods (Mikolov et al., 2013) and uses WordNet (Fellbaum, 1998) for lexical relation acquisition. Our model is distinguished from existing methods in two aspects. First, our model is generic which does not constrain the source domain of metaphor. Second, the developed model does not rely on any labelled data for model training, but rather captures metaphor in an unsupervised, data-driven manner. Linguistic metaphors are identified by modelling the distance (in vector space) between the target word's literal and metaphorical senses. The metaphorical sense within a sentence is identified by its surrounding context within the sentence, using word embedding representations and WordNet. This novel approach allows our model to operate at the sentence level without any preprocessing, e.g., dependency parsing. Taking contexts into account also addresses the issue that a two-word phrase appears literal, but it is metaphoric within a sentence (e.g., the *climb ladder* example).

We evaluate our model against three strong baselines (Melamud et al., 2016; Shutova et al., 2016; Rei et al., 2017) on the task of metaphor identification. Extensive experimentation conducted on a publicly available dataset (Mohammad et al., 2016) shows that our model significantly outperforms the unsupervised learning baselines (Melamud et al., 2016; Shutova et al., 2016) on both phrase and sentence evaluation, and achieves equivalent performance to the state-of-the-art deep learning baseline (Rei et al., 2017) on phrase-level evaluation. In addition, while most of the existing works on metaphor processing solely evaluate the model performance in terms of metaphor classification accuracy, we further conducted another set of experiments to evaluate how metaphor processing can be used for supporting the task of MT. Human evaluation shows that our model improves the metaphoric translation significantly, by testing on two prominent translation systems, namely, Google Translate[1] and Bing Translator[2]. To our best knowledge, this is the first metaphor processing model that is evaluated on MT.

To summarise, the contributions of this paper are two-fold: (1) we proposed a novel framework for metaphor identification which does not require any preprocessing or annotated corpora for training; (2) we conducted, to our knowledge, the first metaphor interpretation study of applying metaphor processing for supporting MT. We describe related work in §2, followed by our labelling method in §4, experimental design in §5, results in §6 and conclusions in §7.

2 Related Work

A wide range of methods have been applied for computational metaphor processing. Turney et al. (2011); Neuman et al. (2013); Assaf et al. (2013) and Tsvetkov et al. (2014) identified metaphors by modelling the abstractness and concreteness of metaphors and non-metaphors, using a machine usable dictionary called MRC Psycholinguistic Database (Coltheart, 1981). They believed that metaphorical words would be more abstract than literal ones. Some researchers used topic models to identify metaphors. For instance, Heintz et al. (2013) used Latent Dirichlet Allocation (LDA) (Blei et al., 2003) to model source and target domains, and assumed that sentences containing words from both domains are metaphorical. Strzalkowski et al. (2013) assumed that metaphorical terms occur out of the topic chain, where a topic chain is constructed by topical words that reveal the core discussion of the text. Shutova et al. (2017) performed metaphorical concept mappings between the source and target domains in multi-languages using both unsupervised and semi-supervised learning approaches. The source and target domains are represented by semantic clusters, which are derived through the distribution of the co-occurrences of words. They also assumed that when contextual vocabularies are from different domains then there is likely to be a metaphor.

There is another line of approaches based on word embeddings. Generally, these works are not limited by conceptual domains and hand-crafted knowledge. Shutova et al. (2016) proposed a model that identified metaphors by employing word and image embeddings. The model first parses sentences into phrases which contain target words. In their word embedding based approach, the metaphoricity of a phrase was identified by measuring the cosine similarity of two component words in the phrase, based on their input vectors from Skip-gram word embeddings. If the cosine similarity is higher than a threshold, the phrase is identified as literal; otherwise metaphorical. Rei et al. (2017) identified metaphors by introducing a deep learning architecture. Instead of using word input vectors directly, they filtered out noisy in-

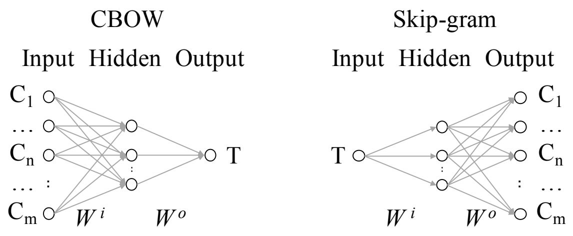

Figure 1: CBOW and Skip-gram framework.

formation in the vector of one word in a phrase, projecting the word vector into another space via a sigmoid activation function. The metaphoricity of the phrases was learnt via training a supervised deep neural network.

The above word embedding based models, while demonstrating some success in metaphor identification, only explored using input vectors, which might hinder their performance. In addition, metaphor identification is highly dependent on its context. Therefore, phrase-level models (e.g., Tsvetkov et al. (2014); Shutova et al. (2016); Rei et al. (2017)) are likely to fail in the metaphor identification task if important contexts are excluded. In contrast, our model can operate at the sentence level which takes into account rich context and hence can improve the performance of metaphor identification.

3 Preliminary: CBOW and Skip-gram

Our metaphor identification framework is built upon word embedding, which is based on Continuous Bag of Words (CBOW) and Skip-gram (Mikolov et al., 2013).

In CBOW (see Figure 1), the input and output layers are context (C) and centre word (T) one-hot encodings, respectively. The model is trained by maximizing the probability of predicting a centre word, given its context (Rong, 2014):

$$\arg\max p(t|c_1, ..., c_n, ..., c_m) \tag{1}$$

where t is a centre word, c_n is the nth context word of t within a sentence, totally m context words. CBOW's hidden layer is defined as:

$$\begin{aligned} H_{CBOW} &= \frac{1}{m} \times W^{i\top} \times \sum_{n=1}^{m} C_n \\ &= \frac{1}{m} \times \sum_{n=1}^{m} v_{c,n}^{i\top} \end{aligned} \tag{2}$$

where C_n is the one-hot encoding of the nth context word, $v_{c,n}^i$ is the nth context word row vector (input vector) in W^i which is a weight matrix between input and hidden layers. Thus, the hidden layer is the transpose of the average of input vectors of context words. The probability of predicting a centre word in its context is given by a softmax function below:

$$u_t = W_t^{o\top} \times H_{CBOW} = v_t^{o\top} \times H_{CBOW} \tag{3}$$

$$p(t|c_1, ..., c_n, ..., c_m) = \frac{\exp(u_t)}{\sum_{j=1}^{V} \exp(u_j)} \tag{4}$$

where W_t^o is equivalent to the output vector v_t^o which is essentially a column vector in a weight matrix W^o that is between hidden and output layers, aligning with the centre word t. V is the size of vocabulary in the corpus.

The output is a one-hot encoding of the centre word. W^i and W^o are updated via back propagation of errors. Therefore, only the value of the position that represents the centre word's probability, i.e., $p(t|c_1, ..., c_n, ..., c_m)$, will get close to the value of 1. In contrast, the probability of the rest of the words in the vocabulary will be close to 0 in every centre word training. W^i embeds context words. Vectors within W^i can be viewed as context word embeddings. W^o embeds centre words, vectors in W^o can be viewed as centre word embeddings.

Skip-gram is the reverse of CBOW (see Figure 1). The input and output layers are centre word and context word one-hot encodings, respectively. The target is to maximize the probability of predicting each context word, given a centre word:

$$\arg\max p(c_1, ..., c_n, ..., c_m|t) \tag{5}$$

Skip-gram's hidden layer is defined as:

$$H_{SG} = W^{i\top} \times T = v_t^{i\top} \tag{6}$$

where T is the one-hot encoding of the centre word t. Skip-gram's hidden layer is equal to the transpose of a centre word's input vector v_t, as only the tth row are kept by the operation. The probability of a context word is:

$$u_{c,n} = W_{c,n}^{o\top} \times H_{SG} = v_{c,n}^{o\top} \times H_{SG} \tag{7}$$

$$p(c_n|t) = \frac{\exp(u_{c,n})}{\sum_{j=1}^{V} \exp(u_j)} \tag{8}$$

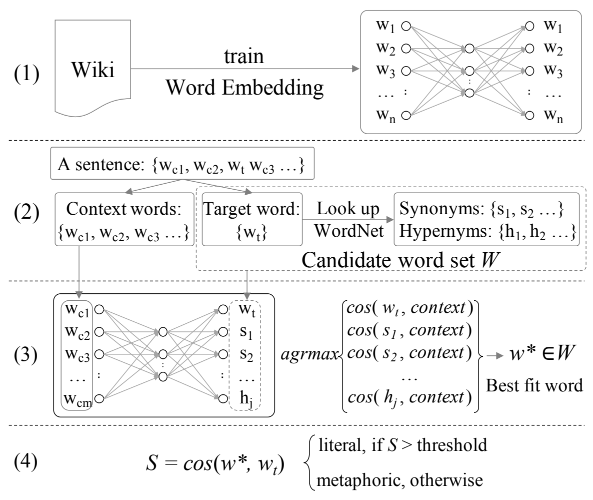

Figure 2: Metaphor identification framework. NB: w^* = best fit word, w_t = target word.

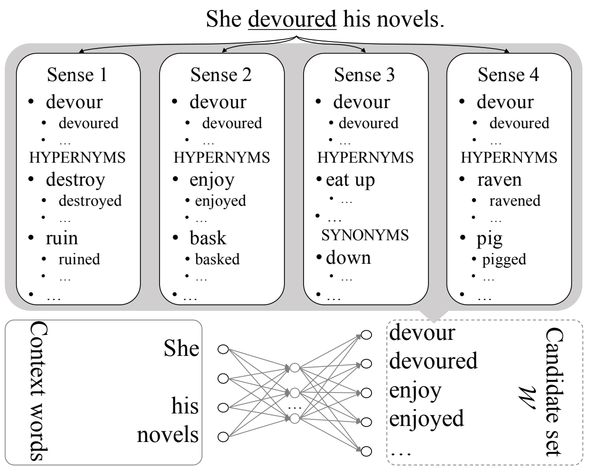

Figure 3: Given CBOW trained input and output vectors, a target word of *devoured*, and a context of *She* [ ] *his novels*, $cos(v^o_{devoured}, v^i_{context}) = -0.01$, $cos(v^o_{enjoyed}, v^i_{context}) = 0.02$.

where c, n is the nth context word, given a centre word. In Skip-gram, W^i aligns to centre words, while W^o aligns to context words. Because the names of centre word and context word embeddings are reversed in CBOW and Skip-gram, we will uniformly call vectors in W^i input vectors v^i, and vectors in W^o output vectors v^o in the remaining sections. Word embeddings represent both input and output vectors.

4 Methodology

In this section, we present the technical details of our metaphor processing framework, built upon two hypotheses. Our first hypothesis (**H1**) is that a metaphorical word can be identified, if the sense the word takes within its context and its literal sense come from different domains. Such a hypothesis is based on the theory of Selectional Preference Violation (Wilks, 1975, 1978) that a metaphorical item can be found in a violation of selectional restrictions, where a word does not satisfy its semantic constrains within a context. Our second hypothesis (**H2**) is that the literal senses of words occur more commonly in corpora than their metaphoric senses (Cameron, 2003; Martin, 2006; Steen et al., 2010; Shutova, 2016).

Figure 2 depicts an overview of our metaphor identification framework. The workflow of our framework is as follows. Step (1) involves training word embeddings based on a Wikipedia dump[3] for obtaining input and output vectors of words. In Step (2), given an input sentence, the target word (i.e., the word in the original text whose metaphoricity is to be determined) and its context words (i.e., all other words in the sentence excluding the target word) are separated. We construct a candidate word set $\mathcal{W}$ which represents all the possible senses of the target word. This is achieved by first extracting the synonyms and direct hypernyms of the target word from WordNet, and then augmenting the set with the inflections of the extracted synonyms and hypernyms, as well as the target word and its inflections. Auxiliary verbs are excluded from this set, as these words frequently appear in most sentences with little lexical meaning. In Step (3), we identify the best fit word, which is defined as the word that represents the literal sense that the target word is most likely taking given its context. Finally, in Step (4), we compute the cosine similarity between the target word and the best fit word. If the similarity is above a threshold, the target word will be identified as literal, otherwise metaphoric (i.e., based on **H1**). We will discuss in detail Step (3) and Step (4) in §4.1.

4.1 Metaphor identification

Step (3): One of the key steps of our metaphor identification framework is to identify the best fit word for a target word given its surrounding context. The intuition is that the best fit word will represent the literal sense that the target word is most likely taking. E.g., for the sentence *"She devoured his novels."* and the corresponding target word *devoured*, the best fit word is *enjoyed*, as shown in

[3]https://dumps.wikimedia.org/enwiki/20170920/

Figure 3. Also note that the best fit word could be the target word itself if the target word is used literally.

Given a sentence s, let w_t be the target word of the sentence, $w^* \in \mathcal{W}$ the best fit word for w_t, and $w_{context}$ the surrounding context for w_t, i.e., all the words in s excluding w_t. We compute the context embedding $v^i_{context}$ by averaging out the input vectors of each context word of $w_{context}$, based on Eq. 2. Next, we rank each candidate word $k \in \mathcal{W}$ by measuring its similarity to the context input vector $v^i_{context}$ in the vector space. The candidate word with the highest similarity to the context is then selected as the best fit word.

$$w^* = \arg\max_k \text{SIM}(v_k, v_{context}) \qquad (9)$$

where v_k is the vector of a candidate word $k \in \mathcal{W}$. In contrast to existing word embedding based methods for metaphor identification which only make use of input vectors (Shutova et al., 2016; Rei et al., 2017), we explore using both input and output vectors of CBOW and Skip-gram embeddings when measuring the similarity between a candidate word and the context. We expect that using a combination of input and output vectors might work better. Specifically, we have experimented with four different model variants as shown below.

$$\text{SIM-CBOW}_I = \cos(v^i_{k,cbow}, v^i_{context,cbow}) \qquad (10)$$

$$\text{SIM-CBOW}_{I+O} = \cos(v^o_{k,cbow}, v^i_{context,cbow}) \qquad (11)$$

$$\text{SIM-SG}_I = \cos(v^i_{k,sg}, v^i_{context,sg}) \qquad (12)$$

$$\text{SIM-SG}_{I+O} = \cos(v^o_{k,sg}, v^i_{context,sg}) \qquad (13)$$

Here, $\cos(\cdot)$ is cosine similarity, $cbow$ is CBOW word embeddings, sg is Skip-gram word embeddings. We have also tried other model variants using output vectors for $v_{context}$. However, we found that the models using output vectors for $v_{context}$ (both CBOW and Skip-gram embeddings) do not improve our framework performance. Due to the page limit we omitted the results of those models in this paper.

Step (4): Given a predicted best fit word w^* identified in Step (3), we then compute the cosine similarity between the lemmatizations of w^* and the target word w_t using their input vectors.

$$\text{SIM}(w^*, w_t) = \cos(v^i_{w^*}, v^i_{w_t}) \qquad (14)$$

We give a detailed discussion in §4.2 of our rationale for using input vectors for Eq. 14.

If the similarity is higher than a threshold (τ) the target word is considered as literal, otherwise, metaphorical (based on **H1**). One benefit of our approach is that it allows one to paraphrase the identified metaphorical target word into the best fit word, representing its literal sense in the context. Such a feature is useful for supporting other NLP tasks such as Machine Translation, which we will explore in §6. In terms of the value of threshold (τ), it is empirically determined based on a development set. Please refer to §5 for details.

To better explain the workflow of our framework, we now go through an example as illustrated in Figure 3. The target word of the input sentence, *"She devoured his novels."* is *devoured*, and its the lemmatised form *devour* has four verbal senses in WordNet, i.e., *destroy completely*, *enjoy avidly*, *eat up completely with great appetite*, and *eat greedily*. Each of these senses has a set of corresponding synonyms and hypernyms. E.g., Sense 3 (*eat up completely with great appetite*) has synonyms *demolish*, *down*, *consume*, and hypernyms *go through*, *eat up*, *finish*, and *polish off*. We then construct a candidate word set $\mathcal{W}$ by including the synonyms and direct hypernyms of the target word from WordNet, and then augmenting the set with the inflections of the extracted synonyms and hypernyms, as well as the target word *devour* and its inflections. We then identify the best fit word given the context *she* [ ] *his novels* based on Eq. 9. Based on **H2**, literal expressions are more common than metaphoric ones in corpora. Therefore, the best fit word is expected to frequently appear within the given context, and thus represents the most likely sense of the target word. For example, the similarity between *enjoy* (i.e., the best fit word) and the the context is higher than that of *devour* (i.e., the target word), as shown in Figure 3.

4.2 Word embedding: output vectors vs. input vectors

Typically, input vectors are used after training CBOW and Skip-gram, with output vectors being abandoned by practical models, e.g., original word2vec model (Mikolov et al., 2013) and Gensim toolkit (Řehůřek and Sojka, 2010), as these models are designed for modelling similarities in semantics. However, we found that using input vectors to measure cosine similarity between two words with different POS types in a phrase is sub-

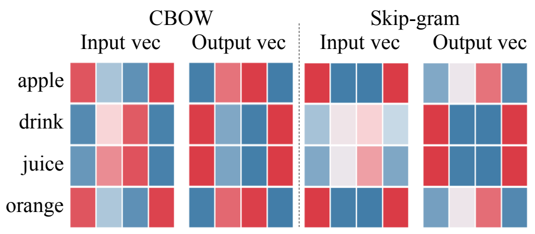

Figure 4: Input and output vector visualization. The bluer, the more negative. The redder, the more positive.

optimal, as words with different POS normally have different semantics. They tend to be distant from each other in the input vector space. Taking Skip-gram for example, empirically, input vectors of words with the same POS, occurring within the same contexts tend to be close in the vector space (Mikolov et al., 2013), as they are frequently updated by back propagating the errors from the same context words. In contrast, input vectors of words with different POS, playing different semantic and syntactic roles tend to be distant from each other, as they seldom occur within the same contexts, resulting in their input vectors rarely being updated equally. Our observation is also in line with Nalisnick et al. (2016), who examine IN-IN, OUT-OUT and IN-OUT vectors to measure similarity between two words. Nalisnick et al. discovered that two words which are similar by function or type have higher cosine similarity with IN-IN or OUT-OUT vectors, while using input and output vectors for two words (IN-OUT) that frequently co-occur in the same context (e.g., a sentence) can obtain a higher similarity score.

For illustrative purpose, we visualize the CBOW and Skip-gram updates between 4-dimensional input and output vectors by Wevi[4] (Rong, 2014), using a two-sentence corpus, *"Drink apple juice."* and *"Drink orange juice."*. We feed these two sentences to CBOW and Skip-gram with 500 iterations. As seen Figure 4, the input vectors of *apple* and *orange* are similar in both CBOW and Skip-gram, which are different from the input vectors of their context words (*drink* and *juice*). However, the output vectors of *apple* and *orange* are similar to the input vectors of *drink* and *juice*.

To summarise, using input vectors to compare similarity between the best fit word and the target word is more appropriate (cf. Eq.14), as they tend to have the same types of POS. When measuring the similarity between candidate words and the context, using output vectors for the former and input vectors for the latter seems to better predict the best fit word.

5 Experimental settings

Baselines. We compare the performance of our framework for metaphor identification against three strong baselines, namely, an unsupervised word embedding based model by Shutova et al. (2016), a supervised deep learning model by Rei et al. (2017), and the Context2Vec model[5] (Melamud et al., 2016) which achieves the best performance on Microsoft Sentence Completion Challenge (Zweig and Burges, 2011). Context2Vec was not designed for processing metaphors, in order to use it for this we plug it into a very similar framework to that described in Figure 2. We use Context2Vec to predict the best fit word from the candidate set, as it similarly uses context to predict the most likely centre word but with bidirectional LSTM based context embedding method. After locating the best fit word with Context2Vec, we identify the metaphoricity of a target word with the same method (see Step (4) in §4), so that we can also apply it for metaphor interpretation. Note that while Shutova et al. and Rei et al. detect metaphors at the phrase level by identifying metaphorical phrases, Melamud et al.'s model can perform metaphor identification and interpretation on sentences.

Dataset. Evaluation was conducted based on a dataset developed by Mohammad et al. (2016). This dataset[6], containing 1,230 literal and 409 metaphor sentences, has been widely used for metaphor identification related research (Shutova et al., 2016; Rei et al., 2017). There is a verbal target word annotated by 10 annotators in each sentence. We use two subsets of the Mohammad et al. set, one for phrase evaluation and one for sentence evaluation. The phrase evaluation dataset was kindly provided by Shutova, which consists of 316 metaphorical and 331 literal phrases (subject-verb and verb-direct object word pairs), parsed from Mohammad et al.'s dataset. Similar to Shutova et al. (2016), we use 40 metaphoric and 40 literal phrases as a development set and the rest as a test

set.

For sentence evaluation, we select 212 metaphorical sentences whose target words are annotated with at least 70% agreement. We also add 212 literal sentences with the highest agreement. Among the 424 sentences, we form our development set with 12 randomly selected metaphoric and 12 literal instances to identify the threshold for detecting metaphors. The remaining 400 sentences are our testing set.

Word embedding training. We train CBOW and Skip-gram models on a Wikipedia dump with the same settings as Shutova et al. (2016) and Rei et al. (2017). That is, CBOW and Skip-gram models are trained iteratively 3 times on Wikipedia with a context window of 5 to learn 100-dimensional word input and output vectors. We exclude words with total frequency less than 100. 10 negative samples are randomly selected for each centre word training. The word down-sampling rate is 10^{-5}. We use Stanford CoreNLP (Manning et al., 2014) lemmatized Wikipedia to train word embeddings for phrase level evaluation, which is in line with Shutova et al. (2016). In sentence evaluation, we use the original Wikipedia for training word embeddings.

6 Experimental Results

6.1 Metaphor identification

Table 1 shows the performance of our model and the baselines on the task of metaphor identification. All the results for our models are based on a threshold of 0.6, which is empirically determined based on the developing set. For sentence level metaphor identification, it can be observed that all our models outperform the baseline (Melamud et al., 2016), with SIM-CBOW$_{I+O}$ giving the highest F1 score of 75% which is a 6% gain over the baseline. We also see that models based on both input and output vectors (i.e., SIM-CBOW$_{I+O}$ and SIM-SG$_{I+O}$) yield better performance than the models based on input vectors only (i.e., SIM-CBOW$_I$ and SIM-SG$_I$). Such an observation supports our assumption that using input and output vectors can better model similarity between words that have different types of POS, than simply using input vectors. When comparing CBOW and Skip-gram based models, we see that CBOW based models generally achieve better performance in precision whereas Skip-gram based models perform better in recall.

In terms of phrase level metaphor identification, we compare our best performing models (i.e., SIM-CBOW$_{I+O}$ and SIM-SG$_{I+O}$) against the approaches of Shutova et al. (2016) and Rei et al. (2017). In contrast to the sentence level evaluation in which SIM-CBOW$_{I+O}$ gives the best performance, SIM-SG$_{I+O}$ performs best for the phrase level evaluation. This is likely due to the fact that Skip-gram is trained by using a centre word to maximise the probability of each context word, whereas CBOW uses the average of context word input vectors to maximise the probability of the centre word. Thus, Skip-gram performs better in modelling one-word context, while CBOW has better performance in modelling multi-context words. When comparing to the baselines, our model SIM-SG$_{I+O}$ significantly outperforms the word embedding based approach by Shutova et al. (2016), and gives the same performance as the deep supervised method (Rei et al., 2017) which requires a large amount of labelled data for training and cost in training time.

SIM-CBOW$_{I+O}$ and SIM-SG$_{I+O}$ are also evaluated with different thresholds for both phrase and sentence level metaphor identification. As can be seen from Table 2, the results are fairly stable when the threshold is set between 0.5 and 0.9 in terms of F1.

6.2 Metaphor processing for MT

We believe that one of the key purposes of metaphor processing is to support other NLP tasks. Therefore, we conducted another set of experiments to evaluate how metaphor processing can be used to support English-Chinese machine translation.

The evaluation task was designed as follows. From the test set for sentence-level metaphor identification which contains 200 metaphoric and

τ	Sentence			Phrase	
	P	**R**	**F1**	**F1**$_{\text{SIM-CBOW}_{I+O}}$	**F1**$_{\text{SIM-SG}_{I+O}}$

0.4	0.69	0.75	0.72	0.65	0.63
0.5	0.67	0.82	0.74	0.71	0.72
0.6	0.66	0.88	**0.75**	**0.72**	**0.74**
0.7	0.64	0.88	0.74	0.72	0.73
0.8	0.63	0.89	0.74	0.72	0.73
0.9	0.63	0.89	0.74	0.71	0.73
1.0	0.50	1.00	0.67	0.65	0.65

Table 2: Model performance vs. different threshold (τ) settings. NB: the sentence level results are based on SIM-CBOW$_{I+O}$.

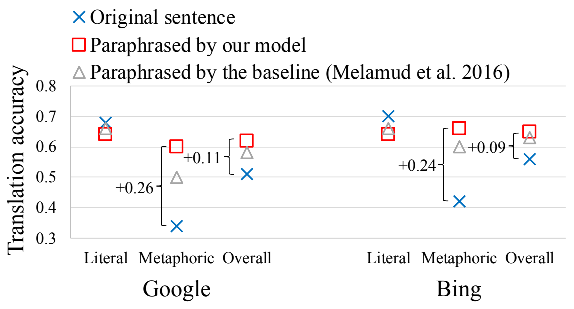

Figure 5: Accuracy of metaphor interpretation, evaluated on Google and Bing Translation.

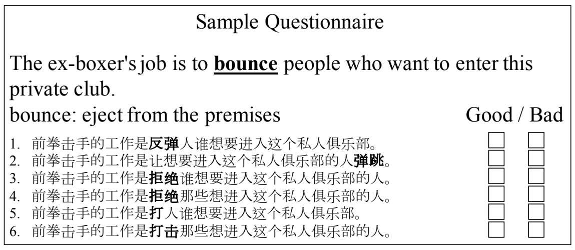
200 literal sentences, we randomly selected 50 metaphoric and 50 literal sentences to construct a set $\mathcal{S}_{\mathcal{M}}$ for the Machine Translation (MT) evaluation task. For each sentence in $\mathcal{S}_{\mathcal{M}}$, if it is predicted as literal by our model, the sentence is kept unchanged; otherwise, the target word of the sentence is paraphrased with the best fit word (refer to §4.1 for details). The metaphor identification step resulted in 42 True Positive (TP) instances where the ground truth label is metaphoric and 19 False Positive (FP) instances where the ground truth label is literal, resulting in a total of 61 instances predicted as metaphorical by our model. We also run one of our baseline models, Context2Vec, on the 61 sentences to predict the best fit words for comparison. Our hypothesis is that by paraphrasing the metaphorically used target word with the best fit word which expresses the target word's real meaning, the performance of translation engines can be improved.

We test our hypothesis on two popular English-Chinese MT systems, i.e., the Google and Bing Translators. We recruited from a UK university 5 Computing Science postgraduate students who are Chinese native speakers to participate the English-Chinese MT evaluation task. During the evaluation, subjects were presented with a questionnaire



Sample Questionnaire

The ex-boxer's job is to **bounce** people who want to enter this private club.

bounce: eject from the premises

		Acc-met.	**Acc-lit.**	**Acc-overall**
Google	Orig. Sent.	0.34	**0.68**	0.51
	Context2Vec	0.50	0.66	0.58
	SIM-CBOW$_{I+O}$	**0.60**	0.64	**0.62**
Bing	Orig. Sent.	0.42	**0.70**	0.56
	Context2Vec	0.60	0.66	0.63
	SIM-CBOW$_{I+O}$	**0.66**	0.64	**0.65**

Table 3: Accuracy of metaphor interpretation, evaluated on Google and Bing Translation.

containing English-Chinese translations of each of the 100 randomly selected sentences. For each sentence predicted as literal (39 out of 100 sentences), there are two corresponding translations by Google and Bing respectively. For each sentence predicted as metaphoric (61 out of 100 sentences), there are 6 corresponding translations.

An example of the evaluation task is shown in Figure 6, in which *"The ex-boxer's job is to bounce people who want to enter this private club."* is the original sentence, followed by an WordNet explanation of the target word of the sentence (i.e., bounce: eject from the premises). There are 6 translations. No. 1-2 are the original sentence translations, translated by Google Translate (GT) and Bing Translator (BT). The target word, *bounce*, is translated, taking the sense of (1) *physically rebounding like a ball* (反弹), (2) *jumping* (弹跳). No. 3-4 are SIM-CBOW$_{I+O}$ paraphrased sentences, translated by GT and BT, respectively, taking the sense of *refusing* (拒绝). No. 5-6 are Context2Vec paraphrased sentences, translated by GT and BT, respectively, taking the sense of *hitting* (5.打; 6.打击).

Subjects were instructed to determine if the translation of a target word can correctly represent its sense within the translated sentence, matching its context (cohesion) in Chinese. Note that we evaluate the translation of the target word, therefore, errors in context word translations are ignored by the subjects. Finally, a label is taken agreed by more than half annotators. Noticeably, based on our observation, there is always a Chinese word corresponding to an English target word in MT, as the annotated target word normally represents important information in the sentence in the applied dataset.

We use translation accuracy as a measure to evaluate the improvement on MT systems after metaphor processing. The accuracy is calculated by dividing the number of correctly translated instances by the total number of instances. As can be seen in Figure 5 and Table 3, after paraphrasing the metaphorical sentences with the SIM-CBOW$_{I+O}$ model, the translation improvement for the metaphorical class is dramatic for both MT systems, i.e., 26% improvement for Google Translate and 24% for Bing Translate. In terms of the literal class, there is some small drop (i.e., 4-6%) in accuracy. This is due to the fact that some literals were wrongly identified as metaphors and hence error was introduced during paraphrasing. Nevertheless, with our model, the overall translation performance of both Google and Bing Translate are significantly improved by 11% and 9%, respectively. Our baseline model Context2Vec also improves the translation accuracy, but is 2-4 % lower than our model in terms of overall accuracy. In summary, the experimental results show the effectiveness of applying metaphor processing for supporting Machine Translation.

7 Conclusion

We proposed a framework that identifies and interprets metaphors at word-level with an unsupervised learning approach. Our model outperforms the unsupervised baselines in both sentence and phrase evaluations. The interpretation of the identified metaphorical words given by our model also contributes to Google and Bing translation systems with 11% and 9% accuracy improvements.

The experiments show that using words' hypernyms and synonyms in WordNet can paraphrase metaphors into their literal counterparts, so that the metaphors can be correctly identified and translated. To our knowledge, this is the first study that evaluates a metaphor processing method on Machine Translation. We believe that compared with simply identifying metaphors, metaphor processing applied in practical tasks, can be more valuable in the real world. Additionally, our experiments demonstrate that using a candidate word output vector instead of its input vector to model the similarity between the candidate word and its context yields better results in the best fit word (the literal counterpart of the metaphor) identification.

CBOW and Skip-gram do not consider the distance between a context word and a centre word in a sentence, i.e., context word contributes to predict the centre word equally. Future work will introduce weighted CBOW and Skip-gram to learn positional information within sentences.

Incorporating Latent Meanings of Morphological Compositions to Enhance Word Embeddings

Abstract

Traditional word embedding approaches learn semantic information at word level while ignoring the meaningful internal structures of words like morphemes. Furthermore, existing morphology-based models directly incorporate morphemes to train word embeddings, but still neglect the latent meanings of morphemes. In this paper, we explore to employ the latent meanings of morphological compositions of words to train and enhance word embeddings. Based on this purpose, we propose three Latent Meaning Models (LMMs), named LMM-A, LMM-S and LMM-M respectively, which adopt different strategies to incorporate the latent meanings of morphemes during the training process. Experiments on word similarity, syntactic analogy and text classification are conducted to validate the feasibility of our models. The results demonstrate that our models outperform the baselines on five word similarity datasets. On Wordsim-353 and RG-65 datasets, our models nearly achieve 5% and 7% gains over the classic CBOW model, respectively. For the syntactic analogy and text classification tasks, our models also surpass all the baselines including a morphology-based model.

1 Introduction

Word embedding, which is also termed distributed word representation, has been a hot topic in the area of Natural Language Processing (NLP). The derived word embeddings have been used in plenty of tasks such as text classification (Liu et al., 2015), information retrieval (Manning et al., 2008), sentiment analysis (Shin et al., 2016), machine translation (Cho et al., 2014) and so on. Recently, some classic word embedding methods have been proposed, like Continuous Bag-of-Word (CBOW), Skip-gram (Mikolov et al., 2013a), Global Vectors (GloVe) (Pennington et al., 2014). These methods can usually capture word-level semantic information but ignore the meaningful inner structures of words like English morphemes or Chinese characters.

The effectiveness of exploiting the internal compositions of words has been validated by some previous work (Luong et al., 2013; Botha and Blunsom, 2014; Chen et al., 2015; Cotterell et al., 2016). Some of them compute the word embeddings by directly adding the representations of morphemes/characters to context words or optimizing a joint objective over distributional statistics and morphological properties (Qiu et al., 2014; Botha and Blunsom, 2014; Chen et al., 2015; Luong et al., 2013; Lazaridou et al., 2013), while others introduce some probabilistic graphical models to build relationship between words and their internal compositions. *e.g.*, Bhatia et al. (2016) treat word embeddings as latent variables for a prior distribution, which reflects words' morphological properties, and feed the latent variables into a neural sequence model to obtain final word embeddings. Cotterell et al. (2016) construct a Gaussian graphical model that binds the morphological analysis to pre-trained word embeddings, which can help to smooth the noisy embeddings. Besides, these two methods also have the ability to predict embeddings for unseen words.

Different from all the above models (we regard them as *Explicit* models in Fig. 1) where internal compositions are directly used to encode morphological regularities into words and the

[*]This is the corresponding author.

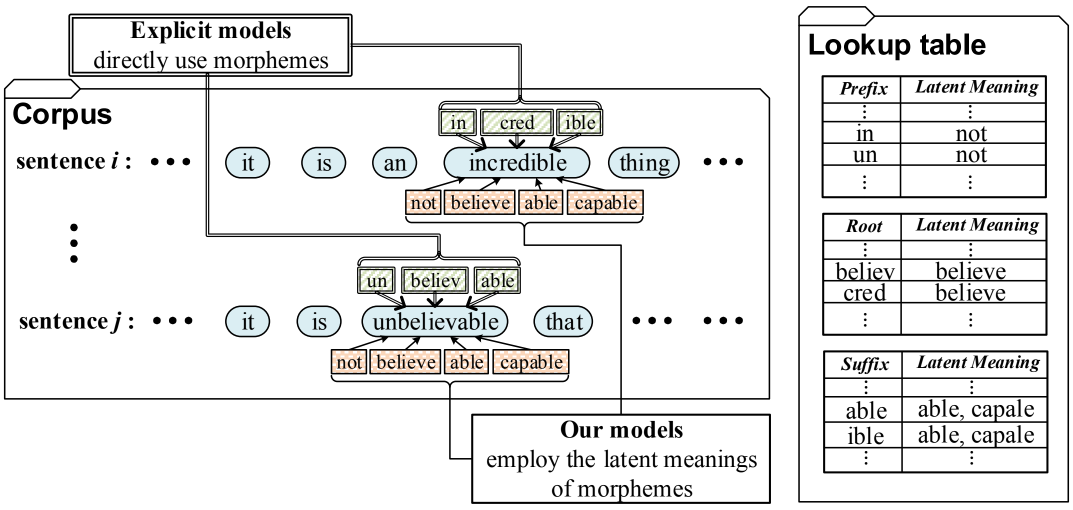

Figure 1: An illustration of explicit models and our models in an English corpus. Although *incredible* and *unbelievable* have different morphemes, their morphemes have the same latent meanings.

composition embeddings like morpheme embeddings are generated as by-products, we explore a new way to employ the latent meanings of morphological compositions rather than the compositions themselves to train word embeddings. As shown in Fig. 1, according to the distributional semantics hypothesis (Sahlgren, 2008), *incredible* and *unbelievable* probably have similar word embeddings because they have similar context. As a matter of fact, *incredible* is a synonym of *unbelievable* and their embeddings are expected to be close enough. Since the morphemes of the two words are different, especially the roots *cred* and *believ*, the explicit models may not significantly shorten the distance between the words in the vector space. Fortunately, the latent meanings of the different morphemes are the same (*e.g.*, the latent meanings of roots *cred*, *believ* are "*believe*") as listed in the lookup table (derived from the resources provided by Michigan State University),[1] which evidently implies that *incredible* and *unbelievable* share the same meanings. In addition, by replacing morphemes with their latent meanings, we can directly and simply quantize the similarities between words and their sub-compositions with the same metrics used in most NLP tasks, *e.g.*, cosine similarity. Subsequently, the similarities are utilized to calculate the weights of latent meanings of morphemes for each word.

In this paper, we try different strategies to modify the input layer and update rules of a neural language model, *e.g.*, CBOW, Skip-gram, and propose three lightweight and efficient models, which are termed Latent Meaning Models (LMMs), to not only encode morphological properties into words but also enhance the semantic similarities among word embeddings. Usually, the vocabulary derived from the corpus contains vast majority or even all of the latent meanings. Rather than generating and training extra embeddings for latent meanings, we directly override the embeddings of the corresponding words in the vocabulary. Moreover, a word map is created to describe the relations between words and the latent meanings of their morphemes.

For comparison, our models together with the state-of-the-art baselines are tested on two basic NLP tasks, which are word similarity and syntactic analogy, and one downstream text classification task. The results show that LMMs outperform the baselines and get satisfactory improvement on these tasks. In all, the main contributions of this paper are summarized as follows.

- Rather than directly incorporating the morphological compositions (surface forms) of words, we decide to employ the latent meanings of the compositions (underlying forms) to train the word embeddings. To validate the feasibility of our purpose, three specific models, named LMMs, are proposed with different strategies to incorporate the latent meanings.

[1]`https://msu.edu/~defores1/gre/roots/gre_rts_afx1.htm`

- We utilize a medium-sized English corpus to train LMMs and the state-of-the-art baselines, and evaluate their performance on two basic NLP tasks, *i.e.*, word similarity and syntactic analogy, and one downstream text classification task. The results show that LMMs outperform the baselines on five word similarity datasets. On the golden standard Wordsim-353 and RG-65, LMMs approximately achieve 5% and 7% gains over CBOW, respectively. For the syntactic analogy and text classification tasks, LMMs also surpass all the baselines.

- We conduct experiments to analyze the impacts of parameter settings, and the results demonstrate that the performance of LMMs on the smallest corpus is similar to the performance of CBOW on the corpus that is five times as large, which convinces us that LMMs are of great advantages to enhance word embeddings compared with traditional methods.

2 Background and Related Work

Considering the high efficiency of CBOW proposed by Mikolov et al. (2013a), our LMMs are built upon CBOW. Here, we first review some backgrounds of CBOW, and then present some related work on recent word-level and morphology-based word embedding methods.

CBOW with Negative Sampling With a sliding window, CBOW utilizes the context words in the window to predict the target word. Given a sequence of tokens $T = \{t_1, t_2, \cdots, t_n\}$, where n is the size of a training corpus, the objective of CBOW is to maximize the following average log probability equation:

$$L = \frac{1}{n} \sum_{i=1}^{n} \log p\big(t_i | context(t_i)\big), \qquad (1)$$

where $context(t_i)$ represents the context words of t_i in the slide window, $p\big(t_i | context(t_i)\big)$ is derived by softmax. Due to huge size of English vocabulary, $p\big(t_i | context(t_i)\big)$ can not be calculated in a tolerable time. Therefore, negative sampling and hierarchical softmax are proposed to solve this problem. Owing to the efficiency of negative sampling, all our models are trained based on it. In terms of negative sampling, the log probability $\log p(t_O|t_I)$ is transformed as:

$$\begin{aligned} &\log \delta\big(vec'(t_O)^T vec(t_I)\big) + \\ &\sum_{i=1}^{m} \log \big[1 - \delta\big(vec'(t_i)^T vec(t_I)\big)\big], \end{aligned} \qquad (2)$$

where m denotes the number of negative samples, and $\delta(\cdot)$ is the sigmoid function. The first item of Eq. (2) is the probability of target word when its context is given. The second item indicates the probability that negative samples do not share the same context as the target word.

Word-level Word Embedding In general, word embedding models can mainly be divided into two branches. One is based on neural network like the classic CBOW model (Mikolov et al., 2013a), while the other is based on matrix factorization. Besides CBOW, Skip-gram (Mikolov et al., 2013a) is another widely used neural-network-based model, which predicts the context by using the target word (Mikolov et al., 2013a). As for matrix factorization, Dhillon et al. (2015) proposed a spectral word embedding method to measure the correlation between word information matrix and context information matrix. In order to combine the advantages of models based on neural network and matrix factorization, Pennington et al. (2014) proposed a famous word embedding model named GloVe, which is reported to outperform the CBOW and Skip-gram models on some tasks. These models are effective to capture word-level semantic information while neglecting inner structures of words. In contrast, the unheeded inner structures are utilized in both our LMMs and other morphology-based models.

Morphology-based Word Embedding Recently, some more fine-grained word embedding models are proposed by exploiting the morphological compositions of words, *e.g.*, root and affixes. These morphology-based models can be divided into two main categories.

The first category directly adds the representations of internal structures to word embeddings or optimizes a joint objective over distributional statistics and morphological properties (Luong et al., 2013; Qiu et al., 2014; Botha and Blunsom, 2014; Lazaridou et al., 2013; Chen et al., 2015; Kim et al., 2016; Cotterell and Schütze, 2015). Chen et al. (2015) proposed a character-enhanced Chinese word embedding model, which splits a Chinese word into several characters and add the characters into the input layer of their models.

Luong et al. (2013) utilized the morpheme segments produced by Morfessor (Creutz and Lagus, 2007) and constructed morpheme trees for words to learn morphologically-aware word embeddings by the recursive neural network. Kim et al. (2016) incorporated the convolutional character information into English words. Their model can learn character-level semantic information for embeddings, which is proved to be effective for some morpheme-rich languages. However, with a huge size architecture, it's very time-consuming. Cotterell et al. (2015) augmented the log linear model to make the words, which share similar morphemes, gather together in vector space.

The other category tries to use probabilistic graphical models to connect words with their morphological compositions, and further learns word embeddings (Bhatia et al., 2016; Cotterell et al., 2016). Bhatia et al. (2016) employed morphemes and made them as prior knowledge of the latent word embeddings, then fed the latent variables into a neural sequence model to obtain final word embeddings. Cotterell et al. (2016) proposed a morpheme-based post-processor for pre-trained word embeddings. They constructed a Gaussian graphical model which can extrapolate continuous representations for unknown words.

However, these morphology-based models directly exploit the internal compositions of words to encode morphological regularities into word embeddings, and some by-products are also produced like morpheme embeddings. In contrast, we employ the latent meanings of morphological compositions to provide deeper insights for training better word embeddings. Furthermore, since the latent meanings are included in the vocabulary, there is no extra embedding being generated.

3 Our Latent Meaning Models

We leverage different strategies to modify the input layer and update rules of CBOW when incorporating the latent meanings of morphemes. Three specific models, named Latent Meaning Model-Average (LMM-A), LMM-Similarity (LMM-S) and LMM-Max (LMM-M), are proposed. It should be stated that, for now, our models mainly concern the derivational morphemes, which can be interpreted to some meaningful words or phrases (*i.e.*, latent meanings), not the inflectional morphemes like tense, number, gender, *etc.*

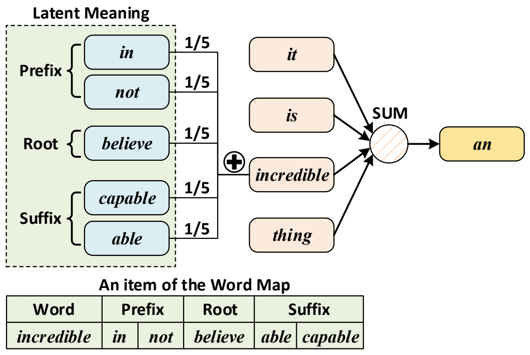

Figure 2: A paradigm of LMM-A. The sentence "*it is an incredible thing*" is selected as an example. When calculating the input vector of "*incredible*", we first find out the latent meanings of its morphemes in the word map, and add the vectors of all latent meanings to the vector of "*incredible*" with equal weights.

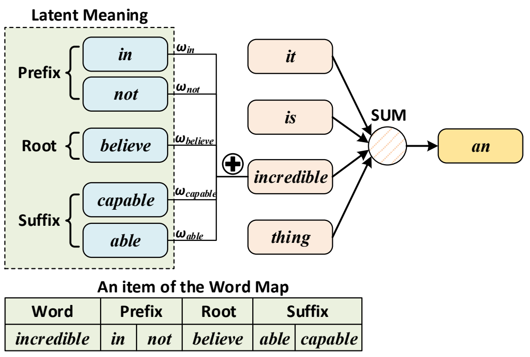
LMM-A assumes that all latent meanings of morphemes of a word have equal contributions to the word. LMM-A is applicable to the condition where words are correctly segmented into morphemes and each morpheme is interpreted to appropriate latent meanings. However, refining the latent meanings for morphemes is time-consuming and needs vast human annotations. To address this concern, LMM-S is proposed. Motivated by the attention scheme, LMM-S holds the assumption that all latent meanings have different contributions, and assigns the outliers small weights to let them have little impact on the representation of the target word. Furthermore, in LMM-M, we only keep the latent meanings which have the greatest contributions to the corresponding word. In what follows, we are going to introduce each of our LMMs in detail. At the end of this section, we will introduce the update rules of the models.

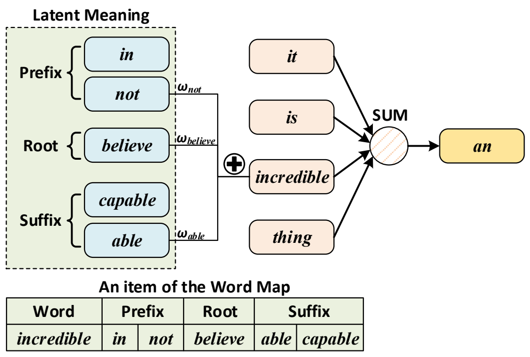
3.1 LMM-A

Given a sequence of tokens $T = \{t_1, t_2, \cdots, t_n\}$, LMM-A assumes that morphemes' latent meanings of token t_i ($i \in [1, n]$) have equal contributions to t_i, as shown in Fig. 2. The item for t_i in the word map is $t_i \mapsto M_i$. M_i is a set of latent meanings of t_i's morphemes, and it consists of three sub-parts P_i, R_i and S_i corresponding to the latent meanings of prefixes, roots and suffixes of t_i, respectively. Hence, at the input layer, the



Word	Prefix		Root	Suffix	
incredible	*in*	*not*	*believe*	*able*	*capable*

Figure 3: A paradigm of LMM-S. In this model, all latent meanings of morphemes of "*incredible*" are added together with different weights.



Word	Prefix		Root	Suffix	
incredible	*in*	*not*	*believe*	*able*	*capable*

Figure 4: A paradigm of LMM-M. The latent meanings with maximum similarities towards "*incredible*" are selected.

modified embedding of t_i can be expressed as

$$\widehat{v}_{t_i} = \frac{1}{2}\big(v_{t_i} + \frac{1}{N_i}\sum_{w \in M_i} v_w\big), \tag{3}$$

where v_{t_i} is the original word embedding of t_i, N_i denotes the length of M_i and v_w indicates the embedding of latent meaning w. Meanwhile, we assume the original word embedding and the average embeddings of v_w ($w \in M_i$) have equal weights, *i.e.*, 0.5. Eventually, $\widehat{v}_{t_i}$ rather than v_{t_i} is utilized for training in CBOW.

3.2 LMM-S

This model is proposed based on the attention scheme. We observe that many morphemes have more than one latent meaning. For instance, prefix *in-* means "*in*" and "*not*", and suffix *-ible* means "*able*" and "*capable*".[2] As Fig. 3 shows, for the item *incredible* $\mapsto \big\{[in, not]$, $[believe]$, $[able, capable]\big\}$ in the word map, the latent meanings have different biases towards "*incredible*". Therefore, we assign different weights to latent meanings. We measure the weights of latent meanings by calculating the normalized similarities between token t_i and the corresponding latent meanings. For LMM-S, the modified embedding of t_i can be rewritten as

$$\widehat{v}_{t_i} = \frac{1}{2}\big[v_{t_i} + \sum_{w \in M_i} \omega_{<t_i,w>} \cdot v_w\big], \tag{4}$$

where v_{t_i} is the original vector of t_i, and $\omega_{<t_i,w>}$ denotes the weight between t_i and the latent meaning w ($w \in M_i$). We use $cos(v_a, v_b)$ to denote the cosine similarity between v_a and v_b, then $\omega_{<t_i,w>}$ is expressed as follows:

$$\omega_{<t_i,w>} = \frac{cos(v_{t_i}, v_w)}{\sum\limits_{x \in M_i} cos(v_{t_i}, v_x)}. \tag{5}$$

3.3 LMM-M

To further eliminate the impacts of some uncorrelated latent meanings to a word, in LMM-M, we only select the latent meanings that have maximum similarities to the token t_i from P_i, R_i and S_i. As is shown in Fig. 4, the latent meaning "*not*" of prefix *in* is finally selected since the similarity between "*not*" and "*incredible*" is larger than that between "*in*" and "*incredible*". For token t_i, LMM-M is mathematically defined as

$$\widehat{v}_{t_i} = \frac{1}{2}\big[v_{t_i} + \sum_{w \in M^i_{max}} \omega_{<t_i,w>} \cdot v_w\big], \tag{6}$$

where $M^i_{max} = \{P^i_{max}, R^i_{max}, S^i_{max}\}$ is the set of latent meanings with maximum similarities towards token t_i, and P^i_{max}, R^i_{max}, S^i_{max} are obtained by the following equations:

$$\begin{aligned} P^i_{max} &= arg\max_{w} cos(v_{t_i}, v_w), w \in P_i, \\ R^i_{max} &= arg\max_{w} cos(v_{t_i}, v_w), w \in R_i, \\ S^i_{max} &= arg\max_{w} cos(v_{t_i}, v_w), w \in S_i. \end{aligned} \tag{7}$$

The normalized weight $\omega_{<t_i,w>}$ ($w \in M^i_{max}$) can similarly be derived like Eq. (5).

[2]All the latent meanings of roots and affixes are referred to the resources we mentioned before.

3.4 Update Rules for LMMs

After modifying the input layer of CBOW, Eq. (1) can be rewritten as

$$\widehat{L} = \frac{1}{n}\sum_{i=1}^{n}\log p\big(v_{t_i}|\sum_{t_j\in context(t_i)}\widehat{v}_{t_j}\big), \qquad (8)$$

where $\widehat{v}_{t_j}$ is the modified vector of v_{t_j} ($t_j \in context(t_i)$). Since the word map describes top-level relations between words and the latent meanings, these relations don't change during the training period. All parameters introduced by our models can be directly derived using the word map and word vectors, thus no extra parameter needs to be trained. When the gradient is propagated back to the input layer, we update not just the word vector v_{t_j} ($t_j \in context(t_i)$) but the vectors of the latent meanings in the vocabulary with the same weights as they are added to the vector v_{t_j}.

4 Experimental Setup

Before conducting experiments, some experimental settings are firstly introduced in this section.

4.1 Corpus and Word Map

We utilize a medium-sized English corpus to train all word embedding models. The corpus stems from the website of the 2013 ACL Workshop on Machine Translation[3] and is used in (Kim et al., 2016). We choose the news corpus of 2009 whose size is about 1.7GB. It contains approximately 500 million tokens and 600,000 words in the vocabulary. To get better quality of the word embeddings, we filter all digits and some punctuation marks out of the corpus.

For many languages, there exist large morphological lexicons or morphological tools that can analyze any word form (Cotterell and Schütze, 2015). To create the word map, we need to obtain the morphemes of each word and interpret them with the lookup table mentioned above to get the latent meanings. Usually, the lookup table can also be derived from the morphological lexicons for different languages, although it costs some time and manpower, we can create the lookup table once for all since it represents the common knowledge with respect to a certain language. Specifically, we first perform an unsupervised morpheme segmentation using Morefessor (Creutz and Lagus, 2007) for the vocabularies. Then we execute matching between the segmentation results and the morphological compositions in the lookup table, and the character sequence with largest overlap ratio will be viewed as a final morpheme and further be replaced by its latent meanings. Although the lookup table employed in this paper contains latent meanings for only 90 prefixes, 382 roots and 67 suffixes, we focus on validating the feasibility of enhancing word embeddings with the latent meanings of morphemes, and expending the lookup table is left as future work.

[3]http://www.statmt.org/wmt13/translation-task.html

4.2 Baselines

For comparison, we choose three word-level state-of-the-art word embedding models including CBOW, Skip-gram (Mikolov et al., 2013a) and GloVe (Pennington et al., 2014), and we also implement an Explicitly Morpheme-related Model (EMM), which is a variant version of the previous work (Qiu et al., 2014). The architecture of EMM is based on our LMM-A, where latent meanings are replaced back to morphemes and the embeddings of morphemes are also learned when training word embeddings. This enables our evaluation to focus on the critical difference between our models and the explicit model (Bhatia et al., 2016). We utilize the source code of word2vec[4] to train CBOW and Skip-gram. GloVe is trained based on the code[5] provided by Pennington et al. (2014). We modify the source of word2vec and train our models and EMM.

4.3 Parameter Settings

Parameter settings have a great effect on the performance of word embeddings (Levy et al., 2015). For fairness, all models are trained based on equal parameter settings. In order to accelerate the training process, CBOW, Skip-gram and EMM together with our models are trained by using the negative sampling technique. It is suggested that the number of negative samples in the range 5-20 is useful for small corpus (Mikolov et al., 2013b). If large corpus is used, the number of negative samples can be as small as 2-5. According to the size of corpus we used, the number of negative samples is empirically set to be 20 in this paper.

Name	Pairs	Name	Pairs
RG-65	65	RW	2034
SCWS	2003	Men-3k	3000
Wordsim-353	353	WS-353-REL	252

Table 1: Details of datasets. The column "Pairs" shows the number of word pairs in each dataset.

The dimension of word embedding is set as 200 like that in (Dhillon et al., 2015). We set the context window size as 5 which is equal to the setting in (Mikolov et al., 2013b).

4.4 Evaluation Benchmarks

4.4.1 Word Similarity

This experiment is conducted to evaluate the ability of word embeddings to capture semantic information from corpus. For English word similarity, we employ two gold standard datasets including Wordsim-353 (Finkelstein et al., 2001) and RG-65 (Rubenstein and Goodenough, 1965) as well as some other widely-used datasets including Rare-Word (Luong et al., 2013), SCWS (Huang et al., 2012), Men-3k (Bruni et al., 2014) and WS-353-Related (Agirre et al., 2009). More details of these datasets are shown in Table 1. Each dataset consists of three columns. The first two columns stand for word pairs and the last column is human score. We utilize the cosine similarity, which is used in many previous works (Mikolov et al., 2013b; Pennington et al., 2014), as the metric to measure the distance between two words. The Spearman's rank correlation coefficient (ρ) is employed to evaluate the similarity between our results and human scores. Higher ρ means better performance.

4.4.2 Syntactic Analogy

Based on the learned word embeddings, the core task of syntactic analogy is to answer the analogy question "a is to b as c is to _ ". We utilize the Microsoft Research Syntactic Analogies dataset, which is created by Mikolov (Mikolov et al., 2013c) with size of 8000. To answer the syntactic analogy question "a is to b as c is to d" where d is unknown, we assume that the word representations of a, b, c, d are v_a, v_b, v_c, v_d, respectively. To get d, we first calculate $\widehat{v}_d = v_b - v_a + v_c$. Then, we find out the word d' whose cosine similarity to $\widehat{v}_d$ is the largest. Finally, we set d as d'.

4.4.3 Text Classification

To further evaluate the learned word embeddings, we also conduct 4 text classification tasks using the 20 Newsgroups dataset.[6] The dataset totally contains around 19000 documents of 20 different newsgroups, and each corresponding to a different topic, such as guns, motorcycles, electronics and so on. For each task, we randomly select the documents of 10 topics and split them into training/validation/test subsets at the ratio of 6:2:2, which are emplyed to train, validate and test an L2-regularized 10-categorization logistic regression (LR) classifier. As mentioned in (Tsvetkov et al., 2015), here we also regard the average word embedding of words (excluding stop words and out-of-vocabulary words) in each document as the feature vector (the input of the classifier) of that document. The LR classifier is implemented with the scikit-learn toolkit (Pedregosa et al., 2011), which is an open-source Python module integrating many state-of-the-art machine learning algorithms.

5 Experimental Results

5.1 The Results on Word Similarity

Word similarity is conducted to test the semantic information which is encoded in word embeddings, and the results are listed in Table 2 (first 6 rows). We observe that our models surpass the comparative baselines on five datasets. Compared with the base model CBOW, it is remarkable that our models approximately achieve improvements of more than 5% and 7%, respectively, in the performance on the golden standard Wordsim-353 and RG-65. On WS-353-REL, the difference between CBOW and LMM-S even reaches 8%. The advantage demonstrates the effectiveness of our methods. Based on our strategy, more semantic information will be captured in corpus when adding more latent meanings in the context window. By incorporating mophemes, EMM also performs better than other baselines but fails to get the performance as well as ours. Actually, EMM mainly tunes the distributions of words in vector space to let the morpheme-similar words gather closer, which means it just encodes more morphological properties into word embeddings but lacks the ability to capture more semantic information. Specially, because of the medium-

size corpus and the experimental settings, GloVe doesn't perform as well as that described in (Pennington et al., 2014).

5.2 The Results on Syntactic Analogy

In (Mikolov et al., 2013c), the dataset is divided into adjectives, nouns and verbs. For brevity, we only report performance on the whole dataset. As the middle row of Table 2 shows, all of our models outperform the comparative baselines to a great extent. Compared with CBOW, the advantage of LMM-A even reaches to 7%. Besides, we observe that the suffix of "*b*" usually is the same as the suffix of "*d*" when answering question "*a* is to *b* as *c* is to *d*". Based on our strategy, morpheme-similar words will not only gather closer but have a trend to group near the latent meanings of their morphemes, which makes our embeddings have the advantage to deal with the syntactic analogy problem. EMM also performs well on this task but is still weaker than our models. Actually, syntactic analogy is also a semantics-related task because "*c*" and "*d*" are with similar meanings. Since our models are better to capture semantic information, they lead to higher performance than the explicitly morphology-based models.

5.3 The Results on Text Classification

For each one of the 4 text classification tasks, we report the classification accuracy over the test set. The average classification accuracy across the 4 tasks is utilized as the evaluation metric for different models. The results are displayed in the bottom row of Table 2. Since we simply use the average embedding of words as the feature vector for 10-categorization classification, the overall classification accuracies of all models are merely aroud 80%. However, the classification accuracies of our LMMs still surpass all the baselines, especailly CBOW and GloVe. Moreover, it can be found that incorporating morphological knowledge (morphemes or latent meanings of morphemes) into word embeddings can contribute to enhancing the performance of word embeddings in the downstream NLP tasks.

5.4 The Impacts of Parameter Settings

Parameter settings can affect the performance of word embeddings. For example, the corpus with larger corpus size (the ratio of tokens used for training) contains more semantic information, which can improve the performance on word similarity. We analyze the impacts of corpus size and window size on the performance of word embeddings. In the analysis of corpus size, we hold the same parameter settings as before. The sizes of tokens used for training are separately 1/5, 2/5, 3/5, 4/5 and 5/5 of the entire corpus mentioned above. We utilize the result of word similarity on Wordsim-353 as the evaluation criterion. From Fig. 5, we observe several phenomena. Firstly, the performance of our LMMs is better than CBOW at each corpus size. Secondly, the performance of CBOW is sensitive to the corpus size. In contrast, LMMs' performance is more stable than CBOW. As we analyzed in word similarity experiment, LMMs can increase the semantic information of word embeddings. It is worth noting that the performance of LMMs on the smallest corpus is even better than CBOW's performance on the largest corpus. In the analysis of window size, we observe that the performance of all word embeddings trained by different models has a trend to ascend with the increasing of window size as illustrated in Fig. 6. Our LMMs outperform CBOW under all the pre-set conditions. Besides, the worst performance of LMMs is nearly equal to the best performance of CBOW.

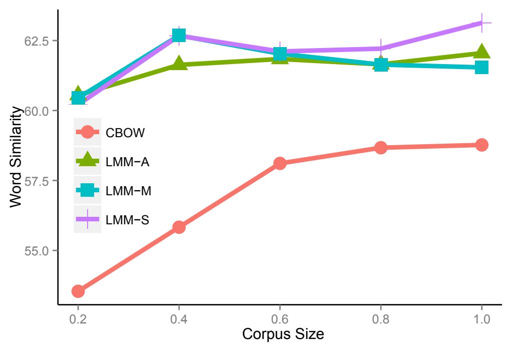

Figure 5: Parameter analysis of corpus size. X-axis denotes the ratio of tokens used for training, and Y-axis denotes the Spearman rank (%) of word similarity.

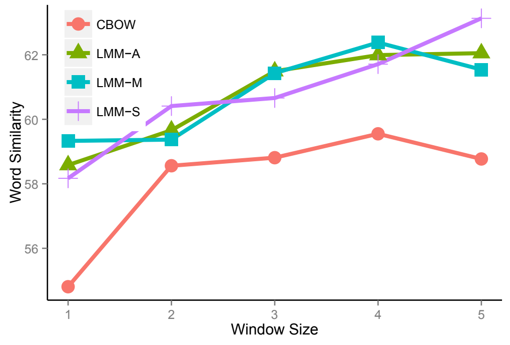

Figure 6: Parameter analysis of window size. X-axis and Y-axis denote the window size and Spearman rank (%) of word similarity, respectively.

5.5 Word Embedding Visualization

To visualize the embeddings of our models, we randomly select several words from the results of LMM-A. The dimensions of the selected word embeddings are reduced from 200 to 2 using Principal Component Analysis (PCA), and the 2-D word embeddings are illustrated in Fig. 7. The words with different colors reflect that they have different morphemes. It is apparent that words with similar morphemes have a trend to group together and stay near the latent meanings of their morphemes. In addition, we can also find some syntactic regularities in Fig. 7, for example, "*physics*" is to "*physicist*" as "*science*" is to "*scientist*", and "*physicist*" and "*scientist*" stay near the latent meaning, *i.e.*, "*human*", of the suffix *-ist*.

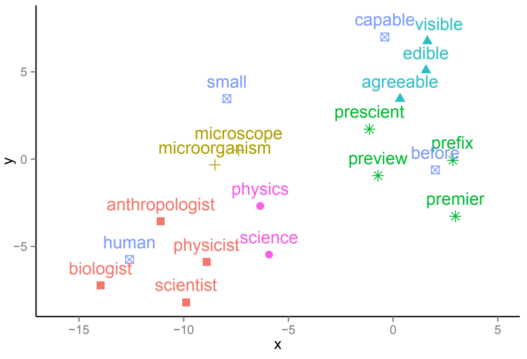

Figure 7: The visualization of word embeddings. Based on PCA, we randomly select several words from word embedding of LMM-A and illustrate them in this figure, "⊠" indicates the latent meanings of morphemes.

6 Conclusion

In this paper, we explored a new direction to employ the latent meanings of morphological compositions rather than the internal compositions themselves to train word embeddings. Three specific models named LMM-A, LMM-S and LMM-M were proposed by modifying the input layer and update rules of CBOW. The source code of LMMs is avaliable at `https://github.com/Y-Xu/lmm`.

To test the performance of our models, we chose three word-level word embedding models and implemented an Explicitly Morpheme-related Model (EMM) as comparative baselines, and tested them on two basic NLP tasks of word similarity and syntactic analogy, and one downstream text classification task. The experimental results demonstrate that our models outperform the baselines on five word similarity datasets. On the syntactic analogy as well as the text classification tasks, our models also surpass all the baselines including the EMM. In the future, we intend to evaluate our models for some morpheme-rich languages like Russian, German and so on.

Abstract

The process of translation is ambiguous, in that there are typically many valid translations for a given sentence. This gives rise to significant variation in parallel corpora, however, most current models of machine translation do not account for this variation, instead treating the problem as a deterministic process. To this end, we present a deep generative model of machine translation which incorporates a chain of latent variables, in order to account for local lexical and syntactic variation in parallel corpora. We provide an in-depth analysis of the pitfalls encountered in variational inference for training deep generative models. Experiments on several different language pairs demonstrate that the model consistently improves over strong baselines.

1 Introduction

Neural architectures have taken the field of machine translation by storm and are in the process of replacing phrase-based systems. Based on the encoder-decoder framework (Sutskever et al., 2014) increasingly complex neural systems are being developed at the moment. These systems find new ways of extracting information from the source sentence and the target sentence prefix for example by using convolutions (Gehring et al., 2017) or stacked self-attention layers (Vaswani et al., 2017). These architectural changes have led to great performance improvements over classical RNN-based neural translation systems (Bahdanau et al., 2014).

Surprisingly, there have been almost no efforts to change the probabilistic model wich is used to train the neural architectures. A notable exception is the work of Zhang et al. (2016) who introduce a sentence-level latent Gaussian variable.

In this work, we propose a more expressive latent variable model that extends the attention-based architecture of Bahdanau et al. (2014). Our model is motivated by the following observation: translations by professional translators vary across translators but also within a single translator (the same translator may produce different translations on different days, depending on his state of health, concentration etc.). Neural machine translation (NMT) models are incapable of capturing this variation, however. This is because their likelihood function incorporates the statistical assumption that there is one (and only one) output[1] for a given source sentence, i.e.,

$$P(y_1^n|x_1^m) = \prod_{i=1}^{n} P(y_i|x_1^m, y_{<i}) \ . \tag{1}$$

Our proposal is to augment this model with latent sources of variation that are able to represent more of the variation present in the training data. The noise sources are modelled as Gaussian random variables.

The contributions of this work are:

- The introduction of an NMT system that is capable of capturing word-level variation in translation data.
- A thorough discussions of issues encountered when training this model. In particular, we motivate the use of KL scaling as introduced by Bowman et al. (2016) theoretically.

[*] Code and a workflow that reproduces the experiments are available at https://github.com/philschulz/stochastic-decoder.

[†] Work done prior to joining Amazon.

[1] Notice that from a statistical perspective the output of an NMT system is a distribution over target sentences and not any particular sentence. The mapping from the output distribution to a sentence is performed by a decision rule (e.g. argmax decoding) which can be chosen independently of the NMT system.

- An empirical demonstration of the improvements achievable with the proposed model.

2 Neural Machine Translation

The NMT system upon which we base our experiments is based on the work of Bahdanau et al. (2014). The likelihood of the model is given in Equation (1). We briefly describe its architecture.

Let $x_1^m = (x_1, \ldots, x_m)$ be the source sentence and y_1^n the target sentence. Let $\text{RNN}(\cdot)$ be any function computed by a recurrent neural network (we use a bi-LSTM for the encoder and an LSTM for the decoder). We call the decoder state at the ith target position t_i; $1 \leq i \leq n$. The computation performed by the baseline system is summarised below.

$$[h_1, \ldots, h_m] = \text{RNN}(x_1^m) \tag{2a}$$

$$\tilde{t}_i = \text{RNN}(t_{i-1}, y_{i-1}) \tag{2b}$$

$$e_{ij} = v_a^\top \tanh\left(W_a[\tilde{t}_i, h_j]^\top + b_a\right) \tag{2c}$$

$$\alpha_{ij} = \frac{\exp(e_{ij})}{\sum_{j=1}^m \exp(e_{ij})} \tag{2d}$$

$$c_i = \sum_{j=1}^m \alpha_{ij} h_j \tag{2e}$$

$$t_i = W_t[\tilde{t}_i, c_i]^\top + b_t \tag{2f}$$

$$\phi_i = \text{softmax}(W_o t_i + b_o) \tag{2g}$$

The parameters $\{W_a, W_t, W_o, b_a, b_t, b_o, v_a\} \subseteq \theta$ are learned during training. The model is trained using maximum likelihood estimation. This means that we employ a cross-entropy loss whose input is the probability vector returned by the softmax.

3 Stochastic Decoder

This section introduces our stochastic decoder model for capturing word-level variation in translation data.

3.1 Motivation

Imagine an idealised translator whose translations are always perfectly accurate and fluent. If an MT system was provided with training data from such a translator, it would still encounter variation in that data. After all, there are several perfectly accurate and fluent translations for each source sentence. These can be highly different in both their lexical as well as their syntactic realisations.

In practice, of course, human translators' performance varies according to their level of education, their experience on the job, their familiarity with the textual domain and myriads of other factors. Even within a single translator variation may occur due to level of stress, tiredness or status of health. That translation corpora contain variation is acknowledged by the machine translation community in the design of their evaluation metrics which are geared towards comparing one machine-generated translation against several human translations (see e.g. Papineni et al., 2002).

Prior to our work, the only attempt at modelling the latent variation underlying these different translations was made by Zhang et al. (2016) who introduced a sentence level Gaussian variable. Intuitively, however, there is more to latent variation than a unimodal density can capture, for example, there may be several highly likely clusters of plausible variations. A cluster may e.g. consist of identical syntactic structures that differ in word choice, another may consist of different syntactic constructs such as active or passive constructions. Multimodal modelling of these variations is thus called for—and our results confirm this intuition.

An example of variation comes from free word order and agreement phenomena in morphologically rich languages. An English sentence with rigid word order may be translated into several orderings in German. However, all orderings need to respect the agreement relationship between the main verb and the subject (indicated by underlining) as well as the dative case of the direct object (dashes) and the accusative of the indirect object (dots). The agreement requirements are fixed and independent of word order.

1. I can't imagine you naked.
   (a) Ich kann mir dich nicht nackt vorstellen.
   (b) Ich kann dich mir nicht nackt vorstellen.
   (c) Dich kann ich mir nicht nackt vorstellen.

Stochastically encoding the word order variation allows the model to learn the same agreement phenomenon from different translation variants as it does not need to encode the word order and agreement relationships jointly in the decoder state.

Further examples of VP and NP variation from an actual translation corpus are shown in Figure 1.

We aim to address these word-level variation phenomena with a stochastic decoder model.

预计听证会将进行两天。	VOM19981105_0700_0262

The House of Representatives republican prosecution hopes to summon over fifteen witnesses including Monica Lewinsky to appear in court.	

Figure 1: Examples from the multiple-translation Chinese corpus (LDC2002T01), where the translations come from different translators. These demonstrate the lexical variation of the verb and variation between passive and raising structures (top), and lexical variation on the agent NP (bottom). Both examples also exhibit appreciable length variation.

3.2 Model formulation

The model contains a latent Gaussian variable for each target position. This variable depends on the previous latent states and the decoder state. Through the use of recurrent networks, the conditioning context does not need to be restricted and the likelihood factorises exactly.

$$P(y_1^n|x_1^m) = \int \mathrm{d}z_0^n \, p(z_0|x_1^m) \times \prod_{i=1}^{n} p(z_i|z_{<i}, y_{<i}, x_1^m) P(y_i|z_1^i, y_{<i}, x_1^m) \tag{3}$$

As can be seen from Equation (3), the model also contains a 0th latent variable that is meant to initialise the chain of latent variables based solely on the source sentence. Contrast this with the model of Zhang et al. (2016) which uses *only* that 0th variable.

A graphical representation of the stochastic decoder model is given in Figure 2a. Its generative story is as follows

$$Z_0|x_1^m \sim \mathcal{N}(\mu_0, \sigma_0^2) \tag{4a}$$
$$Z_i|z_{<i}, y_{<i}, x_1^m \sim \mathcal{N}(\mu_i, \sigma_i^2) \tag{4b}$$
$$Y_i|z_0^i, y_{<i}, x_1^m \sim \mathrm{Cat}(\phi_i) \tag{4c}$$

where $i = 1, \ldots, n$ and both the Gaussian and the Categorical parameters are predicted by neural network architectures whose inputs vary per time step. This probabilistic formulation can be implemented with a multitude of different architectures. We present ours in the next section.

3.3 Neural Architecture

Since the model contains latent variables and is parametrised by a neural network, it falls into the class of deep generative models (DGMs). We use a reparametrisation of the Gaussian variables (Kingma and Welling, 2014; Rezende et al., 2014; Titsias and Lázaro-Gredilla, 2014) to enable backpropagation inside a stochastic computation graph (Schulman et al., 2015). In order to sample d-dimensional Gaussian variable $z \in \mathbb{R}^d$ with mean μ and variance σ^2, we first sample from a standard Gaussian distribution and then transform the sample,

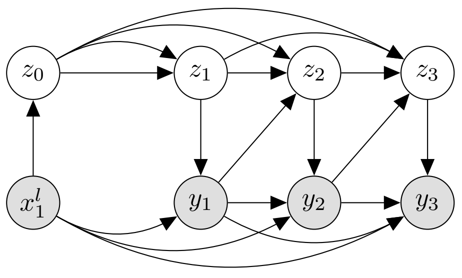
$$z = \mu + \sigma \odot \epsilon \qquad \epsilon \sim \mathcal{N}(0, \mathrm{I}) \ . \tag{5}$$

Here $\mu, \sigma \in \mathbb{R}^d$ and $\odot$ denotes element-wise multiplication (also known as Hadamard product). See the supplement for details on the Gaussian reparametrisation.

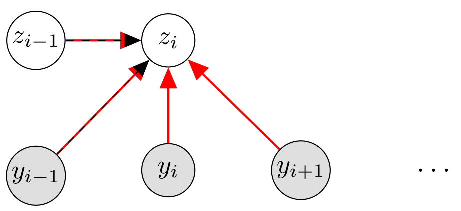
We use neural networks with one hidden layer with a tanh activation to compute the mean and standard deviation of each Gaussian distribution. A softplus transformation is applied to the output of the standard deviation's network to ensure positivity. Let us denote the functions that these networks compute by f.

For the initial latent state z_0 we compute the mean and standard deviation as

$$\mu_0 = f_{\mu_0}(h_m) \qquad \sigma_0 = f_{\sigma_0}(h_m) \ . \tag{6}$$



(a)



(b)

Figure 2: Graphical representation of 2a the generative model and 2b the inference model. Black lines indicate generative parameters (θ) and red lines variational parameters (λ). Dashed red-black lines indicate that the inference model uses feature representations computed by the generative model as inputs. Through the recurrent net, the generative model (2a) also conditions its outputs on all previous latent assignments. We omit these arrows to avoid clutter. The inference model (2b) is only used at training time. Dots indicate further conditioning context.

The parameters of all other latent distributions are computed by functions f_μ and f_σ whose inputs vary per target position.

$$\mu_i = f_\mu\left(t_{i-1}, z_{i-1}\right) \quad \sigma_i = f_\sigma\left(t_{i-1}, z_{i-1}\right) \tag{7}$$

Using these values, each latent variable is sampled according to Equation (5). The sampled latent variables are then used to modify the update of the decoder hidden state (Equation (2b)) as follows:

$$\tilde{t}_i = \text{RNN}\left(t_{i-1}, y_{i-1}, z_i\right) \tag{8}$$

The remaining computations stay unchanged. Notice that the latent values are used directly in updating the decoder state. This makes the decoder state a function of a random variable and thus the decoder state is itself random. Applying this argument recursively shows that also the attention mechanism is random, making the decoder entirely stochastic.

4 Inference and Training

We use variational inference (see e.g. Blei et al., 2017) to train the model. In variational inference, we employ a variational distribution $q(z)$ that approximates the true posterior $p(z|x)$ over the latent variables. The distribution $q(z)$ has its own set of parameters λ that is disjoint from the set of model parameters θ. It is used to maximise the evidence lower bound (ELBO) which is a lower bound on the marginal likelihood $p(x)$. The ELBO is maximised with respect to both the model parameters θ and the variational parameters λ.

Most NLP models that use DGMs only use one latent variable (e.g. Bowman et al., 2016). Models that use several variables usually employ a mean field approximation under which all latent variables are independent. This turns the ELBO into a sum of expectations (e.g. Zhou and Neubig, 2017). For our stochastic decoder we design a more flexible approximation posterior family which respects the dependencies between the latent variables,

$$q(z_0^n) = q(z_0)\prod_{i=1}^{n} q(z_i|z_{<i}) \ . \tag{9}$$

Our stochastic decoder can be viewed as a stack of conditional DGMs (Sohn et al., 2015) in which the latent variables depend on one another. The ELBO thus consists of nested positional ELBOs,

$$\begin{aligned}&\text{ELBO}_0 + \mathbb{E}_{q(z_0)}[\text{ELBO}_1 \\ &+\mathbb{E}_{q(z_1)}[\text{ELBO}_2 + \ldots]] \ ,\end{aligned} \tag{10}$$

where for a given target position i the ELBO is

$$\begin{aligned}\text{ELBO}_i = \ &\mathbb{E}_{q(z_i)}\left[\log p(y_i|x_1^m, y_{<i}, z_{<i}, z_i)\right] \\ &- \text{KL}\left(q(z_i) \mid\mid p(z_i|x_1^m, y_{<i}, z_{<i})\right) \ .\end{aligned} \tag{11}$$

The first term is often called *reconstruction* or *likelihood* term whereas the second term is called the *KL* term. Since the KL term is a function of two Gaussian distributions, and the Gaussian is an exponential family, we can compute it analytically (Michalowicz et al., 2014), without the need for sampling. This is very similar to the hierarchical latent variable model of Rezende et al. (2014).

Following common practice in DGM research, we employ a neural network to compute the variational distributions. To discriminate it from the generative model, we call this neural net the *inference model*. At training time both the source and target sentence are observed. We exploit this by endowing our inference model with a "look-ahead" mechanism. Concretely, samples from the inference network condition on the information available to the generation network (Section 3.3) and also on the target words that are yet to be processed by the generative decoder. This allows the latent distribution to not only encode information about the currently modelled word but also about the target words that follow it. The conditioning of the inference network is illustrated graphically in Figure 2b.

The inference network produces additional representations of the target sentence. One representation encodes the target sentence bidirectionally (12a), in analogy to the source sentence encoding. The second representation is built by encoding the target sentence in reverse (12b). This reverse encoding can be used to provide information about future context to the decoder. We use the symbols b and r for the bidirectional and reverse target encodings, respectively. In our experiments, we again use LSTMs to compute these encodings.

$$\left[b_1, \ldots, b_n\right] = \text{RNN}\left(y_1^n\right) \tag{12a}$$

$$\left[r_1, \ldots, r_n\right] = \text{RNN}\left(y_1^n\right) \tag{12b}$$

In analogy to the generative model (Section 3.3), the inference network uses single hidden layer networks to compute the mean and standard deviations of the latent variable distributions. We denote these functions g and again employ different functions for the initial latent state and all other latent states.

$$\mu_0 = g_{\mu_0}\left(h_m, b_n\right) \tag{13a}$$

$$\sigma_0 = g_{\sigma_0}\left(h_m, b_n\right) \tag{13b}$$

$$\mu_i = g_{\mu}\left(t_{i-1}, z_{i-1}, r_i, y_i\right) \tag{13c}$$

$$\sigma_i = g_{\sigma}\left(t_{i-1}, z_{i-1}, r_i, y_i\right) \tag{13d}$$

As before, we use Equation (5) to sample from the variational distribution.

During training, all samples are obtained from the inference network. Only at test time do we sample from the generator. Notice that since the inference network conditions on representations produced by the generator network, a naïve application of backpropagation would update parts of the generator network with gradients computed for the inference network. We prevent this by blocking gradient flow from the inference net into the generator.

4.1 Analysis of the Training Procedure

The training procedure as outlined above does not work well empirically. This is because our model uses a **strong generator**. By this we mean that the generation model (that is the baseline NMT model) is a very good density model in and by itself and does not need to rely on latent information to achieve acceptable likelihood values during training. DGMs with strong generators have a tendency to not make use of latent information (Bowman et al., 2016). This problem went initially unnoticed because early DGMs (Kingma and Welling, 2014; Rezende et al., 2014) used **weak generators**[2], i.e. models that made very strong independence assumptions and were not able to capture contextual information without making use of the information encoded by the latent variable.

Why DGMs would ignore the latent information can be understood by considering the KL-term of the ELBO. In order for the latent variable to be informative about the observed data, we need them to have high mutual information $I(Z;Y)$.

$$I(Z;Y) = \mathbb{E}_{p(z,y)}\left[\log \frac{p(Z,Y)}{p(Z)p(Y)}\right] \tag{14}$$

Observe that we can rewrite the mutual information as an expected KL divergence by applying the definition of conditional probability.

$$I(Z;Y) = \mathbb{E}_{p(y)}\left[\text{KL}\left(p(Z|Y) \;||\; p(Z)\right)\right] \tag{15}$$

Since we cannot compute the posterior $p(z|y)$ exactly, we approximate it with the variational distribution $q(z|y)$ (the joint is approximated by $q(z|y)p(y)$ where the latter factor is the data distribution). To the extent that the variational distribution recovers the true posterior, the mutual information can be computed this way. In fact, if we take the learned prior $p(z)$ to be an approximation of the marginal $\int q(z|y)p(y)\mathrm{d}y$ it can easily be shown that the thus computed KL term is an upper bound on mutual information (Alemi et al., 2017).

The trouble is that the ELBO (Equation (11)) can be trivially maximised by setting the KL-term to 0 and maximising only the reconstruction term.

[2]The term *weak generator* has first been coined by Alemi et al. (2017).

This is especially likely at the beginning of training when the variational approximation does not yet encode much useful information. We can only hope to learn a useful variational distribution if a) the variational approximation is allowed to move away from the prior and b) the resulting increase in the reconstruction term is higher than the increase in the KL-term (i.e. the ELBO increases overall).

Several schemes have been proposed to enable better learning of the variational distribution (Bowman et al., 2016; Kingma et al., 2016; Alemi et al., 2017). Here we use KL scaling and increase the scale gradually until the original objective is recovered. This has the following effect: during the initial learning stage, the KL-term barely contributes to the objective and thus the updates to the variational parameters are driven by the signal from the reconstruction term and hardly restricted by the prior.

Once the scale factor approaches 1 the variational distribution will be highly informative to the generator (assuming sufficiently slow increase of the scale factor). The KL-term can now be minimised by matching the prior to the variational distribution. Notice that up to this point, the prior has hardly been updated. Thus moving the variational approximation back to the prior would likely reduce the reconstruction term since the standard normal prior is not useful for inference purposes. This is in stark contrast to Bowman et al. (2016) whose prior was a *fixed* standard normal distribution. Although they used KL scaling, the KL term could only be decreased by moving the variational approximation back to the fixed prior. This problem disappears in our model where priors are learned.

Moving the prior towards the variational approximation has another desirable effect. The prior can now learn to emulate the variational "lookahead" mechanism without having access to future contexts itself (recall that the inference model has access to future target tokens). At test time we can thus hope to have learned latent variable distributions that encode information not only about the output at the current position but about future outputs as well.

5 Experiments

We report experiments on the IWSLT 2016 data set which contains transcriptions of TED talks and their respective translations. We trained models to translate from English into Arabic, Czech, French and German. The number of sentences for each language after preprocessing is shown in Table 1.

Data	Arabic	Czech	French	German
Train	224,125	114,389	220,399	196,883
Dev	6,746	5,326	5,937	6,996
Test	2,762	2,762	2,762	2,762

Table 1: Number of parallel sentence pairs for each language paired with English for IWSLT data.

The vocabulary was split into 50,000 subword units using Google's sentence piece[3] software in its standard settings. As our baseline NMT systems we use Sockeye (Hieber et al., 2017)[4]. Sockeye implements several different NMT models but here we use the standard recurrent attentional model described in Section 2. We report baselines with and without dropout (Srivastava et al., 2014). For dropout a retention probability of 0.5 was used.

As a second baseline we use our own implementation of the model of Zhang et al. (2016) which contains a single sentence-level Gaussian latent variable (SENT). Our implementation differs from theirs in three aspects. First, we feed the last hidden state of the bidirectional encoding into encoding of the source and target sentence into the inference network (Zhang et al. (2016) use the average of all states). Second, the latent variable is smaller in size than the one used by (Zhang et al., 2016).[5] This was done to make their model and the stochastic decoder proposed here as similar as possible. Finally, their implementation was based on groundhog whereas ours builds on Sockeye.

Our stochastic decoder model (SDEC) is also built on top of the basic Sockeye model. It adds the components described in Sections 3 and 4. Recall that the functions that compute the means and standard deviations are implemented by neural nets with a single hidden layer with tanh activation. The width of that layer is twice the size of the latent variable. In our experiments we tested different latent variable sizes and used KL scaling (see Section 4.1). The scale started from 0 and was increased by $^1/_{20,000}$ after each mini-batch. Thus, at iteration t the scale is $\min(^t/_{20,000}, 1)$.

All models use 1028 units for the LSTM hid-

[3]https://github.com/google/sentencepiece
[4]https://github.com/awslabs/sockeye
[5]We did, however, find that increasing the latent variable size actually hurt performance in our implementation.

den state (or 512 for each direction in the bidirectional LSTMs) and 256 for the attention mechansim. Training is done with Adam (Kingma and Ba, 2015). In decoding we use a beam of size 5 and output the most likely word at each position. We deterministically set all latent variables to their mean values during decoding. Monte Carlo decoding (Gal, 2016) is difficult to apply to our setting as it would require sampling entire translations.

Results We show the BLEU scores for all models that we tested on the IWSLT data set in Table 2. The stochastic decoder dominates the Sockeye baseline across all 4 languages, and outperforms SENT on most languages. Except on German, there is a trend towards smaller latent variable sizes being more helpful. This is in line with findings by Chung et al. (2015) and Fraccaro et al. (2016) who also used relatively small latent variables. This observation also implies that our model does not improve simply because it has more parameters than the baseline.

That the margin between the SDEC and SENT models is not large was to be expected for two reasons. First, Chung et al. (2015) and Fraccaro et al. (2016) have shown that stochastic RNNs lead to enormous improvements in modelling continuous sequences but only modest increases in performance for discrete sequences (such as natural language). Second, translation performance is measured in BLEU score. We observed that SDEC often reached better ELBO values than SENT indicating a better model fit. How to fully leverage the better modelling ability of stochastic RNNs when producing discrete outputs is a matter of future research.

Qualitative Analysis Finally, we would like to demonstrate that our model does indeed capture variation in translation. To this end, we randomly picked sentences from the IWSLT test set and had our model translate them several times, however, the values of the latent variables were sampled instead of fixed. Contrary to the BLEU-based evaluation, beam search was not used in this evaluation in order to avoid interaction between different latent variable samples. See Figure 3 for examples of syntactic and lexical variation. It is important to note that we do not sample from the categorical output distribution. For each target position we pick the most likely word. A non-stochastic NMT system would always yield the same translation in this scenario. Interestingly, when we applied the sampling procedure to the SENT model it did not produce any variation at all, thus behaving like a deterministic NMT system. This supports our initial point that the SENT model is likely insensitive to local variation, a problem that our model was designed to address. Like the model of Bowman et al. (2016), SENT presumably tends to ignore the latent variable.

6 Related Work

The stochastic decoder is strongly influenced by previous work on stochastic RNNs. The first such proposal was made by Bayer and Osendorfer (2015) who introduced i.i.d. Gaussian latent variables at each output position. Since their model neglects any sequential dependence of the noise sources, it underperformed on several sequence modeling tasks. Chung et al. (2015) made the latent variables depend on previous information by feeding the previous decoder state into the latent variable sampler. Their inference model did not make use of future elements in the sequence.

Using a "look-ahead" mechanism in the inference net was proposed by Fraccaro et al. (2016) who had a separate stochastic and deterministic RNN layer which both influence the output. Since the stochastic layer in their model depends on the deterministic layer but not vice versa, they could first run the deterministic layer at inference time and then condition the inference net's encoding of the future on the thus obtained features. Like us, they used KL scaling during training.

More recently, Goyal et al. (2017) proposed an auxiliary loss that has the inference net predict future feature representations. This approach yields state-of-the-art results but is still in need of a theoretical justification.

Within translation, Zhang et al. (2016) were the first to incorporate Gaussian variables into an NMT model. Their approach only uses one sentence-level latent variable (corresponding to our z_0) and can thus not deal with word-level variation directly. Concurrently to our work, Su et al. (2018) have also proposed a recurrent latent variable model for NMT. Their approach differs from ours in that they do not use a 0^{th} latent variable nor a look-ahead mechanism during inference time. Furthermore, their underlying recurrent model is a GRU.

In the wider field of NLP, deep generative mod-

Figure 3: Sampled translations from our model (SDEC) and the sentent-level latent variable model (SENT). The first SDEC example shows alternation between the German simple past and past perfect. The past perfect introduces a long range dependency between the main and auxiliary verb (underlined) that the model handles well. The second example shows variation in the lexical realisation of the verb. The second variant uses a particle verb and we again observe a long range dependency between the main verb and its particle (underlined).

els have been applied mostly in monolingual settings such as text generation (Bowman et al., 2016; Semeniuta et al., 2017), morphological analysis (Zhou and Neubig, 2017), dialogue modelling (Wen et al., 2017), question selection (Miao et al., 2016) and summarisation (Miao and Blunsom, 2016).

7 Conclusion and Future Work

We have presented a recurrent decoder for machine translation that uses word-level Gaussian variables to model underlying sources of variation observed in translation corpora. Our experiments confirm our intuition that modelling variation is crucial to the success of machine translation. The proposed model consistently outperforms strong baselines on several language pairs.

As this is the first work that systematically considers word-level variation in NMT, there are lots of research ideas to explore in the future. Here, we list the three which we believe to be most promising.

- Latent factor models: our model only contains one source of variation per word. A latent factor model such as DARN (Gregor et al., 2014) would consider several sources simultaneously. This would also allow us to perform a better analysis of the model behaviour as we could correlate the factors with observed linguistic phenomena.
- Richer prior and variational distributions: The diagonal Gaussian is likely too simple a

distribution to appropriately model the variation in our data. Richer distributions computed by normalising flows (Rezende and Mohamed, 2015; Kingma et al., 2016) will likely improve our model.
- Extension to other architectures: Introducing latent variables into non-autoregressive translation models such as the transformer (Vaswani et al., 2017) should increase their translation ability further.

Abstract

Tree-based neural machine translation (NMT) approaches, although achieved impressive performance, suffer from a major drawback: they only use the 1-best parse tree to direct the translation, which potentially introduces translation mistakes due to parsing errors. For statistical machine translation (SMT), forest-based methods have been proven to be effective for solving this problem, while for NMT this kind of approach has not been attempted. This paper proposes a forest-based NMT method that translates a linearized packed forest within a simple sequence-to-sequence framework (i.e., a forest-to-string NMT model). The BLEU score of the proposed method is higher than that of the string-to-string NMT, tree-based NMT, and forest-based SMT systems.

1 Introduction

NMT has witnessed promising improvements recently. Depending on the types of input and output, these efforts can be divided into three categories: *string-to-string* systems (Sutskever et al., 2014; Bahdanau et al., 2014); *tree-to-string* systems (Eriguchi et al., 2016, 2017); and *string-to-tree* systems (Aharoni and Goldberg, 2017; Nadejde et al., 2017). Compared with string-to-string systems, tree-to-string and string-to-tree systems (henceforth, *tree-based systems*) offer some attractive features. They can use more syntactic information (Li et al., 2017), and can conveniently incorporate prior knowledge (Zhang et al., 2017). Because of these advantages, tree-based methods become the focus of many researches of NMT nowadays.

Based on how to represent trees, there are two main categories of tree-based NMT methods: representing trees by a tree-structured neural network (Eriguchi et al., 2016; Zaremoodi and Haffari, 2017), representing trees by linearization (Vinyals et al., 2015; Dyer et al., 2016; Ma et al., 2017). Compared with the former, the latter method has a relatively simple model structure, so that a larger corpus can be used for training and the model can be trained within reasonable time, hence is preferred from the viewpoint of computation. Therefore we focus on this kind of methods in this paper.

In spite of impressive performance of tree-based NMT systems, they suffer from a major drawback: they only use the 1-best parse tree to direct the translation, which potentially introduces translation mistakes due to parsing errors (Quirk and Corston-Oliver, 2006). For SMT, forest-based methods have employed a *packed forest* to address this problem (Huang, 2008), which represents exponentially many parse trees rather than just the 1-best one (Mi et al., 2008; Mi and Huang, 2008). But for NMT, (computationally efficient) forest-based methods are still being explored.[1]

Because of the structural complexity of forests, the lack of appropriate topological ordering, and the hyperedge-attachment nature of weights (see Section 3.1 for details), it is not trivial to linearize a forest. This hinders the development of forest-based NMT to some extent.

Inspired by the tree-based NMT methods based on linearization, we propose an efficient forest-based NMT approach (Section 3), which can encode the syntactic information of a *packed for-*

[*] Contribution during internship at National Institute of Information and Communications Technology.

[1]Zaremoodi and Haffari (2017) have proposed a forest-based NMT method based on a forest-structured neural network recently, but it is computationally *in*efficient (see Section 5).

est on the basis of a novel *weighted* linearization method for a packed forest (Section 3.1), and can decode the linearized packed forest within the simple sequence-to-sequence framework (Section 3.2). Experiments demonstrate the effectiveness of our method (Section 4).

2 Preliminaries

We first review the general sequence-to-sequence model (Section 2.1), then describe tree-based NMT systems based on linearization (Section 2.2), and finally introduce the packed forest, through which exponentially many trees can be represented in a compact manner (Section 2.3).

2.1 Sequence-to-sequence model

Current NMT systems usually resort to a simple framework, i.e., the sequence-to-sequence model (Cho et al., 2014; Sutskever et al., 2014). Given a source sequence $(x_0, \ldots, x_T)$, in order to find a target sequence $(y_0, \ldots, y_{T'})$ that maximizes the conditional probability $p(y_0, \ldots, y_{T'} \mid x_0, \ldots, x_T)$, the sequence-to-sequence model uses one RNN to encode the source sequence into a fixed-length context vector c and another RNN to decode this vector and generate the target sequence. Formally, the probability of the target sequence can be calculated as follows:

$$\begin{aligned} p(y_0, \ldots, &y_{T'} \mid x_0, \ldots, x_T) \\ &= \prod_{t=0}^{T'} p(y_t \mid c, y_0, \ldots, y_{t-1}), \end{aligned} \tag{1}$$

where

$$p(y_t \mid c, y_0, \ldots, y_{t-1}) = g(y_{t-1}, s_t, c), \tag{2}$$

$$s_t = f(s_{t-1}, y_{t-1}, c), \tag{3}$$

$$c = q(h_0, \ldots, h_T), \tag{4}$$

$$h_t = f(e_t, h_{t-1}). \tag{5}$$

Here, g, f, and q are nonlinear functions; h_t and s_t are the hidden states of the source-side RNN and target-side RNN, respectively, c is the context vector, and e_t is the embedding of x_t.

Bahdanau et al. (2014) introduced an attention mechanism to deal with the issues related to long sequences (Cho et al., 2014). Instead of encoding the source sequence into a fixed vector c, the attention model uses different c_i when calculating the target-side output y_i at time step i:

$$c_i = \sum_{j=0}^{T} \alpha_{ij} h_j, \tag{6}$$

$$\alpha_{ij} = \frac{\exp(a(s_{i-1}, h_j))}{\sum_{k=0}^{T} \exp(a(s_{i-1}, h_k))}. \tag{7}$$

The function $a(s_{i-1}, h_j)$ can be regarded as the soft alignment between the target-side RNN hidden state s_{i-1} and the source-side RNN hidden state h_j.

Depending on the format of the source/target sequences, this framework can be regarded as a string-to-string NMT system (Sutskever et al., 2014), a tree-to-string NMT system (Li et al., 2017), or a string-to-tree NMT system (Aharoni and Goldberg, 2017).

2.2 Linear-structured tree-based NMT systems

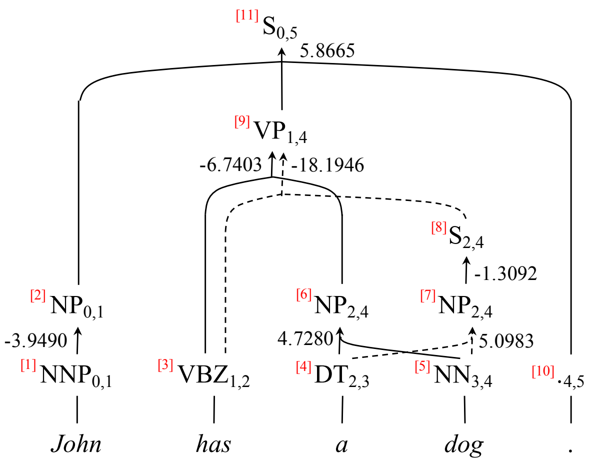
Regarding the linearization adopted for tree-to-string NMT (i.e., linearization of the source side), Sennrich and Haddow (2016) encoded the sequence of dependency labels and the sequence of words simultaneously, partially utilizing the syntax information, while Li et al. (2017) traversed the constituent tree of the source sentence and combined this with the word sequence, utilizing the syntax information completely.

Regarding the linearization used for string-to-tree NMT (i.e., linearization of the target side), Nadejde et al. (2017) used a CCG supertag sequence as the target sequence, while Aharoni and Goldberg (2017) applied a linearization method in a top-down manner, generating a sequence ensemble for the annotated tree in the Penn Treebank (Marcus et al., 1993). Wu et al. (2017) used transition actions to linearize a dependency tree, and employed the sequence-to-sequence framework for NMT.

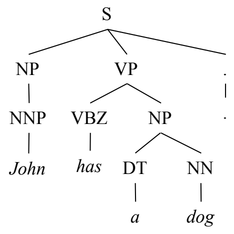
All the current tree-based NMT systems use only one tree for encoding or decoding. In contrast, we hope to utilize multiple trees (i.e., a forest). This is not trivial, on account of the lack of a fixed traversal order and the need for a compact representation.

2.3 Packed forest

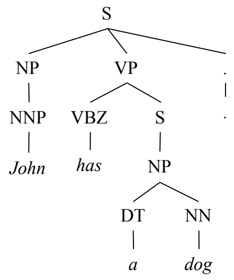
The *packed forest* gives a representation of exponentially many parse trees, and can compactly encode many more candidates than the n-best list



(a) Packed forest



(b) Correct constituent tree, $score = -46.2389$



(c) Incorrect constituent tree, $score = -58.6321$

Figure 1: An example of (a) a packed forest. The numbers in the brackets located at the upper-left corner of each node in the packed forest show one correct topological ordering of the nodes. The packed forest is a compact representation of two trees: (b) the correct constituent tree, and (c) an incorrect constituent tree. Note that the terminal nodes (i.e., words in the sentence) in the packed forest are shown only for illustration, and they do not belong to the packed forest.

(Huang, 2008). Figure 1a shows a packed forest, which can be unpacked into two constituent trees (Figure 1b and Figure 1c).

Formally, a packed forest is a pair $\langle V, E \rangle$, where V is the set of nodes and E is the set of hyperedges. Each $v \in V$ has the form $X_{i,j}$, where X is a constituent label and $i, j \in [0, n]$ are indices of words, showing that the node spans the words ranging from i (inclusive) to j (exclusive). Here, n is the length of the input sentence. Each $e \in E$ is a three-tuple $\langle head(e), tails(e), score(e) \rangle$, where $head(e) \in V$ is similar to the head node in a constituent tree, and $tails(e) \in V^*$ is similar to the set of child nodes in a constituent tree. $score(e) \in \mathbb{R}$ is the log probability that $tails(e)$ represents the tails of $head(e)$ calculated by the parser. Based on $score(e)$, the score of a constituent tree $\mathcal{T}$ can be calculated as follows:

$$score(\mathcal{T}) = -\lambda n + \sum_{e \in E(\mathcal{T})} score(e), \quad (8)$$

where $E(\mathcal{T})$ is the set of hyperedges appearing in tree $\mathcal{T}$, and λ is a regularization coefficient for the sentence length.[2]

[2]Following the configuration of Charniak and Johnson (2005), for all the experiments in this paper, we fixed λ to $\log_2 600$.

3 Forest-based NMT

We first propose a linearization method for the packed forest (Section 3.1), then describe how to encode the linearized forest (Section 3.2), which can then be translated by the conventional decoder (see Section 2.1).

3.1 Forest linearization

Recently, several studies have focused on the linearization methods of a syntax tree, both in the area of tree-based NMT (Section 2.2) and parsing (Vinyals et al., 2015; Dyer et al., 2016; Ma et al., 2017). Basically, these methods follow a fixed traversal order (e.g., depth-first). This does not exist for the packed forest which is a directed acyclic graph (DAG). Furthermore, the weights are attached to edges of a packed forest instead of the nodes. This further increases the difficulty of linearization.

Topological ordering algorithms for DAG (Kahn, 1962; Tarjan, 1976) are not good solutions, because the topological ordering outputted by algorithms is not always optimal for machine trans-

Figure 2: Linearization result of the packed forest in Figure 1a.

lation. In particular, a topological ordering could ignore "word sequential information" and "parent-child information."

For example, for the packed forest in Figure 1a, although "[10]→[1]→[2]→ ··· →[9]→[11]" is a valid topological ordering, the *word sequential information* of the words (e.g., "John" should be located ahead of the period), which is fairly crucial for translation of languages with fixed pragmatic word order such as Chinese or English, is lost.

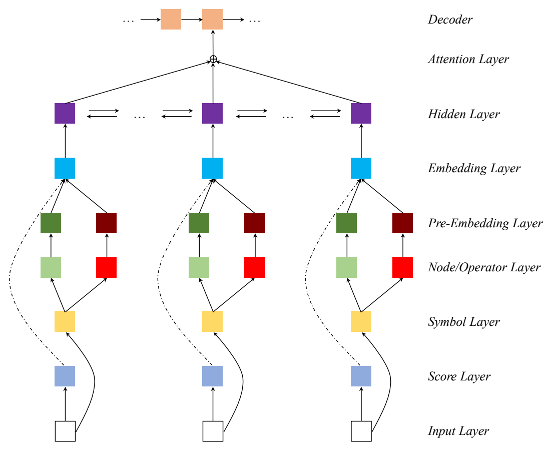
As another example, for the packed forest above, nodes [2], [9], and [10] are all the children of node [11]. However, in the topological order "[1]→[2]→ ··· →[9]→[10]→[11]," node [2] is quite far from node [11], while nodes [9] and [10] are both close to node [11]. The *parent-child information* cannot be reflected in this topological order, which is not what we would expect.

To address the above two problems, we propose a novel linearization algorithm for a packed forest (Algorithm 1). The algorithm linearizes the packed forest from the root node (Line 2) to leaf nodes by calling the EXPANDSEQ procedure (Line 15) recursively, while preserving the word order in the sentence (Line 14). In this way, *word sequential information* is preserved. Within the EXPANDSEQ procedure, once a hyperedge is linearized (Line 16), the tails are also linearized immediately (Line 18). In this way, *parent-child information* is preserved. Intuitively, different parts of constituent trees should be combined in different ways, therefore we define different operators (ⓒ, ⊗, ⊕, or ⊙) to represent the relationships, so that the representations of these parts can be combined in different ways (see Section 3.2 for details). Words are concatenated by the operator "⊙" with each other, a word and a constituent label is concatenated by the operator "⊗", the linearization results of child nodes are concatenated by the operator "⊕" with each other, while the unary operator "ⓒ" is used to indicate that the node is the child node of the previous part. Furthermore, each token in the linearized sequence is related to a score, representing the confidence of the parser.

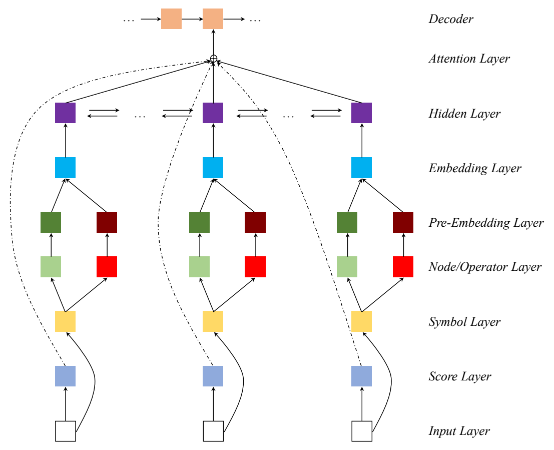
The linearization result of the packed forest in Figure 1a is shown in Figure 2. Tokens in the linearized sequence are separated by slashes. Each token in the sequence is composed of different types of symbols and combined by different operators. We can see that word sequential information is preserved. For example, "NNP⊗*John*" (linearization result of node [1]) is in front of "VBZ⊗*has*" (linearization result of node [3]), which is in front of "DT⊗*a*" (linearization result of node [4]). Moreover, parent-child information is also preserved. For example, "NP⊗*John*" (linearization result of node [2]) is followed by "ⓒNNP⊗*John*" (linearization result of node [1], the child of node [2]).

Note that our linearization method does *not* output fully recoverable packed forests. What we *do* want to do is to encode syntax information as much as possible, so that we can improve the performance of NMT.

Also note that there is one more advantage of our linearization method: the linearized sequence is a weighted sequence, while all the previous studies ignored the weights during linearization.



(a) Score-on-Embedding (SoE)



(b) Score-on-Attention (SoA)

Figure 3: The architecture of the forest-based NMT system.

By preserving only the nodes and hyperedges in the 1-best tree and removing all others, our linearization method can be regarded as a tree-linearization method. Compared with other tree-linearization methods, our method combines several different kinds of information within one symbol, retaining the parent-child information, and incorporating the confidence of the parser in the sequence. We examine whether the weights can be useful not only for linear structured tree-based NMT but also for our forest-based NMT in Section 4.

Furthermore, although our method is non-reversible for packed forests, it is reversible for constituent trees, in that the linearization is processed exactly in the depth-first traversal order and all necessary information in the tree nodes has been encoded. As far as we know, there is no previous work on linearization of packed forests.

3.2 Encoding the linearized forest

The linearized packed forest forms the input of the encoder, which has two major differences from the input of a sequence-to-sequence NMT system. First, the input sequence of the encoder consists of two parts: the symbol sequence and the score sequence. Second, the symbol sequence consists of three types of symbols: words, constituent labels, and operators (Ⓒ, $\otimes$, $\oplus$, or $\odot$) that connect the other two types of symbols. Based on these characteristics, we propose a method of encoding the linearized forest.

Formally, the input layer receives two sequences: the symbol sequence $\mathbf{l} = (l_0, \dots, l_T)$ and the score sequence $\xi = (\xi_0, \dots, \xi_T)$, where l_i denotes the i-th symbol and ξ_i its score. Then, the two sequences are fed into the symbol layer and the score layer, respectively. Any item $l \in \mathbf{l}$ in the symbol layer has the form

$$l = o_0 x_1 o_1 \dots x_{m-1} o_{m-1} x_m, \tag{9}$$

where each x_k $(k = 1, \dots, m)$ is a word or a constituent label, m is the total number of words and constituent labels in a symbol, o_0 is "Ⓒ" or empty, and each o_k $(k = 1, \dots, m-1)$ is either "$\otimes$", "$\oplus$", or "$\odot$". Then, in the node/operator layer, these x and o are separated and rearranged as $\mathbf{x} = (x_1, \dots, x_m, o_0, \dots, o_{m-1})$, which is fed to the pre-embedding layer. The pre-embedding layer generates a sequence $\mathbf{p} = (p_1, \dots, p_m, \dots, p_{2m})$, which is calculated as follows:

$$\mathbf{p} = W_{emb}[I(\mathbf{x})]. \tag{10}$$

Here, the function $I(\mathbf{x})$ returns a list of the indices in the dictionary for all the elements in $\mathbf{x}$, including words, constituent labels, and operators. In addition, W_{emb} is the embedding matrix of size $(|w_{word}| + |w_{label}| + 4) \times d_{word}$, where $|w_{word}|$ and $|w_{label}|$ are the vocabulary size of words and constituent labels, respectively, d_{word} is the dimension of the word embedding, and there are four possible operators: "Ⓒ," "$\otimes$," "$\oplus$," and "$\odot$." Note that $\mathbf{p}$ is a list of $2m$ vectors, and the dimension of each vector is d_{word}. Hereafter, $\mathbf{p}$ for the k-th symbol l_k is denoted by $\mathbf{p}_k$.

Depending on where the score layer is incorporated, we propose two frameworks: Score-on-Embedding (SoE) and Score-on-Attention (SoA), which are illustrated in Figure 3. In SoE, the k-th element of the embedding layer is calculated as follows:

$$e_k = \xi_k \sum_{p \in \mathbf{p}_k} p, \tag{11}$$

while in SoA, the k-th element of the embedding layer is calculated as

$$e_k = \sum_{p \in \mathbf{p}_k} p, \tag{12}$$

where $k = 0, \ldots, T$. Note that $e_k \in \mathbb{R}^{d_{word}}$. In this manner, the proposed forest-to-string NMT framework is connected with the conventional sequence-to-sequence NMT framework.

After calculating the embedding vectors in the embedding layer, the hidden vectors are calculated using Equation (5). When calculating the context vector c_i, SoE and SoA differ from each other. For SoE, the c_i is calculated using Equations (6) and (7), while for SoA, the α_{ij} used to calculate the c_i is determined as follows:

$$\alpha_{ij} = \frac{\exp(\xi_j a(s_{i-1}, h_j))}{\sum_{k=0}^{T} \exp(\xi_k a(s_{i-1}, h_k))}. \tag{13}$$

Then, using the decoder of the sequence-to-sequence framework, the sentence of the target language can be generated.

4 Experiments

4.1 Setup

We evaluated the effectiveness of our forest-based NMT systems on English-to-Chinese and English-to-Japanese translation tasks.[3] The statistics of the corpora used in our experiments are summarized in Table 1.

The packed forests of English sentences were obtained by the constituent parser proposed by Huang (2008).[4] We filtered out the sentences for which the parser was not able to generate any packed forests and those longer than 80 words. For NIST datasets, we simply chose the first reference among the four English references of NIST corpora. For Chinese sentences, we used Stanford segmenter[5] for segmentation. For Japanese sentences, we followed the preprocessing steps recommended in WAT 2017.[6]

Language	Corpus	Usage	#Sent.
English-Japanese	ASPEC	train	100,000
		dev.	1790
		test	1812
English-Chinese	LDC[7]	train	1,423,695
	FBIS		233,510
	NIST MT 02	dev.	876
	NIST MT 03	test	919
	NIST MT 04		1,788
	NIST MT 05		1,082

Table 1: Statistics of the corpora.

We implemented our framework based on `nematus`[8] (Sennrich et al., 2017). For optimization, following previous research such as (Bahdanau et al., 2014), we used the ADADELTA algorithm (Zeiler, 2012). In order to avoid overfitting, we used dropout (Srivastava et al., 2014) on the embedding layer and hidden layer, with the dropout probability set to 0.2. We used the gated recurrent unit (Cho et al., 2014) as the recurrent unit of RNNs, which are bi-directional, with one hidden layer.

Based on the tuning result, we set the maximum length of the input sequence to 300, the hidden layer size as 512, the dimension of word embedding as 620, and the batch size for training as 40. We pruned the packed forest using the algorithm of Huang (2008), removing all hyperedges e which satisfy $\delta(e) > 10^{-5}$, where $\delta(e)$ is the difference between the cost of hyperedge e and that of the globally best derivation. If the linearization of the pruned forest is still longer than 300, then we linearize the 1-best parsing tree instead of the forest. As for the stopping criterion of training process, we evaluated the BLEU score on the development set every 10,000 updates. If BLEU score was not increased in ten consecutive evaluations, then training was stopped. During decoding, we performed beam search with the beam size of 12.

[3]English is commonly chosen as the *target* language. We chose English as the *source* language because a high-performance forest parser is not available for other languages.

4.2 Experimental results

Tables 2 and 3 summarize the experimental results. To avoid the effect of segmentation errors, the performance was evaluated by character-level BLEU (Papineni et al., 2002). We compared our proposed models (i.e., Forest (SoE) and Forest (SoA)) with three types of baseline: a string-to-string model (s2s), forest-based models that do not use score sequences (Forest (No score)), and tree-based models that use the 1-best parsing tree (1-best (No score, SoE, SoA)). For the 1-best models, we preserved the nodes and hyperedges that were used in the 1-best constituent tree in the packed forest, while removing all other nodes and hyperedges. For the "No score" configurations, we forced the input score sequence to be a sequence of 1.0 with the same length as the input symbol sequence, so that neither the embedding layer nor the attention layer were affected by the score sequence.

In addition, we also made a comparison with some state-of-the-art tree-based systems. As the SMT system, we examined Mi et al. (2008). Specifically, we used the implementation of `cicada`.[9] For NMT systems, we compared with three systems: Eriguchi et al. (2016)[10] and Chen et al. (2017),[11] both are publicly available, and we reimplemented the "Mixed RNN Encoder" model of Li et al. (2017), because of its outstanding performance on the NIST MT corpus.

We can see that for both English-Chinese and English-Japanese, compared with the s2s baseline system, both the 1-best and forest-based configurations yield better results. This indicates syntactic information contained in the constituent trees or forests is indeed useful for machine translation. Specifically, we observed the following facts.

First, among the three different frameworks, i.e., SoE, SoA, and No-score, the SoA framework performed the best, while the No-score framework

Figure 4: Chinese translation results of an English sentence.

performed the worst. This indicates that the scores of the edges in constituent trees or packed forests, which reflect the confidence of the correctness of the edges, are indeed useful. In fact, for the 1-best constituent parsing tree, the score of the edge reflects the confidence of the parser. With this information, the NMT system succeeded to learn a better attention, paying more attention to the confident structure and less attention to the unconfident structure, which improved the translation performance. This fact was ignored by previous studies on tree-based NMT. Furthermore, it is better to use the scores to adjust the values of attention instead of rescaling the word embeddings, because modifying word embeddings may alter the semantic meanings of words.

Second, compared with the cases that only use the 1-best constituent trees, with some exceptions, using packed forests yielded statistical significantly better results for the SoE and SoA frameworks. This shows the effectiveness of using more syntactic information. Compared with one constituent tree, the packed forest, which contains multiple different trees, describes the syntactic structure of the sentence in different aspects, which together increase the accuracy of machine translation. However, without using the scores, the 1-best constituent tree is preferred. This is because without using the scores, all trees in the packed forest are treated equally, which makes it easy to import noise into the encoder.

Compared with other types of state-of-the-art systems, our systems using only the 1-best tree (1-best (SoE, SoA)) were better than the other tree-based systems. Moreover, our NMT systems using the packed forests achieved the best performance. These results also support the usefulness of the scores of the edges and packed forests in NMT.

As for the efficiency, the training time of the SoA system was slightly longer than that of the SoE system, which was about twice of the s2s baseline. The training time of the tree-based system was about 1.5 times of the baseline. For the case of Forest (SoA), with 1 core of Tesla P100 GPU and LDC corpus as the training data, training spent about 10 days, and decoding speed was about 10 sentences per second. The reason for the relatively low efficiency is that the linearized sequences of packed forests were much longer than word sequences, enlarging the scale of the inputs. Despite this, the training process ended within reasonable time.

4.3 Qualitative analysis

Figure 4 shows the translation results of an English sentence using several different configurations: the s2s baseline, using only the 1-best tree (SoE), and using the packed forest (SoE). This is a sentence from NIST MT 03, and the training corpus is the LDC corpus.

For the s2s case, no syntactic information was utilized, and therefore the output of the system was not a grammatical Chinese sentence. The attributive phrase of "Czech border region" (i.e., "last summer ... floods") is a complete sentence. However, this is not grammatically allowed in Chinese.

For the case of using 1-best constituent tree, the output was a grammatical Chinese sentence. However, the phrase "adjacent to neighboring Slovakia" was completely ignored in the translation result. Analysis of the constituent tree revealed that this phrase was incorrectly parsed as an "adverb phrase," and consequently the NMT system paid a little attention to it, because of the low confidence given by the parser.

In contrast, the packed forest did not ignore this phrase and translated it correctly. Actually, besides "adverb phrase," this phrase was also correctly parsed as an "adjective phrase," and covered by multiple different nodes in the forest. Because of the wide coverage, it is difficult for the encoder to ignore the phrase.

We also noticed that our method performed better on learning attention. For example, in Figure 4, we observed that for s2s model, the decoder paid attention to the word "Czech" twice, which caused the output sentence containing the corresponding Chinese translation twice. On the other hand, for our forest model, by using the syntax information, the decoder paid an attention to the phrase "In the Czech Republic" only once; therefore the decoder generated the correct output.

5 Related work

Incorporating syntactic information into NMT systems is attracting widespread attention nowadays. Compared with conventional string-to-string NMT systems, tree-based systems demonstrate a better performance with the help of constituent trees or dependency trees.

The first noteworthy study was Eriguchi et al. (2016), which used Tree-structured LSTM (Tai et al., 2015) to encode the HPSG syntax tree of the sentence in the source-side in a bottom-up manner. Then, Chen et al. (2017) enhanced the encoder with a top-down tree encoder.

As a simple extension of Eriguchi et al. (2016), very recently, Zaremoodi and Haffari (2017) proposed a forest-based NMT method by representing the packed forest with a forest-structured neural network. However, their method was evaluated in small-scale MT settings (each training dataset consists of under 10k parallel sentences). In contrast, our proposed method is effective in a large-scale MT setting, and we present qualitative analysis regarding the effectiveness of using forests in NMT.

Although these methods obtained good results, the tree-structured network used by the encoder made the training and decoding relatively slow, restricting the scope of application.

Other attempts at encoding syntactic trees have also been proposed. Eriguchi et al. (2017) combined the Recurrent Neural Network Grammar (Dyer et al., 2016) with NMT systems, while Li et al. (2017) linearized the constituent tree and encoded it using RNNs. The training of these methods is fast, because of the linear structures of RNNs. However, all these syntax-based NMT systems used only the 1-best parsing tree, making the systems sensitive to parsing errors.

Instead of using trees to represent syntactic information, some studies used other data structures to represent the latent syntax of the input sentence. For example, Hashimoto and Tsuruoka (2017) proposed translating using a latent graph. However, such systems do not enjoy the benefit of handcrafted syntactic knowledge, because they do not use a parser trained from a large treebank with human annotations.

Compared with these related studies, our framework utilizes a linearized packed forest, meaning the encoder can encode exponentially many trees in an efficient manner. The experimental results demonstrated these advantages.

6 Conclusion and future work

We proposed a new encoding method for NMT, which encodes a packed forest for the source sentence using linear-structured neural networks, such as RNN. When introducing packed forest, we confirmed that the score of each edge is indispensable. Compared with conventional string-to-string NMT systems and tree-to-string NMT systems, our framework can utilize exponentially many linearized parsing trees during encoding, without significantly decreasing the efficiency. This represents the first attempt to use a forest within the string-to-string NMT framework. The experimental results demonstrate the effectiveness of our method.

As future work, we plan to design some more elaborate structures to incorporate the score layer into the encoder. We will also apply the proposed linearization method to other tasks.

Abstract

Standard machine translation systems process sentences in isolation and hence ignore extra-sentential information, even though extended context can both prevent mistakes in ambiguous cases and improve translation coherence. We introduce a context-aware neural machine translation model designed in such way that the flow of information from the extended context to the translation model can be controlled and analyzed. We experiment with an English-Russian subtitles dataset, and observe that much of what is captured by our model deals with improving pronoun translation. We measure correspondences between induced attention distributions and coreference relations and observe that the model implicitly captures anaphora. It is consistent with gains for sentences where pronouns need to be gendered in translation. Beside improvements in anaphoric cases, the model also improves in overall BLEU, both over its context-agnostic version (+0.7) and over simple concatenation of the context and source sentences (+0.6).

1 Introduction

It has long been argued that handling discourse phenomena is important in translation (Mitkov, 1999; Hardmeier, 2012). Using extended context, beyond the single source sentence, should in principle be beneficial in ambiguous cases and also ensure that generated translations are coherent. Nevertheless, machine translation systems typically ignore discourse phenomena and translate sentences in isolation.

Earlier research on this topic focused on handling specific phenomena, such as translating pronouns (Le Nagard and Koehn, 2010; Hardmeier and Federico, 2010; Hardmeier et al., 2015), discourse connectives (Meyer et al., 2012), verb tense (Gong et al., 2012), increasing lexical consistency (Carpuat, 2009; Tiedemann, 2010; Gong et al., 2011), or topic adaptation (Su et al., 2012; Hasler et al., 2014), with special-purpose features engineered to model these phenomena. However, with traditional statistical machine translation being largely supplanted with neural machine translation (NMT) models trained in an end-to-end fashion, an alternative is to directly provide additional context to an NMT system at training time and hope that it will succeed in inducing relevant predictive features (Jean et al., 2017; Wang et al., 2017; Tiedemann and Scherrer, 2017; Bawden et al., 2018).

While the latter approach, using context-aware NMT models, has demonstrated to yield performance improvements, it is still not clear what kinds of discourse phenomena are successfully handled by the NMT systems and, importantly, how they are modeled. Understanding this would inform development of future discourse-aware NMT models, as it will suggest what kind of inductive biases need to be encoded in the architecture or which linguistic features need to be exploited.

In our work we aim to enhance our understanding of the modelling of selected discourse phenomena in NMT. To this end, we construct a simple discourse-aware model, demonstrate that it achieves improvements over the discourse-agnostic baseline on an English-Russian subtitles dataset (Lison et al., 2018) and study which context information is being captured in the model. Specifically, we start with the Transformer (Vaswani et al., 2017), a state-of-the-art model for context-agnostic NMT, and modify it in such way that it can handle additional context. In our model, a source sentence and a context sentence are first encoded independently, and then a single attention layer, in a combination with a gating function, is used to produce a context-aware representation of the source sentence. The information from context can only flow through this attention layer. When compared to simply concatenating input sentences, as proposed by Tiedemann and Scherrer (2017), our architecture appears both more accurate (+0.6 BLEU) and also guarantees that the contextual information cannot bypass the attention layer and hence remain undetected in our analysis.

We analyze what types of contextual information are exploited by the translation model. While studying the attention weights, we observe that much of the information captured by the model has to do with pronoun translation. It is not entirely surprising, as we consider translation from a language without grammatical gender (English) to a language with grammatical gender (Russian). For Russian, translated pronouns need to agree in gender with their antecedents. Moreover, since in Russian verbs agree with subjects in gender and adjectives also agree in gender with pronouns in certain frequent constructions, mistakes in translating pronouns have a major effect on the words in the produced sentences. Consequently, the standard cross-entropy training objective sufficiently rewards the model for improving pronoun translation and extracting relevant information from the context.

We use automatic co-reference systems and human annotation to isolate anaphoric cases. We observe even more substantial improvements in performance on these subsets. By comparing attention distributions induced by our model against co-reference links, we conclude that the model implicitly captures coreference phenomena, even without having any kind of specialized features which could help it in this subtask. These observations also suggest potential directions for future work. For example, effective co-reference systems go beyond relying simply on embeddings of contexts. One option would be to integrate 'global' features summarizing properties of groups of mentions predicted as linked in a document (Wiseman et al., 2016), or to use latent relations to trace entities across documents (Ji et al., 2017). Our key contributions can be summarized as follows:

- we introduce a context-aware neural model, which is effective and has a sufficiently simple and interpretable interface between the context and the rest of the translation model;
- we analyze the flow of information from the context and identify pronoun translation as the key phenomenon captured by the model;
- by comparing to automatically predicted or human-annotated coreference relations, we observe that the model implicitly captures anaphora.

2 Neural Machine Translation

Given a source sentence $\mathbf{x} = (x_1, x_2, \dots, x_S)$ and a target sentence $\mathbf{y} = (y_1, y_2, \dots, y_T)$, NMT models predict words in the target sentence, word by word.

Current NMT models mainly have an encoder-decoder structure. The encoder maps an input sequence of symbol representations $\mathbf{x}$ to a sequence of distributed representations $\mathbf{z} = (z_1, z_2, \dots, z_S)$. Given $\mathbf{z}$, a neural decoder generates the corresponding target sequence of symbols $\mathbf{y}$ one element at a time.

Attention-based NMT The encoder-decoder framework with attention has been proposed by Bahdanau et al. (2015) and has become the defacto standard in NMT. The model consists of encoder and decoder recurrent networks and an attention mechanism. The attention mechanism selectively focuses on parts of the source sentence during translation, and the attention weights specify the proportions with which information from different positions is combined.

Transformer Vaswani et al. (2017) proposed an architecture that avoids recurrence completely. The Transformer follows an encoder-decoder architecture using stacked self-attention and fully connected layers for both the encoder and decoder. An important advantage of the Transformer is that it is more parallelizable and faster to train than recurrent encoder-decoder models.

From the source tokens, learned embeddings are generated and then modified using positional encodings. The encoded word embeddings are then used as input to the encoder which consists of N

layers each containing two sub-layers: (a) a multi-head attention mechanism, and (b) a feed-forward network.

The self-attention mechanism first computes attention weights: i.e., for each word, it computes a distribution over all words (including itself). This distribution is then used to compute a new representation of that word: this new representation is set to an expectation (under the attention distribution specific to the word) of word representations from the layer below. In multi-head attention, this process is repeated h times with different representations and the result is concatenated.

The second component of each layer of the Transformer network is a feed-forward network. The authors propose using a two-layered network with the ReLU activations.

Analogously, each layer of the decoder contains the two sub-layers mentioned above as well as an additional multi-head attention sub-layer that receives input from the corresponding encoding layer.

In the decoder, the attention is masked to prevent future positions from being attended to, or in other words, to prevent illegal leftward information flow. See Vaswani et al. (2017) for additional details.

The proposed architecture reportedly improves over the previous best results on the WMT 2014 English-to-German and English-to-French translation tasks, and we verified its strong performance on our data set in preliminary experiments. Thus, we consider it a strong state-of-the-art baseline for our experiments. Moreover, as the Transformer is attractive in practical NMT applications because of its parallelizability and training efficiency, integrating extra-sentential information in Transformer is important from the engineering perspective. As we will see in Section 4, previous techniques developed for recurrent encoder-decoders do not appear effective for the Transformer.

3 Context-aware model architecture

Our model is based on Transformer architecture (Vaswani et al., 2017). We leave Transformer's decoder intact while incorporating context information on the encoder side (Figure 1).

Source encoder: The encoder is composed of a stack of N layers. The first $N-1$ layers are identical and represent the original layers of Transformer's encoder. The last layer incorporates contextual information as shown in Figure 1. In addition to multi-head self-attention it has a block which performs multi-head attention over the output of the context encoder stack. The outputs of the two attention mechanisms are combined via a gated sum. More precisely, let $c_i^{(s-attn)}$ be the output of the multi-head self-attention, $c_i^{(c-attn)}$ the output of the multi-head attention to context, c_i their gated sum, and σ the logistic sigmoid function, then

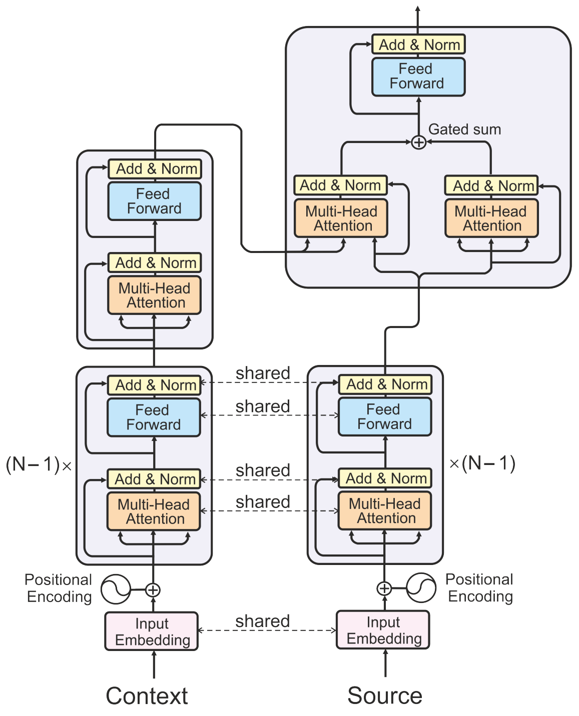

Figure 1: Encoder of the discourse-aware model

$$g_i = \sigma\left(W_g\left[c_i^{(s-attn)}, c_i^{(c-attn)}\right] + b_g\right) \quad (1)$$

$$c_i = g_i \odot c_i^{(s-attn)} + (1 - g_i) \odot c_i^{(c-attn)} \quad (2)$$

Context encoder: The context encoder is composed of a stack of N identical layers and replicates the original Transformer encoder. In contrast to related work (Jean et al., 2017; Wang et al., 2017), we found in preliminary experiments that using separate encoders does not yield an accurate model. Instead we share the parameters of the first $N-1$ layers with the source encoder.

Since major proportion of the context encoder's parameters are shared with the source encoder, we add a special token (let us denote it `<bos>`) to the beginning of context sentences, but not source sentences, to let the shared layers know whether it is encoding a source or a context sentence.

4 Experiments

4.1 Data and setting

We use the publicly available OpenSubtitles2018 corpus (Lison et al., 2018) for English and Russian.[1] As described in the appendix, we apply data cleaning and randomly choose 2 million training instances from the resulting data. For development and testing, we randomly select two subsets of 10000 instances from movies not encountered in training.[2] Sentences were encoded using byte-pair encoding (Sennrich et al., 2016), with source and target vocabularies of about 32000 tokens. We generally used the same parameters and optimizer as in the original Transformer (Vaswani et al., 2017). The hyperparameters, preprocessing and training details are provided in the supplementary material.

5 Results and analysis

We start by experiments motivating the setting and verifying that the improvements are indeed genuine, i.e. they come from inducing predictive features of the context. In subsequent section 5.2, we analyze the features induced by the context encoder and perform error analysis.

5.1 Overall performance

We use the traditional automatic metric BLEU on a general test set to get an estimate of the overall performance of the discourse-aware model, before turning to more targeted evaluation in the next section. We provide results in Table 1.[3] The 'baseline' is the discourse-agnostic version of the Transformer. As another baseline we use the standard Transformer applied to the concatenation of the previous and source sentences, as proposed by Tiedemann and Scherrer (2017). Tiedemann and Scherrer (2017) only used a special symbol to mark where the context sentence ends and the source sentence begins. This technique performed badly with the non-recurrent Transformer architecture in preliminary experiments, resulting in a substantial degradation of performance (over 1 BLEU). Instead, we use a binary flag at every word position in our concatenation baseline telling the encoder whether the word belongs to the context sentence or to the source sentence.

model	**BLEU**
baseline	29.46
concatenation (previous sentence)	29.53
context encoder (previous sentence)	**30.14**
context encoder (next sentence)	29.31
context encoder (random context)	29.69

Table 1: Automatic evaluation: BLEU. Significant differences at $p < 0.01$ are in bold.

We consider two versions of our discourse-aware model: one using the previous sentence as the context, another one relying on the next sentence. We hypothesize that both the previous and the next sentence provide a similar amount of additional clues about the topic of the text, whereas for discourse phenomena such as anaphora, discourse relations and elliptical structures, the previous sentence is more important.

First, we observe that our best model is the one using a context encoder for the previous sentence: it achieves 0.7 BLEU improvement over the discourse-agnostic model. We also notice that, unlike the previous sentence, the next sentence does not appear beneficial. This is a first indicator that discourse phenomena are the main reason for the observed improvement, rather than topic effects. Consequently, we focus solely on using the previous sentence in all subsequent experiments.

Second, we observe that the concatenation baseline appears less accurate than the introduced context-aware model. This result suggests that our model is not only more amendable to analysis but also potentially more effective than using concatenation.

In order to verify that our improvements are genuine, we also evaluate our model (trained with the previous sentence as context) on the same test set with shuffled context sentences. It can be seen that the performance drops significantly when a real context sentence is replaced with a random one. This confirms that the model does rely on context information to achieve the improvement in translation quality, and is not merely better regularized. However, the model is robust towards being shown a random context and obtains a performance similar to the context-agnostic baseline.

[2] The resulting data sets are freely available at http://data.statmt.org/acl18_contextnmt_data/
[3] We use bootstrap resampling (Riezler and Maxwell, 2005) for significance testing

5.2 Analysis

In this section we investigate what types of contextual information are exploited by the model. We study the distribution of attention to context and perform analysis on specific subsets of the test data. Specifically the research questions we seek to answer are as follows:

- For the translation of which words does the model rely on contextual history most?
- Are there any non-lexical patterns affecting attention to context, such as sentence length and word position?
- Can the context-aware NMT system implicitly learn coreference phenomena without any feature engineering?

Since all the attentions in our model are multi-head, by *attention weights* we refer to an average over heads of per-head attention weights.

First, we would like to identify a *useful* attention mass coming to context. We analyze the attention maps between source and context, and find that the model mostly attends to `<bos>` and `<eos>` context tokens, and much less often attends to words. Our hypothesis is that the model has found a way to take no information from context by looking at uninformative tokens, and it attends to words only when it wants to pass some contextual information to the source sentence encoder. Thus we define *useful* contextual attention mass as sum of attention weights to context words, excluding `<bos>` and `<eos>` tokens and punctuation.

5.2.1 Top words depending on context

We analyze the distribution of attention to context for individual source words to see for which words the model depends most on contextual history. We compute the overall average attention to context words for each source word in our test set. We do the same for source words at positions higher than first. We filter out words that occurred less than 10 times in a test set. The top 10 words with the highest average attention to context words are provided in Table 2.

An interesting finding is that contextual attention is high for the translation of "it", "yours", "ones", "you" and "I", which are indeed very ambiguous out-of-context when translating into Russian. For example, "it" will be translated as third person singular masculine, feminine or neuter, or third person plural depending on its antecedent.

word	attn	pos	word	attn	pos
it	0.376	5.5	it	0.342	6.8
yours	0.338	8.4	yours	0.341	8.3
yes	0.332	2.5	ones	0.318	7.5
i	0.328	3.3	'm	0.301	4.8
yeah	0.314	1.4	you	0.287	5.6
you	0.311	4.8	am	0.274	4.4
ones	0.309	8.3	i	0.262	5.2
'm	0.298	5.1	's	0.260	5.6
wait	0.281	3.8	one	0.259	6.5
well	0.273	2.1	won	0.258	4.6

Table 2: Top-10 words with the highest average attention to context words. *attn* gives an average attention to context words, *pos* gives an average position of the source word. Left part is for words on all positions, right — for words on positions higher than first.

"You" can be second person singular impolite or polite, or plural. Also, verbs must agree in gender and number with the translation of "you".

It might be not obvious why "I" has high contextual attention, as it is not ambiguous itself. However, in past tense, verbs must agree with "I" in gender, so to translate past tense sentences properly, the source encoder must predict speaker gender, and the context may provide useful indicators.

Most surprising is the appearance of "yes", "yeah", and "well" in the list of context-dependent words, similar to the finding by Tiedemann and Scherrer (2017). We note that these words mostly appear in sentence-initial position, and in relatively short sentences. If only words after the first are considered, they disappear from the top-10 list. We hypothesize that the amount of attention to context not only depends on the words themselves, but also on factors such as sentence length and position, and we test this hypothesis in the next section.

5.2.2 Dependence on sentence length and position

We compute useful attention mass coming to context by averaging over source words. Figure 2 illustrates the dependence of this average attention mass on sentence length. We observe a disproportionally high attention on context for short sentences, and a positive correlation between the average contextual attention and context length.

It is also interesting to see the importance given to the context at different positions in the source

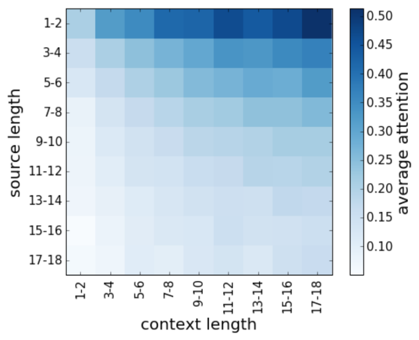

Figure 2: Average attention to context words vs. both source and context length

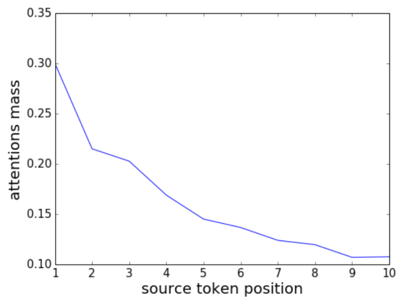

Figure 3: Average attention to context vs. source token position

sentence. We compute an average attention mass to context for a set of 1500 sentences of the same length. As can be seen in Figure 3, words at the beginning of a source sentence tend to attend to context more than words at the end of a sentence. This correlates with standard view that English sentences present hearer-old material before hearer-new.

There is a clear (negative) correlation between sentence length and the amount of attention placed on contextual history, and between token position and the amount of attention to context, which suggests that context is especially helpful at the beginning of a sentence, and for shorter sentences. However, Figure 4 shows that there is no straightforward dependence of BLEU improvement on source length. This means that while attention on context is disproportionally high for short sentences, context does not seem disproportionally more useful for these sentences.

5.3 Analysis of pronoun translation

The analysis of the attention model indicates that the model attends heavily to the contextual history for the translation of some pronouns. Here, we investigate whether this context-aware modelling results in empirical improvements in translation

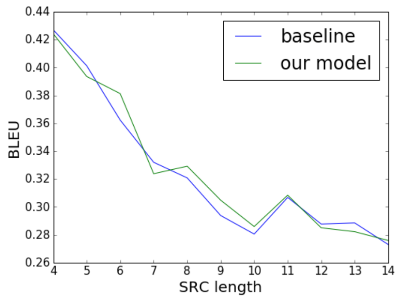

Figure 4: BLEU score vs. source sentence length

quality, and whether the model learns structures related to anaphora resolution.

5.3.1 Ambiguous pronouns and translation quality

Ambiguous pronouns are relatively sparse in a general-purpose test set, and previous work has designed targeted evaluation of pronoun translation (Hardmeier et al., 2015; Miculicich Werlen and Popescu-Belis, 2017; Bawden et al., 2018). However, we note that in Russian, grammatical gender is not only marked on pronouns, but also on adjectives and verbs. Rather than using a pronoun-specific evaluation, we present results with BLEU on test sets where we hypothesize context to be relevant, specifically sentences containing co-referential pronouns. We feed Stanford CoreNLP open-source coreference resolution system (Manning et al., 2014a) with pairs of sentences to find examples where there is a link between one of the pronouns under consideration and the context. We focus on anaphoric instances of “it” (this excludes, among others, pleonastic uses of ”it”), and instances of the pronouns “I”, “you”, and “yours” that are coreferent with an expression in the previous sentence. All these pronouns express ambiguity in the translation into Russian, and the model has learned to attend to context for their translation (Table 2). To combat data sparsity, the test sets are extracted from large amounts of held-out data of OpenSubtitles2018. Table 3 shows BLEU scores for the resulting subsets.

First of all, we see that most of the antecedents in these test sets are also pronouns. Antecedent pronouns should not be particularly informative for translating the source pronoun. Nevertheless, even with such contexts, improvements are generally larger than on the overall test set.

When we focus on sentences where the antecedent for pronoun under consideration contains

pronoun	N	#pronominal antecedent	baseline	our model	difference
it	11128	6604	25.4	26.6	**+1.2**
you	6398	5795	29.7	30.8	**+1.1**
yours	2181	2092	24.1	25.2	**+1.1**
I	8205	7496	30.1	30.0	-0.1

Table 3: BLEU for test sets with coreference between pronoun and a word in context sentence. We show both *N*, the total number of instances in a particular test set, and number of instances with *pronominal antecedent*. Significant BLEU differences are in bold.

word	N	baseline	our model	diff.
it	4524	23.9	26.1	**+2.2**
you	693	29.9	31.7	**+1.8**
I	709	29.1	29.7	**+0.6**

Table 4: BLEU for test sets of pronouns having a nominal antecedent in context sentence. *N*: number of examples in the test set.

type	N	baseline	our model	diff.
masc.	2509	26.9	27.2	**+0.3**
fem.	2403	21.8	26.6	**+4.8**
neuter	862	22.1	24.0	**+1.9**
plural	1141	18.2	22.5	**+4.3**

Table 5: BLEU for test sets of pronoun "it" having a nominal antecedent in context sentence. *N*: number of examples in the test set.

a noun, we observe even larger improvements (Table 4). Improvement is smaller for "I", but we note that verbs with first person singular subjects mark gender only in the past tense, which limits the impact of correctly predicting gender. In contrast, different types of "you" (polite/impolite, singular/plural) lead to different translations of the pronoun itself plus related verbs and adjectives, leading to a larger jump in performance. Examples of nouns co-referent with "I" and "you" include names, titles ("Mr.", "Mrs.", "officer"), terms denoting family relationships ("Mom", "Dad"), and terms of endearment ("honey", "sweetie"). Such nouns can serve to disambiguate number and gender of the speaker or addressee, and mark the level of familiarity between them.

The most interesting case is translation of "it", as "it" can have many different translations into Russian, depending on the grammatical gender of the antecedent. In order to disentangle these cases, we train the Berkeley aligner on 10m sentences and use the trained model to divide the test set with "it" referring to a noun into test sets specific to each gender and number. Results are in Table 5.

pronoun	agreement (in %)			
	random	first	last	attention
it	69	66	72	69
you	76	85	71	80
I	74	81	73	78

Table 6: Agreement with CoreNLP for test sets of pronouns having a nominal antecedent in context sentence (%).

We see an improvement of 4-5 BLEU for sentences where "it" is translated into a feminine or plural pronoun by the reference. For cases where "it" is translated into a masculine pronoun, the improvement is smaller because the masculine gender is more frequent, and the context-agnostic baseline tends to translate the pronoun "it" as masculine.

5.3.2 Latent anaphora resolution

The results in Tables 4 and 5 suggest that the context-aware model exploits information about the antecedent of an ambiguous pronoun. We hypothesize that we can interpret the model's attention mechanism as a latent anaphora resolution, and perform experiments to test this hypothesis.

For test sets from Table 4, we find an antecedent noun phrase (usually a determiner or a possessive pronoun followed by a noun) using Stanford CoreNLP (Manning et al., 2014b). We select only examples where a noun phrase contains a single noun to simplify our analysis. Then we identify which token receives the highest attention weight (excluding `<bos>` and `<eos>` tokens and punctuation). If this token falls within the antecedent span, then we treat it as agreement (see Table 6).

One natural question might be: does the attention component in our model genuinely learn to perform anaphora resolution, or does it capture some simple heuristic (e.g., pointing to the last noun)? To answer this question, we consider several baselines: choosing a random, last or first

pronoun	agreement (in %)			
	random	first	last	attention
it	40	36	52	58
you	42	63	29	67
I	39	56	35	62

Table 7: Agreement with CoreNLP for test sets of pronouns having a nominal antecedent in context sentence (%). Examples with ≥1 noun in context sentence.

noun from the context sentence as an antecedent.

Note that an agreement of the last noun for "it" or the first noun for "you" and "I" is very high. This is partially due to the fact that most context sentences have only one noun. For these examples a random and last predictions are always correct, meanwhile attention does not always pick a noun as the most relevant word in the context. To get a more clear picture let us now concentrate only on examples where there is more than one noun in the context (Table 7). We can now see that the attention weights are in much better agreement with the coreference system than any of the heuristics. This indicates that the model is indeed performing anaphora resolution.

While agreement with CoreNLP is encouraging, we are aware that coreference resolution by CoreNLP is imperfect and partial agreement with it may not necessarily indicate that the attention is particularly accurate. In order to control for this, we asked human annotators to manually evaluate 500 examples from the test sets where CoreNLP predicted that "it" refers to a noun in the context sentence. More precisely, we picked random 500 examples from the test set with "it" from Table 7. We marked the pronoun in a source which CoreNLP found anaphoric. Assessors were given the source and context sentences and were asked to mark an antecedent noun phrase for a marked pronoun in a source sentence or say that there is no antecedent at all. We then picked those examples where assessors found a link from "it" to some noun in context (79% of all examples). Then we evaluated agreement of CoreNLP and our model with the ground truth links. We also report the performance of the best heuristic for "it" from our previous analysis (i.e. last noun in context). The results are provided in Table 8.

The agreement between our model and the ground truth is 72%. Though 5% below the coreference system, this is a lot higher than the best heuristic (+18%). This confirms our conclusion that our model performs latent anaphora resolution. Interestingly, the patterns of mistakes are quite different for CoreNLP and our model (Table 9). We also present one example (Figure 5) where the attention correctly predicts anaphora while CoreNLP fails. Nevertheless, there is room for improvement, and improving the attention component is likely to boost translation performance.

6 Related work

Our analysis focuses on how our context-aware neural model implicitly captures anaphora. Early work on anaphora phenomena in statistical machine translation has relied on external systems for coreference resolution (Le Nagard and Koehn, 2010; Hardmeier and Federico, 2010). Results were mixed, and the low performance of coreference resolution systems was identified as a problem for this type of system. Later work by Hardmeier et al. (2013) has shown that cross-lingual pronoun prediction systems can implicitly learn to resolve coreference, but this work still relied on external feature extraction to identify anaphora candidates. Our experiments show that a context-aware neural machine translation system can implicitly learn coreference phenomena without any feature engineering.

Tiedemann and Scherrer (2017) and Bawden et al. (2018) analyze the attention weights of context-aware NMT models. Tiedemann and Scherrer (2017) find some evidence for above-average attention on contextual history for the translation of pronouns, and our analysis goes further in that we are the first to demonstrate that our context-aware model learns latent anaphora resolution through the attention mechanism. This is contrary to Bawden et al. (2018), who do not observe increased attention between a pronoun and its antecedent in their recurrent model. We deem our model more suitable for analysis, since it has no recurrent connections and fully relies on the attention mechanism within a single attention layer.

7 Conclusions

We introduced a context-aware NMT system which is based on the Transformer architecture. When evaluated on an En-Ru parallel corpus, it outperforms both the context-agnostic baselines and a simple context-aware baseline. We observe that improvements are especially prominent for sentences containing ambiguous pronouns. We also show that the model induces anaphora relations. We believe that further improvements in handling anaphora, and by proxy translation, can be achieved by incorporating specialized features in the attention model. Our analysis has focused on the effect of context information on pronoun translation. Future work could also investigate whether context-aware NMT systems learn other discourse phenomena, for example whether they improve the translation of elliptical constructions, and markers of discourse relations and information structure.

Document Context Neural Machine Translation with Memory Networks

Sameen Maruf and **Gholamreza Haffari**
Faculty of Information Technology, Monash University, Australia
{firstname.lastname}@monash.edu

Abstract

We present a document-level neural machine translation model which takes both source and target document context into account using memory networks. We model the problem as a structured prediction problem with interdependencies among the observed and hidden variables, i.e., the source sentences and their unobserved target translations in the document. The resulting structured prediction problem is tackled with a neural translation model equipped with two memory components, one each for the source and target side, to capture the documental interdependencies. We train the model end-to-end, and propose an iterative decoding algorithm based on block coordinate descent. Experimental results of English translations from French, German, and Estonian documents show that our model is effective in exploiting both source and target document context, and statistically significantly outperforms the previous work in terms of BLEU and METEOR.

1 Introduction

Neural machine translation (NMT) has proven to be powerful (Sutskever et al., 2014; Bahdanau et al., 2015). It is on-par, and in some cases, even surpasses the traditional statistical MT (Luong et al., 2015) while enjoying more flexibility and significantly less manual effort for feature engineering. Despite their flexibility, most neural MT models translate sentences independently. Discourse phenomenon such as pronominal anaphora and lexical consistency, may depend on long-range dependency going farther than a few previous sentences, are neglected in sentence-based translation (Bawden et al., 2017).

There are only a handful of attempts to document-wide machine translation in statistical and neural MT camps. Hardmeier and Federico (2010); Gong et al. (2011); Garcia et al. (2014) propose document translation models based on statistical MT but are restrictive in the way they incorporate the document-level information and fail to gain significant improvements. More recently, there have been a few attempts to incorporate source side context into neural MT (Jean et al., 2017; Wang et al., 2017; Bawden et al., 2017); however, these works only consider a very local context including a few previous source/target sentences, ignoring the global source and target documental contexts. The latter two report deteriorated performance when using the target-side context.

In this paper, we present a document-level machine translation model which combines sentence-based NMT (Bahdanau et al., 2015) with memory networks (Sukhbaatar et al., 2015). We capture the global source and target document context with two memory components, one each for the source and target side, and incorporate it into the sentence-based NMT by changing the decoder to condition on it as the sentence translation is generated. We conduct experiments on three language pairs: French-English, German-English and Estonian-English. The experimental results and analysis demonstrate that our model is effective in exploiting both source and target document context, and statistically significantly outperforms the previous work in terms of BLEU and METEOR.

2 Background

2.1 Neural Machine Translation (NMT)

Our document NMT model is grounded on sentence-based NMT model (Bahdanau et al.,

2015) which contains an encoder to *read* the source sentence as well as an attentional decoder to *generate* the target translation.

Encoder It is a bidirectional RNN consisting of two RNNs running in opposite directions over the source sentence:

$$\overrightarrow{\boldsymbol{h}_i} = \overrightarrow{\text{RNN}}(\overrightarrow{\boldsymbol{h}}_{i-1}, \boldsymbol{E}_S[x_i]), \overleftarrow{\boldsymbol{h}}_i = \overleftarrow{\text{RNN}}(\overleftarrow{\boldsymbol{h}}_{i+1}, \boldsymbol{E}_S[x_i])$$

where $\boldsymbol{E}_S[x_i]$ is embedding of the word x_i from the embedding table $\boldsymbol{E}_S$ of the source language, and $\overrightarrow{\boldsymbol{h}}_i$ and $\overleftarrow{\boldsymbol{h}}_i$ are the hidden states of the forward and backward RNNs which can be based on the LSTM (Hochreiter and Schmidhuber, 1997) or GRU (Cho et al., 2014) units. Each word in the source sentence is then represented by the concatenation of the corresponding bidirectional hidden states, $\boldsymbol{h}_i = [\overrightarrow{\boldsymbol{h}}_i; \overleftarrow{\boldsymbol{h}}_i]$.

Decoder The generation of each word y_j is conditioned on all of the previously generated words $\boldsymbol{y}_{<j}$ via the state of the RNN decoder $\boldsymbol{s}_j$, and the source sentence via a *dynamic* context vector $\boldsymbol{c}_j$:

$$\begin{aligned} y_j &\sim \text{softmax}(\boldsymbol{W}_y \cdot \boldsymbol{r}_j + \boldsymbol{b}_r) \\ \boldsymbol{r}_j &= \tanh(\boldsymbol{s}_j + \boldsymbol{W}_{rc} \cdot \boldsymbol{c}_j + \boldsymbol{W}_{rj} \cdot \boldsymbol{E}_T[y_{j-1}]) \\ \boldsymbol{s}_j &= \tanh(\boldsymbol{W}_s \cdot \boldsymbol{s}_{j-1} + \boldsymbol{W}_{sj} \cdot \boldsymbol{E}_T[y_{j-1}] + \boldsymbol{W}_{sc} \cdot \boldsymbol{c}_j) \end{aligned}$$

where $\boldsymbol{E}_T[y_j]$ is embedding of the word y_j from the embedding table $\boldsymbol{E}_T$ of the target language, and $\boldsymbol{W}$ matrices and $\boldsymbol{b}_r$ vector are the parameters. The dynamic context vector $\boldsymbol{c}_j$ is computed via $\boldsymbol{c}_j = \sum_i \alpha_{ji} \boldsymbol{h}_i$, where

$$\begin{aligned} \boldsymbol{\alpha}_j &= \text{softmax}(\boldsymbol{a}_j) \\ a_{ji} &= \boldsymbol{v} \cdot \tanh(\boldsymbol{W}_{ae} \cdot \boldsymbol{h}_i + \mathbf{W}_{at} \cdot \boldsymbol{s}_{j-1}) \end{aligned}$$

This is known as the *attention* mechanism which dynamically attends to relevant parts of the source necessary for generating the next target word.

2.2 Memory Networks (MemNets)

Memory Networks (Weston et al., 2015) are a class of neural models that use external memories to perform inference based on long-range dependencies. A memory is a collection of vectors $\boldsymbol{M} = \{\boldsymbol{m}_1, .., \boldsymbol{m}_K\}$ constituting the memory cells, where each cell $\boldsymbol{m}_k$ may potentially correspond to a discrete object $\boldsymbol{x}_k$. The memory is equipped with a *read* and optionally a *write* operation. Given a query vector $\boldsymbol{q}$, the output vector generated by reading from the memory is $\sum_{i=1}^{|\boldsymbol{M}|} p_i \boldsymbol{m}_i$, where p_i represents the relevance of the query to the i-th memory cell $\boldsymbol{p} =$ softmax$(\boldsymbol{q}^T \cdot \boldsymbol{M})$. For the rest of the paper, we denote the read operation by MemNet$(\boldsymbol{M}, \boldsymbol{q})$.

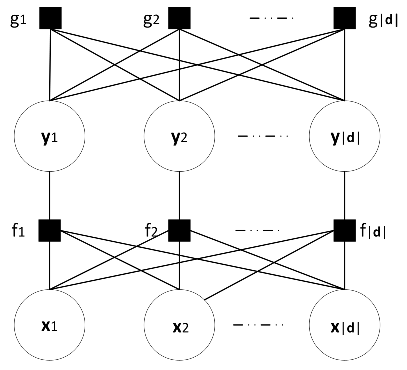

Figure 1: Factor graph for document-level MT

3 Document NMT as Structured Prediction

We formulate document-wide machine translation as a *structured* prediction problem. Given a set of sentences $\{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_{|\boldsymbol{d}|}\}$ in a source document $\boldsymbol{d}$, we are interested in generating the collection of their translations $\{\boldsymbol{y}_1, \ldots, \boldsymbol{y}_{|\boldsymbol{d}|}\}$ taking into account *interdependencies* among them imposed by the document. We achieve this by the factor graph in Figure 1 to model the probability of the target document given the source document. Our model has two types of factors:

- $f_{\boldsymbol{\theta}}(\boldsymbol{y}_t; \boldsymbol{x}_t, \boldsymbol{x}_{-t})$ to capture the interdependencies between the translation $\boldsymbol{y}_t$, the corresponding source sentence $\boldsymbol{x}_t$ and all the other sentences in the source document $\boldsymbol{x}_{-t}$, and
- $g_{\boldsymbol{\theta}}(\boldsymbol{y}_t; \boldsymbol{y}_{-t})$ to capture the interdependencies between the translation $\boldsymbol{y}_t$ and all the other translations in the document $\boldsymbol{y}_{-t}$.

Hence, the probability of a document translation given the source document is

$$\begin{aligned} &P(\boldsymbol{y}_1, \ldots, \boldsymbol{y}_{|\boldsymbol{d}|} | \boldsymbol{x}_1, \ldots, \boldsymbol{x}_{|\boldsymbol{d}|}) \propto \\ &\exp\Big(\sum_t f_{\boldsymbol{\theta}}(\boldsymbol{y}_t; \boldsymbol{x}_t, \boldsymbol{x}_{-t}) + g_{\boldsymbol{\theta}}(\boldsymbol{y}_t; \boldsymbol{y}_{-t})\Big). \end{aligned}$$

The factors $f_{\boldsymbol{\theta}}$ and $g_{\boldsymbol{\theta}}$ are realised by neural architectures whose parameters are collectively denoted by $\boldsymbol{\theta}$.

Training It is challenging to train the model parameters by maximising the (regularised) likelihood since computing the partition function is hard. This is due to the enormity of factors

$g_{\boldsymbol{\theta}}(\boldsymbol{y}_t; \boldsymbol{y}_{-t})$ over a large number of translation variables $\boldsymbol{y}_t$'s (i.e., the number of sentences in the document) as well as their unbounded domain (i.e., all sentences in the target language). Thus, we resort to maximising the *pseudo-likelihood* (Besag, 1975) for training the parameters:

$$\arg\max_{\boldsymbol{\theta}} \prod_{\boldsymbol{d}\in\mathcal{D}} \prod_{t=1}^{|\boldsymbol{d}|} P_{\boldsymbol{\theta}}(\boldsymbol{y}_t|\boldsymbol{x}_t, \boldsymbol{y}_{-t}, \boldsymbol{x}_{-t}) \qquad (1)$$

where $\mathcal{D}$ is the set of bilingual training documents, and $|\boldsymbol{d}|$ denotes the number of (bilingual) sentences in the document $\boldsymbol{d} = \{(\boldsymbol{x}_t, \boldsymbol{y}_t)\}_{t=1}^{|\boldsymbol{d}|}$. We directly model the document-conditioned NMT model $P_{\boldsymbol{\theta}}(\boldsymbol{y}_t|\boldsymbol{x}_t, \boldsymbol{y}_{-t}, \boldsymbol{x}_{-t})$ using a neural architecture which subsumes both the $f_{\boldsymbol{\theta}}$ and $g_{\boldsymbol{\theta}}$ factors (covered in the next section).

Decoding To generate the best translation for a document according to our model, we need to solve the following optimisation problem:

$$\arg\max_{\boldsymbol{y}_1,\ldots,\boldsymbol{y}_{|\boldsymbol{d}|}} \prod_{t=1}^{|\boldsymbol{d}|} P_{\boldsymbol{\theta}}(\boldsymbol{y}_t|\boldsymbol{x}_t, \boldsymbol{y}_{-t}, \boldsymbol{x}_{-t})$$

which is hard (due to similar reasons as mentioned earlier). We hence resort to a block coordinate descent optimisation algorithm. More specifically, we initialise the translation of each sentence using the base neural MT model $P(\boldsymbol{y}_t|\boldsymbol{x}_t)$. We then repeatedly visit each sentence in the document, and update its translation using our document-context dependent NMT model $P(\boldsymbol{y}_t|\boldsymbol{x}_t, \boldsymbol{y}_{-t}, \boldsymbol{x}_{-t})$ while the translations of other sentences are kept fixed.

4 Context Dependent NMT with MemNets

We augment the sentence-level attentional NMT model by incorporating the document context (both source and target) using memory networks when generating the translation of a sentence, as shown in Figure 2.

Our model generates the target translation word-by-word from left to right, similar to the vanilla attentional neural translation model. However, it conditions the generation of a target word not only on the previously generated words and the current source sentence (as in the vanilla NMT model), but also on all the other source sentences of the document and their translations. That is, the generation process is as follows:

$$P_{\boldsymbol{\theta}}(\boldsymbol{y}_t|\boldsymbol{x}_t, \boldsymbol{y}_{-t}, \boldsymbol{x}_{-t}) = \prod_{j=1}^{|\boldsymbol{y}_t|} P_{\boldsymbol{\theta}}(y_{t,j}|\boldsymbol{y}_{t,<j}, \boldsymbol{x}_t, \boldsymbol{y}_{-t}, \boldsymbol{x}_{-t}) \qquad (2)$$

where $y_{t,j}$ is the j-th word of the t-th target sentence, $\boldsymbol{y}_{t,<j}$ are the previously generated words, and $\boldsymbol{x}_{-t}$ and $\boldsymbol{y}_{-t}$ are as introduced previously.

Our model represents the source and target document contexts as external memories, and *attends* to relevant parts of these external memories when generating the translation of a sentence. Let $\boldsymbol{M}[\boldsymbol{x}_{-t}]$ and $\boldsymbol{M}[\boldsymbol{y}_{-t}]$ denote external memories representing the source and target document context, respectively. These contain memory cells corresponding to all sentences in the document except the t-th sentence (described shortly). Let $\boldsymbol{h}_t$ and $\boldsymbol{s}_t$ be representations of the t-th source sentence and its current translation, from the encoder and decoder respectively. We make use of $\boldsymbol{h}_t$ as the query to get the relevant *context* from the source external memory:

$$\boldsymbol{c}_t^{src} = \text{MemNet}(\boldsymbol{M}[\boldsymbol{x}_{-t}], \boldsymbol{h}_t)$$

Furthermore, for the t-th sentence, we get the relevant information from the target context:

$$\boldsymbol{c}_t^{trg} = \text{MemNet}(\boldsymbol{M}[\boldsymbol{y}_{-t}], \boldsymbol{s}_t + \boldsymbol{W}_{at} \cdot \boldsymbol{h}_t)$$

where the query consists of the representation of the translation $\boldsymbol{s}_t$ from the decoder endowed with that of the source sentence $\boldsymbol{h}_t$ from the encoder to make the query robust to potential noises in the current translation and circumvent error propagation, and $\boldsymbol{W}_{at}$ projects the source representation into the hidden state space.

Now that we have representations of the relevant source and target document contexts, Eq. 2 can be re-written as:

$$P_{\boldsymbol{\theta}}(\boldsymbol{y}_t|\boldsymbol{x}_t, \boldsymbol{y}_{-t}, \boldsymbol{x}_{-t}) = \prod_{j=1}^{|\boldsymbol{y}_t|} P_{\boldsymbol{\theta}}(y_{t,j}|\boldsymbol{y}_{t,<j}, \boldsymbol{x}_t, \boldsymbol{c}_t^{trg}, \boldsymbol{c}_t^{src}) \qquad (3)$$

More specifically, the memory contexts $\boldsymbol{c}_t^{src}$ and $\boldsymbol{c}_t^{trg}$ are incorporated into the NMT decoder as:

- **Memory-to-Context** in which the memory contexts are incorporated when computing the next decoder hidden state:

$$\mathbf{s}_{t,j} = \tanh(\boldsymbol{W}_s \cdot \mathbf{s}_{t,j-1} + \boldsymbol{W}_{sj} \cdot \boldsymbol{E}_T[y_{t,j}] + \boldsymbol{W}_{sc} \cdot \boldsymbol{c}_{t,j} + \boldsymbol{W}_{sm} \cdot \boldsymbol{c}_t^{src} + \boldsymbol{W}_{st} \cdot \boldsymbol{c}_t^{trg})$$

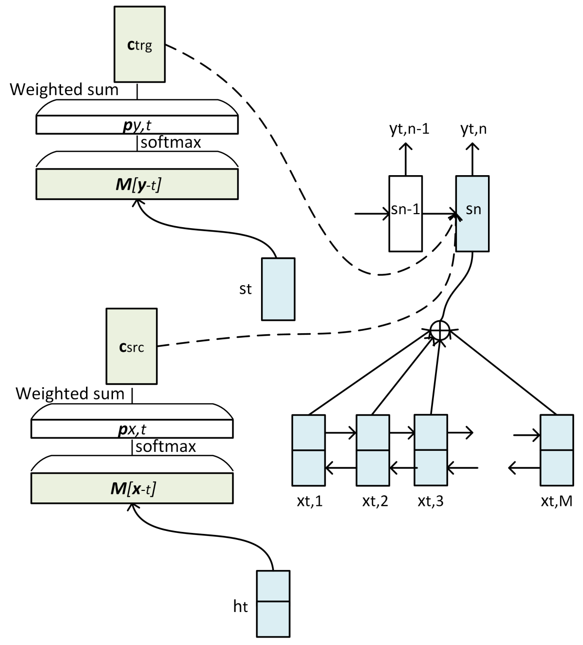

Figure 2: Our Memory-to-Context document-NMT model consisting of sentence-based NMT model with source and target external memories.

- **Memory-to-Output** in which the memory contexts are incorporated in the output layer:

$$y_{t,j} \sim \text{softmax}(\boldsymbol{W}_y \cdot \mathbf{r}_{t,j} + \boldsymbol{W}_{ym} \cdot \boldsymbol{c}_t^{src} + \boldsymbol{W}_{yt} \cdot \boldsymbol{c}_t^{trg} + \mathbf{b}_r)$$

where $\boldsymbol{W}_{sm}$, $\boldsymbol{W}_{st}$, $\boldsymbol{W}_{ym}$, and $\boldsymbol{W}_{yt}$ are the new parameter matrices. We use only the source, only the target, or both external memories as the additional conditioning contexts. Furthermore, we use either the Memory-to-Context or Memory-to-Output architectures for incorporating the document contexts. In the experiments, we will explore these different options to investigate the most effective combination. We now turn our attention to the construction of the external memories for the source and target sides of a document.

The Source Memory We make use of a hierarchical 2-level RNN architecture to construct the external memory of the source document. More specifically, we pass each sentence of the document through a sentence-level bidirectional RNN to get the representation of the sentence (by concatenating the last hidden states of the forward and backward RNNs). We then pass the sentence representations through a document-level bidirectional RNN to propagate sentences' information across the document. We take the hidden states of the document-level bidirectional RNNs as the memory cells of the source external memory.

The source external memory is built once for each minibatch, and does not change throughout the document translation. To be able to fit the computational graph of the document NMT model within GPU memory limits, we pre-train the sentence-level bidirectional RNN using the language modelling training objective. However, the document-level bidirectional RNN is trained together with other parameters of the document NMT model by back-propagating the document translation training objective.

The Target Memory The memory cells of the target external memory represent the current translations of the document. Recall from the previous section that we use coordinate descent iteratively to update these translations. Let $\{\boldsymbol{y}_1, \ldots, \boldsymbol{y}_{|\boldsymbol{d}|}\}$ be the current translations, and let $\{\boldsymbol{s}_{|\boldsymbol{y}_1|}, \ldots, \boldsymbol{s}_{|\boldsymbol{y}_{|\boldsymbol{d}|}|}\}$ be the last states of the decoder when these translations were generated. We use these last decoder states as the cells of the external target memory. We could make use of hierarchical sentence-document RNNs to transform the document translations into memory cells (similar to what we do for the source memory); however, it would have been computationally expensive and may have resulted in error propagation. We will show in the experiments that our efficient target memory construction is indeed effective.

5 Experiments and Analysis

Datasets. We conducted experiments on three language pairs: French-English, German-English and Estonian-English. Table 1 shows the statistics of the datasets used in our experiments. The French-English dataset is based on the TED Talks corpus[1] (Cettolo et al., 2012) where each talk is considered a document. The Estonian-English data comes from the Europarl v7 corpus[2] (Koehn, 2005). Following Smith et al. (2013), we split the speeches based on the `SPEAKER` tag and treat them as documents. The French-English and Estonian-English corpora were randomly split into train/dev/test sets. For German-English, we use the News Commentary v9 corpus[3] for training, `news-dev2009` for development,

De-En	49/.9/1.1/1.6	191/2/3/3	39/23/27/19	45.1/34.7

Table 1: Training/dev/test corpora statistics: number of documents ($\times$100) and sentences ($\times$1000), average document length (in sentences) and source/target vocabulary size ($\times$1000). For De-En, we report statistics of the two test sets `news-test2011` and `news-test2016`.

and `news-test2011` and `news-test2016` as the test sets. The news-commentary corpus has document boundaries already provided.

We pre-processed all corpora to remove very short documents and those with missing translations. Out-of-vocabulary and rare words (frequency less than 5) are replaced by the `<UNK>` token, following Cohn et al. (2016).[4]

Evaluation Measures We use BLEU (Papineni et al., 2002) and METEOR (Lavie and Agarwal, 2007) scores to measure the quality of the generated translations. We use bootstrap resampling (Clark et al., 2011) to measure statistical significance, $p < 0.05$, comparing to the baselines.

Implementation and Hyperparameters We implement our document-level neural machine translation model in C++ using the DyNet library (Neubig et al., 2017), on top of the basic sentence-level NMT implementation in `mantis` (Cohn et al., 2016). For the source memory, the sentence and document-level bidirectional RNNs use LSTM and GRU units, respectively. The translation model uses GRU units for the bidirectional RNN encoder and the 2-layer RNN decoder. GRUs are used instead of LSTMs to reduce the number of parameters in the main model. The RNN hidden dimensions and word embedding sizes are set to 512 in the translation and memory components, and the alignment dimension is set to 256 in the translation model.

Training We use a stage-wise method to train the variants of our document context NMT model. Firstly, we pre-train the Memory-to-Context/Memory-to-Output models, setting their *readings* from the source and target memories to the zero vector. This effectively learns parameters associated with the underlying sentence-based NMT model, which is then used as initialisation when training *all* parameters in the second stage (including the ones from the first stage). For the first stage, we make use of stochastic gradient descent (SGD)[5] with initial learning rate of 0.1 and a decay factor of 0.5 after the fourth epoch for a total of ten epochs. The convergence occurs in 6-8 epochs. For the second stage, we use SGD with an initial learning rate of 0.08 and a decay factor of 0.9 after the first epoch for a total of 15 epochs[6]. The best model is picked based on the dev-set perplexity. To avoid overfitting, we employ dropout with the rate 0.2 for the single memory model. For the dual memory model, we set dropout for Document RNN to 0.2 and for the encoder and decoder to 0.5. Mini-batching is used in both stages to speed up training. For the largest dataset, the document NMT model takes about 4.5 hours per epoch to train on a single P100 GPU, while the sentence-level model takes about 3 hours per epoch for the same settings.

When training the document NMT model in the second stage, we need the target memory. One option would be to use the ground truth translations for building the memory. However, this may result in inferior training, since at the test time, the decoder iteratively updates the translation of sentences based on the noisy translations of other sentences (accessed via the target memory). Hence, while training the document NMT model, we construct the target memory from the translations *generated* by the pre-trained sentence-level model[7]. This effectively exposes the model to its potential test-time mistakes during the training time, resulting in more robust learned parameters.

5.1 Main Results

We have three variants of our model, using: (i) only the source memory (*S-NMT+src mem*), (ii) only the target memory (*S-NMT+trg mem*), or

[4]We do not split words into subwords using BPE (Sennrich et al., 2016) as that increases sentence lengths resulting in removing long documents due to GPU memory limitations, which would heavily reduce the amount of data that we have.

[5]In our initial experiments, we found SGD to be more effective than Adam/Adagrad; an observation also made by Bahar et al. (2017).

[6]For the document NMT model training, we did some preliminary experiments using different learning rates and used the scheme which converged to the best perplexity in the least number of epochs while for sentence-level training we follow Cohn et al. (2016).

[7]We report results for two-pass decoding, i.e., we only update the translations once using the initial translations generated from the base model. We tried multiple passes of decoding at test-time but it was not helpful.

+both mems	50.1	74.4	66.1	80	125.4	102

Table 3: Number of model parameters (millions).

(iii) both the source and target memories (*S-NMT+both mems*). We compare these variants against the standard sentence-level NMT model (*S-NMT*). We also compare the source memory variants of our model to the local context-NMT models[8] of Jean et al. (2017) and Wang et al. (2017), which use a few previous source sentences as context, added to the decoder hidden state (similar to our Memory-to-Context model).

Memory-to-Context We consistently observe +1.15/+1.13 BLEU/METEOR score improvements across the three language pairs upon comparing our best model to *S-NMT* (see Table 2). Overall, our document NMT model with both memories has been the most effective variant for all of the three language pairs.

We further experiment to train the target memory variants using *gold* translations instead of the generated ones for German-English. This led to −0.16 and −0.25 decrease[9] in the BLEU scores for the target-only and both-memory variants, which confirms the intuition of constructing the target memory by exposing the model to its noises during training time.

Memory-to-Output From Table 2, we consistently see +.95/+1.00 BLEU/METEOR improvements between the best variants of our model and the sentence-level baseline across the three language pairs. For French→English, all variants of document NMT model show comparable performance when using BLEU; however, when evaluated using METEOR, the dual memory model is the best. For German→English, the target memory variants give comparable results, whereas for Estonian→English, the dual memory variant proves to be the best. Overall, the Memory-to-Context model variants perform better than their Memory-to-Output counterparts. We attribute this to the large number of parameters in the latter architecture (Table 3) and limited amount of data.

We further experiment with more data for train-

ing the sentence-based NMT to investigate the extent to which document context is useful in this setting. We randomly choose an additional 300K German-English sentence pairs from WMT'14 data to train the base NMT model in stage 1. In stage 2, we use the same document corpus as before to train the document-level models. As seen from Figure 3, the document MT variants still benefit from the document context even when the base model is trained on a larger bilingual corpus. For the Memory-to-Context model, we see massive improvements of +0.72 and +1.44 METEOR scores for the source memory and dual memory model respectively, when compared to the baseline. On the other hand, for the Memory-to-Output model, the target memory model's METEOR score increases significantly by +1.09 compared to the baseline, slightly differing from the corresponding model using the smaller corpus (+1.2).

Local Source Context Models Table 4 shows comparison of our Memory-to-Context model variants to local source context-NMT models (Jean et al., 2017; Wang et al., 2017). For French→English, our source memory model is comparable to both baselines. For German→English, our *S-NMT+src mem* model is comparable to Jean et al. (2017) but outperforms Wang et al. (2017) for one test set according to BLEU, and for both test sets according to METEOR. For Estonian→English, our model outperforms Jean et al. (2017). Our global source context model has only surface-level sentence information, and is oblivious to the individual words in the context since we do an offline training to get the sentence representations (as previously mentioned). However, the other two context baselines have access to that information, yet our model's performance is either better or quite close to those models. We also look into the unigram BLEU scores to see how much our global source memory variants lead to improvement at the word-level. From Table 5, it can be seen that our model's performance is better than the baselines for majority of the cases. The *S-NMT+both mems* model gives the best results for all three language pairs, showing that leveraging both source and target document context is indeed beneficial for improving MT performance.

5.2 Analysis

Using Global/Local Target Context We first investigate whether using a local target context would have been equally sufficient in comparison to our global target memory model for the three datasets. We condition the decoder on the previous target sentence representation (obtained from the last hidden state of the decoder) by adding it as an additional input to all decoder states (*PrevTrg*) similar to our Memory-to-Context model. From Table 6, we observe that for French→English and Estonian→English, using all sentences in the target context or just the previous target sentence gives comparable results. We may attribute this to these specific datasets, that is documents from TED talks or European Parliament Proceedings may depend more on the local than on the global context. However, for German→English (NC-11), the target memory model performs the best show-

Table 6: Analysis of target context model.

ing that for documents with richer context (e.g. news articles) we do need the global target document context to improve MT performance.

Output Analysis To better understand the dual memory model, we look at the first sentence example in Table 7. It can be seen that the source sentence has the noun "Qimonda" but the sentence-level NMT model fails to attend to it when generating the translation. On the other hand, the single memory models are better in delivering some, if not all, of the underlying information in the source sentence but the dual memory model's translation quality surpasses them. This is because the word "Qimonda" was being repeated in this specific document, providing a strong contextual signal to our global document context model while the local context model by Wang et al. (2017) is still unable to correctly translate the noun even when it has access to the word-level information of previous sentences.

We resort to manual evaluation as there is no standard metric which evaluates document-level discourse information like consistency or pronominal anaphora. By manual inspection, we observe that our models can identify nouns in the source sentence to resolve coreferent pronouns, as shown in the second example of Table 7. Here the topic of the sentence is "*the country under the dictatorship of Lukashenko*" and our target and dual memory models are able to generate the appropriate pronoun/determiner as well as accurately translate the word '*diktatuur*', hence producing much better translation as compared to both baselines. Apart from these improvements, our models are better in improving the readability of sentences by generating more context appropriate grammatical structures such as verbs and adverbs.

Furthermore, to validate that our model improves the consistency of translations, we look at five documents (roughly 70 sentences) from the test set of Estonian-English, each of which had a word being repeated in the gold translation. Our model is able to resolve the consistency in 22 out of 32 cases as compared to the sentence-based model which only accurately translates 16 of those. Following Wang et al. (2017), we also investigate the extent to which our model can correct errors made by the baseline system. We randomly choose five documents from the test set. Out of the 20 words/phrases which were incorrectly translated by the sentence-based model, our model corrects 85% of them while also generating 10% new errors.

Source	qimonda täidab lissaboni strateegia eesmärke.

6 Related Work

Document-level Statistical MT There have been a few SMT-based attempts to document MT, but they are either restrictive or do not lead to significant improvements. Hardmeier and Federico (2010) identify links among words in the source document using a word-dependency model to improve translation of anaphoric pronouns. Gong et al. (2011) make use of a cache-based system to save relevant information from the previously generated translations and use that to enhance document-level translation. Garcia et al. (2014) propose a two-pass approach to improve the translations already obtained by a sentence-level model.

Docent is an SMT-based document-level decoder (Hardmeier et al., 2012, 2013), which tries to modify the initial translation generated by the Moses decoder (Koehn et al., 2007) through stochastic local search and hill-climbing. Garcia et al. (2015) make use of neural-based continuous word representations to incorporate distributional semantics into Docent. In another work, Garcia et al. (2017) incorporate new word embedding features into Docent to improve the lexical consistency of translations. The proposed methods fail to yield improvements upon automatic evaluation.

Larger Context Neural MT Jean et al. (2017)

extend the vanilla attention-based neural MT model (Bahdanau et al., 2015) by conditioning the decoder on the previous sentence via attention over its words. Extending their model to consider the global source document context would be challenging due to the large size of computation graph over all the words in the source document. Wang et al. (2017) employ a 2-level hierarichal RNN to summarise three previous source sentences, which is then used as an additional input to the decoder hidden state. Bawden et al. (2017) use multi-encoder NMT models to exploit context from the previous source and target sentence. They highlight the importance of target-side context but report deteriorated BLEU scores when using it. All these works consider a very local source/target context and completely ignore the global source and target document contexts.

7 Conclusion

We have proposed a document-level neural MT model that captures global source and target document context. Our model augments the vanilla sentence-based NMT model with external memories to incorporate documental interdependencies on both source and target sides. We show statistically significant improvements of the translation quality on three language pairs. For future work, we intend to investigate models which incorporate specific discourse-level phenomena.

Which Melbourne? Augmenting Geocoding with Maps

Milan Gritta, Mohammad Taher Pilehvar and Nigel Collier

Language Technology Lab
Department of Theoretical and Applied Linguistics
University of Cambridge

Abstract

The purpose of text geolocation is to associate geographic information contained in a document with a set (or sets) of coordinates, either *implicitly* by using linguistic features and/or *explicitly* by using geographic metadata combined with heuristics. We introduce a geocoder (location mention disambiguator) that achieves state-of-the-art (SOTA) results on three diverse datasets by exploiting the implicit lexical clues. Moreover, we propose a new method for systematic encoding of geographic metadata to generate two *distinct* views of the same text. To that end, we introduce the *Map Vector* (*MapVec*), a sparse representation obtained by plotting prior geographic probabilities, derived from population figures, on a World Map. We then integrate the implicit (language) and explicit (map) features to significantly improve a range of metrics. We also introduce an open-source dataset for geoparsing of news events covering global disease outbreaks and epidemics to help future evaluation in geoparsing.

1 Introduction

Geocoding[1] is a specific case of text geolocation, which aims at disambiguating place references in text. For example, *Melbourne* can refer to more than ten possible locations and a geocoder's task is to identify the place coordinates for the intended *Melbourne* in a context such as "*Melbourne* hosts one of the four annual Grand Slam tennis tournaments." This is central to the success of tasks such as indexing and searching documents by geography (Bhargava et al., 2017), geospatial analysis of social media (Buchel and Pennington, 2017), mapping of disease risk using integrated data (Hay et al., 2013), and emergency response systems (Ashktorab et al., 2014). Previous geocoding methods (Section 2) have leveraged lexical semantics to associate the implicit geographic information in natural language with coordinates. These models have achieved good results in the past. However, focusing *only* on lexical features, to the exclusion of other feature spaces such as the Cartesian Coordinate System, puts a ceiling on the amount of semantics we are able to extract from text. Our proposed solution is the *Map Vector* (*MapVec*), a sparse, geographic vector for explicit modelling of geographic distributions of location mentions. As in previous work, we use population data and geographic coordinates, observing that the most populous *Melbourne* is also the most likely to be the intended location. However, MapVec is the first instance, to our best knowledge, of the topological semantics of context locations explicitly isolated into a standardized vector representation, which can then be easily transferred to an independent task and combined with other features. MapVec is able to encode the prior geographic distribution of any number of locations into a single vector. Our extensive evaluation shows how this representation of context locations can be integrated with linguistic features to achieve a significant improvement over a SOTA lexical model. MapVec can be deployed as a standalone neural geocoder, significantly beating the population baseline, while remaining effective with simpler machine learning algorithms.

This paper's contributions are: (1) *Lexical Geocoder* outperforming existing systems by analysing only the textual context; (2) *MapVec*, a geographic representation of locations using a sparse, probabilistic vector to extract and isolate spatial features; (3) *CamCoder*, a novel geocoder

[1]Also called Toponym Resolution in related literature.

that exploits both lexical and geographic knowledge producing SOTA results across multiple datasets; and (4) *GeoVirus*, an open-source dataset for the evaluation of geoparsing (Location Recognition *and* Disambiguation) of news events covering global disease outbreaks and epidemics.

2 Background

Depending on the task objective, geocoding methodologies can be divided into two *distinct* categories: (1) *document geocoding*, which aims at locating a piece of text as a whole, for example geolocating Twitter users (Rahimi et al., 2016, 2017; Roller et al., 2012; Rahimi et al., 2015), Wikipedia articles and/or web pages (Cheng et al., 2010; Backstrom et al., 2010; Wing and Baldridge, 2011; Dredze et al., 2013; Wing and Baldridge, 2014). This is an active area of NLP research (Hulden et al., 2015; Melo and Martins, 2017, 2015; Iso et al., 2017); (2) *geocoding of place mentions*, which focuses on the disambiguation of location (named) entities i.e. this paper and (Karimzadeh et al., 2013; Tobin et al., 2010; Grover et al., 2010; DeLozier et al., 2015; Santos et al., 2015; Speriosu and Baldridge, 2013; Zhang and Gelernter, 2014). Due to the differences in evaluation and objective, the categories cannot be directly or fairly compared. Geocoding is typically the second step in *Geoparsing*. The first step, usually referred to as *Geotagging*, is a Named Entity Recognition component which extracts all location references in a given text. This phase may optionally include metonymy resolution, see (Zhang and Gelernter, 2015; Gritta et al., 2017a). The goal of geocoding is to choose the correct coordinates for a location mention from a set of candidates. Gritta et al. (2017b) provided a comprehensive survey of five recent geoparsers. The authors established an evaluation framework, with a new dataset, for their experimental analysis. We use this evaluation framework in our experiments. We briefly describe the methodology of each geocoder featured in our evaluation (names are capitalised and appear in italics) as well as survey the related work in geocoding.

Computational methods in geocoding broadly divide into rule-based, statistical and machine learning-based. *Edinburgh Geoparser* (Tobin et al., 2010; Grover et al., 2010) is a fully rule-based geocoder that uses hand-built heuristics combined with large lists from Wikipedia and the Geonames[2] gazetteer. It uses metadata (feature type, population, country code) with heuristics such as contextual information, spatial clustering and user locality to rank candidates. *GeoTxT* (Karimzadeh et al., 2013) is another rule-based geocoder with a free web service[3] for identifying locations in unstructured text and grounding them to coordinates. Disambiguation is driven by multiple heuristics and uses the administrative level (country, province, city), population size, the Levenshtein Distance of the place referenced and the candidate's name and spatial minimisation to resolve ambiguous locations. (Dredze et al., 2013) is a rule-based Twitter geocoder using only metadata (coordinates in tweets, GPS tags, user's reported location) and custom place lists for fast and simple geocoding. *CLAVIN* (Cartographic Location And Vicinity INdexer)[4] is an open-source geocoder, which offers context-based entity recognition and linking. It seems to be mostly rule-based though details of its algorithm are underspecified, short of reading the source code. Unlike the Edinburgh Parser, this geocoder seems to overly rely on population data, seemingly mirroring the behaviour of a naive population baseline. Rule-based systems can perform well though the variance in performance is high (see Table 1). *Yahoo! Placemaker* is a free web service with a proprietary geo-database and algorithm from Yahoo![5] letting anyone geoparse text in a globally-aware and language-independent manner. It is unclear how geocoding is performed, however, the inclusion of proprietary methods makes evaluation broader and more informative.

The statistical geocoder *Topocluster* (DeLozier et al., 2015) divides the world surface into a grid (0.5 x 0.5 degrees, approximately 60K tiles) and uses lexical features to model the geographic distribution of context words over this grid. Building on the work of Speriosu and Baldridge (2013), it uses a window of 15 words (our approach scales this up by more than 20 times) to perform hot spot analysis using Getis-Ord Local Statistic of individual words' association with geographic space. The classification decision was made by finding the grid square with the strongest overlap of

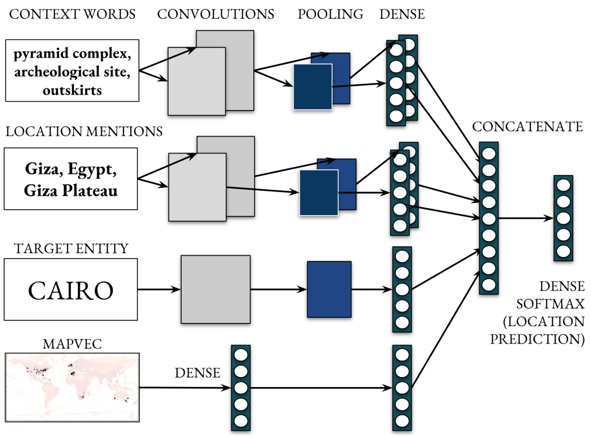
[5]https://developer.yahoo.com/geo/

individual geo-distributions. Hulden et al. (2015) used Kernel Density Estimation to learn the word distribution over a world grid with a resolution of 0.5 x 0.5 degrees and classified documents with Kullback-Leibler divergence or a Naive Bayes model, reminiscent of an earlier approach by Wing and Baldridge (2011). Roller et al. (2012) used the Good-Turing Frequency Estimation to learn document probability distributions over the vocabulary with Kullback-Leibler divergence as the similarity function to choose the correct bucket in the k-d tree (world representation). Iso et al. (2017) combined Gaussian Density Estimation with a CNN-model to geolocate Japanese tweets with Convolutional Mixture Density Networks.

Among the recent machine learning methods, bag-of-words representations combined with a Support Vector Machine (Melo and Martins, 2015) or Logistic Regression (Wing and Baldridge, 2014) have also achieved good results. For Twitter-based geolocation (Zhang and Gelernter, 2014), bag-of-words classifiers were successfully augmented with social network data (Jurgens et al., 2015; Rahimi et al., 2016, 2015). The machine learning-based geocoder by *Santos et al. (2015)* supplemented lexical features, represented as a bag-of-words, with an exhaustive set of manually generated geographic features and spatial heuristics such as geospatial containment and geodesic distances between entities. The ranking of locations was learned with LambdaMART (Burges, 2010). Unlike our geocoder, the addition of geographic features did not significantly improve scores, reporting: “The geo-specific features seem to have a limited impact over a strong baseline system.” Unable to obtain a codebase, their results feature in Table 1. The latest neural network approaches (Rahimi et al., 2017) with normalised bag-of-word representations have achieved SOTA scores when augmented with social network data for Twitter document (user’s concatenated tweets) geolocation (Bakerman et al., 2018).

3 Methodology

Figure 1 shows our new geocoder *CamCoder* implemented in Keras (Chollet, 2015). The lexical part of the geocoder has three inputs, from the top: Context Words (location mentions excluded), Location Mentions (context words excluded) and the Target Entity (up to 15 words long) to be



CONTEXT WORDS
CONVOLUTIONS
POOLING
DENSE
pyramid complex, archeological site, outskirts
LOCATION MENTIONS
Giza, Egypt, Giza Plateau

CAIRO
DENSE SOFTMAX (LOCATION PREDICTION)
MAPVEC
DENSE

Figure 1: The *CamCoder* neural architecture. It is possible to split CamCoder into a *Lexical* (top 3 inputs) model and a *MapVec* model (see Table 2).

geocoded. Consider an example disambiguation of *Cairo* in a sentence: *“The Giza pyramid complex is an archaeological site on the Giza Plateau, on the outskirts of Cairo, Egypt.”*. Here, *Cairo* is the Target Entity; *Egypt*, *Giza* and *Giza Plateau* are the Location Mentions; the rest of the sentence forms the Context Words (excluding stopwords). The *context window* is up to 200 words each side of the Target Entity, approximately an order of magnitude larger than most previous approaches.

We used separate layers, convolutional and/or dense (fully-connected), with ReLu activations (Nair and Hinton, 2010) to break up the task into smaller, focused modules in order to learn distinct lexical feature patterns, phrases and keywords for different types of inputs, concatenating only at a higher level of abstraction. Unigrams and bigrams were learned for context words and location mentions (1,000 filters of size 1 and 2 for each input), trigrams for the target entity (1,000 filters of size 3). Convolutional Neural Networks (CNNs) with Global Maximum Pooling were chosen for their position invariance (detecting location-indicative words anywhere in context) and efficient input size scaling. The dense layers have 250 units each, with a dropout layer ($p = 0.5$) to prevent overfitting. The fourth input is MapVec, the geographic vector representation of location mentions. It feeds into two dense layers with 5,000 and 1,000 units respectively. The concatenated hidden layers then get fully connected to the softmax layer. The model is optimised with RMSProp (Tieleman and Hinton, 2012). We approach geocoding as a classification task where the model predicts one of

7,823 classes (units in the softmax layer in Figure 1), each being a 2x2 degree tile representing part of the world's surface, slightly coarser than MapVec (see Section 3.1 next). The coordinates of the location candidate with the smallest *FD* (Equation 1) are the model's final output.

$$FD = error - error\,\frac{candidatePop}{maximumPop}\,Bias \quad (1)$$

FD for each candidate is computed by reducing the prediction *error* (the distance from predicted coordinates to candidate coordinates) by the value of *error* multiplied by the estimated prior probability (candidate population divided by maximum population) multiplied by the *Bias* parameter. The value of $Bias = 0.9$ was determined to be optimal for highest development data scores and is *identical for all* highly diverse test datasets. Equation 1 is designed to bias the model towards more populated locations to reflect real-world data.

3.1 The Map Vector (MapVec)

Word embeddings and/or distributional vectors encode a word's meaning in terms of its *linguistic* context. However, location (named) entities also carry explicit *topological semantic knowledge* such as a coordinate position and a population count for all places with an identical name. Until now, this knowledge was only used as part of simple disparate heuristics and manual disambiguation procedures. However, it is possible to plot this spatial data on a world map, which can then be reshaped into a 1D *feature vector*, or a *Map Vector*, the geographic representation of location mentions. MapVec is a novel standardised method for generating geographic features from text documents *beyond* lexical features. This enables a strong geocoding classification performance gain by extracting additional spatial knowledge that would normally be ignored. Geographic semantics cannot be inferred from language alone (too imprecise and incomplete). Word embeddings and distributional vectors use language/words as an *implicit* container of geographic information. Map Vector uses a low-resolution, probabilistic world map as an *explicit* container of geographic information, giving us two types of semantic features from the same text. In related papers on the generation of location representations, Rahimi et al. (2017) inverted the task of geocoding Twitter users to predict word probability from a set of coordinates. A continuous representation of a *region* was generated by using the hidden layer of the neural network. However, all locations in the same region will be assigned an identical vector, which assumes that their semantics are also identical. Another way to obtain geographic representations is by generating embeddings directly from Geonames data using heuristics-driven DeepWalk (Perozzi et al., 2014) with geodesic distances (Kejriwal and Szekely, 2017). However, to assign a vector, places must first be disambiguated (catch-22). While these generation methods are original and interesting in theory, deploying them in the real-world is infeasible, hence we invented the Map Vector.

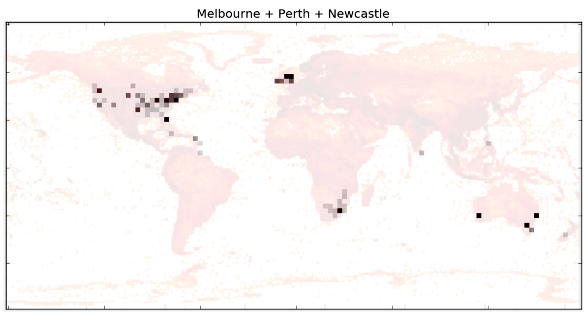

Figure 2: MapVec visualisation (before reshaping into a 1D vector) for *Melbourne*, *Perth* and *Newcastle*, showing their combined prior geographic probabilities. Darker tiles have higher probability.

MapVec initially begins as a 180x360 world map of geodesic tiles. There are other ways of representing the surface of the Earth such as using nested hierarchies (Melo and Martins, 2015) or k-dimensional trees (Roller et al., 2012), however, this is beyond the scope of this work. The 1x1 tile size, in degrees of geographic coordinates, was empirically determined to be optimal to keep MapVec's size computationally efficient while maintaining meaningful resolution. This map is then populated with the *prior geographic distribution* of each location mentioned in context (see Figure 2 for an example). We use population count to *estimate* a location's prior probability as more populous places are more likely to be mentioned in common discourse. For each location mention and for each of its ambiguous candidates, their prior probability is added to the correct tile indicating its geographic position (see Algorithm 1). Tiles that cover areas of open water (64.1%) were removed to reduce size. Finally,

```
Data: Text ← article, paragraph, tweet, etc.
Result: MapVec location(s) representation
Locs ← extractLocations(Text);
MapVec ← new array(length=23,002);
for each l in Locs do
    Cands ← queryCandidatesFromDB($l$);
    maxPop ← maxPopulationOf(Cands);
    for each c in Cands do
        prior ← populationOf($c$) / maxPop;
        i ← coordinatesToIndex($c$);
        MapVec[i] ← MapVec[i] + prior;
    end
end
m ← max(MapVec);
return MapVec / m;
```

Algorithm 1: MapVec generation. For each extracted location ***l*** in *Locs*, estimate the prior probability of each candidate ***c***. Add ***c***'s prior probability to the appropriate array position at index ***i*** representing its geographic position/tile. Finally, normalise the array (to a $[0 - 1]$ range) by dividing by the maximum value of the MapVec array.

this world map is reshaped into a one-dimensional *Map Vector* of length 23,002.

The following features of MapVec are the most salient: *Interpretability:* Word vectors typically need intrinsic (Gerz et al., 2016) and extrinsic tasks (Senel et al., 2017) to interpret their semantics. MapVec generation is a fully transparent, human readable and modifiable method. *Efficiency:* MapVec is an efficient way of embedding *any number* of locations using the same standardised vector. The alternative means creating, storing, disambiguating and computing with millions of unique location vectors. *Domain Independence:* Word vectors vary depending on the source, time, type and language of the training data and the parameters of generation. MapVec is language-independent and stable over time, domain, size of dataset since the world geography is objectively measured and changes very slowly.

3.2 Data and Preprocessing

Training data was generated from geographically annotated Wikipedia pages (dumped February 2017). Each page provided up to 30 training instances, limited to avoid bias from large pages. This resulted in collecting approximately 1.4M training instances, which were uniformly subsampled down to 400K to shorten training cycles as further increases offer diminishing returns. We used the Python-based NLP toolkit Spacy[6] (Honnibal and Johnson, 2015) for text preprocessing. All words were lowercased, lemmatised, any stopwords, dates, numbers and so on were replaced with a special token ("0"). Word vectors were initialised with pretrained word embeddings[7] (Pennington et al., 2014). We do not employ explicit feature selection as in (Bo et al., 2012), only a minimum frequency count, which was shown to work almost as well as deliberate selection (Van Laere et al., 2014). The vocabulary size was limited to the most frequent 331K words, minimum ten occurrences for words and two for location references in the 1.4M training corpus. A final training instance comprises four types of context information: Context Words (excluding location mentions, up to 2x200 words), Location Mentions (excluding context words, up to 2x200 words), Target Entity (up to 15 words) and the MapVec geographic representation of context locations. We have also checked for any overlaps between our Wikipedia-based training data and the WikToR dataset. Those examples were removed. The aforementioned 1.4M Wikipedia training corpus was once again uniformly subsampled to generate a *disjoint* development set of 400K instances. While developing our models mainly on this data, we also used small subsets of LGL (18%), GeoVirus (26%) and WikToR (9%) described in Section 4.2 to verify that development set improvements generalised to target domains.

4 Evaluation

Our evaluation compares the geocoding performance of six systems from Section 2, our geocoder (CamCoder) and the population baseline. Among these, our CNN-based model is the only neural approach. We have included all open-source/free geocoders *in working order* we were able to find and they are the most up-to-date versions. Tables 1 and 2 feature several machine learning algorithms including Long-Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) to reproduce context2vec (Melamud et al., 2016), Naive Bayes (Zhang, 2004) and Random Forest (Breiman, 2001) using three diverse datasets.

[6] https://spacy.io/
[7] https://nlp.stanford.edu/

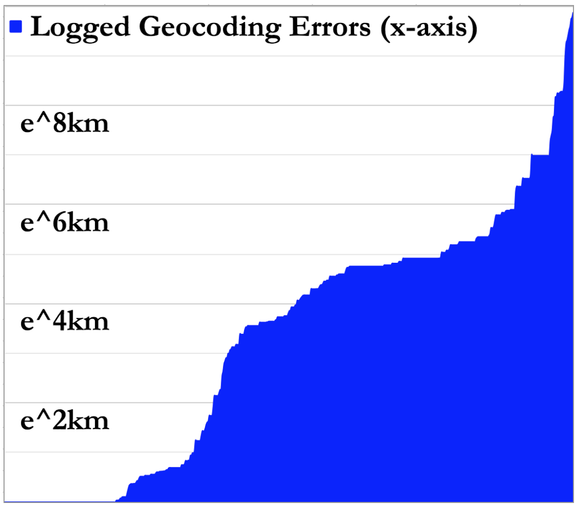

Figure 3: The AUC (range $[0-1]$) is calculated using the Trapezoidal Rule. Smaller errors mean a smaller (blue) area, which means a lower score and therefore better geocoding results.

4.1 Geocoding Metrics

We use the three standard and comprehensive metrics, each measuring an important aspect of geocoding, giving an accurate, holistic evaluation of performance. A more detailed cost-benefit analysis of geocoding metrics is available in (Karimzadeh, 2016) and (Gritta et al., 2017b). (1) *Average (Mean) Error* is the sum of all geocoding errors per dataset divided by the number of errors. It is an informative metric as it also indicates the total error but treats all errors as equivalent and is sensitive to outliers; (2) *Accuracy@161km* is the percentage of errors that are smaller than 161km (100 miles). While it is easy to interpret, giving fast and intuitive understanding of geocoding performance in percentage terms, it ignores all errors greater than 161km; (3) *Area Under the Curve* (*AUC*) is a comprehensive metric, initially introduced for geocoding in (Jurgens et al., 2015). AUC reduces the importance of large errors (1,000km+) since accuracy on successfully resolved places is more desirable. While it is not an intuitive metric, AUC is robust to outliers and measures *all* errors. A versatile geocoder should be able to maximise all three metrics.

4.2 Evaluation Datasets

News Corpus: The Local Global Corpus (LGL) by Lieberman et al. (2010) contains 588 news articles (4460 test instances), which were collected from geographically distributed newspaper sites. This is the most frequently used geocoding evaluation dataset to date. The toponyms are mostly smaller places no larger than a US state. Approximately 16% of locations in the corpus do not have any coordinates assigned; hence, we do not use those in the evaluation, which is also how the previous figures were obtained. *Wikipedia Corpus*: This corpus was deliberately designed for ambiguity hence the population heuristic is not effective. Wikipedia Toponym Retrieval (WikToR) by Gritta et al. (2017b) is a programmatically created corpus and although not necessarily representative of the real world distribution, it is a test of ambiguity for geocoders. It is also a large corpus (25,000+ examples) containing the first few paragraphs of 5,000 Wikipedia pages. High quality, free and open datasets are not readily available (GeoVirus tries to address this). The following corpora could not be included: WoTR (DeLozier et al., 2016) due to limited coverage (southern US) and domain type (historical language, the 1860s), (De Oliveira et al., 2017) contains fewer than 180 locations, GeoCorpora (Wallgrün et al., 2017) could not be retrieved in full due to deleted Twitter users/tweets, GeoText (Eisenstein et al., 2010) only allows for user geocoding, SpatialML (Mani et al., 2010) involves prohibitive costs, GeoSemCor (Buscaldi and Rosso, 2008) was annotated with WordNet senses (rather than coordinates).

4.3 GeoVirus: a New Test Dataset

We now introduce GeoVirus, an open-source test dataset for the evaluation of geoparsing of news events covering global disease outbreaks and epidemics. It was constructed from free WikiNews[8] and collected during 08/2017 - 09/2017. The dataset is suitable for the evaluation of Geotagging/Named Entity Recognition and Geocoding/Toponym Resolution. Articles were identified using the WikiNews search box and keywords such as Ebola, Bird Flu, Swine Flu, AIDS, Mad Cow Disease, West Nile Disease, etc. Off-topic articles were not included. Buildings, POIs, street names and rivers were not annotated.

Annotation Process. (1) The WikiNews contributor(s) who wrote the article annotated most, but not all location references. The first author checked those annotations and identified further references, then proceeded to extract the place name, indices of the start and end characters in

text, assigned coordinates and the Wikipedia page URL for each location. (2) A second pass over the entire dataset by the first author to check and/or remedy annotations. (3) A computer program checked that locations were tagged correctly, checking coordinates against the Geonames Database, URL correctness, eliminating any duplicates and validating XML formatting. Places without a Wikipedia page (0.6%) were assigned Geonames coordinates. (4) The second author annotated a random 10% sample to obtain an Inter-Annotator Agreement, which was 100% for geocoding and an F-Score of 92.3 for geotagging. *GeoVirus in Numbers:* Annotated locations: 2,167, Unique: 685, Continents: 94, Number of articles: 229, Most frequent places (21% of total): US, Canada, China, California, UK, Mexico, Kenya, Africa, Australia, Indonesia; Mean location occurrence: 3.2, Total word count: 63,205.

5 Results

All tested models (except CamCoder) operate as end-to-end systems; therefore, it is not possible to perform geocoding separately. Each system geoparses its particular majority of the dataset to obtain a representative data sample, shown in Table 1 as strongly correlated scores for subsets of different sizes, with which to assess model performance. Table 1 also shows scores in *brackets* for the overlapping partition of all systems in order to compare performance on identical instances: GeoVirus 601 (26%), LGL 787 (17%) and WikToR 2,202 (9%). The geocoding difficulty based on the ambiguity of each dataset is: LGL (moderate to hard), WIK (very hard), GEO (easy to moderate). A population baseline also features in the evaluation. The baseline is conceptually simple: choose the candidate with the highest population, akin to the most frequent word sense in WSD. Table 1 shows the effectiveness of this heuristic, which is competitive with many geocoders, even *outperforming* some. However, the baseline is not effective on WikToR as the dataset was deliberately constructed as a tough ambiguity test. Table 1 shows how several geocoders mirror the behaviour of the population baseline. This simple but effective heuristic is rarely used in system comparisons, and where evaluated (Santos et al., 2015; Leidner, 2008), it is inconsistent with expected figures (due to unpublished resources, we are unable to investigate).

We note that no single computational paradigm dominates Table 1. The rule-based (Edinburgh, GeoTxt, CLAVIN), statistical (Topocluster), machine learning (CamCoder, Santos) and other (Yahoo!, Population) geocoders occupy different ranks across the three datasets. Due to space constraints, Table 1 does not show figures for another type of scenario we tested, a shorter lexical context, using 200 words instead of the standard 400. CamCoder proved to be robust to reduced context, with only a small performance decline. Using the same format as Table 1, AUC errors for LGL increased from 22 (18) to 23 (19), WIK from 33 (37) to 37 (40) and GEO remained the same at 31 (32). This means that reducing model input size to save computational resources would still deliver accurate results. Our CNN-based lexical model performs at SOTA levels (Table 2) proving the effectiveness of linguistic features while being

Geocoder	System configuration			Dataset			Average
	Language Features	+	MapVec Features	LGL	WIK	GEO	
CamCoder	CNN		MLP	**0.22**	**0.33**	**0.31**	**0.29**

Population	–		–	0.27	0.68	0.32	0.42

Table 2: AUC scores for *CamCoder* and its *Lexical* and *MapVec* components (model ablation). Lower AUC scores are better. [†]Standard context2vec model augmented with MapVec representation.

the outstanding geocoder on the highly ambiguous WikToR data. The Multi-Layer Perceptron (MLP) model using only MapVec with no lexical features is almost as effective but more importantly, it is significantly better than the population baseline (Table 2). This is because the Map Vector benefits from wide contextual awareness, encoded in Algorithm 1, while a simple population baseline does not. When we combined the lexical *and* geographic feature spaces in one model (CamCoder[9]), we observed a substantial increase in the SOTA scores. We have also reproduced the *context2vec* model to obtain a continuous context representation using bidirectional LSTMs to encode lexical features, denoted as LSTM[10] in Table 2. This enabled us to test the effect of integrating MapVec into another deep learning model as opposed to CNNs. Supplemented with MapVec, we observed a significant improvement, demonstrating how enriching various neural models with a geographic vector representation boosts classification results.

Deep learning is the dominant paradigm in our experiments. However, it is important that MapVec is still effective with simpler machine learning algorithms. To that end, we have evaluated it with the Random Forest *without* using any lexical features. This model was well suited to the geocoding task despite training with only half of the 400K training data (due to memory constraints, partial fit is unavailable for batch training in SciKit Learn). Scores were on par with more sophisticated systems. The Naive Bayes was less effective with MapVec though still somewhat viable as a geocoder given the lack of lexical features and a naive algorithm, narrowly beating population. GeoVirus scores remain highly competitive across most geocoders. This is due to the nature of the dataset; locations skewed towards their dominant "senses" simulating ideal geocoding conditions, enabling high accuracy for the population baseline. GeoVirus alone may not serve as the best scenario to assess a geocoder's performance, however, it is nevertheless important and valuable to determine behaviour in a standard environment. For example, GeoVirus helped us diagnose Yahoo! Placemaker's lower accuracy in what should be an easy test for a geocoder. The figures show that while the average error is low, the accuracy@161km is noticeably lower than most systems. When coupled with other complementary datasets such as LGL and WikToR, it facilitates a comprehensive assessment of geocoding behaviour in many types of scenarios, exposing potential domain dependence. We note that GeoVirus has a dual function, NER (not evaluated but useful for future work) and Geocoding. We made all of our resources freely available[11] for full reproducibility (Goodman et al., 2016).

5.1 Discussion and Errors

The Pearson correlation coefficient of the target entity *ambiguity* and the *error size* was only $r \approx 0.2$ suggesting that CamCoder's geocoding errors do not simply rise with location ambiguity. Errors were also not correlated ($r \approx 0.0$) with population size with all types of locations geocoded to various degrees of accuracy. All error curves follow

[9]Single model settings/parameters for all tests.

[10]`https://keras.io/layers/recurrent/`

[11]`https://github.com/milangritta/`

a power law distribution with between 89% and 96% of errors less than 1500km, the rest rapidly increasing into thousands of kilometers. Errors also appear to be uniformly geographically distributed across the world. The strong lexical component shown in Table 2 is reflected by the lack of a relationship between *error size* and the *number of locations* found in the context. The *number of total words* in context is also independent of geocoding accuracy. This suggests that CamCoder learns strong linguistic cues beyond simple association of place names with the target entity and is able to cope with flexible-sized contexts. A CNN Geocoder would expect to perform well for the following reasons: Our context window is 400 words rather than 10-40 words as in previous approaches. The model learns 1,000 feature maps per input and per feature type, tracking 5,000 different word patterns (unigrams, bigrams and trigrams), a significant text processing capability. The lexical model also takes advantage of our own 50-dimensional word embeddings, tuned on geographic Wikipedia pages only, allowing for greater generalisation than bag-of-unigrams models; and the large training/development datasets (400K each), optimising geocoding over a diverse global set of places allowing our model to generalise to unseen instances. We note that MapVec generation is sensitive to NER performance with higher F-Scores leading to better quality of the geographic vector representation(s). Precision errors can introduce noise while recall errors may withhold important locations. The average F-Score for the featured geoparsers is $F \approx 0.7$ (standard deviation ≈ 0.1). Spacy's NER performance over the three datasets is also $F \approx 0.7$ with a similar variation between datasets. In order to further interpret scores in Tables 1 and 2, with respect to maximising geocoding performance, we briefly discuss the *Oracle* score. Oracle is the geocoding performance upper bound given by the Geonames data, i.e. the *highest possible score(s)* using Geonames coordinates as the geocoding output. In other words, it quantifies the *minimum error* for each dataset given the *perfect* location disambiguation. This means it quantifies the difference between "gold standard" coordinates and the coordinates in the Geonames database. The following are the Oracle scores for LGL (*AUC=0.04, a@161km=99*) annotated with Geonames, WikToR (*AUC=0.14, a@161km=92*) and GeoVirus (*AUC=0.27, a@161km=88*), which are annotated with Wikipedia data. Subtracting the Oracle score from a geocoder's score quantifies the scope of its *theoretical future improvement*, given a particular database/gazetteer.

6 Conclusions and Future Work

Geocoding methods commonly employ lexical features, which have proved to be very effective. Our lexical model was the best language-only geocoder in extensive tests. It is possible, however, to go *beyond* lexical semantics. Locations also have a rich topological meaning, which has not yet been successfully isolated and deployed. We need a means of extracting and encoding this additional knowledge. To that end, we introduced MapVec, an algorithm and a container for encoding context locations in geodesic vector space. We showed how CamCoder, using lexical *and* MapVec features, outperformed both approaches, achieving a new SOTA. MapVec remains effective with various machine learning frameworks (Random Forest, CNN and MLP) and substantially improves accuracy when combined with other neural models (LSTMs). Finally, we introduced GeoVirus, an open-source dataset that helps facilitate geoparsing evaluation across more diverse domains with different lexical-geographic distributions (Flatow et al., 2015; Dredze et al., 2016). Tasks that could benefit from our methods include social media placing tasks (Choi et al., 2014), inferring user location on Twitter (Zheng et al., 2017), geolocation of images based on descriptions (Serdyukov et al., 2009) and detecting/analyzing incidents from social media (Berlingerio et al., 2013). Future work may see our methods applied to *document* geolocation to assess the effectiveness of scaling geodesic vectors from paragraphs to entire documents.

Learning Prototypical Goal Activities for Locations

Tianyu Jiang and Ellen Riloff

{tianyu, riloff}@cs.utah.edu

Abstract

People go to different places to engage in activities that reflect their goals. For example, people go to restaurants to eat, libraries to study, and churches to pray. We refer to an activity that represents a common reason *why* people typically go to a location as a *prototypical goal activity (goal-act)*. Our research aims to learn goal-acts for specific locations using a text corpus and semi-supervised learning. First, we extract activities and locations that co-occur in goal-oriented syntactic patterns. Next, we create an *activity profile matrix* and apply a semi-supervised label propagation algorithm to iteratively revise the activity strengths for different locations using a small set of labeled data. We show that this approach outperforms several baseline methods when judged against goal-acts identified by human annotators.

1 Introduction

Every day, people go to different places to accomplish goals. People go to stores to buy clothing, go to restaurants to eat, and go to the doctor for medical services. People travel to specific destinations to enjoy the beach, go skiing, or see historical sites. For most places, people typically go there for a common set of reasons, which we will refer to as *prototypical goal activities (goal-acts)* for a location. For example, a prototypical goal-act for restaurants would be "*eat food*" and for IKEA would be "*buy furniture*".

Previous research has established that recognizing people's goals is essential for narrative text understanding and story comprehension (Schank and Abelson, 1977; Wilensky, 1978; Lehnert, 1981; Elson and McKeown, 2010; Goyal et al., 2013). Goals and plans are essential to understand people's behavior and we use our knowledge of prototypical goals to make inferences when reading. For example, consider the following pair of sentences: *"Mary went to the supermarket. She needed milk."* Most people will infer that Mary purchased milk, unless told otherwise. But a purchase event is not explicitly mentioned. In contrast, a similar sentence pair *"Mary went to the theatre. She needed milk."* feels incongruent and does not produce that inference. Recognizing goals is also critical for conversational dialogue systems. For example, if a friend tells you that they went to a restaurant, you might reply *"What did you eat?"*, but if a friend says that they went to Yosemite, a more appropriate response might be *"Did you hike?"* or *"Did you see the waterfalls?"*.

Our knowledge of prototypical goal activities also helps us resolve semantic ambiguity. For example, consider the following sentences:

(a) *She went to the kitchen and got chicken.*
(b) *She went to the supermarket and got chicken.*
(c) *She went to the restaurant and got chicken.*

In sentence (a), we infer that she retrieved chicken (e.g., from the refrigerator) but did not pay for it. In (b), we infer that she paid for the chicken but probably did not eat it at the supermarket. In (c), we infer that she ate the chicken at the restaurant. Note how the verb "*got*" maps to different presumed events depending on the location.

Our research aims to learn the prototypical goal-acts for locations using a text corpus. First, we extract activities that co-occur with locations in goal-oriented syntactic patterns. Next, we construct an *activity profile matrix* that consists of an activity vector (profile) for each of the locations. We then apply a semi-supervised label propagation algorithm to iteratively revise the activity profile strengths based on a small set of labeled locations.

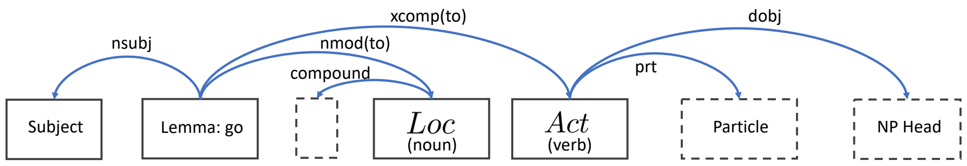

Figure 1: Dependency relation structure for "go to" pattern.

We also incorporate external resources to measure similarity between different activity expressions. Our results show that this semi-supervised learning approach outperforms several baseline methods in identifying the prototypical goal activities for locations.

2 Related Work

Recognizing plans and goals is fundamental to narrative story understanding (Schank and Abelson, 1977; Bower, 1982). Conceptual knowledge structures developed in prior work have shown the importance of this type of knowledge, including plans (Wilensky, 1978), goal trees (Carbonell, 1979), and plot units (Lehnert, 1981). Wilensky's research aimed to understand the actions of characters in stories by analyzing their goals, and their plans to accomplish those goals. For example, someone's goal might be to obtain food with a plan to go to a restaurant. Our work aims to learn prototypical goals associated with a location, to support similar inference capabilities during story understanding.

Goals and plans can also function to trigger *scripts* (Cullingford, 1978), such as the $RESTAURANT script. There has been growing interest in learning narrative event chains and script knowledge from large text corpora (e.g., (Chambers and Jurafsky, 2008, 2009; Jans et al., 2012; Pichotta and Mooney, 2014, 2016)). In addition, Goyal et al. (2010; 2013) developed a system to automatically produce plot unit representations for short stories. A manual analysis of their stories revealed that 61% of Positive/Negative Affect States originated from completed plans and goals, and 46% of Mental Affect States originated from explicitly stated or inferred plans and goals.

Elson & McKeown (2010) included plans and goals in their work on creating extensive story bank annotations that capture the knowledge needed to understand narrative structure. Researchers have also begun to explore NLP methods for recognizing the goals, desires, and plans of characters in stories. Recent work has explored techniques to detect wishes (desires) in natural language text (Goldberg et al., 2009) and identify desire fulfillment (Chaturvedi et al., 2016; Rahimtoroghi et al., 2017).

Graph-based semi-supervised learning has been successfully used for many tasks, including sentiment analysis (Rao and Ravichandran, 2009; Feng et al., 2013), affective event recognition (Ding and Riloff, 2016) and class-instance extraction (Talukdar and Pereira, 2010). The semi-supervised learning algorithm used in this paper is modeled after a framework developed by Zhu et al. (2003) based on harmonic energy minimization and a label propagation algorithm described in (Zhu and Ghahramani, 2002).

3 Learning Prototypical Goal Activities

Our aim is to learn the most prototypical goal-acts for locations. To tackle this problem, we first extract locations and related activities from a large text corpus. Then we use a semi-supervised learning method to identify the goal activities for individual locations. In the following sections we describe these processes in detail.

3.1 Location and Activity Extraction

To collect information about locations and activities, we use the 2011 Spinn3r dataset (Burton et al., 2011). Since our interest is learning about the activities of ordinary people in their daily lives, we use the Weblog subset of the Spinn3r corpus, which contains over 133 million blog posts.

We use the text data to identify activities that are potential goal-acts for a location. However we also need to identify locations and want to include both proper names (e.g., Disneyland) as well as nominals (e.g., store, beach), so Named Entity Recognition will not suffice. Consequently, we extract (Loc, Act) pairs using syntactic patterns.

First, we apply the Stanford dependency parser (Manning et al., 2014). We then extract sentences that match the pattern "go to X to Y" with the

	$a_1 =$ buy book	$a_2 =$ eat burger	...	$a_m =$ pray
$l_1 =$ McDonald's	.10	.30		.01
$l_2 =$ Burger King	.12	.50		.02
$l_3 =$ bookstore	.40	.02		.04
$\vdots$		$\vdots$		
$l_n =$ church	.05	.01		.70

Table 1: An illustration of the activity profile matrix Y.

following conditions: (1) there exists a subject connecting to "go", (2) X has an **nmod** (nominal modifier) relation to "go" (lemma), (3) X is a noun or noun compound, (4) Y has an **xcomp** relation (open clausal complement) with "go", and (5) Y is a verb. Figure 1 depicts the intended syntactic structure, which we will informally call the "go to" pattern. For sentences that match this pattern, we extract X as a location and Y as an activity. If the verb is followed by a particle and/or noun phrase (NP), then we also include the particle and head noun of the NP. For example, we extract activities such as "*pray*", "*clean up*", and "*buy sweater*".

This syntactic structure was chosen to identify activities that are described as being the reason why someone went to the location. However it is not perfect. In some cases, X is not a location (e.g., *"go to great lengths to ..."* yields "*lengths*" as a location), or Y is not a goal-act for X (e.g., *"go to the office to retrieve my briefcase ..."* yields "*retrieve briefcase*" which is not a prototypical goal for "*office*"). Interestingly, the pattern extracts some nominals that are not locations in a strict sense, but behave as locations. For example, *"go to the doctor"* extracts "*doctor*" as a location. Literally a doctor is a person, but in this context it really refers to the doctor's office, which is a location. The pattern also extracts entities such as "*roof*", which are not generally thought of as locations but do have a fixed physical location. Other extracted entities are virtual but function as locations, such as "*Internet*". For the purposes of this work, we use the term **location** in a general sense to include any place or object that has a physical, virtual or implied location.

The "go to" pattern worked quite well at extracting (Loc, Act) pairs, but in relatively small quantities due to the very specific nature of the syntactic structure. So we tried to find additional activities for those locations. Initially, we tried harvesting activities that occurred in close proximity (within 5 words) to a known location, but the results were too noisy. Instead, we used the pattern "Y in/at X" with the same syntactic constraints for Y (the extracted activity) and X (a location extracted by the "go to" pattern).

We discovered many sentences in the corpus that were exactly or nearly the same, differing only by a few words, which resulted in artificially high frequency counts for some (Loc, Act) pairs. So we filtered duplicate or near-duplicate sentences by computing the longest common substring of sentence pairs that extracted the same (Loc, Act). If the shared substring had length ≥ 5, then we discarded the "duplicate" sentence.

Finally, we applied three filters. To keep the size of the data manageable, we discarded locations and activities that were each extracted with frequency < 30 by our patterns. And we manually filtered locations that are Named Entities corresponding to cities or larger geo-political regions (e.g., provinces or countries). Large regions defined by government boundaries fall outside the scope of our task because the set of activities that typically occur in (say) a city or country is so broad. Finally, we added a filter to try to remove extremely general activities that can occur almost anywhere (e.g., visit). If an activity co-occurred with $> 20\%$ of the extracted (distinct) locations, then we discarded it.

After these filters, we extracted 451 distinct locations, 5143 distinct activities, roughly $200,000$ distinct (Loc, Act) pairs, and roughly $500,000$ instances of (Loc, Act) pairs.

3.2 Activity Profiles for Locations

We define an *activity profile matrix* Y of size $n \times m$, where n is the number of distinct locations and m is the number of distinct activities. $Y_{i,j}$ represents the strength of the jth activity a_j being a goal-act for l_i. We use $\mathbf{y}_i \in \mathbb{R}^m$ to denote the ith row of Y. Table 1 shows an illustration of (partial) activity profiles for four locations.[1] Our goal is

[1]Not actual values, for illustration only.

to learn the $Y_{i,j}$ values so that activities with high strength are truly goal-acts for location l_i.

We could build the activity profile for location l_i using the co-occurrence data extracted from the blog corpus. For example, we could estimate $P(a_j \mid l_i)$ directly from the frequency counts of the activities extracted for l_i. However, a high co-occurrence frequency doesn't necessarily mean that the activity represents a prototypical goal. For example, the activity *"have appointment"* frequently co-occurs with *"clinic"* but doesn't reveal the underlying reason for going to the clinic (e.g., probably to see a doctor or undergo a medical test). To appreciate the distinction, imagine that you asked a friend why she went to a health clinic, and she responded with "because I had an appointment". You would likely view her response as being snarky or evasive (i.e., she didn't want to tell you the reason). In Section 4, we will evaluate this approach as a baseline and show that it does not perform well.

3.3 Semi-Supervised Learning of Goal-Act Probabilities

Our aim is to learn the activity profiles for locations using a small amount of labeled data, so we frame this problem as a semi-supervised learning task. Given a small number of "seed" locations coupled with predefined goal-acts, we want to learn the goal-acts for new locations.

3.3.1 Location Similarity Graph

We use $l_i \in L$ to represent location l_i, where $|L| = n$. We define an undirected graph $G = (V, E)$ with vertices representing locations ($|V| = n$) and edges $E = V \times V$, such that each pair of vertices v_i and v_k is connected with an edge e_{ik} whose weight represents the similarity between l_i and l_k.

We can then represent the edge weights as an $n \times n$ symmetric weight matrix W indicating the similarity between locations. There could be many ways to define the weights, but for now we use the following definition from (Zhu et al., 2003), where σ^2 is a hyper-parameter[2]:

$$W_{i,k} = \exp\left(-\frac{1}{\sigma^2}\left(1 - sim\left(l_i, l_k\right)\right)\right) \quad (1)$$

To assess the similarity between locations, we measure the cosine similarity between vectors of their co-occurrence frequencies with activities. Specifically, let matrix $F_{n\times m} = [\mathbf{f}_1, ..., \mathbf{f}_n]^{\mathrm{T}}$ where $\mathbf{f}_i$ is a vector of length m capturing the co-occurrence frequencies between location l_i and each activity a_j in the extracted data (i.e., $F_{i,j}$ is the number of times that activity a_j occurred with location l_i). We then define location similarity as:

$$sim(l_i, l_k) = \frac{\mathbf{f}_i^{\mathrm{T}}\mathbf{f}_k}{\|\mathbf{f}_i\|\|\mathbf{f}_k\|} \quad (2)$$

3.3.2 Initializing Activity Profiles

We use semi-supervised learning with a set of "seed" locations from human annotations, and another set of locations that are unlabeled. So we subdivide the set of locations into $S = \{l_1, ..., l_s\}$, which are the seed locations, and $U = \{l_{s+1}, ..., l_{s+u}\}$, which are the unlabeled locations, such that $s + u = n$. For an unlabeled location $l_i \in U$, the initial activity profile is the normalized co-occurrence frequency vector $\overline{\mathbf{f}}_i$.

For each seed location $l_i \in S$, we first automatically construct an activity profile vector $\overline{\mathbf{h}}_i$ based on the gold goal-acts which were obtained from human annotators as described in Section 4.1. All activities not in the gold set are assigned a value of zero. Each activity a_j in the gold set is assigned a probability $P(a_j \mid l_i)$ based on the gold answers. However, the gold goal-acts may not match the activity phrases found in the corpus (see discussion in Section 4.3), so we smooth the vector created with the gold goal-acts by averaging it with the normalized co-occurrence frequency vector $\overline{\mathbf{f}}_i$ extracted from the corpus.

The activity profiles of seed locations stay constant through the learning process. We use $\mathbf{y}_i^0$ to denote the initial activity profiles. So when $l_i \in S$, $\mathbf{y}_i^0 = (\overline{\mathbf{f}}_i + \overline{\mathbf{h}}_i)/2$.

3.3.3 Learning Goal-Act Strengths

We apply a learning framework developed by (Zhu et al., 2003) based on harmonic energy minimization and extend it to multiple labels. Intuitively, we assume that similar locations should share similar activity profiles,[3] which motivates the following objective function over matrix Y:

$$\begin{gathered}\arg\min_{Y} \sum_{i,k} W_{i,k}\|\mathbf{y}_i - \mathbf{y}_k\|^2, \\ \text{s.t. } \mathbf{y}_i = \mathbf{y}_i^0 \text{ for each } l_i \in S\end{gathered} \quad (3)$$

Let $D = (d_i)$ denote an $n \times n$ diagonal matrix where $d_i = \sum_{k=1}^{n} W_{i,k}$. Let's split Y by the sth

[2]We use the same value $\sigma^2 = 0.03$ as (Zhu et al., 2003).

[3]This is a heuristic but is not always true.

row: $Y = \begin{bmatrix} Y_s \\ Y_u \end{bmatrix}$, then split W(similarly for D) into four blocks by the sth row and column:

$$W = \begin{bmatrix} W_{ss} & W_{su} \\ W_{us} & W_{uu} \end{bmatrix} \tag{4}$$

From (Zhu et al., 2003), Eq (3) is given by:

$$Y_u = (D_{uu} - W_{uu})^{-1} W_{us} Y_s \tag{5}$$

We then use the label propagation algorithm described in (Zhu and Ghahramani, 2002) to compute Y:

Algorithm 1

```
repeat
    $Y \leftarrow D^{-1}WY$
    Clamp $\mathbf{y}_i = \mathbf{y}_i^0$ for each $l_i \in S$
until convergence
```

3.3.4 Activity Similarity

One problem with the above algorithm is that it only takes advantage of relations between vertices (i.e., locations). If there are intrinsic relations between activities, they could be exploited as a complementary source of information to benefit the learning. Intuitively, different pairs of activities share different similarities, e.g., "*eat burgers*" should be more similar to "*have lunch*" than "*read books*".

Under this idea, similar to the previous location similarity weight matrix W, we want to define an activity similarity weight matrix $A_{m\times m}$ where $A_{i,k}$ indicates the similarity weight between activity a_i and a_k:

$$A_{i,k} = \exp\left(-\frac{1}{\sigma^2}\left(1 - sim\left(a_i, a_k\right)\right)\right) \tag{6}$$

where σ^2 is the same as in Eq (1).

We explore 3 different similarity functions $sim(a_i, a_k)$ based on co-occurrence with locations, word matching, and embedding similarities.

First, similar to Eq (2), we can use each activity's co-occurrence frequency with all locations as its location profile and define a similarity score based on cosine values of location profile vectors:

$$sim^L(a_i, a_k) = \frac{\mathbf{g}_i^{\mathrm{T}} \mathbf{g}_k}{\|\mathbf{g}_i\| \|\mathbf{g}_k\|} \tag{7}$$

where the predefined co-occurrence frequency matrix $F = [\mathbf{f}_1, ..., \mathbf{f}_n]^{\mathrm{T}} = [\mathbf{g}_1, ..., \mathbf{g}_m]$.

As a second option, the similarity between activities can often be implied by their lexical overlap, e.g., two activities sharing the same verb or noun might be related. For each word belonging to any of our activities, we use WordNet (Miller, 1995) to find its synonyms. We also include the word itself in the synonym set. If the synonym sets of two words overlap, we call these two words "**match**". Then we define the lexical overlap similarity function between a_i and a_k:

$$sim^O(a_i, a_k) = \begin{cases} 1 & \text{if verb and noun match} \\ 0.5 & \text{if verb or noun match} \\ 0 & \text{otherwise} \end{cases} \tag{8}$$

As a third option, we can use 300-dimension word embedding vectors (Pennington et al., 2014) trained on 840 billion tokens of web data to compute semantic similarity. We compute an activity's embedding as the average of its words' embeddings. Let $sim^E(a_i, a_k)$ be the cosine value between the embedding vectors of a_i and a_k:

$$sim^E(a_i, a_k) = cos\langle \text{Embed}(a_i), \text{Embed}(a_k)\rangle \tag{9}$$

Finally, we can plug these similarity functions into Eq (6). We use A^L, A^O, A^E to denote the corresponding matrix. We can also plug in multiple similarity metrics such as $(sim^L + sim^E)/2$ and use combination symbols A^{L+E} to denote the matrix.

3.3.5 Injecting Activity Similarity

Once we have a similarity matrix for activities, the next question is how will it help with the activity profile computation? Recall from Eq (5), we know that the activity profile of an unlabeled location can be represented by a linear combination of other locations' activity profiles. The activity profile matrix Y is an $n \times m$ matrix where each row is the activity profile for a location. We can also view Y as a matrix whose each column is the location profile for an activity. Using the same idea, we can make each column approximate a linear combination of its highly related columns (i.e., the location profile of an activity will become more similar to the location profiles of its similar activities). Our expectation is that this approximation will help improve the quality of Y.

By being right multiplied by matrix A, Y gets updated from manipulating its columns (activities) as well. We modify the algorithm accordingly as below:

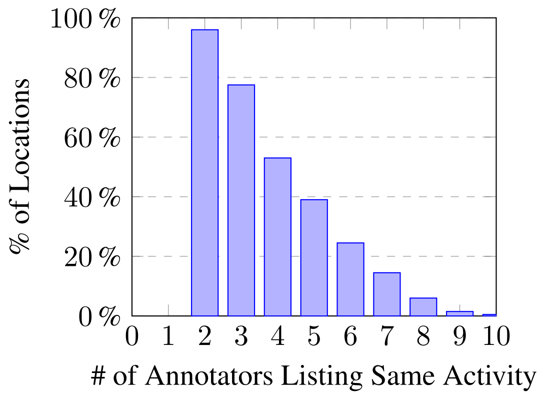

Figure 2: Percentage of locations that have at least one goal-act assigned by multiple annotators.

Algorithm 2

```
repeat
    $Y \leftarrow D^{-1}WYA$
    Clamp $\mathbf{y}_i = \mathbf{y}_i^0$ for each $l_i \in S$
until convergence
```

4 Evaluation

4.1 Gold Standard Data

Since this is a new task and there is no existing dataset for evaluation, we use crowd-sourcing via Amazon Mechanical Turk (AMT) to acquire gold standard data. First, we released a qualification test containing 15 locations along with detailed annotation guidelines. 25 AMT workers finished our assignment, and we chose 15 of them who did the best job following our guidelines to continue. We gave the 15 qualified workers 200 new locations, consisting of 152 nominals and 48 proper names,[4] randomly selected from our extracted data and set aside as test data. For each location, we asked the AMT workers to complete the following sentence:

People go to *LOC* to ______ ______
VERB NOUN

LOC was replaced by one of the 200 locations. Annotators were asked to provide an activity that is the primary reason why a person would go to that location, in the form of just a VERB or a VERB NOUN pair. Annotators also had the option to label a location as an "ERROR" if they felt that the provided term is not a location, since our location extraction was not perfect.

[4]Same distribution as in the whole location set.

Only 10 annotators finished labeling our test cases, so we used their answers as the gold standard. We discarded 12 locations that were labeled as an "ERROR" by ≥ 3 workers.[5] This resulted in a test set of 188 locations paired with 10 manually defined goal-acts for each one.

A key question that we wanted to investigate through this manual annotation effort is to know whether people truly do associate the same prototypical goal activities with locations. To what extent do people agree when asked to list goal-acts? Also, some places clearly have a smaller set of goal-acts than others. For example, the primary reason to go to an airport is to catch a flight, but there's a larger set of common reasons why people go to Yosemite (e.g.,"*hiking camping*", "*rock climbing*", "*see waterfalls*", etc.).

Complicating matters, the AMT workers often described the same activity with different words (e.g., "*buy book*" vs. "*purchase book*"). Automatically recognizing synonymous event phrases is a difficult NLP problem in its own right.[6] So solely for the purpose of analysis, we manually merged activities that have a nearly identical meaning. We were extremely conservative and did not merge similar or related phrases that were not synonymous because the granularity of terms may matter for this task (e.g., we did not merge "*eat burger*" and "*eat lunch*" because one may apply to a specific location while the other does not).

Figure 2 shows the results of our analysis. Only 1 location was assigned exactly the same goal-act by all 10 annotators. But at least half (5) of the annotators listed the same goal-act for 40% of the locations. And nearly 80% of locations had one or more goal-acts listed by ≥ 3 people. These results show that people often do share the same associations between prototypical goal-acts and locations. These results are also very conservative because many different answers were also similar (e.g. "*eat burger*", "*eat meal*").

In Table 2 we show examples of locations and the goal-acts listed for them by the human annotators. If multiple people gave the same answer, we show the number in parentheses. For example, given the location "Toys R Us", 9 people listed "*buy toys*" as a goal-act and 1 person listed "*browse gifts*". We see from Table 2 that

[5]We found that the workers rarely used the "ERROR" label, so setting this threshold to be 3 was a strong signal.

[6]We tried using WordNet synsets to conflate phrases, but it didn't help much.

Location	Gold Goal-Acts
Toys R Us	buy toys (9), browse gifts
sink	wash hands (7), wash dishes (3)
airport	catch flight (7), board planes, take airplane, take trips
bookstore	buy books (6), browse books (2), browse bestsellers, read book
lake	go fishing (3), go swimming (3), drive boat (2), ride boat, see scenery
chiropractor	get treatment (3), adjust backs (3), alleviate pain (2), get adjustment, get aligned
Chinatown	buy goods (2), buy duck, buy souvenirs, eat dim sum, eat rice, eat wontons, find Chinese, speak Chinese, visit restaurants

Table 2: Goal-acts provided by human annotators.

some locations yield very similar sets of goal-acts (e.g., sink, airport, bookstore), while other locations show more diversity (e.g., lake, chiropractor, Chinatown).

4.2 Baselines

To assess the difficulty of this NLP task, we created 3 baseline systems for comparison with our learning approach. All of these methods take the list of activities that co-occurred with a location l_i in our extracted data and rank them.

The first baseline, **FREQ**, ranks the activities based on the co-occurrence frequency $F_{i,j}$ between l_i and a_j in our patterns. The second baseline, **PMI**, ranks the activities using point-wise mutual information. The third baseline, **EMBED**, ranks the activities based on the cosine similarity of the semantic embedding vectors for l_i and a_j. We use GloVe (Pennington et al., 2014) 300-dimension embedding vectors pre-trained on 840 billion tokens of web data. For locations and activities with multiple words, we create an embedding by averaging the vectors of their constituent words.

4.3 Matching Activities

The gold standard contains a set of goal-acts for each location. Since the same activity can be expressed with many different phrases, the only way to truly know whether two phrases refer to the same activity is manual evaluation, which is expensive. Furthermore, many activities are very similar or highly related, but not exactly the same. For example, "*eat burger*" and "*eat food*" both describe eating activities, but the latter is more general than the former. Considering them to be the same is not always warranted (e.g., "*eat burger*" is a logical goal-act for McDonald's but not for Baskin-Robbins which primarily sells ice cream). As another example, "*buy chicken*" and "*eat chicken*" refer to different events (buying and eating) so they are clearly not the same semantically. But at a place like KFC, buying chicken implies eating chicken, and vice versa, so they seem like equally good answers as goal-acts for KFC. Due to the complexities of determining which gold standard answers belong in equivalence classes, we considered all of the goal-acts provided by the human annotators to be acceptable answers.

	MRR_E	MRR_P	TOP1	TOP2	TOP3
EMBED	0.02	0.09	0.05	0.08	0.12
PMI	0.20	0.33	0.25	0.36	0.41
FREQ	0.23	0.34	0.23	0.32	0.40
AP	0.28	0.38	0.29	0.41	0.47
AP+A^L	0.28	0.40	0.32	**0.44**	0.49
AP+A^O	0.23	0.33	0.24	0.35	0.43
AP+A^E	0.25	0.36	0.28	0.40	0.47
AP+A^{L+E}	**0.29**	**0.42**	**0.35**	**0.44**	**0.52**

Table 3: Scores for MRR and Top k results.

To determine whether an activity a_j produced by our system matches any of the gold goal-acts for a location l_i, we report results using two types of matching criteria. **Exact Match** judges a_j to be a correct answer for l_i if (1) it exactly matches (after lemmatization) any activity in l_i's gold set, or (2) a_j's *verb* and *noun* both appear in l_i's gold set, though possibly in different phrases. For example, if a gold set contains "*buy novels*" and "*browse books*", then "*buy books*" will be a match.

Since Exact Match is very conservative, we also define a **Partial Match** criterion to give 50% credit for answers that partially overlap with a gold answer. An activity a_j is a partial match for l_i if either its *verb* or *noun* matches any of the activities in l_i's gold set of goal-acts. For example, "*buy burger*" would be a partial match with "*buy food*" because their verbs match.

4.4 Evaluation Metrics

All of our methods produce a ranked list of hypothesized goal-acts for a location. So we use Mean Reciprocal Rank (MRR) to judge the quality of the top 10 activities in each ranked list. We report two types of MRR scores.

MRR based on the Exact Match criteria (MRR_E) is computed as follows, where n is the number of locations in the test set:

$$\text{MRR}_\text{E} = \frac{1}{n}\sum_{i=1}^{n} \frac{1}{\text{rank of } 1^{st} \text{ Exact Match}} \tag{10}$$

We also compute MRR using both the Exact Match and Partial Match criteria. First, we need to identify the "best" answer among the 10 activities in the ranked list, which depends both on each activity's ranking and its matching score. The matching score for activity a_j is defined as:

$$\text{score}(a_j) = \begin{cases} 1 & \text{if } a_j \text{ is an Exact Match} \\ 0.5 & \text{if } a_j \text{ is a Partial Match} \\ 0 & \text{otherwise} \end{cases}$$

Given 10 ranked activities a_1 ... a_{10} for l_i, we then compute:

$$\text{best\_score}(l_i) = \max_{j=1..10} \frac{\text{score}(a_j)}{\text{rank}(a_j)}$$

And then finally define MRR_P as follows:

$$\text{MRR}_\text{P} = \frac{1}{n}\sum_{i=1}^{n} \text{best\_score}(l_i) \tag{11}$$

4.5 Experimental Results

Unless otherwise noted, all of our experiments report results using 4-fold cross-validation on the 200 locations in our test set. We used 4 folds to ensure 50 seed locations for each run (i.e., 1 fold for training and 3 folds for testing).

The first two columns of Table 3 show the MRR results under Exact Match and Partial Match conditions. The first 3 rows show the results for the baseline systems, and the remaining rows show results for our Activity Profile (AP) semi-supervised learning method. We show results for 5 variations of the algorithm: **AP** uses Algorithm 1, and the others use Algorithm 2 with different Activity Similarity measures: **AP+A$^\mathbf{L}$** (location profile similarity), **AP+A$^\mathbf{O}$** (overlap similarity), **AP+A$^\mathbf{E}$** (embedding similarity), and **AP+A$^\mathbf{L+E}$** (location profiles plus embeddings).

Table 3 shows that our AP algorithm outperforms all 3 baseline methods. When adding Activity Similarity into the algorithm, we find that A^L slightly improves performance, but A^O and A^E do not. However, we also tried combining them and obtained improved results by using A^L and A^E together, yielding an MRR_P score of 0.42.

To gain more insight about the behavior of the models, Table 3 also shows results for the top-ranked 1, 2, and 3 answers. For these experiments, the system gets full credit if any of its top k answers exactly matches the gold standard, or 50% credit if a partial match is among its top k answers. These results show that our AP method produces more correct answers at the top of the list than the baseline methods.

Table 4 shows six locations with their gold answers and the Top 3 goal-acts hypothesized by our best AP system and the PMI and FREQ baselines. The activities in **boldface** were deemed correct (including Partial Match). For "bookstore" and "pharmacy", all of the methods perform well. Note the challenge of recognizing that different phrases mean essentially the same thing (e.g., "*fill prescription*", "*pick up prescription*", "*find medicine*"). For "university" and "Meijer", the AP method produces more appropriate answers than the baseline methods. For "market" and "phone", all three methods struggle to produce good answers. Since "market" is polysemous, we see activities related to both stores and financial markets. And "phone" arguably is not a location at all, but most human annotators treated it as a virtual location, listing goal-acts related to telephones. However our algorithm considered phones to be similar to computers, which makes sense for today's smartphones. In general, we also observed that Internet sites behave as virtual locations in language (e.g., "*I went to YouTube...*").

4.6 Discussion

The goal-acts learned by our system were extracted from the Spinn3r dataset, while the gold standard answers were provided by human annotators, so the same (or very similar) activities are often expressed in different ways (see Section 4.3). This raises the question: what is the upper bound on system performance when evaluating against human-provided goal-acts? To answer this, we compared all of the activities that co-occurred with each location in the corpus against its gold goal-acts. Only 36% of locations had at least one gold goal-act among its extracted activities when matching identical strings (after lemmatization). Because of this issue, our Exact Match criteria also allowed for combining verbs and nouns from different gold answers. Under this Exact Match criteria, 73% of locations had at least one gold goal-act

Location	Gold Activity List	AP+A^{L+E} Top 3	PMI Top 3	FREQ Top 3
bookstore	buy book (6) browse book (2) browse bestseller read book	**buy book** **purchase book** **see book**	**buy copy** **purchase book** **buy book**	**buy book** **browse** **find book**
pharmacy	get drug (4) fill prescription (3) get prescription (2) buy medicine	**find medicine** **get prescription** **pick up prescription**	**buy pill** **fill prescription** **pick up prescription**	**buy pill** **fill prescription** **pick up prescription**
university	get degree (4) gain education (5) watch sport	**gain education** **further education** **gain knowledge**	study law study psychology pursue study	enrol[7] enroll take class
Meijer	buy grocery (8) buy cream obtain grocery	**buy item** go shopping get item	check out deal have shopping post today	get item save money check out
market	buy grocery (6) buy fresh, buy goods buy shirt, find produce	make money eat out eat lunch	have demand increase competition lead player	trade intervene make money
phone	make call (4), ERROR (2) answer call, call friend have conversation stop ring	play game browse website view website	put number have number put card	plug glance have number

Table 4: Examples of Top 3 hypothesized prototypical goal activities.

among the extracted activities, so this represents an upper bound on performance using this metric. Under the Partial Match criteria, 98% of locations had at least one gold goal-act among the extracted activities, but only 50% credit was awarded for these cases so the maximum score possible would be ∼86%.

We also manually inspected 200 gold locations to analyze their types. We discovered some related groups, but substantial diversity overall. The largest group contains ∼20% of the locations, which are many kinds of stores (e.g., Ikea, WalMart, Apple store, shoe store). Even within a group, different locations often have quite different sets of co-occurring activities. In fact, we discovered some spelling variants (e.g., "WalMart" and "wal mart"), but they also have substantially different activity vectors (e.g., because one spelling is much more frequent), so the model learns about them independently.[8] Other groups include restaurants (∼5%), home-related (e.g., bathroom) (∼5%), education (∼5%), virtual (e.g., Wikipedia) (∼3%), medical (∼3%) and landscape (e.g., hill) (∼3%). It is worth noting that our locations were extracted by two syntactic patterns and it remains to be seen if this has brought in any bias — detecting location nouns (especially nominals) is a challenging problem in its own right.

5 Conclusions and Future Work

We introduced the problem of learning prototypical goal activities for locations. We obtained human annotations and showed that people do associate prototypical goal-acts with locations. We then created an activity profile framework and applied a semi-supervised label propagation algorithm to iteratively update the activity strengths for locations. We demonstrated that our learning algorithm identifies goal-acts for locations more accurately than several baseline methods.

However, this problem is far from solved. Challenges also remain in how to evaluate the accuracy of goal knowledge extracted from text corpora. Nevertheless, our work represents a first step toward learning goal knowledge about locations, and we believe that learning knowledge about plans and goals is an important direction for natural language understanding research. In future work, we hope to see if we can take advantage of more contextual information as well as other external knowledge to improve the recognition of goal-acts.

Acknowledgments

We are grateful to Haibo Ding for valuable comments on preliminary versions of this work.

[7]A lemmatization error for the verb "enrolled".

[8]Of course normalizing location names beforehand may be beneficial in future work.

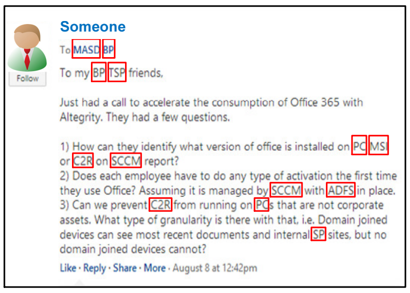
Abstract

Acronyms are abbreviations formed from the initial components of words or phrases. In enterprises, people often use acronyms to make communications more efficient. However, acronyms could be difficult to understand for people who are not familiar with the subject matter (new employees, etc.), thereby affecting productivity. To alleviate such troubles, we study how to automatically resolve the true meanings of acronyms in a given context. Acronym disambiguation for enterprises is challenging for several reasons. First, acronyms may be highly ambiguous since an acronym used in the enterprise could have multiple internal and external meanings. Second, there are usually no comprehensive knowledge bases such as Wikipedia available in enterprises. Finally, the system should be generic to work for any enterprise. In this work we propose an end-to-end framework to tackle all these challenges. The framework takes the enterprise corpus as input and produces a high-quality acronym disambiguation system as output. Our disambiguation models are trained via distant supervised learning, without requiring any manually labeled training examples. Therefore, our proposed framework can be deployed to any enterprise to support high-quality acronym disambiguation. Experimental results on real world data justified the effectiveness of our system.

1 Introduction

Acronyms are abbreviations formed from the initial components of words or phrases (e.g., "AI" from "Artificial Intelligence"). As acronyms can shorten long names and make communications more efficient, they are widely used at almost everywhere in enterprises, including notifications, emails, reports and social network posts. Figure 1 shows a sample enterprise social network post. As we can see, acronyms are frequently used there.



Someone
To MASD BP
To my BP TSP friends,

Just had a call to accelerate the consumption of Office 365 with Altegrity. They had a few questions.

1) How can they identify what version of office is installed on PC MSI or C2R on SCCM report?
2) Does each employee have to do any type of activation the first time they use Office? Assuming it is managed by SCCM with ADFS in place.
3) Can we prevent C2R from running on PCs that are not corporate assets. What type of granularity is there with that, i.e. Domain joined devices can see most recent documents and internal SP sites, but no domain joined devices cannot?

Figure 1: Acronyms in Enterprises

Despite the fact that acronyms can make communications more efficient, sometimes they could be difficult to understand, especially for people who are not familiar with the specific areas, such as new employees and patent lawyers. We randomly sampled 1000 documents from a Microsoft question answering forum and found out that only **7%** of the acronyms co-occur with the corresponding meanings in the same document, which means **93%** of the time when the user does not understand an acronym, she will need to find clues outside of the document. Therefore, it is particularly useful to develop a system that can automatically resolve the true meanings of acronyms in enterprise documents. Such system could be run online as a querying tool to handle any adhoc document, or run offline to annotate acronyms with their true meanings in a large corpus. In the offline mode, the true meanings can be further indexed by an enterprise search engine, so that when users search for the true meaning, documents containing the acronym can also be found.

The enterprise acronym disambiguation task is challenging due to the high ambiguity of acronyms, e.g., "SP" could stand for "Service Pack", "SharePoint" or "Surface Pro" in Microsoft. And there is one additional challenge compared with previous disambiguation tasks: in an enterprise document, an acronym could refer

[*]Work done while authors were at Microsoft Research.

to either an internal meaning (concepts created by the enterprise that may or may not be found outside) or an external meaning (all concepts that are not internal). For example, regarding the acronym "AI", "Asset Intelligence" is an internal meaning mainly used only in Microsoft, while "Artificial Intelligence" is an external meaning widely used in public. A good acronym disambiguation system should be able to handle both internal and external meanings. As we will explain in details, it is important to make such distinction and different strategies are needed for such two cases.

For internal meanings, there are some previous work on word sense disambiguation (Navigli, 2009) and acronym disambiguation (Feng et al., 2009; Pakhomov et al., 2005; Pustejovsky et al., 2001; Stevenson et al., 2009; Yu et al., 2006) on a closed-domain corpus. The main challenge here is that there are rarely any domain-specific knowledge bases available in enterprises, therefore all the signals for disambiguation (including potential meanings, and their popularity scores, context representations, etc.) need to be mined from plain text. Training data should also be automatically generated to make the system easily scale out to all enterprises. Compared with previous work, we developed a more comprehensive and advanced set of features in the disambiguation model, and also used a much less restrictive way to discover meaning candidates and training data, so that both precision and recall can be improved. Moreover, one main limitation of all previous work is that they do not distinguish internal and external meanings. They merely rely on the enterprise corpus to discover information about external meanings, which we observe is quite ineffective. The reason is that for popular external meaning like "Artificial Intelligence", people often directly use its acronym in enterprises without explanation, therefore there is limited information about the connection between the acronym and the external meaning in the enterprise corpus. On the other hand, there are much more such information available in the public domain, which should be leveraged by the system.

If we consider utilizing a public knowledge base such as Wikipedia to better handle external meanings of acronyms, the problem becomes very related to the well studied Entity Linking (Ji and Grishman, 2011; Cucerzan, 2007; Dredze et al., 2010; Hoffart et al., 2011; Li et al., 2013, 2016; Ratinov et al., 2011; Shen et al., 2012) problem, which is to map entity mentions in texts to their corresponding entities in a reference knowledge base (e.g. Wikipedia). But our disambiguation task is different from the entity linking task, because the system also needs to handle internal meanings which are not covered by any knowledge bases, and ultimately needs to decide whether an acronym refers to an internal meaning or an external meaning. It is nontrivial to combine the information mined from the enterprise corpus and the public knowledge base so that the system can get the best of both worlds. For instance, we have tried to run an internal disambiguator (leveraging information mined from enterprise corpus) and then resort to a public entity linking system if the internal one's confidence is low, but the performance is very poor. Even for external meanings, it is important to leverage signals from the enterprise corpus since the context surrounding them could be quite different from that in the external world, and context is one of the most important factor for disambiguation. For example, in public world, when people mention "Operating System" they mainly talk about how to install or use it; while within Microsoft, when people mention "Operating System" most of the time they focus on how to design or implement it.

In this work, we design a novel, end-to-end framework to address all the above challenges. Our framework takes the enterprise corpus and certain public knowledge base as input and produces a high-quality acronym disambiguation system as output. The models are all trained via distant supervised learning, therefore our system requires no manually labeled training examples and can be easily deployed to any enterprises.

2 Problem Statement

The *Enterprise Acronym Disambiguation* problem is comprised of two sub-problems. The first one is *Acronym Meaning Mining* (Adar, 2004; Ao and Takagi, 2005; Park and Byrd, 2001; Schwartz and Hearst, 2002; Jain et al., 2007; Larkey et al., 2000; Nadeau and Turney, 2005; Taneva et al., 2013), which aims at mining acronym/meaning pairs from the enterprise corpus. Each meaning m should contain the full name expansion e, popularity score p (indicating how often m is used as the genuine meaning of acronym a) and context words W (i.e. words frequently used in context of the meaning). The popularity score and context words can provide critical information for making disambiguation decisions. The second one is *Meaning Candidate Ranking*, whose goal is to rank the candidate meanings associated with the target acronym a and select the genuine meaning m based on the given context.

In this paper we assume the acronyms for disambiguation are provided as input to the system, either by the user or by an existing acronym detection module. We do not try to optimize the performance of acronym detection (e.g. identifying acronyms beyond the simple capitalized rule, or distinguishing cases where a capitalized term is not an acronym but a regular English word, such as "OK"). The task of acronym detection is also interesting and important. But due to the space limit, it is beyond the scope of this paper.

3 Framework

We propose a novel end-to-end framework to solve the *Enterprise Acronym Disambiguation* problem. Our framework takes the enterprise corpus as input and produces a high-quality acronym disambiguation system as output. Figure 2 shows the details of our proposed framework. In the mining module, we will sequentially perform Candidates Generation, Popularity Calculation, Candidates Deduplication and Context Harvesting on the input enterprise corpus. The details of these steps will be discussed in Section 4. After mining steps, we will get an acronym/meaning repository storing all the mined acronym/meaning pairs. Feed this repository together with the training data (automatically generated via distant supervision from the enterprise corpus) to the training module, we will get a candidate ranking model, a confidence estimation model and a final selection model. These models form the final acronym disambiguator and will be used in the testing module for actual acronym disambiguation. In the testing module, given the target acronym along with some context as input, the system will output the predicted meaning. Note that the mining and training module run offline once for the entire corpus or periodically when the corpus update, while the testing can be run online repeatedly for processing new documents.

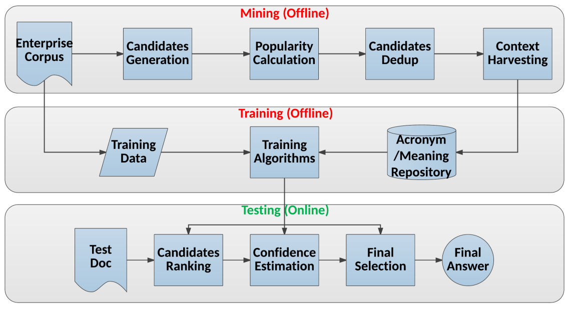


Figure 2: Framework

4 Acronym Meaning Mining

4.1 Candidates Generation

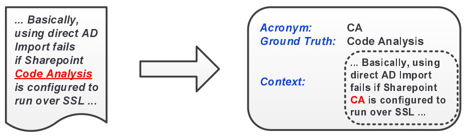
As there is no reference dictionary or knowledge base available in enterprise telling us the potential meanings of acronyms, we have to extract them from plain text. We propose a strategy called *Hybrid Generation* to balance extraction accuracy and coverage. Namely, we treat a phrase as a meaning candidate for an acronym if: (1) the initial letters of the phrase match the acronym **and** the phrase and the acronym co-occur in at least one document in the enterprise corpus; **or** (2) it is a valid candidate for the acronym in public knowledge bases (e.g. Wikipedia). The insight of this strategy is that the valid candidates missed by condition (1) are mainly public meanings which can be found in public knowledge bases. With this strategy we can make our system understand both the internal world and the external world.

4.2 Popularity Calculation

As mentioned in Section 2, for each candidate meaning, we need to calculate its popularity score, which reveals how often the candidate meaning is used as the genuine meaning of the acronym. In previous research on *Entity Linking*, popularity is calculated as the fraction of times a candidate being the target page for an anchor text in a reference knowledge base (e.g. Wikipedia). However, in enterprises, we do not have a knowledge base with anchor links. Thus we cannot calculate popularity in the same way. Here we propose to calculate two types of popularity to mimic the effect.

1. *Marginal Popularity*.
$$MP(m_i) = \frac{Count(m_i)}{\sum_{j=1}^{n} Count(m_j)}, \quad (1)$$
where $m_1, m_2, \ldots, m_n$ are the meaning candidates of acronym a and $Count(m_i)$ is the number of occurrences for m_i in the corpus.

2. *Conditional Popularity*.
$$CP(m_i) = \frac{Count(m_i, a)}{\sum_{j=1}^{n} Count(m_j, a)}, \quad (2)$$
where $m_1, m_2, \ldots, m_n$ are the meaning candidates of acronym a and $Count(m_i, a)$ is the number of document-level co-occurrences for m_i and a in the corpus.



... Basically, using direct AD Import fails if Sharepoint Code Analysis is configured to run over SSL ...
Acronym:
CA
Ground Truth:
Code Analysis
Context:
... Basically, using direct AD Import fails if Sharepoint CA is configured to run over SSL ...

Figure 3: Distant Supervision Example

Conditional Popularity can more reasonably reveal how often the acronym is used to represent each meaning candidate. However, due to the data sparsity issue in enterprises, many valid candidates may get zero value for conditional popularity since they may never co-occur with the acronyms in the enterprise corpus. The Marginal Popularity does not have this problem since it is calculated from the raw counts of the candidates. Yet on the other hand, high marginal popularity score does not necessarily indicate high correlation between the candidate and the acronym. It is unclear how to combine the two scores into one popularity score, so we use both of them as features in the disambiguation model.

4.3 Candidates Deduplication

In enterprises, people often create many variants (including abbreviations, plurals or even misspellings) for the same meaning, therefore many mined meaning candidates are actually equivalent. For example, for the meaning "Certificate Authority" of the acronym "CA", the variants include "Cert Auth", "Certificate Authorities" and many others. It is important to deduplicate these variants before sending them to the disambiguation module. The deduplication helps aggregate disambiguation evidences and reduce noises. We design several heuristic rules[1] to perform the deduplication. Experiments show that the rules can accurately group the variants together. After grouping, we sort the variants within the same group based on their marginal popularity. The candidate with the largest marginal popularity is selected as the canonical candidate for the group. Other variants in the group will be deleted from the candidate list and their popularity scores will be aggregated to the canonical candidate. We maintain a table to record the variants for each canonical candidate.

4.4 Context Harvesting

In this step, we aim to harvest context words for each meaning candidate. These context words could be used to calculate context similarity with the query context. For each meaning candidate m, we put its canonical form and all its variants (from the variants table in Section 4.3) into set S. Then we scan the enterprise corpus, each time we find a match of any $e \in S$, we harvest the words in a width-W word window surrounding e as the context words of m. In our experiments we set window size as 30 after trying to vary the window size from 10 to 50 and finding 30 gives the best result.

As mentioned before, some popular public meanings might be mentioned very rarely by their full names in the enterprise corpus since people directly use their acronyms most of the time. Therefore, the above context harvesting process can only get very few context words for those public meanings. To alleviate this, for each public meaning we add its Wikipedia page's content as complementary context. By doing so, we ensure almost all valid candidates get a reasonable amount of context words.

5 Meaning Candidate Ranking

5.1 Candidate Ranking

We first train a candidate ranking model to rank candidates with respect to the likelihood of being the genuine meaning for the target acronym.

5.1.1 Training Data Generation

In order to train a robust ranking model, we need to get adequate amount of labeled training data. Manually labeling is obviously too expensive and it requires a lot of domain knowledge, which severely limits our framework's generalization capability. To tackle this problem, we propose to automatically generate training data via distant supervision. The intuition is that since acronyms and the corresponding meanings are semantically equivalent, people use them interchangeably in enterprises. Therefore we can fetch documents containing the meaning, replace the meaning with the corresponding acronym and treat the meaning as ground truth. Figure 3 shows an example of this automatic training data generation process.

5.1.2 Training Algorithm

Any learning-to-rank algorithms can be used here. In our system we utilize the LambdaMART algorithm (Burges, 2010) to train the model.

[1]Due to space limitations, the detailed rules are omitted. Example rules are "word overlap percentage after stemming > 0.8", "corresponding component words share same prefix".

5.1.3 Features

Now we explain the features we developed for the candidate ranking model. First, we have the *Marginal Popularity* score and *Conditional Popularity* score as two context-independent features, which could compensate for each other. However, as discussed in the previous section, some popular public meanings (e.g., "Artificial Intelligence") can be rarely mentioned in enterprise corpus by their full names, therefore both their marginal popularity score and conditional popularity score can be very low. To address this, we add a third feature called *Wiki Popularity*, which is calculated from Wikipedia anchor texts to capture how often an acronym refers to a public meaning in Wikipedia. The fourth feature we adopt is *Context Similarity*. We convert the harvested context for the meaning and the query context of the target acronym into TFIDF vectors and then compute their cosine similarity[2]. We also include two features (i.e. *LeftNeighborScore* and *RightNeighborScore*) to capture the effect of the immediate neighboring words, which are more important than further context words since immediate words could form phrases with the acronym. For example, if we see an acronym "SP" followed by the word "2", then likely it stands for "Service Pack". However, if we see "SP" followed by "2003", then probably its genuine meaning is "SharePoint". The last feature we use is *FullNamePercentage*. This feature is defined as the percentage of the meaning candidate's component words appearing in the context of the target acronym. Table 1 summarizes the features used to train the candidate ranking model.

5.2 Confidence Estimation

After getting the ranking results, we propose to apply a confidence estimation step to decide whether to trust the top ranked answer. There are two motivations behind. First, our candidate generation approach is not perfect, therefore we could encounter cases in which the genuine meaning is not in our candidates. For such cases, the top ranked answer is obviously incorrect. Second, our training data is biased towards the internal meanings since external meanings may rarely appear with full names. As a result, the learned ranking model may lack the capability to properly rank the external meanings. In such cases, we would better have the system return nothing rather than directly provide a wrong answer to mislead the user. In this step, we train a confidence estimation model, which will estimate the top result's confidence.

[2]One popular alternative to measure context similarity is using word embeddings (Mikolov et al., 2013; Li et al., 2015). In our system we experimented replacing TFIDF cosine similarity with word embedding similarity, or adding word embedding similarity as an additional feature, but both hurt the disambiguation accuracy. So we only included the TFIDF cosine similarity as the context similarity feature in our system.

5.2.1 Training Data Generation

Similar to the ranker training, here the training data is also automatically generated. We run the learned ranker on some distant labeled data (generated from a different corpus), and then check if the top ranked answer is correct or not. If it is correct, we generate a positive training example; otherwise we make a negative training example.

5.2.2 Training Algorithm

Any classification algorithms can be used here. In our system we utilize the MART boosted tree algorithm (Friedman, 2000) to train the model.

5.2.3 Features

We design 7 features (summarized in Table 2) to train the confidence estimation model. There are two intuitions behind: (1) If the top-ranked answer's ranking score is very small, or the top-ranked answer's score is close to the second-ranked answer's score, then the ranking is not very confident; (2) If the acronym has a dominating candidate in the public domain (e.g., "Personal Computer" is the dominating candidate for "PC"), and the candidates' Wiki popularity distribution is significantly different from their marginal/conditional popularity distributions, then the ranker's output is not very confident. The first intuition covers the first 3 features, while the second intuition covers the last 4 features.

5.3 Final Selection

We have discussed that one particular motivation for confidence estimation is that the candidate ranking stage has some bias so it does not always rank public meanings at top when they are correct. Therefore, assuming the confidence estimation model can remove incorrect top-ranked result, we still need one additional step to decide if any public meaning is correct, which we call a final selection model. In this step, we determine whether to return the most popular public meaning (based on Wiki Popularity) as the final answer, and this step is only triggered when the confidence estimator judges that the ranking result is unconfident.

Feature	Description
MarginalPopularity	The meaning candidate's marginal popularity score
ConditionalPopularity	The meaning candidate's conditional popularity score
WikiPopularity	The meaning candidate's Wiki popularity score
ContextSimilarity	TFIDF cosine similarity between meaning context and acronym context
LeftNeighborScore	Probability of acronym and meaning sharing the same immediate left word
RightNeighborScore	Probability of acronym and meaning sharing the same immediate right word
FullNamePercentage	Percentage of meaning candidate's component words appearing in acronym context

Table 1: Candidate Ranking Features

Feature	Description
Top1Score	Top 1 ranked meaning candidate's ranking score
Top1&2ScoreDiff	Difference between 1st and 2nd ranked meaning candidates' ranking score
Top1&2CtxSimDiff	Difference between 1st and 2nd ranked meaning candidates' context similarity score
Top1WikiPopularity	Top 1 ranked meaning candidate's Wiki popularity score
MaxWikiPopularity	Max Wiki popularity score among all the meaning candidates
MaxWP&MPGap	Max gap between Wiki and marginal popularity among all the meaning candidates
MaxWP&CPGap	Max gap between Wiki and conditional popularity among all the meaning candidates

Table 2: Confidence Estimation Features

The goal of the final selection model is similar to that of the confidence estimation model. In confidence estimation, we judge whether the top-ranked answer is correct; while in final selection, we check whether the most popular external meaning is correct. Thanks to this similarity, we can reuse the data, features and training algorithm in confidence estimation model. We take the same training data in Section 5.2.1 and update the labels correspondingly: if the genuine answer is the most popular external meaning, we generate a positive example; otherwise we make a negative one.

6 Experiments

6.1 Data

6.1.1 Mining and Training Corpus

We use both the Microsoft Answer Corpus (MAC) and the Microsoft Yammer Corpus (MYC) as the mining corpus. These corpus are kindly shared to us by Microsoft for research purpose. MAC contains 0.3 million web pages from a Microsoft internal question answering forum. MYC is consisted of 6.8 million posts from Microsoft's Yammer social network. In total, our mining module harvested 5287 acronyms and 17258 meaning candidates from this joint corpus.

For model training, the confidence estimation model and final selection model need to be trained on a different corpus than the candidate ranking model. So we train the candidate ranking model on MAC, with 12500 training examples being automatically generated; and train the confidence estimation and final selection model on MYC, with 40000 training instances being generated.

6.1.2 Evaluation Datasets

We prepared four datasets[3] for evaluation purposes. The first one ***Manual*** is obtained from the recent pages of Microsoft answer forum. Note these pages are disjoint from those used as mining/training corpus. We randomly sampled 300 pages and filtered out pages which do not contain ambiguous acronyms. After filtering, 240 test cases were left and we manually labeled them.

The second one ***Distant*** is generated via distant labeling on Microsoft Office365 documents. We sampled 2000 documents which contain at least one occurrence of a meaning candidate. Then we replaced the meanings with the corresponding acronyms and treat the meanings as ground truths. We manually checked through this dataset to remove some bad cases (e.g., "AS" for "App Store"). This resulted in a test set of 1949 test cases.

Comparing the ***Manual*** dataset with the ***Distant*** dataset, the ***Manual*** one, though in smaller size, can more accurately evaluate the system performance, since the target acronyms in it are sampled from the real distribution, while in the ***Distant*** dataset acronyms are artificially generated from

[3]Due to data confidentiality issue, we were unable to directly release these datasets.

randomly sampled meanings.

We also want to compare our method with the state-of-the-art Entity Linking (EL) systems based on public knowledge bases such as Wikipedia. However, it is unfair to directly compare as most enterprise specific meanings are unknown to them. Therefore, we need to only consider cases where the true meaning is a public meaning covered by both our system and the compared system. By filtering the distant dataset from Office365, we get the third dataset ***JoinW*** (1659 test cases) for comparing with the Wikifier (Ratinov et al., 2011), and the fourth dataset ***JoinA*** (237 test cases) for comparing with AIDA (Hoffart et al., 2011).

6.2 Compared Methods

6.2.1 Ablations of Our System

We compare the following ablations of our system, to illustrate the effectiveness of the features and components.

- **Internal Popularity (IP)**: Only the internal popularity features (i.e., marginal popularity and conditional popularity).
- **Popularity (P)**: The internal popularity features plus Wiki popularity features.
- **Popularity+Context (P+C)**: The popularity features plus context similarity feature.
- **Popularity+Context+Neighbbor (P+C+N)**: The popularity features, context similarity feature and immediate neighbor features.
- **Popularity+ Context+ Neighbbor+ Fullname (a.k.a. Candidate Ranker, or CR)**: Using all the features in candidate ranking module.
- **Candidate Ranker + Confidence Estimator (CR+ CE)**: Using the candidate ranking model plus the confidence estimation model.
- **Candidate Ranker + Confidence Estimator + Final Selector (a.k.a. Acronym Disambiguator, or AD)**: Using the candidate ranking model, the confidence estimation model and the final selection model. Full version of our system.

6.2.2 State-of-the-art EL Systems

We also compare our method with two state-of-the-art Entity Linking (EL) systems.

- **Wikifier**: a popular EL system using machine learning to combine various features together.
- **AIDA**: a robust EL system using mention-entity graph to find the best mention-entity mapping.

6.3 Quality of Mined Acronyms/Meanings

We first conduct experiments to evaluate the quality of the acronym/meaning pairs harvested through our offline mining module. Out of the 17258 mined pairs, we randomly sampled 2000 of them and asked 5 domain experts to manually check their validness. An acronym/meaning pair is considered as valid if the majority of the experts think the acronym is indeed used to abbreviate the meaning. For example, (*AS*, *Analysis Service*) is a valid pair, but (*AS*, *App Store*) is considered as invalid because people will not actually use *AS* to represent *App Store*. Among the sampled 2000 pairs, **94.5%** are labeled as valid, indicating our offline mining module can accurately extract acronym/meaning pairs from enterprise corpus. It is hard to precisely evaluate the coverage/recall of our mining method, since it is very difficult to obtain the complete meaning list for a given acronym. To get a rough idea, we randomly picked up 100 acronyms and asked the 5 domain experts to enumerate the valid meanings for these acronyms. In total we got 230 valid meanings and **all** of them are covered by the mined pairs.

6.4 Disambiguation Performance

We first conduct experiments to evaluate the disambiguation performance of our ranking model, and compare the helpfulness of the features used in the model. Figure 4 shows the precision (i.e., percentage of correctly disambiguated cases among all predicted cases), recall (i.e., percentage of correctly disambiguated cases among all test cases) and F_1 (i.e., harmonic mean of precision and recall) of the compared methods on the *Manual* dataset and the *Distant* dataset. In terms of the helpfulness of the features, the context similarity feature and the immediate neighbor features contribute most to the performance gain. Other features are less helpful, yet still bring improvements to the overall performance.

Next we conduct experiments to illustrate the effectiveness of the confidence estimation module and the final selection module in our system. Figure 5 shows the precision, recall and F_1 of the compared system configurations on the *Manual* and *Distant* dataset. As can be seen, the confidence estimation module can improve precision at the cost of hurting recall. Fortunately, the final selection module can recover some recall losses without sacrificing too much on precision. In

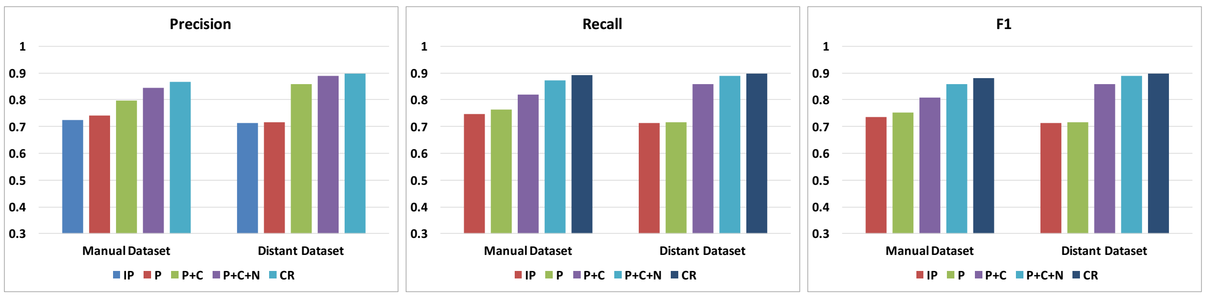


Figure 4: Ranking Performance

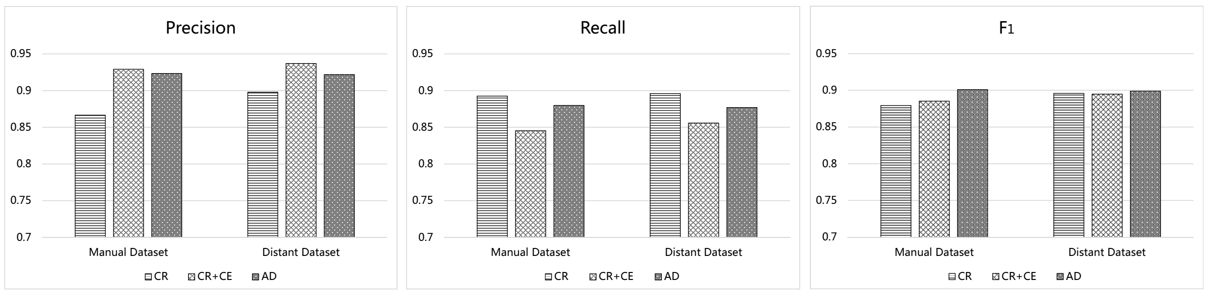

Figure 5: Effectiveness of Confidence Estimator and Final Selector

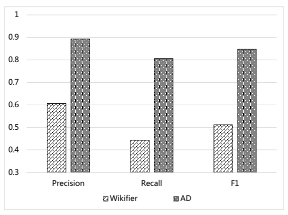
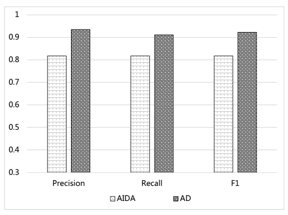
terms of the F_1 measure, the final system achieves the best performance.

Note that the ablation **P+C** naturally corresponds to the existing acronym disambiguation approaches (Feng et al., 2009; Pakhomov et al., 2005; Pustejovsky et al., 2001; Stevenson et al., 2009; Yu et al., 2006) mainly relying on context words and domain specific resources. These approaches do not specifically distinguish internal and external meanings. They merely rely on the internal corpus to discover information about external meanings, which is quite ineffective in the scenario of enterprise acronym disambiguation (as discussed in Section 1). In comparison, our system (**AD**) is able to leverage public resources together with the internal corpus to better handle the problem and therefore significantly outperforms them.



(a) *Wikifier vs. AD*



(b) *AIDA vs. AD*

Figure 6: Comparison with EL Systems

6.5 Comparison with EL Systems

We also compare our system (**AD**) with two state-of-the-art Entity Linking (EL) systems: **Wikifier** and **AIDA**. As explained in Section 6.1.2, we made two datasets (i.e., *JoinW* and *JoinA*) for fair comparisons. Figure 6(a) and Figure 6(b) present the comparison of our AD system against Wikifer and AIDA, respectively. As we can see from the figures, AD significantly outperforms both Wikifier and AIDA on all three measures. The reason is that even for public meanings (e.g., Operating System) indexed by Wikifier and AIDA, the usage of them could be quite different in enterprises (e.g., inside Microsoft people talk more about designing Operating System rather than how to install it). Wikifier and AIDA utilize information from public knowledge bases (e.g., Wikipedia) to generate features, therefore can hardly capture such enterprise-specific signals. In contrast, our AD system mines disambiguation features directly from the enterprise corpus and utilizes them together with the public signals. As a result, it can more accurately represent the characteristics of the enterprise and lead to much better disambiguation performances.

7 Related Work

Acronym meaning discovery has received a lot of attentions in vertical domains (mainly in biomedical). Most of the proposed approaches (Adar, 2004; Ao and Takagi, 2005; Park and Byrd, 2001; Schwartz and Hearst, 2002; Wren et al., 2002) utilized generic rules or text patterns (e.g. brackets, colons) to discover acronym meanings. These methods are usually based on the assumption that acronyms are co-mentioned with the corresponding meanings in the same document. However, in enterprises, this assumption rarely holds. Enterprises themselves are closed ecosystems, so it is very common for people to define the acronyms somewhere and use them elsewhere. As a result, such methods cannot be used for acronym meaning discovery in enterprises.

Recently, there have been a few works (Jain et al., 2007; Larkey et al., 2000; Nadeau and Turney, 2005; Taneva et al., 2013) on automatically mining acronym meanings by leveraging Web data (e.g., query sessions, click logs). However, it is hard to apply them directly to enterprises, since most data in enterprises are raw text and therefore the query sessions/click logs are rarely available.

Acronym disambiguation can be seen as a special case for the Entity Linking (EL) (Ji and Grishman, 2011; Dredze et al., 2010) problem. Approaches that link entity mentions to Wikipedia date back to Bunescu et. al's work (Bunescu and Paşca, 2006). They computed the cosine similarity between the text around the mention and the entity candidate's Wikipedia page. The referent entity with the maximum similarity score is selected as the disambiguation result. Cucerzan's work (Cucerzan, 2007) is the first one to realize the effectiveness of using topical coherence to globally perform EL. In that work, the topical coherence between the referent entity candidate and other entities within the same context is calculated based on their overlaps in categories and incoming links in Wikipedia. Recently, several methods (Hoffart et al., 2011; Li et al., 2013, 2016; Ratinov et al., 2011; Shen et al., 2012; Cheng and Roth, 2013) also tried to enrich "context similarity" and "topical coherence" using hybrid strategies. Shen et. al (Shen et al., 2015) provided a comprehensive survey for the techniques used in EL. However, these EL techniques cannot be used for acronym disambiguation in enterprises, since most enterprise meanings are not covered by public knowledge bases, and there are rarely any domain-specific knowledge bases available in enterprises. Automatic knowledge base construction (Suchanek et al., 2013) is promising, but the quality is far from applicable. Moreover, the structural information (e.g. entity taxonomy, cross-document hyperlinks) within Wikipedia, is rarely available in enterprises.

Most of the previous work (Feng et al., 2009; Pakhomov et al., 2005; Pustejovsky et al., 2001; Stevenson et al., 2009; Yu et al., 2006) on acronym disambiguation heavily rely on context words and domain specific resources. In comparison, our method explored a more comprehensive set of domain-independent features. Moreover, our method used a much less restrictive way to discover meaning candidates and training data, which is far more general than the methods relying on strict definition patterns (Schwartz and Hearst, 2002). Another particular limitation of all these previous work is that they do not distinguish internal and external meanings. They merely rely on the internal corpus to discover information about external meanings, which is quite ineffective.

8 Conclusions

In this paper, we studied the *Acronym Disambiguation for Enterprises* problem. We proposed a novel, end-to-end framework to solve this problem. Our framework takes the enterprise corpus as input and produces a high-quality acronym disambiguation system as output. The disambiguation models are trained via distant supervised learning, without requiring any manually labeled training examples. Different from all the previous acronym disambiguation approaches, our system is capable of accurately resolving acronyms to both enterprise-specific meanings and public meanings. Experimental results on Microsoft enterprise data demonstrated that our system can effectively construct acronym/meaning repositories from scratch and accurately disambiguate acronyms to their meanings with over 90% precision. Furthermore, our proposed framework can be easily deployed to any enterprises without requiring any domain knowledge.

Abstract

Existing temporal relation (TempRel) annotation schemes often have low inter-annotator agreements (IAA) even between experts, suggesting that the current annotation task needs a better definition. This paper proposes a new multi-axis modeling to better capture the temporal structure of events. In addition, we identify that event end-points are a major source of confusion in annotation, so we also propose to annotate TempRels based on start-points only. A pilot expert annotation effort using the proposed scheme shows significant improvement in IAA from the conventional 60's to 80's (Cohen's Kappa). This better-defined annotation scheme further enables the use of crowdsourcing to alleviate the labor intensity for each annotator. We hope that this work can foster more interesting studies towards event understanding.[1]

1 Introduction

Temporal relation (TempRel) extraction is an important task for event understanding, and it has drawn much attention in the natural language processing (NLP) community recently (UzZaman et al., 2013; Chambers et al., 2014; Llorens et al., 2015; Minard et al., 2015; Bethard et al., 2015, 2016, 2017; Leeuwenberg and Moens, 2017; Ning et al., 2017, 2018a,b).

Initiated by TimeBank (TB) (Pustejovsky et al., 2003b), a number of TempRel datasets have been collected, including but not limited to the verb-clause augmentation to TB (Bethard et al., 2007), TempEval1-3 (Verhagen et al., 2007, 2010; UzZaman et al., 2013), TimeBank-Dense (TB-Dense) (Cassidy et al., 2014), EventTimeCorpus (Reimers et al., 2016), and datasets with both temporal and other types of relations (e.g., coreference and causality) such as CaTeRs (Mostafazadeh et al., 2016) and RED (O'Gorman et al., 2016). These datasets were annotated by experts, but most still suffered from low inter-annotator agreements (IAA). For instance, the IAAs of TB-Dense, RED and THYME-TimeML (Styler IV et al., 2014) were only below or near 60% (given that events are already annotated). Since a low IAA usually indicates that the task is difficult even for humans (see Examples 1-3), the community has been looking into ways to simplify the task, by reducing the label set, and by breaking up the overall, complex task into subtasks (e.g., getting agreement on which event pairs should have a relation, and then what that relation should be) (Mostafazadeh et al., 2016; O'Gorman et al., 2016). In contrast to other existing datasets, Bethard et al. (2007) achieved an agreement as high as 90%, but the scope of its annotation was narrowed down to a very special verb-clause structure.

(*e1*, *e2*), (*e3*, *e4*), and (*e5*, *e6*): TempRels that are difficult even for humans. Note that only relevant events are highlighted here.
Example 1: Serbian police tried to eliminate the pro-independence Kosovo Liberation Army and (***e1:restore***) order. At least 51 people were (***e2:killed***) in clashes between Serb police and ethnic Albanians in the troubled region.
Example 2: Service industries (***e3:showed***) solid job gains, as did manufacturers, two areas expected to be hardest (***e4:hit***) when the effects of the Asian crisis hit the American economy.
Example 3: We will act again if we have evidence he is (***e5:rebuilding***) his weapons of mass destruction capabilities, senior officials say. In a bit of television diplomacy, Iraq's deputy foreign minister (***e6:responded***) from Baghdad in less than one hour, saying that ...

This paper proposes a new approach to handling

[1]The dataset is publicly available at https://cogcomp.org/page/publication_view/834.

these issues in TempRel annotation. **First**, we introduce *multi-axis modeling* to represent the temporal structure of events, based on which we anchor events to different semantic axes; only events from the same axis will then be temporally compared (Sec. 2). As explained later, those event pairs in Examples 1-3 are difficult because they represent different semantic phenomena and belong to different axes. **Second**, while we represent an event pair using two time intervals (say, $[t^1_{start}, t^1_{end}]$ and $[t^2_{start}, t^2_{end}]$), we suggest that comparisons involving end-points (e.g., t^1_{end} vs. t^2_{end}) are typically more difficult than comparing start-points (i.e., t^1_{start} vs. t^2_{start}); we attribute this to the ambiguity of expressing and perceiving durations of events (Coll-Florit and Gennari, 2011). We believe that this is an important consideration, and we propose in Sec. 3 that TempRel annotation should focus on start-points. Using the proposed annotation scheme, a pilot study done by experts achieved a high IAA of .84 (Cohen's Kappa) on a subset of TB-Dense, in contrast to the conventional 60's.

In addition to the low IAA issue, TempRel annotation is also known to be labor intensive. Our **third contribution** is that we facilitate, for the first time, the use of crowdsourcing to collect a new, high quality (under multiple metrics explained later) TempRel dataset. We explain how the crowdsourcing quality was controlled and how *vague* relations were handled in Sec. 4, and present some statistics and the quality of the new dataset in Sec. 5. A baseline system is also shown to achieve much better performance on the new dataset, when compared with system performance in the literature (Sec. 6). The paper's results are very encouraging and hopefully, this work would significantly benefit research in this area.

2 Temporal Structure of Events

Given a set of events, one important question in designing the TempRel annotation task is: which pairs of events should have a relation? The answer to it depends on the modeling of the overall temporal structure of events.

2.1 Motivation

TimeBank (Pustejovsky et al., 2003b) laid the foundation for many later TempRel corpora, e.g., (Bethard et al., 2007; UzZaman et al., 2013; Cassidy et al., 2014).[2] In TimeBank, the annotators were allowed to label TempRels between any pairs of events. This setup models the overall structure of events using *a general graph*, which made annotators inadvertently overlook some pairs, resulting in low IAAs and many false negatives.

Example 4: Dense Annotation Scheme.
Serbian police (***e7:tried***) to (***e8:eliminate***) the pro-independence Kosovo Liberation Army and (***e1:restore***) order. At least 51 people were (***e2:killed***) in clashes between Serb police and ethnic Albanians in the troubled region.
Given 4 NON-GENERIC events above, the dense scheme presents 6 pairs to annotators one by one: (*e7*, *e8*), (*e7*, *e1*), (*e7*, *e2*), (*e8*, *e1*), (*e8*, *e2*), and (*e1*, *e2*). Apparently, not all pairs are well-defined, e.g., (*e8*, *e2*) and (*e1*, *e2*), but annotators are forced to label all of them.

To address this issue, Cassidy et al. (2014) proposed a dense annotation scheme, TB-Dense, which annotates all event pairs within a sliding, two-sentence window (see Example 4). It requires all TempRels between GENERIC[3] and NON-GENERIC events to be labeled as *vague*, which conceptually models the overall structure by *two disjoint time-axes*: one for the NON-GENERIC and the other one for the GENERIC.

However, as shown by Examples 1-3 in which the highlighted events are NON-GENERIC, the TempRels may still be ill-defined: In Example 1, Serbian police tried to restore order but ended up with conflicts. It is reasonable to argue that the attempt to ***e1:restore*** order happened *before* the conflict where 51 people were ***e2:killed***; or, 51 people had been ***killed*** but order had not been ***restored*** yet, so ***e1:restore*** is *after* ***e2:killed***. Similarly, in Example 2, service industries and manufacturers were originally expected to be hardest ***e4:hit*** but actually ***e3:showed*** gains, so ***e4:hit*** is *before* ***e3:showed***; however, one can also argue that the two areas had ***showed*** gains but had not been ***hit***, so ***e4:hit*** is *after* ***e3:showed***. Again, ***e5:rebuilding*** is a hypothetical event: "we will act if ***rebuilding*** is true". Readers do not know for sure if "he is already rebuilding weapons but we have no evidence", or "he will be building weapons in the future", so annotators may disagree on the relation between ***e5:rebuilding*** and ***e6:responded***. Despite, importantly, minimizing missing annota-

[2]EventTimeCorpus (Reimers et al., 2016) is based on TimeBank, but aims at anchoring events onto explicit time expressions in each document rather than annotating TempRels between events, which can be a good complementary to other TempRel datasets.

[3]For example, *lions eat meat* is GENERIC.

tions, the current dense scheme forces annotators to label many such ill-defined pairs, resulting in low IAA.

2.2 Multi-Axis Modeling

Arguably, an ideal annotator may figure out the above ambiguity by him/herself and mark them as *vague*, but it is not a feasible requirement for all annotators to stay clear-headed for hours; let alone crowdsourcers. What makes things worse is that, after annotators spend a long time figuring out these difficult cases, whether they disagree with each other or agree on the vagueness, the final decisions for such cases will still be *vague*.

As another way to handle this dilemma, TB-Dense resorted to a 80% confidence rule: annotators were allowed to choose a label if one is 80% sure that it was the writer's intent. However, as pointed out by TB-Dense, annotators are likely to have rather different understandings of 80% confidence and it will still end up with disagreements.

In contrast to these annotation difficulties, humans can easily grasp the meaning of news articles, implying a potential gap between the difficulty of the annotation task and the one of understanding the actual meaning of the text. In Examples 1-3, the writers did not intend to explain the TempRels between those pairs, and the original annotators of TimeBank[4] did not label relations between those pairs either, which indicates that both writers and readers did not think the TempRels between these pairs were crucial. Instead, what is crucial in these examples is that "Serbian police ***tried*** to restore order but ***killed*** 51 people", that "two areas were ***expected*** to be hit but ***showed*** gains", and that "***if*** he rebuilds weapons ***then*** we will act." To "***restore*** order", to be "hardest ***hit***", and "if he was ***rebuilding***" were only the intention of police, the opinion of economists, and the condition to ***act***, respectively, and whether or not they actually happen is not the focus of those writers.

This discussion suggests that a single axis is too restrictive to represent the complex structure of NON-GENERIC events. Instead, we need a modeling which is more restrictive than a general graph so that annotators can focus on relation annotation (rather than looking for pairs first), but also more flexible than a single axis so that ill-defined

[4]Recall that they were given the entire article and only salient relations would be annotated.

Event Type	Category
INTENTION, OPINION	On an orthogonal axis
HYPOTHESIS, GENERIC	On a parallel axis
NEGATION	Not on any axis
STATIC, RECURRENT	Other

Table 1: The interpretation of various event types that are not on the main axis in the proposed multi-axis modeling. The names are rather straightforward; see examples for each in Appendix A.

relations are not forcibly annotated. Specifically, we need axes for intentions, opinions, hypotheses, etc. in addition to the main axis of an article. We thus argue for *multi-axis modeling*, as defined in Table 1. Following the proposed modeling, Examples 1-3 can be represented as in Fig. 1. This modeling aims at capturing what the author has explicitly expressed and it only asks annotators to look at comparable pairs, rather than forcing them to make decisions on often vaguely defined pairs.

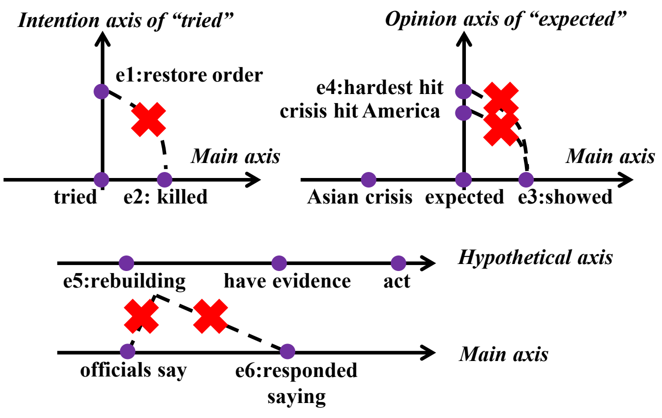

Figure 1: A multi-axis view of Examples 1-3. Only events on the same axis are compared.

In practice, we annotate one axis at a time: we first classify if an event is anchorable onto a given axis (this is also called the anchorability annotation step); then we annotate every pair of anchorable events (i.e., the relation annotation step); finally, we can move to another axis and repeat the two steps above. Note that ruling out cross-axis relations is only a strategy we adopt in this paper to separate well-defined relations from ill-defined relations. We do not claim that cross-axis relations are unimportant; instead, as shown in Fig. 2, we think that cross-axis relations are a different semantic phenomenon that requires additional investigation.

2.3 Comparisons with Existing Work

There have been other proposals of temporal structure modelings (Bramsen et al., 2006; Bethard et al., 2012), but in general, the semantic phenomena handled in our work are very different and complementary to them. (Bramsen et al., 2006) introduces "temporal segments" (a fragment of text that does not exhibit abrupt changes) in the medical domain. Similarly, their temporal segments can also be considered as a special temporal structure modeling. But a key difference is that (Bramsen et al., 2006) only annotates inter-segment relations, ignoring intra-segment ones. Since those segments are usually large chunks of text, the semantics handled in (Bramsen et al., 2006) is in a very coarse granularity (as pointed out by (Bramsen et al., 2006)) and is thus different from ours.

(Bethard et al., 2012) proposes a tree structure for children's stories, which "typically have simpler temporal structures", as they pointed out. Moreover, in their annotation, an event can only be linked to a single nearby event, even if multiple nearby events may exist, whereas we do not have such restrictions.

In addition, some of the semantic phenomena in Table 1 have been discussed in existing work. Here we compare with them for a better positioning of the proposed scheme.

2.3.1 Axis Projection

TB-Dense handled the incomparability between main-axis events and HYPOTHESIS/NEGATION by *treating an event as having occurred* if the event is HYPOTHESIS/NEGATION.[5] In our multi-axis modeling, the strategy adopted by TB-Dense falls into a more general approach, "axis projection". That is, projecting events across different axes to handle the incomparability between any two axes (not limited to HYPOTHESIS/NEGATION). Axis projection works well for certain event pairs like ***Asian crisis*** and ***e4:hardest hit*** in Example 2: as in Fig. 1, ***Asian crisis*** is *before* ***expected***, which is again *before* ***e4:hardest hit***, so ***Asian crisis*** is *before* ***e4:hardest hit***.

Generally, however, since there is no direct evidence that can guide the projection, annotators may have different projections (imagine projecting ***e5:rebuilding*** onto the main axis: is it in the past or in the future?). As a result, axis projection requires many specially designed guidelines or strong external knowledge. Annotators have to rigidly follow the sometimes counter-intuitive guidelines or "guess" a label instead of looking for evidence in the text.

[5]In the case of Example 3, it is to treat ***rebuilding*** as actually happened and then link it to ***responded***.

When strong external knowledge is involved in axis projection, it becomes a reasoning process and the resulting relations are a different type. For example, a reader may reason that in Example 3, it is well-known that they did "act again", implying his ***e5:rebuilding*** had happened and is *before* ***e6:responded***. Another example is in Fig. 2. It is obvious that relations based on these projections are not the same with and more challenging than those same-axis relations, so in the current stage, we should focus on same-axis relations only.

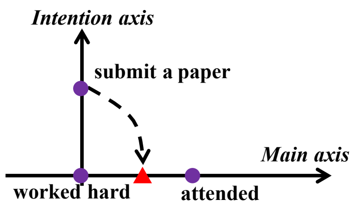

Figure 2: In *I worked hard to submit a paper ... I attended the conference*, the projection of ***submit a paper*** onto the main axis is clearly *before* ***attended***. However, this projection requires strong external knowledge that a paper should be submitted before attending a conference. Again, this projection is only a guess based on our external knowledge and it is still open whether the paper is submitted or not.

2.3.2 Introduction of the Orthogonal Axes

Another prominent difference to earlier work is the introduction of orthogonal axes, which has not been used in any existing work as we know. A special property is that the intersection event of two axes can be compared to events from both, which can sometimes bridge events, e.g., in Fig. 1, ***Asian crisis*** is seemingly *before* ***hardest hit*** due to their connections to ***expected***. Since ***Asian crisis*** is on the main axis, it seems that ***e4:hardest hit*** is on the main axis as well. However, the "***hardest hit***" in "***Asian crisis*** *before* ***hardest hit***" is only a projection of the original ***e4:hardest hit*** onto the real axis and is valid only when this OPINION is true.

Nevertheless, OPINIONS are not always true and INTENTIONS are not always fulfilled. In Example 5, ***e9:sponsoring*** and ***e10:resolve*** are the opinions of the West and the speaker, respectively; whether or not they are true depends on the authors' implications or the readers' understandings, which is often beyond the scope of TempRel annotation.[6] Example 6 demonstrates a similar situation for INTENTIONS: when reading the sentence of ***e11:report***, people are inclined to believe that it is fulfilled. But if we read the sentence of ***e12:report***, we have reason to believe that it is not. When it comes to ***e13:tell***, it is unclear if everyone told the truth. The existence of such examples indicates that orthogonal axes are a better modeling for INTENTIONS and OPINIONS.

Example 5: Opinion events may not always be true.
He is ostracized by the West for (***e9:sponsoring***) terrorism.
We need to (***e10:resolve***) the deep-seated causes that have resulted in these problems.
Example 6: Intentions may not always be fulfilled.
A passerby called the police to (***e11:report***) the body.
A passerby called the police to (***e12:report***) the body. Unfortunately, the line was busy.
I asked everyone to (***e13:tell***) the truth.

2.3.3 Differences from Factuality

Event modality have been discussed in many existing event annotation schemes, e.g., Event Nugget (Mitamura et al., 2015), Rich ERE (Song et al., 2015), and RED. Generally, an event is classified as *Actual* or *Non-Actual*, a.k.a. factuality (Saurí and Pustejovsky, 2009; Lee et al., 2015).

The main-axis events defined in this paper seem to be very similar to *Actual* events, but with several important differences: **First**, future events are *Non-Actual* because they indeed have not happened, but they may be on the main axis. **Second**, events that are not on the main axis can also be *Actual* events, e.g., intentions that are fulfilled, or opinions that are true. **Third**, as demonstrated by Examples 5-6, identifying anchorability as defined in Table 1 is relatively easy, but judging if an event actually happened is often a high-level understanding task that requires an understanding of the entire document or external knowledge.

Interested readers are referred to Appendix B for a detailed analysis of the difference between *Anchorable* (onto the main axis) and *Actual* on a subset of RED.

3 Interval Splitting

All existing annotation schemes adopt the interval representation of events (Allen, 1984) and there are 13 relations between two intervals (for readers who are not familiar with it, please see Fig. 4 in the appendix). To reduce the burden of annotators, existing schemes often resort to a reduced set of the 13 relations. For instance, Verhagen et al. (2007) merged all the overlap relations into a single relation, *overlap*. Bethard et al. (2007); Do et al. (2012); O'Gorman et al. (2016) all adopted this strategy. In Cassidy et al. (2014), they further split *overlap* into *includes*, *included* and *equal*.

Let $[t^1_{start}, t^1_{end}]$ and $[t^2_{start}, t^2_{end}]$ be the time intervals of two events (with the implicit assumption that $t_{start} \le t_{end}$). Instead of reducing the relations between two intervals, we try to explicitly compare the time points (see Fig. 3). In this way, the label set is simply *before, after* and *equal*,[7] while the expressivity remains the same. This interval splitting technique has also been used in (Raghavan et al., 2012).

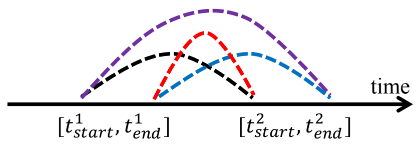

Figure 3: The comparison of two event time intervals, $[t^1_{start}, t^1_{end}]$ and $[t^2_{start}, t^2_{end}]$, can be decomposed into four comparisons t^1_{start} vs. t^2_{start}, t^1_{start} vs. t^2_{end}, t^1_{end} vs. t^2_{start}, and t^1_{end} vs. t^2_{end}, without loss of generality.

In addition to same expressivity, interval splitting can provide even more information when the relation between two events is *vague*. In the conventional setting, imagine that the annotators find that the relation between two events can be either *before* or *before and overlap*. Then the resulting annotation will have to be *vague*, although the annotators actually agree on the relation between t^1_{start} and t^2_{start}. Using interval splitting, however, such information can be preserved.

An obvious downside of interval splitting is the increased number of annotations needed (4 point comparisons vs. 1 interval comparison). In practice, however, it is usually much fewer than 4 comparisons. For example, when we see $t^1_{end} < t^2_{start}$ (as in Fig. 3), the other three can be skipped because they can all be inferred. Moreover, although the number of annotations is increased, the work load for human annotators may still be the same, because even in the conventional scheme, they still need to think of the relations between start- and

[6]For instance, there is undoubtedly a *causal* link between ***e9:sponsoring*** and ***ostracized***.

[7]We will discuss *vague* in Sec. 4.

end-points before they can make a decision.

3.1 Ambiguity of End-Points

During our pilot annotation, the annotation quality dropped significantly when the annotators needed to reason about relations involving end-points of events. Table 2 shows four metrics of task difficulty when only t^1_{start} vs. t^2_{start} or t^1_{end} vs. t^2_{end} are annotated. Non-anchorable events were removed for both jobs. The first two metrics, qualifying pass rate and survival rate are related to the two quality control protocols (see Sec. 4.1 for details). We can see that when annotating the relations between end-points, only one out of ten crowdsourcers (11%) could successfully pass our qualifying test; and even if they had passed it, half of them (56%) would have been kicked out in the middle of the task. The third line is the overall accuracy on gold set from all crowdsourcers (excluding those who did not pass the qualifying test), which drops from 67% to 37% when annotating end-end relations. The last line is the average response time per annotation and we can see that it takes much longer to label an end-end TempRel (52s) than a start-start TempRel (33s). This important discovery indicates that the TempRels between end-points is probably governed by a different linguistic phenomenon.

Metric	t^1_{start} vs. t^2_{start}	t^1_{end} vs. t^2_{end}
Qualification pass rate	50%	11%
Survival rate	74%	56%
Accuracy on gold	67%	37%
Avg. response time	33s	52s

Table 2: Annotations involving the end-points of events are found to be much harder than only comparing the start-points.

We hypothesize that the difficulty is a mixture of how durative events are expressed (by authors) and perceived (by readers) in natural language. In cognitive psychology, Coll-Florit and Gennari (2011) discovered that human readers take longer to perceive durative events than punctual events, e.g., *owe 50 bucks* vs. *lost 50 bucks*. From the writer's standpoint, durations are usually fuzzy (Schockaert and De Cock, 2008), or assumed to be a prior knowledge of readers (e.g., college takes 4 years and watching an NBA game takes a few hours), and thus not always written explicitly. Given all these reasons, we ignore the comparison of end-points in this work, although event duration is indeed, another important task.

4 Annotation Scheme Design

To summarize, with the proposed multi-axis modeling (Sec. 2) and interval splitting (Sec. 3), our annotation scheme is two-step. First, we mark every event candidate as being temporally *Anchorable* or not (based on the time axis we are working on). Second, we adopt the dense annotation scheme to label TempRels only between *Anchorable* events. Note that we only work on verb events in this paper, so non-verb event candidates are also deleted in a preprocessing step. We design crowdsourcing tasks for both steps and as we show later, high crowdsourcing quality was achieved on both tasks. In this section, we will discuss some practical issues.

4.1 Quality Control for Crowdsourcing

We take advantage of the quality control feature in CrowdFlower in our crowdsourcing jobs. For any job, a set of examples are annotated by experts beforehand, which is considered gold and will serve two purposes. (i) Qualifying test: Any crowdsourcer who wants to work on this job has to pass with 70% accuracy on 10 questions randomly selected from the gold set. (ii) Surviving test: During the annotation process, questions from the gold set will be randomly given to crowdsourcers without notice, and one has to maintain 70% accuracy on the gold set till the end of the annotation; otherwise, he or she will be forbidden from working on this job anymore and all his/her annotations will be discarded. At least 5 different annotators are required for every judgement and by default, the majority vote will be the final decision.

4.2 Vague Relations

How to handle *vague* relations is another issue in temporal annotation. In non-dense schemes, annotators usually skip the annotation of a *vague* pair. In dense schemes, a majority agreement rule is applied as a postprocessing step to back off a decision to *vague* when annotators cannot pass a majority vote (Cassidy et al., 2014), which reminds us that annotators often label a *vague* relation as non-vague due to lack of thinking.

We decide to proactively reduce the possibility of such situations. As mentioned earlier, our label set for t^1_{start} vs. t^2_{start} is *before*, *after*, *equal* and *vague*. We ask two questions: Q1=Is it possible that t^1_{start} is before t^2_{start}? Q2=Is it possible that t^2_{start} is before t^1_{start}? Let the answers be A1 and A2. Then we have a one-to-one mapping as follows: A1=A2=yes$\mapsto$*vague*, A1=A2=no$\mapsto$*equal*, A1=yes, A2=no$\mapsto$*before*, and A1=no, A2=yes$\mapsto$*after*. An advantage is that one will be prompted to think about all possibilities, thus reducing the chance of overlook.

Finally, the annotation interface we used is shown in Appendix C.

5 Corpus Statistics and Quality

In this section, we first focus on annotations on the main axis, which is usually the primary storyline and thus has most events. Before launching the crowdsourcing tasks, we checked the IAA between two experts on a subset of TB-Dense (about 100 events and 400 relations). A Cohen's Kappa of .85 was achieved in the first step: anchorability annotation. Only those events that both experts labeled *Anchorable* were kept before they moved onto the second step: relation annotation, for which the Cohen's Kappa was .90 for Q1 and .87 for Q2. Table 3 furthermore shows the distribution, Cohen's Kappa, and F_1 of each label. We can see the Kappa and F_1 of *vague* (κ=.75, F_1=.81) are generally lower than those of the other labels, confirming that temporal *vagueness* is a more difficult semantic phenomenon. Nevertheless, the overall IAA shown in Table 3 is a significant improvement compared to existing datasets.

	b	a	e	v	Overall
Distribution	.49	.23	.02	.26	1
IAA: Cohen's κ	.90	.87	1	.75	.84
IAA: F_1	.92	.93	1	.81	.90

Table 3: IAA of two experts' annotations in a pilot study on the main axis. Notations: **b**efore, **a**fter, **e**qual, and **v**ague.

With the improved IAA confirmed by experts, we sequentially launched the two-step crowdsourcing tasks through CrowdFlower on top of the same 36 documents of TB-Dense. To evaluate how well the crowdsourcers performed on our task, we calculate two quality metrics: accuracy on the gold set and the Worker Agreement with Aggregate (WAWA). WAWA indicates the average number of crowdsourcers' responses agreed with the aggregate answer (we used majority aggregation for each question). For example, if N individual responses were obtained in total, and n of them were correct when compared to the aggregate answer, then WAWA is simply n/N. In the first step, crowdsourcers labeled 28% of the events as *Non-Anchorable* to the main axis, with an accuracy on the gold of .86 and a WAWA of .79.

With *Non-Anchorable* events filtered, the relation annotation step was launched as another crowdsourcing task. The label distribution is b=.50, a=.28, e=.03, and v=.19 (consistent with Table 3). In Table 4, we show the annotation quality of this step using accuracy on the gold set and WAWA. We can see that the crowdsourcers achieved a very good performance on the gold set, indicating that they are consistent with the authors who created the gold set; these crowdsourcers also achieved a high-level agreement under the WAWA metric, indicating that they are consistent among themselves. These two metrics indicate that the annotation task is now well-defined and easy to understand even by non-experts.

No.	Metric	Q1	Q2	All
1	Accuracy on Gold	.89	.88	.88
2	WAWA	.82	.81	.81

Table 4: Quality analysis of the relation annotation step of MATRES. "Q1" and "Q2" refer to the two questions crowdsourcers were asked (see Sec. 4.2 for details). Line 1 measures the level of consistency between crowdsourcers and the authors and line 2 measures the level of consistency among the crowdsourcers themselves.

We continued to annotate INTENTION and OPINION which create orthogonal branches on the main axis. In the first step, crowdsourcers achieved an accuracy on gold of .82 and a WAWA of .89. Since only 16% of the events are in this category and these axes are usually very short (e.g., ***allocate*** *funds to* ***build*** *a museum*.), the annotation task is relatively small and two experts took the second step and achieved an agreement of .86 (F_1).

We name our new dataset *MATRES* for Multi-Axis Temporal RElations for Start-points. Each individual judgement cost us $0.01 and MATRES in total cost about $400 for 36 documents.

5.1 Comparison to TB-Dense

To get another checkpoint of the quality of the new dataset, we compare with the annotations of TB-Dense. TB-Dense has 1.1K verb events, between which 3.4K event-event (EE) relations are annotated. In the new dataset, 72% of the events (0.8K) are anchored onto the main axis, resulting in 1.6K EE relations, and 16% (0.2K) are anchored onto orthogonal axes, resulting in 0.2K EE relations.

The following comparison is based on the 1.8K EE relations in common. Moreover, since TB-Dense annotations are for intervals instead of start-points only, we converted TB-Dense's interval relations to start-point relations (e.g., if ***A*** includes ***B***, then t^{A}_{start} is before t^{B}_{start}).

	b	a	e	v	All
b	455	11	5	42	513
a	45	309	16	68	438
e	13	7	2	10	32
v	450	138	20	192	800
All	963	465	43	312	1783

Table 5: An evaluation of MATRES against TB-Dense. Horizontal: MATRES. Vertical: TB-Dense (with interval relations mapped to start-point relations). Please see explanation of these numbers in text.

The confusion matrix is shown in Table 5. A few remarks about how to understand it: **First**, when TB-Dense labels *before* or *after*, MATRES also has a high-probability of having the same label (b=455/513=.89, a=309/438=.71); when MATRES labels *vague*, TB-Dense is also very likely to label *vague* (v=192/312=.62). This indicates the *high agreement level* between the two datasets if the interval- or point-based annotation difference is ruled out. **Second**, many *vague* relations in TB-Dense are labeled as *before*, *after* or *equal* in MATRES. This is expected because TB-Dense annotates relations between *intervals*, while MATRES annotates *start-points*. When durative events are involved, the problem usually becomes more difficult and interval-based annotation is more likely to label *vague* (see earlier discussions in Sec. 3). Example 7 shows three typical cases, where ***e14:became***, ***e17:backed***, ***e18:rose*** and ***e19:extending*** can be considered durative. If only their start-points are considered, the crowdsourcers were correct in labeling ***e14*** before ***e15***, ***e16*** after ***e17***, and ***e18*** equal to ***e19***, although TB-Dense says *vague* for all of them. **Third**, *equal* seems to be the relation that the two dataset mostly disagree on, which is probably due to crowdsourcers' lack of understanding in time granularity and event coreference. Although *equal* relations only constitutes a small portion in all relations, it needs further investigation.

6 Baseline System

We develop a baseline system for TempRel extraction on MATRES, assuming that all the events and axes are given. The following commonly-

Example 7: Typical cases that TB-Dense annotated *vague* but MATRES annotated *before*, *after*, and *equal*, respectively.
At one point , when it (***e14:became***) clear controllers could not contact the plane, someone (***e15:said***) a prayer. *TB-Dense:* vague*; MATRES:* before
The US is bolstering its military presence in the gulf, as President Clinton (***e16:discussed***) the Iraq crisis with the one ally who has (***e17:backed***) his threat of force, British prime minister Tony Blair. *TB-Dense:* vague*; MATRES:* after
Average hourly earnings of nonsupervisory employees (***e18:rose***) to $12.51. The gain left wages 3.8 percent higher than a year earlier, (***e19:extending***) a trend that has given back to workers some of the earning power they lost to inflation in the last decade. *TB-Dense:* vague*; MATRES:* equal

used features for each event pair are used: (i) The part-of-speech (POS) tags of each individual event and of its neighboring three words. (ii) The sentence and token distance between the two events. (iii) The appearance of any modal verb between the two event mentions in text (i.e., will, would, can, could, may and might). (iv) The appearance of any temporal connectives between the two event mentions (e.g., before, after and since). (v) Whether the two verbs have a common synonym from their synsets in WordNet (Fellbaum, 1998). (vi) Whether the input event mentions have a common derivational form derived from WordNet. (vii) The head words of the preposition phrases that cover each event, respectively. And (viii) event properties such as Aspect, Modality, and Polarity that come with the TimeBank dataset and are commonly used as features.

The proposed baseline system uses the averaged perceptron algorithm to classify the relation between each event pair into one of the four relation types. We adopted the same train/dev/test split of TB-Dense, where there are 22 documents in train, 5 in dev, and 9 in test. Parameters were tuned on the train-set to maximize its F_1 on the dev-set, after which the classifier was retrained on the union of train and dev. A detailed analysis of the baseline system is provided in Table 6. The performance on *equal* and *vague* is lower than on *before* and *after*, probably due to shortage in these labels in the training data and the inherent difficulty in event coreference and temporal vagueness. We can see, though, that the overall performance on MATRES is much better than those in the literature for TempRel extraction, which used to be in the low 50's (Chambers et al., 2014; Ning et al., 2017). The same system was also retrained and tested on the original annotations of TB-Dense (Line "Original"), which confirms the significant improvement if the proposed annotation scheme is used. Note that we *do not* mean to say that the proposed baseline system itself is better than other existing algorithms, but rather that the proposed annotation scheme and the resulting dataset lead to better defined machine learning tasks. In the future, more data can be collected and used with advanced techniques such as ILP (Do et al., 2012), structured learning (Ning et al., 2017) or multi-sieve (Chambers et al., 2014).

	Training			Testing		
	P	R	F_1	P	R	F_1
Before	.74	.91	.82	.71	.80	.75
After	.73	.77	.75	.55	.64	.59
Equal	1	.05	.09	-	-	-
Vague	.75	.28	.41	.29	.13	.18
Overall	**.73**	**.81**	**.77**	**.66**	**.72**	**.69**
Original	.44	.67	.53	.40	.60	.48

Table 6: Performance of the proposed baseline system on MATRES. Line "Original" is the same system retrained on the original TB-Dense and tested on the same subset of event pairs. Due to the limited number of *equal* examples, the system did not make any *equal* predictions on the testset.

7 Conclusion

This paper proposes a new scheme for TempRel annotation between events, simplifying the task by focusing on a single time axis at a time. We have also identified that end-points of events is a major source of confusion during annotation due to reasons beyond the scope of TempRel annotation, and proposed to focus on start-points only and handle the end-points issue in further investigation (e.g., in event duration annotation tasks). Pilot study by expert annotators shows significant IAA improvements compared to literature values, indicating a better task definition under the proposed scheme. This further enables the usage of crowdsourcing to collect a new dataset, MATRES, at a lower time cost. Analysis shows that MATRES, albeit crowdsourced, has achieved a reasonably good agreement level, as confirmed by its performance on the gold set (agreement with the authors), the WAWA metric (agreement with the crowdsourcers themselves), and consistency with TB-Dense (agreement with an existing dataset). Given the fact that existing schemes suffer from low IAAs and lack of data, we hope that the findings in this work would provide a good start towards understanding more sophisticated semantic phenomena in this area.

Exemplar Encoder-Decoder for Neural Conversation Generation

Gaurav Pandey, Danish Contractor, Vineet Kumar and Sachindra Joshi
IBM Research AI

Abstract

In this paper we present the Exemplar Encoder-Decoder network (EED), a novel conversation model that learns to utilize *similar* examples from training data to generate responses. Similar conversation examples (context-response pairs) from training data are retrieved using a traditional TF-IDF based retrieval model. The retrieved responses are used to create exemplar vectors that are used by the decoder to generate the response. The contribution of each retrieved response is weighed by the similarity of corresponding context with the input context. We present detailed experiments on two large data sets and find that our method outperforms state of the art sequence to sequence generative models on several recently proposed evaluation metrics. We also observe that the responses generated by the proposed EED model are more informative and diverse compared to existing state-of-the-art method.

1 Introduction

With the availability of large datasets and the recent progress made by neural methods, variants of sequence to sequence learning (seq2seq) (Sutskever et al., 2014) architectures have been successfully applied for building conversational systems (Serban et al., 2016, 2017b). However, despite these methods being the state-of-the art frameworks for conversation generation, they suffer from problems such as lack of diversity in responses and generation of short, repetitive and uninteresting responses (Liu et al., 2016; Serban et al., 2016, 2017b). A large body of recent literature has focused on overcoming such challenges (Li et al., 2016a; Lowe et al., 2017).

In part, such problems arise as all information required to generate responses needs to be captured as part of the model parameters learnt from the training data. These model parameters alone may not be sufficient for generating natural conversations. Therefore, despite providing enormous amount of data, neural generative systems have been found to be ineffective for use in real world applications (Liu et al., 2016).

In this paper, we focus our attention on closed domain conversations. A characteristic feature of such conversations is that over a period of time, some conversation contexts[1] are likely to have occurred previously (Lu et al., 2017b). For instance, Table 1 shows some contexts from the Ubuntu dialog corpus. Each row presents an input dialog context with its corresponding gold response followed by a similar context and response seen in training data – as can be seen, contexts for "*installing dms*", "*sharing files*", "*blocking ufw ports*" have all occurred in training data. We hypothesize that being able to refer to training responses for previously seen similar contexts could be a helpful signal to use while generating responses.

In order to exploit this aspect of closed domain conversations we build our neural encoder-decoder architecture called the *Exemplar Encoder Decoder (EED)*, that learns to generate a response for a given context by exploiting *similar* contexts from training conversations. Thus, instead of having the seq2seq model learn patterns of language only from aligned parallel corpora, we assist the model by providing it *closely* related (*similar*) samples from the training data that it can *refer* to while generating text.

Specifically, given a context c, we retrieve a set

[1]We use the phrase "dialog context", "conversation context" and "context" interchangeably throughout the paper.

Table 1: Sample input contexts and corresponding gold responses from Ubuntu *validation* dataset along with similar contexts seen in training data and their corresponding responses. We refer to training data as training data for the Ubuntu corpus. The highlighted words are common between the gold response and the exemplar response.

of context-response pairs $(c^{(k)}, r^{(k)})$, $1 \leq k \leq K$ using an inverted index of training data. We create an *exemplar vector* $e^{(k)}$ by encoding the response $r^{(k)}$ (also referred to as exemplar response) along with an encoded representation of the current context c. We then learn the *importance* of each exemplar vector $e^{(k)}$ based on the likelihood of it being able to generate the ground truth response. We believe that $e^{(k)}$ may contain information that is helpful in generating the response. Table 1 highlights the words in exemplar responses that appear in the ground truth response as well.

Contributions: We present a novel Exemplar Encoder-Decoder (EED) architecture that makes use of similar conversations, fetched from an index of training data. The retrieved context-response pairs are used to create *exemplar* vectors which are used by the decoder in the EED model, to learn the importance of training context-response pairs, while generating responses. We present detailed experiments on the publicly benchmarked Ubuntu dialog corpus data set (Lowe et al., 2015) as well a large collection of more than 127,000 technical support conversations. We compare the performance of the EED model with the existing state of the art generative models such as HRED (Serban et al., 2016) and VHRED (Serban et al., 2017b). We find that our model out-performs these models on a wide variety of metrics such as the recently proposed *Activity Entity* metrics (Serban et al., 2017a) as well as Embedding-based metrics (Lowe et al., 2015). In addition, we present qualitative insights into our results and we find that exemplar based responses are more informative and diverse.

The rest of the paper is organized as follows. Section 2 briefly describes the recent works in neural dialogue generation The details of the proposed EED model for dialogue generation are described in detail in Section 3. In Section 4, we describe the datasets as well as the details of the models used during training. We present quantitative and qualitative results of EED model in Section 5.

2 Related Work

In this section, we compare our work against other data-driven end-to-end conversation models. End-to-end conversation models can be further classified into two broad categories — *generation* based models and *retrieval* based models.

Generation based models cast the problem of dialogue generation as a sequence to sequence learning problem. Initial works treat the entire context as a single long sentence and learn an encoder-decoder framework to generate response word by word (Shang et al., 2015; Vinyals and Le, 2015). This was followed by work that models context better by breaking it into conversation history and last utterance (Sordoni et al., 2015b). Context was further modeled effectively by using a hierarchical encoder decoder (HRED) model which first learns a vector representation of each utterance and then combines these representations to learn vector representation of context (Serban et al., 2016). Later, an alternative hierarchical model called VHRED (Serban et al., 2017b) was proposed, where generated responses were conditioned on latent variables. This leads to more informative responses and adds diversity to response generation. Models that explicitly incorporate diversity in response generation have also been studied in literature (Li et al., 2016b; Vijayakumar et al., 2016; Cao and Clark, 2017; Zhao et al., 2017).

Our work differs from the above as none of these above approaches utilize similar conversation contexts observed in the training data explicitly.

Retrieval based models on the other hand treat the conversation context as a query and obtain a set of responses using information retrieval (IR) techniques from the conversation logs (Ji et al., 2014). There has been further work where the responses are further ranked using a deep learning based model (Yan et al., 2016a,b; Qiu et al., 2017). On the other hand of the spectrum, end-to-end deep learning based rankers have also been employed to generate responses (Wu et al., 2017; Henderson et al., 2017). Recently a framework has also been proposed that uses a discriminative dialog network that ranks the candidate responses received from a response generator network and trains both the networks in an end to end manner (Lu et al., 2017a).

In contrast to the above models, we use the input contexts as well as the retrieved responses for generating the final responses. Contemporaneous to our work, a generative model for machine translation that employs retrieved translation pairs has also been proposed (Gu et al., 2017). We note that while the underlying premise of both the papers remains the same, the difference lies in the mechanism of incorporating the retrieved data.

3 Exemplar Encoder Decoder

3.1 Overview

A conversation consists of a sequence of utterances. At a given point in the conversation, the utterances expressed prior to it are jointly referred to as the context. The utterance that immediately follows the context is referred to as the response. As discussed in Section 1, given a conversational context, we wish to to generate a response by utilizing similar context-response pairs from the training data. We retrieve a set of K exemplar context-response pairs from an inverted index created using the training data in an off-line manner. The input and the retrieved context-response pairs are then fed to the Exemplar Encoder Decoder (EED) network. A schematic illustration of the EED network is presented in Figure 1. The EED encoder combines the input context and the retrieved responses to create a set of *exemplar vectors*. The EED decoder then uses the exemplar vectors based on the similarity between the input context and retrieved contexts to generate a response. We now provide details of each of these modules.

3.2 Retrieval of Similar Context-Response Pairs

Given a large collection of conversations as $(context,\ response)$ pairs, we index each response and its corresponding context in $tf - idf$ vector space. We further extract the last *turn* of a conversation and index it as an additional attribute of the context-response document pairs so as to allow directed queries based on it.

Given an input context c, we construct a query that weighs the last utterance in the context twice as much as the rest of the context and use it to retrieve the top-k similar context-response pairs from the index based on a BM25 (Robertson et al., 2009) retrieval model. These retrieved pairs form our exemplar context-response pairs $(c^{(k)}, r^{(k)})$, $1 \leq k \leq K$.

3.3 Exemplar Encoder Network

Given the exemplar pairs $(c^{(k)}, r^{(k)})$, $1 \leq k \leq K$ and an input context-response pair (c, r), we feed the input context c and the exemplar contexts $c^{(1)}, \ldots, c^{(K)}$ through an encoder to generate the embeddings as given below:

$$c_e = Encode_c(c)$$
$$c_e^{(k)} = Encode_c(c^{(k)}),\ 1 \leq k \leq K$$

Note that we do not constrain our choice of encoder and that any parametrized differentiable architecture can be used as the encoder to generate the above embeddings. Similarly, we feed the exemplar responses $r^{(1)}, \ldots, r^{(K)}$ through a response encoder to generate response embeddings $r_e^{(1)}, \ldots, r_e^{(K)}$, that is,

$$r_e^{(k)} = Encode_r(r^{(k)}),\ 1 \leq k \leq K \qquad (1)$$

Next, we concatenate the exemplar response encoding $r_e^{(k)}$ with an encoded representation of current context c_e as shown in equation 2 to create the exemplar vector $e^{(k)}$. This allows us to include in-

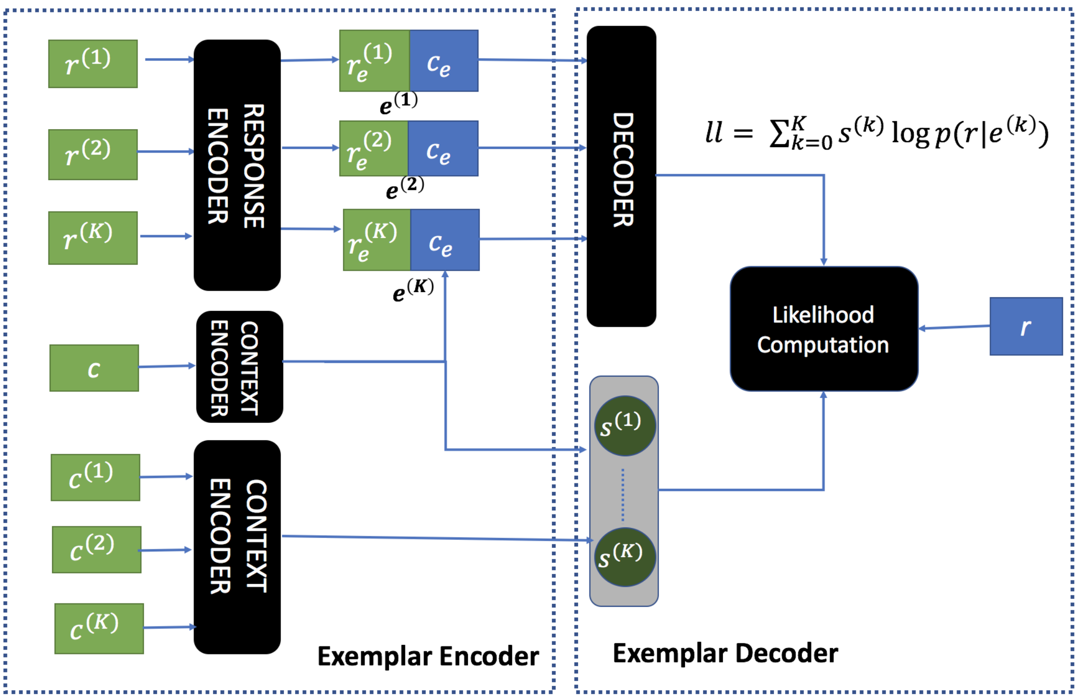

Figure 1: A schematic illustration of the EED network. The input context-response pair is (c, r), while the exemplar context-response pairs are $(c^{(k)}, r^{(k)})$, $1 \leq k \leq K$.

formation about similar responses along with the encoded input context representation.

$$e^{(k)} = [c_e; r_e^{(k)}],\ 1 \leq k \leq K \tag{2}$$

The exemplar vectors $e^{(k)}$, $1 \leq k \leq K$ are further used by the decoder for generating the ground truth response as described in the next section.

3.4 Exemplar Decoder Network

Recall that we want the exemplar responses to help generate the responses based on how similar the corresponding contexts are with the input context. More similar an exemplar context is to the input context, higher should be its effect in generating the response. To this end, we compute the similarity scores $s^{(k)}$, $1 \leq k \leq K$ using the encodings computed in Section 3.3 as shown below.

$$s^{(k)} = \frac{\exp(c_e^{\mathrm{T}} c_e^{(k)})}{\sum_{l=1}^{K} \exp(c_e^{\mathrm{T}} c_e^{(l)})} \tag{3}$$

Next, each exemplar vector $e^{(k)}$ computed in Section 3.3, is fed to a decoder, where the decoder is responsible for predicting the ground truth response from the exemplar vector. Let $p^{dec}(r|e^{(k)})$ be the distribution of generating the ground truth response given the exemplar embedding. The objective function to be maximized, is expressed as a function of the scores $s^{(k)}$, the decoding distribution p^{dec} and the exemplar vectors $e^{(k)}$ as shown below:

$$ll = \sum_{k=1}^{K} s^{(k)} \log p^{dec}(r|e^{(k)}) \tag{4}$$

Note that we weigh the contribution of each exemplar vector to the final objective based on how similar the corresponding context is to the input context. Moreover, the similarities are differentiable function of the input and hence, trainable by back propagation. The model should learn to assign higher similarities to the exemplar contexts, whose responses are helpful for generating the correct response.

The model description uses encoder and decoder networks that can be implemented using any differentiable parametrized architecture. We discuss our choices for the encoders and decoder in the next section.

3.5 The Encoders and Decoder

In this section, we discuss the various encoders and the decoder used by our model. The conversation context consists of an ordered sequence of utterances and each utterance can be further viewed as a sequence of words. Thus, context can be viewed as having multiple levels of hierarchies—at the word level and then at the utterance (sentence) level. We use a hierarchical recurrent encoder—popularly employed as part of the HRED framework for generating responses and query suggestions (Sordoni et al., 2015a; Serban et al., 2016, 2017b). The word-level encoder encodes the vector representations of words of an utterance to an utterance vector. Finally, the utterance-level encoder encodes the utterance vectors to a context vector.

Let $(\mathbf{u}_1, \ldots, \mathbf{u}_N)$ be the utterances present in the context. Furthermore, let $(w_{n1}, \ldots, w_{nM_n})$ be the words present in the n^{th} utterance for $1 \leq n \leq N$. For each word in the utterance, we retrieve its corresponding embedding from an embedding matrix. The word embedding for w_{nm} will be denoted as w_{enm}. The encoding of the n^{th} utterance can be computed iteratively as follows:

$$h_{nm} = f_1(h_{nm-1}, w_{enm}),\ 1 \leq m \leq M_n \qquad (5)$$

We use an LSTM (Hochreiter and Schmidhuber, 1997) to model the above equation. The last hidden state h_{nM_n} is referred to as the utterance encoding and will be denoted as h_n.

The utterance-level encoder takes the utterance encodings $h_1, \ldots, h_N$ as input and generates the encoding for the context as follows:

$$c_{en} = f_2(c_{en-1}, h_n),\ 1 \leq n \leq N \qquad (6)$$

Again, we use an LSTM to model the above equation. The last hidden state c_{eN} is referred to as the context embedding and is denoted as c_e.

A single level LSTM is used for embedding the response. In particular, let $(w_1, \ldots, w_M)$ be the sequence of words present in the response. For each word w, we retrieve the corresponding word embedding w_e from a word embedding matrix. The response embedding is computed from the word embeddings iteratively as follows:

$$r_{em} = g(r_{em-1}, w_{em}),\ 1 \leq m \leq M \qquad (7)$$

Again, we use an LSTM to model the above equation. The last hidden state r_{em} is referred to as the response embedding and is denoted as r_e.

4 Experimental Setup

4.1 Datasets

4.1.1 Ubuntu Dataset

We conduct experiments on Ubuntu Dialogue Corpus (Lowe et al., 2015)(v2.0)[2]. Ubuntu dialogue corpus has about 1M context response pairs along with a label. The label value 1 indicates that the response associated with a context is the correct response and is incorrect otherwise. As we are only interested in positive labeled data we work with $label = 1$. Table 2 depicts some statistics for the dataset.

	Size
Training Pairs	499,873
Validation Pairs	19,560
Test Pairs	18,920
$\lvert V \rvert$	538,328

Table 2: Dataset statistics for Ubuntu Dialog Corpus v2.0 (Lowe et al., 2015), where $|V|$ represents the size of vocabulary.

4.1.2 Tech Support Dataset

We also conduct our experiments on a large technical support dataset with more than 127K conversations. We will refer to this dataset as Tech Support dataset in the rest of the paper. Tech Support dataset contains conversations pertaining to an employee seeking assistance from an agent (technical support) — to resolve problems such as password reset, software installation/licensing, and wireless access. In contrast to Ubuntu dataset, this dataset has clearly two distinct users — employee and agent. In our experiments we model the *agent* responses only.

For each conversation in the tech support data, we sample context and response pairs to create a dataset similar to the Ubuntu dataset format. Note that multiple context-response pairs can be generated from a single conversation. For each conversation, we sample 25% of the possible context-response pairs. We create validation pairs by selecting 5000 conversations randomly and sampling context response pairs). Similarly, we create test pairs from a different subset of 5000 conversations. The remaining conversations are used to

[2]https://github.com/rkadlec/ubuntu-ranking-dataset-creator

create training context-response pairs. Table 3 depicts some statistics for this dataset:

	Size
Conversations	127,466
Training Pairs	204,808
Validation Pairs	8,738
Test Pairs	8,756
$\|V\|$	293,494

Table 3: Dataset statistics for Tech Support dataset.

4.2 Model and Training Details

The EED and HRED models were implemented using the PyTorch framework (Paszke et al., 2017). We initialize the word embedding matrix as well as the weights of context and response encoders from the standard normal distribution with mean 0 and variance 0.01. The biases of the encoders and decoder are initialized with 0. The word embedding matrix is shared by the context and response encoders. For Ubuntu dataset, we use a word embedding size of 600, whereas the size of the hidden layers of the LSTMs in context and response encoders and the decoder is fixed at 1200. For Tech support dataset, we use a word embedding size of 128. Furthermore, the size of the hidden layers of the multiple LSTMs in context and response encoders and the decoder is fixed at 256. A smaller embedding size was chosen for the Tech Support dataset since we observed much less diversity in the responses of the Tech Support dataset as compared to Ubuntu dataset.

Two different encoders are used for encoding the input context (not shown in Figure 1 for simplicity). The output of the first context encoder is concatenated with the exemplar response vectors to generate exemplar vectors as detailed in Section 3.3. The output of the second context encoder is used to compute the scoring function as detailed in Section 3.4. For each input context, we retrieve 5 similar context-response pairs for Ubuntu dataset and 3 context-response pairs for Tech support dataset using the tf-idf mechanism discussed in Section 3.2.

We use the Adam optimizer (Kingma and Ba, 2014) with a learning rate of $1e-4$ for training the model. A batch size of 20 samples was used during training. In order to prevent overfitting, we use early stopping with log-likelihood on validation set as the stopping criteria. In order to generate the samples using the proposed EED model, we identify the exemplar context that is most similar to the input context based on the learnt scoring function discussed in Section 3.4. The corresponding exemplar vector is fed to the decoder to generate the response. The samples are generated using a beam search with width 5. The average per-word log-likelihood is used to score the beams.

5 Results & Evaluation

5.1 Quantitative Evaluation

5.1.1 Activity and Entity Metrics

A traditional and popular metric used for comparing a generated sentence with a ground truth sentence is BLEU (Papineni et al., 2002) and is frequently used to evaluate machine translation. The metric has also been applied to compute scores for predicted responses in conversations, but it has been found to be less indicative of actual performance (Liu et al., 2016; Sordoni et al., 2015a; Serban et al., 2017a), as it is extremely sensitive to the exact words in the ground truth response, and gives equal importance to stop words/phrases and informative words.

Serban et al. (2017a) recently proposed a new set of metrics for evaluating dialogue responses for the Ubuntu corpus. It is important to highlight that these metrics have been specifically designed for the Ubuntu corpus and evaluate a generated response with the ground truth response by comparing the coarse level representation of an utterance (such as entities, activities, Ubuntu OS commands). Here is a brief description of each metric:

- **Activity**: Activity metric compares the activities present in a predicted response with the ground truth response. Activity can be thought of as a verb. Thus, all the verbs in a response are mapped to a set of manually identified list of 192 verbs.

- **Entity**: This compares the technical entities that overlap with the ground truth response. A total of 3115 technical entities is identified using public resources such as Debian package manager APT.

	Activity			Entity			Tense	Cmd
Model	**P**	**R**	**F1**	**P**	**R**	**F1**	**Acc.**	**Acc.**
LSTM*	1.7	1.03	1.18	1.18	0.81	0.87	14.57	94.79
VHRED*	**6.43**	4.31	4.63	3.28	2.41	2.53	20.2	92.02
HRED*	5.93	4.05	4.34	2.81	2.16	2.22	22.2	92.58
EED	6.42	**4.77**	**4.87**	**3.8**	**2.91**	**2.99**	**31.73**	**95.06**

Table 4: Activity & Entity metrics for the Ubuntu corpus. LSTM*, HRED* & VHRED* as reported by Serban et al. (2017a).

- **Tense**: This measure compares the time tense of ground truth with predicted response.

- **Cmd**: This metric computes accuracy by comparing commands identified in ground truth utterance with a predicted response.

Table 4 compares our model with other recent generative models (Serban et al., 2017a) — LSTM (Shang et al., 2015), HRED (Serban et al., 2016) & VHRED (Serban et al., 2017b).We do not compare our model with Multi-Resolution RNN (MRNN) (Serban et al., 2017a), as MRNN explicitly utilizes the activities and entities during the generation process. In contrast, the proposed EED model and the other models used for comparison are agnostic to the activity and entity information. We use the standard script[3] to compute the metrics.

The EED model scores better than generative models on almost all of the metrics, indicating that we generate more *informative* responses than other state-of-the-art generative based approaches for Ubuntu corpus. The results show that responses associated with similar contexts may contain the activities and entities present in the ground truth response, and thus help in response generation. This is discussed further in Section 5.2. Additionally, we compared our proposed EED with a retrieval only baseline. The retrieval baseline achieves an activity F1 score of 4.23 and entity F1 score of 2.72 compared to 4.87 and 2.99 respectively achieved by our method on the Ubuntu corpus.

The Tech Support dataset is not evaluated using the above metrics, since activity and entity information is not available for this dataset.

5.1.2 Embedding Metrics

Embedding metrics (Lowe et al., 2017) were proposed as an alternative to word by word comparison metrics such as BLEU. We use pre-trained Google news word embeddings[4] similar to Serban et al. (2017b), for easy reproducibility as these metrics are sensitive to the word embeddings used. The three metrics of interest utilize the word vectors in ground truth response and a predicted response and are discussed below:

- **Average**: Average word embedding vectors are computed for the candidate response and ground truth. The cosine similarity is computed between these averaged embeddings. High similarity gives as indication that ground truth and predicted response have similar words.

- **Greedy**: Greedy matching score finds the most similar word in predicted response to ground truth response using cosine similarity.

- **Extrema**: Vector extrema score computes the maximum or minimum value of each dimension of word vectors in candidate response and ground truth.

Of these, the embedding average metric is the most reflective of performance for our setup. The extrema representation, for instance, is very sensitive to text length and becomes ineffective beyond single length sentences(Forgues et al., 2014). We use the publicly available script[5] for all our computations. As the test outputs for HRED are not available for Technical Support dataset, we use our

Table 7: Contexts, exemplar responses and responses generated by HRED, VHRED and the proposed EED model. We use the published responses for HRED and VHRED. GT indicates the ground truth response. The change of turn is indicated by $\rightarrow$. The highlighted words in **bold** are common between the exemplar response and the response predicted by EED.

own implementation of HRED. Table 5 compares our model with HRED, and depicts that our model scores better on all metrics for Technical Support dataset, and on majority of the metrics for Ubuntu dataset.

We note that the improvement achieved by the

EED model on activity and entity metrics are much more significant than those on embedding metrics. This suggests that the EED model is better able to capture the specific information (objects and actions) present in the conversations.

Finally, we evaluate the diversity of the generated responses for EED against HRED by counting the number of unique tokens, token-pairs and token-triplets present in the generated responses on Ubuntu and Tech Support dataset. The results are shown in Table 6. As can be observed, the responses in EED have a larger number of distinct tokens, token-pairs and token-triplets than HRED, and hence, are arguably more diverse.

5.2 Qualitative Evaluation

Table 7 presents the responses generated by HRED, VHRED and the proposed EED for a few selected contexts along with the corresponding similar exemplar responses. As can be observed from the table, the responses generated by EED tend to be more specific to the input context as compared to the responses of HRED and VHRED. For example, in conversations 1 and 2 we find that both HRED and VHRED generate simple generic responses whereas EED generates responses with additional information such as the type of disk partition used or a command not working. This is also confirmed by the quantitative results obtained using activity and entity metrics in the previous section. We further observe that the exemplar responses contain informative words that are utilized by the EED model for generating the responses as highlighted in Table 7.

6 Conclusions

In this work, we propose a deep learning method, Exemplar Encoder Decoder (EED), that given a conversation context uses similar contexts and corresponding responses from training data for generating a response. We show that by utilizing this information the system is able to outperform state of the art generative models on publicly available Ubuntu dataset. We further show improvements achieved by the proposed method on a large collection of technical support conversations.

While in this work, we apply the exemplar encoder decoder network on conversational task, the method is generic and could be used with other tasks such as question answering and machine translation. In our future work we plan to extend the proposed method to these other applications.

DialSQL: Dialogue Based Structured Query Generation

Izzeddin Gur and **Semih Yavuz** and **Yu Su** and **Xifeng Yan**

{izzeddingur,syavuz,ysu,xyan}@cs.ucsb.edu

Abstract

The recent advance in deep learning and semantic parsing has significantly improved the translation accuracy of natural language questions to structured queries. However, further improvement of the existing approaches turns out to be quite challenging. Rather than solely relying on algorithmic innovations, in this work, we introduce DialSQL, a dialogue-based structured query generation framework that leverages human intelligence to boost the performance of existing algorithms via user interaction. DialSQL is capable of identifying potential errors in a generated SQL query and asking users for validation via simple multi-choice questions. User feedback is then leveraged to revise the query. We design a generic simulator to bootstrap synthetic training dialogues and evaluate the performance of DialSQL on the WikiSQL dataset. Using SQLNet as a black box query generation tool, DialSQL improves its performance from 61.3% to 69.0% using only 2.4 validation questions per dialogue.

1 Introduction

Building natural language interfaces to databases (NLIDB) is a long-standing open problem and has significant implications for many application domains. It can enable users without SQL programming background to freely query the data they have. For this reason, generating SQL queries from natural language questions has gained a renewed interest due to the recent advance in deep learning and semantic parsing (Yaghmazadeh et al., 2017; Zhong et al., 2017; Xu et al., 2017; Iyer et al., 2017).

While new methods race to achieve the state-of-the-art performance on NLIDB datasets such as WikiSQL (Xu et al., 2017; Zhong et al., 2017), the accuracy is still not high enough for real use. For example, SQLNet (Xu et al., 2017) achieves 61.3% accuracy on WikiSQL. After analyzing the error cases of Seq2SQL (Zhong et al., 2017) and SQLNet, we recognized that many wrong translations cannot be easily corrected due to the lack of external knowledge and semantic understanding.

In this paper, we aim to alleviate the aforementioned problem by putting human users in the loop. Previous human-in-the-loop NLIDBs (Li and Jagadish, 2014; Yaghmazadeh et al., 2017) rely on users to carefully go through a generated SQL query and revise it accordingly, which is not feasible for users who do not know the SQL language. Instead, we resort to a different approach by introducing a goal-oriented dialogue model, DialSQL, that interacts with users to extract and correct potential errors in the generated queries.

Given a SQL query generated from a natural language question, we assume any segment, or span, of the generated query such as a `WHERE` clause can be potentially erroneous. The goal of DialSQL is to extract the erroneous spans and ask users multi-choice questions to validate and correct these errors. DialSQL is based on a hierarchical encoder-decoder architecture with attention and pointer mechanisms. The model first encodes each turn of interaction and runs a dialogue level RNN network on the dialogue history. The output of the network is then used to predict the error category, i.e., whether it is a selection, projection, or aggregation error. Conditioned on the error category, the output of a second RNN is used to predict the start and end positions of the error span by pointing to the query tokens. Finally, candidate choices are decoded from the error category and span representations. Following previous

Natural Language Question :	What are the countries that joined the NATO before 2004 ?
Ground Truth SQL Query :	SELECT country WHERE date of join < 2004
Initial SQL Query :	SELECT count (country) WHERE date of join = 2004

Turn Side	NL Expression using Rule-Based Templates	Response
System:	Could you please confirm if you are asking **total number of the results**?	validate_agg (1, 2)
User:	No, that's not true.	negate()
System:	Could you please select one of the following options : (i) **average number of results**, (ii) **all the results**?	offer_agg (average, no_agg)
User:	It should be **all the results**.	select(2)
System:	Could you please confirm if **date of join is 2004** ?	validate_where_change(6, 11)
User:	That's wrong.	negate()
System:	Could you please select one of the following options : (i) **date of join is before 2004**, (ii) **date of invitation is before 2004**?	offer_where (date of join < 2004, date of invitation < 2004)
User:	**Date of join is before 2004**.	select(1)

Table 1: DialSQL model running example. Initial SQL query is generated by running a black box model on the question. Natural language (NL) expressions are generated using a template based method. Substrings in red represent the error spans and substrings in blue represent the choices offered. Each response is accompanied with natural language utterances for clarity.

work (Zhong et al., 2017; Xu et al., 2017), we only use column names and do not utilize table values.

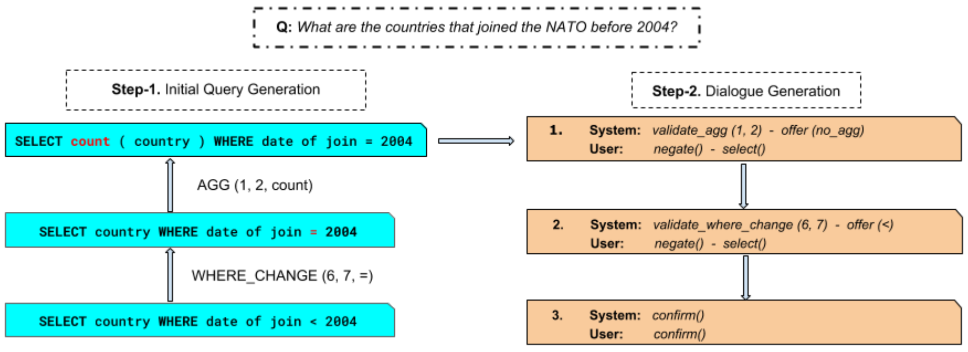
How to train and evaluate DialSQL become two challenging issues due to the lack of error data and interaction data. In this work, we construct a simulator to generate simulated dialogues, a general approach practiced by many dialogue studies. Inspired by the agenda-based methods for user simulation (Schatzmann et al., 2007), we keep an agenda of pending actions that are needed to induce the ground truth query. At the start of the dialogue, a new query is carefully synthesized by randomly altering the ground truth query and the agenda is populated by the sequence of altering actions. Each action consists of three sub-actions: (i) Pick an error category and extract a span; (ii) Raise a question; (iii) Update the query by randomly altering the span and remove the action from the agenda. Consider the example in Figure 1: Step-1 synthesizes the initial query by randomly altering the `WHERE` clause and `AGGREGATION`; Step-2 generates the simulated dialogue by validating the altered spans and offering the correct choice.

To evaluate our model, we first train DialSQL on the simulated dialogues. Initial queries for new questions are manufactured by running a black box SQL generation system on the new questions. When tested on the WikiSQL (Zhong et al., 2017) dataset, our model increases the query match accuracy of SQLNet (Xu et al., 2017) from 61.3% to 69.0% using on average 2.4 validation questions per query.

2 Related Work

Research on natural language interfaces to databases (NLIDBs), or semantic parsing, has spanned several decades. Early rule-based NLIDBs (Woods, 1973; Androutsopoulos et al., 1995; Popescu et al., 2003) employ carefully designed rules to map natural language questions to formal meaning representations like SQL queries. While having a high precision, rule-based systems are brittle when facing with language variations. The rise of statistical models (Zettlemoyer and Collins, 2005; Kate et al., 2005; Berant et al., 2013), especially the ongoing wave of neural network models (Yih et al., 2015; Dong and Lapata, 2016; Sun et al., 2016; Zhong et al., 2017; Xu et al., 2017; Guo and Gao, 2018; Yavuz et al., 2016), has enabled NLIDBs that are more robust to language variations. Such systems allow users to formulate questions with greater flexibility. However, although state-of-the-art systems have achieved a high accuracy of 80% to 90% (Dong and Lapata, 2016) on well-curated datasets like GEO (Zelle and Ray, 1996) and ATIS (Zettlemoyer and Collins, 2007), the best accuracies on datasets with questions formulated by real human users, e.g., WebQuestions (Berant et al., 2013), GraphQuestions (Su et al., 2016), and WikiSQL (Zhong et al., 2017), are still far from enough for real use, typically in the range of 20% to 60%.

Human-in-the-loop systems are a promising paradigm for building practical NLIDBs. A number of recent studies have explored this paradigm with two types of user interaction: coarse-grained and fine-grained. Iyer et al. (2017) and Li et



Q: What are the countries that joined the NATO before 2004?

User: negate() - select()
3. System: confirm()
User: confirm()

Figure 1: An instantiation of our dialogue simulation process. Step-1 synthesizes the initial query (top) by randomly altering the ground truth query (bottom). Step-2 generates the dialogue by validating the sequence of actions populated in Step-1 with the user. Each action is defined by the error category, start and end positions of the error span, and the random replacement, ex. `AGG (1, 2, count)`.

al. (2016) incorporate coarse-grained user interaction, i.e., asking the user to verify the correctness of the final results. However, for real-world questions, it may not always be possible for users to verify result correctness, especially in the absence of supporting evidence. Li and Jagadish (2014) and Yaghmazadeh et al. (2017) have shown that incorporating fine-grained user interaction can greatly improve the accuracy of NLIDBs. However, they require that the users have intimate knowledge of SQL, an assumption that does not hold for general users. Our method also enables fine-grained user interaction for NLIDBs, but we solicit user feedback via a dialogue between the user and the system.

Our model architecture is inspired by recent studies on hierarchical neural network models (Sordoni et al., 2015; Serban et al., 2015; Gur et al., 2017). Recently, Saha et al. (2018) propose a hierarchical encoder-decoder model augmented with key-value memory network for sequential question answering over knowledge graphs. Users ask a series of questions, and their system finds the answers by traversing a knowledge graph and resolves coreferences between questions. Our interactive query generation task significantly differs from their setup in that we aim to explicitly detect and correct the errors in the generated SQL query via a dialogue between our model and the user.

Agenda based user simulations have been investigated in goal-oriented dialogues for model training (Schatzmann et al., 2007). Recently, Seq2seq neural network models are proposed for user simulation (Asri et al., 2016) that utilize additional state tracking signals and encode dialogue turns in a more coarse way. We design a simulation method for the proposed task where we generate dialogues with annotated errors by altering queries and tracking the sequence of alteration steps.

3 Problem Setup and Datasets

We study the problem of building an interactive natural language interface to databases (INLIDB) for synthesizing SQL queries from natural language questions. In particular, our goal is to design a dialogue system to extract and validate potential errors in generated queries by asking users multi-choice questions over multiple turns. We will first define the problem formally and then explain our simulation strategy.

3.1 Interactive Query Generation

At the beginning of each dialogue, we are given a question $Q = \{q_1, q_2, \cdots, q_N\}$, a table with column names $T = \{T_1, T_2, \cdots, T_K\}$ where each name is a sequence of words, and an initial SQL query U generated using a black box SQL generation system. Each turn t is represented by a tuple of system and user responses, (S_t, R_t), and augmented with the dialogue history (list of previous turns), H_t. Each system response is a triplet of error category c, error span s, and a set of candidate choices C, i.e., $S_t = (c, s, C)$. An error category (Table 2) denotes the type of the error that we seek to correct and an error span is the segment of the current query that indicates the actual error. Candidate choices depend on the error category and range over the following possibilities: (i) a column name, (ii) an aggregation operator, or (iii) a where condition. User responses are represented by ei-

Error Category	Meaning in a dialogue
validate_sel	Validate the select clause
validate_agg	Validate the aggregation operator
validate_where_changed	Validate if a segment of a where clause is incorrect
validate_where_removed	Validate if a new where clause is needed
validate_where_added	Validate if an incorrect where clause exists
no_error	Validate if there is no remaining error

Table 2: The list of error categories and their explanations for our interactive query generation task.

ther an affirmation or a negation answer and an index c' to identify a choice. We define the *interactive query generation task* as a list of subtasks: at each turn t, (i) predict c, (ii) extract s from U, and (iii) decode C. The task is supervised and each subtask is annotated with labeled data.

Consider the example dialogue in Table 1. We first predict `validate_agg` as the error category and error span ($start = 1, end = 2$) is decoded by pointing to the *aggregation* segment of the query. Candidate choices, `(average, no_agg)`, are decoded using the predicted error category, predicted error span, and dialogue history. We use a template based natural language generation (NLG) component to convert system and user responses into natural language.

3.2 Dialogue Simulation for INLIDB

In our work, we evaluate our model on the WikiSQL task. Each example in WikiSQL consists of a natural language question and a table to query from. The task is to generate a SQL query that correctly maps the question to the given table. Unfortunately, the original WikiSQL lacks error data and user interaction data to train and evaluate DialSQL. We work around this problem by designing a simulator to bootstrap training dialogues and evaluate DialSQL on the test questions of WikiSQL.

Inspired by the agenda-based methods (Schatzmann et al., 2007), we keep an agenda of pending actions that are needed to induce the ground truth query. At the start of the dialogue, we synthesize a new query by randomly altering the ground truth query and populating the agenda by the sequence of altering actions. Each action launches a sequence of sub-actions: (i) Randomly select an error category and extract a related span from the current query, (ii) randomly generate a valid choice for the chosen span, and (iii) update the current query by replacing the span with the choice. The dialogue is initiated with the final query and a rule-based system interacts with a rule-based user simulator to populate the dialogue. The rule-based system follows the sequence of altering actions previously generated and asks the user simulator a single question at each turn. The user simulator has access to the ground truth query and answers each question by comparing the question (error span and the choice) with the ground truth.

Consider the example in Figure 1 where Step-1 synthesizes the initial query and Step-2 simulates a dialogue using the outputs of Step-1. Step-1 first randomly alters the `WHERE` clause; the operator is replaced with a random operator. The updated query is further altered and the final query is passed to Step-2. In Step-2, the system starts with validating the aggregation with the user simulator. In this motivating example, the aggregation is incorrect and the user simulator negates and selects the offered choice. During training, there is only a single choice offered and DialSQL trains to produce this choice; however, during testing, it can offer multiple choices. In the next step, the system validates the `WHERE` clause and generates a `no_error` action to issue the generated query. At the end of this process, we generate a set of labeled dialogues by executing Step-1 and Step-2 consecutively. DialSQL interacts with the same rule-based simulator during testing and the SQL queries obtained at the end of the dialogues are used to evaluate the model.

4 Dialogue Based SQL Generation

In this section, we present our DialSQL model and describe its operation in a fully supervised setting. DialSQL is composed of three layers linked in a hierarchical structure where each layer solves a different subtask : (i) Predicting error category, (ii) Decoding error span, and (iii) Decoding candidate choices (illustrated in Figure 2). Given a (Q, T, U) triplet, the model first encodes Q, each column name $T_i \in T$, and query U into vector representations in parallel using Recurrent Neural Networks (RNN). Next, the first layer of the model encodes the dialogue history with an RNN and predicts the error category from this encoding. The second layer is conditioned on the error category and decodes the start and end positions of the error span by attending over the outputs of query encoder. Finally, the last layer is conditioned on both error category and error span and decodes a list of choices to offer to the user.

4.1 Preliminaries and Notation

Each token w is associated with a vector e_w from rows of an embeddings matrix E. We aim at obtaining vector representations for question, table headers, and query, then generating error category, error span, and candidate choices.

For our purposes, we use GRU units (Cho et al., 2014) in our RNN encoders which are defined as

$$h_t = f(x_t; h_{t-1})$$

where h_t is the hidden state at time t. f is a nonlinear function operating on input vector x_t and previous state h_{t-1}. We refer to the last hidden state of an RNN encoder as the encoding of a sequence.

4.2 Encoding

The core of our model is a hierarchical encoder-decoder neural network that encodes dialogue history and decodes errors and candidate choices at the end of each user turn. The input to the model is the previous system turn and the current user turn and the output is the next system question.

Encoding Question, Column Names, and Query. Using decoupled RNNs (Enc), we encode natural language question, column names, and query sequences in parallel and produce outputs and hidden states. o^Q, o^{T_i}, and o^U denote the sequence of hidden states at each step and h^Q, h^{T_i}, and h^U denote the last hidden states of question, column name, and query encoders, respectively. Parameters of the encoders are decoupled and only the word embedding matrix E is shared.

Encoding System and User Turns Since there is only a single candidate choice during training, we ignore the index and encode user turn by doing an embedding lookup using the validation answer (affirmation or negation). Each element (error category, error span, and candidate choice) of the system response is encoded by doing an embedding lookup and different elements are used as input at different layers of our model.

Encoding Dialogue History At the end of each user turn, we first concatenate the previous error category and the current user turn encodings to generate the turn level input. We employ an RNN to encode dialogue history and current turn into a fixed length vector as

$$\begin{aligned} h_0^{D_1} &= h^Q \\ o_t^{D_1}, g_t^{D_1} &= Enc([E_c, E_a]) \\ h_t^{D_1} &= [Attn(g_t^{D_1}, H^T), o_t^D] \end{aligned}$$

where $[.]$ is vector concatenation, E_c is the error category encoding, E_a is the user turn encoding, $h_0^{D_1}$ is the initial hidden state, and $h_t^{D_1}$ is the current hidden state. $Attn$ is an attention layer with a bilinear product defined as in (Luong et al., 2015)

$$Attn(h, O) = \sum softmax(tanh(hWO)) * O$$

where W is attention parameter.

4.3 Predicting Error Category

We predict the error category by attending over query states using the output of the dialogue encoder as

$$\begin{aligned} c_t &= tanh(Lin([Attn(h_t^{D_1}, O^U), h_t^{D_1}])) \\ l_t &= softmax(c_t \cdot E(C)) \end{aligned}$$

where Lin is a linear transformation, $E(C)$ is a matrix with error category embeddings, and l_t is the probability distribution over categories.

4.4 Decoding Error Span

Consider the case in which there are more than one different `WHERE` clauses in the query and each clause has an error. In this case, the model needs to monitor previous error spans to avoid decoding the same error. DialSQL runs another RNN to generate a new dialogue encoding to solve the aforementioned problem as

$$\begin{aligned} h_0^{D_2} &= h^Q \\ o_t^{D_2}, g_t^{D_2} &= Enc(E_c) \\ h_t^{D_2} &= [Attn(g_t^{D_2}, H^T) o_t^{D_2}] \end{aligned}$$

where $h_0^{D_2}$ is the initial hidden state, and $h_t^{D_2}$ is the current hidden state. Start position i of the error span is decoded using the following probability distribution over query tokens

$$p_i = softmax(tanh(h_t^{D_2} L_1 H^U))$$

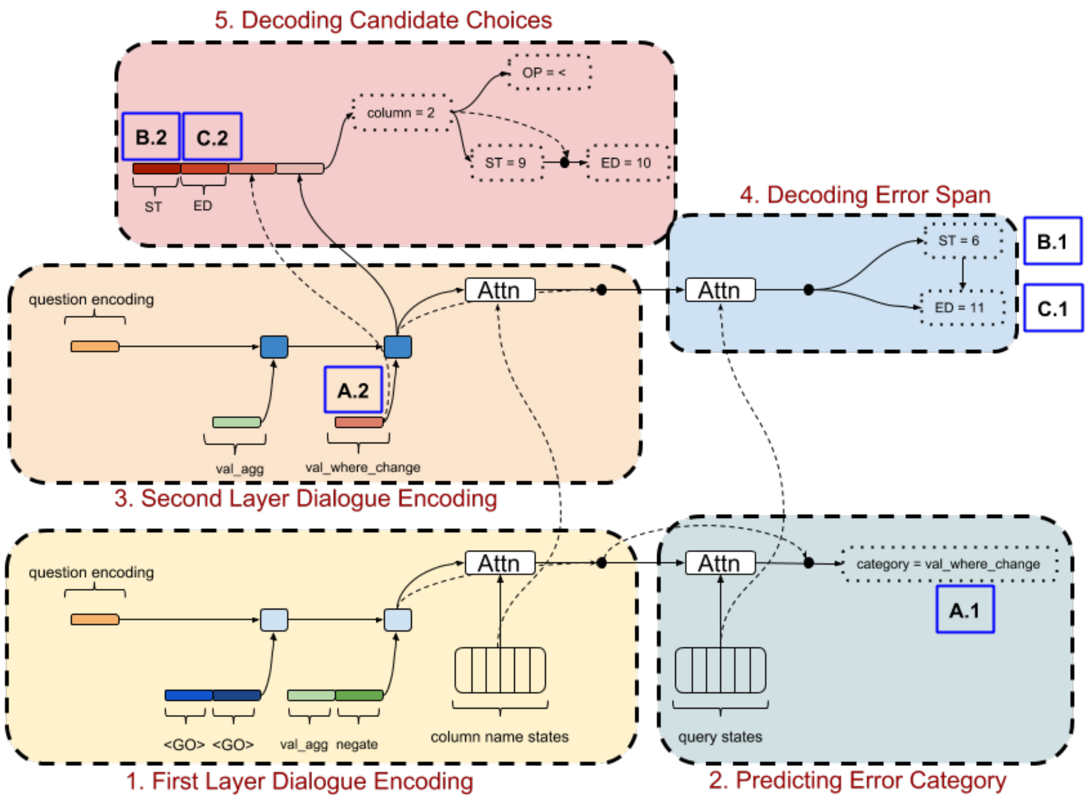

Figure 2: DialSQL model: Boxes are RNN cells, colors indicate parameter sharing. Dashed lines denote skip connections, dashed boxes denote classifications, and black circles denote vector concatenation. Blue boxes with capital letters and numbers (X.1, X.2) denote that the embeddings of predicted token at X.1 is passed as input to X.2. Each component in the pipeline is numbered according to execution order. `<GO>` is a special token to represent the start of a sequence and `ST` and `ED` denote the start and end indices of a span, respectively.

where p_i is the probability of start position over the ith query token. End position j of the error span is predicted by conditioning on the start position

$$c_i = \sum p_i * H^U$$
$$\hat{p}_j = softmax(tanh([h_t^{D_2}, c_i]L_2 H^U))$$

where $\hat{p}_j$ is the probability of end position over the jth query token. Conditioning on the error category will localize the span prediction problem as each category is defined by only a small segment of the query.

4.5 Decoding Candidate Choices

Given error category c and error span (i, j), DialSQL decodes a list of choices that will potentially replace the error span based on user feedback. Inspired by SQLNet (Xu et al., 2017), we describe our candidate choice decoding approach as follows.

Select column choice. We define the following scores over column names,

$$h = Attn(Lin([o_{i-1}^U, o_j^U, E_c]), H^T)$$
$$s_{sel} = u^T * tanh(Lin([H^T, h]))$$

where o_{i-1}^U is the output vector of the query encoder preceding the start position, and o_j^U is the output of query encoder at the end position.

Aggregation choice. Conditioned on the encoding e of the select column, we define the following scores over the set of aggregations (`MIN`, `MAX`, `COUNT`, `NO_AGGREGATION`)

$$s_{agg} = v^T * tanh(Lin(Attn(e, H^Q)))$$

Where condition choice. We first decode the condition column name similar to decoding select column. Given the encoding e of condition column, we define the following scores over the set of operators ($=, <, >$)

$$s_{op} = w^T * tanh(Lin(Attn(e, H^Q)))$$

Next, we define the following scores over question tokens for the start and end positions of the condition value

$$s_{st} = Attn(e, H^Q)$$
$$s_{ed} = Attn([e, h_{st}, H^Q])$$

where h_{st} is the context vector generated from the first attention. We denote the number of candidate choices to be decoded by k. We train DialSQL with $k = 1$. The list of $k > 1$ candidate choices is decoded similar to beam search during testing. As an example, we select k column names that have the highest scores as the candidate where column choices. For each column name, we first generate k different operators and from the set of $k * 2$ column name and operator pairs; select k operators that have the highest joint probability. Ideally, DialSQL should be able to learn the type of errors present in the generated query, extract precise error spans by pointing to query tokens, and using the location of the error spans, generate a set of related choices.

5 Experimental Results and Discussion

In this section, we evaluate DialSQL on WikiSQL using several evaluation metrics by comparing with previous literature.

5.1 Evaluation Setup and Metrics

We measure the query generation accuracy as well as the complexity of the questions and the length of the user interactions.

Query-match accuracy. We evaluate DialSQL on WikiSQL using query-match accuracy (Zhong et al., 2017; Xu et al., 2017). Query-match accuracy is the proportion of testing examples for which the generated query is exactly the same as the ground truth, except the ordering of the `WHERE` clauses.

Dialogue length. We count the number of turns to analyze whether DialSQL generates any redundant validation questions.

Question complexity. We use the average number of tokens in the generated validation questions to evaluate if DialSQL can generate simple questions without overwhelming users.

Since SQLNet and Seq2SQL are single-step models, we can not analyze DialSQL's performance by comparing against these on the last two metrics. We overcome this issue by generating simulated dialogues using an oracle system that has access to the ground truth query. The system compares `SELECT` and `AGGREGATION` clauses of the predicted query and the ground truth; asks a validation question if they differ. For each `WHERE` clause pairs of generated query and the ground truth, the system counts the number of matching segments namely `COLUMN, OP`, and `VALUE`. The system takes all the pairs with the highest matching scores and asks a validation question until one of the queries has no remaining `WHERE` clause. If both queries have no remaining clauses, the dialogue terminates. Otherwise, the system asks a `validate_where_added` (`validate_where_removed`) question when the generated query (ground truth query) has more remaining clauses. We call this strategy *Oracle-Matching (OM)*. OM ensures that the generated dialogues have the minimum number of turns possible.

5.2 Training Details

We implement DialSQL in TensorFlow (Abadi et al., 2016) using the Adam optimizer (Kingma and Ba, 2014) for the training with a learning rate of 1e−4. We use an embedding size of 300, RNN state size of 50, and a batch size of 64. The embeddings are initialized from pretrained GloVe embeddings (Pennington et al., 2014) and fine-tuned during training. We use bidirectional RNN encoders with two layers for questions, column names, and queries. Stanford CoreNLP tokenizer (Manning et al., 2014) is used to parse questions and column names. Parameters of each layer are decoupled from each other and only the embedding matrix is shared. The total number of turns is limited to 10 and 10 simulated dialogues are generated for each example in the WikiSQL training set. SQLNet and Seq2SQL models are trained on WikiSQL using the existing implemention provided by their authors. The code is available at `https://github.com/izzeddingur/DialSQL`.

5.3 Evaluation on the WikiSQL Dataset

Table 3 presents the results of query match accuracy. We observe that DialSQL model with a number of 5 choices improves the performance of both SQLNet and Seq2SQL by 7.7% and 9.4%, respectively. The higher gain on Seq2SQL model can be attributed that the single-step Seq2SQL makes more errors: DialSQL has more room for improvement. We also show the results of DialSQL where

Model	QM-Dev	QM-Test
Seq2SQL (Xu et al., 2017)	53.5%	51.6%
SQLNet (Xu et al., 2017)	63.2%	61.3%
BiAttn (Guo and Gao, 2018)	64.1%	62.5%
Seq2SQL - DialSQL	62.2%	61%
SQLNet - DialSQL	70.9%	69.0%
Seq2SQL - DialSQL$^+$	68.9%	67.8%
SQLNet - DialSQL$^+$	74.8%	73.9%
Seq2SQL - DialSQL*	84.4%	84%
SQLNet - DialSQL*	82.9%	83.7%

Table 3: Query-match accuracy on the WikiSQL development and test sets. The first two scores of our model are generated using 5 candidate choices, ($^+$) denotes a variant where users can revisit their previous answers, and (*) denotes a variant with more informative user responses.

users are allowed to revisit their previous answers and with more informative user responses; instead the model only validates the error span and the user directly gives the correct choice. In this scenario, the performance further improves on both development and test sets. It seems decoding candidate choices is a hard task and has room for improvement. For the rest of the evaluation, we present results with multi-choice questions.

5.4 Query Complexity and Dialogue Length

In Table 4, we compare DialSQL to the OM strategy on query complexity (QC) and dialogue length (DL) metrics. DialSQL and SQLNet-OM both have very similar query complexity scores showing that DialSQL produces simple questions. The number of questions DialSQL asks is around 3 for both query generation models. Even though SQLNet-OM dialogues have much smaller dialogue lengths, we attribute this to the fact that 61.3% of the dialogues have empty interactions since OM will match every segment in the generated query and the ground truth. The average number of turns in dialogues with non-empty interactions, on the other hand, is 3.10 which is close to DialSQL.

5.5 A Varying Number of Choices

In Figure 3, we plot the accuracy of DialSQL on WikiSQL with a varying number of choices at each turn. We train DialSQL once and generate a different number of choices at each turn by offering top-k candidates during testing. We observe that offering even a single candidate improves the performance of SQLNet remarkably, 1.9% and

Model	QC Dev	DL Dev	QC Test	DL Test
Seq2SQL - OM	3.47 (2.25)	0.84 (1.77)	3.51 (2.41)	0.88 (1.8)
SQLNet - OM	3.37 (2.63)	0.61 (1.45)	3.34 (2.51)	0.63 (1.49)
Seq2SQL - DialSQL	3.53 (1.79)	5.54 (2.32)	3.55 (1.81)	5.55 (2.34)
SQLNet - DialSQL	3.6 (1.86)	5.57 (2.34)	3.17 (1.55)	4.77 (1.57)

Table 4: Average query complexity and dialogue length on the WikiSQL datasets (values in paranthesis are standard deviations). Metrics for SQLNet and Seq2SQL models are generated by the OM strategy as described earlier.

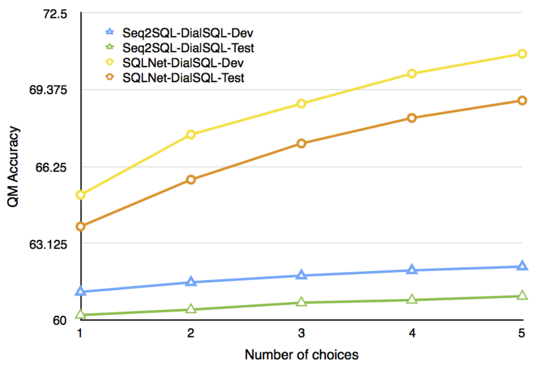

Figure 3: DialSQL performance on WikiSQL with a varying number of choices at each turn.

2.5% for development and test sets, respectively. As the number of choices increases, the performance of DialSQL improves in all the cases. Particularly, for the SQLNet-DialSQL model we observe more accuray gain. We increased the number of choices to 10 and observed no notable further improvement in the development set which suggests that 5 is a good value for the number of choices.

5.6 Error Distribution

We examine the error distribution of DialSQL and SQLNet. In DialSQL, almost all the errors are caused by `validate_sel` and `validate_where_change`, while in SQLNet `validate_where_change` is the major cause of error and other errors are distributed uniformly.

5.7 Human Evaluation

We extend our evaluation of DialSQL using human subject experiment so that real users interact with the system instead of our simulated user. We randomly pick 100 questions from WikiSQL development set and run SQLNet to generate initial candidate queries. Next, we run DialSQL using these candidate queries to generate 100 dialogues, each of which is evaluated

Model	Accuracy
SQLNet	58
DialSQL w/ User Simulation	75
DialSQL w/ Real Users	65 (1.4)

Table 5: QM accuracies of SQLNet, DialSQL with user simulation, and DialSQL with real users (value in paranthesis is standard deviation).

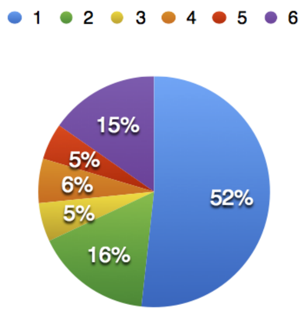

Figure 4: Distribution of user preference for DialSQL ranking (scaled to 1-6 with 6 is *None of the above.*).

by 3 different users. At each turn, we show users the headers of the corresponding table, original question, system response, and list of candidate choices for users to pick. For each error category, we generate 5 choices except for the `validate_where_added` category for which we only show 2 choices (YES or NO). Also, we add an additional choice of *None of the above* so that users can keep the previous prediction unchanged. At the end of each turn, we also ask users to give an *overall score* between 1 and 3 to evaluate whether they had a successful interaction with the DialSQL for the current turn. On average, the length of the generated dialogues is 5.6.

In Table 5, we compare the performance of SQLNet, DialSQL with user simulation, and DialSQL with real users using QM metric. We present the average performance across 3 different users with the standard deviation estimated over all dialogues. We observe that when real users interact with our system, the overall performance of the generated queries are better than SQLNet model showing that DialSQL can improve the performance of a strong NLIDB system in a real setting. However, there is still a large room for improvement between simulated dialogues and real users.

In Figure 4, we present the correlation between DialSQL ranking of the candidate choices and user preferences. We observe that, user answers and DialSQL rankings are positively correlated; most of the time users prefer the top-1 choice. Interestingly, 15% of the user answers is *None of the above*. This commonly happens in the scenario where DialSQL response asks to replace a correct condition and users prefer to keep the original prediction unchanged. Another scenario where users commonly select *None of the above* is when table headers without the content remain insufficient for users to correctly disambiguate condition values from questions. We also compute the Mean Reciprocal Rank (MMR) for each user to measure the correlation between real users and DialSQL. Average MMR is 0.69 with standard deviation of 0.004 which also shows that users generally prefer the choices ranked higher by DialSQL. The overall score of each turn also suggests that users had a reasonable conversation with DialSQL. The average score is 2.86 with standard deviation of 0.14, showing users can understand DialSQL responses and can pick a choice confidently.

6 Conclusion

We demonstrated the efficacy of the DialSQL, improving the state of the art accuracy from 62.5% to 69.0% on the WikiSQL dataset. DialSQL successfully extracts error spans from queries and offers several alternatives to users. It generates simple questions over a small number of turns without overwhelming users. The model learns from only simulated data which makes it easy to adapt to new domains. We further investigate the usability of DialSQL in a real life setting by conducting human evaluations. Our results suggest that the accuracy of the generated queries can be improved via real user feedback.

Abstract

One of the main challenges online social systems face is the prevalence of antisocial behavior, such as harassment and personal attacks. In this work, we introduce the task of predicting from the very start of a conversation whether it will get out of hand. As opposed to detecting undesirable behavior after the fact, this task aims to enable early, actionable prediction at a time when the conversation might still be salvaged.

To this end, we develop a framework for capturing pragmatic devices—such as politeness strategies and rhetorical prompts—used to start a conversation, and analyze their relation to its future trajectory. Applying this framework in a controlled setting, we demonstrate the feasibility of detecting early warning signs of antisocial behavior in online discussions.

1 Introduction

"Or vedi l'anime di color cui vinse l'ira."[1]
– Dante Alighieri, Divina Commedia, Inferno

Online conversations have a reputation for going awry (Hinds and Mortensen, 2005; Gheitasy et al., 2015): antisocial behavior (Shepherd et al., 2015) or simple misunderstandings (Churchill and Bly, 2000; Yamashita and Ishida, 2006) hamper the efforts of even the best intentioned collaborators. Prior computational work has focused on characterizing and detecting content exhibiting antisocial online behavior: trolling (Cheng et al., 2015, 2017), hate speech (Warner and Hirschberg, 2012; Davidson et al., 2017), harassment (Yin et al., 2009), personal attacks (Wulczyn et al., 2017) or, more generally, toxicity (Chandrasekharan et al., 2017; Pavlopoulos et al., 2017b).

Our goal is crucially different: instead of identifying antisocial comments *after the fact*, we aim to detect *warning signs* indicating that a civil conversation is at risk of derailing into such undesirable behaviors. Such warning signs could provide potentially actionable knowledge at a time when the conversation is still salvageable.

As a motivating example, consider the pair of conversations in Figure 1. Both exchanges took place in the context of the Wikipedia discussion page for the article on the Dyatlov Pass Incident, and both show (ostensibly) civil disagreement between the participants. However, only one of these conversations will eventually turn awry and devolve into a personal attack ("Wow, you're coming off as a total d**k. [...] What the hell is wrong with you?"), while the other will remain civil.

As humans, we have some intuition about which conversation is more likely to derail.[2] We may note the repeated, direct questioning with which **A1** opens the exchange, and that **A2** replies with yet another question. In contrast, **B1**'s softer, hedged approach ("it seems", "I don't think") appears to invite an exchange of ideas, and **B2** actually addresses the question instead of stonewalling. Could we endow artificial systems with such intuitions about the future trajectory of conversations?

In this work we aim to computationally capture linguistic cues that predict a conversation's future health. Most existing conversation modeling approaches aim to detect characteristics of an observed discussion or predict the outcome after the discussion concludes—e.g., whether it involves a present dispute (Allen et al., 2014; Wang and Cardie, 2014) or contributes to the even-

[1] "Now you see the souls of those whom anger overcame."

[2] In fact, humans achieve an accuracy of 72% on this balanced task, showing that it is feasible, but far from trivial.

A1: Why there's no mention of it here? Namely, an altercation with a foreign intelligence group? True, by the standards of sources some require it wouln't even come close, not to mention having some really weak points, but it doesn't mean that it doesn't exist.

A2: So what you're saying is we should put a bad source in the article because it exists?

B1: Is the St. Petersberg Times considered a reliable source by wikipedia? It seems that the bulk of this article is coming from that one article, which speculates about missile launches and UFOs. I'm going to go through and try and find corroborating sources and maybe do a rewrite of the article. I don't think this article should rely on one so-so source.

B2: I would assume that it's as reliable as any other mainstream news source.

Figure 1: Two examples of initial exchanges from conversations concerning disagreements between editors working on the Wikipedia article about the Dyatlov Pass Incident. Only one of the conversations will eventually turn awry, with an interlocutor launching into a personal attack.

tual solution of a problem (Niculae and Danescu-Niculescu-Mizil, 2016). In contrast, for this new task we need to discover interactional signals of the *future* trajectory of an *ongoing* conversation.

We make a first approach to this problem by analyzing the role of politeness (or lack thereof) in keeping conversations on track. Prior work has shown that politeness can help shape the course of offline (Clark, 1979; Clark and Schunk, 1980), as well as online interactions (Burke and Kraut, 2008), through mechanisms such as softening the perceived force of a message (Fraser, 1980), acting as a buffer between conflicting interlocutor goals (Brown and Levinson, 1987), and enabling all parties to save face (Goffman, 1955). This suggests the potential of politeness to serve as an indicator of whether a conversation will sustain its initial civility or eventually derail, and motivates its consideration in the present work.

Recent studies have computationally operationalized prior formulations of politeness by extracting linguistic cues that reflect politeness strategies (Danescu-Niculescu-Mizil et al., 2013; Aubakirova and Bansal, 2016). Such research has additionally tied politeness to social factors such as individual status (Danescu-Niculescu-Mizil et al., 2012; Krishnan and Eisenstein, 2015), and the success of requests (Althoff et al., 2014) or of collaborative projects (Ortu et al., 2015). However, to the best of our knowledge, this is the first computational investigation of the relation between politeness strategies and the future trajectory of the conversations in which they are deployed. Furthermore, we generalize beyond predefined politeness strategies by using an unsupervised method to discover additional rhetorical prompts used to initiate different types of conversations that may be specific to online collaborative settings, such as coordinating work (Kittur and Kraut, 2008) or conducting factual checks.

We explore the role of such pragmatic and rhetorical devices in foretelling a particularly perplexing type of conversational failure: when participants engaged in previously civil discussion start to attack each other. This type of derailment "from within" is arguably more disruptive than other forms of antisocial behavior, such as vandalism or trolling, which the interlocutors have less control over or can choose to ignore.

We study this phenomenon in a new dataset of Wikipedia talk page discussions, which we compile through a combination of machine learning and crowdsourced filtering. The dataset consists of conversations which begin with ostensibly civil comments, and either remain healthy or derail into personal attacks. Starting from this data, we construct a setting that mitigates effects which may trivialize the task. In particular, some topical contexts (such as politics and religion) are naturally more susceptible to antisocial behavior (Kittur et al., 2009; Cheng et al., 2015). We employ techniques from causal inference (Rosenbaum, 2010) to establish a controlled framework that focuses our study on topic-agnostic linguistic cues.

In this controlled setting, we find that pragmatic cues extracted from the very first exchange in a conversation (i.e., the first comment-reply pair) can indeed provide some signal of whether the conversation will subsequently go awry. For example, conversations prompted by hedged remarks sustain their initial civility more so than those prompted by forceful questions, or by direct language addressing the other interlocutor.

In summary, our main contributions are:

- We articulate the new task of detecting early on whether a conversation will derail into personal attacks;
- We devise a controlled setting and build a labeled dataset to study this phenomenon;

- We investigate how politeness strategies and other rhetorical devices are tied to the future trajectory of a conversation.

More broadly, we show the feasibility of automatically detecting warning signs of future misbehavior in collaborative interactions. By providing a labeled dataset together with basic methodology and several baselines, we open the door to further work on understanding factors which may derail or sustain healthy online conversations. To facilitate such future explorations, we distrubute the data and code as part of the Cornell Conversational Analysis Toolkit.[3]

2 Further Related Work

Antisocial behavior. Prior work has studied a wide range of disruptive interactions in various online platforms like Reddit and Wikipedia, examining behaviors like aggression (Kayany, 1998), harassment (Chatzakou et al., 2017; Vitak et al., 2017), and bullying (Akbulut et al., 2010; Kwak et al., 2015; Singh et al., 2017), as well as their impact on aspects of engagement like user retention (Collier and Bear, 2012; Wikimedia Support and Safety Team, 2015) or discussion quality (Arazy et al., 2013). Several studies have sought to develop machine learning techniques to detect signatures of online toxicity, such as personal insults (Yin et al., 2009), harassment (Sood et al., 2012) and abusive language (Nobata et al., 2016; Gambäck and Sikdar, 2017; Pavlopoulos et al., 2017a; Wulczyn et al., 2017). These works focus on detecting toxic behavior after it has already occurred; a notable exception is Cheng et al. (2017), which predicts future community enforcement against users in news-based discussions. Our work similarly aims to understand *future* antisocial behavior; however, our focus is on studying the trajectory of a conversation rather than the behavior of individuals across disparate discussions.

Discourse analysis. Our present study builds on a large body of prior work in computationally modeling discourse. Both unsupervised (Ritter et al., 2010) and supervised (Zhang et al., 2017a) approaches have been used to categorize behavioral patterns on the basis of the language that ensues in a conversation, in the particular realm of online discussions. Models of conversational behavior have also been used to predict conversation outcomes, such as betrayal in games (Niculae et al., 2015), and success in team problem solving settings (Fu et al., 2017) or in persuading others (Tan et al., 2016; Zhang et al., 2016).

While we are inspired by the techniques employed in these approaches, our work is concerned with predicting the future trajectory of an ongoing conversation as opposed to a post-hoc outcome. In this sense, we build on prior work in modeling conversation trajectory, which has largely considered *structural* aspects of the conversation (Kumar et al., 2010; Backstrom et al., 2013). We complement these structural models by seeking to extract potential signals of future outcomes from the *linguistic discourse* within the conversation.

3 Finding Conversations Gone Awry

We develop our framework for understanding linguistic markers of conversational trajectories in the context of Wikipedia's *talk page* discussions—public forums in which contributors convene to deliberate on editing matters such as evaluating the quality of an article and reviewing the compliance of contributions with community guidelines. The dynamic of conversational derailment is particularly intriguing and consequential in this setting by virtue of its collaborative, goal-oriented nature. In contrast to unstructured commenting forums, cases where one *collaborator* turns on another over the course of an initially civil exchange constitute perplexing pathologies. In turn, these toxic attacks are especially disruptive in Wikipedia since they undermine the social fabric of the community as well as the ability of editors to contribute (Henner and Sefidari, 2016).

To approach this domain we reconstruct a complete view of the conversational process in the edit history of English Wikipedia by translating sequences of revisions of each talk page into structured conversations. This yields roughly 50 million conversations across 16 million talk pages.

Roughly one percent of Wikipedia comments are estimated to exhibit antisocial behavior (Wulczyn et al., 2017). This illustrates a challenge for studying conversational failure: one has to sift through many conversations in order to find even a small set of examples. To avoid such a prohibitively exhaustive analysis, we first use a machine learning classifier to identify candidate conversations that are likely to contain a toxic contribution, and then use crowdsourcing to vet the resulting labels and construct our controlled dataset.

[3] `http://convokit.infosci.cornell.edu`

Job 1: Ends in personal attack. We show three annotators a conversation and ask them to determine if its last comment is a personal attack toward someone else in the conversation.			**Job 2: Civil start.** We split conversations into snippets of three consecutive comments. We ask three annotators to determine whether any of the comments in a snippet is toxic.			
Annotators	**Conversations**	**Agreement**	**Annotators**	**Conversations**	**Snippets**	**Agreement**
367	4,022	67.8%	247	1,252	2,181	87.5%

Table 1: Descriptions of crowdsourcing jobs, with relevant statistics. More details in Appendix A.

Candidate selection. Our goal is to analyze how the start of a *civil* conversation is tied to its potential future derailment into personal attacks. Thus, we only consider conversations that start out as ostensibly civil, i.e., where at least the first exchange does not exhibit any toxic behavior,[4] and that continue beyond this first exchange. To focus on the especially perplexing cases when the attacks come *from within*, we seek examples where the attack is initiated by one of the two participants in the initial exchange.

To select candidate conversations to include in our collection, we use the toxicity classifier provided by the Perspective API,[5] which is trained on Wikipedia talk page comments that have been annotated by crowdworkers (Wulczyn et al., 2016). This provides a toxicity score t for all comments in our dataset, which we use to preselect two sets of conversations: (a) candidate conversations that are civil throughout, i.e., conversations in which all comments (including the initial exchange) are not labeled as toxic ($t < 0.4$); and (b) candidate conversations that turn toxic after the first (civil) exchange, i.e., conversations in which the N-th comment ($N > 2$) is labeled toxic ($t \geq 0.6$), but all the preceding comments are not ($t < 0.4$).

Crowdsourced filtering. Starting from these candidate sets, we use crowdsourcing to vet each conversation and select a subset that are perceived by humans to either stay civil throughout ("on-track" conversations), or start civil but end with a *personal attack* ("awry-turning" conversations). To inform the design of this human-filtering process and to check its effectiveness, we start from a seed set of 232 conversations manually verified by the authors to end in personal attacks (more details about the selection of the seed set and its role in the crowd-sourcing process can be found in Appendix A). We take particular care to not over-constrain crowdworker interpretations of what personal attacks may be, and to separate toxicity from civil disagreement, which is recognized as a key aspect of effective collaborations (Coser, 1956; De Dreu and Weingart, 2003).

We design and deploy two filtering jobs using the CrowdFlower platform, summarized in Table 1 and detailed in Appendix A. **Job 1** is designed to select conversations that contain a "rude, insulting, or disrespectful" comment towards another user in the conversation—i.e., a personal attack. In contrast to prior work labeling antisocial comments in isolation (Sood et al., 2012; Wulczyn et al., 2017), annotators are asked to label personal attacks in the *context* of the conversations in which they occur, since antisocial behavior can often be context-dependent (Cheng et al., 2017). In fact, in order to ensure that the crowdworkers read the entire conversation, we also ask them to indicate who is the target of the attack. We apply this task to the set of candidate awry-turning conversations, selecting the 14% which all three annotators perceived as ending in a personal attack.[6]

Job 2 is designed to filter out conversations that do not actually start out as civil. We run this job to ensure that the *awry-turning* conversations are civil up to the point of the attack—i.e., they *turn* awry—discarding 5% of the candidates that passed Job 1. We also use it to verify that the candidate *on-track* conversations are indeed civil throughout, discarding 1% of the respective candidates. In both cases we filter out conversations in which three annotators could identify at least one comment that is "rude, insulting, or disrespectful".

Controlled setting. Finally, we need to construct a setting that affords for meaningful comparison between conversations that derail and those that stay on track, and that accounts for trivial topical confounds (Kittur et al., 2009; Cheng et al., 2015). We mitigate topical confounds using matching, a technique developed for causal inference in observational studies (Rubin, 2007). Specifically, start-

[4]For the sake of generality, in this work we focus on this most basic conversational unit: the first comment-reply pair starting a conversation.

[5]https://www.perspectiveapi.com/

[6]We opted to use unanimity in this task to account for the highly subjective nature of the phenomenon.

ing from our human-vetted collection of conversations, we pair each *awry-turning* conversation, with an *on-track* conversation, such that both took place on the same talk page. If we find multiple such pairs, we only keep the one in which the paired conversations take place closest in time, to tighten the control for topic. Conversations that cannot be paired are discarded.

This procedure yields a total of 1,270 paired awry-turning and on-track conversations (including our initial seed set), spanning 582 distinct talk pages (averaging 1.1 pairs per page, maximum 8) and 1,876 (overlapping) topical categories. The average length of a conversation is 4.6 comments.

4 Capturing Pragmatic Devices

We now describe our framework for capturing linguistic cues that might inform a conversation's future trajectory. Crucially, given our focus on conversations that start seemingly civil, we do not expect overtly hostile language—such as insults (Yin et al., 2009)—to be informative. Instead, we seek to identify pragmatic markers within the initial exchange of a conversation that might serve to reveal or exacerbate underlying tensions that eventually come to the fore, or conversely suggest sustainable civility. In particular, in this work we explore how politeness strategies and rhetorical prompts reflect the future health of a conversation.

Politeness strategies. Politeness can reflect a-priori good will and help navigate potentially face-threatening acts (Goffman, 1955; Lakoff, 1973), and also offers hints to the underlying intentions of the interlocutors (Fraser, 1980). Hence, we may naturally expect certain politeness strategies to signal that a conversation is likely to stay on track, while others might signal derailment.

In particular, we consider a set of pragmatic devices signaling politeness drawn from Brown and Levinson (1987). These linguistic features reflect two overarching types of politeness. *Positive* politeness strategies encourage social connection and rapport, perhaps serving to maintain cohesion throughout a conversation; such strategies include gratitude ("*thanks* for your help"), greetings ("*hey*, how is your day so far") and use of "please", both at the start ("*Please* find sources for your edit...") and in the middle ("Could you *please* help with...?") of a sentence. *Negative* politeness strategies serve to dampen an interlocutor's imposition on an addressee, often through conveying indirectness or uncertainty on the part of the commenter. Both commenters in example **B** (Fig. 1) employ one such strategy, hedging, perhaps seeking to soften an impending disagreement about a source's reliability ("I *don't think...*", "I would *assume...*"). We also consider markers of *impolite* behavior, such as the use of direct questions ("*Why*'s there no mention of it?') and sentence-initial second person pronouns ("*Your* sources don't matter..."), which may serve as forceful-sounding contrasts to negative politeness markers. Following Danescu-Niculescu-Mizil et al. (2013), we extract such strategies by pattern matching on the dependency parses of comments.

Types of conversation prompts. To complement our pre-defined set of politeness strategies, we seek to capture domain-specific rhetorical patterns used to initiate conversations. For instance, in a collaborative setting, we may expect conversations that start with an invitation for working together to signal less tension between the participants than those that start with statements of dispute. We discover types of such *conversation prompts* in an unsupervised fashion by extending a framework used to infer the rhetorical role of questions in (offline) political debates (Zhang et al., 2017b) to more generally extract the rhetorical functions of comments. The procedure follows the intuition that the rhetorical role of a comment is reflected in the type of replies it is likely to elicit. As such, comments which tend to trigger similar replies constitute a particular type of prompt.

To implement this intuition, we derive two different low-rank representations of the common lexical phrasings contained in comments (agnostic to the particular topical content discussed), automatically extracted as recurring sets of arcs in the dependency parses of comments. First, we derive *reply-vectors* of phrasings, which reflect their propensities to *co-occur*. In particular, we perform singular value decomposition on a term-document matrix $\mathcal{R}$ of phrasings and replies as $\mathcal{R} \approx \hat{\mathcal{R}} = U_R S V_R^T$, where rows of U_R are low-rank reply-vectors for each phrasing.

Next, we derive *prompt-vectors* for the phrasings, which reflect similarities in the subsequent replies that a phrasing *prompts*. We construct a prompt-reply matrix $\mathcal{P} = (p_{ij})$ where $p_{ij} = 1$ if phrasing j occurred in a reply to a comment containing phrasing i. We project $\mathcal{P}$ into the same space as U_R by solving for $\hat{\mathcal{P}}$ in $\mathcal{P} = \hat{\mathcal{P}} S V_R^T$ as

Prompt Type	Description	Examples
`Factual check`	Statements about article content, pertaining to or contending issues like factual accuracy.	The terms **are used** interchangeably in the US. The census **is not talking about** families here.
`Moderation`	Rebukes or disputes concerning moderation decisions such as blocks and reversions.	**If** you continue, you may **be blocked** from editing. He's **accused** me **of** being a troll.
`Coordination`	Requests, questions, and statements of intent pertaining to collaboratively editing an article.	It's a long list so I **could do with** your **help**. **Let me know** if you agree with this and I'll go ahead [...]
`Casual remark`	Casual, highly conversational aside-remarks.	**What's with** this flag image? **I'm surprised** there wasn't an article before.
`Action statement`	Requests, statements, and explanations about various editing actions.	**Please consider improving** the article to address the issues [...] The page **was deleted as** self-promotion.
`Opinion`	Statements seeking or expressing opinions about editing challenges and decisions.	I **think** that it **should be** the other way around. This article **seems to have** a lot of bias.

Table 2: Prompt types automatically extracted from talk page conversations, with interpretations and examples from the data. Bolded text indicate common prompt phrasings extracted by the framework. Further examples are shown in Appendix B, Table 4.

$\hat{\mathcal{P}} = \mathcal{P}V_R S^{-1}$. Each row of $\hat{\mathcal{P}}$ is then a prompt-vector of a phrasing, such that the prompt-vector for phrasing i is close to the reply-vector for phrasing j if comments with phrasing i tend to prompt replies with phrasing j. Clustering the rows of $\hat{\mathcal{P}}$ then yields k conversational *prompt types* that are unified by their similarity in the space of replies. To infer the prompt type of a new comment, we represent the comment as an average of the representations of its constituent phrasings (i.e., rows of $\hat{\mathcal{P}}$) and assign the resultant vector to a cluster.[7]

To determine the prompt types of comments in our dataset, we first apply the above procedure to derive a set of prompt types from a *disjoint* (unlabeled) corpus of Wikipedia talk page conversations (Danescu-Niculescu-Mizil et al., 2012). After initial examination of the framework's output on this external data, we chose to extract $k = 6$ prompt types, shown in Table 2 along with our interpretations.[8] These prompts represent signatures of conversation-starters spanning a wide range of topics and contexts which reflect core elements of Wikipedia, such as moderation disputes and coordination (Kittur et al., 2007; Kittur and Kraut, 2008). We assign each comment in our present dataset to one of these types.[9]

5 Analysis

We are now equipped to computationally explore how the pragmatic devices used to start a conversation can signal its future health. Concretely, to quantify the relative propensity of a linguistic marker to occur at the start of awry-turning versus on-track conversations, we compute the log-odds ratio of the marker occurring in the initial exchange—i.e., in the first or second comments—of awry-turning conversations, compared to initial exchanges in the on-track setting. These quantities are depicted in Figure 2A.[10]

Focusing on the **first** comment (represented as ◇s), we find a rough correspondence between linguistic *directness* and the likelihood of future personal attacks. In particular, comments which contain *direct questions*, or exhibit *sentence-initial you* (i.e., "2nd person start"), tend to start awry-turning conversations significantly more often than ones that stay on track (both $p < 0.001$).[11] This effect coheres with our intuition that directness signals some latent hostility from the conversation's initiator, and perhaps reinforces the forcefulness of contentious impositions (Brown and Levinson, 1987). This interpretation is also sug-

[7] We scale rows of U_R and $\hat{\mathcal{P}}$ to unit norm. We assign comments whose vector representation has (ℓ_2) distance ≥ 1 to all cluster centroids to an extra, infrequently-occurring null type which we ignore in subsequent analyses.

[8] We experimented with more prompt types as well, finding that while the methodology recovered finer-grained types, and obtained qualitatively similar results and prediction accuracies as described in Sections 5 and 6, the assignment of comments to types was relatively sparse due to the small data size, resulting in a loss of statistical power.

[9] While the particular prompt types we discover are specific to Wikipedia, the methodology for inferring them is unsupervised and is applicable in other conversational settings.

[10] To reduce clutter we only depict features which occur a minimum of 50 times and have absolute log-odds ≥ 0.2 in at least one of the data subsets. The markers indicated as statistically significant for Figure 2A remain so after a Bonferroni correction, with the exception of factual checks, hedges (lexicon, ◇), gratitude (◇), and opinion.

[11] All p values in this section are computed as two-tailed binomial tests, comparing the proportion of awry-turning conversations exhibiting a particular device to the proportion of on-track conversations.

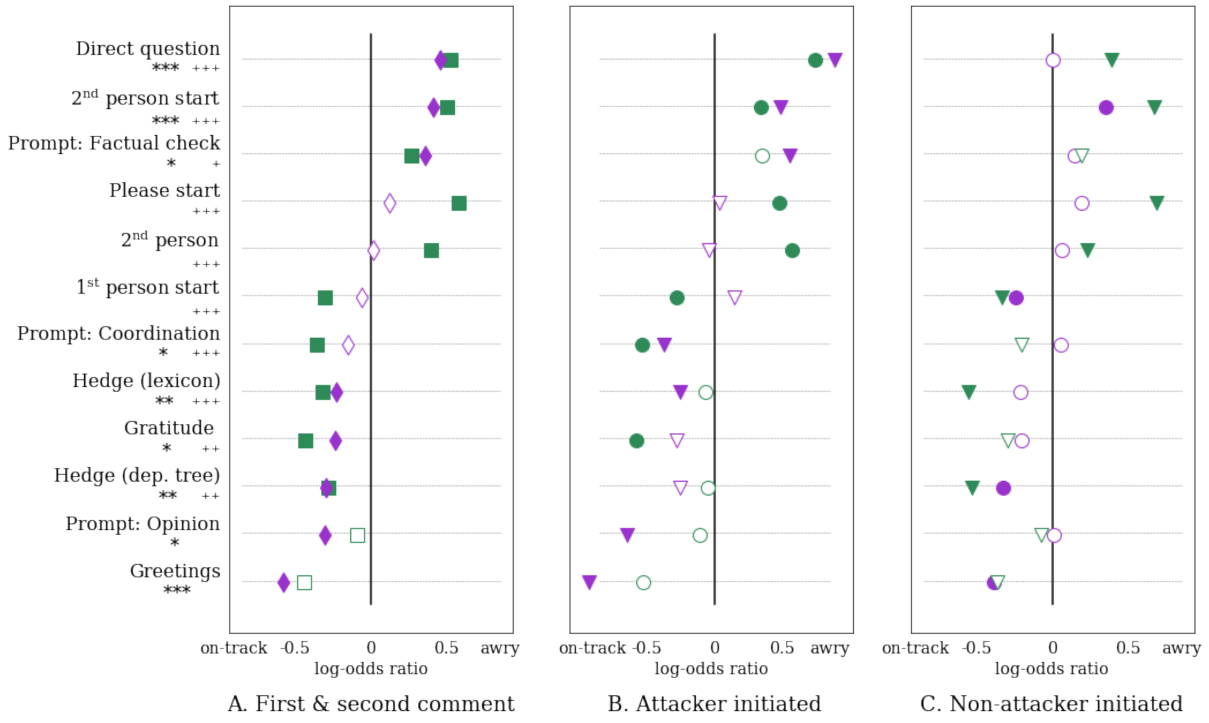

Figure 2: Log-odds ratios of politeness strategies and prompt types exhibited in the first and second comments of conversations that turn awry, versus those that stay on-track. **All**: Purple and green markers denote log-odds ratios in the first and second comments, respectively; points are solid if they reflect significant ($p < 0.05$) log-odds ratios with an effect size of at least 0.2. **A**: ◇s and □s denote **first** and **second** comment log-odds ratios, respectively; * denotes statistically significant differences at the $p < 0.05$ (*), $p < 0.01$ (**) and $p < 0.001$ (***) levels for the first comment (two-tailed binomial test); + denotes corresponding statistical significance for the second comment. **B** and **C**: ▽s and ◯s correspond to effect sizes in the comments authored by the **attacker** and **non-attacker**, respectively, in **attacker initiated** (**B**) and **non-attacker initiated** (**C**) conversations.

gested by the relative propensity of the `factual check` prompt, which tends to cue disputes regarding an article's factual content ($p < 0.05$).

In contrast, comments which initiate on-track conversations tend to contain *gratitude* ($p < 0.05$) and *greetings* ($p < 0.001$), both positive politeness strategies. Such conversations are also more likely to begin with `coordination` prompts ($p < 0.05$), signaling active efforts to foster constructive teamwork. Negative politeness strategies are salient in on-track conversations as well, reflected by the use of *hedges* ($p < 0.01$) and `opinion` prompts ($p < 0.05$), which may serve to soften impositions or factual contentions (Hübler, 1983).

These effects are echoed in the **second** comment—i.e., the **first reply** (represented as □s). Interestingly, in this case we note that the difference in pronoun use is especially marked. First replies in conversations that eventually derail tend to contain more *second person pronouns* ($p < 0.001$), perhaps signifying a replier pushing back to contest the initiator; in contrast, on-track conversations have more *sentence-initial I/We* (i.e., "1st person start", $p < 0.001$), potentially indicating the replier's willingness to step into the conversation and work with—rather than argue against—the initiator (Tausczik and Pennebaker, 2010).

Distinguishing interlocutor behaviors. Are the linguistic signals we observe solely driven by the eventual attacker, or do they reflect the behavior of both actors? To disentangle the attacker and non-attackers' roles in the initial exchange, we examine their language use in these two possible cases: when the *future* attacker initiates the conversation, or is the first to reply. In **attacker-initiated** conversations (Figure 2B, 608 conversations), we see that both actors exhibit a propensity for the linguistically direct markers (e.g., *direct questions*) that tend to signal future attacks. Some of these markers are used particularly often by the **non-attacking replier** in awry-turning conversations (e.g., *second person pronouns*, $p < 0.001$, ○s), further suggesting the dynamic of the replier pushing back at—and perhaps even escalating—the attacker's initial hint of aggression. Among conversations initiated instead by the **non-attacker** (Figure 2C, 662 conversations), the non-attacker's linguistic behavior in the first comment (○s) is less distinctive from that of initiators in the on-track setting (i.e., log-odds ratios closer to 0); markers of future derailment are (unsurprisingly) more pronounced once the eventual attacker (▽s) joins the conversation in the second comment.[12]

More broadly, these results reveal how different politeness strategies and rhetorical prompts deployed in the initial stages of a conversation are tied to its future trajectory.

6 Predicting Future Attacks

We now show that it is indeed feasible to predict whether a conversation will turn awry based on linguistic properties of its very first exchange, providing several baselines for this new task. In doing so, we demonstrate that the pragmatic devices examined above encode signals about the future trajectory of conversations, capturing some of the intuition humans are shown to have.

We consider the following balanced prediction task: given a pair of conversations, which one will eventually lead to a personal attack? We extract all features from the very first exchange in a conversation—i.e., a comment-reply pair, like those illustrated in our introductory example (Figure 1). We use logistic regression and report accuracies on a leave-one-page-out cross validation, such that in each fold, all conversation pairs from a given talk page are held out as test data and pairs from all other pages are used as training data (thus preventing the use of page-specific information). Prediction results are summarized in Table 3.

Language baselines. As baselines, we consider several straightforward features: word count (which performs at chance level), sentiment lexicon (Liu et al., 2005) and bag of words.

Pragmatic features. Next, we test the predictive power of the **prompt types** and **politeness strategies** features introduced in Section 4. The 12 prompt type features (6 features for each comment in the initial exchange) achieve 59.2% accuracy, and the 38 politeness strategies features (19 per comment) achieve 60.5% accuracy. The **pragmatic** features combine to reach 61.6% accuracy.

[12]As an interesting avenue for future work, we note that some markers used by non-attacking initiators potentially still anticipate later attacks, suggested by, e.g., the relative prevalence of *sentence-initial you* ($p < 0.05$, ○s).

Feature set	**# features**	**Accuracy**
Bag of words	5,000	56.7%
Sentiment lexicon	4	55.4%
Politeness strategies	38	60.5%
Prompt types	12	59.2%
Pragmatic (all)	50	61.6%
Interlocutor features	5	51.2%
Trained toxicity	2	60.5%
Toxicity + ***Pragmatic***	52	64.9%
Humans		72.0%

Table 3: Accuracies for the balanced future-prediction task. Features based on pragmatic devices are **bolded**, reference points are *italicized*.

Reference points. To better contextualize the performance of our features, we compare their predictive accuracy to the following reference points:

Interlocutor features: Certain kinds of interlocutors are potentially more likely to be involved in awry-turning conversations. For example, perhaps newcomers or anonymous participants are more likely to derail interactions than more experienced editors. We consider a set of features representing participants' experience on Wikipedia (i.e., number of edits) and whether the comment authors are anonymous. In our task, these features perform at the level of random chance.

Trained toxicity: We also compare with the toxicity score of the exchange from the Perspective API classifier—a perhaps unfair reference point, since this supervised system was trained on additional human-labeled training examples from the same domain and since it was used to create the very data on which we evaluate. This results in an accuracy of 60.5%; combining trained toxicity with our pragmatic features achieves 64.9%.

Humans: A sample of 100 pairs were labeled by (non-author) volunteer human annotators. They were asked to guess, from the initial exchange, which conversation in a pair will lead to a personal attack. Majority vote across three annotators was used to determine the human labels, resulting in an accuracy of 72%. This confirms that humans have some intuition about whether a conversation might be heading in a bad direction, which our features can partially capture. In fact, the classifier using pragmatic features is accurate on 80% of the examples that humans also got right.

Attacks on the horizon. Finally, we seek to understand whether cues extracted from the first exchange can predict future discussion trajectory beyond the immediate next couple of comments. We thus repeat the prediction experiments on the subset of conversations in which the first personal attack happens after the fourth comment (282 pairs), and find that the pragmatic devices used in the first exchange maintain their predictive power (67.4% accuracy), while the sentiment and bag of words baselines drop to the level of random chance.

Overall, these initial results show the feasibility of reconstructing some of the human intuition about the future trajectory of an ostensibly civil conversation in order to predict whether it will eventually turn awry.

7 Conclusions and Future Work

In this work, we started to examine the intriguing phenomenon of conversational derailment, studying how the use of pragmatic and rhetorical devices relates to future conversational failure. Our investigation centers on the particularly perplexing scenario in which one participant of a civil discussion later attacks another, and explores the new task of predicting whether an initially healthy conversation will derail into such an attack. To this end, we develop a computational framework for analyzing how general politeness strategies and domain-specific rhetorical prompts deployed in the initial stages of a conversation are tied to its future trajectory.

Making use of machine learning and crowdsourcing tools, we formulate a tightly-controlled setting that enables us to meaningfully compare conversations that stay on track with those that go awry. The human accuracy on predicting future attacks in this setting (72%) suggests it is feasible at least at the level of human intuition. We show that our computational framework can recover some of that intuition, hinting at the potential of automated methods to identify signals of the future trajectories of online conversations.

Our approach has several limitations which open avenues for future work. Our correlational analyses do not provide any insights into *causal* mechanisms of derailment, which randomized experiments could address. Additionally, since our procedure for collecting and vetting data focused on precision rather than recall, it might miss more subtle attacks that are overlooked by the toxicity classifier. Supplementing our investigation with other indicators of antisocial behavior, such as editors blocking one another, could enrich the range of attacks we study. Noting that our framework is not specifically tied to Wikipedia, it would also be valuable to explore the varied ways in which this phenomenon arises in other (possibly non-collaborative) public discussion venues, such as Reddit and Facebook Pages.

While our analysis focused on the very first exchange in a conversation for the sake of generality, more complex modeling could extend its scope to account for conversational features that more comprehensively span the interaction. Beyond the present binary classification task, one could explore a sequential formulation predicting whether the next turn is likely to be an attack as a discussion unfolds, capturing conversational dynamics such as sustained escalation.

Finally, our study of derailment offers only one glimpse into the space of possible conversational trajectories. Indeed, a manual investigation of conversations whose eventual trajectories were misclassified by our models—as well as by the human annotators—suggests that interactions which initially seem prone to attacks can nonetheless maintain civility, by way of level-headed interlocutors, as well as explicit acts of reparation. A promising line of future work could consider the complementary problem of identifying pragmatic strategies that can help bring uncivil conversations back on track.

Abstract

One of possible ways of obtaining continuous-space sentence representations is by training neural machine translation (NMT) systems. The recent attention mechanism however removes the single point in the neural network from which the source sentence representation can be extracted. We propose several variations of the attentive NMT architecture bringing this meeting point back. Empirical evaluation suggests that the better the translation quality, the worse the learned sentence representations serve in a wide range of classification and similarity tasks.

1 Introduction

Deep learning has brought the possibility of automatically learning continuous representations of sentences. On the one hand, such representations can be geared towards particular tasks such as classifying the sentence in various aspects (e.g. sentiment, register, question type) or relating the sentence to other sentences (e.g. semantic similarity, paraphrasing, entailment). On the other hand, we can aim at "universal" sentence representations, that is representations performing reasonably well in a range of such tasks.

Regardless the evaluation criterion, the representations can be learned either in an unsupervised way (from simple, unannotated texts) or supervised, relying on manually constructed training sets of sentences equipped with annotations of the appropriate type. A different approach is to obtain sentence representations from training neural machine translation models (Hill et al., 2016).

Since Hill et al. (2016), NMT has seen substantial advances in translation quality and it is thus natural to ask how these improvements affect the learned representations.

One of the key technological changes was the introduction of "attention" (Bahdanau et al., 2014), making it even the very central component in the network (Vaswani et al., 2017). Attention allows the NMT system to dynamically choose which parts of the source are most important when deciding on the current output token. As a consequence, there is no longer a static vector representation of the sentence available in the system.

In this paper, we remove this limitation by proposing a novel encoder-decoder architecture with a structured fixed-size representation of the input that still allows the decoder to explicitly focus on different parts of the input. In other words, our NMT system has both the capacity to attend to various parts of the input and to produce static representations of input sentences.

We train this architecture on English-to-German and English-to-Czech translation and evaluate the learned representations of English on a wide range of tasks in order to assess its performance in learning "universal" meaning representations.

In Section 2, we briefly review recent efforts in obtaining sentence representations. In Section 3, we introduce a number of variants of our novel architecture. Section 4 describes some standard and our own methods for evaluating sentence representations. Section 5 then provides experimental results: translation and representation quality. The relation between the two is discussed in Section 6.

2 Related Work

The properties of continuous sentence representations have always been of interest to researchers working on neural machine translation. In the first works on RNN sequence-to-sequence models, Cho et al. (2014) and Sutskever et al. (2014)

	Bahdanau et al. ATTN	Sutskever et al. FINAL	Cho et al. FINAL-CTX	*POOL	*POOL-CTX	ATTN-CTX	Compound attention ATTN-ATTN

Table 1: Different RNN-based architectures and their properties. Legend: "pooling" – vectors combined by mean or max (AVGPOOL, MAXPOOL); "sent. emb." – sentence embedding, i.e. the fixed-size sentence representation computed by the encoder. "init" – initial decoder state. "ctx" – context vector, i.e. input for the decoder cell. "input for att." – input for the decoder attention.

provided visualizations of the phrase and sentence embedding spaces and observed that they reflect semantic and syntactic structure to some extent.

Hill et al. (2016) perform a systematic evaluation of sentence representation in different models, including NMT, by applying them to various sentence classification tasks and by relating semantic similarity to closeness in the representation space.

Shi et al. (2016) investigate the syntactic properties of representations learned by NMT systems by predicting sentence- and word-level syntactic labels (e.g. tense, part of speech) and by generating syntax trees from these representations.

Schwenk and Douze (2017) aim to learn language-independent sentence representations using NMT systems with multiple source and target languages. They do not consider the attention mechanism and evaluate primarily by similarity scores of the learned representations for similar sentences (within or across languages).

3 Model Architectures

Our proposed model architectures differ in (a) which encoder states are considered in subsequent processing, (b) how they are combined, and (c) how they are used in the decoder.

Table 1 summarizes all the examined configurations of RNN-based models. The first three (ATTN, FINAL, FINAL-CTX) correspond roughly to the standard sequence-to-sequence models, Bahdanau et al. (2014), Sutskever et al. (2014) and Cho et al. (2014), resp. The last column (ATTN-ATTN) is our main proposed architecture: compound attention, described here in Section 3.1.

In addition to RNN-based models, we experiment with the Transformer model, see Section 3.3.

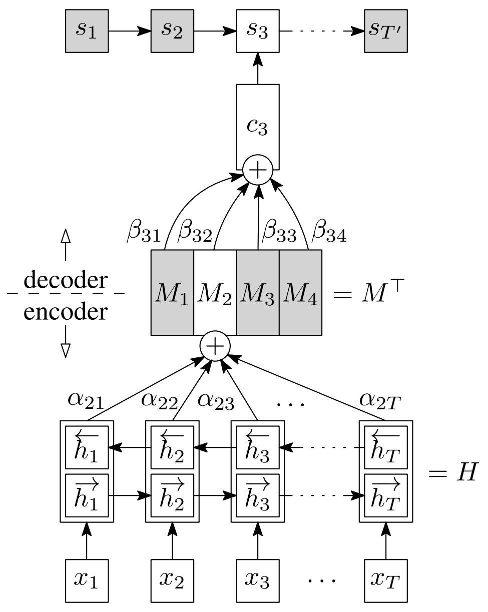

Figure 1: An illustration of compound attention with 4 attention heads. The figure shows the computations that result in the decoder state s_3 (in addition, each state s_i depends on the previous target token y_{i-1}). Note that the matrix M is the same for all positions in the output sentence and it can thus serve as the source sentence representation.

3.1 Compound Attention

Our compound attention model incorporates attention in both the encoder and the decoder, Fig. 1.

Encoder with inner attention. First, we process the input sequence $x_1, x_2, \ldots, x_T$ using a bi-directional recurrent network with gated recurrent units (GRU, Cho et al., 2014):

$$\begin{aligned}\overrightarrow{h_t} &= \overrightarrow{\text{GRU}}(x_t, \overrightarrow{h_{t-1}}),\\ \overleftarrow{h_t} &= \overleftarrow{\text{GRU}}(x_t, \overleftarrow{h_{t+1}}),\\ h_t &= [\overrightarrow{h_t}, \overleftarrow{h_t}].\end{aligned}$$

We denote by u the combined number of units in the two RNNs, i.e. the dimensionality of h_t.

Next, our goal is to combine the states $(h_1, h_2, \dots, h_T) = H$ of the encoder into a vector of fixed dimensionality that represents the entire sentence. Traditional seq2seq models concatenate the final states of both encoder RNNs ($\overrightarrow{h_T}$ and $\overleftarrow{h_1}$) to obtain the sentence representation (denoted as FINAL in Table 1). Another option is to combine all encoder states using the average or maximum over time (Collobert and Weston, 2008; Schwenk and Douze, 2017) (AVGPOOL and MAXPOOL in Table 1 and following).

We adopt an alternative approach, which is to use *inner attention*[1] (Liu et al., 2016; Li et al., 2016) to compute several weighted averages of the encoder states (Lin et al., 2017). The main motivation for incorporating these multiple "views" of the state sequence is that it removes the need for the RNN cell to accumulate the representation of the whole sentence as it processes the input, and therefore it should have more capacity for modeling local dependencies.

Specifically, we fix a number r, the number of *attention heads*, and compute an $r \times T$ matrix A of attention weights α_{jt}, representing the importance of position t in the input for the j^{th} attention head. We then use this matrix to compute r weighted sums of the encoder states, which become the rows of a new matrix M:

$$M = AH. \qquad (1)$$

A vector representation of the source sentence (the "sentence embedding") can be obtained by flattening the matrix M. In our experiments, we project the encoder states $h_1, h_2, \dots, h_T$ down to a given dimensionality before applying Eq. (1), so that we can control the size of the representation.

Following Lin et al. (2017), we compute the attention matrix by feeding the encoder states to a two-layer feed-forward network:

$$A = \operatorname{softmax}(U \tanh(W H^\top)), \qquad (2)$$

where W and U are weight matrices of dimensions $d \times u$ and $r \times d$, respectively (d is the number of hidden units); the softmax function is applied along the second dimension, i.e. across the encoder states.

[1]Some papers call the same or similar approach *self-attention* or *single-time attention*.

Attentive decoder. In vanilla seq2seq models with a fixed-size sentence representation, the decoder is usually conditioned on this representation via the initial RNN state. We propose to instead leverage the structured sentence embedding by applying attention to its components. This is no different from the classical attention mechanism used in NMT (Bahdanau et al., 2014), except that it acts on this fixed-size representation instead of the sequence of encoder states.

In the i^{th} decoding step, the attention mechanism computes a distribution $\{\beta_{ij}\}_{j=1}^{r}$ over the r components of the structured representation. This is then used to weight these components to obtain the context vector c_i, which in turn is used to update the decoder state. Again, we can write this in matrix form as

$$C = BM, \qquad (3)$$

where $B = (\beta_{ij})_{i=1,j=1}^{T',r}$ is the attention matrix and $C = (c_i, c_2, \dots, c_{T'})$ are the context vectors.

Note that by combining Eqs. (1) and (3), we get

$$C = (BA)H. \qquad (4)$$

Hence, the composition of the encoder and decoder attentions (the "compound attention") defines an implicit alignment between the source and the target sequence. From this viewpoint, our model can be regarded as a restriction of the conventional attention model.

The decoder uses a conditional GRU cell (cGRU$_{\text{att}}$; Sennrich et al., 2017), which consists of two consecutively applied GRU blocks. The first block processes the previous target token y_{i-1}, while the second block receives the context vector c_i and predicts the next target token y_i.

3.2 Constant Context

Compared to the FINAL model, the compound attention architecture described in the previous section undoubtedly benefits from the fact that the decoder is presented with information from the encoder (i.e. the context vectors c_i) in every decoding step. To investigate this effect, we include baseline models where we replace all context vectors c_i with the entire sentence embedding (indicated by the suffix "-CTX" in Table 1). Specifically, we provide either the flattened matrix M (for models with inner attention; ATTN or ATTN-CTX), the final state of the encoder (FINAL-CTX), or the result of mean- or max-pooling (*POOL-CTX) as a constant input to the decoder cell.

Name	Cl.	Train	Test	Task	Example Input and Label
MR	2	11k	—	sentiment (movies)	*an idealistic love story that brings out the latent 15-year-old romantic in everyone.* (+)
CR	2	4k	—	product review polarity	*no way to contact their customer service.* (−)
SUBJ	2	10k	—	subjectivity	*a little weak – and it isn't that funny.* (subjective)
MPQA	2	11k	—	opinion polarity	*was hoping* (+), *breach of the very constitution* (−)
SST2	2	68k	2k	sentiment (movies)	*contains very few laughs and even less surprises* (−)
SST5	5	10k	2k	sentiment (movies)	*it's worth taking the kids to.* (4)
TREC	6	5k	500	question type	*What was Einstein s IQ?* (NUM)
MRPC	2	4k	2k	semantic equivalence	*Lawtey is not the first faith-based program in Florida's prison system. / But Lawtey is the first entire prison to take that path.* (−)
SNLI	3	559k	10k	natural language inference	*Two doctors perform surgery on patient. / Two surgeons are having lunch.* (contradiction)
SICK-E	3	5k	5k	natural language inference	*A group of people is near the ocean / A crowd of people is near the water* (entailment)

Table 2: SentEval classification tasks. Tasks without a test set use 10-fold cross-validation.

Name	Train	Test	Method

STS13	—	2k	cosine similarity
STS14	—	4k	cosine similarity
STS15	—	9k	cosine similarity
STS16	—	9k	cosine similarity

Table 3: SentEval semantic relatedness tasks.

3.3 Transformer with Inner Attention

The Transformer (Vaswani et al., 2017) is a recently proposed model based entirely on feed-forward layers and attention. It consists of an encoder and a decoder, each with 6 layers, consisting of multi-head attention on the previous layer and a position-wise feed-forward network.

In order to introduce a fixed-size sentence representation into the model, we modify it by adding inner attention after the last encoder layer. The attention in the decoder then operates on the components of this representation (i.e. the rows of the matrix M). This variation on the Transformer model corresponds to the ATTN-ATTN column in Table 1 and is therefore denoted TRF-ATTN-ATTN.

4 Representation Evaluation

Continuous sentence representations can be evaluated in many ways, see e.g. Kiros et al. (2015), Conneau et al. (2017) or the RepEval workshops.[2]

We evaluate our learned representations with classification and similarity tasks from SentEval (Section 4.1) and by examining clusters of sentence paraphrase representations (Section 4.2).

4.1 SentEval

We perform evaluation on 10 classification and 7 similarity tasks using the SentEval[3] (Conneau et al., 2017) evaluation tool. This is a superset of the tasks from Kiros et al. (2015).

Table 2 describes the classification tasks (number of classes, data size, task type and an example) and Table 3 lists the similarity tasks. The similarity (relatedness) datasets contain pairs of sentences labeled with a real-valued similarity score. A given sentence representation model is evaluated either by learning to directly predict this score given the respective sentence embeddings ("regression"), or by computing the cosine similarity of the embeddings ("similarity") without the need of any training. In both cases, Pearson and Spearman correlation of the predictions with the gold ratings is reported.

See Dolan et al. (2004) for details on MRPC and Hill et al. (2016) for the remaining tasks.

4.2 Paraphrases

We also evaluate the representation of paraphrases. We use two paraphrase sources for this purpose: COCO and HyTER Networks.

COCO (Common Objects in Context; Lin et al., 2014) is an object recognition and image captioning dataset, containing 5 captions for each image. We extracted the captions from its validation set to form a set of $5 \times 5\text{k} = 25\text{k}$ sentences grouped by the source image. The average sentence length is 11 tokens and the vocabulary size is 9k types.

HyTER Networks (Dreyer and Marcu, 2014) are large finite-state networks representing a sub-

[2]https://repeval2017.github.io/

[3]https://github.com/facebookresearch/SentEval/

set of all possible English translations of 102 Arabic and 102 Chinese sentences. The networks were built by manually based on reference sentences in Arabic, Chinese and English. Each network contains up to hundreds of thousands of possible translations of the given source sentence. We randomly generated 500 translations for each source sentence, obtaining a corpus of 102k sentences grouped into 204 clusters, each containing 500 paraphrases. The average length of the 102k English sentences is 28 tokens and the vocabulary size is 11k token types.

For every model, we encode each dataset to obtain a set of sentence embeddings with cluster labels. We then compute the following metrics:

Cluster classification accuracy (denoted "Cl"). We remove 1 point (COCO) or half of the points (HyTER) from each cluster, and fit an LDA classifier on the rest. We then compute the accuracy of the classifier on the removed points.

Nearest-neighbor paraphrase retrieval accuracy (NN). For each point, we find its nearest neighbor according to cosine or L_2 distance, and count how often the neighbor lies in the same cluster as the original point.

Inverse Davies-Bouldin index (iDB). The Davies-Bouldin index (Davies and Bouldin, 1979) measures cluster separation. For every pair of clusters, we compute the ratio R_{ij} of their combined scatter (average L_2 distance to the centroid) $S_i + S_j$ and the L_2 distance of their centroids d_{ij}, then average the maximum values for all clusters:

$$R_{ij} = \frac{S_i + S_j}{d_{ij}} \tag{5}$$

$$\mathrm{DB} = \frac{1}{N} \sum_{i=1}^{N} \max_{j \neq i} R_{ij} \tag{6}$$

The lower the DB index, the better the separation. To match with the rest of our metrics, we take its inverse: $\mathrm{iDB} = \frac{1}{\mathrm{DB}}$.

5 Experimental Results

We trained English-to-German and English-to-Czech NMT models using Neural Monkey[4] (Helcl and Libovický, 2017a). In the following, we distinguish these models using the code of the target language, i.e. *de* or *cs*.

The *de* models were trained on the Multi30K multilingual image caption dataset (Elliott et al., 2016), extended by Helcl and Libovický (2017b), who acquired additional parallel data using back-translation (Sennrich et al., 2016) and perplexity-based selection (Yasuda et al., 2008). This extended dataset contains 410k sentence pairs, with the average sentence length of 12 ± 4 tokens in English. We train each model for 20 epochs with the batch size of 32. We truecased the training data as well as all data we evaluate on. For German, we employed Neural Monkey's reversible pre-processing scheme, which expands contractions and performs morphological segmentation of determiners. We used a vocabulary of at most 30k tokens for each language (no subword units).

The *cs* models were trained on CzEng 1.7 (Bojar et al., 2016).[5] We used byte-pair encoding (BPE) with a vocabulary of 30k sub-word units, shared for both languages. For English, the average sentence length is 15 ± 19 BPE tokens and the original vocabulary size is 1.9M. We performed 1 training epoch with the batch size of 128 on the entire training section (57M sentence pairs).

The datasets for both *de* and *cs* models come with their respective development and test sets of sentence pairs, which we use for the evaluation of translation quality. (We use 1k randomly selected sentence pairs from CzEng 1.7 dtest as a development set. For evaluation, we use the entire etest.)

We also evaluate the InferSent model[6] (Conneau et al., 2017) as pre-trained on the natural language inference (NLI) task. InferSent has been shown to achieve state-of-the-art results on the SentEval tasks. We also include a bag-of-words baseline (GloVe-BOW) obtained by averaging GloVe[7] word vectors (Pennington et al., 2014).

5.1 Translation Quality

We estimate translation quality of the various models using single-reference case-sensitive BLEU (Papineni et al., 2002) as implemented in Neural Monkey (the reference implementation is `mteval-v13a.pl` from NIST or Moses).

Tables 4 and 5 provide the results on the two datasets. The *cs* dataset is much larger and the training takes much longer. We were thus able to experiment with only a subset of the possible model configurations.

cs-AVGPOOL	1000	—	11.1	10.6	—
cs-MAXPOOL	1000	—	5.4	5.4	3.0

Table 5: Translation quality of *cs* models.

The columns "Size" and "Heads" specify the total size of sentence representation and the number of heads of encoder inner attention.

In both cases, the best performing is the ATTN Bahdanau et al. model, followed by Transformer (*de* only) and our ATTN-ATTN (compound attention). The non-attentive FINAL Cho et al. is the worst, except cs-MAXPOOL.

For 5 selected *cs* models, we also performed the WMT-style 5-way manual ranking on 200 sentence pairs. The annotations are interpreted as simulated pairwise comparisons. For each model, the final score is the number of times the model was judged better than the other model in the pair. Tied pairs are excluded. The results, shown in Table 5, confirm the automatic evaluation results.

We also checked the relation between BLEU and the number of heads and representation size. While there are many exceptions, the general tendency is that the larger the representation or the more heads, the higher the BLEU score. The Pearson correlation between BLEU and the number of heads is 0.87 for *cs* and 0.31 for *de*.

5.2 SentEval

Due to the large number of SentEval tasks, we present the results abridged in two different ways: by reporting averages (Table 6) and by showing only the best models in comparison with other methods (Table 7). The full results can be found in the supplementary material.

Table 6 provides averages of the classification and similarity results, along with the results of selected tasks (SNLI, SICK-E). As the baseline for classifications tasks, we assign the most frequent class to all test examples.[8] The *de* models are generally worse, most likely due to the higher OOV rate and overall simplicity of the training sentences. On *cs*, we see a clear pattern that more heads hurt the performance. The *de* set has more variations to consider but the results are less conclusive.

For the similarity results, it is worth noting that cs-ATTN-ATTN performs very well with 1 attention head but fails miserably with more heads. Otherwise, the relation to the number of heads is less clear.

Table 7 compares our strongest models with other approaches on all tasks. Besides InferSent and GloVe-BOW, we include SkipThought as evaluated by Conneau et al. (2017), and the NMT-based embeddings by Hill et al. (2016) trained on the English-French WMT15 dataset (this is the best result reported by Hill et al. for NMT).

We see that the supervised InferSent clearly outperforms all other models in all tasks except for MRPC and TREC. Results by Hill et al. are always lower than our best setups, except MRPC and TREC again. On classification tasks, our models are outperformed even by GloVe-BOW, except for the NLI tasks (SICK-E and SNLI) where cs-FINAL-CTX is better.

5.3 Paraphrase Scores

Table 6 also provides our measurements based on sentence paraphrases. For paraphrase retrieval (NN), we found cosine distance to work better

[8]For MR, CR, SUBJ, and MPQA, where there is no distinct test set, the class is established on the whole collection. For other tasks, the class is learned from the training set.

than L_2 distance. We therefore do not list L_2-based results (except in the supplementary material).

This evaluation seems less stable and discerning than the previous two, but we can again confirm the victory of InferSent followed by our non-attentive *cs* models. *cs* and *de* models are no longer clearly separated.

6 Discussion

To assess the relation between the various measures of sentence representations and translation quality as estimated by BLEU, we plot a heatmap of Pearson correlations in Fig. 2. As one example, Fig. 3 details the *cs* models' BLEU scores and AvgAcc.

A good sign is that on the *cs* dataset, most metrics of representation are positively correlated (the pairwise Pearson correlation is 0.78 ± 0.32 on average), the outlier being TREC (-0.16 ± 0.16 correlation with the other metrics on average)

On the other hand, most representation metrics correlate with BLEU negatively (-0.57 ± 0.31) on *cs*. The pattern is less pronounced but still clear also on the *de* dataset.

A detailed understanding of what the learned representations contain is difficult. We can only speculate that if the NMT model has some capability for following the source sentence superficially, it will use it and spend its capacity on closely matching the target sentences rather than on deriving some representation of meaning which would reflect e.g. semantic similarity. We assume that this can be a direct consequence of NMT being trained for cross entropy: putting the exact word forms in exact positions as the target sentence requires. Performing well in single-reference BLEU is not an indication that the system understands the meaning but rather that it can maximize the chance of producing the n-grams required by the reference.

The negative correlation between the number of attention heads and the representation metrics from Fig. 3 (-0.81 ± 0.12 for *cs* and -0.18 ± 0.19 for *de*, on average) can be partly explained by the following observation. We plotted the induced alignments (e.g. Fig. 4) and noticed that the heads tend to "divide" the sentence into segments. While one would hope that the segments correspond to some meaningful units of the sentence (e.g. subject, predicate, object), we failed to find any such interpretation for ATTN-ATTN and for *cs* models in general. Instead, the heads divide the source sentence more or less equidistantly, as documented by Fig. 5. Such a multi-headed sentence representation is then *less* fit for representing e.g. paraphrases where the subject and object swap their position due to passivization, because their representations are then accessed by different heads, and thus end up in different parts of the sentence embedding vector.

For de-ATTN-CTX models, we observed a much

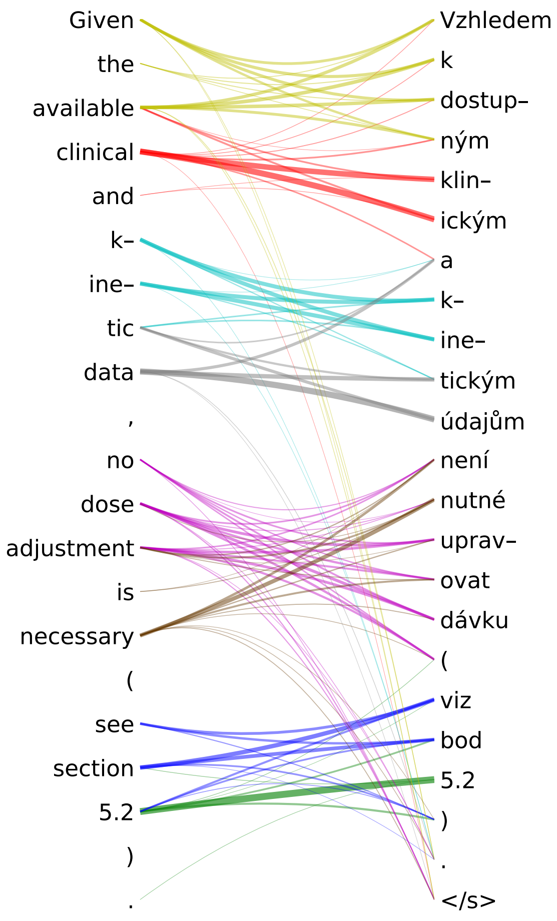

Figure 4: Alignment between a source sentence (left) and the output (right) as represented in the ATTN-ATTN model with 8 heads and size of 1000. Each color represents a different head; the stroke width indicates the alignment weight; weights ≤ 0.01 pruned out. (Best viewed in color.)

flatter distribution of attention weights for each head and, unlike in the other models, we were often able to identify a head focusing on the main verb. This difference between ATTN-ATTN and some ATTN-CTX models could be explained by the fact that in the former, the decoder is oblivious to the ordering of the heads (because of decoder attention), and hence it may not be useful for a given head to look for a specific syntactic or semantic role.

7 Conclusion

We presented a novel variation of attentive NMT models (Bahdanau et al., 2014; Vaswani et al., 2017) that again provides a single meeting point with a continuous representation of the source sentence. We evaluated these representations with a

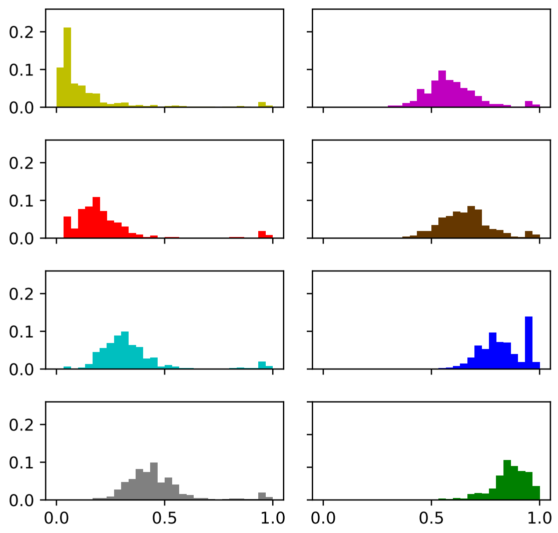

Figure 5: Attention weight by relative position in the source sentence (average over dev set excluding sentences shorter than 8 tokens). Same model as in Fig. 4. Each plot corresponds to one head.

number of measures reflecting how well the meaning of the source sentence is captured.

While our proposed "compound attention" leads to translation quality not much worse than the fully attentive model, it generally does not perform well in the meaning representation. Quite on the contrary, the better the BLEU score, the worse the meaning representation.

We believe that this observation is important for representation learning where bilingual MT now seems less likely to provide useful data, but perhaps more so for MT itself, where the struggle towards a high single-reference BLEU score (or even worse, cross entropy) leads to systems that refuse to consider the meaning of the sentence.

Automatic Metric Validation for Grammatical Error Correction

Leshem Choshen[1] and Omri Abend[1,2]

Abstract

Metric validation in Grammatical Error Correction (GEC) is currently done by observing the correlation between human and metric-induced rankings. However, such correlation studies are costly, methodologically troublesome, and suffer from low inter-rater agreement. We propose MAEGE, an automatic methodology for GEC metric validation, that overcomes many of the difficulties with existing practices. Experiments with MAEGE shed a new light on metric quality, showing for example that the standard M^2 metric fares poorly on corpus-level ranking. Moreover, we use MAEGE to perform a detailed analysis of metric behavior, showing that correcting some types of errors is consistently penalized by existing metrics.

1 Introduction

Much recent effort has been devoted to automatic evaluation, both within GEC (Napoles et al., 2015; Felice and Briscoe, 2015; Ng et al., 2014; Dahlmeier and Ng, 2012, see §2), and more generally in text-to-text generation tasks. Within Machine Translation (MT), an annual shared task is devoted to automatic metric development, accompanied by an extensive analysis of metric behavior (Bojar et al., 2017). Metric validation is also raising interest in GEC, with several recent works on the subject (Grundkiewicz et al., 2015; Napoles et al., 2015, 2016b; Sakaguchi et al., 2016), all using correlation with human rankings (henceforth, *CHR*) as their methodology.

Human rankings are often considered as ground truth in text-to-text generation, but using them reliably can be challenging. Other than the costs of compiling a sizable validation set, human rankings are known to yield poor inter-rater agreement in MT (Bojar et al., 2011; Lopez, 2012; Graham et al., 2012), and to introduce a number of methodological problems that are difficult to overcome, notably the treatment of ties in the rankings and uncomparable sentences (see §3). These difficulties have motivated several proposals to alter the MT metric validation protocol (Koehn, 2012; Dras, 2015), leading to a recent abandoning of evaluation by human rankings due to its unreliability (Graham et al., 2015; Bojar et al., 2016). These conclusions have not yet been implemented in GEC, despite their relevance. In §3 we show that human rankings in GEC also suffer from low inter-rater agreement, motivating the development of alternative methodologies.

The main contribution of this paper is an automatic methodology for metric validation in GEC called MAEGE (Methodology for Automatic Evaluation of GEC Evaluation), which addresses these difficulties. MAEGE requires no human rankings, and instead uses a corpus with gold standard GEC annotation to generate lattices of corrections with similar meanings but varying degrees of grammaticality. For each such lattice, MAEGE generates a partial order of correction quality, a quality score for each correction, and the number and types of edits required to fully correct each. It then computes the correlation of the induced partial order with the metric-induced rankings.

MAEGE addresses many of the problems with existing methodology:

- Human rankings yield low inter-rater and intra-rater agreement (§3). Indeed, Choshen and Abend (2018a) show that while annotators often generate different corrections given a sentence, they generally agree on whether a correction is valid or not. Unlike CHR, MAEGE bases its scores on human corrections, rather than on rankings.

- CHR uses system outputs to obtain human rankings, which may be misleading, as systems may share similar biases, thus neglecting to evaluate some types of valid corrections (§7). MAEGE addresses this issue by systematically traversing an inclusive space of corrections.

- The difficulty in handling ties is addressed by only evaluating correction pairs where one contains a sub-set of the errors of the other, and is therefore clearly better.

- MAEGE uses established statistical tests for determining the significance of its results, thereby avoiding ad-hoc methodologies used in CHR to tackle potential biases in human rankings (§5, §6).

In experiments on the standard NUCLE test set (Dahlmeier et al., 2013), we find that MAEGE often disagrees with CHR as to the quality of existing metrics. For example, we find that the standard GEC metric, M^2, is a poor predictor of corpus-level ranking, but a good predictor of sentence-level pair-wise rankings. The best predictor of corpus-level quality by MAEGE is the reference-less LT metric (Miłkowski, 2010; Napoles et al., 2016b), while of the reference-based metrics, GLEU (Napoles et al., 2015) fares best.

In addition to measuring metric reliability, MAEGE can also be used to analyze the sensitivities of the metrics to corrections of different types, which to our knowledge is a novel contribution of this work. Specifically, we find that not only are valid edits of some error types better rewarded than others, but that correcting certain error types is consistently penalized by existing metrics (Section 7). The importance of interpretability and detail in evaluation practices (as opposed to just providing bottom-line figures), has also been stressed in MT evaluation (e.g., Birch et al., 2016).

2 Examined Metrics

We turn to presenting the metrics we experiment with. The standard practice in GEC evaluation is to define differences between the source and a correction (or a reference) as a set of edits (Dale et al., 2012). An edit is a contiguous span of tokens to be edited, a substitute string, and the corrected error type. For example: "I want book" might have an edit (2-3, "a book", ArtOrDet); applying the edit results in "I want a book". Edits are defined (by the annotation guidelines) to be maximally independent, so that each edit can be applied independently of the others. We denote the examined set of metrics with METRICS.

BLEU. BLEU (Papineni et al., 2002) is a reference-based metric that averages the output-reference n-gram overlap precision values over different ns. While commonly used in MT and other text generation tasks (Sennrich et al., 2017; Krishna et al., 2017; Yu et al., 2017), BLEU was shown to be a problematic metric in monolingual translation tasks, in which much of the source sentence should remain unchanged (Xu et al., 2016). We use the NLTK implementation of BLEU, using smoothing method 3 by Chen and Cherry (2014).

GLEU. GLEU (Napoles et al., 2015) is a reference-based GEC metric inspired by BLEU. Recently, it was updated to better address multiple references (Napoles et al., 2016a). GLEU rewards n-gram overlap of the correction with the reference and penalizes unchanged n-grams in the correction that are changed in the reference.

iBLEU. iBLEU (Sun and Zhou, 2012) was introduced to monolingual translation in order to balance BLEU, by averaging it with the BLEU score of the source and the output. This yields a metric that rewards similarity to the source, and not only overlap with the reference:

$$iBLEU(S,R,O) = \alpha BLEU(O,R) - (1-\alpha) BLEU(O,S)$$

We set $\alpha = 0.8$ as suggested by Sun and Zhou.

F-Score computes the overlap of edits to the source in the reference, and in the output. As system edits can be constructed in multiple ways, the standard M^2 scorer (Dahlmeier and Ng, 2012) computes the set of edits that yields the maximum F-score. As M^2 requires edits from the source to the reference, and as MAEGE generates new source sentences, we use an established protocol to automatically construct edits from pairs of strings (Felice et al., 2016; Bryant et al., 2017). The protocol was shown to produce similar M^2 scores to those produced with manual edits. Following common practice, we use the Precision-oriented $F_{0.5}$.

SARI. SARI (Xu et al., 2016) is a reference-based metric proposed for sentence simplification.

SARI averages three scores, measuring the extent to which n-grams are correctly added to the source, deleted from it and retained in it. Where multiple references are present, SARI's score is determined not as the maximum single-reference score, but some averaging over them. As this may lead to an unintuitive case, where a correction which is identical to the output gets a score of less than 1, we experiment with an additional metric, MAX-SARI, which coincides with SARI for a single reference, and computes the maximum single-reference SARI score for multiple-references.

Levenshtein Distance. We use the Levenshtein distance (Kruskal and Sankoff, 1983), i.e., the number of character edits needed to convert one string to another, between the correction and its closest reference ($MinLD_{O\to R}$). To enrich the discussion, we also report results with a measure of conservatism, $LD_{S\to O}$, i.e., the Levenshtein distance between the correction and the source. Both distances are normalized by the number of characters in the second string (R, O respectively). In order to convert these distance measures into measures of similarity, we report $1 - \frac{LD(c1,c2)}{len(c1)}$.

Grammaticality is a reference-less metric, which uses grammatical error detection tools to assess the grammaticality of GEC system outputs. We use LT (Miłkowski, 2010), the best performing non-proprietary grammaticality metric (Napoles et al., 2016b). The detection tool at the base of LT can be much improved. Indeed, Napoles et al. (2016b) reported that the proprietary tool they used detected 15 times more errors than LT. A sentence's score is defined to be $1 - \frac{\#errors}{\#tokens}$. See (Asano et al., 2017; Choshen and Abend, 2018b) for additional reference-less measures, published concurrently with this work.

I-Measure. I-Measure (Felice and Briscoe, 2015) is a weighted accuracy metric over tokens. I-measure rank determines whether a correction is better than the source and to what extent. Unlike in this paper, I-measure assumes that every pair of intersecting edits (i.e., edits whose spans of tokens overlap) are alternating, and that non-intersecting edits are independent. Consequently, where multiple references are present, it extends the set of references, by generating every possible combination of independent edits. As the number of combinations is generally exponential in the number of references, the procedure can be severely inefficient.

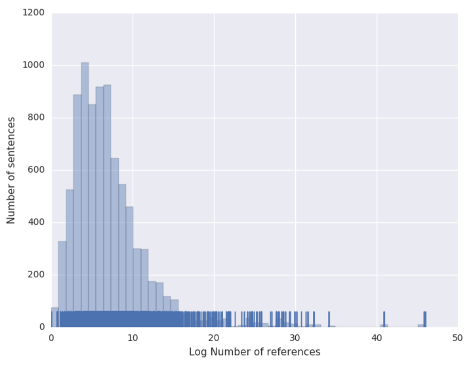

Figure 1: Histogram and rug plot of the log number of references under I-measure assumptions, i.e. overlapping edits alternate as valid corrections of the same error. There are billions of ways to combine 8 references on average.

Indeed, a sentence in the test set has 3.5 billion references on average, where the median is 512 (See Figure 1). I-measure can also be run without generating new references, but despite parallelization efforts, this version did not terminate after 140 CPU days, while the cumulative CPU time of the rest of the metrics was less than 1.5 days.

3 Human Ranking Experiments

Correlation with human rankings (CHR) is the standard methodology for assessing the validity of GEC metrics. While informative, human rankings are costly to produce, present low inter-rater agreement (shown for MT evaluation in (Bojar et al., 2011; Dras, 2015)), and introduce methodological difficulties that are hard to overcome. We begin by showing that existing sets of human rankings produce inconsistent results with respect to the quality of different metrics, and proceed by proposing an improved protocol for computing this correlation in the future.

There are two existing sets of human rankings for GEC that were compiled concurrently: GJG15 by Grundkiewicz et al. (2015), and NSPT15 by Napoles et al. (2015). Both sets are based on system outputs from the CoNLL 2014 (Ng et al., 2014) shared task, using sentences from the NUCLE test set. We compute CHR against each. System-level correlations are computed by TrueSkill (Sakaguchi et al., 2014), which adopts its methodology from MT.[1]

[1]There's a minor problem in the output of the NTHU system: a part of the input is given as sentence 39 and sentence 43 is missing. We corrected it to avoid unduly penalizing NTHU for all the sentences in this range.

Table 1 shows CHR with Spearman ρ (Pearson r shows similar trends). Results on the two datasets diverge considerably, despite their use of the same systems and corpus (albeit a different sub-set thereof). For example, BLEU receives a high positive correlation on GJG15, but a negative one on NSPT15; GLEU receives a correlation of 0.51 against GJG15 and 0.76 against NSPT15; and M^2 ranges between 0.4 (GJG15) and 0.7 (NSPT15). In fact, this variance is already apparent in the *published* correlations of GLEU, e.g., Napoles et al. (2015) reported a ρ of 0.56 against NSPT15 and Napoles et al. (2016b) reported a ρ of 0.85 against GJG15.[2] This variance in the metrics' scores is an example of the low agreement between human rankings, echoing similar findings in MT (Bojar et al., 2011; Lopez, 2012; Dras, 2015).

Another source of inconsistency in CHR is that the rankings are relative and sampled, so datasets rank different sets of outputs (Lopez, 2012). For example, if a system is judged against the best systems more often then others, it may unjustly receive a lower score. TrueSkill is the best known practice to tackle such issues (Bojar et al., 2014), but it produces a probabilistic corpus-level score, which can vary between runs (Sakaguchi et al., 2016).[3] This makes CHR more difficult to interpret, compared to classic correlation coefficients.

We conclude by proposing a practice for reporting CHR in future work. First, we combine both sets of human judgments to arrive at the statistically most powerful test. Second, we compute the metrics' corpus-level rankings according to the same subset of sentences used for human rankings. The current practice of allowing metrics to rank systems based on their output on the entire CoNLL test set (while human rankings are only collected for a sub-set thereof), may bias the results due to potential non-uniform system performance on the test set. We report CHR according to the proposed protocol in Table 1 (left column).

	Combined		GJG15		NSPT15	
	ρ	P-val	ρ	Rank	ρ	Rank
GLEU	0.771	0.001	0.512	1	0.758	1
LT	0.692	0.006	0.358	4	0.615	3
M^2	0.626	0.017	0.398	3	0.703	2
SARI	0.596	0.025	0.323	6	0.599	4
MAX-SARI	0.552	0.041	0.292	7	0.577	5
$MinLD_{O\rightarrow R}$	0.191	0.513	0.350	5	-0.187	7
BLEU	0.143	0.626	0.455	2	-0.126	6
iBLEU	-0.059	0.840	0.226	8	-0.462	8
$LD_{S\rightarrow O}$	-0.481	0.081	-0.178		-0.505	

Table 1: Metrics correlation with human judgments. The *Combined* column presents the Spearman correlation coefficient (ρ) according to the combined set of human rankings, with its associated P-value. The GJG15 and NSPT15 columns present the Spearman correlation according to the two sets of human rankings, as well as the rank of the metric according to this correlation. Measures are ordered by their rank in the combined human judgments. The discrepancy between the ρ values obtained against GJG15 and NSPT15 demonstrate low inter-rater agreement in human rankings.

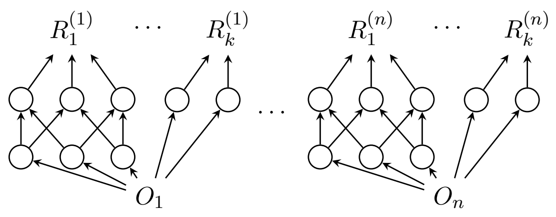

Figure 2: An illustration of the generated corrections lattices. The O_is are the original sentences, directed edges represent an application of an edit and $R_j^{(i)}$ is the j-th perfect correction of O_i (i.e., the perfect correction that result from applying all the edits of the j-th annotation of O_i).

4 Constructing Lattices of Corrections

In the following sections we present MAEGE an alternative methodology to CHR, which uses human corrections to induce more reliable and scalable rankings to compare metrics against. We begin our presentation by detailing the method MAEGE uses to generate source-correction pairs and a partial order between them. MAEGE operates by using a corpus with gold annotation, given as edits, to generate lattices of corrections, each defined by a sub-set of the edits. Within the lattice, every pair of sentences can be regarded as a potential source and a potential output. We create sentence chains, in an increasing order of quality, taking a source sentence and applying edits in some order one after the other (see Figure 2 and 3).

Formally, for each sentence s in the corpus and each annotation a, we have a set of typed edits $edits(s,a) = \{e_{s,a}^{(1)}, \ldots, e_{s,a}^{(n_{s,a})}\}$ of size $n_{s,a}$. We call $2^{edits(s,a)}$ the *corrections lattice*, and denote it with $E_{s,a}$. We call, s, the correction corresponding to $\emptyset$ the *original*. We define a partial order relation between $x, y \in E_{s,a}$ such that $x < y$ if $x \subset y$. This order relation is assumed to be the gold standard ranking between the corrections.

For our experiments, we use the NUCLE test data (Ng et al., 2014). Each sentence is paired with two annotations. The other eight available

[2]The difference between our results and previously reported ones is probably due to a recent update in GLEU to better tackles multiple references (Napoles et al., 2016a).

[3]The standard deviation of the results is about 0.02.

Figure 3: An example chain from a corrections lattice – each sentence is the result of applying a single edit to the sentence below it. The top sentence is a perfect correction, while the bottom is the original.

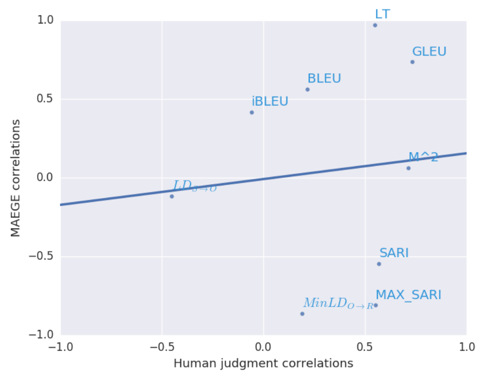

Figure 4: A scatter plot of the corpus-level correlation of metrics according to the different methodologies. The x-axis corresponds to the correlation according to human rankings (*Combined* setting), and the y-axis corresponds to the correlation according to MAEGE. While some get similar correlation (e.g., GLEU), other metrics change drastically (e.g., SARI).

references, produced by Bryant and Ng (2015), are used as references for the reference-based metrics. Denote the set of references for s with R_s.

Sentences which require no correction according to at least one of the two annotations are discarded. In 26 cases where two edit spans intersect in the same annotation (out of a total of about 40K edits), the edits are manually merged or split.

5 Corpus-level Analysis

We conduct a corpus-level analysis, namely testing the ability of metrics to determine which corpus of corrections is of better quality. In practice, this procedure is used to rank systems based on their outputs on the test corpus.

In order to compile corpora corresponding to systems of different quality levels, we define several corpus models, each applying a different expected number of edits to the original. Models are denoted with the expected number of edits they apply to the original which is a positive number $M \in \mathbb{R}^+$. Given a corpus model M, we generate a corpus of corrections by traversing the original sentences, and for each sentence s uniformly sample an annotation a (i.e., a set of edits that results in a perfect correction), and the number of edits applied n_{edits}, which is sampled from a clipped binomial probability with mean M and variance 0.9. Given n_{edits}, we uniformly sample from the lattice $E_{s,a}$ a sub-set of edits of size n_{edits}, and apply this set of edits to s. The corpus of $M = 0$ is the set of originals.

The corpus of source sentences, against which all other corpora are compared, is sampled by traversing the original sentences, and for each sentence s, uniformly sample an annotation a, and given s, a, uniformly sample a sentence from $E_{s,a}$.

Given a metric $m \in$ METRICS, we compute its score for each sampled corpus. Where corpus-level scores are not defined by the metrics themselves, we use the average sentence score instead. We compare the rankings induced by the scores of m and the ranking of systems according to their corpus model (i.e., systems that have a higher M should be ranked higher), and report the correlation between these rankings.

5.1 Experiments

Setup. For each model, we sample one correction per NUCLE sentence, noting that it is possible to reduce the variance of the metrics' corpus-level scores by sampling more. Corpus models of integer values between 0 and 10 are taken. We report Spearman ρ, commonly used for system-level rankings (Bojar et al., 2017).[4]

Results. Results, presented in Table 2 (left part), shows that LT correlates best with the rankings induced by MAEGE, where GLEU is second. M^2's correlation is only 0.06. We note that the LT requires a complementary metric to penalize grammatical outputs that diverge in meaning from the source (Napoles et al., 2016b). See §8.

Comparing the metrics' quality in corpus-level evaluation with their quality according to CHR (§3), we find they are often at odds. Figure 4 plots the Spearman correlation of the different metrics according to the two validation methodologies,

[4]Using Pearson correlation shows similar trends.

Table 2: Corpus-level Spearman ρ, sentence-level Pearson r and Kendall τ with the metrics (left). † represents P-value < 0.001. LT correlates best at the corpus level and has the highest sentence-level τ, while iBLEU has the highest sentence-level r.

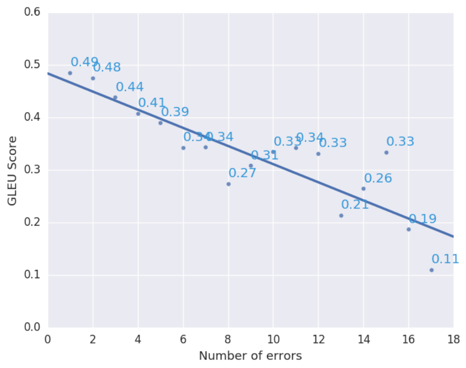

Figure 5: Average GLEU score of originals (y-axis), plotted against the number of errors they contain (x-axis). Their substantial correlation indicates that GLEU is globally reliable.

showing correlations are slightly correlated, but disagreements as to metric quality are frequent and substantial (e.g., with iBLEU or SARI).

6 Sentence-level Analysis

We proceed by presenting a method for assessing the correlation between metric-induced scores of corrections of the same sentence, and the scores given to these corrections by MAEGE. Given a sentence s and an annotation a, we sample a random permutation over the edits in $edits(s,a)$. We denote the permutation with $\sigma \in S_{n_{s,a}}$, where $S_{n_{s,a}}$ is the permutation group over $\{1,\cdots,n_{s,a}\}$. Given σ, we define a monotonic chain in $E_{i,j}$ as:

$$chain(s,a,\sigma) = \Big(\emptyset < \{e_{s,a}^{(\sigma(1))}\} < \{e_{s,a}^{(\sigma(1))}, e_{s,a}^{(\sigma(2))}\} < \dots < edits(s,a)\Big)$$

For each chain, we uniformly sample one of its elements, mark it as the source, and denote it with src. In order to generate a set of chains, MAEGE traverses the original sentences and annotations, and for each sentence-annotation pair, uniformly samples n_{ch} chains without repetition. It then uniformly samples a source sentence from each chain. If the number of chains in $E_{s,a}$ is smaller than n_{ch}, MAEGE selects all the chains.

Given a metric $m \in$ METRICS, we compute its score for every correction in each sampled chain against the sampled source and available references. We compute the sentence-level correlation of the rankings induced by the scores of m and the rankings induced by $<$. For computing rank correlation (such as Spearman ρ or Kendall τ), such a relative ranking is sufficient.

We report Kendall τ, which is only sensitive to the relative ranking of correction pairs within the same chain. Kendall is minimalistic in its assumptions, as it does not require numerical scores, but only assuming that $<$ is well-motivated, i.e., that applying a set of valid edits is better in quality than applying only a subset of it.

As $<$ is a partial order, and as Kendall τ is standardly defined over total orders, some modification is required. τ is a function of the number of compared pairs and of discongruent pairs (ordered differently in the compared rankings):

$$\tau = 1 - \frac{2\,|\text{discongruent pairs}|}{|\text{all pairs}|}.$$

To compute these quantities, we extract all unique pairs of corrections that can be compared with $<$ (i.e., one applies a sub-set of the edits of the other), and count the number of discongruent ones between the metric's ranking and $<$. Significance is modified accordingly.[5] Spearman ρ is

[5]Code can be found in https://github.com/borgr/EoE

less applicable in this setting, as it compares total orders whereas here we compare partial orders.

To compute linear correlation with Pearson r, we make the simplifying assumption that all edits contribute equally to the overall quality. Specifically, we assume that a perfect correction (i.e., the top of a chain) receives a score of 1. Each original sentence s (the bottom of a chain), for which there exists annotations $a_1, \ldots, a_n$, receives a score of

$$1 - \min_i \frac{|edits(s, a_i)|}{|tokens(s)|}.$$

The scores of partial (non-perfect) corrections in each chain are linearly spaced between the score of the perfect correction and that of the original. This scoring system is well-defined, as a partial correction receives the same score according to all chains it is in, as all paths between a partial correction and the original have the same length.

6.1 Experiments

Setup. We experiment with $n_{ch} = 1$, yielding 7936 sentences in 1312 chains (same as the number of original sentences in the NUCLE test set). We report the Pearson correlation over the scores of all sentences in all chains (r), and Kendall τ over all pairs of corrections within the same chain.

Results. Results are presented in Table 2 (right part). No metric scores very high, neither according to Pearson r nor according to Kendall τ. iBLEU correlates best with $<$ according to r, obtaining a correlation of 0.23, whereas LT fares best according to τ, obtaining 0.222.

Results show a discrepancy between the low corpus-level and sentence-level r correlations of M^2 and its high sentence-level τ. It seems that although M^2 orders pairs of corrections well, its scores are not a linear function of MAEGE's scores. This may be due to M^2's assignment of the minimal possible score to the source, regardless of its quality. M^2 thus seems to predict well the relative quality of corrections of the same sentence, but to be less effective in yielding a globally coherent score (cf. Felice and Briscoe (2015)).

GLEU shows the inverse behaviour, failing to correctly order pairs of corrections of the same sentence, while managing to produce globally coherent scores. We test this hypothesis by computing the average difference in GLEU score between all pairs in the sampled chains, and find it to be slightly negative (-0.00025), which is in line with GLEU's small negative τ. On the other hand, plotting the GLEU scores of the originals grouped by the number of errors they contain, we find they correlate well (Figure 5), indicating that GLEU performs well in comparing the quality of corrections of different sentences. Four sentences with considerably more errors than the others were considered outliers and removed.

7 Metric Sensitivity by Error Type

MAEGE's lattice can be used to analyze how the examined metrics reward corrections of errors of different types. For each edit type t, we denote with S_t the set of correction pairs from the lattice that only differ in an edit of type t. For each such pair (c, c') and for each metric m, we compute the difference in the score assigned by m to c and c'. The average difference is denoted with $\Delta_{m,t}$.

$$\Delta_{m,t} = \frac{1}{|S_t|} \sum_{(c,c') \in S_t} \left[m(src, c, R) - m(src, c', R) \right]$$

R is the corresponding reference set. A negative (positive) $\Delta_{m,t}$ indicates that m penalizes (awards) valid corrections of type t.

7.1 Experiments

Setup. We sample chains using the same sampling method as in §6, and uniformly sample a source from each chain. For each edit type t, we detect all pairs of corrections in the sampled chains that only differ in an edit of type t, and use them to compute $\Delta_{m,t}$. We use the set of 27 edit types given in the NUCLE corpus.

Results. Table 3 presents the results, showing that under all metrics, some edits types are penalized and others rewarded. iBLEU and LT penalize the least edit types, and GLEU penalizes the most, providing another perspective on GLEU's negative Kendall τ (§6). Certain types are penalized by almost all metrics. One such type is Vm, wrong verb modality (e.g., "as they [$\emptyset \rightsquigarrow$ may] not want to know"). Another such type is Npos, a problem in noun possessive (e.g., "their [facebook's $\rightsquigarrow$ Facebook] page"). Other types, such as Mec, mechanical (e.g., "[real-life $\rightsquigarrow$ real life]"), and V0, missing verb (e.g., "'Privacy', this is the word that [$\emptyset \rightsquigarrow$ is] popular"), are often rewarded by the metrics.

In general, the tendency of reference-based metrics (the vast majority of GEC metrics) to penalize edits of various types suggests that many edit

Table 3: Average change in metric score by metric and edit types ($\Delta_{m,t}$; see text). Rows correspond to edit types (abbreviations in Dahlmeier et al. (2013)); columns correspond to metrics. Some edit types are consistently penalized.

types are under-represented in available reference sets. Automatic evaluation of systems that perform these edit types may, therefore, be unreliable. Moreover, not addressing these biases in the metrics may hinder progress in GEC. Indeed, M^2 and GLEU, two of the most commonly used metrics, only award a small sub-set of edit types, thus offering no incentive for systems to improve performance on such types.[6]

8 Discussion

We revisit the argument that using system outputs to perform metric validation poses a methodological difficulty. Indeed, as GEC systems are developed, trained and tested using available metrics, and as metrics tend to reward some correction types and penalize others (§7), it is possible that GEC development adjusts to the metrics, and neglects some error types. Resulting tendencies in GEC systems would then yield biased sets of outputs for human rankings, which in turn would result in biases in the validation process.

To make this concrete, GEC systems are often precision-oriented: trained to prefer not to correct than to invalidly correct. Indeed, Choshen and Abend (2018a) show that modern systems tend to be highly conservative, often performing an order of magnitude fewer changes to the source than references do. Validating metrics on their ability to rank conservative system outputs (as is de facto the common practice) may produce a different picture of metric quality than when considering a more inclusive set of corrections.

We use MAEGE to mimic a setting of ranking against precision-oriented outputs. To do so, we perform corpus-level and sentence-level analyses, but instead of randomly sampling a source, we invariably take the original sentence as the source. We thereby create a setting where all edits applied are valid (but not all valid edits are applied).

Comparing the results to the regular MAEGE correlation (Table 4), we find that LT remains reliable, while M^2, that assumes the source receives the worst possible score, gains from this unbalanced setting. iBLEU drops, suggesting it may need to be retuned to this setting and give less weight to $BLEU(O, S)$, thus becoming more like BLEU and GLEU. The most drastic change we see is in SARI and MAX-SARI, which flip their sign and present strong performance. Interestingly, the metrics that benefit from this precision-oriented setting in the corpus-level are the same metrics that perform better according to CHR than to MAEGE (Figure 4). This indicates the different trends produced by MAEGE and CHR, may result

[6] $LD_{S\to O}$ tends to award valid corrections of almost all types. As source sentences are randomized across chains, this indicates that on average, corrections with more applied edits tend to be more similar to comparable corrections on the lattice. This is also reflected by the slightly positive sentence-level correlation of $LD_{S\to O}$ (§6).

	Corpus-level		Sentence-level			
	ρ	P-val	r	P-val	τ	P-val

Table 4: Corpus-level Spearman ρ, sentence-level Pearson r and Kendall τ correlations using origin as the source with the various metrics (left). Correlations using a random source are found in parenthesis. † represents $P - value < 0.001$. LT is the best corpus correlated, and has the best τ while iBLEU has the best r

from the latter's use of precision-oriented outputs.

Drawbacks. Like any methodology MAEGE has its simplifying assumptions and drawbacks; we wish to make them explicit. First, any biases introduced in the generation of the test corpus are inherited by MAEGE (e.g., that edits are contiguous and independent of each other). Second, MAEGE does not include errors that a human will not perform but machines might, e.g., significantly altering the meaning of the source. This partially explains why LT, which measures grammaticality but not meaning preservation, excels in our experiments. Third, MAEGE's scoring system (§6) assumes that all errors damage the score equally. While this assumption is made by GEC metrics, we believe it should be refined in future work by collecting user information.

9 Conclusion

In this paper, we show how to leverage existing annotation in GEC for performing validation reliably. We propose a new automatic methodology, MAEGE, which overcomes many of the shortcomings of the existing methodology. Experiments with MAEGE reveal a different picture of metric quality than previously reported. Our analysis suggests that differences in observed metric quality are partly due to system outputs sharing consistent tendencies, notably their tendency to under-predict corrections. As existing methodology ranks system outputs, these shared tendencies bias the validation process. The difficulties in basing validation on system outputs may be applicable to other text-to-text generation tasks, a question we will explore in future work.

Abstract

Statistical significance testing is a standard statistical tool designed to ensure that experimental results are not coincidental. In this opinion/theoretical paper we discuss the role of statistical significance testing in Natural Language Processing (NLP) research. We establish the fundamental concepts of significance testing and discuss the specific aspects of NLP tasks, experimental setups and evaluation measures that affect the choice of significance tests in NLP research. Based on this discussion, we propose a simple practical protocol for statistical significance test selection in NLP setups and accompany this protocol with a brief survey of the most relevant tests. We then survey recent empirical papers published in ACL and TACL during 2017 and show that while our community assigns great value to experimental results, statistical significance testing is often ignored or misused. We conclude with a brief discussion of open issues that should be properly addressed so that this important tool can be applied in NLP research in a statistically sound manner[1].

1 Introduction

The field of Natural Language Processing (NLP) has recently made great progress due to the data revolution that has made abundant amounts of textual data from a variety of languages and linguistic domains (newspapers, scientific journals, social media etc.) available. This, together with the emergence of a new generation of computing resources and the related development of Deep Neural Network models, have resulted in dramatic improvements in the capabilities of NLP algorithms.

[1]The code for all statistical tests detailed in this paper is found on: https://github.com/rtmdrr/testSignificanceNLP.git

The extended reach of NLP algorithms has also resulted in NLP papers giving much more emphasis to the experiment and result sections by showing comparisons between multiple algorithms on various datasets from different languages and domains. This emphasis on empirical results highlights the role of statistical significance testing in NLP research: if we rely on empirical evaluation to validate our hypotheses and reveal the correct language processing mechanisms, we better be sure that our results are not coincidental.

This paper aims to discuss the various aspects of proper statistical significance testing in NLP and to provide a simple and sound guide to the way this important tool should be used. We also discuss the particular challenges of statistical significance in the context of language processing tasks.

To facilitate a clear and coherent presentation, our (somewhat simplified) model of an NLP paper is one that presents a new algorithm and makes the hypothesis that this algorithm is better than a previous strong algorithm, which serves as the baseline. This hypothesis is verified in experiments where the two algorithms are applied to the same datasets (test sets), reasoning that if one algorithm is consistently better than the other, hopefully with a sufficiently large margin, then it should also be better on future, currently unknown, datasets. Yet, the experimental differences might be coincidental. Here comes statistical significance testing into the picture: we have to make sure that the probability of falsely concluding that one algorithm is better than the other is very small.

We note that in this paper we do not deal with the problem of drawing valid conclusions from multiple comparisons between algorithms across a large number of datasets , a.k.a. replicability analysis (see (Dror et al., 2017)). Instead, our focus is on a single comparison: how can we make sure that the difference between the two algorithms, as observed in an individual comparison, is not coincidental. Statistical significance testing of each individual comparison is the basic building block of replicability analysis – its accurate performance is a pre-condition for any multiple dataset analysis.

Statistical significance testing (§ 2) is a well researched problem in the statistical literature. However, the unique structured nature of natural language data is reflected in specialized evaluation measures such as BLEU (machine translation, (Papineni et al., 2002)), ROUGE (extractive summarization, (Lin, 2004)), UAS and LAS (dependency parsing, (Kübler et al., 2009)). The distribution of these measures is of great importance to statistical significance testing. Moreover, certain properties of NLP datasets and the community's evaluation standards also affect the way significance testing should be performed. An NLP-specific discussion of significance testing is hence in need.

In § 3 we discuss the considerations to be made in order to select the proper statistical significance test in NLP setups. We propose a simple decision tree algorithm for this purpose, and survey the prominent significance tests – parametric and non-parametric – for NLP tasks and data.

In § 4 we survey the current evaluation and significance testing practices of the community. We provide statistics collected from the long papers of the latest ACL proceedings (Barzilay and Kan, 2017) as well as from the papers published in the TACL journal during 2017. Our analysis reveals that there is still a room for improvement in the way statistical significance is used in papers published in our top-tier publication venues. Particularly, a large portion of the surveyed papers do not test the significance of their results, or use incorrect tests for this purpose.

Finally, in § 5 we discuss open issues. A particularly challenging problem is that while most significance tests assume the test set consists of independent observations, most NLP datasets consist of dependent data points. For example, many NLP standard evaluation sets consist of sentences coming from the same source (e.g. newspaper) or document (e.g. newspaper article) or written by the same author. Unfortunately, the nature of these dependencies is hard to characterize, let alone to quantify. Another important problem is how to test significance when cross-validation, a popular evaluation methodology in NLP papers, is performed.

Besides its practical value, we hope this paper will encourage further research into the role of statistical significance testing in NLP and on the questions that still remain open.

2 Preliminaries

In this section we provide the required preliminaries for our discussion. We start with a formal definition of statistical significance testing and proceed with an overview of the prominent evaluation measures in NLP.

2.1 Statistical Significance Testing

In this paper we focus on the setup where the performance of two algorithms, A and B, on a dataset X, is compared using an evaluation measure $\mathcal{M}$. Let us denote $\mathcal{M}(ALG, X)$ as the value of the evaluation measure $\mathcal{M}$ when algorithm ALG is applied to the dataset X. Without loss of generality, we assume that higher values of the measure are better. We define the difference in performance between the two algorithms according to the measure $\mathcal{M}$ on the dataset X as:

$$\delta(X) = \mathcal{M}(A, X) - \mathcal{M}(B, X). \quad (1)$$

In this paper we will refer to $\delta(X)$ as our test statistic. Using this notation we formulate the following statistical hypothesis testing problem:[2]

$$\begin{aligned} H_0 &: \delta(X) \leq 0 \\ H_1 &: \delta(X) > 0. \end{aligned}$$

In order to decide whether or not to reject the null hypothesis, that is reaching the conclusion that $\delta(X)$ is indeed greater than 0, we usually compute a $p-$value for the test. The $p-$value is defined as the probability, under the null hypothesis H_0, of obtaining a result equal to or more extreme than what was actually observed. For the one-sided hypothesis testing defined here, the $p-$value is defined as:

$$Pr(\delta(X) \geq \delta_{observed} | H_0).$$

Where $\delta_{observed}$ is the performance difference between the algorithms (according to $\mathcal{M}$) when applied to X. The smaller the p-value, the higher the significance, or, in other words, the stronger

[2]For simplicity we consider a one-sided hypothesis, it can be easily re-formulated as a double-sided hypothesis.

the indication provided by the data that the null-hypothesis, H_0, does not hold. In order to decide whether H_0 should be rejected, the researcher should pre-define an arbitrary, fixed threshold value α, a.k.a *the significance level*. Only if $p-$value $< \alpha$ then the null hypothesis is rejected.

In significance (or hypothesis) testing we consider two error types. *Type* I *error* refers to the case where the null hypothesis is rejected when it is actually true. *Type* II *error* refers to the case where the null hypothesis is not rejected although it should be. A common approach in hypothesis testing is to choose a test that guarantees that the probability of making a type I error is upper bounded by the test significance level α, mentioned above, while achieving the highest possible *power*: i.e. the lowest possible probability of making a type II error.

2.2 Evaluation Measures in NLP

Evaluation Measure	ACL 17	TACL 17
F-scores	78 (39.8%)	9 (25.71%)
Accuracy	67 (34.18%)	13 (37.14%)
Precision/ Recall	44 (22.45%)	6 (17.14%)
BLEU	26 (13.27%)	4 (11.43%)
ROUGE	12 (6.12%)	0 (0%)
Pearson/ Spearman correlations	4 (2.04%)	6 (17.14%)
Perplexity	7 (3.57%)	2 (5.71%)
METEOR	6 (3.06%)	1 (2.86%)
UAS+LAS	1 (0.51%)	3 (8.57%)

Table 1: The most common evaluation measures in (long) ACL and TACL 2017 papers, ordered by ACL frequency. For each measure we present the total number of papers where it is used and the fraction of papers in the corresponding venue.

In order to draw valid conclusions from the experiments formulated in § 2.1 it is crucial to apply the correct statistical significance test. In § 3 we explain that the choice of the significance test is based, among other considerations, on the distribution of the test statistics, $\delta(X)$. From equation 1 it is clear that $\delta(X)$ depends on the evaluation measure $\mathcal{M}$. We hence turn to discuss the evaluation measures employed in NLP.

In § 4 we analyze the (long) ACL and TACL 2017 papers, and observe that the most commonly used evaluation measures are the 12 measures that appear in Table 1. Notice that seven of these measures: Accuracy, Precision, Recall, F-score, Pearson and Spearman correlations and Perplexity, are not specific to NLP. The other five measures: BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), METEOR (Banerjee and Lavie, 2005), UAS and LAS (Kübler et al., 2009), are unique measures that were developed for NLP applications. BLEU and METEOR are standard evaluation measures for machine translation, ROUGE for extractive summarization, and UAS and LAS for dependency parsing. While UAS and LAS are in fact accuracy measures, BLEU, ROUGE and METEOR are designed for tasks where there are several possible outputs - a characteristic property of several NLP tasks. In machine translation, for example, a sentence in one language can be translated in multiple ways to another language. Consequently, BLEU takes an n-gram based approach on the surface forms, while METEOR considers only unigram matches but uses stemming and controls for synonyms.

All 12 measures return a real number, either in $[0, 1]$ or in $\mathbb{R}$. Notice though that accuracy may reflect an average over a set of categorical scores (observations), e.g., in document-level binary sentiment analysis where every document is tagged as either positive or negative. In other cases, the individual observations are also continuous. For example, when comparing two dependency parsers, we may want to understand how likely it is, given our results, that one parser will do better than the other on a new sentence. In such a case we will consider the sentence-level UAS or LAS differences between the two parsers on all the sentences in the test set. Such sentence level UAS or LAS scores - the individual observations to be considered in the significance test - are real-valued.

With the basic concepts clarified, we are ready to discuss the considerations to be made when choosing a statistical significance test.

3 Statistical Significance in NLP

The goal of this section is to detail the considerations involved in the selection of a statistical significance test for an NLP application. Based on these considerations we provide a practical recipe that can be applied in order to make a good choice. In order to make this paper a practical guide for the community, we also provide a short description of the significance tests that are most relevant for NLP setups.

3.1 Parametric vs. Non-parametric Tests

As noted above, a major consideration in the selection of a statistical significance test is the distribution of the test statistic, $\delta(X)$, under the null hypothesis. If the distribution is known, then the suitable test will come from the family of *parametric tests*, that uses this distribution in order to achieve powerful results (i.e., low probability of making a type II error, see § 2). If the distribution is unknown then any assumption made by a test may lead to erroneous conclusions and hence we should rely on *non-parametric tests* that do not make any such assumption. While non-parametric tests may be less powerful than their parametric counterparts, they do not make unjustified assumptions and are hence statistically sound even when the test statistic distribution is unknown.

But how can one know the test statistic distribution? One possibility is to apply tests designed to evaluate the distribution of a sample of observations. For example, the Shapiro-Wilk test (Shapiro and Wilk, 1965) tests the null hypothesis that a sample comes from a normally distributed population, the Kolmogorov-Smirnov test quantifies the distance between the empirical distribution function of the sample and the cumulative distribution function of the reference distribution, and the Anderson-Darling test (Anderson and Darling, 1954) tests whether a given sample of data is drawn from a given probability distribution. As discussed below, there seems to be other heuristics that are used in practice but are not often mentioned in research papers.

In what follows we discuss the prominent parametric and non-parametric tests for NLP setups. Based on this discussion we end this section with a simple decision tree that aims to properly guide the significance test choice process.

3.2 Prominent Significance Tests

3.2.1 Parametric Tests

Parametric significance tests assume that the test statistic is distributed according to a known distribution with defined parameters, typically the normal distribution. While this assumption may be hard to verify (see discussion above), when it holds, these parametric tests have stronger statistical power compared to non-parametric tests that do not make this assumption (Fisher, 1937).

Here we discuss the prominent parametric test for NLP setups - the paired student's t-test.

Paired Student's t-test This test assesses whether the population means of two sets of measurements differ from each other, and is based on the assumption that both samples come from a normal distribution (Fisher, 1937).

In practice, t-test is often applied with evaluation measures such as accuracy, UAS and LAS, that compute the mean number of correct predictions per input example. When comparing two dependency parsers, for example, we can apply the test to check if the averaged difference of their UAS scores is significantly larger than zero, which can serve as an indication that one parser is better than the other.

Although we have not seen this discussed in NLP papers, we believe that the decision to use the t-test with these measures is based on the Central Limit Theorem (CLT). CLT establishes that, in most situations, when independent random variables are added, their properly normalized sum tends toward a normal distribution even if the original variables themselves are not normally distributed. That is, accuracy measures in structured tasks tend to be normally distributed when the number individual predictions (e.g. number of words in a sentence when considering sentence-level UAS) is large enough.

One case where it is theoretically justified to employ the t-test is described in (Sethuraman, 1963). The authors prove that for large enough data, the sampling distribution of a certain function of the Pearson's correlation coefficient follows the Student's t-distribution with $n - 2$ degrees of freedom. With the recent surge in word similarity research with word embedding models, this result is of importance to our community.

For other evaluation measures, such as F-score, BLEU, METEOR and ROUGE that do not compute means, the common practice is to assume that they are not normally distributed (Yeh, 2000; Berg-Kirkpatrick et al., 2012). We believe this issue requires a further investigation and suggest that it may be best to rely on the normality tests discussed in § 3.1 when deciding whether or not to employ the t-test.

3.2.2 Non-parametric Tests

When the test statistic distribution is unknown, non-parametric significance testing should be used. The non-parametric tests that are commonly used in NLP setups can be divided into two families that differ with respect to their statistical power and computational complexity.

The first family consists of tests that do not consider the actual values of the evaluation measures. The second family do consider the values of the measures: it tests repeatedly sample from the test data, and estimates the p-value based on the test statistic values in the samples. We refer to the first family as the family of *sampling-free* tests and to the second as the family of *sampling-based* tests.

The two families of tests reflect different preferences with respect to the balance between statistical power and computational efficiency. Sampling-free tests do not consider the evaluation measure values, only higher level statistics of the results such as the number of cases in which each of the algorithms performs better than the other. Consequently, their statistical power is lower than that of sampling-based tests that do consider the evaluation measure values. Sampling-based tests, however, compensate for the lack of distributional assumptions over the data with re-sampling – a computationally intensive procedure. Sampling-based methods are hence not the optimal candidates for very large datasets.

We consider here four commonly used sampling-free tests: the sign test and two of its variants, and the wilcoxon signed-rank test.

Sign test This test tests whether matched pair samples are drawn from distributions with equal medians. The test statistic is the number of examples for which algorithm A is better than algorithm B, and the null hypothesis states that given a new pair of measurements (e.g. evaluations (a_i, b_i) of the two algorithms on a new test example), then a_i and b_i are equally likely to be larger than the other (Gibbons and Chakraborti, 2011).

The sign test has limited practical implications since it only checks if algorithm A is better than B and ignores the extent of the difference. Yet, it has been used in a variety of NLP papers (e.g. (Collins et al., 2005; Chan et al., 2007; Rush et al., 2012)). The assumptions of this test is that the data samples are i.i.d, the differences come from a continuous distribution (not necessarily normal) and that the values are ordered.

The next test is a special case of the sign test for binary classification (or a two-tailed sign test).

McNemar's test (McNemar, 1947) This test is designed for paired nominal observations (binary labels). The test is applied to a 2×2 contingency table, which tabulates the outcomes of two algorithms on a sample of n examples. The null hypothesis for this test states that the marginal probability for each outcome (label one or label two) is the same for both algorithms. That is, when applying both algorithms on the same data we would expect them to be correct/incorrect on the same proportion of items. Under the null hypothesis, with a sufficiently large number of disagreements between the algorithms, the test statistic has a distribution of χ^2 with one degree of freedom. This test is appropriate for binary classification tasks, and has been indeed used in such NLP works (e.g. sentiment classificaiton, (Blitzer et al., 2006; Ziser and Reichart, 2017)). The **Cochran's Q test** (Cochran, 1950) generalizes the McNemar's test for multi-class classification setups.

The sign test and its variants consider only pairwise ranks: which algorithm performs better on each test example. In NLP setups, however, we also have access to the evaluation measure values, and this allows us to rank the differences between the algorithms. The Wilcoxon signed-rank test makes use of such a rank and hence, while it does not consider the evaluation measure values, it is more powerful than the sign test and its variants.

Wilcoxon signed-rank test (Wilcoxon, 1945) Like the sign test variants, this test is used when comparing two matched samples (e.g. UAS values of two dependency parsers on a set of sentences). Its null hypothesis is that the differences follow a symmetric distribution around zero. First, the absolute values of the differences are ranked. Then, each rank gets a sign according to the sign of the difference. The Wilcoxon test statistic sums these signed ranks. The test is actually applicable for most NLP setups and it has been used widely (e.g. (Søgaard et al., 2014; Søgaard, 2013; Yang and Mitchell, 2017)) due to its improved power compared to the sign test variants.

As noted above, sampling-free tests trade statistical power for efficiency. Sampling-based methods take the opposite approach. This family includes two main methods: permutation/randomization tests (Noreen, 1989) and the paired bootstrap (Efron and Tibshirani, 1994).

Pitman's permutation test This test estimates the test statistic distribution under the null hypothesis by calculating the values of this statistic under all possible labellings (permutations) of the test set. The (two-sided) p-value of the test is calculated as the proportion of these permutations where the absolute difference was greater than or equal to the absolute value of the difference in the output of the algorithm.

Obviously, permutation tests are computationally intensive due to the exponentially large number of possible permutations. In practice, approximate randomization tests are used where a pre-defined limited number of permutations are drawn from the space of all possible permutations, without replacements (see, e.g. (Riezler and Maxwell, 2005) in the context of machine translation). The bootstrap test (Efron and Tibshirani, 1994) is based on a closely related idea.

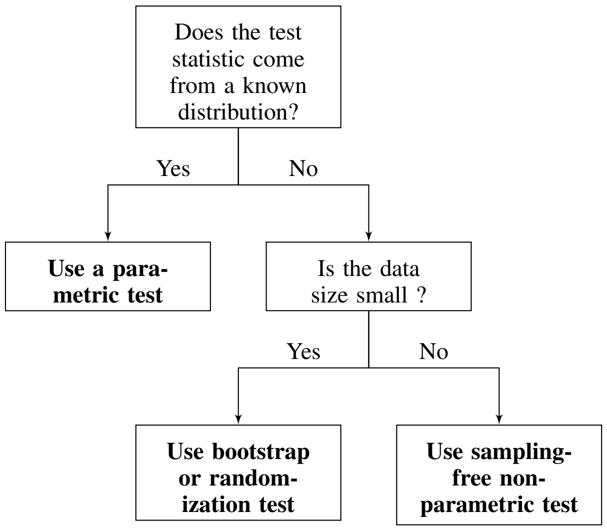
Paired bootstrap test This test is very similar to approximate randomization of the permutation test, with the difference that the sampling is done with replacements (i.e., an example from the original test data can appear more than once in a sample). The idea of bootstrap is to use the samples as surrogate populations, for the purpose of approximating the sampling distribution of the statistic. The p-value is calculated in a similar manner to the permutation test.

Bootstrap was used with a variety of NLP tasks, including machine translation, text summarization and semantic parsing (e.g. (Koehn, 2004; Li et al., 2017; Wu et al., 2017; Ouchi et al., 2017)). The test is less effective for small test sets, as it assumes that the test set distribution does not deviate too much from the population distribution.

Clearly, Sampling-based methods are computationally intensive and can be intractable for large datasets, even with modern computing power. In such cases, sampling-free methods form an available alternative.

3.3 Significance Test Selection

With the discussion of significance test families - parametric vs. non-parametric (§ 3.1), and the properties of the actual significance tests (§ 3.2) we are now ready to provide a simple recipe for significance test selection in NLP setups. The decision tree in Figure 1 provides an illustration.



Does the test statistic come from a known distribution?
Yes
No
Use a parametric test
Is the data size small ?
Yes
No
Use bootstrap or randomization test
Use sampling-free non-parametric test

Figure 1: Decision tree for statistical significance test selection.

If the distribution of the test statistic is known, then parametric tests are most appropriate. These tests are more statistically powerful and less computationally intensive compared to their non-parametric counterparts. The stronger statistical power of parametric tests stems from the stronger, parametric assumptions they make, while the higher computational demand of some non-parametric tests is the result of their sampling process.

When the distribution of the test statistic is unknown, the first non-parametric family of choice is that of sampling-based tests. These tests consider the actual values of the evaluation measures and are not restricted to higher order properties (e.g. ranks) of the observed values – their statistical power is hence higher. As noted in (Riezler and Maxwell, 2005), in the case where the distributional assumptions of the parametric tests are violated, sampling-based tests have more statistical power than parametric tests.

Nonetheless, sampling-based tests are computationally intensive – the exact permutation test, for example, requires the generation of all 2^n data permutations (where n is the number of points in the dataset). To overcome this, approximate randomization can be used, as was done, e.g., by Yeh (2000) for test sets of more than 20 points. The other alternative for very large datasets are sampling-free tests that are less powerful but are computationally feasible.

In what follows we check whether recent ACL and TACL papers follow these guidelines.

4 Survey of ACL and TACL papers

General Statistics	ACL '17	TACL '17
Total number of papers	196	37
# relevant (experimental) papers	180	33
# different tasks	36	15
# different evaluation measures	24	19
Average number of measures per paper	2.34	2.1
# papers that **do not** report significance	117	15
# papers that report significance	63	18
# papers that report significance but use the **wrong** statistical test	6	0
# papers that report significance but do not mention the test name	21	3
# papers that have to report replicability	110	19
# papers that report replicability	3	4
# papers that perform cross validation	23	5

Table 2: Statistical significance statistics for empirical ACL and TACL 2017 papers.

We analyzed the long papers from the proceedings of the 55th Annual Meeting of the Association for Computational Linguistics (ACL17, (Barzilay and Kan, 2017)), a total of 196 papers, and the papers from the Transactions of the Association of Computational Linguistics journal (TACL17), Volume 5, Issue 1, a total of 37 papers. We have focused on empirical papers where at least one comparison between methods was performed.

Table 2 presents the main results from our survey. The top part of the table presents general statistics of our dataset. In both conference and journal papers, the variety of different NLP tasks is quite large: 36 tasks in ACL 2017 and 15 tasks in TACL. Interestingly, in almost every paper in our survey the researchers chose to analyze their results using more than one evaluation measure, with an average of 2.34 (ACL) and 2.1 (TACL). Table 1 presents the most common of these evaluation measures.

Statistical Test	ACL '17	TACL '17
Bootstrap	6	1
t-test	17	2
Wilcoxon	3	0
Chi square	3	1
Randomization	3	1
McNemar	2	3
Sign	2	3
Permutation	1	4

Table 3: Number of times each of the prominent statistical significance tests in ACL and TACL 2017 papers was used. 42 ACL and 15 TACL papers reported the significance test name. 5 ACL papers mentioned an unrecognized test name.

The lower part of Table 2 depicts the disturbing reality of statistical significance testing in our research community. Out of the 180 experimental long papers of ACL 2017, only 63 papers included a statistical significance test. Moreover, out of these 63 papers 21 did not mention the name of the significance test they employed. Of the 42 papers that did mention the name of the significance test, 6 used the wrong test according to the considerations discussed in § 3.[3] In TACL, where the review process is presumably more strict and of higher quality, out of 33 experimental papers, 15 did not include statistical significance testing, and all the papers that report significance and mentioned the name of the test used a valid test.

While this paper focuses on the correct choice of a significance test, we also checked whether the papers in our sample account for the effect of multiple hypothesis testing when testing statistical significance (see (Dror et al., 2017)). When testing multiple hypotheses, as in the case of comparing the participating algorithms across a large number of datasets, the probability of making one or more false claims may be very high, even if the probability of drawing an erroneous conclusion in each individual comparison is small. In ACL 2017, out

[3]We considered the significance test to be inappropriate in three cases: 1. Using the t-test when the evaluation measure is not an average measure; 2. Using the t-test for a classification task (i.e. when the observations are categorical rather then continuous), even if the evaluation measure is an average measure; and 3. Using a Boostrap test with a small test set size.

of 110 papers that used multiple datasets only 3 corrected for multiplicity (all using the Bonferroni correction). In TACL, the situation is slightly better with 4 papers correcting for multiplicity out of 19 that should have done that.

Regarding the statistical tests that were used in the papers that did report significance (Table 3), in ACL 2017 most of the papers used the Student's t-test that assumes the data is i.i.d and that the test statistics are normally distributed. As discussed in § 3 this is not the case in many NLP applications. Gladly, in TACL, t-test is not as prominent.

One final note is about the misuse of the word **significant**. We noticed that in a considerable number of papers this word was used as a synonym for words such as important, considerable, meaningful, substantial, major, notable etc. We believe that we should be more careful when using this word, ideally keeping its statistical sense and using other, more general words to indicate a substantial impact.

We close this discussion with two important open issues.

5 Open Questions

In this section we would like to point on two issues that remain open even after our investigation. We hope that bringing these issues to the attention of the research community will encourage our fellow researchers to come up with appropriate solutions.

The first open issue is that of *dependent observations*. An assumption shared by the statistical significance tests described in § 3, that are commonly used in NLP setups, is that the data samples are independent and identically distributed. This assumption, however, is rarely true in NLP setups.

For example, the popular WSJ Penn Treebank corpus (Marcus et al., 1993) consists of 2,499 articles from a three year Wall Street Journal (WSJ) collection of 98,732 stories. Obviously, some of the sentences included in the corpus come from the same article, were written by the same author or were reviewed before publication by the same editor. As another example, many sentences in the Europarl parallel corpus (Koehn, 2005) that is very popular in the machine translation literature are taken from the same parliament discussion. An independence assumption between the sentences in these corpora is not likely to hold.

This dependence between test examples violates the conditions under which the theoretical guarantees of the various tests were developed. The impact of this phenomenon on our results is hard to quantify, partly because it is hard to quantify the nature of the dependence between test set examples in NLP datasets. Some papers are even talking about abandoning the null hypothesis statistical significance test approach due to this hard-to-meet assumption (Koplenig, 2017; McShane et al., 2017; Carver, 1978; Leek et al., 2017). In our opinion, this calls for a future collaboration with statisticians in order to better understand the extent to which existing popular significance tests are relevant for NLP, and to develop alternative tests if necessary.

Another issue that deserves some thought is that of cross-validation. To increase the validity of reported results, it is customary in NLP papers to create a number of random splits of the experimental corpus into train, development and test portions (see Table 2). For each such split (fold), the tested algorithms are trained and tuned on the training and development datasets, respectively, and their results on the test data are recorded. The final reported result is typically the average of the test set results across the splits. Some papers also report the fraction of the folds for which one algorithm was better than the others. While cross-validation is surely a desired practice, it is challenging to report statistical significance when it is employed. Particularly, the test sets of the different folds are obviously not independent – their content is even likely to overlap.

One solution we would like to propose here is based on replicability analysis (Dror et al., 2017). This paper proposes a statistical significance framework for multiple comparisons performed with dependent test sets, using the $K_{Bonferroni}$ estimator for the number of datasets with significant effect. One statistically sound way to test for significance when a cross-validation protocol is employed is hence to calculate the p-value for each fold separately, and then to perform replicability analysis for dependent datasets with $K_{Bonferroni}$. Only if this analysis rejects the null hypothesis in all folds (or in more than a predefined threshold number of folds), the results should be declared significant. Here again, further statistical investigation may lead to additional, potentially better, solutions.

6 Conclusions

We discussed the use of significance testing in NLP. We provided the main considerations for significance test selection, and proposed a simple test selection protocol. We then surveyed the state of significance testing in recent top venue papers and concluded with open issues. We hope this paper will serve as a guide for NLP researchers and, not less importantly, that it will encourage discussions and collaborations that will contribute to the soundness and correctness of our research.

Abstract

Many natural language processing tasks can be modeled into structured prediction and solved as a search problem. In this paper, we distill an ensemble of multiple models trained with different initialization into a single model. In addition to learning to match the ensemble's probability output on the reference states, we also use the ensemble to explore the search space and learn from the encountered states in the exploration. Experimental results on two typical search-based structured prediction tasks – transition-based dependency parsing and neural machine translation show that distillation can effectively improve the single model's performance and the final model achieves improvements of 1.32 in LAS and 2.65 in BLEU score on these two tasks respectively over strong baselines and it outperforms the greedy structured prediction models in previous literatures.

1 Introduction

Search-based structured prediction models the generation of natural language structure (part-of-speech tags, syntax tree, translations, semantic graphs, etc.) as a search problem (Collins and Roark, 2004; Liang et al., 2006; Zhang and Clark, 2008; Huang et al., 2012; Sutskever et al., 2014; Goodman et al., 2016). It has drawn a lot of research attention in recent years thanks to its competitive performance on both accuracy and running time. A stochastic policy that controls the whole search process is usually learned by imitating a *reference policy*. The imitation is usually addressed as training a classifier to predict the reference policy's search action on the encountered states when performing the reference policy. Such imitation process can sometimes be problematic. One problem is the ambiguities of the reference policy, in which multiple actions lead to the optimal structure but usually, only one is chosen as training instance (Goldberg and Nivre, 2012). Another problem is the discrepancy between training and testing, in which during the test phase, the learned policy enters non-optimal states whose search action is never learned (Ross and Bagnell, 2010; Ross et al., 2011). All these problems harm the generalization ability of search-based structured prediction and lead to poor performance.

Previous works tackle these problems from two directions. To overcome the ambiguities in data, techniques like *ensemble* are often adopted (Di-

Table 1: The search-based structured prediction view of transition-based dependency parsing (Nivre, 2008) and neural machine translation (Sutskever et al., 2014).

etterich, 2000). To mitigate the discrepancy, exploration is encouraged during the training process (Ross and Bagnell, 2010; Ross et al., 2011; Goldberg and Nivre, 2012; Bengio et al., 2015; Goodman et al., 2016). In this paper, we propose to consider these two problems in an integrated *knowledge distillation* manner (Hinton et al., 2015). We distill a single model from the ensemble of several baselines trained with different initialization by matching the ensemble's output distribution on the reference states. We also let the ensemble randomly explore the search space and learn the single model to mimic ensemble's distribution on the encountered exploration states. Combing the distillation from reference and exploration further improves our single model's performance. The workflow of our method is shown in Figure 1.

We conduct experiments on two typical search-based structured prediction tasks: transition-based dependency parsing and neural machine translation. The results of both these two experiments show the effectiveness of our knowledge distillation method by outperforming strong baselines. In the parsing experiments, an improvement of 1.32 in LAS is achieved and in the machine translation experiments, such improvement is 2.65 in BLEU. Our model also outperforms the greedy models in previous works.

Major contributions of this paper include:

- We study the knowledge distillation in search-based structured prediction and propose to distill the knowledge of an ensemble into a single model by learning to match its distribution on both the reference states (§3.2) and exploration states encountered when using the ensemble to explore the search space (§3.3). A further combination of these two methods is also proposed to improve the performance (§3.4).
- We conduct experiments on two search-based structured prediction problems: transition-based dependency parsing and neural machine translation. In both these two problems, the distilled model significantly improves over strong baselines and outperforms other greedy structured prediction (§4.2). Comprehensive analysis empirically shows the feasibility of our distillation method (§4.3).

2 Background

2.1 Search-based Structured Prediction

Structured prediction maps an input $\mathbf{x} = (x_1, x_2, ..., x_n)$ to its structural output $\mathbf{y} = (y_1, y_2, ..., y_m)$, where each component of $\mathbf{y}$ has some internal dependencies. Search-based structured prediction (Collins and Roark, 2004; Daumé III et al., 2005; Daumé III et al., 2009; Ross and Bagnell, 2010; Ross et al., 2011; Doppa et al., 2014; Vlachos and Clark, 2014; Chang et al., 2015) models the generation of the structure as a search problem and it can be formalized as a tuple $(\mathcal{S}, \mathcal{A}, \mathcal{T}(s, a), \mathcal{S}_0, \mathcal{S}_T)$, in which $\mathcal{S}$ is a set of states, $\mathcal{A}$ is a set of actions, $\mathcal{T}$ is a function that maps $\mathcal{S} \times \mathcal{A} \rightarrow \mathcal{S}$, $\mathcal{S}_0$ is a set of initial states, and $\mathcal{S}_T$ is a set of terminal states. Starting from an initial state $s_0 \in \mathcal{S}_0$, the structured prediction model repeatably chooses an action $a_t \in \mathcal{A}$ by following a *policy* $\pi(s)$ and applies a_t to s_t and enter a new state s_{t+1} as $s_{t+1} \leftarrow \mathcal{T}(s_t, a_t)$, until a final state $s_T \in \mathcal{S}_T$ is achieved. Several natural language structured prediction problems can be modeled under the search-based framework including dependency parsing (Nivre, 2008) and neural machine translation (Liang et al., 2006; Sutskever et al., 2014). Table 1 shows the search-based structured prediction view of these two problems.

In the data-driven settings, $\pi(s)$ controls the whole search process and is usually parameterized by a classifier $p(a \mid s)$ which outputs the proba-

```
Input: training data: ${\mathbf{x}^{(n)}, \mathbf{y}^{(n)}}_{n=1}^{N}$; the
       reference policy: $\pi_{\mathcal{R}}(s, \mathbf{y})$.
Output: classifier $p(a|s)$.
1  $D \leftarrow \emptyset$;
2  for $n \leftarrow 1...N$ do
3      $t \leftarrow 0$;
4      $s_t \leftarrow s_0(\mathbf{x}^{(n)})$;
5      while $s_t \notin \mathcal{S}_T$ do
6          $a_t \leftarrow \pi_{\mathcal{R}}(s_t, \mathbf{y}^{(n)})$;
7          $D \leftarrow D \cup \{s_t\}$;
8          $s_{t+1} \leftarrow \mathcal{T}(s_t, a_t)$;
9          $t \leftarrow t + 1$;
10     end
11 end
12 optimize $\mathcal{L}_{NLL}$;
```

bility of choosing an action a on the given state s. The commonly adopted greedy policy can be formalized as choosing the most probable action with $\pi(s) = \text{argmax}_a\, p(a \mid s)$ at test stage. To learn an optimal classifier, search-based structured prediction requires constructing a reference policy $\pi_{\mathcal{R}}(s, \mathbf{y})$, which takes an input state s, gold structure $\mathbf{y}$ and outputs its reference action a, and training $p(a \mid s)$ to imitate the reference policy. Algorithm 1 shows the common practices in training $p(a \mid s)$, which involves: first, using $\pi_{\mathcal{R}}(s, \mathbf{y})$ to generate a sequence of reference states and actions on the training data (line 1 to line 11 in Algorithm 1); second, using the states and actions on the reference sequences as examples to train $p(a \mid s)$ with negative log-likelihood (NLL) loss (line 12 in Algorithm 1),

$$\mathcal{L}_{NLL} = \sum_{s \in D} \sum_{a} -\mathbb{1}\{a = \pi_{\mathcal{R}}\} \cdot \log p(a \mid s)$$

where D is a set of training data.

The reference policy is sometimes sub-optimal and ambiguous which means on one state, there can be more than one action that leads to the optimal prediction. In transition-based dependency parsing, Goldberg and Nivre (2012) showed that one dependency tree can be reached by several search sequences using Nivre (2008)'s *arc-standard* algorithm. In machine translation, the ambiguity problem also exists because one source language sentence usually has multiple semantically correct translations but only one reference translation is presented. Similar problems have also been observed in semantic parsing (Goodman et al., 2016). According to Frénay and Verleysen (2014), the widely used NLL loss is vulnerable to ambiguous data which make it worse for search-based structured prediction.

Besides the ambiguity problem, training and testing discrepancy is another problem that lags the search-based structured prediction performance. Since the training process imitates the reference policy, all the states in the training data are optimal which means they are guaranteed to reach the optimal structure. But during the test phase, the model can predict non-optimal states whose search action is never learned. The greedy search which is prone to error propagation also worsens this problem.

2.2 Knowledge Distillation

A cumbersome model, which could be an ensemble of several models or a single model with larger number of parameters, usually provides better generalization ability. *Knowledge distillation* (Buciluǎ et al., 2006; Ba and Caruana, 2014; Hinton et al., 2015) is a class of methods for transferring the generalization ability of the cumbersome *teacher model* into a small *student model*. Instead of optimizing NLL loss, knowledge distillation uses the distribution $q(y \mid x)$ outputted by the teacher model as "soft target" and optimizes the knowledge distillation loss,

$$\mathcal{L}_{KD} = \sum_{x \in D} \sum_{y} -q(y \mid x) \cdot \log p(y \mid x).$$

In search-based structured prediction scenario, x corresponds to the state s and y corresponds to the action a. Through optimizing the distillation loss, knowledge of the teacher model is learned by the student model $p(y \mid x)$. When correct label is presented, NLL loss can be combined with the distillation loss via simple interpolation as

$$\mathcal{L} = \alpha \mathcal{L}_{KD} + (1 - \alpha)\mathcal{L}_{NLL} \qquad (1)$$

3 Knowledge Distillation for Search-based Structured Prediction

3.1 Ensemble

As Hinton et al. (2015) pointed out, although the real objective of a machine learning algorithm is to generalize well to new data, models are usually trained to optimize the performance on training data, which bias the model to the training data.

In search-based structured prediction, such biases can result from either the ambiguities in the training data or the discrepancy between training and testing. It would be more problematic to train $p(a \mid s)$ using the loss which is in-robust to ambiguities and only considering the optimal states.

The effect of ensemble on ambiguous data has been studied in Dietterich (2000). They empirically showed that ensemble can overcome the ambiguities in the training data. Daumé III et al. (2005) also use weighted ensemble of parameters from different iterations as their final structure prediction model. In this paper, we consider to use ensemble technique to improve the generalization ability of our search-based structured prediction model following these works. In practice, we train M search-based structured prediction models with different initialized weights and ensemble them by the average of their output distribution as $q(a \mid s) = \frac{1}{M}\sum_m q_m(a \mid s)$. In Section 4.3.1, we empirically show that the ensemble has the ability to choose a good search action in the optimal-yet-ambiguous states and the non-optimal states.

3.2 Distillation from Reference

As we can see in Section 4, ensemble indeed improves the performance of baseline models. However, real world deployment is usually constrained by computation and memory resources. Ensemble requires running the structured prediction models for multiple times, and that makes it less applicable in real-world problem. To take the advantage of the ensemble model while avoid running the models multiple times, we use the knowledge distillation technique to distill a single model from the ensemble. We started from changing the NLL learning objective in Algorithm 1 into the distillation loss (Equation 1) as shown in Algorithm 2. Since such method learns the model on the states produced by the reference policy, we name it as *distillation from reference*. Blocks connected by in dashed red lines in Figure 1 show the workflow of our *distillation from reference*.

3.3 Distillation from Exploration

In the scenario of search-based structured prediction, transferring the teacher model's generalization ability into a student model not only includes matching the teacher model's soft targets on the reference search sequence, but also imitating the search decisions made by the teacher model. One way to accomplish the imitation can be sampling search sequence from the ensemble and learn from the soft target on the sampled states. More concretely, we change $\pi_{\mathcal{R}}(s, \mathbf{y})$ into a policy $\pi_{\mathcal{E}}(s)$ which samples an action a from $q(a \mid s)^{\frac{1}{T}}$, where T is the temperature that controls the sharpness of the distribution (Hinton et al., 2015). The algorithm is shown in Algorithm 2. Since such distillation generate training instances from exploration, we name it as *distillation from exploration*. Blocks connected by in solid blue lines in Figure 1 show the workflow of our *distillation from exploration*.

On the sampled states, reference decision from $\pi_{\mathcal{R}}$ is usually non-trivial to achieve, which makes learning from NLL loss infeasible. In Section 4, we empirically show that fully distilling from the soft target, i.e. setting $\alpha = 1$ in Equation 1, achieves comparable performance with that both from distillation and NLL.

Algorithm 2: Knowledge distillation for search-based structured prediction.

```
Input: training data: $\{\mathbf{x}^{(n)}, \mathbf{y}^{(n)}\}_{n=1}^{N}$; the
       reference policy: $\pi_{\mathcal{R}}(s, \mathbf{y})$; the
       exploration policy: $\pi_{\mathcal{E}}(s)$ which
       samples an action from the annealed
       ensemble $q(a \mid s)^{\frac{1}{T}}$
Output: classifier $p(a \mid s)$.
1  $D \leftarrow \emptyset$;
2  for $n \leftarrow 1...N$ do
3      $t \leftarrow 0$;
4      $s_t \leftarrow s_0(\mathbf{x}^{(n)})$;
5      while $s_t \notin \mathcal{S}_T$ do
6          if distilling from reference then
7              $a_t \leftarrow \pi_{\mathcal{R}}(s_t, \mathbf{y}^{(n)})$;
8          else
9              $a_t \leftarrow \pi_{\mathcal{E}}(s_t)$;
10         end
11         $D \leftarrow D \cup \{s_t\}$;
12         $s_{t+1} \leftarrow \mathcal{T}(s_t, a_t)$;
13         $t \leftarrow t + 1$;
14     end
15 end
16 if distilling from reference then
17     optimize $\alpha\mathcal{L}_{KD} + (1 - \alpha)\mathcal{L}_{NLL}$;
18 else
19     optimize $\mathcal{L}_{KD}$;
20 end
```

3.4 Distillation from Both

Distillation from reference can encourage the model to predict the action made by the reference policy and distillation from exploration learns the model on arbitrary states. They transfer the generalization ability of the ensemble from different aspects. Hopefully combining them can further improve the performance. In this paper, we combine distillation from reference and exploration with the following manner: we use $\pi_{\mathcal{R}}$ and $\pi_{\mathcal{E}}$ to generate a set of training states. Then, we learn $p(a \mid s)$ on the generated states. If one state was generated by the reference policy, we minimize the interpretation of distillation and NLL loss. Otherwise, we minimize the distillation loss only.

4 Experiments

We perform experiments on two tasks: transition-based dependency parsing and neural machine translation. Both these two tasks are converted to search-based structured prediction as Section 2.1.

For the transition-based parsing, we use the stack-lstm parsing model proposed by Dyer et al. (2015) to parameterize the classifier.[1] For the neural machine translation, we parameterize the classifier as an LSTM encoder-decoder model by following Luong et al. (2015).[2] We encourage the reader of this paper to refer corresponding papers for more details.

4.1 Settings

4.1.1 Transition-based Dependency Parsing

We perform experiments on Penn Treebank (PTB) dataset with standard data split (Section 2-21 for training, Section 22 for development, and Section 23 for testing). Stanford dependencies are converted from the original constituent trees using Stanford CoreNLP 3.3.0[3] by following Dyer et al. (2015). Automatic part-of-speech tags are assigned by 10-way jackknifing whose accuracy is 97.5%. Labeled attachment score (LAS) excluding punctuation are used in evaluation. For the other hyper-parameters, we use the same settings as Dyer et al. (2015). The best iteration and α is determined on the development set.

[1]The code for parsing experiments is available at: https://github.com/Oneplus/twpipe.

[2]We based our NMT experiments on OpenNMT (Klein et al., 2017). The code for NMT experiments is available at: https://github.com/Oneplus/OpenNMT-py.

[3]stanfordnlp.github.io/CoreNLP/history.html

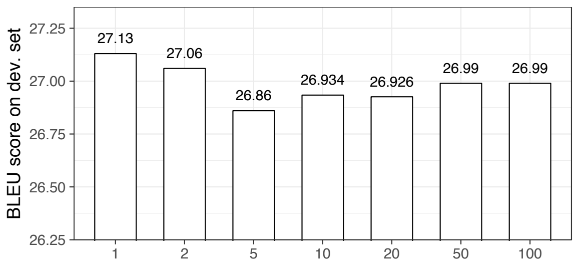

Figure 2: The effect of using different Ks when approximating distillation loss with K-most probable actions in the machine translation experiments.

Reimers and Gurevych (2017) and others have pointed out that neural network training is nondeterministic and depends on the seed for the random number generator. To control for this effect, they suggest to report the average of M differently-seeded runs. In all our dependency parsing, we set $n = 20$.

4.1.2 Neural Machine Translation

We conduct our experiments on a small machine translation dataset, which is the German-to-English portion of the IWSLT 2014 machine translation evaluation campaign. The dataset contains around 153K training sentence pairs, 7K development sentence pairs, and 7K testing sentence pairs. We use the same preprocessing as Ranzato et al. (2015), which leads to a German vocabulary of about 30K entries and an English vocabulary of 25K entries. One-layer LSTM for both encoder and decoder with 256 hidden units are used by following Wiseman and Rush (2016). BLEU (Papineni et al., 2002) was used to evaluate the translator's performance.[4] Like in the dependency parsing experiments, we run $M = 10$ differently-seeded runs and report the averaged score.

Optimizing the distillation loss in Equation 1 requires enumerating over the action space. It is expensive for machine translation since the size of the action space (vocabulary) is considerably large (25K in our experiments). In this paper, we use the K-most probable actions (translations on target side) on one state to approximate the whole probability distribution of $q(a \mid s)$ as $\sum_a q(a \mid s) \cdot \log p(a \mid s) \approx \sum_k^K q(\hat{a}_k \mid s) \cdot \log p(\hat{a}_k \mid s)$, where $\hat{a}_k$ is the k-th probable action. We fix α to

1 and vary K and evaluate the distillation model's performance. These results are shown in Figure 2 where there is no significant difference between different Ks and in speed consideration, we set K to 1 in the following experiments.

4.2 Results

4.2.1 Transition-based Dependency Parsing

Table 2 shows our PTB experimental results. From this result, we can see that the ensemble model outperforms the baseline model by 1.90 in LAS. For our distillation from reference, when setting $\alpha = 1.0$, best performance on development set is achieved and the test LAS is 91.99.

We tune the temperature T during exploration and the results are shown in Figure 3. Sharpen the distribution during the sampling process generally performs better on development set. Our distillation from exploration model gets almost the same performance as that from reference, but simply combing these two sets of data outperform both models by achieving an LAS of 92.14.

We also compare our parser with the other parsers in Table 2. The second group shows the greedy transition-based parsers in previous literatures. Andor et al. (2016) presented an alternative state representation and explored both greedy and beam search decoding. (Ballesteros et al., 2016) explores training the greedy parser with dynamic oracle. Our distillation parser outperforms all these greedy counterparts. The third group shows parsers trained on different techniques including decoding with beam search (Buckman et al., 2016; Andor et al., 2016), training transition-based parser with beam search (Andor et al., 2016), graph-based parsing (Dozat and Manning, 2016), distilling a graph-based parser from the output of 20 parsers (Kuncoro et al., 2016), and converting constituent parsing results to dependencies (Kuncoro et al., 2017). Our distillation parser still outperforms its transition-based counterparts but lags the others. We attribute the gap between our parser with the other parsers to the difference in parsing algorithms.

	BLEU

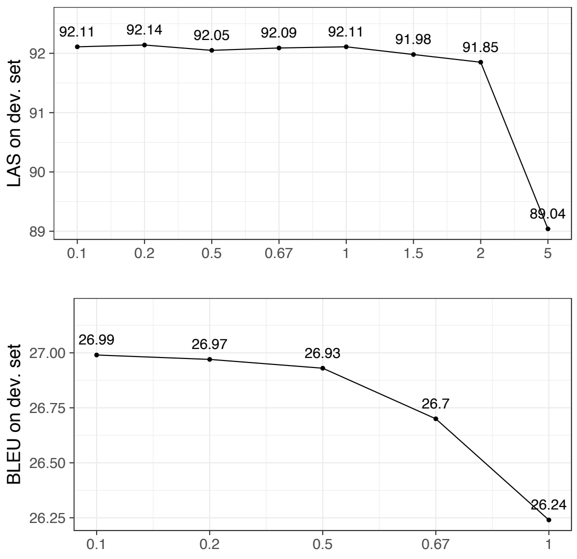

Figure 3: The effect of T on PTB (above) and IWSLT 2014 (below) development set.

4.2.2 Neural Machine Translation

Table 3 shows the experimental results on IWSLT 2014 dataset. Similar to the PTB parsing results, the ensemble 10 translators outperforms the baseline translator by 3.47 in BLEU score. Distilling from the ensemble by following the reference leads to a single translator of 24.76 BLEU score.

Like in the parsing experiments, sharpen the distribution when exploring the search space is more helpful to the model's performance but the differences when $T \leq 0.2$ is not significant as shown in Figure 3. We set $T = 0.1$ in our distillation from exploration experiments since it achieves the best development score. Table 3 shows the exploration result of a BLEU score of 24.64 and it slightly lags the best reference model. Distilling from both the reference and exploration improves the single model's performance by a large margin and achieves a BLEU score of 25.44.

We also compare our model with other translation models including the one trained with reinforcement learning (Ranzato et al., 2015) and that using beam search in training (Wiseman and Rush, 2016). Our distillation translator outperforms these models.

Both the parsing and machine translation experiments confirm that it's feasible to distill a reasonable search-based structured prediction model by just exploring the search space. Combining the reference and exploration further improves the model's performance and outperforms its greedy structured prediction counterparts.

4.3 Analysis

In Section 4.2, improvements from distilling the ensemble have been witnessed in both the transition-based dependency parsing and neural machine translation experiments. However, questions like "Why the ensemble works better? Is it feasible to fully learn from the distillation loss without NLL? Is learning from distillation loss stable?" are yet to be answered. In this section, we first study the ensemble's behavior on "problematic" states to show its generalization ability. Then, we empirically study the feasibility of fully learning from the distillation loss by studying the effect of α in the distillation from reference setting. Finally, we show that learning from distillation loss is less sensitive to initialization and achieves a more stable model.

	optimal-yet-ambiguous	non-optimal
Baseline	68.59	89.59
Ensemble	74.19	90.90
Distill (both)	81.15	91.38

Table 4: The ranking performance of parsers' output distributions evaluated in MAP on "problematic" states.

4.3.1 Ensemble on "Problematic" States

As mentioned in previous sections, "problematic" states which is either ambiguous or non-optimal harm structured prediciton's performance. Ensemble shows to improve the performance in Section 4.2, which indicates it does better on these states. To empirically testify this, we use dependency parsing as a testbed and study the ensemble's output distribution using the dynamic oracle.

The dynamic oracle (Goldberg and Nivre, 2012; Goldberg et al., 2014) can be used to efficiently determine, given any state s, which transition action leads to the best achievable parse from s; if some errors may have already made, what is the best the parser can do, going forward? This allows us to analyze the accuracy of each parser's individual decisions, in the "problematic" states. In this paper, we evaluate the output distributions of the baseline and ensemble parser against the *reference actions* suggested by the dynamic oracle. Since dynamic oracle yields more than one reference actions due to ambiguities and previous mistakes and the output distribution can be treated as their scoring, we evaluate them as a ranking problem. Intuitively, when multiple reference actions exist, a good parser should push probability mass to these actions. We draw problematic states by sampling from our baseline parser. The comparison in Table 4 shows that the ensemble model significantly outperforms the baseline on ambiguous and non-optimal states. This observation indicates the ensemble's output distribution is more "informative", thus generalizes well on problematic states and achieves better performance. We also observe that the distillation model perform better than both the baseline and ensemble. We attribute this to the fact that the distillation model is learned from exploration.

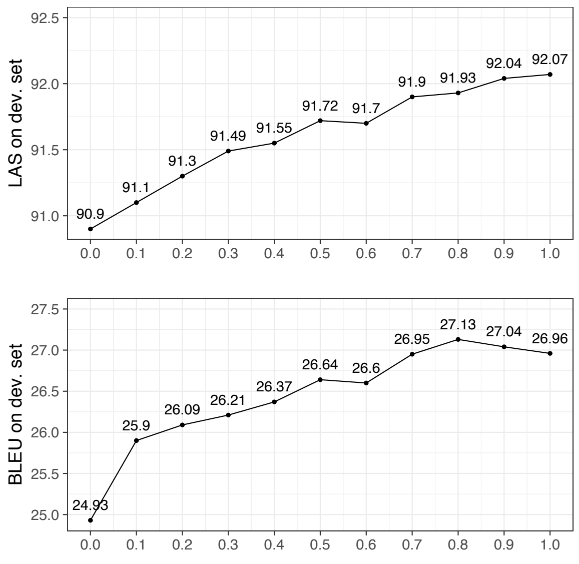

Figure 4: The effect of α on PTB (above) and IWSLT 2014 (below) development set.

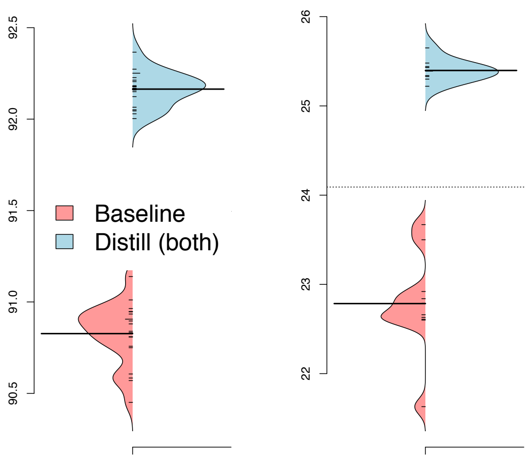

Figure 5: The distributions of scores for the baseline model and our *distillation from both* on PTB test (left) and IWSLT 2014 test (right) on differently-seeded runs.

system	seeds	min	max	σ

Baseline	10	21.63	23.67	0.55
Distill (both)	10	24.22	25.65	0.12

Table 5: The minimal, maximum, and standard derivation values on differently-seeded runs.

4.3.2 Effect of α

Over our distillation from reference model, we study the effect of α in Equation 1. We vary α from 0 to 1 by a step of 0.1 in both the transition-based dependency parsing and neural machine translation experiments and plot the model's performance on development sets in Figure 4. Similar trends are witnessed in both these two experiments that model that's configured with larger α generally performs better than that with smaller α. For the dependency parsing problem, the best development performance is achieved when we set $\alpha = 1$, and for the machine translation, the best α is 0.8. There is only 0.2 point of difference between the best α model and the one with α equals to 1. Such observation indicates that when distilling from the reference policy paying more attention to the distillation loss rather than the NLL is more beneficial. It also indicates that fully learning from the distillation loss outputted by the ensemble is reasonable because models configured with $\alpha = 1$ generally achieves good performance.

4.3.3 Learning Stability

Besides the improved performance, knowledge distillation also leads to more stable learning. The performance score distributions of differently-seed runs are depicted as violin plot in Figure 5. Table 5 also reveals the smaller standard derivations are achieved by our distillation methods. As Keskar et al. (2016) pointed out that the generalization gap is not due to *overfit*, but due to the network converge to *sharp minimizer* which generalizes worse, we attribute the more stable training from our distillation model as the distillation loss presents less *sharp minimizers*.

5 Related Work

Several works have been proposed to applying knowledge distillation to NLP problems. Kim and Rush (2016) presented a distillation model which focus on distilling the structured loss from a large model into a small one which works on sequence-level. In contrast to their work, we pay more attention to action-level distillation and propose to do better action-level distillation by both from reference and exploration.

Freitag et al. (2017) used an ensemble of 6-translators to generate training reference. Exploration was tried in their work with beam-search. We differ their work by training the single model to match the distribution of the ensemble.

Using ensemble in exploration was also studied in reinforcement learning community (Osband et al., 2016). In addition to distilling the ensemble on the labeled training data, a line of semi-supervised learning works show that it's effective to transfer knowledge of cumbersome model into a simple one on the unlabeled data (Liang et al., 2008; Li et al., 2014). Their extensions to knowledge distillation call for further study.

Kuncoro et al. (2016) proposed to compile the knowledge from an ensemble of 20 transition-based parsers into a voting and distill the knowledge by introducing the voting results as a regularizer in learning a graph-based parser. Different from their work, we directly do the distillation on the classifier of the transition-based parser.

Besides the attempts for directly using the knowledge distillation technique, Stahlberg and Byrne (2017) propose to first build the ensemble of several machine translators into one network by unfolding and then use SVD to shrink its parameters, which can be treated as another kind of knowledge distillation.

6 Conclusion

In this paper, we study knowledge distillation for search-based structured prediction and propose to distill an ensemble into a single model both from reference and exploration states. Experiments on transition-based dependency parsing and machine translation show that our distillation method significantly improves the single model's performance. Comparison analysis gives empirically guarantee for our distillation method.

Abstract

We introduce a novel architecture for dependency parsing: *stack-pointer networks* (**STACKPTR**). Combining pointer networks (Vinyals et al., 2015) with an internal stack, the proposed model first reads and encodes the whole sentence, then builds the dependency tree top-down (from root-to-leaf) in a depth-first fashion. The stack tracks the status of the depth-first search and the pointer networks select one child for the word at the top of the stack at each step. The STACKPTR parser benefits from the information of the whole sentence and all previously derived subtree structures, and removes the left-to-right restriction in classical transition-based parsers. Yet, the number of steps for building any (including non-projective) parse tree is linear in the length of the sentence just as other transition-based parsers, yielding an efficient decoding algorithm with $O(n^2)$ time complexity. We evaluate our model on 29 treebanks spanning 20 languages and different dependency annotation schemas, and achieve state-of-the-art performance on 21 of them.

1 Introduction

Dependency parsing, which predicts the existence and type of linguistic dependency relations between words, is a first step towards deep language understanding. Its importance is widely recognized in the natural language processing (NLP) community, with it benefiting a wide range of NLP applications, such as coreference resolution (Ng, 2010; Durrett and Klein, 2013; Ma et al., 2016), sentiment analysis (Tai et al., 2015), machine translation (Bastings et al., 2017), information extraction (Nguyen et al., 2009; Angeli et al., 2015; Peng et al., 2017), word sense disambiguation (Fauceglia et al., 2015), and low-resource languages processing (McDonald et al., 2013; Ma and Xia, 2014). There are two dominant approaches to dependency parsing (Buchholz and Marsi, 2006; Nivre et al., 2007): local and greedy *transition-based* algorithms (Yamada and Matsumoto, 2003; Nivre and Scholz, 2004; Zhang and Nivre, 2011; Chen and Manning, 2014), and the globally optimized *graph-based* algorithms (Eisner, 1996; McDonald et al., 2005a,b; Koo and Collins, 2010).

Transition-based dependency parsers read words sequentially (commonly from left-to-right) and build dependency trees incrementally by making series of multiple choice decisions. The advantage of this formalism is that the number of operations required to build any projective parse tree is linear with respect to the length of the sentence. The challenge, however, is that the decision made at each step is based on local information, leading to error propagation and worse performance compared to graph-based parsers on root and long dependencies (McDonald and Nivre, 2011). Previous studies have explored solutions to address this challenge. Stack LSTMs (Dyer et al., 2015; Ballesteros et al., 2015, 2016) are capable of learning representations of the parser state that are sensitive to the complete contents of the parser's state. Andor et al. (2016) proposed a globally normalized transition model to replace the locally normalized classifier. However, the parsing accuracy is still behind state-of-the-art graph-based parsers (Dozat and Manning, 2017).

Graph-based dependency parsers, on the other hand, learn scoring functions for parse trees and perform exhaustive search over all possible trees for a sentence to find the globally highest scoring

[*]Work done while at Carnegie Mellon University.

tree. Incorporating this global search algorithm with distributed representations learned from neural networks, neural graph-based parsers (Kiperwasser and Goldberg, 2016; Wang and Chang, 2016; Kuncoro et al., 2016; Dozat and Manning, 2017) have achieved the state-of-the-art accuracies on a number of treebanks in different languages. Nevertheless, these models, while accurate, are usually slow (e.g. decoding is $O(n^3)$ time complexity for first-order models (McDonald et al., 2005a,b) and higher polynomials for higher-order models (McDonald and Pereira, 2006; Koo and Collins, 2010; Ma and Zhao, 2012b,a)).

In this paper, we propose a novel neural network architecture for dependency parsing, *stack-pointer networks* (**STACKPTR**). STACKPTR is a transition-based architecture, with the corresponding asymptotic efficiency, but still maintains a global view of the sentence that proves essential for achieving competitive accuracy. Our STACKPTR parser has a pointer network (Vinyals et al., 2015) as its backbone, and is equipped with an internal stack to maintain the order of head words in tree structures. The STACKPTR parser performs parsing in an incremental, top-down, depth-first fashion; at each step, it generates an arc by assigning a child for the head word at the top of the internal stack. This architecture makes it possible to capture information from the whole sentence and all the previously derived subtrees, while maintaining a number of parsing steps linear in the sentence length.

We evaluate our parser on 29 treebanks across 20 languages and different dependency annotation schemas, and achieve state-of-the-art performance on 21 of them. The contributions of this work are summarized as follows:

(i) We propose a neural network architecture for dependency parsing that is simple, effective, and efficient.

(ii) Empirical evaluations on benchmark datasets over 20 languages show that our method achieves state-of-the-art performance on 21 different treebanks[1].

(iii) Comprehensive error analysis is conducted to compare the proposed method to a strong graph-based baseline using biaffine attention (Dozat and Manning, 2017).

2 Background

We first briefly describe the task of dependency parsing, setup the notation, and review Pointer Networks (Vinyals et al., 2015).

2.1 Dependency Parsing and Notations

Dependency trees represent syntactic relationships between words in the sentences through labeled directed edges between head words and their dependents. Figure 1 (a) shows a dependency tree for the sentence, "But there were no buyers".

In this paper, we will use the following notation:

Input: $\mathbf{x} = \{w_1, \ldots, w_n\}$ represents a generic sentence, where w_i is the ith word.

Output: $\mathbf{y} = \{p_1, p_2, \cdots, p_k\}$ represents a generic (possibly non-projective) dependency tree, where each path $p_i = \$, w_{i,1}, w_{i,2}, \cdots, w_{i,l_i}$ is a sequence of words from the root to a leaf. "\$" is an universal virtual root that is added to each tree.

Stack: σ denotes a stack configuration, which is a sequence of words. We use $\sigma|w$ to represent a stack configuration that pushes word w into the stack σ.

Children: $\mathrm{ch}(w_i)$ denotes the list of all the children (modifiers) of word w_i.

2.2 Pointer Networks

Pointer Networks (PTR-NET) (Vinyals et al., 2015) are a variety of neural network capable of learning the conditional probability of an output sequence with elements that are discrete tokens corresponding to positions in an input sequence. This model cannot be trivially expressed by standard sequence-to-sequence networks (Sutskever et al., 2014) due to the variable number of input positions in each sentence. PTR-NET solves the problem by using attention (Bahdanau et al., 2015; Luong et al., 2015) as a pointer to select a member of the input sequence as the output.

Formally, the words of the sentence $\mathbf{x}$ are fed one-by-one into the encoder (a multiple-layer bi-directional RNN), producing a sequence of *encoder hidden states* s_i. At each time step t, the decoder (a uni-directional RNN) receives the input from last step and outputs *decoder hidden state* h_t. The *attention vector* a^t is calculated as follows:

$$\begin{array}{rcl} e_i^t & = & score(h_t, s_i) \\ a^t & = & softmax(e^t) \end{array} \quad (1)$$

where $score(\cdot, \cdot)$ is the *attention scoring function*, which has several variations such as dot-product,

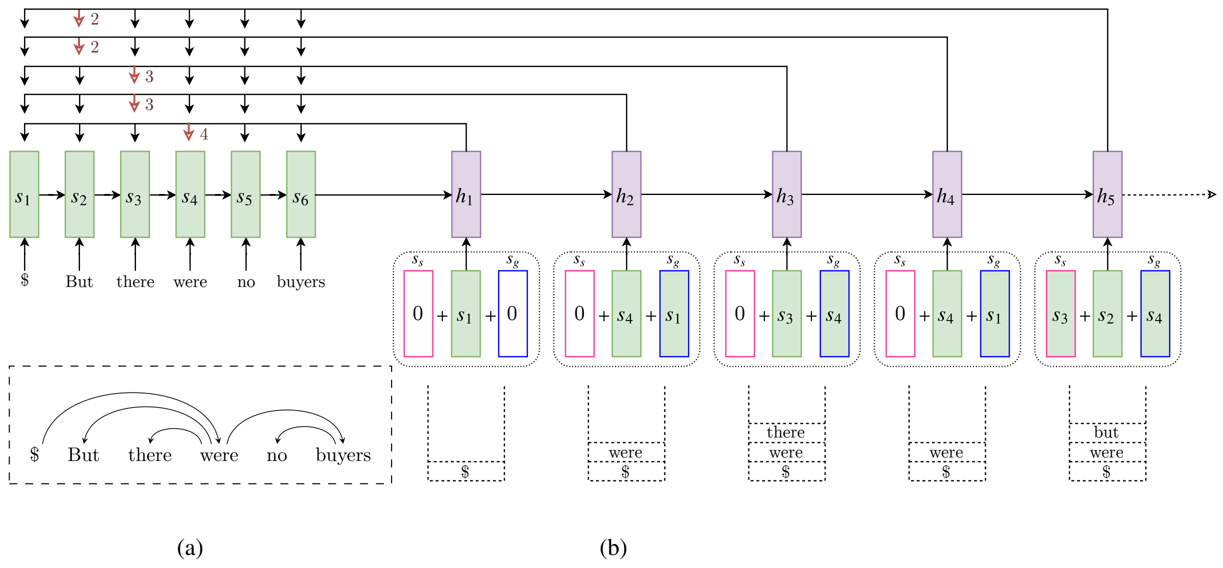

Figure 1: Neural architecture for the StackPtr network, together with the decoding procedure of an example sentence. The BiRNN of the encoder is elided for brevity. For the inputs of decoder at each time step, vectors in red and blue boxes indicate the sibling and grandparent.

concatenation, and biaffine (Luong et al., 2015). Ptr-Net regards the attention vector a^t as a probability distribution over the source words, i.e. it uses a^t_i as pointers to select the input elements.

3 Stack-Pointer Networks

3.1 Overview

Similarly to Ptr-Net, StackPtr first reads the whole sentence and encodes each word into the encoder hidden state s_i. The internal stack σ is always initialized with the root symbol \$. At each time step t, the decoder receives the input vector corresponding to the top element of the stack σ (the head word w_p where p is the word index), generates the hidden state h_t, and computes the attention vector a^t using Eq. (1). The parser chooses a specific position c according to the attention scores in a^t to generate a new dependency arc (w_h, w_c) by selecting w_c as a child of w_h. Then the parser pushes w_c onto the stack, i.e. $\sigma \rightarrow \sigma|w_c$, and goes to the next step. At one step if the parser points w_h to itself, i.e. $c = h$, it indicates that all children of the head word w_h have already been selected. Then the parser goes to the next step by popping w_h out of σ.

At test time, in order to guarantee a valid dependency tree containing all the words in the input sentences exactly once, the decoder maintains a list of "available" words. At each decoding step, the parser selects a child for the current head word, and removes the child from the list of available words to make sure that it cannot be selected as a child of other head words.

For head words with multiple children, it is possible that there is more than one valid selection for each time step. In order to define a deterministic decoding process to make sure that there is only one ground-truth choice at each step (which is necessary for simple maximum likelihood estimation), a predefined order for each $\text{ch}(w_i)$ needs to be introduced. The predefined order of children can have different alternatives, such as left-to-right or inside-out[2]. In this paper, we adopt the inside-out order[3] since it enables us to utilize second-order *sibling* information, which has been proven beneficial for parsing performance (McDonald and Pereira, 2006; Koo and Collins, 2010) (see § 3.4 for details). Figure 1 (b) depicts the architecture of StackPtr and the decoding procedure for the example sentence in Figure 1 (a).

3.2 Encoder

The encoder of our parsing model is based on the bi-directional LSTM-CNN architecture (BLSTM-CNNs) (Chiu and Nichols, 2016; Ma and Hovy, 2016) where CNNs encode character-level information of a word into its character-level repre-

[2]Order the children by the distances to the head word on the left side, then the right side.

[3]We also tried left-to-right order which obtained worse parsing accuracy than inside-out.

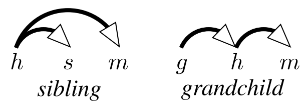
sentation and BLSTM models context information of each word. Formally, for each word, the CNN, with character embeddings as inputs, encodes the character-level representation. Then the character-level representation vector is concatenated with the word embedding vector to feed into the BLSTM network. To enrich word-level information, we also use POS embeddings. Finally, the encoder outputs a sequence of hidden states s_i.

3.3 Decoder

The decoder for our parser is a uni-directional LSTM. Different from previous work (Bahdanau et al., 2015; Vinyals et al., 2015) which uses word embeddings of the previous word as the input to the decoder, our decoder receives the encoder hidden state vector (s_i) of the top element in the stack σ (see Figure 1 (b)). Compared to word embeddings, the encoder hidden states contain more contextual information, benefiting both the training and decoding procedures. The decoder produces a sequence of decoder hidden states h_i, one for each decoding step.

3.4 Higher-order Information

As mentioned before, our parser is capable of utilizing higher-order information. In this paper, we incorporate two kinds of higher-order structures — *grandparent* and *sibling*. A sibling structure is a head word with two successive modifiers, and a grandparent structure is a pair of dependencies connected head-to-tail:



To utilize higher-order information, the decoder's input at each step is the sum of the encoder hidden states of three words:

$$\beta_t = s_h + s_g + s_s$$

where β_t is the input vector of decoder at time t and h, g, s are the indices of the head word and its grandparent and sibling, respectively. Figure 1 (b) illustrates the details. Here we use the element-wise sum operation instead of concatenation because it does not increase the dimension of the input vector β_t, thus introducing no additional model parameters.

3.5 Biaffine Attention Mechanism

For attention score function (Eq. (1)), we adopt the biaffine attention mechanism (Luong et al., 2015; Dozat and Manning, 2017):

$$e_i^t = h_t^T \mathbf{W} s_i + \mathbf{U}^T h_t + \mathbf{V}^T s_i + \mathbf{b}$$

where $\mathbf{W}, \mathbf{U}, \mathbf{V}$, $\mathbf{b}$ are parameters, denoting the weight matrix of the bi-linear term, the two weight vectors of the linear terms, and the bias vector.

As discussed in Dozat and Manning (2017), applying a multilayer perceptron (MLP) to the output vectors of the BLSTM before the score function can both reduce the dimensionality and overfitting of the model. We follow this work by using a one-layer perceptron to s_i and h_i with elu (Clevert et al., 2015) as its activation function.

Similarly, the dependency label classifier also uses a biaffine function to score each label, given the head word vector h_t and child vector s_i as inputs. Again, we use MLPs to transform h_t and s_i before feeding them into the classifier.

3.6 Training Objectives

The STACKPTR parser is trained to optimize the probability of the dependency trees given sentences: $P_\theta(\mathbf{y}|\mathbf{x})$, which can be factorized as:

$$\begin{aligned} P_\theta(\mathbf{y}|\mathbf{x}) &= \prod_{i=1}^{k} P_\theta(p_i|p_{<i}, \mathbf{x}) \\ &= \prod_{i=1}^{k} \prod_{j=1}^{l_i} P_\theta(c_{i,j}|c_{i,<j}, p_{<i}, \mathbf{x}), \end{aligned} \tag{2}$$

where θ represents model parameters. $p_{<i}$ denotes the preceding paths that have already been generated. $c_{i,j}$ represents the jth word in p_i and $c_{i,<j}$ denotes all the proceeding words on the path p_i. Thus, the STACKPTR parser is an autoregressive model, like sequence-to-sequence models, but it factors the distribution according to a top-down tree structure as opposed to a left-to-right chain. We define $P_\theta(c_{i,j}|c_{i,<j}, p_{<i}, \mathbf{x}) = a^t$, where attention vector a^t (of dimension n) is used as the distribution over the indices of words in a sentence.

Arc Prediction Our parser is trained by optimizing the conditional likelihood in Eq (2), which is implemented as the cross-entropy loss.

Label Prediction We train a separated multi-class classifier in parallel to predict the dependency labels. Following Dozat and Manning (2017), the classifier takes the information of the head word and its child as features. The label classifier is trained simultaneously with the parser by optimizing the sum of their objectives.

3.7 Discussion

Time Complexity. The number of decoding steps to build a parse tree for a sentence of length n is $2n-1$, linear in n. Together with the attention mechanism (at each step, we need to compute the attention vector a^t, whose runtime is $O(n)$), the time complexity of decoding algorithm is $O(n^2)$, which is more efficient than graph-based parsers that have $O(n^3)$ or worse complexity when using dynamic programming or maximum spanning tree (MST) decoding algorithms.

Top-down Parsing. When humans comprehend a natural language sentence, they arguably do it in an incremental, left-to-right manner. However, when humans consciously annotate a sentence with syntactic structure, they rarely ever process in fixed left-to-right order. Rather, they start by reading the whole sentence, then seeking the main predicates, jumping back-and-forth over the sentence and recursively proceeding to the sub-tree structures governed by certain head words. Our parser follows a similar kind of annotation process: starting from reading the whole sentence, and processing in a top-down manner by finding the main predicates first and only then search for sub-trees governed by them. When making latter decisions, the parser has access to the entire structure built in earlier steps.

3.8 Implementation Details

Pre-trained Word Embeddings. For all the parsing models in different languages, we initialize word vectors with pretrained word embeddings. For Chinese, Dutch, English, German and Spanish, we use the structured-skipgram (Ling et al., 2015) embeddings. For other languages we use Polyglot embeddings (Al-Rfou et al., 2013).

Optimization. Parameter optimization is performed with the Adam optimizer (Kingma and Ba, 2014) with $\beta_1 = \beta_2 = 0.9$. We choose an initial learning rate of $\eta_0 = 0.001$. The learning rate η is annealed by multiplying a fixed decay rate $\rho = 0.75$ when parsing performance stops increasing on validation sets. To reduce the effects of "gradient exploding", we use gradient clipping of 5.0 (Pascanu et al., 2013).

Dropout Training. To mitigate overfitting, we apply dropout (Srivastava et al., 2014; Ma et al., 2017). For BLSTM, we use recurrent dropout (Gal and Ghahramani, 2016) with a drop rate of 0.33 between hidden states and 0.33 between layers. Following Dozat and Manning (2017), we also use embedding dropout with a rate of 0.33 on all word, character, and POS embeddings.

Hyper-Parameters. Some parameters are chosen from those reported in Dozat and Manning (2017). We use the same hyper-parameters across the models on different treebanks and languages, due to time constraints. The details of the chosen hyper-parameters for all experiments are summarized in Appendix A.

4 Experiments

4.1 Setup

We evaluate our StackPtr parser mainly on three treebanks: the English Penn Treebank (PTB version 3.0) (Marcus et al., 1993), the Penn Chinese Treebank (CTB version 5.1) (Xue et al., 2002), and the German CoNLL 2009 corpus (Hajič et al., 2009). We use the same experimental settings as Kuncoro et al. (2016).

To make a thorough empirical comparison with previous studies, we also evaluate our system on treebanks from CoNLL shared task and the Universal Dependency (UD) Treebanks[4]. For the CoNLL Treebanks, we use the English treebank from CoNLL-2008 shared task (Surdeanu et al., 2008) and all 13 treebanks from CoNLL-2006 shared task (Buchholz and Marsi, 2006). The experimental settings are the same as Ma and Hovy (2015). For UD Treebanks, we select 12 languages. The details of the treebanks and experimental settings are in § 4.5 and Appendix B.

Evaluation Metrics Parsing performance is measured with five metrics: unlabeled attachment score (UAS), labeled attachment score (LAS), unlabeled complete match (UCM), labeled complete match (LCM), and root accuracy (RA). Following previous work (Kuncoro et al., 2016; Dozat and Manning, 2017), we report results excluding punctuations for Chinese and English. For each experiment, we report the mean values with corresponding standard deviations over 5 repetitions.

[4]http://universaldependencies.org/

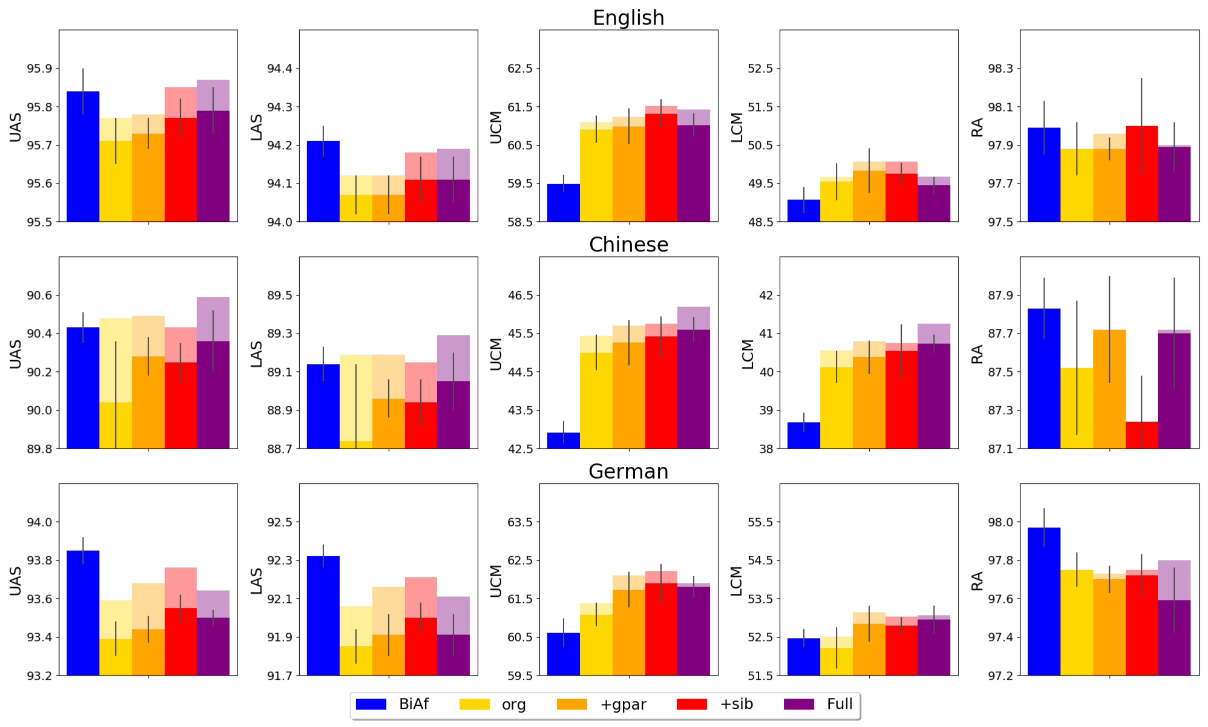


Figure 2: Parsing performance of different variations of our model on the test sets for three languages, together with baseline BIAF. For each of our STACKPTR models, we perform decoding with beam size equal to 1 and 10. The improvements of decoding with beam size 10 over 1 are presented by stacked bars with light colors.

Baseline For fair comparison of the parsing performance, we re-implemented the graph-based Deep Biaffine (BIAF) parser (Dozat and Manning, 2017), which achieved state-of-the-art results on a wide range of languages. Our re-implementation adds character-level information using the same LSTM-CNN encoder as our model (§ 3.2) to the original BIAF model, which boosts its performance on all languages.

4.2 Main Results

We first conduct experiments to demonstrate the effectiveness of our neural architecture by comparing with the strong baseline BIAF. We compare the performance of four variations of our model with different decoder inputs — Org, +gpar, +sib and Full — where the Org model utilizes only the encoder hidden states of head words, while the +gpar and +sib models augments the original one with grandparent and sibling information, respectively. The Full model includes all the three information as inputs.

Figure 2 illustrates the performance (five metrics) of different variations of our STACKPTR parser together with the results of baseline BIAF re-implemented by us, on the test sets of the three languages. On UAS and LAS, the Full variation of STACKPTR with decoding beam size 10 outperforms BIAF on Chinese, and obtains competitive performance on English and German. An interesting observation is that the Full model achieves the best accuracy on English and Chinese, while performs slightly worse than +sib on German. This shows that the importance of higher-order information varies in languages. On LCM and UCM, STACKPTR significantly outperforms BIAF on all languages, showing the superiority of our parser on complete sentence parsing. The results of our parser on RA are slightly worse than BIAF. More details of results are provided in Appendix C.

4.3 Comparison with Previous Work

Table 1 illustrates the UAS and LAS of the four versions of our model (with decoding beam size 10) on the three treebanks, together with previous top-performing systems for comparison. Note that the results of STACKPTR and our re-implementation of BIAF are the average of 5 repetitions instead of a single run. Our Full model significantly outperforms all the transition-based parsers on all three languages, and achieves better results than most graph-based parsers. Our

Table 2: Parsing performance on the test data of PTB with different versions of POS tags.

re-implementation of BIAF obtains better performance than the original one in Dozat and Manning (2017), demonstrating the effectiveness of the character-level information. Our model achieves state-of-the-art performance on both UAS and LAS on Chinese, and best UAS on English. On German, the performance is competitive with BIAF, and significantly better than other models.

4.4 Error Analysis

In this section, we characterize the errors made by BIAF and STACKPTR by presenting a number of experiments that relate parsing errors to a set of linguistic and structural properties. For simplicity, we follow McDonald and Nivre (2011) and report labeled parsing metrics (either accuracy, precision, or recall) for all experiments.

4.4.1 Length and Graph Factors

Following McDonald and Nivre (2011), we analyze parsing errors related to structural factors.

Sentence Length. Figure 3 (a) shows the accuracy of both parsing models relative to sentence lengths. Consistent with the analysis in McDonald and Nivre (2011), STACKPTR tends to perform better on shorter sentences, which make fewer parsing decisions, significantly reducing the chance of error propagation.

Dependency Length. Figure 3 (b) measures the precision and recall relative to dependency lengths. While the graph-based BIAF parser still performs better for longer dependency arcs and transition-based STACKPTR parser does better for shorter ones, the gap between the two systems is marginal, much smaller than that shown

Table 3: UAS and LAS on 14 treebanks from CoNLL shared tasks, together with several state-of-the-art parsers. Bi-Att is the bi-directional attention based parser (Cheng et al., 2016), and NeuroMST is the neural MST parser (Ma and Hovy, 2017). "Best Published" includes the most accurate parsers in term of UAS among Koo et al. (2010), Martins et al. (2011), Martins et al. (2013), Lei et al. (2014), Zhang et al. (2014), Zhang and McDonald (2014), Pitler and McDonald (2015), and Cheng et al. (2016).

in McDonald and Nivre (2011). One possible reason is that, unlike traditional transition-based parsers that scan the sentence from left to right, STACKPTR processes in a top-down manner, thus sometimes unnecessarily creating shorter dependency arcs first.

Root Distance. Figure 3 (c) plots the precision and recall of each system for arcs of varying distance to the root. Different from the observation in McDonald and Nivre (2011), STACKPTR does not show an obvious advantage on the precision for arcs further away from the root. Furthermore, the STACKPTR parser does not have the tendency to over-predict root modifiers reported in McDonald and Nivre (2011). This behavior can be explained using the same reasoning as above: the fact that arcs further away from the root are usually constructed early in the parsing algorithm of traditional transition-based parsers is not true for the STACKPTR parser.

4.4.2 Effect of POS Embedding

The only prerequisite information that our parsing model relies on is POS tags. With the goal of achieving an end-to-end parser, we explore the effect of POS tags on parsing performance. We run experiments on PTB using our STACKPTR parser with gold-standard and predicted POS tags, and without tags, respectively. STACKPTR in these experiments is the Full model with beam=10.

Table 2 gives results of the parsers with different versions of POS tags on the test data of PTB. The parser with gold-standard POS tags significantly outperforms the other two parsers, showing that dependency parsers can still benefit from accurate POS information. The parser with predicted (imperfect) POS tags, however, performs even slightly worse than the parser without using POS tags. It illustrates that an end-to-end parser that doesn't rely on POS information can obtain competitive (or even better) performance than parsers using imperfect predicted POS tags, even if the POS tagger is relative high accuracy (accuracy $> 97\%$ in this experiment on PTB).

4.5 Experiments on Other Treebanks

4.5.1 CoNLL Treebanks

Table 3 summarizes the parsing results of our model on the test sets of 14 treebanks from the CoNLL shared task, along with the state-of-the-art baselines. Along with BIAF, we also list the performance of the bi-directional attention based Parser (Bi-Att) (Cheng et al., 2016) and the neural MST parser (NeuroMST) (Ma and Hovy, 2017) for comparison. Our parser achieves state-of-the-art performance on both UAS and LAS on eight languages — Arabic, Czech, English, German, Portuguese, Slovene, Spanish, and Swedish. On Bulgarian and Dutch, our parser obtains the best UAS. On other languages, the performance of our parser is competitive with BIAF, and significantly better than others. The only exception is Japanese, on which NeuroMST obtains the best scores.

Table 4: UAS and LAS on both the development and test datasets of 12 treebanks from UD Treebanks, together with BIAF for comparison.

4.5.2 UD Treebanks

For UD Treebanks, we select 12 languages — Bulgarian, Catalan, Czech, Dutch, English, French, German, Italian, Norwegian, Romanian, Russian and Spanish. For all the languages, we adopt the standard training/dev/test splits, and use the universal POS tags (Petrov et al., 2012) provided in each treebank. The statistics of these corpora are provided in Appendix B.

Table 4 summarizes the results of the STACKPTR parser, along with BIAF for comparison, on both the development and test datasets for each language. First, both BIAF and STACKPTR parsers achieve relatively high parsing accuracies on all the 12 languages — all with UAS are higher than 90%. On nine languages — Catalan, Czech, Dutch, English, French, German, Norwegian, Russian and Spanish — STACKPTR outperforms BIAF for both UAS and LAS. On Bulgarian, STACKPTR achieves slightly better UAS while LAS is slightly worse than BIAF. On Italian and Romanian, BIAF obtains marginally better parsing performance than STACKPTR.

5 Conclusion

In this paper, we proposed STACKPTR, a transition-based neural network architecture, for dependency parsing. Combining pointer networks with an internal stack to track the status of the top-down, depth-first search in the decoding procedure, the STACKPTR parser is able to capture information from the whole sentence and all the previously derived subtrees, removing the left-to-right restriction in classical transition-based parsers, while maintaining linear parsing steps, w.r.t the length of the sentences. Experimental results on 29 treebanks show the effectiveness of our parser across 20 languages, by achieving state-of-the-art performance on 21 corpora.

There are several potential directions for future work. First, we intend to consider how to conduct experiments to improve the analysis of parsing errors qualitatively and quantitatively. Another interesting direction is to further improve our model by exploring reinforcement learning approaches to learn an optimal order for the children of head words, instead of using a predefined fixed order.

Abstract

Due to the presence of both Twitter-specific conventions and non-standard and dialectal language, Twitter presents a significant parsing challenge to current dependency parsing tools. We broaden English dependency parsing to handle social media English, particularly social media African-American English (AAE), by developing and annotating a new dataset of 500 tweets, 250 of which are in AAE, within the Universal Dependencies 2.0 framework. We describe our standards for handling Twitter- and AAE-specific features and evaluate a variety of cross-domain strategies for improving parsing with no, or very little, in-domain labeled data, including a new data synthesis approach. We analyze these methods' impact on *performance disparities* between AAE and Mainstream American English tweets, and assess parsing accuracy for specific AAE lexical and syntactic features. Our annotated data and a parsing model are available at: http://slanglab.cs.umass.edu/TwitterAAE/.

1 Introduction

Language on Twitter diverges from well-edited Mainstream American English (MAE, also called Standard American English) in a number of ways, presenting significant challenges to current NLP tools. It contains, among other phenomena, non-standard spelling, punctuation, capitalization, and syntax, as well as Twitter-specific conventions such as hashtags, usernames, and retweet tokens (Eisenstein, 2013). Additionally, it contains an abundance of dialectal language, including African-American English (AAE), a dialect of American English spoken by millions of individuals, which contains lexical, phonological, and syntactic features not present in MAE (Green, 2002; Stewart, 2014; Jones, 2015).

Since standard English NLP tools are typically trained on well-edited MAE text, their performance is degraded on Twitter, and even more so for AAE tweets compared to MAE tweets—gaps exist for part-of-speech tagging (Jørgensen et al., 2016), language identification, and dependency parsing (Blodgett et al., 2016; Blodgett and O'Connor, 2017). Expanding the linguistic coverage of NLP tools to include minority and colloquial dialects would help support equitable language analysis across sociolinguistic communities, which could help information retrieval, translation, or opinion analysis applications (Jurgens et al., 2017). For example, sentiment analysis systems ought to count the opinions of all types of people, whether they use standard dialects or not.

In this work, we broaden Universal Dependencies (Nivre et al., 2016) parsing[1] to better handle social media English, in particular social media AAE. First, we develop standards to handle Twitter-specific and AAE-specific features within Universal Dependencies 2.0 (§3), by selecting and annotating a new dataset of 500 tweets, 250 of which are in AAE.

Second, we evaluate several state-of-the-art dependency parsers, finding that, as expected, they perform poorly on our dataset relative to the UD English Treebank (§4). Third, since the UD English Treebank contains substantial amounts of traditional MAE data for training, we investigate cross-domain training methods to improve Twitter AAE dependency parsing with no, or very little,

[1]http://universaldependencies.org/

in-domain labeled data, by using Twitter-specific taggers, embeddings, and a novel heuristic training data synthesis procedure. This helps close some of the gap between MAE and AAE performance. Finally, we provide an error analysis of the parsers' performance on AAE lexical and syntactic constructions in our dataset (§5.4).[2]

2 Related Work

2.1 Parsing for Twitter

Parsing for noisy social media data presents interesting and significant challenges. Foster et al. (2011) develop a dataset of 519 constituency-annotated English tweets, which were converted to Stanford dependencies. Their analysis found a substantial drop in performance of an off-the-shelf dependency parser on the new dataset compared to a WSJ test set. Sanguinetti et al. (2017) annotated a dataset of 6,738 Italian tweets according to UD 2.0 and examined the performance of two parsers on the dataset, finding that they lagged considerably relative to performance on the Italian UD Treebank.

Kong et al. (2014) develop an English dependency parser designed for Twitter, annotating a dataset of 929 tweets (TWEEBANK V1) according to the unlabeled FUDG dependency formalism (Schneider et al., 2013). It has substantially different structure than UD (for example, prepositions head PPs, and auxiliaries govern main verbs).

More recently, Liu et al. (2018) developed TWEEBANK V2, fully annotating TWEEBANK V1 according to UD 2.0 and annotating additionally sampled tweets, for a total of 3,550 tweets. They found that creating consistent annotations was challenging, due to frequent ambiguities in interpreting tweets; nevertheless, they were able to train a pipeline for tokenizing, tagging, and parsing the tweets, and develop ensemble and distillation models to improve parsing accuracy. Our work encounters similar challenges; in our approach, we intentionally oversample AAE-heavy messages for annotation, detail specific annotation decisions for AAE-specific phenomena (§3.2), and analyze parser performance between dialects and for particular constructions (§5.3–5.4). Future work may be able to combine these annotations for effective multi-dialect Twitter UD parsers, which may allow for the use of pre-existing downstream tools like semantic relation extractors (e.g. White et al. (2016)).

One line of work for parsing noisy social media data, including Khan et al. (2013) and Nasr et al. (2016), examines the effects of the domain mismatches between traditional sources of training data and social media data, finding that matching the data as closely as possible aids performance. Other work focuses on normalization, including Daiber and van der Goot (2016) and van der Goot and van Noord (2017), which develop a dataset of 500 manually normalized and annotated tweets, and uses normalization within a parser. Separately, Zhang et al. (2013) created a domain-adaptable, parser-focused system by directly linking parser performance to normalization performance.

2.2 Parsing for Dialects

For Arabic dialects, Chiang et al. (2006) parse Levantine Arabic by projecting parses from Modern Standard Arabic translations, while Green and Manning (2010) conduct extensive error analysis of Arabic constituency parsers and the Penn Arabic Treebank. Scherrer (2011) parse Swiss German dialects by transforming Standard German phrase structures. We continue in this line of work in our examination of AAE-specific syntactic structures and generation of synthetic data with such structures (§4.2.1).

Less work has examined parsing dialectal language on social media. Recently, Wang et al. (2017) annotate 1,200 Singlish (Singaporean English) sentences from a Singaporean talk forum, selecting sentences containing uniquely Singaporean vocabulary items. Like other work, they observe a drop in performance on dialectal Singlish text, but increase performance through a stacking-based domain adaptation method.

3 Dataset and Annotation

3.1 Dataset

Our dataset contains 500 tweets, with a total of 5,951 non-punctuation edges, sampled from the publicly available TwitterAAE corpus.[3] Each tweet in that corpus is accompanied by a model's demographically-aligned topic model probabilities jointly inferred from Census demographics and word likelihood by Blodgett et al. (2016), including the African-American and White topics.

[2]Our annotated dataset and trained dependency parser are available at http://slanglab.cs.umass.edu/TwitterAAE/ and annotations are available in the public Universal Dependencies repository.

[3]http://slanglab.cs.umass.edu/TwitterAAE/

We create a balanced sample to get a range of dialectal language, sampling 250 tweets from those where the African-American topic has at least 80% probability, and 250 from those where the White topic has at least 80% probability. We refer to these two subcorpora as AA and WH; Blodgett et al. (2016) showed the former exhibits linguistic features typical of AAE.

The 250 AA tweets include many alternate spellings of common words that correspond to well-known phonological phenomena—including *da, tha* (the), *dat, dhat* (that), *dis, dhis* (this), *ion, iont* (I don't), *ova* (over), *yo* (your), *dere, der* (there), *den, dhen* (then), *ova* (over), and *nall, null* (no, nah)—where each of the mentioned italicized AAE terms appears in the AAE data, but never in the MAE data. We examine these lexical variants more closely in §5.4. Across the AA tweets, 18.0% of tokens were not in a standard English dictionary, while the WH tweets' OOV rate was 10.7%.[4] We further observe a variety of AAE syntactic phenomena in our AA tweets, several of which are described in §3.2 and §5.4.

3.2 Annotation

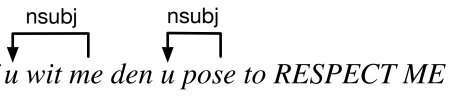
To effectively measure parsing quality and develop better future models, we first focus on developing high-quality annotations for our dataset, for which we faced a variety of challenges. We detail our annotation principles using Universal Dependency 2.0 relations (Nivre et al., 2016).

All tweets were initially annotated by two annotators, and disagreements resolved by one of the annotators. Annotation decisions for several dozen tweets were discussed in a group of three annotators early in the annotation process.

Our annotation principles are in alignment with those proposed by Liu et al. (2018), with the exception of contraction handling, which we discuss briefly in §3.2.2.

3.2.1 Null Copulas

The AAE dialect is prominently characterized by the drop of copulas, which can occur when the copula is present tense, not first person, not accented, not negative, and expressing neither the habitual nor the remote present perfect tenses (Green, 2002). We frequently observed null copulas, as in:



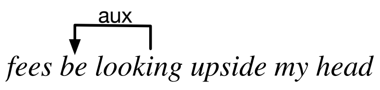
If u wit me den u pose to RESPECT ME

"If you (are) with me, then you (are) supposed to respect me"

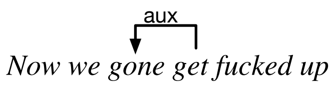
The first dropped *are* is a null copula; UD2.0 would analyze the MAE version as *you* $\xleftarrow{nsubj}$ *me* $\xrightarrow{cop}$ *are*, which we naturally extend to analyze the null copula by simply omitting *cop* (which is now over a null element, so cannot exist in a dependency graph). The second *are* is a null auxiliary (in MAE, *you* $\xleftarrow{nsubj}$ *supposed* $\xrightarrow{aux}$ *are*), a tightly related phenomenon (for example, Green et al. (2007) studies both null copulas and null auxiliary *be* in infant AAE), which we analyze similarly by simply omitting the *aux* edge.

3.2.2 AAE Verbal Auxiliaries

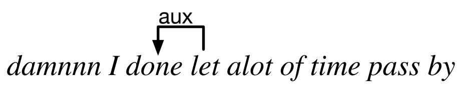
We observed AAE verbal auxiliaries, e.g.,



fees be looking upside my head



Now we gone get fucked up



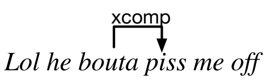
damnnn I done let alot of time pass by

including habitual *be* ("Continually, over and over, fees are looking at me..."), future *gone* ("we are going to get..."), and completive *done* ("I did let time pass by," emphasizing the speaker completed a time-wasting action).

We attach the auxiliary to the main verb with the *aux* relation, as UD2.0 analyzes other English auxiliaries (e.g. *would* or *will*).

3.2.3 Verbs: Auxiliaries vs. Main Verbs

We observed many instances of quasi-auxiliary, "-to" shortened verbs such as *wanna, gotta, finna, bouta, tryna, gonna*, which can be glossed as *want to*, *got to*, *fixing to*, *about to*, etc. They control modality, mood and tense—for example, *finna* and *bouta* denote an immediate future tense; Green (2002, ch. 2) describes *finna* as a preverbal marker. From UD's perspective, it is difficult to decide if they should be subordinate auxiliaries or main verbs. In accordance with the UD Treebank's handling of MAE *want to X* and *going to X* as main verbs (*want* $\xrightarrow{xcomp}$ *X*), we analyzed them similarly, e.g.



Lol he bouta piss me off "He is about to piss me off"

[4]The dictionary of 123,377 words with American spellings was generated using http://wordlist.aspell.net/.

This is an instance of a general principle that, if there is a shortening of an MAE multiword phrase into a single word, the annotations on that word should mirror the edges in and out of the original phrase's subgraph (as in Schneider et al. (2013)'s fudge expressions).

However, in contrast to the UD Treebank, we did not attempt to split up these words into their component words (e.g. *wanna* $\rightarrow$ *want to*), since to do this well, it would require a more involved segmentation model over the dozens or even hundreds of alternate spellings each of the above can take;[5] we instead rely on Owoputi et al. (2013); O'Connor et al. (2010)'s rule-based tokenizer that never attempts to segment within such shortenings. This annotation principle is in contrast to that of Liu et al. (2018), which follows UD tokenization for contractions.

3.2.4 Non-AAE Twitter issues

We also encountered many issues general to Twitter but not AAE; these are still important to deal with since AAE tweets include more non-standard linguistic phenomena overall. When possible, we adapted Kong et al. (2014)'s annotation conventions into the Universal Dependencies context, which are the only published conventions we know of for Twitter dependencies (for the FUDG dependency formalism). Issues include:

- @-mentions, which require different treatment when they are terms of address, versus nominal elements within a sentence.

- Hashtags, which in their tag-like usage are utterances by themselves (*#tweetliketheoppositegender Oh damn .*). or sometimes can be words with standard syntactic relations within the sentence (*#She's A Savage*, having *#She's* $\xleftarrow{\text{nsubj}}$ Savage). Both hashtag and @-mention ambiguities are handled by Owoputi et al. (2013)'s POS tagger.

- Multiple utterances, since we do not attempt sentence segmentation, and in many cases sentential utterances are not separated by explicit punctuation. FUDG allows for multiple roots for a text, but UD does not; instead we follow UD's convention of the *parataxis* relation for what they describe as "side-by-side run-on sentences."

- Emoticons and emoji, which we attach as *discourse* relations to the utterance root, following UD's treatment of interjections.

- Collapsed phrases, like *omw* for "on my way." When possible, we used the principle of annotating according to the root of the subtree of the original phrase. For example, UD 2.0 prescribes *way* $\xrightarrow{xcomp}$ *get* for the sentence *On my way to get...*; therefore we use *omw* $\xrightarrow{xcomp}$ *get* for *omw to get*.

- Separated words, like *uh round* for "around," which we analyze as multiword phrases (*flat* or *compound*).

We discuss details for these and other cases in the online appendix.

4 Experiments

4.1 Models

Our experiments use the following two parsers.

UDPipe (Straka et al., 2016) is a neural pipeline containing a tokenizer, morphological analyzer, tagger, and transition-based parser intended to be easily retrainable. The parser attains 80.2% LAS (labeled attachment score) on the UD English treebank with automatically generated POS tags, and was a baseline system used in the CoNLL 2017 Shared Task (Zeman et al., 2017).[6]

Deep Biaffine (Dozat et al., 2017; Dozat and Manning, 2016) is a graph-based parser incorporating neural attention and biaffine classifiers for arcs and labels. We used the version of the parser in the Stanford CoNLL 2017 Shared Task submission, which attained 82.2% LAS on the UD English treebank with automatically generated tags, and achieved the best performance in the task. The model requires pre-trained word embeddings. [7]

4.2 Experimental Setup

We considered a series of experiments within both a cross-domain scenario (§4.2.1), where we trained only on UD Treebank data, and an in-domain scenario (§4.2.2) using small amounts of our labeled data. We use the parsing systems' default hyperparameters (e.g. minibatch size and learning rate) and the default training/development split of the treebank (both systems perform early stopping based on development set performance).

[5]For example, Owoputi et al. (2013)'s Twitter word cluster 0011000 has 36 forms of *gonna* alone: http://www.cs.cmu.edu/~ark/TweetNLP/cluster_viewer.html

[6]https://github.com/ufal/udpipe

[7]https://github.com/tdozat/UnstableParser/

4.2.1 Cross-Domain Settings

Morpho-Tagger vs. ARK POS tags: The UD Treebank contains extensive fine-grained POS and morphological information, on which UDPipe's morphological analyzer and tagging system is originally trained. This rich information should be useful for parsing, but the analyzers may be highly error-prone on out-of-domain, dialectal Twitter data, and contribute to poor parsing performance. We hypothesize that higher quality, even if coarser, POS information should improve parsing.

To test this, we retrain UDPipe in two different settings. We first retrain the parser component with fine-grained PTB-style POS tags and morphological information provided by the tagger component;[8] we call this the *Morpho-Tagger* setting. Second, we retrain the parser with morphological information stripped and its tags predicted from the ARK Twitter POS tagger (Owoputi et al., 2013), which is both tailored for Twitter and displays a smaller AAE vs MAE performance gap than traditional taggers (Jørgensen et al., 2016); we call this the *ARK Tagger* setting.[9] The ARK Tagger's linguistic representation is impoverished compared to Morpho-Tagger: its coarse-grained POS tag system does not include tense or number information, for example.[10]

Synthetic Data: Given our knowledge of Twitter- and AAE-specific phenomena that do not occur in the UD Treebank, we implemented a rule-based method to help teach the machine-learned parser these phenomena; we generated synthetic data for three Internet-specific conventions and one set of AAE syntactic features. (This is inspired by Scherrer (2011)'s rule transforms between Standard and Swiss German.) We performed each of the following transformations separately on a copy of the UD Treebank data and concatenated the transformed files together for the final training and development files, so that each final file contained several transformed copies of the original UD Treebank data.

1. *@-mentions, emojis, emoticons, expressions, and hashtags:* For each sentence in the UD Treebank we inserted at least one @-mention, emoji, emoticon, expression (Internet-specific words and abbreviations such as *lol*, *kmsl*, and *xoxo*), or hashtag, annotated with the correct relation, at the beginning of the sentence. An item of the same type was repeated with 50% probability, and a second item was inserted with 50% probability. @-mentions were inserted using the *ATMENTION* token and emojis using the *EMOJI* token. Emoticons were inserted from a list of 20 common emoticons, expressions were inserted from a list of 16 common expressions, and hashtags were sampled for insertion according to their frequency in a list of all hashtags observed in the TwitterAAE corpus.

2. *Syntactically participating @-mentions:* To replicate occurrences of syntactically participating @-mentions, for each sentence in the UD Treebank with at least one token annotated with an *nsubj* or *obj* relation and an *NNP* POS tag, we replaced one at random with the *ATMENTION* token.

3. *Multiple utterances:* To replicate occurrences of multiple utterances, we randomly collapsed pairs of two short sentences ($<$ 15 tokens) together, attaching the root of the second to the root of the first with the *parataxis* relation.

4. *AAE preverbal markers and auxiliaries:* We introduced instances of verbal constructions present in AAE that are infrequent or non-existent in the UD Treebank data. First, constructions such as *going to*, *about to*, and *want to* are frequently collapsed to *gonna*, *bouta*, and *wanna*, respectively (see §3.2.2); for each sentence with at least one of these constructions, we randomly chose one to collapse. Second, we randomly replaced instances of *going to* with *finna*, a preverbal marker occurring in AAE and in the American South (Green, 2002). Third, we introduced the auxiliaries *gone* and *done*, which denote future tense and past tense, respectively; for the former, for each sentence containing at least one auxiliary *will*, we replace it with *gone*, and for the latter, for each sentence containing at least one non-auxiliary, non-passive, past-tense verb, we choose one and insert *done* before it. Finally, for each sentence containing at least one copula, we delete one at random.

Word Embeddings: Finally, since a tremendous variety of Twitter lexical items are not present in the UD Treebank, we use 200-dimensional word embeddings that we trained with *word2vec*[11] (Mikolov et al., 2013) on the

[8] We also retrained this component, to maintain consistency of training and development split. We also remove the universal (coarse) POS tags it produces, replacing them with the same PTB tags.

[9] We strip lemmas from training and development files for both settings.

[10] Derczynski et al. (2013)'s English Twitter tagger, which outputs PTB-style tags, may be of interest for future work.

[11] https://github.com/dav/word2vec

TwitterAAE corpus, which contains 60.8 million tweets. Before training, we processed the corpus by replacing @-mentions with ATMENTION, replacing emojis with EMOJI, and replacing sequences of more than two repeated letters with two repeated letters (e.g. *partyyyyy* $\rightarrow$ *partyy*). This resulted in embeddings for 487,450 words.

We retrain and compare UDPipe on each of the *Morpho-Tagger* and *ARK Tagger* settings with synthetic data and pre-trained embeddings, and without. We additionally retrain Deep Biaffine with and without synthetic data and embeddings.[12]

4.2.2 In-domain Training

We additionally investigate the effects of small amounts of in-domain training data from our dataset. We perform 2-fold cross-validation, randomly partitioning our dataset into two sets of 250 tweets. We compare two different settings (all using the UDPipe *ARK Tagger* setting):

Twitter-only: To explore the effect of training with Twitter data alone, for each set of 250 we trained on that set alone, along with our Twitter embeddings, and tested on the remaining 250.

UDT+Twitter: To explore the additional signal provided by the UD Treebank, for each set of 250 we trained on the UD Treebank concatenated with that set (with the tweets upweighted to approximately match the size of the UD Treebank, in order to use similar hyperparameters) and tested on the remaining 250.

5 Results and Analysis

In our evaluation, we ignored punctuation tokens (labeled with *punct*) in our LAS calculation.

5.1 Effects of Cross-Domain Settings

***Morpho-Tagger* vs. ARK Tagger:** As hypothesized, UDPipe's *ARK Tagger* setting outperformed the *Morpho-Tagger* across all settings, ranging from a 2.8% LAS improvement when trained only on the UD Treebank with no pre-trained word embeddings, to 4.7% and 5.4% improvements when trained with Twitter embeddings and both Twitter embeddings and synthetic data, respectively. The latter improvements suggest that the *ARK Tagger* setup is able to take better advantage of Twitter-specific lexical information from the embeddings and syntactic patterns from the synthetic data. Table 1 shows the LAS for our various settings.

[12]As the existing implementation of Deep Biaffine requires pre-trained word embeddings, for the Deep Biaffine baseline experiments we use the CoNLL 2017 Shared Task 100-dimensional embeddings that were pretrained on the English UD Treebank.

Model	LAS
(1) UDPipe, Morpho-Tagger, UDT	50.5
(2) + Twitter embeddings	53.9
(3) + synthetic, Twitter embeddings	58.9
(4) UDPipe, ARK Tagger, UDT	53.3
(5) + Twitter embeddings	58.6
(6) + synthetic, Twitter embeddings	64.3
Deep Biaffine, UDT	
(7) + CoNLL MAE embeddings	62.3
(8) + Twitter embeddings	63.7
(9) + synthetic, Twitter embeddings	65.0

Table 1: Results from cross-domain training settings (see §4.2.1).

Model	LAS
(10) UDPipe, Twitter embeddings	62.2
(11) + UDT	70.3

Table 2: Results from in-domain training settings (with the *ARK Tagger* setting, see §4.2.2).

After observing the better performance of the *ARK Tagger* setting, we opted not to retrain the Deep Biaffine parser in any *Morpho-Tagger* settings due to the model's significantly longer training time; all our Deep Biaffine results are reported for models trained with an *ARK Tagger* setting.

Synthetic data and embeddings: We observed that synthetic data and Twitter-trained embeddings were independently helpful; embeddings provided a 1.4–5.3% boost across the UDPipe and Deep Biaffine models, while synthetic data provided a 1.3–5.7% additional boost (Table 1).

UDPipe vs. Deep Biaffine: While the baseline models for UDPipe and Deep Biaffine are not directly comparable (since the latter required pre-trained embeddings), in the Twitter embeddings setting Deep Biaffine outperformed UDPipe by 5.1%. However, given access to both synthetic data and Twitter embeddings, UDPipe's performance approached that of Deep Biaffine.

5.2 Effects of In-Domain Training

Perhaps surprisingly, training with even limited amounts of in-domain training data aided in parsing performance; training with just in-domain data produced an LAS comparable to that of the baseline Deep Biaffine model, and adding UD Treebank data further increased LAS by 8.1%, indicat-

Model	AA LAS	WH LAS	Gap
(1) UDPipe, Morpho-Tagger	43.0	57.0	14.0
(2) + Twitter embeddings	45.5	61.2	15.7
(3) + synthetic, Twitter embeddings	50.7	66.2	15.5
(4) UDPipe, ARK Tagger	50.2	56.1	5.9
(5) + Twitter embeddings	54.1	62.5	8.4
(6) + synthetic, Twitter embeddings	59.9	68.1	8.2
Deep Biaffine, ARK Tagger			
(7) + CoNLL MAE embeddings	56.1	67.7	11.6
(8) + Twitter embeddings	58.7	66.7	8.0
(9) + synthetic, Twitter embeddings	59.9	70.8	10.9

Table 3: AA and WH tweets' labeled attachment scores for UD Treebank-trained models (see §5.3 for discussion); *Gap* is the WH − AA difference in LAS.

ing that they independently provide critical signal.

5.3 AAE/MAE Performance Disparity

For each model in each of the cross-domain settings, we calculated the LAS on the 250 tweets drawn from highly African-American tweets and the 250 from highly White tweets (see §3 for details); we will refer to these as the AA and WH tweets, respectively. We observed clear disparities in performance between the two sets of tweets, ranging from 5.9% to 15.7% (Table 3). Additionally, across settings, we observed several patterns.

First, the UDPipe *ARK Tagger* settings produced significantly smaller gaps (5.9–8.4%) than the corresponding *Morpho-Tagger* settings (14.0–15.7%). Indeed, most of the performance improvement of the *ARK Tagger* setting comes from the AA tweets; the LAS on the AA tweets jumps 7.2–9.2% from each *Morpho-Tagger* setting to the corresponding *ARK Tagger* setting, compared to differences of −0.9–1.9% for the WH tweets.

Second, the Deep Biaffine *ARK Tagger* settings produced larger gaps (8.0–11.6%) than the UDPipe *ARK Tagger* settings, with the exception of the embeddings-only setting.

Finally, we observed the surprising result that adding Twitter-trained embeddings and synthetic data, which contains both Twitter-specific and AAE-specific features, increases the performance gap across both UDPipe settings. We hypothesize that while UDPipe is able to effectively make use of both Twitter-specific lexical items and annotation conventions within MAE-like syntactic structures, it continues to be stymied by AAE-like syntactic structures, and is therefore unable to make use of the additional information.

We further calculated recall for each relation type across the AA tweets and WH tweets, and the resulting performance gap, under the UDPipe *Morpho-Tagger* and *ARK Tagger* models trained with synthetic data and embeddings. Table 4 shows these calculations for the 15 relation types for which the performance gap was highest and which had at least 15 instances in each of the AA and WH tweet sets, along with the corresponding calculation under the *ARK Tagger* model. The amount by which the performance gap is reduced from the first setting to the second setting is also reported. Of the 15 relations shown, the gap was reduced for 14, and 7 saw a reduction of at least 10%.

5.4 Lexical and Syntactic Analysis of AAE

In this section, we discuss AAE lexical and syntactic variations observed in our dataset, with the aim of providing insight into decreased AA parsing accuracy, and the impact of various parser settings on their parsing accuracy.

AAE contains a variety of phonological features which present themselves on Twitter through a number of lexical variations (Green, 2002; Jones, 2015), many of which are listed in §3.1, instances of which occur a total of 80 times in the AA tweets; notably, none occur in the WH tweets.

We investigated the accuracy of various cross-domain parser settings on these lexical variants; for each of the baseline *Morpho-Tagger*, baseline *ARK Tagger*, *ARK Tagger* with embeddings, and *ARK Tagger* with synthetic data and embeddings models, we counted the number of instances of lexical variants from §3.1 for which the model gave the correct head with the correct label.

While the lexical variants challenged all four models, switching from the *Morpho-Tagger* set-

	Morpho-Tagger			**ARK Tagger**			
Relation	**AA Recall**	**WH Recall**	**Gap (WH - AA)**	**AA Recall**	**WH Recall**	**Gap (WH - AA)**	**Reduction**
compound	36.4	71.2	34.8	42.4	72.9	30.5	4.4

Table 4: Recall by relation type under UDPipe's *Morpho-Tagger* and *ARK Tagger* settings (+synthetic+embeddings; (3) and (6) from Table 3; §5.3). *Reduction* is the reduction in performance gap from the *Morpho-Tagger* setting to the *ARK Tagger* setting; bolded numbers indicate a gap reduction of ≥ 10.0.

Feature	**AA Count**	**WH Count**	**Example**
Dropped copula	44	0	*MY **bestfrienddd mad** at me tho*
Habitual *be*, describing repeated actions	10	0	*fees **be** looking upside my head likee ion kno wat **be** goingg on .* *I kno that clown, u don't **be** around tho*
Dropped possessive marker	5	0	*ATMENTION on Tv...tawkn bout dat **man** gf* *Twink rude lol can't be calling ppl ugly that's **somebody** child lol...*
Dropped 3rd person singular	5	0	*When a female **owe** you sex you don't even wanna have a conversation with her*
Future *gone*	4	0	*she **gone** dance without da bands lol*
it is instead of *there is*	2	1	***It was** too much goin on in dat mofo .*
Completive *done*	1	0	*damnnn I **done** let alot of time pass by . .*

Table 5: Examples of AAE syntactic phenomena and occurrence counts in the 250 AA and 250 WH tweet sets.

ting to the *ARK Tagger* settings produced significant accuracy increases (Table 6). We observed that the greatest improvement came from using the *ARK Tagger* setting with Twitter-trained embeddings; the Twitter-specific lexical information provided by the embeddings was critical to recognizing the variants. Surprisingly, adding synthetic data decreased the model's ability to parse the variants.

We next investigated the presence of AAE syntactic phenomena in our dataset. Table 5 shows examples of seven well-documented AAE morphological and syntactic features and counts of their occurrences in our AA and WH tweet sets; again, while several of the phenomena, such as dropped copulas and habitual *be*, occur frequently in our AA tweets, there is only one instance of any of these features occurring in the WH tweet set.

We measured the parsing accuracy for the two most frequent syntactic features, dropped copulas and habitual *be*, across the four models; accuracies are given in Table 6. For dropped copulas, we measured parsing correctness by checking if the parser correctly attached the subject to the correct predicate word via the *nsubj* relation; for the first example in Table 5, for example, we considered the parser correct if it attached *bestfrienddd* to *mad* via the *nsubj* relation. For habitual *be*, we checked for correct attachment via the *aux* or *cop* relations as in the first and second examples in Ta-

AAE Feature	**Morpho-Tagger Baseline**	**ARK Tagger Baseline**	**ARK Tagger with Embeddings**	**ARK Tagger with Synthetic, Embeddings**
Lexical Variants (§3.1)	16.3 (13/80)	61.3 (49/80)	63.8 (51/80)	57.5 (46/80)
Dropped copula	54.5 (24/44)	70.5 (31/44)	61.4 (27/44)	68.2 (30/44)
Habitual *be*	50.0 (5/10)	80.0 (8/10)	90.0 (9/10)	90.0 (9/10)

Table 6: Parsing accuracies of syntactic and lexical variations across four UDPipe models (see §5.4).

ble 5, respectively.

As before, we observed significant increases in accuracy moving from the *Morpho-Tagger* to the *ARK Tagger* settings. However, neither adding embeddings nor synthetic data appeared to significantly increase accuracy for these features. From manual inspection, most of the dropped copulas errors appear to arise either from challenging questions (e.g. *ATMENTION what yo number ?*) or from mis-identification of the word to which to attach the subject (e.g. *He claim he in love llh*, where *he* was attached to *llh* rather than to *love*).

6 Conclusion

While current neural dependency parsers are highly accurate on MAE, our analyses suggest that AAE text presents considerable challenges due to lexical and syntactic features which diverge systematically from MAE. While the cross-domain strategies we presented can greatly increase accurate parsing of these features, narrowing the performance gap between AAE- and MAE-like tweets, much work remains to be done for accurate parsing of even linguistically well-documented features.
